where V_N is the pure retention volume. The idea of employing the additivity of the molar free energy of solution in terms of groups of atoms in the sorbate molecule for the calculation of retention parameters is extremely attractive[5,6], although it is based solely on phenomenological observations[7]. A test of the applicability of this additivity principle to gas-chromatographic systems has been described in detail[7-13].

For monofunctional aliphatic compounds, it is possible to formulate an equation involving the number of methylene (n_{CH_2}) and methyl (n_{CH_3}) groups in the sorbate molecule and the energy F of the interaction of the atomic group with the stationary phase (the subscripts x, CH_2, and CH_3 denote the parameters of the functional group investigated and the methylene and methyl groups respectively):

$$\ln V_N = F_{CH_3} n_{CH_3} + F_{CH_2} n_{CH_2} + F_x. \quad (2)$$

The total number of carbon atoms in the sorbate molecule $n = n_{CH_3} + n_{CH_2}$. For $n > 5$, the last equation can be fitted by a linear relation of the type[14-16]:

$$\ln V_N = F_{CH_2} n_{CH_2} + F_x. \quad (3)$$

Eqn.(3) is used most widely in practical qualitative analysis in GLC although the error of the correlations in terms of the corresponding variables has been estimated in only a small number of publications[17-19]. In precise measurements of retention parameters, it was found that, even for the homologous series of n-paraffins in non-polar or weakly polar stationary phases, Eqn.(3) does not hold, and particularly marked deviations are observed in the case of stationary phases whose molecules contain cyclic groups of atoms[20-24]. However, despite the reliable data presented in the studies quoted above, reports are being published from time to time claiming a satisfactory linear relation between $\ln V_N$ and n (see, for example, the report of Wainwright et al.[25], who do not even indicate the errors of the calculated data and whose method of calculating the dead retention volume does not appear trustworthy).

Numerous publications have shown[26-29] that the slopes of the relations between $\ln V_N$ and n are not the same for different homologous series. In the presence of polar functional groups, both in the sorbate molecule and in the molecule of the stationary phase, the relation between $\ln V_N$ and n becomes non-linear[26,30]. Even when non-polar and weakly polar sorbates and stationary phases are used, the errors of calculations by Eqn.(3) for homologous series of sorbates are at least 3% [31] and the linearity of the relation between $\ln V_N$ and n holds only for a comparatively small number of members of homologous series. For example, the linear relation between I and n (I is the Kovàts retention index proportional to $\ln V_N$) holds only for two–three neighbouring homologues in the series of phenols [on a column with poly(phenylether)] and for the series of phenols, it is not even possible to find linear sections[32]. Some investigators[33] suggest that an empirical correction factor be introduced to correct the non-linearity of the relation between I and n, which converts Eqn.(3) into a semiparametric equation. When the methylsilicone elastomer OV-1 is used, the correlation coefficient for different homologous series varies in the range from 0.97 to 0.98, which is unacceptable for chromatographic measurements.

The number of carbon atoms in the sorbate molecule is by no means the only parameter which can be used to construct linear relations between the free energy of solution and the chemical composition of the molecule; attempts to set up correlations between $\ln V_N$ and I and the number of silicon[34], sulphur[35], nitrogen, and oxygen[36] atoms, phenyl groups[37], double bonds[38,39], and homogeneous *cis–trans* configurations[17,40] in sorbate molecules have been described. Parameters such as the equivalent chain length *Me*,[41,42] the steroid number R_{Mg} in the series of steroids[43,44], and the equivalent length of the carbon chain in the case of unsaturated aliphatic esters[45-48] have an analogous significance.

Eqn.(3) is not used solely for the interpolation or extrapolation of retention data for a selected homologous series; it also makes it possible to estimate the contribution of functional groups to the molar free energy of the interaction of the sorbate with the stationary phase. Thus the increments in $\ln V_N$ for a large number of functional groups (H, CH_3, C_2H_5, F, Cl, Br, I, OCH_3, CN, NO_2) in anilines, phenols, pyridines, aromatic hydrocarbons, cyclohexanes, and hexanes have been determined with the aid of an equation of type (3) using Carbowax 20M and Apiezon L as stationary phases[49].

In general, a functional group can be understood not only as a group containing heteroatoms but as any structural group distinguished both by the presence of multiple or aromatic bonds and by a non-linear arrangement of carbon atoms in space. In particular, for hydrocarbons, the presence of such structural groups in the molecule can be the cause of a change in the retention of the sorbate. In order to take into account the influence of individual structural groups as well as groups of carbon atoms linked by multiple bonds on the free energy of solution, it has been suggested[50] that the homomorphous factor H be calculated:

$$H = I_x - I_h, \qquad (4)$$

where the subscript h refers to a homomorphous paraffin, i.e. to a saturated hydrocarbon having the same carbon skeleton as the compound investigated.

The principal information obtained with the aid of Eqn.(4) characterises the influence of multiple bonds on retention parameters. The values of H have been determined in a number of studies[50-59] for non-polar and weakly polar stationary phases. On the other hand, similar measurements can be carried out also for polar sorbates, for example for alkylchlorosilanes[60] on weakly polar silicone stationary phases (PMS-100, E-301, SE-30, and DC-550); however, in such systems account must be taken of the length of the alkyl group in the member of the homologous series (the relation between I and n is non-linear). Since the considerations arising in the determination of the homomorphous factor H do not differ fundamentally from those used to determine F_X, the errors in the calculation of H by Eqn.(4) are also of the same order of magnitude. For example, the relative standard error $s°$ is in the range 2–5% for aromatic hydrocarbons, alkyl sulphides, and ketones[61]. The contributions of aliphatic isoalkyl and unsaturated groups of atoms as well as sulphur atoms in metameric thiatridecanes have been determined[62].

Since the fundamental non-linearity of the relation between $\ln V_N$ and n has been demonstrated in numerous studies, a series of approaches have been devised, using specific mathematical modifications of Eqn.(3) to reconcile the calculated and experimental data with the aid of empirical parameters. For example, the following relation has been obtained in a series of studies by Golovnya and coworkers[62-69]:

$$I = k_1 + k_2 n + k_3/n, \qquad (5)$$

where k represent constants. It has been used to interpret retention data for n-alkyl sulphides[63], n-alkyl isoalkyl sulphides[64], alkyl vinyl, alkyl allyl, and alkyl propyl sulphides[65], thiophen, furan, and benzene derivatives[66], aliphatic di-isoalkyl sulphides[67], heterocyclic compounds[68], and di- tri-, and tetra-sulphides with an S–S bond[69] on four stationary phases (Apiezon M, silicone OV-17, Triton X-305, and PEG-1000).

The relevant considerations do not change fundamentally if the increments of the free energy of solution of the atomic groups of the sorbate are replaced by bond increments[70,71]. The assumption of the additivity of the values of ΔG_s for different bonds leads to the same computational errors as the hypothesis that the ΔG_s are additive with respect to atomic groups[72-75]. An attempt to take into account the influence of neighbouring bonds on the retention parameter for a selected bond has been made in a study[76] where the so-called bonding indices χ were used. However, in order to obtain linear relations, it was necessary to introduce a series of empirical parameters (for example, the distance A between the neighbouring bonds or methyl groups):

$$I = 200(\chi - 1.4142) + 100 + A^2. \qquad (6)$$

This equation has been used to calculate the retention parameters of isoalkanes[76]. The influence of neighbouring bonds and substituents on the increments in I for individual functional groups has been determined in a study[77] where mono- and di-alkylbenzenes were separated on squalane, Yukon LB-550X, and Yukon HB-280X at 100 °C; the average standard error of the calculation s was six retention index units.

The principle of additivity underlying Eqn.(3) is applicable primarily to monofunctional homologous series. When polyfunctional sorbates are considered, the additivity of the contributions of the functional groups to the molar free energy of solution holds only for substances where the functional groups are separated by a linear carbon chain consisting of at least three carbon atoms. In other cases account must be taken of the mutual influence of the carbon groups, which is expressed by the so-called second-order increments[54,55,59]. The magnitude of these corrections is so great that they cannot be neglected: for example, for paraffins with molecules containing three and four methyl side groups, they amount to 30 and 40 Kováts index units† respectively[76]. The second-order corrections are particularly large for very polar sorbates: thus for alcohols they vary in the range from 170 to 270 units. However, when weakly polar stationary phases such as methylpolysiloxanes or phenylmethylsiloxanes of the PPMS type are used, even the introduction of corrections of this kind does not reduce the errors of the calculation for polyfunctional sorbates below 4% and for a more polar stationary phase (SKTFT-50X) the error increases to 10%.

The non-additivity of the values of I in a homologous series is indicated by data presented in numerous publications. Thus, for the homologous series of isoparaffins on a series of stationary phases [tetracosane, squalane, dotriacontane, di(4-isopropylbenzyl)benzene and its analogues], the quantity I varies from 56 to 64 units[77], whereas the value required by theory is 100 units. According to the results of the same study[77], the increment in the retention index for alkylbenzenes varies from 102 to 95 for the homologous series investigated. Similar variations have been noted for n-alkynes on stationary phases of low polarity and, when polar stationary phases are used, the corresponding increments are in the range between 84 and 94 units.[78,79] The increment in the retention index in the homologous series is 90–95 units for dibasic acid esters[80], 50–125 units for alkylbiphenyls[81], 75–105 [82] and 60–100 units[83] for alkylbenzenes on three stationary phases of different polarity, and between 94 and 100 units for olefins[84].

Such phenomena indicate the need to seek more complex mathematical relations for the calculation of experimental retention parameters. Thus an equation of the type

$$I = k_1 + k_2 n + k_3 n^2 \qquad (7)$$

has been used[79] to calculate the retention indices of n-alkynes on a highly polar stationary phase—1,2,3-tris(2-cyanoethoxy)propane. However, no account was taken in the above study[79] of adsorption at the gas–liquid interface.

The data presented indicate a low accuracy of the calculation of retention parameters in homologous series using only one variable parameter—the number of carbon atoms in the molecule. Fairly large errors have also been observed after the introduction of second-order corrections taking into account the immediate environment of the functional groups. These failures are readily explicable in the analysis of the physicochemical basis of the relations employed. The molar free energy consists of two components: the molar heat of solution ΔH_S and the molar entropy of solution ΔS_S. If ΔH_S is treated to a first approximation as a quantity additive with respect to the atomic groups of the molecule, then ΔS_S is determined by the relative positions of the atomic groups rather than by their complete set. The greater the contribution of the entropy factor to the molar free energy of solution, the less applicable the principle of additivity to the description for the behaviour of the molar free energy of solution, i.e. to the calculation of $\ln V_N$ and I.

Despite the lack of a physicochemical basis, the principle of additivity is so simple and attractive that attempts to use it in the calculation of retention parameters have continued—mainly by increasing the number of empirical and semi-empirical parameters in the overall equation. Thus a multiparametric equation has been used[85] to describe the retention of diphenyl ether derivatives on weakly polar stationary phases. A three-parameter equation has been used[86] to describe the retention of aromatic ethers and their fluoroderivatives (taking into account the relative positions of the substituents).

One of the most fruitful approaches in the empirical calculation of retention in GLC involved the use of the principles of topological analysis[87,88]. According to this method, one must take into account the immediate environment of a given functional group–the first, second, third, etc. spheres. The reliability and accuracy of the calculation increase with increase in the number of surrounding spheres taken into account but at the same time there is also a sharp increase of the number of empirical parameters to be determined beforehand for the calculation, which requires in its turn the accumulation of extensive experimental data for the retention of the test compounds. Thus, in the calculation of the retention of alkanes with allowance for the influence of the first sphere of the environment, use is made of 14 parameters, while in the calculation with allowance for the influence of the second sphere the number of such parameters increases to 2000.[7] At the same time it has been shown that[7], even when 90 empirical parameters are used for C_4–C_8 olefins, the average standard deviation of the calculated data from experimental results is 11%.[7] The principles of the topological calculation of the retention indices of isoalkanes have been discussed[89]; the same method has been used[10] to calculate the retention parameters of 84 linear alkenes (up to tetradecane) on squalane using 25 empirical parameters. The average standard deviation of the calculated results from the experimental data is 3–4 units.

As a rule, in the topological analysis of experimental data and in the derivation of computational equations, computers are widely used because of the large number of calculations. For example, the DARC programme has been used in a series of investigations[87,91–93]; in calculations by means of this programme with 18 empirical topological constants, the average standard deviation from the experimental data for C_6–C_8 isoalkanes is 3.1 units[94] (one should bear in mind that the experimental data for 50 hydrocarbons must be used to calculate 17 topological parameters). With increase of the number of the empirical topological parameters to 23, the average standard deviation decreases by a factor of two. However, errors of such magnitude are characteristic solely of interpolation calculations; in the extrapolation of data the errors usually increase several times. The application of other computer programs leads to errors of the same order of magnitude[95–98].

Despite the considerable number of experimentally determined parameters for calculations in accordance with the topological scheme, the final result depends in many respects on the intuition of the investigator, who must choose correctly the test substances[76]. In order to increase the accuracy of the calculations and to reduce the required number of empirical parameters, the treatment has been restricted in certain studies to isotopological series of compounds, which reduces the error of the calculation almost by a factor of two[94]. Another (similar) characteristic of the sorbates—the degree of bonding—has been used also to calculate retention parameters[99]. The bonding indices have been employed to calculate the retention of polycyclic aromatic hydrocarbons[100],

† Henceforth for brevity the expression "Kováts index units" will be replaced by "units".

alcohols, ketones, and ethers on polar stationary phases[100] and of hydrocarbons, ethers, carbonyl compounds, and alcohols[102] on weakly polar stationary phases. It has been shown[102] that, whereas the employment of bonding indices for hydrocarbons has resulted in an error of calculation less than one unit, for oxygen-containing compounds the error is much greater (between 5 and 190 units). The errors can be reduced only by employing multiparametric equations.

The data described above permit certain conclusions. The principle of the additivity of the molar free energy of solution (for the determination of I, $\ln V_N$, and $\ln K$) does not hold even for members of a homologous series and can be used only for a preliminary estimation of the order of magnitude of the yields of the test components. The contribution of each functional group to the molar free energy of solution depends to a large extent on the influence of the neighbouring groups of atoms, which makes it necessary to resort to methods of topological analysis for a complete quantitative estimation of the interaction energy. The method of topological analysis as well as multiparametric equations with empirical constants can ensure a comparatively low error of the calculation (approximately 5–10 units), but such methods require a large number of preliminary experimental data. The greater the number of empirical constants used in the calculation, the greater the accuracy. The value of the data obtained by this approach is also reduced by the fact that they are of the interpolation type, the errors increasing appreciably on extrapolation of the equations to higher homologues. Consequently the methods employing the principle of additivity can be regarded only as a first approximation in the calculation of retention data and also as a convenient method of an abbreviated formulation of experimental information for homologous and isotopological series of sorbates.

III. CORRELATION BETWEEN THE RETENTION PARAMETERS AND THE PHYSICOCHEMICAL PROPERTIES OF SORBATES

Purely empirical methods based on the principle of additivity for the calculation of the retention characteristics require preliminary experimental studies if sufficiently accurate results are to be obtained. It is useful to attempt to diminish the set of predetermined parameters by introducing into the equations parameters related to the physicochemical properties of the substances to be separated. The retention parameters are related to the properties of the sorbates and of the stationary phase and their simplest correlations with the properties of sorbates merit particular attention.

The boiling point of the sorbate T_b is the characteristic most widely used for correlations, because it is one of the most readily available. The following relation has been postulated in a series of studies[103–109]:

$$\ln V_N = k_1 + k_2 T_b \ . \qquad (8)$$

Indeed the relative retention volume r can be expressed in terms of V_N and the activity coefficient γ:

$$r = V_{N_1}/V_{N_2} = \gamma_1 p_2^0/\gamma_2 p_1^0 \qquad (9)$$

where p^0 is the vapour pressure of the pure sorbate. Then

$$\ln r = \ln(\gamma_1/\gamma_2) + \ln(p_2^0/p_1^0) \ . \qquad (10)$$

According to Trouton's rule (a not altogether correct approximation), the molar entropy of evaporation ΔS_v at the boiling point of a given substance is constant, whereupon

$$RT \ln p^0 = k_3 - \Delta H_v \ , \qquad (11)$$

where ΔH_v is the molar heat of evaporation. Subject to a series of significant stipulations, the molar heat of evaporation can be replaced by the boiling point, which permits a reformulation of Eqn.(11):

$$\ln p^0 = k_4 + k_5 T_b \ . \qquad (12)$$

Finally, if it is assumed that γ_1/γ_2 is constant, we obtain an equation of type (8) linearly relating the boiling point of the sorbate to its retention.

All the assumptions made virtually reduce the applicability of the linear relation between the logarithm of the retention volume and the boiling point of the sorbate to the members of a single homologous series and even here the relation is considerably strained. This is indicated by data obtained for paraffins and olefins on non-polar stationary phases, i.e. for the most ideal solution; for this correlation, $s^0 = 2\%$.[104] The average standard error of the calculation for simple monofunctional compounds based on the linear relation between I and T_b amounts to 5 K when Apiezon L and Carbowax-20M are used as the stationary phases, the error increasing for the lowest members of the homologous series[110]. The relation holds accurately for isomeric hydrocarbons, which actually makes it possible to correct some boiling points of sorbates[111].

The use of the correlation between the boiling points of sorbates and their retentions can be recommended only for non-polar stationary phases. With increase of the polarity of the stationary phase, the correlations become non-linear[109,112,113]. To correct this disadvantage, various correction factors have been proposed. For example, the ratio z of the number of carbon atoms in the aromatic ring to the total number of carbon atoms in the molecule has been employed[113]. The equation derived is applicable to alkylbenzenes with Carbowax-1500 as the stationary phase:

$$I = 6.5T_b + 7.66z - 305 \ . \qquad (13)$$

The average standard deviation of the data evaluated by this equation for C_7–C_{13} alkylbenzenes is 6.5 units. Particularly large deviations from the linear relation between I and T_b are observed in cases where there is steric hindrance to the interaction: for aromatic hydrocarbons[113–116], phenols[117], and heterocyclic compounds[118]. The claims that the deviations s for correlations of this kind involving a series of different classes of substances, including polar compounds, do not exceed one unit are rendered unreliable by all these factors[119–124].

As stated above, the similarity of the properties leads to a satisfactory correlation between I and T_b for isomeric compounds. The difference between Kováts indices for such compounds ΔI is linearly related to T_b:[125,126]

$$\Delta I = k\Delta T_b \ , \qquad (14)$$

but the proportionality coefficient k varies within wide limits. For example, Kováts and Vehroi[127,128] have found it to be 5, while Gastegnau and Villesot[129] obtained a value of 6.5.

Since the molar heat of evaporation varies somewhat with temperature, it has been suggested[130] that the column temperature T_c be taken into account by the relation

$$\ln V_g = k_1 + k_2 T_b/T_c \qquad (15)$$

where V_g is the specific retention volume. A family of parallel lines have been obtained in terms of the variables of this equation for hydrocarbons on the silicone elastomer E-301 and have been used to identify substances in homologous series[131–133], although more careful studies[134] indicate some curvature in relations of this kind.

The availability of the boiling points of many organic compounds has led to a large number of attempts to employ T_b as a parameter defining retention. For example, the temperature retention index has been proposed[133]. It is related to

the Kovats index in the following manner:

$$(\lg V_{Nx} - \lg V_{Nn})/(\lg V_{N(n+1)} - \lg V_{Nn}) = (T_{bx} - T_{bn})/(T_{b(n+1)} - T_{bn}), \quad (16)$$

where the subscript x refers to the test substance, n to the n-paraffin with n carbon atoms in the molecule, and $n+1$ to the n-paraffin with $n+1$ carbon atoms in the molecule.

By analogy, the following form of the index has been put forward[135]:

$$I_b = 100n + 100(\lg T_{bx} - \lg T_{bn})/(\lg T_{b(n+1)} - \lg T_{bn}) \quad (17)$$

and Shlyakhov et al. proposed yet another formulation[136]:

$$I^0 = (T_{bx} - T_{bn})/(T_{b(n+1)} - T_{bn}) + 100n . \quad (18)$$

The average discrepancy between I and I_ν is 16 units and even on non-polar sorbates such as isoparaffins this quantity is 5.1 units[134], which significantly reduces the value of such indices for practical GLS: however, some workers[135] believe that it is possible to employ the temperature retention index for hydrocarbons.

The molar volume of the sorbate $\overline{V}$ is also used to set up correlations with retention parameters. A linear relation between $\overline{V}$ and $\lg r$ has been established for a non-polar stationary phase[134,135], but, with increase of the polarity of the stationary phase, the correlation between these quantities disappears. A similar correlation has been found for alkynes[136]. The molar volumes of organic compounds are less readily available than the boiling points, which has been one of the main causes of the small popularity of such correlations. Furthermore, correlations of this kind are valid only for a limited number of systems.

The refractive index and the molar refraction characterise the ability of the sorbate to exhibit a dispersion interaction with the stationary phase. Correlations between these quantities and the retention parameters have been found in a number of studies, for example, for acid esters on a silicone stationary phase[137] and for hydrocarbons on phthalate esters[138]. In the latter case the discrepancy between the experimental and calculated data is on average 4 units. Correlations of the same type have been found for dimethylbiphenyls and xylenes[139], perhalogenoalkanes[140], and certain other classes of organic compounds[141,142]. The attempts to establish correlations between the retentions and the parachors of sorbates has been described[143].

It has been shown[143] that $\ln V_N$ is proportional to the quantity $(M - 170)^{1/3}$ for organoarsenic compounds on a silicone stationary phase (M is the molecular weight of the sorbate). By analogy with the Kovats retention indices, a molecular retention index has been proposed[144], using the molecular weights of the test substance and n-paraffins. In the presence of steric hindrance to intermolecular interaction, the correlation between the retention and the molecular weight disappears[145]. However, the molecular weight of the sorbate as well as its refractive index and molar refraction can be correlated solely with the energy of the dispersion interaction and for this reason the application of the above quantities is limited solely to non-polar systems, where the dispersion interaction plays the main role.

The orientational and inductive interactions of the sorbate with the stationary phase can be taken into account by resorting to the dipole moment of the molecule μ (the orientational interaction energy is proportional to the square of the dipole moment of the species). The following equation has been proposed[146,147] for the relation between the retention volume and the dipole moment of the sorbate molecule:

$$\ln V_N = k_1 + k_2\mu . \quad (19)$$

However, the dipole moment enters into this equation with a power exponent of unity, which conflicts with the equation for the orientational interaction energy. A correlation between the retention characteristics and the molecular dipole moment of the sorbate has been found for xylidines[148], although such correlations have not been observed for oxygen-containing compounds[149]. The proportionality of the "polar" component of the retention volume to the square of the molecular dipole moment of the sorbate has been established for mononitro-derivatives of aromatic hydrocarbons[150]; on passing to dinitro-derivatives, the proportionality ceases to hold.

We believe that the use of the dipole moment of the entire molecule in the description of the intermolecular interaction in gas-chromatographic solutions is incorrect, since the orientational interactions in such solutions takes place between bond microdipoles[151]. A correlation between the retention and the dipole moment of the sorbate molecule is therefore hardly general. The same considerations apply also to another correlation parameter—the dielectric constant of the sorbate molecule[152,153]. An attempt to use the dispersion interaction as well as the orientational forces to characterise the retention has been made in a study[154] where the bonding parameter [the term $f(\chi)$] and the dipole moment were introduced into the equation

$$I = f(\chi) + k_1\mu^2 + k_2 . \quad (20)$$

The average discrepancy between the retention parameters calculated by this equation and found experimentally is 5–6 units.

The linear correlation postulated[155] between V_g and the viscosity of the sorbate has been tested for a series of dinitriles in polar stationary phases.

The size and shape of the molecule are taken into account by the Wiener three-parameter equation for the calculation of the Kovats indices of alkylbenzenes[156,157]. This approach is intermediate between the pure empirical calculation from the atomic group increments and the attempts to employ a definite physical parameter of the sorbate molecule.

Apart from the physical parameters of sorbate molecules, chemical characteristics such as the Hammett, Taft, Jaffé, and Palm constants have also been used to establish correlations with retention parameters. The Hammett–Taft constants are related to the ionisation potentials of molecules and are determined empirically from the reactivities of specific functional groups. In particular the Hammett constants characterise the energy of the hydrogen bond with phenols.

A relation was derived[158] for a pair of substituted phenols (subscripts 0 and x), which includes the Hammett constant σ, the constant k_1, and the activity coefficients of the phenol molecule (γ) and of a homomorphous molecule which does not form a hydrogen bond (γ^*):

$$\ln(\gamma_0/\gamma_x) = \ln(\gamma_0^*/\gamma_x^*) + k_1\sigma . \quad (21)$$

It follows from Eqn.(20) that, in order to ensure the linearity of the relation between the activity coefficients and the Hammett constants, the ratio γ_0^*/γ_x^* must be constant, i.e. Eqn.(21) is valid only for an isotopical series. As a rule, this is the case for isomeric compounds where the hydrogen bond energy makes a significant contribution to the overall intermolecular interaction energy. When a polyester stationary phase was used, a linear correlation between $\ln(\gamma_0^*/\gamma_x^*)$ and σ for phenols was observed with a correlation coefficient of 0.89 and an error s^0 of 3%.[158] This correlation coefficient for GLC data is extremely low, which indicates a low suitability of the correlation between the retention characteristics and the chemical constants for *a priori* calculations in GLC. A detailed thermodynamic analysis of the application

of Hammett–Taft contants in chromatographic calculations has been carried out[159-161].

The application of Hammett, Taft, and other constants is to some extent justified when there is a significant contribution of specific interactions (for example, hydrogen bonding) to the overall molecular interaction energy in the gas-chromatographic solution. There is hardly any physicochemical justification for the application of these constants in the calculation of the retention parameters of aromatic hydrocarbons and some of their derivatives. However, numerous attempts to find linear correlations of the type[139,162,170]

$$\ln r = k_1 + k_2\sigma \ , \qquad (22)$$

have in fact been made for such systems.

A more complex equation, containing a series of Hammett constants (σ_1, σ_2, and σ_3) has been proposed[49] for the retention parameters of derivatives of aromatic hydrocarbons on Apiezon L and Carbowax 20M:

$$\Delta\ln V_N = k_1\sigma_1 + k_2\sigma_2 + k_3\sigma_3 \ . \qquad (23)$$

The proportionality constants in this equation are found by regression analysis. The relative average standard deviation of the calculated data from experimental quantities was 1.5% for the system investigated. The comparatively high accuracy of the proposed computational method can be explained by the introduction into the equation of three constants with three proportionality coefficients: even without a physicochemical justification, the use of an empirical three-parameter equation can ensure approximately this accuracy of the calculation.

As already stated above, the application of Hammett type constants for the construction of correlations between the retention characteristics and the physicochemical properties of the sorbate is justified only for systems with a significant specific interaction. For the remaining systems (and these are the majority in GLC), one has to introduce a series of correction factors, including the interaction factor i, the resonance factor $\overline{R}$, and the Taft constant σ_0:[171]

$$\ln r = k_1(\sigma_0 + i\Delta\sigma\overline{R}) + k_2 \ . \qquad (24)$$

A number of studies[172-175], in which the characteristics of the steric hindrance to intermolecular interaction E_j, the contribution of the structural element of the sorbate molecule to the retention index I_i, and the empirical increment of the Kovats index for the selected structural group in the aliphatic compounds I_i^0 were used in the calculations, have been carried out on the application of the Taft constant to the calculation of the retention indices of bifunctional compounds (dihalogenoalkanes, halogenoepoxy-compounds, and ethers):

$$I_i = I_i^0 + k_1\sigma + k_2E_j \ . \qquad (25)$$

Correlations between the retention parameters of alkylbenzenes and the Taft constants have also been found in another study[176]. Correlations have also been established between the retention parameters of tri- and tetra-methylbenzenes and the Jaffé constants[177], between the retention parameters of aromatic hydrocarbons and their ionisation potentials[178,179], and between the retention parameters of a series of sorbates and the Palm constants and the Newman's rule of six[180,181]. The following equation was found to hold in the study of alkylpyridines on Carbowax-400, glycerol, Apiezon L, and dinonyl phthalate with a correlation coefficient of 0.99 and $s = 0.021\ln V_N$:[182]

$$\lg\frac{\gamma_0}{\gamma_x} = \lg\frac{\gamma_0^*}{\gamma_x^*} + k_1\sum\sigma_0 + k_2\sum E_s \ , \qquad (26)$$

where E_S is the steric Palm constant. The following equation has been derived[183] for the retention parameters of phenols on silicone OV-225 and neopentyl glycol adipate using the molecular refraction R_0 (I_{St}—data for the standard compound);

$$I = k_1I_{st} + k_2\sum\sigma + k_3\sum R_0 + k_4 \ . \qquad (27)$$

It has been suggested[184,185] that the mean square of the molecular radius be used in combination with the boiling point, or the molecular weight, or the density of the sorbate. The employment of such two-parameter correlations makes it possible to calculate the retention parameters for isoalkanes with s ranging from 1.3 to 5.5 units, the error of the calculation increasing with increase of the number of carbon atoms in the isoalkane molecule.

The single-parameter relations for the retention parameters presented above suffer from a very significant disadvantage: in their derivation it is postulated that the retention in GLC depends only on the properties of the sorbate, i.e. that the stationary phase should not make any contribution to the retention of the sorbate. Such neglect of the influence of the intermolecular interaction in gas-chromatographic solutions cannot fail to be reflected in the accuracy of correlation calculations of this kind. Only single-parameter relations describe the behaviour of the pure sorbate and not the properties of the solution and therefore such relations are at best useful for the description of the retention of small groups of sorbates with similar physicochemical properties using non-specific stationary phases (non-polar phases are best). An increase in the number of parameters in the correlation equation increases the accuracy of the calculation not so much because of the more complete allowance for all the intermolecular interaction factors in solutions as by virtue of the minimisation of the errors in the employment of a large number of empirical proportionality coefficients.

One of the successful trends in the use of two-parameter correlation equations has been developed by Dimov and coworkers[186-194], who postulated a correlation between the Kovats indices and the molar volume and the vapour pressure of the sorbate. In the derivation of correlation equations use is made of the Hildebrand–Scatchard theory of regular solutions, according to which a relation of the following type holds:

$$r = p_{12}^0\overline{V}_{21} \qquad (28)$$

(subscripts 12 and 21 show that the given quantity is the ratio of the corresponding characteristics of substances 1 and 2 being compared). According to this theory, for athermal solutions the free energy of solution is limited by the change in molar entropy on dissolution:

$$\Delta S_s^0 = -R\ln\overline{V}_{21} \ . \qquad (29)$$

The last two relations are based on the so-called physicochemical interaction indices (PCI). However, although two independent parameters of the sorbate were used in the calculations, the accuracy of the calculated data is far from being acceptable: for example, the mean square deviation of the PCI from the experimental values of I for isoparaffins on squalane was 7 units[186]. Such deviations are not surprising bearing in mind that solutions of isoalkanes in a paraffinic stationary phase can never be treated as athermal[195].

The significant errors in the calculation caused Dimov and coworkers to introduce a series of corrections, which are treated as corrections to the entropy of solution (more correctly this was an attempt to compensate for the deficiencies of the extremely simplified model of the gas-chromatographic solution). This correction (SN) was calculated from the following equation:

$$SN = k_1 + k_2X_1 + k_3X_2 + k_4X_3 + k_5X_4 + \ldots \ , \qquad (30)$$

where $X_1 = n_g$, $X_2 = n_{b\text{-}CH_3}/n_L$, $X_3 = (n_b + n_{CH_3})/(n_L + n - n_t)$, $X_4 = n_b n_{CH_3}/n_L(N - n_t)$, n_g is the number of possible conformations of the carbon chain of the molecule, n_b the number of n-butane units in the sorbate molecule, n_L the length of the n-paraffin chain, n_t the number of quaternary carbon atoms, and n the number of carbon atoms in the molecule.

Although Eqn.(30) involves the characteristics of the molecular structure of the sorbate, no justification for this is presented. Thus it reduces to a typical equation for correlations using the regression analysis of the experimental data. As was to be expected, the employment of additional five empirical proportionality coefficients made it possible to reduce the error of the calculation for isoalkanes on squalane to 1.4 units[191]; it must be emphasised that this error characterises interpolation calculations. When attempts were made to extrapolate the relations to higher homologues or isoalkanes with a larger number of carbon atoms in the molecule, the error increased severalfold (for practical GLC, the greatest difficulties arise precisely for alkanes with a large number of carbon atoms in the molecule, for which as a rule there are no published retention characteristics). For example, the employment of the relations obtained[191] in the extrapolation calculations of the parameters I of isoalkanes entails an error of approximately 5 units. The method of Dimov and coworkers has been used for the interpolation calculations of the Kováts indices for alkanes[192], alkylbenzenes[193], and cycloalkanes[194].

It has been suggested that the ratio $I_h/T_b\overline{V}$ (I_h are the retention indices of halogenoalkanes when the standard compounds used in the calculations are not n-alkanes, as for the Kováts indices, but the corresponding halogeno-n-alkanes) be employed for interpolation calculations[196]. For halogenoalkanes, this ratio is approximately constant, but, on passing to more polar sorbents, for example, alcohols on squalane[197], it becomes variable. On the other hand, when stationary phases of the type of Carbowax are used in the separation of n-alkyl alcohols, the above ratio again becomes constant. Thus a necessary condition for the constancy of the ratio is the similarity of the physicochemical properties of the sorbate and the stationary phases. However, even when this condition is observed, the attempt to apply $I/T_b\overline{V}$ as a characteristic of isoalkyl alcohols showed that it depends on the structure of the sorbate molecule[198].

An attempt at a thermodynamic justification of the preferential employment of the entropy factor for the calculation of the retention parameters of hydrocarbons has been made[199] using the Flory–Huggins equations. The free energy of mixing was treated[199] as the sum of the contributions of the entropy of mixing and the residual free energy of solution. Comparison of the calculated and experimental data for isoparaffins on Apiezon M showed that $s = 3$ units for this method. A formula has been proposed[134] for the retention index using the ratios of the molar volumes of the sorbate and the stationary phase. The error of the interpolation calculations using this retention index for C_6–C_8 isoparaffins (stationary phase—squalane) is 1.5 units and is close to the error of experimental data.

Unfortunately, even the two-parameter relations based on the properties of the pure sorbates do not permit the attainment of the required universality in calculations of the retention. It is not fortuituous that the method of calculation using eight additional empirical characteristics, which require the use of computers for the necessary calculations, was described in one of the latest communications by Dimov[200]. An example of the correlation equations proposed by Dimov for isoalkanes is given below[200]:

$$SN = 4.28 - 0.79n_r + 0.27n_i - 0.05n_d + \\ + 2.46n_{CH_3} + 1.50n_b - 2.21n + 0.57n_t \ , \qquad (31)$$

where n_t is the number of branches in the main carbon chain of the sorbate molecule, n_i the number of carbon atoms in the branches of the sorbate molecule, and n_d the number of methylene groups located between the branches of the carbon chain of the sorbate molecule.

Analogous equations have been derived with a series of empirical constants for olefins, cycloalkanes, and alkylbenzenes. In order to set up the necessary computer program, it is necessary to employ the experimental data for 17 to 20 hydrocarbons. The mean square deviation of the calculated data is approximately 2 units. It must be emphasised that all the calculations are of the interpolation type.

Takacs and coworkers[201–207] attempted to use not only the properties of the pure sorbate but also the characteristics of their interaction with the stationary phase for the derivation of correlation equations; this is undoubtedly an advance in the development of scientifically based methods for the calculation of retention in GLC. The properties of the pure sorbate are characterised by the sum of the atomic contribution I_a and the bond contribution I_b, while the interaction with the stationary phase is estimated in terms of the quantity I_i:

$$I = I_a + I_b + I_i + I_m + I_i \ , \qquad (32)$$

where I_m is the molecular index. The computational scheme postulates the additivity of all the increments of the equation, I_a is assumed to be 0.1 of the atomic weight of the given atom, and I_b is calculated by an iterative method from the experimental data using the number of bonds of the same type. The ratio of I_i and I_m was chosen in such a way that it is 25% of I at 100 °C and 25.5% at 50 °C.[201–209] Unfortunately, the correction for the influence of the stationary phase was assumed to be constant for all sorbates, which makes the above concept a variant of correlations with physicochemical properties of sorbates. The advantages of Takacs's method includes the endeavour to treat the retention parameters by resorting to molecular constants, excluding empirical characteristics of the individual sorbates such as the boiling point, the molecular weight, the refraction, etc.

In the calculation of the retention indices of the C_8–C_{10} isoparaffins on squalane the error of the calculation was 1.25 units,[205] which is comparable to the experimental error. In a later study[206] this error was as much as 2.7 units. An attempt has been made[210] to calculate the retention indices of olefins on squalane using the Takacs method; the average standard error (based on interpolation data) was then 16.7 units and for linear undecenes it was 14.5 units. The introduction of new corrections for the calculation of the Kováts indices made it possible to reduce the error to 3.7 units[208]. It has been found[208] that the ratio I_i/I_m is not the same for different sorbates; this to a large extent vitiates the Takacs equation. The large number of empirical parameters and the arbitrary nature of the derivation of the relations in the Takacs approach have been pointed out[211]. However, the approach itself has been applied in a number of subsequent studies. For example, a method has been described[209] for the calculation of I for alkylbenzene on Apiezon L, Carbowax-20M, diethylene adipate, and diethylene sebacate with the aid of a computer. The Kováts indices for alkanes have also been calculated[210].

An increase of the number of factors involved in the calculation is characteristic of many studies in which the retention indices of sorbates are related to physicochemical characteristics. A multifactor correlation equation for the specific retention volume, including the molecular weight of the sorbate M and the π-electron cloud density ρ_π, has been proposed[212,213]; the quantity E_S provides a measure of the steric hindrance to intermolecular interaction:

$$\ln V_g = k_1 M + k_2 \rho_\pi + k_3 E_s + k_4 \ . \qquad (33)$$

The coefficients of this equation are calculated by regression analysis from the experimental retention parameters. However, even this large number of empirical parameters does not enable one to obtain sufficiently accurate results in calculations by Eqn.(33); in the calculation of the V_g for polysubstituted aromatic hydrocarbons the error $s^0 = 25\%$ and can be reduced only by taking into account additional empirical corrections.

Thus the more complex the structure of the sorbate molecule, the greater the number of physicochemical characteristics which must be introduced into the equation for the calculation of retention characteristics. In practice it is impossible to isolate 1–2 dominant physicochemical parameters of the sorbate which would ensure a sufficiently high accuracy of the calculated data. The endeavour of some investigators to employ for this purpose the methods of factorial analysis[214-221], where the maximum number of sorbate parameters are introduced into the computational equations and then the characteristics which influence the retention parameters to the greatest extent are selected on the basis of experimental data, therefore appears to be quite natural.

Studies have shown[214] that the most important parameters of the sorbates are the molecular weight, the molar heat of evaporation, the molar refraction, and the constants of the equation of state. The molecular weight and the molar refraction characterise mainly the energy of dispersion interaction, while the remaining characteristics refer to the overall quantitative estimate of the energy of the interaction of the sorbate molecules with one another. Less important factors are the boiling point and the logarithm of the vapour pressure of the pure sorbate. Its density, dipole moment, vapour pressure, and dielectric constant are parameters for which the correlation with the retention characteristics is very weak. The smallest error of the calculation (approximately 5 units for butyric acid esters) is attained when one of two sets of sorbate parameters is used: (1) the boiling point, the van der Waals constants, the molar refraction, and the specific contribution of the ester group to the intermolecular interaction and (2) the boiling point, the van der Waals constants, the specific contribution of the ester group to the intermolecular interaction, and the number of carbon atoms in the molecule[220]. When an attempt was made to calculate the retention parameters of eighteen aliphatic acid esters on 25 stationary phases, it was shown[222] that the correlation of the results with five sorbate parameters ensures $s = 2.8$ units, an increase of one in the number of parameters employed reducing the error to 2.1 units.

A variant of factorial analysis has been used in studies[223, 224], where the retention factors P of alkylpyridines and ketones were calculated using a parameter proportional to the size of the sorbate molecule x_1, its polarity x_2, the characteristic of the steric environment of the functional groups x_3, and the number of pairs of vicinal alkyl groups x_4:

$$P = k_1 + k_2x_1 + k_3x_2 + k_4x_3 + k_5x_4 \ . \qquad (34)$$

A modification of this equation was presented in a subsequent study by the same workers[225], where the dipole moment of the sorbate molecule (μ) and the number of alkyl substituents in the α-position relative to the functional group (n_0) were used:

$$I = k_1 + k_2n + k_2\mu + k_3n_0 \ . \qquad (35)$$

The last equation was used to calculate the retention parameters of derivatives of aromatic hydrocarbons and pyridine on stationary phases such as Apiezon L, Carbowax 20M, silicone XE-60, and diethylene adipate; $s^0 = 3\%$ for phenols, $s = 56$ for anilines, $s = 14$ for alkylbenzenes, and s is up to 32 units for polar benzene derivatives. Such errors show that the last two equations yield only estimates.

Thus analysis of the attempt to use only the physicochemical characteristics of the sorbate without taking into account intermolecular interaction in gas-chromatographic solutions permits the conclusion that a more or less accurate calculation of retention parameters requires the employment of a number of empirical parameters together with the selected physicochemical constants, which is so large that the complexity of the calculations approaches that of the calculations using topological analysis. Thus the employment of only the characteristics of the sorbate does not lead to the solution of the problem of the calculation of retention parameters, because one then ignores the influence of the stationary phase on the intermolecular interaction in solution. The choice of one or several parameters of sorbates for the calculation of retention parameters can be justified only for a comparatively narrow range of substances and only for interpolation calculations.

The attempts at quantum-mechanical calculations of retention indices using the Hückel method of linear combinations of molecular orbitals are actually close to the above group of methods[226]:

$$I = k_1E + \sum k_2Q_i + k_3, \qquad (36)$$

where E is a dimensionless parameter which depends on the molar volume of the sorbate and the overall energy of the electrons in the molecule and Q_i is the effective charge on the ith atom of the sorbate molecule. The application of Eqn. (36) to the calculation of Kovats indices for cyclohexane derivatives on Apiezon L leads to $s = 14.5$ units. A reduction of the errors to 7–8 units is achieved when E is replaced by the sum of the indices referring to the σ- and π-electrons of the sorbate molecule[227]. The average deviation of the calculated data from the experimental results for 59 derivatives of cholestanyl acetate on SE-30 silicone is 5.7 units, the error increasing to 19.2 units on QF-1 silicone and to 39 units on more polar stationary phases. In calculations for narrow groups of sorbates, the error falls to 0.3 of a unit[226, 228]. The errors of calculations using quantum-mechanical data show that it is undesirable to employ characteristics of this kind: quantum-mechanical calculations for complex molecules are extremely laborious and the information obtained concerning the distribution of electron density in the molecule is only partly employed for calculations on the intermolecular interaction. Finally, the large number of what are essentially empirical parameters in the quantum-mechanical calculations for complex molecules of organic substances makes these methods similar to purely empirical procedures.

GLC practice has shown that the influence of the stationary phase on the retention must be taken into account in all methods for *a priori* calculations. Numerous instances have been described in the literature where a change in the nature of the stationary phase not only alters the relative retention parameters but also alters the sequence in which the substances are eluted from the column. Such phenomena are not reflected in any of the equations quoted in this section of the review. From this standpoint, it would appear to be useful to combine in the computational equations both the properties of the pure sorbates and the characteristics of the stationary phase. The latter quantities can be specified in terms of the Rohrschneider[229] or MacReynolds equations. When the three-parameter Rohrschneider equation is used, the error s in calculations for simple monofunctional sorbates is 12.6 units, while the application of the five-parameter Rohrschneider equation to the same systems lowers the error to 4.1 units. An intermediate error (6 units) has been obtained using the four-parameter Rohrschneider equation[230]. Similar correlations have been used[231] on 14 polysiloxane stationary phases for esters; the correct choice of test substances reduced the

error of the calculation from 6.7 to 4.7 units[232]. The constants of the MacReynolds equation proved to be less suitable for calculations than the corresponding constants of the Rohrschneider equation[233]: the errors for the three-parameter equation reached 30 units.

A series of column parameters and three–four constants of the sorbate have been used in the calculations of the values of I for alcohols, ethers, olefins, and aromatic and aliphatic hydrocarbons on Apiezon L, OV-25 silicone, and 5CP silar[234] with the column temperature programmed in the range from 25° to 250–300 °C. The MacReynolds constants, the molecular weight of the sorbate, its boiling point and molar volume were used. The discrepancies between the calculated and experimental data were 8–10 units.

An attempt to combine factorial analysis with the topo logical method has been described in a study[235], where the advantage of such combinations is emphasised. On the other hand, the influence of the stationary phase on the separation is taken into account by the appropriate choice of test substances, whose initial empirical constants are determined. The nature of these test substances must be as close as possible to that of the substances investigated.

Thus the data examined show that, only by resorting to the characteristics of the interaction of the stationary phase with the sorbate, can one devise an acceptable method for the calculation of the retention parameters of sorbates differing in physicochemical properties. The neglect of the influence of the stationary phase on the retention converts computational methods into specific procedures with extremely limited applications.

IV. THE POSSIBILITY OF USING THEORIES OF SOLUTIONS FOR THE CALCULATION OF RETENTION PARAMETERS

In contrast to the correlations between the retention parameters and the properties of pure sorbates, the application of the theory of non-electrolyte solutions makes it possible to relate the intermolecular interaction energy in solution to the retention parameter of the sorbate. From this standpoint, the employment of theories of solutions is extremely promising for *a priori* calculations of retention parameters. Unfortunately, the lack of a general theory of dilute non-electrolyte solutions or at least of a theory of gas-chromatographic solutions has largely retarded the application of individual variants of theories of solutions to practical calculations of retention parameters. Most of the theories of solutions employed model ideas which simplify unduly the picture of the intermolecular interaction in the gas-chromatographic solution.

Gas-chromatographic solutions have the following specific properties[151]: (a) the concentration of the solution is extremely low and as a rule ranges from 0.1 to 0.001%, (b) the sorbate molecule is much smaller than the molecule of the stationary phase and the intermolecular interaction therefore involves the entire sorbate molecule and part of the molecule of the stationary phase, and (c) the temperature of the stationary phase in the chromatographic column is usually closer to its melting point than to its boiling point, which makes it preferable to use the structure of the solid as an approximation to the structure of the stationary phase. The low concentrations of gas-chromatographic solutions suggest that the main type of interaction in them is that between the sorbate molecules and the surrounding molecules of the stationary phase. The concentration effects in dissolution play only a secondary role for gas-chromatographic solutions, whereas in the classical theories of solutions mainly concentration effects are investigated[1,2].

In comparing data obtained in the classical theory of solutions and the quantities characteristic of GLC, one should note that these two groups of data differ significantly: in the traditional theory of solutions the principal aim is to study the changes in the properties of substances on mixing (the liquid components are mixed), whereas in the study of gas-chromatographic solutions the main question is the alteration of the energy characteristics of the substance when it passes from the gas phase to the solution. The only thermodynamic quantity which has the same significance for the two approaches being compared is the activity coefficient γ and we shall therefore endeavour to confine ourselves to the consideration of attempts at calculations of this parameter.

Many theoretical concepts of the classical theories of non-electrolyte solutions are inapplicable, in principle, to gas-chromatographic solutions. These include all the theories which treat the liquid as a set of solid spherical particles. In view of the wide variety of gas-chromatographic systems consisting of molecules with comparatively complex conformations, only phenomenological theories of solutions can be used for gas-chromatographic calculations.

Since the model of the solid state constitutes the best approximation to the structure of the gas-chromatographic solution, theories treating the liquid as a quasi-crystal lattice have gained great popularity in GLC: each atomic group of the molecules of the stationary phase in the sorbate occupies one site in such a lattice. The ideas of Miller and Guggenheim[236,237] and of Flory and Huggins[238,239] constitute the basis of the equation which represents the excess free energy of solution, proportional to $\ln\gamma$, as the sum of $\ln\gamma^e$ (γ^e reflects the change in intermolecular forces on dissolution) and $\ln\gamma^s$ (this term characterises the entropy contribution due to the different dimensions of the molecules of the stationary phase and the sorbate)[240]. For low values of γ^e, these two parameters can be regarded as independent and then, neglecting the change in the energy of intermolecular forces on dissolution, one can formulate the following equation[241]:

$$\ln\gamma = \ln(1/r_1) + 6\ln\frac{6r_1}{5r_1+1} + \overline{F} \quad , \tag{37}$$

where r_1 is the ratio of the molar volumes of the sorbate and the stationary phase and F the interaction parameter consisting of the enthalpy ($\overline{F}_h$) and entropy components. The following relation is valid for athermal solutions:

$$-\Delta S_s^e/R = \ln(1/r_1) + 6\ln\frac{6r_1}{5r_1+1} + \overline{F}_s \quad , \tag{38}$$

where ΔS_s^e is the excess molar entropy of solution. In some cases $\overline{F}_s$ makes the main contribution to ΔS_s^e.[242] Eqn.(38) has been tested experimentally in relation to the retention parameters of paraffins and cycloparaffins on dinonyl phthalate[243].

A somewhat different form of the Flory–Huggins equation has been proposed for gas-chromatographic calculations[244]:

$$\ln\gamma = \ln r_1 + r_1 + 1 \quad . \tag{39}$$

The authors[244] point out the incorrectness of the representation of r_1 by the ratio of the molar volumes of the sorbate and the stationary phase and suggest that the ratio of the numbers of carbon atoms in the linear chains of the molecules of the sorbate and the stationary phase be used. If it is supposed that $\ln r_1 \ll r_1$, it is possible to derive the following correlation equation[245]:

$$\ln\gamma = k_1 + k_2 r_1 \quad . \tag{40}$$

The Flory–Huggins equation has also been used to calculate the retention parameters of C_1–C_6 alcohols on poly(ethylene glycol)-400;[246] the error s^0 in this method of calculation is 4%.

The Flory–Huggins ideas describe fairly satisfactorily the energy contributions associated with the difference between the sizes of the molecules of the stationary phase and the sorbate; unfortunately the problems of the calculation of $\bar{F}_s$ and $\bar{F}_h$ have been inadequately investigated to date. The Hildebrand–Scatchard theory for regular solutions can be applied to calculations of $\bar{F}_h$ using the so-called solubility parameter $\delta = [(\Delta H_v - RT)/V]^{0.5}$. When the latter is taken into account, Eqn.(36) can be formulated thus:

$$\ln \gamma = \ln(1/r_1) + 6 \ln \frac{6r_1}{5r_1 + 1} + \frac{\bar{V}^*}{RT}(\delta_1^2 - \delta_2^2)^2 , \qquad (41)$$

where $\bar{V}^*$ is the apparent molar volume of the sorbate.

In calculations of the retention parameters of C_5–C_7 isoparaffins, C_6–C_7 olefins, and cycloalkanes with the same number of carbon atoms in the molecule, the error is $s^0 = 1.8\%$.[243] However, the quantity $\bar{V}^*$ is to a large extent formal and all the factors contributing to the entropy of solutions are not reflected in Eqn.(41); furthermore, the need to determine the molar volumes and heats of evaporation increases the difficulty of the preliminary experiments required for calculations involving this equation.

Eqn.(41) is applicable only to systems in which the species are linked solely by dispersion forces. On the other hand, if orientational and inductive forces are manifested in the solution, it is necessary to introduce the corresponding corrections and the last term on the right-hand side of Eqn.(40) assumes the following form[246]:

$$\frac{\bar{V}^*}{RT}[(\delta_1^2 - \delta_2^2)^2 + (\omega_1^2 - \omega_2^2)^2 - f]$$

where

$$(\omega_1^2 - \omega_2^2)^2 = \frac{3.25 \cdot 10^7}{\bar{V}_1^2 RT}(\mu_1^2 \bar{V}_1 + \mu_2^2 \bar{V}_2) .$$

The quantity f is a correction for the negative deviation from Raoult's law. It is actually calculated as the discrepancy between the calculated and experimental data. When this equation is used for interpolation calculations of the retention parameters of hexenes on dimethylformamide, $s^0 = 6.7\%$.[247] The application of the modified Hildebrand–Scatchard equation to polar systems has been discussed in detail[248–250].

When the last equations are employed, there are certain difficulties associated with the necessity to determine the molar volumes of the sorbates and the stationary phase. In order to overcome these difficulties, it is suggested that these characteristics be calculated by indirect methods, for example, from the additive contributions of atomic groups[251] and from the solubility and viscosity[252,253]; it has also been suggested[254,255] that the effective molar volume be used as corrections for the surface tensions of the liquids.

The simplified ideas underlying the Hildebrand–Scatchard theory preclude the attainment of an acceptable accuracy in the calculation of gas-chromatographic retention characteristics for a wide range of compounds. It is difficult to expect that the two-parameter relation for the molar heat of solution as a function of ΔH_v and $\bar{V}$ will describe correctly the entire set of forces acting in a gas-chromatographic solution. The conversion of Eqn.(40) into three- and four-parameter modifications gives rise to only an apparent effect: it is known[214] that, when a three-parameter relation is available, the minimisation of the experimental proportionality coefficients can lead to fairly accurate interpolated data regardless of the nature of the correlation and the parameters employed for it.

It has also been suggested that the parameter $\bar{F}_h$ be evaluated as the mean (geometrical or arithmetical) of the energies of the sorbate and stationary phase molecules[256] or on the basis of Barker's theory[257,258]. The latter ideas have been used in a series of investigations[259–263] in which $\bar{F}_h$ was treated as the result of the interaction between the individual segments of the molecules, which gives the best description of the real pattern of the interaction in the gas-chromatographic solution. The authors[259–263] used the following equation:

$$\bar{F}_h = [q_1(u_1 - u_2)^2 E_i/kT]\, m_2^2 , \qquad (42)$$

where q_1 is the total number of points of contact, u_i the fraction of points of contact of type i for the given molecule, m_2 the mole fraction of the stationary phase in solution, and E_i the interaction energy. It has been postulated that E_i is independent of the medium surrounding the sorbate molecule. It has been shown[264] that the quantity $\bar{F}_h$ characterises the molar enthalpy of mixing. Barker's theory has also been used to calculate the retention parameters of alkanes[265–268], but no quantitative estimates of the accuracy of the method employed are indicated.

Prigogine's theory of solutions has been modified for gas-chromatographic systems[269]:

$$\bar{F}_h = h_1 k_i / 4RT, \quad \bar{F}_s = k_1(\lambda + k_i)^2/2R,$$
$$\lambda = 1 - (k_n/\bar{r})_2 (k_n/\bar{r})_1, \quad k_i = (\varepsilon_{22} - \varepsilon_{11})/\varepsilon_{22} , \qquad (43)$$

where $3k_n/\bar{r}$ is the number of external degrees of freedom of the molecular segment, k_i a constant proportional to the depth of the potential well for the 1–1 and 2–2 interactions of the substances and determined from the critical temperature and the volume of the hard spheres, h_1 the configurational enthalpy, k_n the configurational heat capacity, and ε the interspecies interaction potential. The quantity $k_n/\bar{r}$ can be determined directly. An empirical equation involving the number of segments in the sorbate molecule has been proposed for this purpose[269].

The activity coefficients of C_4–C_{10} n-alkanes in C_{22}–C_{36} n-paraffin stationary phases have been calculated to test Eqns.(43).[244] The experimental data showed that the ratio $k_n/\bar{r}$ increases linearly with the number of carbon atoms in the molecule of the stationary phase (the stationary phase is designated by subscript 2 and the sorbate by subscript 1). The authors[244] used the following equation for their calculations:

$$\bar{F} = 18(n_1 + 1)[1/(n_2 + 1) - 1/(n_1 + 1)]^2 \cdot E_i/kT . \qquad (44)$$

The configurational enthalpy and the parameter k_i were calculated from the formulae

$$h_1 = \Delta H_v + RT \qquad (45)$$

$$k_i = \frac{T_2^c \tilde{V}_2^{1/3}}{T_1^c \tilde{V}_1^{1/3}} - 1 \qquad (46)$$

where subscript c refers to the critical parameter and $\tilde{V}$ is the van der Waals volume.

The relative average standard deviation of the calculated quantities from the experimental data was 0.8%. According to the authors[244], the question of the influence of $\bar{F}_s$ on the retention parameters remained unelucidated in view of the inadequate accuracy of the experimental results. On the other hand, it has been claimed[270] that $\bar{F}$ is wholly determined by $\bar{F}_s$, while $\bar{F}_h$ has the greatest influence on the experimental error. In fact, however, the neglect or underestimate of the contribution of any of the components of $\bar{F}$ to the retention parameter distorts the real pattern of the intermolecular interaction in gas-chromatographic solutions, where the influences of the entropy and enthalpy of solution on the free energy of solution are comparable.

Prigogine's theory of solutions has been used[271] to describe the properties of solutions of benzene in polyphenyl stationary phases. The entropy of mixing was calculated on the basis of the lattice model of the liquid state and the energy

of the intermolecular forces was calculated using the theorem of corresponding states, although the latter employs a number of assumptions which are by no means correct.

The group method[271] operates, in conformity with its physical significance, also with two components of the free energy of the interaction of the sorbate with the stationary phase, namely the entropy component γ_S, calculated from the Flory–Huggins equation, and the group component γ_j, calculated from the equation

$$\gamma_j = n_{mj}(\lg\gamma_m - \lg\gamma_m^*) \quad , \qquad (47)$$

where n_{mj} is the number of groups k in the molecule j, γ_m the activity coefficient of the structural group k in solution, and γ_m^* the activity coefficient of group k in the pure solvent. After a series of simplifications, the following equation has been proposed for homologous series of sorbates, incorporating the constants of the interactions of individual structural groups[272]:

$$\lg\gamma = k_1 + k_2/(n_1 + k_3) + k_4k_5/n_1 + \\ + n_2/(k_5 + n_2) + k_6(k_5 - n_1)^2 \quad . \qquad (48)$$

All the constants in Eqn.(48) (from k_1 to k_6) are determined experimentally with the aid of test sorbates. The error of the calculated data is in this case 5–10%.

The relations for the calculation of the energy of intermolecular interaction by the method of the group theory have been examined in a general form[273,274]. It has been postulated that the interaction energy is additive with respect to the structural groups of the molecule in the stationary phase and the sorbate (the groups m_i^v and m_i^u respectively). For dilute binary solutions, the excess molar heat of solution is calculated from the equation

$$\Delta H_s^e = k_{12}s_1 \quad , \qquad (49)$$

where

$$k_{ij} = -\sum_{uv} k^{uv}(m_i^u/s_i - m_j^u/s_j)(m_i^v/s_i - m_j^v/s_j)s^u s^v,$$

$$s_i = \sum m_i^u s^u, \quad k^{uv} = \varepsilon^{uv} - 0.5(\varepsilon^{uu} + \varepsilon^{vv}) \quad .$$

Comparison of the calculated and experimental molar heats of solution of hydrocarbons of different classes shows that the average standard error of the calculation is 0.14 kJ mol^{-1}. It has been noted that the molar entropies of mixing of hydrocarbons calculated from the Flory–Huggins equation differ from the experimental values by a factor of 10–20. This shows that the description of the entropy of solution cannot be restricted to a single factor—the different dimensions of the molecules of the sorbate and the stationary phase. As shown in the next section, the entropy of solution consists of 4–5 main components, among which the factor associated with the differences between the dimensions of the molecules of the sorbate and the stationary phase is not the main one.

Calculations of the activity coefficients by the group method showed[274] that s^0 = 1.6% for acids in water, 4.5% for alcohols in water, 2.4% for alcohols in paraffins, 5% for ketones in paraffins, 5–8% for cycloalkanes in heptane, and 5–13% for paraffins and cycloalkanes in triethylene glycol. It is noteworthy that the errors of the calculation are smaller for extremely non-ideal systems such as those in alcohols and paraffins, while for solutions close to ideality (solutions of hydrocarbons in hydrocarbons) the errors of the calculation are large. This apparently indicates an unsuccessful choice of test substances for the determination of the empirical coefficients in the case of non-polar and weakly polar systems, while the final result of the calculation depends on the intuition of the investigator, as in factorial analysis. In the model of the group theory, the activity coefficients are calculated using a large number of empirical corrections introduced in the form of interaction coefficients and the effective cross-sections (encounter probabilities) of individual structural groups $s^{u,v}$. Despite this, the given model is closest to the approach based on the theory of group additivity and examined in Section II of this review. The errors themselves are also of the same order of magnitude as for the purely empirical methods for the calculation of retention parameters.

The application of the free volume theory to the calculation of the activity coefficients of spherical molecules has been described[275]. According to this theory, the potential energy of the liquid depends on the difference between its real volume and its calculated van der Waals volume. The introduction of a series of simplifying assumptions made it possible to calculate the activity coefficients of a number of molecules containing germanium, silicon, and titanium; the errors of the calculation proved to be smaller than those arising in the application of the Guggenheim and Hildebrand–Scatchard theories. A number of inorganic compounds have been investigated in a study[276,277] where the free volume theory was also used for the calculations.

The theory of conformal solutions[278], the theory of athermal solutions[278,279], and the theory of regular solutions[241] have also been used to calculate the retention parameters. The last two theories are more suitable for correlation calculations, because the concepts of athermal and regular solutions are invalid for real gas-chromatographic solutions.

The study of the statistical thermodynamics of solutions constitutes one of the trends in the theory of solutions, which are promising from the standpoint of their application to GLC: no model ideas, i.e. ideas simplifying the real picture of the interaction, are then put forward. The energy of the intermolecular interaction is calculated as the sum of the elementary functions of state of the molecules in solution: the intermolecular interaction energy of each conformation of the molecule and its statistical weight. However, the *a priori* determination of these parameters still encounters difficulties which cannot be overcome and which are associated with the inadequacy of our information about the real conformations and interactions of the molecules in solution. Nevertheless certain ideas on statistical thermodynamics have begun to be used in calculations of the relative retention; for example, the relative retentions of the stereoisomers of substituted cyclohexanoic acids have been calculated[280], with errors ranging from 0.1 to 1.5%, from the ratio of the partition functions based on the parameters of the rotational spectra of the molecules.

Analysis of the data described in this section permits certain conclusions concerning the possibility of employing the theories of solutions for the calculation of retention parameters in GLC. According to some results[151,269], three main factors contribute to the excess free energy of solution in GLC: (a) the geometrical effects arising as a consequence of the difference between the sizes of the molecules of the stationary phase and the sorbate (see the Flory–Huggins theory); (b) the energy effect associated with the energy of the intermolecular forces in solution ($\bar{F}_n$); (c) the structural effect associated with the change in the conformation of the molecule on dissolution and with the restriction of the number of degrees of freedom on passing from the gas to the liquid phase ($\bar{F}_s$). The effect (a) has been fairly thoroughly investigated and has been described mathematically, but its contribution does not always exceed 5–10% even to the entropy of solution. For the remaining two effects, the modern theories of dilute non-electrolyte solutions cannot provide an adequately accurate mathematical description, which is the reason why workers in the field of chromatography have been disappointed by the application of theories of solutions to the calculation of retention parameters in GLC. The significant model limitations (hard spheres, theorem of corresponding states, etc.) of solution theories preclude

their application to the description of the properties of a wide variety of gas-chromatographic systems. The introduction of additional empirical parameters lowers the value of solution theories to the level of the methods of empirical calculations of retention parameters.

V. SEMIEMPIRICAL CALCULATIONS OF THE MOLAR HEATS AND ENTROPIES OF SOLUTION

Most of the studies on the application of solution theories in calculations of retention parameters are associated with the evaluation of the activity coefficients, which are not in general direct retention characteristics: the calculation of activity coefficients requires (in the ideal case) the availability of data on the fugacity or (usually) the movement of the saturated sorbate vapour. At the same time the determination of thermodynamic functions for the phase equilibrium in gas-chromatographic systems does not require any information at all about the vapour pressure or fugacities of sorbates, i.e. such information in no way assists in the calculation of retention parameters. Furthermore, the molar free energy of solution (the free energy of the phase transition) as well as quantities proportional to it (I and $\ln V_N$) are hardly susceptible to calculation by additivity methods or methods involving the employment of correlations between the retention parameters and the physicochemical properties of the sorbates.

Consequently it is useful to seek a compromise, which combines the main advantages of the theoretical foundations of the intermolecular interaction, the solution theories, the correlations with physicochemical properties, and the additive contribution of individual atomic groups to the interaction energy. We believe that the application of these ideas is possible in the separate analysis of two main components of the molar free energy of solution—the molar heat of solution and the molar entropy of solution. A series of ideas in statistical thermodynamics and molecular physics can be related to each of these thermodynamic quantities, including the experience accumulated in the employment of the physicochemical characteristics of sorbates and stationary phases as well as purely empirical approximations.

In a series of studies of Sakharov and coworkers[281-288] gas-chromatographic solutions have been treated as quasi-crystalline lattices and the molar heats of solution ΔH_s have been treated as the sum of the energy of intermolecular forces and the work of formation of a hole within the solvent in which the sorbate molecule is accommodated. If the treatment is restricted to isomeric substances, then the molar heat of formation of the hole ΔH_h can be neglected for comparative calculations. The energy of intermolecular forces $\Delta H_s - RT$ can be quite correctly represented as the sum of the increments (ΔH_i) due to individual atoms (or groups of atoms) in the sorbate molecule. The energy of the intermolecular forces between the nth atom of the sorbate molecule and the stationary phase is calculated as the difference between the energy of the interaction of an isolated nth atom with the stationary phase E_n and the quantity E'_n reflecting the intermolecular shielding of the same atom in the sorbate molecule, i.e. ΔH_n represents the effective interaction of the nth atom with the stationary phase. It has been postulated[281-288] that the values of $\Sigma E'_n$ for isomeric compounds are identical and that $\Delta\Sigma E_n$ represents the difference between the molar heats of formation of these isomers (this claim is not altogether correct). Finally, it has been suggested that the molar entropy of solution is proportional to the molar heat of solution or, in other words, that the molar free energy depends solely on the molar heat of solution.

Linear correlations between $\ln r$ and the difference between the molar heats of formation of isomers have been found experimentally for C_4–C_7 alkanes and cycloalkanes using a non-polar stationary phase. This made it possible to formulate the following rule: "of two isomers with similar structure, the resonance and polar factors in the molecules of which are equal, the isomer with the greater (molar) heat of solution in the non-polar solvent has a smaller (molar) heat of formation"[281]. It is noteworthy that the suggested analogy between the energy of intermolecular forces in solution and the energy of formation of the molecule is formal, which is the reason for the considerable scatter of experimental points in many instances relative to the calculated relations. For example, the relations between the Kováts indices of isomeric olefins and their molar heats of formation[285] consist of a family of straight lines with different slopes and each straight line corresponds to a group of isomers with the same number of branches in the carbon chain around the double bond. Similar relations have been found for alkylbenzenes and certain other classes of compounds. The disadvantages of this concept include the correlation of the retention characteristics solely with the properties of the isomers being separated and the neglect of the influence of the stationary phase on the retention.

It is noteworthy that the approach of Sakharov and coworkers to the treatment of the intermolecular interaction in gas-chromatographic solutions has yet another positive aspect: attention is concentrated on the evaluation of the relative retention parameters r and I. Indeed, in GLC practice the main criterion of the selectivity of the stationary phase is the relative retention parameter which makes it possible to infer whether the separation of the relevant sorbates ($r \neq 1$) on a given stationary phase is possible and how difficult it is to achieve (the value of r and to some extent the value of V_N or V_g). The simplicity of the calculation of the relative retention parameters from experimental data, the low experimental error in the determination of these quantities, and their simplified theoretical treatment, where the effects of many factors cancel out made the relative retention parameters the most popular in GLC practice at the same time and, which is no less important, the most reproducible[289]. The principal thermodynamic relations between the relative retention parameters and the intermolecular interaction parameters are fairly simple (the superscript 0 denotes a relative molar thermodynamic function):

$$\Delta G_s^0 = -RT \ln r = \Delta H_s^0 - T\Delta S_s^0 \quad . \qquad (50)$$

It is therefore useful to describe briefly the semiempirical concept underlying the calculation of the relative molar thermodynamic functions of dissolution[290-292]. In this concept the gas-chromatographic solution is regarded as a quasi-crystalline lattice where each site is occupied by an atom (or atomic group incorporating all the chemically linked hydrogen atoms). Since the sorbate molecule is surrounded on all sides by the molecules of the stationary phase (infinitely dilute solution), the calculation of the intermolecular interaction in the given system reduces to the calculation of the energy of the interaction between the atomic groups of the sorbate molecules and the surrounding atomic groups of the stationary phase, and the relative positions of the molecules must be selected on the basis of the minimum potential energy of the system.

In conformity with the traditional ideas concerning the formation of a solution, the experimental molar heat of solution ΔH_S can be represented as the sum of the energy of the intermolecular forces between the sorbate molecule and the stationary phase E_i, the molar heat of formation of the hole, and the term RT reflecting the change in the energy of the

system on condensation of the ideal gas into the liquid phase:

$$\Delta H_s = E_i + \Delta H_h + RT \quad . \tag{51}$$

If the treatment is restricted to systems with dispersion interaction, the calculation of the energy of intermolecular forces is feasible. Sakharov[281] proposed the following equation for the energy of the dispersion interaction of the *i*th atom with the stationary phase:

$$U_d = -0.9 \int_{r_i+r_0}^{\infty} 0.75h\nu \frac{\alpha_i \cdot 4\pi r^2 \bar{\rho}}{r^6} dr = 0.9\pi h\nu \frac{\alpha_i \bar{\rho}}{(r_i + r_1)^3} \quad , \tag{52}$$

where α is the polarisability, $\bar{\rho}$ the density of the polarisability of the medium, i.e. of the stationary phase (the ratio of the molar refraction to the molar volume of the stationary phase), r_i the van der Waals radius of the *i*th atom, h the Planck constant, ν the average vibration frequency of the molecules of the stationary phase with the *i*th atom, and r_1 the average van der Waals radius of the functional groups of the stationary phase. Sakharov suggested that the quantity $D = \alpha_i/(r_i + r_1)^3$ be called the "dispersity" of the atom or atomic group and demonstrated, by analysing the literature data, a correlation between the Kováts index and the "dispersity".

A somewhat simpler relation between the dispersion interaction and the molar heats of solution in a non-polar stationary phase has been derived differently[290]. The dispersion interaction energy of a pair of fairly remote spherical particles (the distance between them is greater than the covalent radius) is described by an equation which includes the polarisabilities of the atomic groups of the sorbate (α_i) and the stationary phase (α_2):

$$U_d = -k\alpha_i\alpha_2\bar{r}^6 \quad . \tag{53}$$

When the interaction of atoms or atomic groups in a gas-chromatographic solution is considered, then Eqn.(53) is valid. On replacing the atomic polarisability by the atomic refraction R_0, we obtain the equation

$$D_n = R_{0i}R_{02}/(\bar{r}_i + \bar{r}_2)^6 \quad . \tag{54}$$

Indeed the linear correlation between ΔH_S and ΣD_n holds for a number of classes of non-polar and moderately polar compounds[293,294].

If the term $\bar{r}_1 + \bar{r}_2$ is represented as the sum of the van der Waals radii of an atom (or atomic group) in the sorbate and an atom (atomic group) in the stationary phase, then the values of D_S can be readily tabulated for all the atoms and atomic groups incorporating chemically bound hydrogen atoms[291]. The constants of the intramolecular shielding of the atoms or atomic groups of the sorbate can be readily calculated on the basis of the species constructed taking into account stereochemical ideas[295]. Thus the increments of the energy of the dispersion interaction of the atoms and atomic groups of the sorbate molecule with the medium (stationary phase) can be calculated from the molecular characteristics[290,291]. The quantity E_i is calculated as the sum of n increments due to the atomic groups of the molecule:

$$E_i = i \sum_n K_n D_n \quad , \tag{55}$$

where i is the normalising multiplier and K_n the coefficient of the intramolecular shielding of the atomic group of the sorbate. The normalising coefficient is calculated from the experimental molar heats of solution of n-paraffins and takes into account the influence of the real non-polar medium on the molar heat of solution. It varies non-linearly with the number of carbon atoms in the n-paraffin molecule, approaching exponentially a limiting value at $n > 7$.

Allowance for the work of formation of a hole in the gas-chromatographic solution is a difficult problem, whose solution depends on the real structure of the stationary phase. It has been suggested[283,296] that the work of formation of a hole in the solvent is proportional to the surface tension of the stationary phase and the surface area of the sorbate molecule. However, such hypotheses are valid only for a structureless stationary phase, which can be represented approximately as a system of randomly distributed small spherical molecules. The real stationary phases in GLC consist of an anisotropic medium with a distinct structure, which has been confirmed by X-ray diffraction studies[297]. For example, liquid paraffin stationary phases constitute a system of mutually oriented linear hydrocarbon chains, which migrate freely in parallel planes with a minimal energy expenditure. Therefore, if the accommodation of the sorbate molecule in a paraffin stationary phase requires merely a shift of a paraffin molecule in a parallel plane (longitudinal shift), then the work of formation of a hole is minimal; this applies to the dissolution of n-paraffins; the work of formation of a hole in n-paraffins is assumed to be zero in comparative calculations. On the other hand, when the structure of the stationary phase changes on dissolution, then the work of formation of the hole can no longer be neglected. For example, on dissolution of a branched isoparaffin in an n-paraffin stationary phase the molecules of the stationary phase move apart in a plane at right angles to their longitudinal axis (transverse shift). In the transverse shift of the molecules of the stationary phase the work of formation of a hole is proportional to the number of branches of the hydrocarbon chain of the sorbate molecule, although in the general case the relative positions of the branches also influence the work of formation of the hole[291,298].

In the chromatography of polar sorbates on non-polar or weakly polar stationary phases, a new factor appears—the concentration effect Δk,[299–304] which is due to the association of the molecules of the polar sorbate in the non-polar solvent, which occurs even at infinitesimal concentrations of the solution. The effect is particularly large for alcohols and other sorbates forming a hydrogen bond (approximately 14 kJ mol^{-1}); for the remaining polar sorbates, the energy of the concentration effect is approximately 3–6 kJ mol^{-1}.[301]

In the determination of the energy of intermolecular forces of polar sorbates in polar stationary phases account must be taken of the orientation interaction, which arises under the influence of the dipole moments of the functional groups of the stationary phase and the sorbates, which are determined by stereochemical factors. The bond microdipoles are partly shielded by the chemically linked atoms or atomic groups; apart from the bond microdipoles, the so-called secondary dipoles, formed by chemically non-linked atoms or atomic groups, participate in the orientation interaction. The contribution of the orientation interaction to the energy of the intermolecular forces can be determined solely by considering specific systems with allowance for the optimum relative positions of the molecules of the sorbate in the stationary phase. Examples of the determination of the extent of the orientation interaction in gas-chromatographic systems have been published[305–307].

The intermolecular forces in solutions of aromatic and other cyclic molecules must be calculated taking into account the relative spatial distribution of the molecules, the electronic effects of various substituents in the aromatic ring, and a number of other features characteristic of systems with steric hindrance to interaction. These questions have been discussed in detail[304,308–316].

The calculation of the relative molar entropy of solution for gas-chromatographic systems involves considerable difficulties. It follows from Section IV that the application of the

Flory–Huggins equation alone to the solution of this problem is inadequate. The difference between the molar entropies of the sorbate in the gas phase and in solution ΔS_S is determined by the following factors[317]. In the gas phase the entropy of the molecule includes the entropy of the rotational movement S_r [the sum of the entropies of the internal (S_{ri}) and external (S_{re}) rotational movements], the electronic entropy, the vibrational entropy, the nuclear components, and the translational entropy S_{tr}. On passing to the solution, the sorbate molecule loses some of its degree of freedom, i.e. the entropy decreases and the molar entropy of solution, calculated from gas-chromatographic data, is therefore always negative. The decrease of the entropy of sorbate molecules is determined primarily by the decrease in the rotational and translational entropies; as a consequence of the comparatively weak intermolecular forces in gas-chromatographic solutions, the remaining forms of the entropy of the sorbate molecules do not change on passing from the gas to the liquid phase.

Using the fundamental relations of statistical thermodynamics[318], it is possible to formulate the equation

$$\Delta S_{tr} = R \ln V^0 - k_1 , \qquad (56)$$

where V^0 is the molar volume of the ideal liquid related to the van der Waals molar volume of this liquid by the equation

$$RT \ln V^0 = R \ln M - R \ln \tilde{V} + k_2 . \qquad (57)$$

Eqn.(56) characterises the change in the translational entropy when the sorbate molecules pass from the gas to the liquid phase.

The so-called compensation effect[319], observed for many gas-chromatographic systems[320–323], makes a definite contribution to the entropy of solution. The essential feature of this effect consists in the linear relation between ΔS_S and ΔH_S for many simple systems, whose slope is an inverse function of temperature. The following equation is then obtained for the relative molar entropy of solution (the ratio for the sorbates x and r):

$$\Delta S_S^0 = \Delta H_S^0 T / k_1 + R \ln (M_x / M_r) - R \ln (\tilde{V}_x / \tilde{V}_r) + \Delta S_{re}^0 + \Delta S_{ri}^0 . \qquad (58)$$

For isomeric compounds, the values of $\tilde{V}$ are approximately the same. Calculations of the molar entropy of solution have been performed in a number of studies[308,324,325], where the influence of a change in the rotational entropy on ΔS_r was demonstrated.

The thermodynamic approach to the calculation of the molar heat and entropy of solution described above makes it possible not only to calculate the individual thermodynamic functions of solution but also to calculate, using their combination, the overall parameters of the selectivity of the stationary phase—the Kováts index and the relative retention, and the knowledge of the relative molar heats of solution makes it possible to calculate these quantities for any column temperature.

The given method makes it possible to obtain fairly accurately extrapolated retention parameters for extremely complex molecules. For example, the Kováts indices for C_9 and C_{10} isoparaffins on squalane have been calculated with an average standard error of 2.2 units[298]. Such an accuracy of extrapolation calculations is not ensured by any of the other methods considered in this review. The standard error of the calculation of the Kováts indices of C_7 and C_8 olefins on squalane by the same method proved to be 5.2 units, which is also the best result for such systems. In calculations of this kind, one introduces initially specific relations associated with the characteristics of the interaction of the individual structural groups of the sorbate molecules with the stationary phase and then these are used in the evaluation of the thermodynamic functions of solution, from which the Kováts indices are calculated.

Analysis of different investigations has shown that each group of methods has definite advantages and that at the present stage of the development of the theory of non-electrolyte solutions one cannot neglect any of these procedures.

When fairly extensive experimental data for test sorbates, grouped in specific series, are available, the optimum interpolated retention parameters can be calculated empirically by combining the methods of the topological and factorial analyses with the constants (for example, constants of the Rohrschneider type) for the stationary phase.

For interpolation calculations within narrow groups of sorbates with similar physicochemical properties, it is most rational to employ the correlations between the retention parameters and the physicochemical properties of the sorbates. The calculation of the thermodynamic functions of solution is possible only after a detailed analysis of the characteristics of the intermolecular interactions in the systems investigated. However, these are not only interpolation but also extrapolation calculations, which is particularly important for high-molecular-weight sorbates, whose retention parameters are usually unknown. The accuracy of the calculations using the fundamental functions of solution is highest among the methods considered.

Reactions of Peroxydisulphuryl Difluoride and Halogen Fluorosulphates with Organic Compounds

A.V.Fokin, Yu.N.Studnev, L.D.Kuznetsova, and I.N.Krotovich

The literature data on the reactions of peroxydisulphuryl difluoride and halogenofluorosulphates with various classes of organic compounds and on the methods of synthesis and properties of the above reagents are surveyed and described systematically. Attention is concentrated on the possibility of selective reactions which apparently predetermine the subsequent extensive employment of peroxydisulphuryl difluoride and halogen fluorosulphates for synthetic purposes. The bibliography includes 226 references.

I. INTRODUCTION

Peroxydisulphuryl difluoride $(OSO_2F)_2$ and halogen fluorosulphates $HalOSO_2F$, which were first synthesised at the end of the 1950's and the beginning of the 1960's[1-7], have comparatively recently attracted the attention of organic chemists as exceptionally active reagents permitting in a number of instances reactions which had not been feasible hitherto and a deeper understanding of the nature of the reactivities of many organic compounds, including those which had been previously regarded as the most inert.

Peroxydisulphuryl difluoride and halogen fluorosulphates are genetically related although their reactivities are to some extent different.

Peroxydisulphuryl difluoride—the peroxide of fluorosulphonic acid—differs from the majority of the known peroxides by the complete absence of explosive properties and a high stability in a pure state. By virtue of its structure, it is capable of supplying the $\dot{O}SO_2F$ radical, and is usually regarded as one of the most effective radical reagents. However, direct oxidations, which have been most thoroughly investigated in the case of inorganic substances, are also known.

Halogen fluorosulphates are mixed anhydrides of the corresponding halogen oxy-acids (for example hypochlorous and hypobromous) and fluorosulphonic acid. The name "halogenofluorosulphates" is used together with "halogen fluorosulphate".

In view of the similarity of the electronegativities of the fluorine atom and the fluorosulphate group, reactions of the radical type are more characteristic of fluorine fluorosulphate. In chlorine, bromine, and iodine fluorosulphates the halogen atoms carry a positive charge as a result of polarisation, so that these compounds are extremely effective electrophiles.

Since peroxydisulphuryl difluoride has been hitherto an essential precursor of halogen fluorosulphates (except fluorine fluorosulphate), its properties have naturally been investigated to a greater extent.

To ensure a compact exposition of the relevant data, in addition to the nomenclature generally adopted (such as, for example, the term methyl fluorosulphate CH_3OSO_2F), in a number of instances, as in the majority of original communications, the fluorosulphate group has been treated as a substituent: for example, bis(fluorosulphato)dichloromethane $CCl_2(OSO_2F)_2$ and tetrakis(fluorosulphato)methane $C(OSO_2F)_4$.

Individual questions of the chemistry of peroxydisulphuryl difluoride and halogen fluorosulphates have been dealt with in a number of publications[8-10], but sufficiently complete surveys are not available and in the present review an attempt has been made to make good this deficiency.

II. PROPERTIES OF PEROXYDISULPHURYL DIFLUORIDE AND HALOGEN FLUOROSULPHATES

Peroxydisulphuryl difluoride and chlorine and bromine fluorosulphates are low-boiling liquids, fluorine fluorosulphate is a gas, and iodine fluorosulphate and bromine and iodine trisfluorosulphates are readily fusible substances (see Table). The infrared and Raman spectra[3,11,22-29] as well as ^{19}F NMR spectra[3,7,12,30-36] of the above compounds have been studied in detail.

The high reactivity of peroxydisulphuryl difluoride is due to the ease of its dissociation into radicals[3,14-19,37]:

$$S_2O_6F_2 \rightleftarrows 2OSO_2F \quad .$$

The molar dissociation energies of the O—O bond in peroxydisulphuryl difluoride and of the O—Hal bond in chlorine and fluorine fluorosulphates are listed in the Table. A calculation has been performed for the fluorosulphate radical by the LCAO-MO SCF method[38] and studies have been made of its infrared spectrum[39], its absorption spectrum in the visible region[14,15,40-42], and its fluorescence spectrum excited by laser radiation[43-46].

Solutions of peroxydisulphuryl difluoride in fluorosulphonic acid are not conducting[47], in contrast to solutions of, for example, iodine fluorosulphate[13].

Peroxydisulphuryl difluoride and halogen fluorosulphates are highly reactive compounds. They are best stored (except fluorine fluorosulphate) in sealed glass tubes, when no changes are observed in the specimen even after several months. The majority of the reactions can be carried out in

apparatus made of Pyrex glass, but at elevated temperatures quartz, Teflon, stainless steel, nickel, and monel metal are usually employed.

Certain physicochemical properties of peroxydisulphuryl difluoride and halogen fluorosulphates*.

*Note: E is the dissociation energy of the O–O or O–Hal bonds and λ_{vap} is the latent heat of evaporation.

**At 760 mmHg.

***Other values of E: 91.221 ± 0.628 kJ mol^{-1};[14] 94.487 kJ mol^{-1};[15] 112.968 kJ mol^{-1};[16] 104.60 kJ mol^{-1};[17] 93.722 ± 3.766 kJ mol^{-1}.[18,19]

****According to the results of Schack and Wilson[11], the boiling point is 43.4 °C, λ_{vap} = 31.610 kJ mol^{-1}, and Trouton's constant is 23.8.

*****According to the results of Roberts and Cady[6], the boiling point is 120.5 °C and d_4^{25} = 2.600 g cm^{-3}.

In contrast to organic compounds, peroxydisulphuryl difluoride and chlorine, bromine, and iodine fluorosulphates are insensitive to external influences (impact, brief contact with an open flame) and to changes in phase state, but fluorine fluorosulphate has shown a high tendency towards explosive decomposition even at temperatures below 0°C[48], which is apparently characteristic of liquefied $FOSO_2F$. The usual thermal decomposition of fluorine fluorosulphate at 236–263 °C leads to sulphuryl fluoride and oxygen[49], while in the presence of chlorine at 90–110 °C the products are peroxydisulphuryl difluoride, chlorine monofluoride, and a small amount of chlorine fluorosulphate[50]. Both reactions have been studied kinetically and the calculated data agree satisfactorily with experiment[51].

Both peroxydisulphuryl difluoride and halogen fluorosulphates react vigorously at room temperature with traces of moisture, benzene, acetone, and other organic compounds (sometimes with inflammation). Liquid chlorine fluorosulphate and peroxydisulphuryl difluoride ignite incompletely fluorinated greases. At low temperatures peroxydisulphuryl difluoride is much less reactive than chlorine and particularly bromine fluorosulphate. Peroxydisulphuryl difluoride therefore tends to accumulate in the reaction mass in many instances; as the temperature is raised, this can be the cause of a vigorous reaction and ejection of the mixture. Peroxydisulphuryl difluoride behaves analogously also in water containing ice, where it is initially precipitated as the lower layer.

The facts presented indicate the highly corrosive nature of the reagents; experiments employing them require reliable protection from atmospheric moisture, are potentially dangerous, must be carried out with adequate caution, and protective measures must be taken.

In order to increase the selectivity of the reactions, usually reduced temperatures (down to −100 °C), inert (highly fluorinated) solvents, very slow mixing of the reactants (for example, by diffusion *in vacuo*), and similar procedures are used. The method of generating peroxydisulphuryl difluoride *in situ* by an electrochemical method is apparently extremely promising[52–54].

In a more detailed consideration of the properties of peroxydisulphuryl difluoride and halogen fluorosulphates one must emphasise that they react vigorously with many elements (the reactions of peroxydisulphuryl difluoride with the halogens described in the next section) and their hydrides, oxides, peroxides, and salts.

Peroxydisulphuryl difluoride readily oxidises sulphur[55–57], selenium[58,59], tellurium[60,61], and antimony[62], complex cations being formed in the first stage, for example[56,57]:

$$2S_8 + (OSO_2F)_2 \xrightarrow[HSO_3F]{t^\circ} S_{16}^{+2}(OSO_2F^-)_2 \quad \text{(red soln)}$$

$$S_8 + (OSO_2F)_2 \xrightarrow[HSO_3F]{0^\circ} S_8^{+2}(OSO_2F^-)_2 \quad \text{(blue soln)}$$

Many salts of fluorosulphonic acid, including complex salts, have been obtained by treating metals and their oxides or salts with peroxydisulphuryl difluoride (data up to 1972 inclusive have been surveyed in a review[9]) or halogen fluorosulphates; vigorous research is being continued[63–73], for example, the following methods of synthesis have been proposed[67,73]:

$$Ag + (OSO_2F)_2 \rightarrow Ag(OSO_2F)_2$$

$$Au + BrOSO_2F \rightarrow Br_3[Au(SO_3F)_4]$$

Fluorine fluorosulphate readily fluorinates not only salts[74], bromine[7], and iodine[75], but also xenon at 170–180 °C[76]:

$$FOSO_2F \xrightarrow{CsOSF_5} SF_5OF$$

$$FOSO_2F \xrightarrow{I_2} IF_3(OSO_2F)_2 + (OSO_2F)_2$$

$$FOSO_2F \xrightarrow{Xe} XeF_2 + (OSO_2F)_2$$

Peroxydisulphuryl difluoride reacts vigorously with ammonia, hydrogen sulphide, and hydrogen chloride[77]; chlorine fluorosulphate also readily reacts with the last substance[78]:

$$HCl + ClOSO_2F \rightarrow Cl_2 + HSO_3F$$

The main products of the reactions of peroxydisulphuryl difluoride[79–82] and fluorine[83], chlorine[78], and bromine[82] fluorosulphates with nitrogen oxide, tetroxide, and pentoxide, as well as the reactions of peroxydisulphuryl difluoride with nitryl and nitrosyl chlorides[82] are nitryl and nitrosyl fluorosulphates, for example:

$$HalOSO_2F + N_2O_4 \rightarrow NO_2OSO_2F + HalNO_2$$

Hal=F, Cl;

$$(OSO_2F)_2 + 2ClNO_2 \rightarrow 2NO_2OSO_2F + Cl_2$$

Peroxydisulphuryl difluoride interacts vigorously with tetrafluorohydrazine[84,85]:

$$(OSO_2F)_2 + N_2F_4 \rightarrow 2F_2NOSO_2F$$

The substitution of halogen atoms in chlorosulphonic acid[86], chlorosulphonyl isocyanate[87], and phosphoryl bromide[88] or chloride[89] on treatment with chlorine fluorosulphate, bromine fluorosulphate, or peroxydisulphuryl difluoride yielded the corresponding fluorosulphates:

$$ClSO_2NCO + BrOSO_2F \xrightarrow{20^\circ} FSO_2OSO_2NCO$$

$$Br_3PO + (OSO_2F)_2 \rightarrow (FSO_2O)_3PO + Br(OSO_2F)_3$$

SO_2Cl_2,[89] SOClF,[55] and $SeOCl_2$[90] react analogously. The reaction with *N*-chlorosulphinylamine is more complex[91]:

$$ClNSO + ClOSO_2F \rightarrow Cl_2 + SO_2F_2 + SO(OSO_2F)_2 + N_2 + S_2O_5F_2 + SO_2 + ClN(SO_2F)_2 + Cl_2NSO_2F \ .$$

Chlorine[92,93] and bromine[94] fluorosulphates have been used to prepare chlorine and bromine perchlorates:

$$NO_2ClO_4 + BrOSO_2F \rightarrow BrOClO_3 \ .$$

Peroxydisulphuryl difluoride only oxidises phosphorus trifluoride, thionyl fluoride, and carbon monoxide[55,95,96], but adds to arsenic trifluoride[97], sulphur dioxide[5,55,98,99], and sulphur tetrafluoride[55,99]; in the presence of potassium fluoride, a mixed peroxide can be obtained from thionyl tetrafluoride[100]:

$$(OSO_2F)_2 \xrightarrow{AsF_3} AsF_3(OSO_2F)_2 \ ; \quad \xrightarrow{SO_2} F_2S_2O_6 \ ; \quad \xrightarrow{SF_4} F_4S(OSO_2F)_2 \ ; \quad \xrightarrow{OSF_4,\ KF} F_5SOOSO_2F \ .$$

The reactions with CO,[95,96] SO_2,[98,99] and SF_4[99] have been studied by kinetic methods.

Fluorine fluorosulphate[75,101–104] and (even at room temperature) chlorine fluorosulphate[78] readily combine with sulphur dioxide and carbon monoxide:

$$HalOSO_2F \xrightarrow{SO_2} HalSO_2OSO_2F \ ; \quad \xrightarrow{CO} HalCOOSO_2F \ ;$$

Hal F, Cl .

The kinetics of the reactions involving SO_2[101] and CO[103,104] have been investigated at 60–120 °C and 30–90 °C respectively.

Peroxydisulphuryl difluoride and fluorine fluorosulphate could not be made to add to difluorodiazine[105].

On interaction with peroxydisulphuryl difluoride, metal carbonyls form fluorosulphonate salts of different composition[55,106,107], for example:

$$W(CO)_6 + (OSO_2F)_2 \rightarrow WO(SO_3F)_4 \ .$$

Although the reagents considered belong to the class of the most vigorous oxidants, nevertheless a detailed study has been made of the possibility of increasing the oxidation state of the halogen atoms in halogen fluorosulphates. The interaction of peroxydisulphuryl difluoride with OF_2,[32,108] ClO_2,[109] I_2O_4 and I_2O_5,[110–112] $(SF_5O)_2$,[113] and $(SeF_5O)_2$[114] has also been investigated, for example:

$$(OSO_2F)_2 + (SF_5O)_2 \rightarrow 2SF_5OOSO_2F \ .$$

Chlorine (but not bromine) fluorosulphate readily interacts with ozone at 0 °C[115]:

$$ClOSO_2F + O_3 \rightarrow O_2ClOSO_2F \ .$$

Chlorine oxide difluoride has also been used to oxidise chlorine fluorosulphate[116]. Treatment of iodine fluorosulphate with chlorine and bromine yielded the fluorosulphates $IHal_2OSO_2F$ and $I_2HalOSO_2F$ (Hal = Cl or Br)[13,117]; the interaction of ICl_2OSO_2F and IBr_2OSO_2F leads to $IBrClOSO_2F$.[118]

The above main types of reactions of peroxydisulphuryl difluoride and halogen fluorosulphates (oxidation, introduction of the fluorosulphate group, or halogenation and addition to unsaturated compounds) are as a rule also characteristic of reactions with organic compounds.

III. METHODS OF SYNTHESIS OF PEROXYDISULPHURYL DIFLUORIDE AND HALOGEN FLUOROSULPHATES

Peroxydisulphuryl difluoride and halogen fluorosulphates have not as yet become readily available and widely used reagents but the methods of their synthesis have been developed and described in fair detail.

The historical aspects of the early methods of synthesis have been examined in other reviews[8,9], which also present data (partly supplemented in the review of Gillespie and Morton[119] and certain publications[27,120]) concerning related compounds containing the $Br_n^+SO_3F^-$ (n = 2,3) and $I_n^+SO_3F^-$ (n = 2–7) polycations.

The fluorination of sulphur trioxide with fluorine in the presence of silver difluoride still apparently remains the most suitable procedure for the synthesis of peroxydisulphuryl difluoride[121,122]:

$$SO_3 + F_2 \xrightarrow{AgF_2;\ 150°} (OSO_2F)_2 + FOSO_2F \ .$$

The reaction has been carried out repeatedly[1–4,48,55,100,121,123]; its main disadvantage is the possibility of the formation of the potentially dangerous fluorine fluorosulphate[48,122]. By varying the conditions, the latter can be isolated as the main product[2–4]. It has been recommended that small amounts of peroxydisulphuryl difluoride be obtained[9] at 170 °C under static conditions without a catalyst[100]. It is apparently more desirable to employ for this purpose the complex salt $CsAgF_4$[124]:

$$CsAgF_4 + SO_3 \xrightarrow{25°} (OSO_2F)_2 + CsAg(OSO_2F)_3 \ .$$

The methods of synthesis of peroxydisulphuryl difluoride by the electrolysis of fluorosulphonic acid in the presence of potassium fluorosulphate *in vacuo* at −23 °C (current yield 55%)[123], by the photochemical fluorination of sulphur trioxide with fluorine[125–127], and by the fluorination of copper or nickel fluorosulphates at 200 °C[123] are evidently not of preparative interest [with the exception of the generation of $(OSO_2F)_2$ *in situ*[52–54]]. The above photochemical reactions and the interaction of oxygen fluorides with sulphur trioxide[127–129] and particularly sulphur dioxide[128,130] lead to the formation not only of fluorine fluorosulphate but also of fluorine peroxyfluorosulphate $FOOSO_2F$. Fluorine fluorosulphate and sulphuryl fluoride have been obtained by the photochemical fluorination of $F_2S_2O_6$.[131]

Photochemical[108] or thermal[5,132] fluorination of peroxydisulphuryl difluoride leads to fluorine fluorosulphate whose treatment with sulphur trioxide at 90–300 °C[3,20,55] or with ultraviolet radiation[126,127,133] regenerates peroxydisulphuryl difluoride:

$$(OSO_2F)_2 \underset{+SO_3}{\overset{+F_2}{\rightleftharpoons}} 2FOSO_2F \ .$$

The fluorination of sulphur trioxide and fluorosulphonic acid with xenon fluorides[76,134–139], chromium pentafluoride[140], uranium hexfluoride[141,142], and trifluoromethyl hypofluorite[143], the decomposition of silver fluorosulphate[67], the reactions described above[75,76], and the oxidation of fluorosulphonic acid in accordance with the scheme[144]

$$HSO_3F + O_2^+[AsF_6]^- \rightarrow (OSO_2F)_2$$

are fairly exotic methods of synthesis of peroxydisulphuryl difluoride.

Very pure fluorine fluorosulphate is formed on decomposition of tetrafluoroammonium fluorosulphate[145]:

$$NF_4OSO_2F \xrightarrow{10°} NF_3 + FOSO_2F \ .$$

Chlorine, bromine, and iodine fluorosulphates are obtained by treating peroxydisulphuryl difluoride with the corresponding halogens:

$$(OSO_2F)_2 + Hal_2 \rightarrow 2HalOSO_2F \ ; \quad Hal=Cl, Br, I \ .$$

The reaction with chlorine requires fairly severe conditions—the mixture of reactants must be heated in an autoclave for 5 days at 125 °C[7]; the process kinetics have been investigated[21]. It has been shown comparatively recently with the aid of spectra that, in solution in fluorosulphonic acid, chlorine interacts with $(OSO_2F)_2$ even at room temperature[146]. Bromine[6,12] and iodine[6,13,119] react at 25 °C and, depending on the molar ratios, it is possible to obtain either mono or tris-fluorosulphates of bromine or iodine:

$$(OSO_2F)_2 + Br_2 \rightarrow BrOSO_2F \underset{+Br_2}{\overset{+(OSO_2F)_2}{\rightleftharpoons}} Br(OSO_2F)_3 \ .$$

It follows from the foregoing that in the general case the ease of synthesis of halogen fluorosulphates is determined by the availability of peroxydisulphuryl difluoride. It is of interest to note that the interaction of iodine monochloride with peroxydisulphuryl difluoride leads to iodine trisfluorosulphate[55]:

$$ICl + (OSO_2F)_2 \rightarrow I(OSO_2F)_3 + Cl_2 \ .$$

Another pathway leading to the formation of the above reagents is based on the synthesis of chlorine fluorosulphate by the addition of chlorine monofluoride to sulphur trioxide[11,35,147,148]:

$$ClF + SO_3 \rightarrow ClOSO_2F \ .$$

The initial substances are condensed at −196 °C and are slowly heated to room temperature[11,35,148]. Ultraviolet irradiation of the chlorine fluorosulphate formed in almost quantitative yield gives rise to peroxydisulphuryl difluoride (yield 94–97%)[11,149] and treatment with bromine produces bromine fluorosulphate in 93% yield[148]:

$$ClOSO_2F \begin{cases} \xrightarrow{h\nu} (OSO_2F)_2 + Cl_2 \ ; \\ \xrightarrow{Br_2} BrOSO_2F \ . \end{cases}$$

The report of the possible formation of chlorine fluorosulphate in the reaction of nitryl chloride with the anhydride of fluorosulphonic acid[150] has not been reliably confirmed.

Thus the methods of synthesis of peroxydisulphuryl difluoride and halogen fluorosulphates are not complex and these substances can be readily obtained in any laboratory where studies with fluorine or fluorides are prosecuted.

IV. SUBSTITUTION OF HYDROGEN AND HALOGEN ATOMS AND CERTAIN FUNCTIONAL GROUPS

In view of the highly corrosive nature of peroxydisulphuryl difluoride and halogen fluorosulphates, the study of their reactions with organic compounds was begun in relation to the fully halogenated derivatives. Already at the beginning of the 1960's, it was shown that both peroxydisulphuryl difluoride[55] and bromine[6,12] and iodine[13] fluorosulphates react vigorously with carbon tetrachloride at room temperature to form phosgene:

$$CCl_4 \begin{cases} \xrightarrow{(OSO_2F)_2} COCl_2 + O(SO_2F)_2 + Cl_2 \ ; \\ \xrightarrow{2BrOSO_2F} COCl_2 + O(SO_2F)_2 + 2BrCl \ . \end{cases}$$

The above reactions can be regarded formally as direct oxidation, but one cannot rule out the possibility also of the intermediate formation and then decomposition of bis(fluorosulphato)dichloromethane. The latter hypothesis was soon confirmed and, depending on the reactant ratio, mono-, bis-, tris-, and tetrakis-(fluorosulphato)methanes were obtained at −22 °C[89]:

$$CCl_4 \xrightarrow[-BrCl]{+BrOSO_2F} CCl_n(OSO_2F)_{4-n} \ ; \quad n = 0-3$$

The second chlorine atom in carbon tetrachloride is apparently somewhat more readily substituted by the fluorosulphato-group using bromine fluorosulphate, since bis-(fluorosulphato)dichloromethane is formed together with the mono(fluorosulphato)-derivative even in the presence of a fivefold excess of carbon tetrachloride[89].

Further study of the reactivity of the above reagents showed that substitution by the fluorosulphato-group of the hydrogen atoms in alkanes, including hydrogen-containing polychlorofluoroalkanes but not bromoalkanes, and also in the OH, NH, NH_2, and similar groups is most characteristic of peroxydisulphuryl difluoride. Chlorine and bromine fluorosulphates are more effective for the substitution of halogen atoms (sometimes even fluorine atoms) by the fluorosulphato-group. The chlorinating (brominating) effect of these fluorosulphates in reactions with alkanes is not usually manifested, but this rule does not extend to functional groups and aromatic compounds.

Here one must bear in mind that the fluorosulphonic acid formed on substitution of hydrogen atoms by peroxydisulphuryl difluoride frequently tends to cause the degradation of the reaction products. On the other hand, the substitution of halogen atoms on treatment with chlorine and bromine fluorosulphates is accompanied by the liberation of the corresponding halogen or mixed halogen, which can be removed much more readily.

Next we shall consider the interactions of peroxydisulphuryl difluoride and then of the halogen fluorosulphates with various bonds and groups.

A. Aliphatic Compounds

1. Substitution of Hydrogen Atoms in Alkanes and Substituted Alkanes

Peroxydisulphuryl difluoride successfully substitutes the hydrogen atom in methylene chloride by the fluorosulphato-group even at −25 °C[77]. The attempt to substitute the second hydrogen atom was unsuccessful and only phosgene was isolated, in contrast to the interaction with methyl fluorosulphate, where bis(fluorosulphato)methane is formed smoothly and with a high yield[77]:

$$(OSO_2F)_2 \begin{cases} \xrightarrow{CH_2Cl_2} CHCl_2OSO_2F \xrightarrow{(OSO_2F)_2} COCl_2 \ ; \\ \xrightarrow{CH_3OSO_2F} CH_2(OSO_2F)_2 \ . \end{cases}$$

The reaction with methylene chloride has been carried out in trichlorofluoromethane; in the absence of the latter, vigorous explosions were observed.

Fairly unambiguous results are apparently achieved when peroxydisulphuryl difluoride is used at the instant of formation in electrolysis. Thus, by bubbling methane into the anodic compartment of the electrolytic cell containing a 1 M solution of potassium fluorosulphate in fluorosulphonic acid, it is possible to obtain selectively methyl fluorosulphate (yield 1–61%) or bis(fluorosulphato)methane (yield 6–63%), depending on the current density, temperature, and the degree of dispersion of the gas streams[52–54]:

$$CH_4 \xrightarrow[KSO_3F/HSO_3F]{(OSO_2F)_2} CH_3OSO_2F + CH_2(OSO_2F)_2 \ .$$

Analogous results have been obtained also for ethane[52,53]. The process kinetics have been investigated[54], suggesting a radical reaction mechanism.

Under these conditions, acetone is cleaved, bis(fluorosulphato)methane is formed from acetic acid, and in propionic acid the hydrogen atom in the β-position is substituted by the fluorosulphato-group, which leads to the relatively unstable β-fluorosulphatopropionic acid[52]:

$$(OSO_2F)_2 \mid KSO_3F/HSO_3F \mid \begin{cases} \xrightarrow{(CH_3)_2CO} MeOSO_2F + CH_2(OSO_2F)_2 + CH_3C(O)OSO_2F \\ \xrightarrow{C_2H_5COOH} FSO_2OCH_2CH_2COOH \xrightarrow[-HSO_3F]{-25^\circ} CH_2{=}CHCOOH \end{cases}$$

It was shown for the first time in 1972[151] that peroxydisulphuryl difluoride is effective even in relation to the primary hydrogen atoms in monohydrochloro- fluoro- and monohydroperfluoro-alkanes, which are exceptionally inert as regards radical substitution[77,151]. The reaction has been achieved with dichlorofluoro- and trifluoro-methanes, monohydroperfluoroethane[77], and monohydroperfluoropropane[151] at room temperature or with heating to 40–50 °C, for example:

$$CF_3(CF_2)_2H + (OSO_2F)_2 \rightarrow CF_3(CF_2)_2OSO_2F + HSO_3F .$$

The secondary hydrogen atoms in 2-chloro-2-hydro- and 2-hydroperfluoro-propanes are substituted even more readily (at 5–10 °C) by the fluorosulphato-group, but only hexafluoroacetone has been obtained from 2,2-dihydrohexafluoropropane[152]:

$$(CF_3)_2CH_2 + (OSO_2F)_2 \rightarrow (CF_3)_2CO .$$

The selectivity of the action of peroxydisulphuryl difluoride in relation to the hydrogen atom is indicated by the successful substitution of the latter in difluoronitromethane[153], α-hydroperfluoropropionitrile[152], ω-hydroperfluoroheptanonitrile[151], and 1-hydrotetrafluoroethylsulphur pentafluoride and 2-hydrohexafluoro-2-propylsulphur pentafluoride[154]:

$$(OSO_2F)_2 \begin{cases} \xrightarrow{O_2NCF_2H} O_2NCF_2OSO_2F \\ \xrightarrow{H(CF_2)_6CN} FSO_2O(CF_2)_6CN \\ \xrightarrow{(CF_3)_2CHSF_5} (CF_3)_2C(SF_5)OSO_2F \end{cases}$$

Treatment of 2,2,2-trifluoroethylsulphur pentafluoride with two moles of peroxydisulphuryl difluoride led only to trifluoroacetyl fluoride[154]:

$$CF_3CH_2SF_5 + (OSO_2F)_2 \rightarrow CF_3C(=O)F .$$

There is no doubt about the radical nature of the reactions considered, but no examples of the dimerisation of the hydrocarbon radicals formed as a result of the abstraction of a hydrogen atom by the fluorosulphate radical have been noted.

According to the authors[151], they obtained proof that such radicals really exist by treating a film of the vinylidene fluoride–perfluoropropene copolymer with gaseous peroxydisulphuryl difluoride at 50 °C, which makes it possible to introduce into the specimen a fairly large number of fluorosulphato-groups (the sulphur content was 7.21%). Even after the removal of these groups by treatment with aqueous pyridine, the polymer remained rigid and insoluble in acetonitrile, which is explained by its "cross-linked" nature[151].

Peroxydisulphuryl difluoride also readily interacts with the potassium salts of bromodinitromethane[153] and dinitroacetonitrile[100]. A radical-ion reaction mechanism has been put forward[100]:

$$\dot{O}SO_2F + [NCC(NO_2)_2]^- \xrightleftharpoons{-SO_2F^-} [NCC(NO_2)_2]^{\cdot} \xrightarrow{\dot{O}SO_2F} NCC(NO_2)_2OSO_2F .$$

As mentioned above, halogen fluorosulphates are inert with respect to the CH bond at the usual temperatures but vigorously substitute halogens. The only exception is apparently fluorine fluorosulphate, which reacts with chloroform in the gas phase even at −78 °C to form dichloromethyl fluorosulphate (80%) and trichlorofluoromethane (13%)[155]:

$$FOSO_2F + CHCl_3 \rightarrow CHCl_2OSO_2F + CFCl_3 .$$

Although in the main the process is directed towards the substitution of a halogen atom, the substitution of a hydrogen atom by fluorine under these conditions cannot in all probability be accounted for by the effect of chlorine monofluoride.

Chlorine fluorosulphate has been used successfully to chlorinate nitroform and dinitroacetonitrile salts[153]:

$$ClOSO_2F + KC(NO_2)_3 \rightarrow ClC(NO_2)_3 .$$

2. Substitution of Halogen Atoms in Halogenoalkanes and Carboxylic and Sulphonic Acid Chlorides

In contrast to the reactions discussed above, peroxydisulphuryl difluoride substitutes selectively the bromine atoms in methyl bromide[77] and in 1-bromopropane[156] by the fluorosulphato-group at room or a reduced temperature:

$$(OSO_2F)_2 + CH_3Br \rightarrow CH_3OSO_2F + BrOSO_2F + Br_2 .$$

In all probability, in this case peroxydisulphuryl difluoride substitutes bromine atoms only in the first instants, since the bromine fluorosulphate formed is much more reactive in the process. The bromine evolved readily interacts with peroxydisulphuryl difluoride, generating bromine fluorosulphate. These factors explain both the selectivity of the above reactions and the ease of substitution of the bromine atoms in other bromine-containing compounds.

Thus peroxydisulphuryl difluoride successfully substitutes the bromine atoms in bromotrifluoro-[157], dibromodifluoro-, tribromofluoro-, and tetrabromo-methanes[158]. In the last two examples carbonyl compounds are formed, including the relatively unstable carbonyl bisfluorosulphate[158]:

$$(OSO_2F)_2 \begin{cases} \xrightarrow{CBr_3F} FC(OSO_2F)_3 + FC(O)OSO_2F \\ \xrightarrow{CBr_4} OC(OSO_2F)_2 + CO_2 + S_2O_5F_2 \end{cases}$$

The reaction has also been extended to bromotris(difluoroamino)methane[159], 3-bromoheptafluoro-2-butanone[160], and trifluoroacetyl bromide[161]:

$$(OSO_2F)_2 \begin{cases} \xrightarrow{(F_2N)_3CBr} (F_2N)_3COSO_2F \\ \xrightarrow{CF_3C(O)CFBrCF_3} CF_3C(O)CF(CF_3)OSO_2F \\ \xrightarrow{CF_3C(O)Br} CF_3C(O)OSO_2F + CF_3OSO_2F \end{cases}$$

Chlorine atoms are substituted by peroxydisulphuryl difluoride with much more difficulty. As mentioned above, the only compounds which react under comparatively mild conditions are carbon tetrachloride (phosgene is formed at 25 °C[55]) and trichlorofluoromethane (20 days, 40 °C[142]). The chlorine atom in chlorotrifluoromethane could be substituted by the fluorosulphato-group only by heating the reactants at 150 °C and a pressure of 304×10^5 N m^{-2} for five days[157]. It has been shown spectroscopically[146] that 1,1,2-trichlorotrifluoroethane also reacts at 150 °C and only in the presence of fluorosulphonic acid. Peroxydisulphuryl difluoride substitutes the difluoroamino-group in difluoroaminocarbonyl chloride[162]:

$$(OSO_2F)_2 \begin{cases} \xrightarrow{CCl_3F} CCl_2FOSO_2F \\ \xrightarrow[HSO_3F]{CClF_2CCl_2F} CClF_2CClFOSO_2F \\ \xrightarrow{ClC(O)NF_2} ClC(O)OSO_2F + F_2NOSO_2F \end{cases}$$

The single example of the substitution of the chlorine atom in chloroform by fluorine fluorosulphate was described above[155].

Chlorine fluorosulphate has been used successfully even at temperatures below 0 °C to synthesise chloromethyl and chloroethyl fluorosulphates from methylene chloride and dichloroethane[86,163]. Treatment of *sym*-tetrachloroethane with two moles of chlorine fluorosulphate leads to a mixture of 1,1- and 1,2-bis(fluorosulphato)dichloroethanes in proportions of 3:1[164]:

$$ClOSO_2F \xrightarrow{ClCH_2CH_2Cl} ClCH_2CH_2OSO_2F \ ;$$
$$ClOSO_2F \xrightarrow{Cl_2CHCHCl_2} Cl_2CHCH(OSO_2F)_2 + FSO_2OCHClCHClOSO_2F \ .$$

At −40 °C chlorine fluorosulphate substitutes selectively the chlorine atom in alkyl monochloroacetates by the fluorosulphato-group[86,163]:

$$ClOSO_2F + ClCH_2COOR \rightarrow FSO_2OCH_2COOR \ .$$

The esters of fluorosulphatoacetic acid formed are relatively unstable at room temperature but, by virtue of their high reactivity, can be used *in situ* in further syntheses[86].

In the presence of fluorosulphonic acid, chlorine fluorosulphate substitutes vigorously the first chlorine atom in 1,1,2-trichlorotrifluoroethane by the fluorosulphato-group even at room temperature (with a small exothermic heat change)[165]:

$$CClF_2CCl_2F + ClOSO_2F \rightarrow CClF_2CClFOSO_2F + Cl_2 \ .$$

This indicates a much greater effectiveness of chlorine fluorosulphate in relation to the C–Hal bonds compared with peroxydisulphuryl difluoride, since the latter undergoes an analogous reaction only at 150 °C.[146]

Dichlorodifluoromethane and *sym*-tetrachlorodifluoroethane react analogously; at 70–85 °C it is possible to substitute two or three chlorine atoms in these compounds, while at 120 °C all the chlorine atoms and one fluorine atom are substituted in *sym*-tetrachlorodifluoroethane[146,165]:

$$ClOSO_2F \xrightarrow{CClF_2CCl_2F,\ 85°} CClF_2CF(OSO_2F)_2 \ ;$$
$$ClOSO_2F \xrightarrow{CCl_2FCCl_2F,\ 85°} FSO_2OCClFCF(OSO_2F)_2 \xrightarrow[120°]{ClOSO_2F} (FSO_2O)_2CFC(O)OSO_2F \ .$$

It must be emphasised that the substitution takes place smoothly only in the presence of fluorosulphonic acid, the employment of which as the solvent tends to reduce the reaction temperature[146,165].

The role of fluorosulphonic acid† apparently reduces to enhancing the polarisation of the chlorine atom in chlorine fluorosulphate. A study of ^{19}F NMR spectra showed that, after mixing in equimolar proportions, the individual signals of chlorine fluorosulphate (−112.2 p.p.m. relative to CF_3COOH) and fluorosulphonic acid (−119 p.p.m.) disappear and a single signal (broadened singlet) appears at −116.1 p.p.m.[86] An equimolar mixture of chlorine fluorosulphate and fluorosulphonic acid can be separated into its components almost quantitatively by fractionation[86]. It may be that the halogen is substituted via a one-electron transfer mechanism[86]:

$$Cl{-}O{-}SO_2F + H^+ + SO_3F^- \rightarrow Cl{-}\overset{+}{O}(H){-}SO_2F + SO_3F^- \ ;$$

$$R{:}{\rightarrow}Cl + Cl{:}\overset{\delta+}{O}(H){-}SO_2F \rightarrow \dot{R} + \cdot\overset{+}{O}(H){-}SO_2F + Cl_2$$

$$ROSO_2F \xleftarrow[-HSO_3F]{SO_3F^-} R{-}\overset{+}{O}(H){-}SO_2F \ .$$

Subsequently it was shown that the reactivity of chlorine fluorosulphate increases significantly also after the addition of bromine[166,167]. This involves the substitution of the primary chlorine atom in chloropentafluoroethane and 1,2-dichlorohexafluoropropane sulphato-group, while in 1,2-dichlorotetrafluoroethane one or both chlorine atoms are substituted depending on the conditions[167]:

$$ClOSO_2F + ClCF_2CF_2Cl \xrightarrow[130°,\ 5\ days]{Br_2} ClCF_2CF_2OSO_2F \xrightarrow[140°,\ 14\ days]{ClOSO_2F,\ Br_2} FSO_2OCF_2CF_2OSO_2F \ .$$

Without the addition of bromine, the chlorine atoms in these compounds are not substituted either by peroxydisulphuryl difluoride or chlorine fluorosulphate[166,167]. The authors naturally explained the effectiveness of bromine by the formation of bromine fluorosulphate *in situ* (cf. Schack and Wilson[148]) and its subsequent regeneration during the reaction.

The chlorine atoms in 2-chlorotetrafluoroethyltrifluoromethyl ether[166] and, with catalysis by fluorosulphonic acid, in chlorocarbonyl fluorosulphate[146] and C_2–C_9 perfluoroacyl chlorides[86,168] have also been substituted by the fluorosulphato-group following the addition of bromine:

$$ClOSO_2F \xrightarrow{CF_3OCF_2CF_2Cl,\ Br_2,\ 110°} CF_3OCF_2CF_2OSO_2F + Cl_2 \ ;$$
$$ClOSO_2F \xrightarrow[30°]{ClC(O)OSO_2F,\ HSO_3F} S_2O_5F_2 + CO_2 + Cl_2 \ :$$
$$ClOSO_2F \xrightarrow[20-60°]{CF_3C(O)Cl,\ HSO_3F} CF_3C(O)OSO_2F + Cl_2 \ .$$

The fluorides of perfluorocarboxylic acids are much less reactive and the mixed anhydride of perfluoropelargonic and fluorosulphonic acid has been obtained in only a low yield by heating the corresponding acid fluoride with chlorine fluorosulphate (28 h at 80 °C), the reaction being catalysed by fluorosulphonic acid[86].

As was to be expected, the bromine atom in bromoperfluoroalkanes reacts with chlorine fluorosulphate more readily than the chlorine atom. The primary bromine atoms in perfluorinated bromo- and 1,2-dibromoethanes and also in 1,2- and 1,3-dibromopropanes are substituted at 25 °C (after 21–24 days); at 50–65 °C both primary bromine atoms of dibromoperfluoroalkanes react[167]:

$$ClOSO_2F \xrightarrow[65°,\ 2\ days]{BrCF_2CF_2Br,} \underset{64\%}{FSO_2OCF_2CF_2OSO_2F} + \underset{31\%}{ClCF_2CF_2OSO_2F} \ ;$$
$$ClOSO_2F \xrightarrow[50°,\ 11\ days]{Br(CF_2)_3Br,} \underset{57\%}{FSO_2O(CF_2)_3OSO_2F} + \underset{10\%}{Cl(CF_2)_3OSO_2F} \ .$$

The secondary bromine atoms in 1,2-dibromo- and 2-bromoperfluoro-propanes are not substituted under these conditions[167].

As mentioned above, bromine fluorosulphate substitutes by perfluorosulphato-groups all the chlorine atoms in carbon tetrachloride[89]. Mixtures of mono- and bis-(fluorosulphato)-derivatives are formed from trichlorofluoromethane at −55 °C and from oxalyl chloride at −2 °C.[89] Chlorocarbonyl

† Chlorosulphonic acid interacts with chlorine fluorosulphate and is converted into fluorosulphonic acid[86].

fluorosulphate has been obtained by the reaction of bromine fluorosulphate with a sevenfold excess of phosgene at −65 °C, but only the difluoroamino-group is substituted in difluoroaminocarbonyl chloride[162]:

$$BrOSO_2F \xrightarrow{CCl_3F} CCl_2FOSO_2F + CClF(OSO_2F)_2 \ ;$$
$$BrOSO_2F \xrightarrow{ClC(O)C(O)Cl} ClC(O)C(O)OSO_2F + FSO_2OC(O)C(O)OSO_2F \ ;$$
$$BrOSO_2F \xrightarrow{ClC(O)NF_2} ClC(O)OSO_2F + N_2F_4 \ .$$

The above facts clearly show that bromine fluorosulphate is more reactive towards the C—Cl bond than not only peroxydisulphuryl difluoride but also chlorine fluorosulphate.

In conclusion, one should note that bromine fluorosulphate has been used successfully to substitute the chlorine atoms in methanesulphonyl[169] and trifluoromethanesulphonyl chlorides[170] by the fluorosulphato-group. Methanesulphonyl fluorosulphate proved to be metastable; at 80 °C it decomposes into methanesulphonyl fluoride and sulphur trioxide[169]:

$$BrOSO_2F \xrightarrow{CH_3SO_2Cl} CH_3SO_2OSO_2F \xrightarrow{80^\circ} CH_3SO_2F + SO_3 \ ;$$
$$BrOSO_2F \xrightarrow{CF_3SO_2Cl} CF_3SO_2OSO_2F \ .$$

3. *Reactions with Alcohols and Carboxylic Acids*

The reactions of peroxydisulphuryl difluoride with alcohols have attracted the attention of investigators as possible ways of synthesising organic peroxides and mixed peroxides (of the type of ROOSO$_2$F), the potential initiators of radical

The yield of fluorosulphuryl trifluoromethyl peroxide does not exceed 50%, since in the presence of potassium and particularly caesium fluoride it can decompose approximately under the conditions of its synthesis[100]:

$$CsF + CF_3OOSO_2F \xrightarrow{25^\circ,\ 2\ h} CsOCF_3 + SO_2F_2 + O_2 \ .$$

Fluorosulphuryl perfluoroisopropyl peroxide decomposes during storage in glass vessels at room temperature[100], while fluorosulphonyl perfluoro-t-butyl peroxide decomposes only on heating to 100 °C[173]:

$$(CF_3)_3COOSO_2F \rightarrow CF_3OSO_2F + (CF_3)_2CO \ .$$

The above facts show that the radical-ion mechanism proposed[100] for the reactions of peroxydisulphuryl difluoride with anions is apparently not fully justified at least for perfluoroalkyl alkoxides. This can be seen particularly clearly in relation to perfluoro-t-alkyl alcohols and the corresponding alkoxides. Not even traces of the mixed peroxide or the corresponding perfluoro-t-alkoxy-radicals could be detected in reactions with alcohols[77] as a consequence of the ready decomposition of the perfluoro-t-alkoxy-radical via the mechanism

$$C_2F_5C(CF_3)_2OH + \dot{O}SO_2F \rightarrow C_2F_5C(CF_3)_2\dot{O} + HSO_3F \ ;$$
$$C_2F_5C(CF_3)_2\dot{O} \rightarrow (CF_3)_2CO + \dot{C}F_5 \ ;$$
$$C_2F_5C(CF_3)_2\dot{O} \rightarrow C_2F_5C(O)CF_3 + \dot{C}F_3 \ ;$$
$$\dot{C}F_5 + (OSO_2F)_2 \rightarrow C_2F_5OSO_2F + \dot{O}SO_2F \ ;$$
$$\dot{C}F_3 + (OSO_2F)_2 \rightarrow CF_3OSO_2F + \dot{O}SO_2F \ .$$

All the final compounds presented in the above scheme have been identified; perfluoroethyl fluorosulphate and trifluoro-

Bearing in mind that only trifluoromethyl fluorosulphate is formed also in the reaction of peroxydisulphuryl difluoride with sodium trifluoroacetate[100], it is apparently hardly possible to expect an acceptable stability of fluorosulphuryl trifluoroacetyl peroxide even if the latter is formed under these conditions.

The reactions of chlorine and bromine fluorosulphates with alcohols and carboxylic acids began to be investigated only recently. The interaction of chlorine fluorosulphate with polyfluoroalcohols in dichlorodifluoromethane or 1,1,2-trichlorotrifluoroethane at −30°– −15 °C leads to the corresponding hypochlorites[175]:

$$ClOSO_2F + RCH_2OH \rightarrow RCH_2OCl + HSO_3F \ ;$$
$$R = H(CF_2)_n,\ O_2NCF_2;\ n = 2, 4, 6 \ .$$

The yield of hypochlorites does not exceed 40%, apparently as a consequence of decomposition under the influence of fluorosulphonic acid and the acid sulphates formed from the corresponding alcohols as side products. In the absence of water and acid impurities, such hypochlorites are fairly stable, particularly higher hypochlorites[175]. However, treatment of 2,2-dinitropropanediol with chlorine fluorosulphate led to the isolation of only dichlorodinitromethane in a low yield[153].

It has been noted[176] that chlorine fluorosulphate chlorinates trifluoro- and chlorodifluoro-acetic acids as well as their salts more effectively than chlorine monofluoride at temperatures between −78° and −45 °C. The hypochlorites of these acids are volatile and tend to decompose with detonation even at a pressure of the pure substance in a vacuum system of ~ 40 mmHg; they have been fairly fully characterised[176] and have been used successfully *in situ* for the synthesis (at −78 °C) of chloroperfluoro-esters[176,177] and perfluoroalkyl halides[167,178]. Perfluorodicarboxylic acids have also been introduced into the latter reaction[167,178]. Bromine fluorosulphate reacts similarly[167,178]:

$$ClOSO_2F \xrightarrow{CF_3COOH} CF_3CC(O)OCl \begin{cases} \xrightarrow{CF_2=CFCF_3} CF_3COOCF_2CClFCF_3 \ ; \\ \xrightarrow{25°} CF_3Cl \ ; \end{cases}$$
$$ClOSO_2F + CF_2(CF_2COOH)_2 \rightarrow Cl(CF_2)_3Cl + Cl(CF_2)_2COF + Cl(CF_2)_3OSO_2F \ ;$$
$$BrOSO_2F + C_2F_5COONa \rightarrow C_2F_5Br \ .$$

4. *Reactions with Peroxides, Ethers, Carboxylic Acid Anhydrides, and Certain Other Compounds*

Peroxydisulphuryl difluoride is inert with respect to perfluoroalkyl ethers up to 140 °C[166] and does not interact with perfluoroepoxypropane[151].

Bis(trifluoromethyl) peroxide reacts with peroxydisulphuryl difluoride only at fairly high temperatures (up to 240 °C)[179, 180], forming the corresponding mixed peroxide; the process kinetics have been studied in the range 185–230 °C[179]. The same peroxide has been obtained from bis(trifluoromethyl) trioxide in a yield of 87% at a temperature as low as 75 °C[181]:

$$(OSO_2F)_2 \begin{cases} \xrightarrow{CF_3OOCF_3} CF_3OOSO_2F \ ; \\ \xrightarrow{CF_3OOOCF_3} CF_3OOSO_2F \ . \end{cases}$$

The reaction involving difluorophosphoryl trifluoromethyl peroxide CF_3OOPOF_2 at room temperature was found to entail only a slow decomposition to COF_2, POF_3, etc.[182]

The anhydrides of perfluorinated mono- and di-carboxylic acids react with peroxydisulphuryl difluoride slowly at 25 °C and rapidly at 100 °C, forming mixed anhydrides of fluorosulphonic and carboxylic acids and also perfluoroalkyl fluorosulphates, which, together with carbon dioxide, are apparently the products of the decomposition of the mixed peroxides of fluorosulphonic and carboxylic acids[183]:

$$(OSO_2F)_2 \begin{cases} \xrightarrow{(CF_3CO)_2O} CF_3COOSO_2F + CF_3OSO_2F + CO_2 \ ; \\ \xrightarrow{OCOCF_2CF_2CO} FSO_2OCF_2CF_2COOSO_2F + CO_2 \ . \end{cases}$$

In another study[184] only fluoroalkyl fluorosulphates were isolated in an analogous reaction; in this case difluoromethyl fluorosulphate was obtained from difluoroacetic acid anhydride with retention of the hydrogen atom.

Chlorine fluorosulphate and trifluoroacetic anhydride give rise to a mixed anhydride (yield 80–85%) and chlorotrifluoromethane[167]:

$$ClOSO_2F + (CF_3CO)_2O \rightarrow CF_3COOSO_2F + CClF_3 + CO_2 \ .$$

Other reactions accompanied by the rupture of carbon–carbon bonds include the interaction between peroxydisulphuryl difluoride and oxalyl chloride[162] and also the substitution of the cyano-group in ethyl cyanodinitroacetate by a chlorine atom on treatment with chlorine fluorosulphate at temperatures between −20° and −30 °C[153]:

$$(OSO_2F)_2 + ClC(O)C(O)Cl \rightarrow ClCOOSO_2F \ ;$$
$$ClOSO_2F + NCC(NO_2)_2COOC_2H_5 \rightarrow ClC(NO_2)_2COOC_2H_5 \ .$$

Dichlorodinitromethane has been obtained in a low yield from ethyl chlorodinitroacetate on treatment with $ClOSO_2F$.[153]

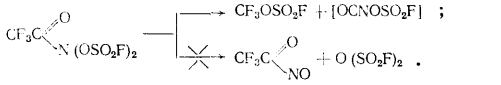
In addition it has been shown that peroxydisulphuryl difluoride readily substitutes the methyl groups in organotin compounds[185]:

$$(OSO_2F)_2 + (CH_3)_4Sn \rightarrow (CH_3)_2Sn(OSO_2F)_2 + (CH_3)_3SnOSO_2F \ .$$

5. *Substitution of Hydrogen or Halogen Atoms in Amines, Imines, Halogenoimines, and Carboxylic Acid Amides*

Peroxydisulphuryl difluoride smoothly substitutes the hydrogen atom in bis(trifluoromethyl)amine by the fluorosulphato-group[77]. Hexafluoroacetone imine reacts in a more complex manner; together with substitution, the imine undergoes oxidative dimerisation and peroxydisulphuryl difluoride apparently adds to the resulting diazadiene[77]:

$$(OSO_2F)_2 \begin{cases} \xrightarrow{(CF_3)_2NH} (CF_3)_2NOSO_2F \ ; \\ \xrightarrow{(CF_3)_2C=NH} (CF_3)_2CNOSO_2F + (CF_3)_2CNN=C(CF_3)_2 + \\ \quad + FSO_2OC(CF_3)_2N=NC(CF_3)_2OSO_2F \ . \end{cases}$$



The reactions take place at temperatures as low as 0–25 °C and are clearly of a radical type. In contrast to this, the sodium salt of fluorosulphurylcarbamoyl fluoride reacts slowly with peroxydisulphuryl difluoride only at 70 °C and the yield of the final product is only 17%[186]:

$$(OSO_2F)_2 + Na^+[FSO_2NCOF]^- \rightarrow FSO_2N(OSO_2F)COF \ .$$

The reaction of peroxydisulphuryl difluoride with perfluorocarboxylic acid amides is extremely unusual[187]. In the presence of $(OSO_2F)_2$ a suspension of the initial amide in 1,1,2-trichlorotrifluoroethane dissolves fully at temperatures as low as −30– −25 °C, but fluorosulphonic acid precipitates from solution only after several hours, usually after the temperature of the mixture approaches room temperature[187]:

$$RC(O)NH_2 + 2(OSO_2F)_2 \rightarrow RC(O)N(OSO_2F)_2 + 2HSO_3F \ ;$$
$$R = CF_3,\ C_3F_7,\ C_6F_{13} \ .$$

Although the amount of the fluorosulphonic acid formed is consistent with stoichiometry, *N*,*N*-bis(fluorosulphato)amides have been obtained in yields less than 25%, because, under the conditions of the synthesis and on isolation, they decompose into perfluoroalkyl fluorosulphate and possibly fluorosulphatoisocyanate. The expected perfluoroacylnitroso-compounds and pyrosulphuryl difluorides could not be isolated in this reaction[187]:

Chlorine and bromine fluorosulphates have been used successfully even at reduced temperatures to substitute fluorine[187] and chlorine[77] atoms respectively in hexafluoroacetone *N*-halogenoimines by the fluorosulphato-group, for example:

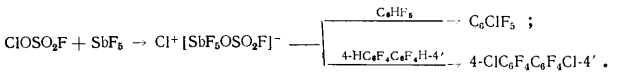
$$ClOSO_2F + (CF_3)_2C{=}NF \rightarrow (CF_3)_2C{=}NOSO_2F \ .$$

Also at reduced temperatures, chlorine fluorosulphate vigorously substitutes the hydrogen atoms in the amides of trifluoroacetic and heptafluorobutyric acids by chlorine:

However, the yields of *N*,*N*-dichloroamides are low, possibly as a consequence of the formation of fluorosulphonic acid[163,189].

B. Aromatic Compounds

As early as 1971, Merrill reported[156] at the VIth International Symposium on the Chemistry of Fluorine that a hydrogen atom in benzene can be substituted by the fluorosulphato-group on treatment with peroxydisulphuryl difluoride in trichlorofluoromethane at −45 °C:



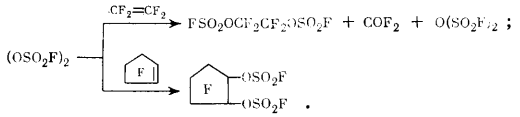
$$(OSO_2F)_2 + C_6H_6 \rightarrow C_6H_5OSO_2F \ .$$

Toluene, which is substituted in the ring, reacts even more vigorously, but the position of the fluorosulphato-group relative to the methyl group has not been established[77].

Chlorine fluorosulphate proved to be a unique chlorinating agent for benzene. At a temperature as low as −100 °C and for the molar ratio $ClOSO_2F:C_6H_6 = 1:1.5$, hexachlorobenzene was obtained unexpectedly in a yield of ~ 80%[190]:

$$ClOSO_2F + C_6H_6 \rightarrow C_6Cl_6 \ .$$

The complex of chlorine fluorosulphate with antimony pentafluoride has been used successfully to chlorinate pentafluorobenzene and octafluorobiphenyl[191]:



Iodine fluorosulphate interacts vigorously with pyridine, but the yellow solid formed decomposes rapidly and is converted into a brown oil, whose structure has not been established[13].

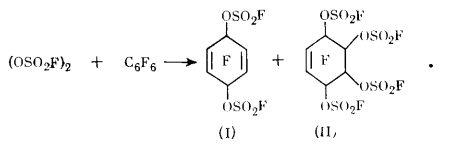
V. ADDITION OF PEROXYDISULPHURYL DIFLUORIDE AND HALOGEN FLUOROSULPHATES TO UNSATURATED COMPOUNDS

1. Addition to Carbon–Carbon Multiple Bonds

The addition of peroxydisulphuryl difluoride to carbon–carbon double bonds was achieved for the first time in 1961 in relation to tetrafluoroethylene and perfluorocyclopentene[55]:

The olefin, diluted with nitrogen, was added slowly *in vacuo* (~ 125 mmHg) to peroxydisulphuryl difluoride. A slight increase of the rate of supply of tetrafluoroethylene led to a rapid increase of temperature and the formation of a brown gas in the reactor, which, according to the authors[55], might have indicated the appearance of free radicals. At the same time the appearance of a solid white powder in the gas connections and on the walls of the vessel was observed; up to 5% of tetrafluoroethylene was oxidised to carbonyl fluoride[55].

Subsequently the corresponding vicinal bis(fluorosulphato)-polyfluoroalkanes were obtained from chlorotrifluoroethylene[157], perfluoropropene[151,192], perfluorobutene[157,192,193], perfluorocyclobutene[192], 1,2-dichlorohexafluorocyclopentene[151], and perfluoro-derivatives of pent-2-ene and hex-2-enes[193]. Peroxydisulphuryl difluoride adds just as readily to trichloroethylene (the hydrogen atom is not then substituted)[156] and also to bis(trifluoromethyl)keten[194]:



The above reactions were as a rule carried out at room temperature and, more rarely, with slight heating§. The radical nature of these reactions is confirmed not only by the clear signs of the polymerisation of tetrafluoroethylene[55] but also by the fact that a mixture of perfluoro-derivatives of bis(fluorosulphato)propane and bis(fluorosulphato)hexanes is formed from hexafluoropropene (in yields of 63 and 22% respectively)[151]:

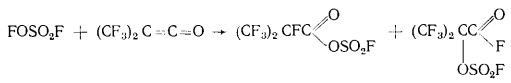
Under very mild conditions (at −78 °C), peroxydisulphuryl difluoride adds to vinyl chloride and fluoride, but the compounds formed decompose on heating to room temperature[157].

The addition of peroxydisulphuryl difluoride to alkenes takes place non-stereospecifically. A mixture of *cis*- and *trans*-isomers is formed from 1,2-dichlorohexafluorocyclopentene[151], while acyclic internal C_4–C_6 *trans*-perfluoroolefins give rise to a mixture of *erythro*- and *threo*-isomers[193].

The exceptionally high reactivity of peroxydisulphuryl difluoride was manifested in its interaction with perfluorobenzene. It was found that the latter behaves in this instance as an unsaturated compound and readily combines with fluorosulphato-groups at 0–5 °C[195]:

One must note that the reaction is preferably carried out in an inert solvent, for example, in 1,1,2-trichlorotrifluoroethane, since in its absence there is an abrupt increase of temperature and pressure, which can lead to the ejection of the reaction mass[195]. At the beginning 1,4-addition of

§ The authors[151] note that, on heating a mixture of 1,2-dichlorohexafluorocyclopentene and peroxydisulphuryl difluoride from −30° to ~ 15 °C, a vigorous uncontrollable reaction is observed; satisfactory yields have been obtained only by adding the peroxide to the olefin heated to 50 °C.



peroxydisulphuryl difluoride to perfluorobenzene takes place preferentially, but, even when an excess of perfluorobenzene by a factor of 1,5 together with 1,4-bis(fluorosulphato)perfluorocyclohexa-2,5-diene (I) is used, up to 10% of 1,2,3,4-tetrakis(fluorosulphato)perfluorocyclohex-5-ene (II) is formed. Possibly this can be explained by the fact that either the diene (I) is more reactive than hexafluorobenzene or by the partial 1,2-addition of peroxydisulphuryl difluoride, the conjugated diene being naturally more reactive. The hexene (II) as well as hexakis(fluorosulphato)perfluorohexane¶ can be obtained in quantitative yields using the corresponding molar amounts of the reactants, but the reaction with the third mole of peroxydisulphuryl difluoride is usually completed only after 5–6 h at 20–25 °C[195]:

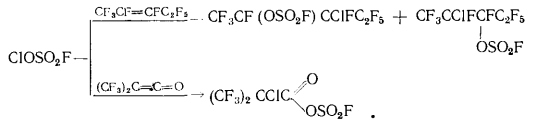
$$3\,(OSO_2F)_2 + C_6F_6 \rightarrow C_6F_6(OSO_2F)_6 \ .$$

Halogen fluorosulphates add to alkenes still more vigorously than peroxydisulphuryl difluoride. The reagents diluted with nitrogen were initially combined *in vacuo* at room temperature. As a result, the corresponding fluorosulphonate esters were obtained from tetrafluoroethylene in a high yield[7]:

$$HalOSO_2F + CF_2{=}CF_2 \rightarrow HalCF_2CF_2OSO_2F \ ;$$
$$Hal{=}F,\ Cl,\ Br \ .$$

Fluorine fluorosulphate adds just as readily to tetrachloroethylene and perfluorocyclopentene[7], trichloroethylene (at −78 °C)[155], and a mixture of the *cis*- and *trans*-isomers of perfluorobut-2-ene[161]. A mixture of regioisomers has been obtained from bis(trifluoromethyl)keten in yields of 87 and 13%[194]:

However, β-fluoroethyl fluorosulphate could not be isolated from the products of the reaction of fluorine fluorosulphate and ethylene (*in vacuo* at −50 °C)[7].



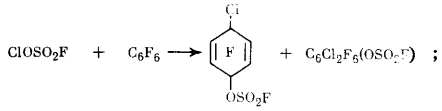
Apart from tetrafluoroethylene, fluoro- and chlorofluoroolefins are absorbed, as reported for the first time in 1973[196,197], by liquid chlorine fluorosulphate with a large exothermic effect at a temperature as low as 0–20 °C. On the basis of qualitative observations, the authors[196,197] reached the preliminary conclusion that the reactivity of the above olefins in the reaction with liquid chlorine fluorosulphate increases in the sequence which corresponds to their interaction with nucleophiles:

Continuation of research on these lines showed that chlorine fluorosulphate adds vigorously to trichloroethylene at temperatures between −50° and −55 °C[164], to tetrachloroethylene at −20 °C[78], and to trifluoroethylene, chlorotrifluoroethylene, perfluoropropene†, bis(trifluoromethyl)-keten[199], and *trans*-perfluorohex-2-ene[200] at temperatures as low as −65°–−70 °C, i.e. at the limit corresponding to the freezing of the mixture of reactants. However, it has been suggested[197] that the slow reaction of liquid chlorine fluorosulphate with tetrafluoroethylene is probably due to the poor solubility of the latter, since tetrafluoroethylene reacts with solutions of chlorine fluorosulphate in dichlorodifluoromethane or in 2-chlorotetrafluoroethyl fluorosulphate at a very high rate and a temperature as low as −70 °C[199]. Heating to 50–60 °C is required only for addition to 1,1-bis(fluorosulphonyl)difluoroethylene[201]:

$$ClOSO_2F + (FSO_2)C{=}CF_2 \rightarrow (FSO_2)_2\,CClCF_2OSO_2F \ .$$

Mixtures of regioisomers have been obtained in reactions with trifluoroethylene[199], chlorotrifluoroethylene[197,198], and *trans*-perfluoropent-2-ene[200], which can be explained in all probability by competition between the electronic and steric factors (the relative yields depend very little on the process temperature[199]). However, in contrast to the reaction with fluorine fluorosulphate[194], only one isomer is obtained from bis(trifluoromethyl)keten[199]:

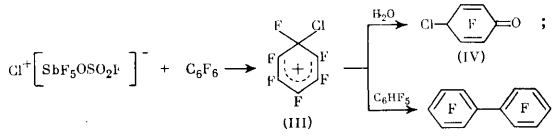
In the presence of a perfluorocarboxylic acid, the interaction of chlorine fluorosulphate with perfluoropropene leads to a mixture of 2-chloroperfluoropropyl fluorosulphate and 2-chloroperfluoropropyl perfluorocarboxylate, the yield of the latter increasing with increasing excess of the acid[199]:



In the light of recent data[176,177], one cannot rule out the possibility that the formation of the ester is preceded by a stage involving the formation of the acyl hypochlorite.

At −100 °C chlorine fluorosulphate adds readily to ethylene[199] and at −30– −25 °C to acetylene, whose triple bond is fully saturated[164,189]:

$$ClOSO_2F + CH{\equiv}CH \rightarrow CHCl_2CH(OSO_2F)_2 + FSO_2OCHClCHClOSO_2F \ .$$



Symmetrical bis(fluorosulphato)dichloroethane was then obtained only in the form of an admixture (5–7%)[164].

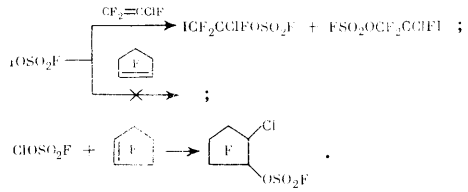
Like peroxydisulphuryl difluoride but at an even lower temperature (between −20° and −25 °C), chlorine fluorosulphate reacts with perfluorobenzene[195]. The interaction with one mole also results in the formation of a 1,4-substituted cyclohexadiene containing an admixture (up to 10%) of a tetrasubstituted cyclohexene#. The latter as well as a hexasubstituted cyclohexane can be isolated in almost quantitative yields[195]:

$$3ClOSO_2F + C_6F_6 \longrightarrow C_6Cl_3F_6(OSO_2F)_3 \ .$$

The benzenium ion (III) can be generated by treating hexafluorobenzene with the complex of chlorine fluorosulphate and antimony pentafluoride, the hydrolysis of the ion yielding the ketone (IV) and its reaction with pentafluorobenzene giving rise to decafluorobiphenyl[191]:

¶ A mixture of stereoisomers is formed in both cases[195].

† The reaction has been carried out successfully also at −45 °C.[198]



A complex mixture of regio- and stereo-isomers[195].

As already mentioned, bromine fluorosulphate adds exceptionally readily to tetrafluoroethylene[7] and also to hexafluoropropene[198] and perfluorobut-2-ene[160]. As in the case of chlorine fluorosulphate, the reaction with chlorotrifluoroethylene results in the formation of two regioisomers[160]. The product of the addition of bromine fluorosulphate to vinyl fluoride proved to be unstable[160].

The possibility of the addition of iodine fluorosulphate to alkenes was reported almost simultaneously by Fokin in Venice[189,202] and by Schack and Christe in San Francisco[203]. Iodine fluorosulphate is much less reactive in these reactions than fluorine, chlorine, or bromine fluorosulphates and interacts only slowly at 20–40 °C with tetrafluoroethylene, hexafluoropropene[202–204], partly fluorinated propenes, and vinylidene fluoride[205]. 2-Iodoperfluoroisobutyl fluorosulphate has been obtained in a yield less than 30% only after keeping the mixture of reactants at 20–25 °C for three weeks, but iodine fluorosulphate adds relatively easily to bis(trifluoromethyl)keten[205]:

$$IOSO_2F \left\{ \begin{array}{l} \xrightarrow{(CF_3)_2C=CF_2} (CF_3)_2CICF_2OSO_2F \ ; \\ \xrightarrow{(CF_3)_2C=C=O} (CF_3)_2CIC(O)OSO_2F \ . \end{array} \right.$$

Mixtures of regioisomers have been obtained from chlorotrifluoroethylene[203,205] and trifluoroethylene[205]. Iodine fluorosulphate does not add to perfluorocyclobutene[205] and perfluorocyclopentene[203], but chlorine fluorosulphate reacts readily with perfluorocyclopentene[203]:

2. Addition to Nitrogen–Carbon Multiple Bonds

Peroxydisulphuryl difluoride does not interact with perfluoro-2-azapropene[9] and perfluoro-2-azabut-1-ene[206]. The addition to pentafluoroguanidine is accompanied by the substitution of the difluoroamino-groups by fluorosulphato-groups[207,208], while the addition to fluorosulphonyl isocyanate under the influence of ultraviolet radiation is accompanied by the elimination of sulphur trioxide[209]:

$$(OSO_2F)_2 \left\{ \begin{array}{l} \xrightarrow{(F_2N)_2C=NF} (FSO_2O)_3CNFOSO_2F \ ; \\ \xrightarrow[FSO_2NCO,\,h\nu]{} FSO_2N(OSO_2F)C(=O)F + SO_3 \ . \end{array} \right.$$

Peroxydisulphuryl difluoride reacts under mild conditions with diazadienes—conjugated[77] and even those where the double bonds are separated by a sulphur atom[210]:

$$(OSO_2F)_2 \left\{ \begin{array}{l} \xrightarrow{(CF_3)_2C=NN=C(CF_3)_2} FSO_2OC(CF_3)_2N=NC(CF_3)_2OSO_2F \ ; \\ \xrightarrow{(CF_3)_2C=NSN=C(CF_3)_2} FSO_2OC(CF_3)_2N=S=NC(CF_3)_2OSO_2F \ . \end{array} \right.$$

The interaction of peroxydisulphuryl difluoride with chlorocyanogen and trifluoroacetonitrile at 80 °C is completed by the complete saturation of the triple bond, which the authors[211] explain by the intermediate formation of the nitrene (V), for example, via the mechanism

$$CF_3C\equiv N + \dot{O}SO_2F \rightarrow FSO_2OC(CF_3)=\dot{N} \ ;$$
$$FSO_2OC(CF_3)=\dot{N} + \dot{O}SO_2F \rightarrow \underset{(V)}{(FSO_2O)_2C(CF_3)\ddot{N}} \ ;$$
$$(FSO_2O)_2C(CF_3)\ddot{N} + (OSO_2F)_2 \rightarrow (FSO_2O)_2C(CF_3)N(OSO_2F)_2 \ .$$

In contrast to peroxydisulphuryl difluoride, chlorine and bromine fluorosulphates add exceptionally readily to perfluoro-2-azabut-1-ene[206] and pentafluoroguanidine[207,212]:

$$ClOSO_2F \left\{ \begin{array}{l} \xrightarrow{C_2F_5N=CF_2} C_2F_5NClCF_2OSO_2F \ ; \\ \xrightarrow{FN=C(NF_2)_2} FNClC(NF_2)_2OSO_2F \ . \end{array} \right.$$

Chlorine fluorosulphate interacts just as vigorously with trifluoromethyl, fluoroformyl, and trifluoroacetyl isocyanates[213], but fluorine fluorosulphate reacts with fluorosulphonyl isocyanate only under ultraviolet irradiation[209]:

$$ClOSO_2F + CF_3C(=O)NCO \rightarrow CF_3C(=O)NClC(=O)OSO_2F \ ;$$
$$FOSO_2F + FSO_2NCO \xrightarrow{h\nu} FSO_2N(OSO_2F)C(=O)F \ .$$

Despite the clear difference between the reaction mechanisms[209,213], the mode of addition indicated corresponds rigorously to the polarity of the reactants.

Only one mole of chlorine fluorosulphate adds easily to the nitriles of perfluorocarboxylic[168] and nitroperfluorocarboxylic[153] acids (at −40°–−30 °C) (in contrast to the reactions with peroxydisulphuryl difluoride[211]), for example:

$$ClOSO_2F + C_3F_7CN \rightarrow \underset{(VI)}{C_3F_7C(=NCl)OSO_2F} \ .$$

Treatment of the chloroimine (VI) with the second mole of chlorine fluorosulphate leads solely to the perfluoroacyl fluorosulphate and the anhydride of fluorosulphonic acid, approximately half of the chloroimine (VI) being converted. This can apparently be accounted for by the fact that the dichloroamine (VII) formed reacts with chlorine fluorosulphate more readily than the chloroimine (VI), splitting off the anhydride of fluorosulphonic acid and possibly nitrogen trichloride[168]:

$$C_3F_7C(=NCl)OSO_2F \xrightarrow{ClOSO_2F} \underset{(VII)}{[C_3F_7C(OSO_2F)_2NCl_2]} \xrightarrow{ClOSO_2F}$$
$$\rightarrow C_3F_7C(=O)OSO_2F + O(SO_2F)_2 + [NCl_3] \ .$$

Analogous results have been obtained also for the reactions of the nitriles of perfluorocarboxylic acids with two moles of chlorine fluorosulphate[168].

VI. OXIDATION OF CERTAIN NITROGEN-, SULPHUR-, SELENIUM-, AND IODINE-CONTAINING ORGANIC COMPOUNDS AS WELL AS CARBOXYLIC ACIDS

It is fairly difficult to achieve selective oxidation by the reagents considered, but in a series of instances this has been clearly demonstrated.

Peroxydisulphuryl difluoride oxidises almost quantitatively (yield 98%) bis(trifluoromethyl)hydroxylamine to bis(trifluoromethyl)nitroxide[77], from which only trifluoromethyl

fluorosulphate is formed subsequently, as from trifluoronitrosomethane[184]:

$$(OSO_2F)_2 + (CF_3)_2NOH \rightarrow (CF_3)_2NO \xrightarrow{(OSO_2F)_2} CF_3OSO_2F\ ,$$
$$(OSO_2F)_2 + CF_3NO \rightarrow CF_3OSO_2F\ .$$

Treatment of 2-nitrotetrafluoronitrosoethane with chlorine fluorosulphate leads to a chloroalkane and nitrosyl fluorosulphate[189]. An unstable, possibly salt-like, intermediate is apparently formed in the first stage and then decomposes under the usual conditions[189]:

$$R_FNO + ClOSO_2F \rightarrow R_FCl + NOSO_3F\ .$$

Trifluoromethanethiol is not oxidised unambiguously by peroxydisulphuryl difluoride, the product being a disulphide (yield 30%), from which trifluoromethyl fluorosulphate was subsequently obtained[77]. On the other hand, trifluorothioloacetic acid is converted qualitatively (for a molar reactant ratio of 2:1) into the corresponding disulphide, whose further treatment with peroxydisulphuryl difluoride yields trifluoroacetyl fluorosulphate[77]:

$$(OSO_2F)_2 \begin{cases} \xrightarrow{CF_3SH} (CF_3S)_2 + O(SO_2F)_2 + SO_2 + S\ ; \\ \xrightarrow{(CF_3S)_2} CF_3OSO_2F + SO_2 + S\ ; \\ \xrightarrow{2CF_3C(=O)SH} [CF_3C(O)S]_2 \xrightarrow{(OSO_2F)_2} CF_3C(O)OSO_2F + O(SO_2F)_2 + SO_2 + S\ . \end{cases}$$

The reaction of chlorine fluorosulphate with perfluoroalkyl and pentafluorophenyl diselenides is accompanied by the dissociation of the selenium–selenium bond[214]:

$$(CF_3Se)_2 + ClOSO_2F \rightarrow CF_3SeOSO_2F\ .$$

Only trifluoromethyl fluorosulphate was obtained initially from trifluoroiodomethane on treatment with peroxydisulphuryl difluoride[158] or chlorine fluorosulphate[165]:

$$ClOSO_2F + CF_3I \rightarrow CF_3OSO_2F\ .$$

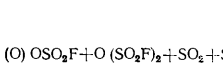
However, in 1977 Naumann reported[215] that tervalent iodine compounds (VIII) are formed from perfluoroalkyl iodides and chlorine fluorosulphate in accordance with the mechanism

$$ClOSO_2F + R_FI \rightarrow [R_FICl OSO_2F] \xrightarrow{ClOSO_2F} \underset{(VIII)}{R_FI(OSO_2F)_2}\ .$$

Further study of this reaction showed that alkyl iodides are converted, on reaction with peroxydisulphuryl difluoride[204] or chlorine fluorosulphate[167] at a temperature as low as −50– −40 °C, into cream-coloured or white solid compounds of type (VIII), which decompose into alkyl fluorosulphates and iodine fluorosulphate when the alkyl radical has a straight-chain structure. Only perfluoroisopropyliodine bisfluorosulphate (m.p.101 °C) proved to be stable; on the basis of Raman spectra, the authors[167] attributed the dimeric structure (IX) to this substance:

$$RI \xrightarrow[[ClOSO_2F]]{(OSO_2F)_2} \underset{(VIII)}{RI(OSO_2F)_2} \xrightarrow{\sim 30-\ -20^\circ} ROSO_2F + IOSO_2F\ ;$$
$$R = CH_3,\ CF_3,\ C_3F_7,\ C_7F_{15}$$
$$(CF_3)_2CFI + ClOSO_2F \rightarrow \underset{(IX)}{\{[(CF_3)_2CF]_2I\}^+[I(SO_3F)_4]^-}\ .$$

Peroxydisulphuryl difluoride has been used successfully to synthesise iodine tristrifluoromethanesulphonate[216], but it was not possible to oxidise iodosyl trifluoromethanesulphonate to iodyl trifluoromethanesulphonate by this reagent as a consequence of the cleavage of the carbon–sulphur bond[112]:



$$(OSO_2F)_2 \begin{cases} \xrightarrow{CF_3SO_3H,\ I_2} (CF_3SO_2O)_3I\ ; \\ \xrightarrow{CF_3SO_2OIO} CF_3OSO_2F\ . \end{cases}$$

It must be emphasised that apparently fairly extensive possibilities arise in processes of the type considered when peroxydisulphuryl difluoride is used *in situ*, i.e. in its electrochemical generation directly in the reaction mixture. Perfluoroalkyl fluorosulphates have been obtained by this method from perfluoroalkyl iodides in high yields and mono- and bis-fluorosulphates have been obtained from the di-iodo-derivatives[217], for example:

$$C_4F_9I \xrightarrow[HSO_3F/KSO_3F]{\text{electrolysis}} C_4F_9OSO_2F\ .$$

Carboxylic acids undergo mild oxidation to lactones (via fluorosulphato-substituted acids), from which cyclic unsaturated ketones are formed on keeping in the electrolyte for a longer period (up to 48 h)[218,219]. Unambiguous and readily reproducible results have been obtained for valeric and higher aliphatic acids as well as ω-cyclohexyl-substituted propionic and butyric acids. However, a mixture of 3- and 4-fluorosulphates (in proportions of 3:4) is obtained from the unsubstituted butyric acid, the yield of lactones being low and unstable. The sequence of transformations can be represented schematically as follows[219]:

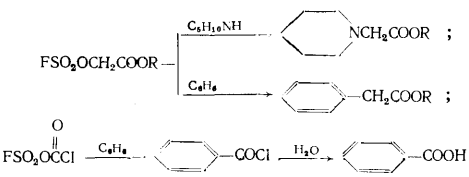
$$RR'CH(CH_2)_nCOOH + HSO_3F \rightarrow FSO_3^- + RR'CH(CH_2)_nCO_2H_2^+ \rightarrow$$
$$\xrightarrow{(OSO_2F)_2} FSO_2OCRR'(CH_2)_nCO_2H_2^+ \rightarrow$$

R and R′ = H, alkyl, or cycloalkyl; n = 2 or 3.

The xenon difluoride–fluorosulphonic acid system, in which peroxydisulphuryl difluoride is formed[135–138] (see above), has been used to generate radical-cations from perfluoro-derivatives of naphthalene and biphenyl[139].

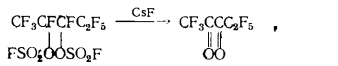
VII. CONCLUSION

The data described show that the reactions of peroxydisulphuryl difluoride and halogen fluorosulphates have been more widely investigated at present in relation to inorganic than organic compounds, this being confirmed also by the number of the corresponding publications. The very small number of kinetic studies, particularly on organic substances, is striking. Nevertheless the available information already provides an idea concerning the exceptionally high and extremely novel reactivity of the reagents considered and also about their extensive synthetic possibilities.



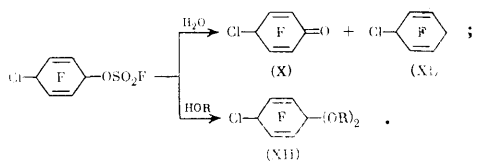
There is apparently no doubt about the radical nature of the absolute majority of the reactions of peroxydisulphuryl difluoride. The unusually high reactivity of the fluorosulphate radical is indicated, for example, by its ability to saturate perfluorobenzene completely at room temperature[195], whereas the analogous reaction of bis(trifluoromethyl)nitroxide requires prolonged heating at 120 °C.[220] Facts such as the necessity to add fluorosulphonic acid in order to substitute the chlorine atom in 1,1,2-trichlorotrifluoroethane[146] and also the substitution of the fluorosulphato-group in the ring and not the methyl group of toluene at temperatures below 0 °C are clear exceptions[77].

Except for fluorine fluorosulphate, which reacts via both radical and ionic mechanisms, halogen fluorosulphates are extremely vigorous electrophiles. Thus, despite the generally known inertness of perfluoro-olefins, particularly higher perfluoro-olefins, to the action of electrophiles, chlorine fluorosulphate adds readily to these compounds at temperatures as low as −65– −70 °C regardless of their structure[199] and at room temperature it adds to all the bonds of perfluorobenzene[195]. Chlorine fluorosulphate is apparently one of the strongest chlorinating agents, having a

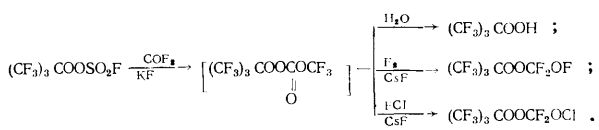


positively polarised chlorine atom, since, for example, its ability to chlorinate benzene to perchlorobenzene at −100 °C has no analogies in other systems[190].

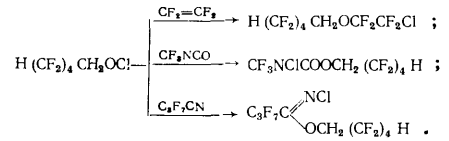
The "anomalies" enumerated undoubtedly require further thought and study using modern methods of physicochemical analysis, possibly also as regards the reaction kinetics, in order to elucidate the true mechanisms of these phenomena.



The possibility of introducing fluorosulphato-groups into various classes of organic compounds either by the addition of peroxydisulphuryl difluoride and halogen fluorosulphates to multiple carbon–carbon and carbon–nitrogen bonds§ or by the substitution of hydrogen, halogen, or certain functional groups. The fluorosulphato-group, which is one of the most readily eliminated groups, can be substituted in its turn by other functional groups on treatment with nucleophiles. The high reactivity of alkyl and acyl fluorosulphates is indicated, for example, by the alkylation of not only amines but also of benzene, even at reduced temperatures in the absence of a catalyst, by the relatively unstable fluorosulphatoacetate esters *in situ*[86,221] and also by the acylation of benzene by chlorocarbonyl fluorosulphate under approximately similar conditions[78]:



Primary perfluoroalkyl fluorosulphates are readily converted into the corresponding derivatives of perfluorocarboxylic acids, while the secondary compounds are converted into carbonyl compounds, for example into α-diketones[193]:



The diene (XI) is formed together with the ketone (X) from 4-chloroperfluoro-2,5-cyclohexadienyl fluorosulphate on hydrolysis, while treatment with alcohols leads to the stable ketals (XII)[222]:

Peroxy-compounds which could not be synthesised previously have been obtained from perfluoro-t-butylfluorosulphuryl peroxide[174,223]:

The hypochlorites derived from polyfluoro-alcohols, obtained by chlorination with chlorine fluorosulphate, also exhibit a high reactivity; they readily add to multiple carbon–carbon and carbon–nitrogen bonds[175,224]:

In conclusion we should like to emphasise that at present increasing attention is being devoted to the study of the properties and reactivities of the hypohalite derivatives of other strong acids such as nitric[10], perchloric[10,92–94], and trifluoromethanesulphonic[225,226]. Although many of these are much less stable than halogen fluorosulphates (for example, it has been recommended[226] that $ClOSO_2CF_3$ and $BrOSO_2CF_3$ are not heated above 0 °C), these compounds too are being used to an increasing extent in organic synthesis[10,225,226].

§ One cannot rule out the possibility that perfluoroazaalkenes do not react with peroxydisulphuryl difluoride[9,206] merely because of their poor solubility, as was observed previously in the reaction of tetrafluoroethylene with chlorine fluorosulphate[199].

Fluorine-containing α-Dicarbonyl Compounds and Their Derivatives

V.I.Saloutin, K.I.Pashkevich, and I.Ya.Postovskii (deceased)

The synthesis of fluorine-containing α-dicarbonyl compounds and their derivatives, their chemical properties (including the formation of heterocycles), and their applications are considered. Data emphasising their characteristic features due to the presence of fluorine atoms are presented.
The bibliography includes 97 references.

I. INTRODUCTION

α-Dicarbonyl compounds (α-DCC), namely α-diketones, α-ketoaldehydes, α-ketoacids, and their derivatives are used in industry and in laboratory syntheses. The presence of the α-dicarbonyl group in compounds of this class is responsible for their high reactivity in relation to many types of reagents. They are also convenient objects for the study of certain theoretical problems of organic chemistry (rotational isomerism relative to a single C–C bond and the mutual influence of substituents). Among compounds of this type, biologically active substances, analytical reagents, and valuable monomers have been discovered. The introduction of fluorine atoms into α-DCC molecules leads in many instances to a change of the reactivity of the substances and the appearance of new aspects of their applications. At the present time extensive data have accumulated in the literature on fluorine-containing α-DCC but no surveys on this problem have been published†.

This review surveys the literature data on the synthesis, chemical reactions, and practical applications of fluorine-containing α-diketones, α-ketoaldehydes, α-ketoacids, and their derivatives. The literature up to 1980 inclusive is covered.

II. METHODS OF SYNTHESIS

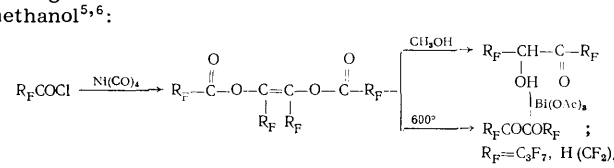
The preparation of a fairly large number of fluorine-containing α-diketones, α-ketoaldehydes, α-ketoacids, and their derivatives by various methods has been described in the literature; these data can be conveniently divided into two groups: the preparation of α-diketones and aldehydes and the preparation of α-ketoacids and their derivatives.

1. Fluorine-containing α-Diketones and α-Ketoaldehydes

A number of methods for the synthesis of fluorine-containing α-DCC are based on reactions of substances in which the carbonyl group is linked to a halogen atom and fluoroalkyl or fluoroacyl groups (acid halides, ketones, and acid anhydrides). These methods as a rule involve radical processes (the abstraction of radicals, recombination of fluoroacyl radicals, or oxidation).

† Some information about α-DCC is available in reviews[1,2] devoted mainly to other problems.

1,4-Difluorobutane-2,3-dione and 1,4-dichloro-1,4-difluorobutane-2,3-dione have been obtained (in yields of 42 and 58% respectively) by the reaction of monofluro- or chlorofluoro-acetyl chlorides with iron pentacarbonyl in an autoclave at 180 °C.[3] Diacetyl is formed by this method in 86% yield[3]:



$$CHFXCOCl \xrightarrow[180°]{Fe(CO)_5} CHFXCOCOCHFX + CHFXCOF \ ; \quad X=H,Cl \ .$$

In the reactions of trifluoroacetyl and difluoroacetyl chlorides, perfluorodiacetyl and 1,1,4,4-tetrafluorobutane-2,3-dione are not formed, the degradation of the initial acid chlorides being observed with formation of iron fluorides, carbon, and small amounts of carbonyl fluoride and hexafluoroethane[3].

1,1,4,4-Tetrafluorobutane-2,3-dione and perfluorodiacetyl have been obtained by the reaction of difluoro- and trifluoroacetic anhydrides with iron pentacarbonyl (in yields of 11 and 6.5%).[4] Under the same conditions, diacetyl is formed from acetic anhydride in 90% yield[4]. Together with perfluorodiacetyl, the following compounds have been obtained from trifluoroacetic anhydride: iron trifluoroacetate, carbon monoxide, iron fluorides, trifluoroacetyl fluoride, hexafluorobut-2-en-2,3-diyl bistrifluoroacetate, and hexafluoroethane[4]. Analogous products are formed from difluoroacetic anhydride[4].

It is believed[3,4] that, with decrease of the fluorine content in the initial acid chlorides and anhydrides, the yield of acid fluorides falls, while that of α-diketones increases in connection with the decrease of the concentrations of iron fluorides in the reaction mixture.

When heptafluorobutyryl and ω-hydro-octafluorovaleryl chlorides react with nickel tetracarbonyl in benzonitrile at 25 °C, the corresponding enediol esters are formed in yields of 51 and 19%, the esters being converted into α-diketones by pyrolysis at 600 °C *in vacuo*[5,6]. The same α-diketones are formed on oxidation with bismuth triacetate of fluorine-containing α-ketonalcohols obtained from enediol esters and methanol[5,6]:

$$R_F = C_3F_7, \ H(CF_2)_4 \ .$$

The attempt to obtain decafluorobenzil from pentafluorobromo- or pentafluoroiodo-benzene and nickel tetracarbonyl in aprotic solvents was unsuccessful; the reaction products were only decafluorobiphenyl, decafluorobenzophenone, and pentafluorobenzene[7]. The authors[7] attribute the absence of

decafluorobenzil to the instability of the pentafluorobenzoyl radical, which decomposes before it can dimerise.

1,1,1-Trifluorobutane-2,3-dione and trifluoromethylglyoxyal are formed from ethyl trifluoromethyl ketone and trifluoroacetone when they are oxidised by selenium dioxide. However, these compounds could not be isolated in a pure state and they were characterised in the form of glyoximes[8]:

$$CF_3COCH_2X \xrightarrow{SeO_2} [CF_3COCOX] \xrightarrow{NH_2OH} \text{(dioxime)};$$

X=H, CH_3.

The above method is apparently without value for the synthesis of fluorine-containing α-DCC, because the attempt to hydrolyse perfluorodipropylglyoxime was unsuccessful[9]. More interesting results were obtained on oxidation of benzyl fluoroalkyl ketones[10]:

$$C_6H_5CH_2COC_3F_7 \xrightarrow{SeO_2} C_6H_5COCOC_3F_7;$$

$$C_6H_5CH_2CO(CF_2)_4COCH_2C_6H_5 \xrightarrow{SeO_2} C_6H_5COCO(CF_2)_4COCOC_6H_5.$$

In certain studies on the photolysis of hexafluoroacetone the formation of perfluorodiacetyl on recombination of trifluoroacyl radicals was postulated[11,12]. Although perfluorodiacetyl was not isolated in the above studies[11,12], in the investigation of the flash photolysis of hexafluoroacetone at −78 °C it was identified[12] from the phosphorescence spectra in the presence of hexafluoroacetone.

$$CF_3COCF_3 \xrightarrow{h\nu} CF_3COCOCF_3.$$

A large number of methods for the synthesis of fluorine-containing α-diketones, based on the reactions of compounds containing multiple bonds (fluoro-olefins, fluoroacetylenes, and fluoroallenes) have been described. Perfluorodiacetyl was synthesised for the first time by the oxidation of 2,3-dichlorohexafluorobut-2-ene with chromium trioxide in 20% oleum[13]. Trifluoroacetyl chloride and 2,3-dichloro-1,1,1,4,4,4-hexafluorobutylene sulphate are formed together with perfluorodiacetyl[13]:

$$CF_3CCl=CClCF_3 \xrightarrow[20\%\text{ oleum}]{CrO_3} CF_3COCOCF_3 + \text{(Cl, Cl, CF}_3\text{, O, O, S, O, O)} + CF_3COCl.$$

The above investigators studied the formation of perfluorodiacetyl in the oxidation of hexafluorobut-2-yne by chromium trioxide or potassium perchlorate in 20% oleum[14]:

$$CF_3CH=CHCF_3 \xrightarrow{27\%} CF_3COCOCF_3 \xrightarrow{7.3\%} CF_3CF=CFCF_3$$
$$CF_3C\equiv CCF_3 \xrightarrow{17\%} CF_3COCOCF_3 \xrightarrow{31-36\%} CF_3CCl=CClCF_3.$$

2,3-Dichlorohexafluorobutylene sulphate, formed on oxidation of 2,3-dichlorohexafluorobut-2-ene, is converted into perfluorodiacetyl on treatment with catalytic amounts of triphenylphosphine, triphenyl phosphite, tributylamine, or pyridine[15]:

$$\text{(Cl, Cl, CF}_3\text{, O, O, S, O, O)} \xrightarrow[80-90\%]{} CF_3COCOCF_3 + SO_2Cl_2.$$

Perfluorodiacetyl has been obtained from perfluorobut-2-ene via hexafluoro-2,3-dimethoxybutylene sulphate[16,17], formed in the reaction of sulphur trioxide with vicinal dimethoxy-derivatives of hexafluorobut-2-ene:

$$CF_3CF=CFCF_3 \xrightarrow{CH_3OH,\ CH_3ONa} CF_3C(OCH_3)=C(OCH_3)CF_3 \xrightarrow[-SO_2]{SO_3}$$
$$\rightarrow CF_3COCOCF_3 + \text{(OCH}_3\text{, OCH}_3\text{, CF}_3\text{, O, O, S, O, O)} \xrightarrow{H_2SO_4} CF_3COCOCF_3.$$
24% 79%

This is one of the best methods from the standpoint of the yields of products and the availability of the initial reactants. Unfortunately it is apparently not universal and is suitable only for the synthesis of perfluorodiacetyl, since, after the increase of the length of the fluoroalkyl residues, the reaction of the fluoro-olefin with sodium methoxide in methanol leads to the formation of mixtures of products[17].

Perfluorocyclobutane-1,2-dione has been synthesised in 30–50% yield on treatment of 1,2-dimethoxyperfluorocyclobutane with sulphuric acid[18]:

$$2CF_2=CFOCH_3 \longrightarrow \text{(OCH}_3\text{, F, F, OCH}_3\text{)} \xrightarrow{H_2SO_4} \text{(F, F, O, O)}.$$
83% 30–50%

Treatment of perfluorobut-2-ene with bromine fluorosulphate yielded 2,3-di(fluorosulphate)perfluorobutane, whose treatment with alkali metal fluorides did not permit the isolation of perfluorodiacetyl[19]. However, in another study[20] the reaction of bromine fluorosulphate with perfluorobut-2-ene yielded 2-bromo-3-fluorosulphatoperfluorobutane, which is converted into 2-bromoperfluoro-2-butanone on treatment with a caesium fluoride. The reaction of the butanone with peroxydisulphuryl difluoride yields 3-fluorosulphatoperfluoro-2-butanone, which reacts with caesium fluoride to form perfluorodiacetyl[20]:

$$CF_3CF=CFCF_3 \xrightarrow{BrOSO_2F} CF_3CF(OSO_2F)CFBrCF_3 \xrightarrow[-SO_2F_2]{CsF}$$
$$\rightarrow CF_3COCFBrCF_3 \xrightarrow[-BrOSO_2F]{(OSO_2F)_2} CF_3COCF(OSO_2F)CF_3 \xrightarrow[-SO_2F_2]{CsF} CF_3COCOCF_3;$$

$$CF_3CF\ CFCF_3 \xrightarrow{BrOSO_2F} CF_3CF(FO_2SO)CF(OSO_2F)CF_3 \xrightarrow{M} C_nF_{2n+2} + SO_2F_2 + CO_2 + CO + O_2.$$

The method of synthesis of symmetrical and asymmetric perfluoro-α-diketones by the reaction of peroxydisulphuryl difluoride with internal fluoro-olefins and subsequent treatment of the products with caesium fluoride is of undoubted interest[21].

Perfluoro-α-ketofluorosulphate-derivatives have now become fairly readily available as a result of their synthesis from the epoxy-derivatives of internal fluoro-olefins and fluorosulphonic acid, which made it possible to obtain a large number of fluorine-containing α-diketones[22–24].

$$R_FCF(O)CFR'_F \xrightarrow{HOSO_2F} R_FCF(OSO_2F)COR'_F + R_FCOCF(OSO_2F)R'_F \xrightarrow{CsF} R_FCOCOR'_F;$$
40–90%

R_F=CF_3, C_2F_5, C_3F_7; R'_F=CF_3, C_2F_5, C_3F_7, $CF(CF_3)_2$.

The last two methods are the most general for the synthesis of aliphatic and alicyclic perfluoro- α-diketones[21–24].

Perfluoro-2,5-dimethylhexane-3,4-dione has been isolated in 28% yield together with perfluoro-2,4-dimethyl-3-pentanone on reaction of perfluoropropene with oxalyl difluoride under pressure in acetonitrile in the presence of potassium hydrogen difluoride[25]:

$$CF_3CF=CF_2 + FOC-COF \xrightarrow[28\%]{KHF_2} (CF_3)_2CFCOCOCF(CF_3)_2 + (CF_3)_2CFCOCF(CF_3)_2.$$

An analogous but somewhat modified method, in which oxalyl dichloride can be used as the starting material, has also been proposed[26].

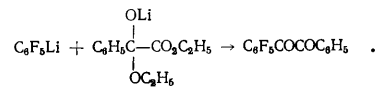
2-Chloroperfluoro-2-methylpentane-3,4-dione has been obtained with other products in 38% yield on treatment of tetrakis(trifluoromethyl)allene with nitrosyl chloride[27]:

$$(CF_3)_2C{=}C{=}C(CF_3)_2 \xrightarrow[180°]{NOCl} \underset{38\%}{CF_3COCOCCl(CF_3)_2} .$$

When hexafluorobut-2-yne or perfluorodiphenylacetylene reacts with bis(trifluoromethyl)nitroxide, perfluorodiacetyl or decafluorobenzil are formed in yields of 73% (for a 50% conversion) and 25% respectively[28]:

$$R_FC{\equiv}CR_F \xrightarrow{(CF_3)_2NO^\bullet} R_FCOCOR_F ;$$
$$R_F{=}CF_3,\ C_6F_5 .$$

Hexafluorobut-2-yne also gives rise to perfluorodiacetyl on reaction with perfluoromorpholine oxide[29]:



α-Diketones containing pentafluorophenyl groups are synthesised mainly with the aid of aromatic organometallic compounds. Decafluorobenzil is formed in 43–55% yield when pentafluorophenyl-lithium reacts with dimethyl oxalate at low temperatures (between −40° and −78 °C): [30]

$$C_6F_5Li + CH_3OOC-COOCH_3 \rightarrow C_6F_5COCOC_6F_5 .$$

Decafluorobenzil can be obtained in 26–32% yield from phenylcopper and oxalyl dichloride in ether[31]:

$$C_6F_5Li + CuBr \rightarrow C_6F_5Cu \xrightarrow{ClOC-COCl} C_6F_5COCOC_6F_5 .$$

Pentafluorobenzil can be obtained in 40% yield via the following mechanism[30]:

Pentachloropentafluorobenzil has been synthesised by the reaction of pentafluorophenyl-lithium with methyl pentachlorobenzoyl formate at −78 °C (yield 87%): [30]

$$C_6F_5Li + C_6Cl_5COCO_2CH_3 \rightarrow C_6F_5COCOC_6Cl_5 .$$

2. Fluorine-Containing α-Ketoacids and Their Derivatives

The main methods of synthesis of fluorine-containing α-ketoacids and their derivatives involve the interaction of the epoxy-derivatives of terminal fluoro-olefins and perfluoroazirines with nucleophiles (H_2O, ROH, RNH_2) or electrophiles (SO_2).

The hydrate of trifluoropyruvic acid has been obtained by treating epoxyhexafluoropropane with water[32,33]. This method proved to be general and has been used successfully to synthesise the hydrates of fluorine-containing α-ketoacids with longer fluoroalkyl residues from the corresponding epoxy-derivatives of higher fluoro-olefins[34,35]:

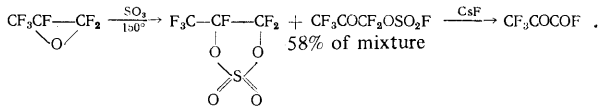
$$R_FCF{-}CF_2 \xrightarrow{H_2O} \underset{40-80\%}{R_FCOCO_2H{\cdot}H_2O} ,$$

$R_F{=}CF_3$ [32, 33]; C_2F_5 [34]; $H(CF_2)_n$, where n = 2, 4 [34], 6 [35]; C_4F_9 [34].

The synthesis of trifluoropyruvic acid by the hydrolysis of perfluoro-2-methyl-2*H*-azirine and perfluoro-3-methyl-2*H*-azirine has been described[36]:

$$CF_3CF{-}CF \xrightarrow[70°]{H_2O} [CF_3COCO_2H] \xrightarrow{C_6H_5NH_2} \underset{33\%}{CF_3COCO_2^-\overset{+}{N}H_3C_6H_5} .$$

The hydrate of trifluoropyruvic acid is formed on acid hydrolysis of α,α-diaminoperfluoropropionamide[37]:



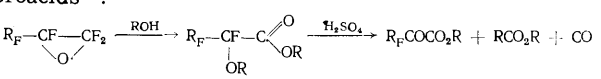
$$CF_3CF{-}CF_2 + H_2NR \rightarrow CF_3C(NHR)_2CONHR \xrightarrow{H_2O,\ H_3PO_4} CF_3COCO_2H{\cdot}H_2O .$$

On the interaction with water, the fluoride of trifluoropyruvic acid yield trifluoropyruvic acid hydrate; the starting materials for the synthesis of the acid fluoride are epoxyhexafluoropropane and an aromatic carbonyl compound (benzophenone, acetophenone, benzaldehyde, etc.)[38–45]:

$$CF_3CF{-}CF_2 \xrightarrow{ArCOR} CF_3COCOF + CF_3COF$$
$$\downarrow H_2O$$
$$CF_3COCO_2H{\cdot}H_2O \xrightarrow{H_2SO_4} CF_3COCO_2H .$$

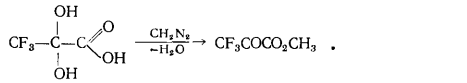
One must note that the mechanism of this reaction still remains obscure.

The fluoride of trifluoropyruvic acid has also been obtained from epoxyhexafluoropropane and sulphur trioxide at 150 °C with subsequent elimination of sulphuryl fluoride by treating the mixture of the addition products with caesium fluoride[46]:



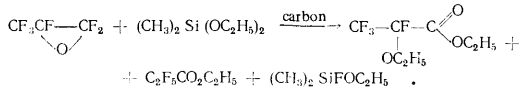
Pyrolysis of 1-nitro-perfluoro-2-propyl nitrite in a flow system gives rise to trifluoropyruvyl fluoride in a yield of approximately 10%: [47]

$$O_2N{-}CF_2{-}\underset{\underset{ONO}{|}}{CF}{-}CF_3 \xrightarrow{250°} CF_3COCOF + NO .$$

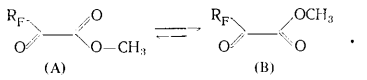


The study of the infrared spectra and of the temperature variation of the ^1H NMR spectra of solutions of hydrated fluorine-containing α-ketoacids showed that they exist in the form of fluoro-α,α-dihydroxyacids $R_FC(OH)_2COOH$. They differ in this respect from the usual fluorine-free α-ketoacids, which do not form stable hydrates capable of being isolated in a crystalline form[34].

On treatment of the hydrates of fluorine-containing α-ketoacids with phosphorus pentoxide, the anhydrous α-ketoacids are formed[35]. The alkyl esters of carboxylic 2-alkoxyperfluoroacids have been synthesised in high yields (50–96%) by the reaction of the epoxy-derivatives of terminal fluoro-olefins with alcohols[32,33,48–51]. Methyl tetrafluoro-2-methoxypropionate is converted on treatment with sulphuric acid at 140 °C into methyl trifluoropyruvate[48]. However, the alkyl esters of higher carboxylic 2-alkoxyfluoroacids give rise under these conditions to a mixture of alkyl esters of carboxylic fluoro-α-ketoacids and the products of the decarbonylation of the esters of the corresponding carboxylic fluoroacids[51]:

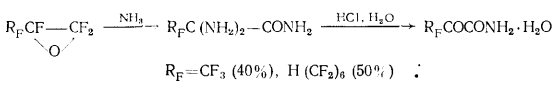


R = alkyl, $R_F = CF_3$ (Ref.48; C_2F_5 (Ref.51); C_4F_9(Ref.51); $H(CF_2)_n$, where n = 2, 4 (Ref.51).

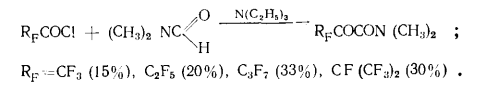


By reducing the reaction temperature to 100 °C or 60 °C (on replacing sulphuric acid with 20% oleum), it was possible to obtain the pure methyl esters of higher polyfluoro-α-ketoacids[51]. Methyl trifluoropyruvate has been obtained by treating the hydrate of trifluoropyruvic acid with diazomethane[48]:

Ethyl 2-ethoxytetrafluoropropionate is formed when epoxyhexafluoropropane reacts with diethoxydimethylsilane[52]:



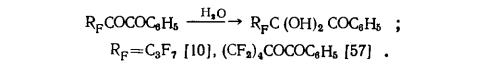
The study of the infrared spectra and dipole moments of solutions of the methyl esters of fluorine-containing α-ketoacids in carbon tetrachloride established that they exist in the form of equilibrium mixtures of the *trans*- and *cis*-conformers (A) and (B) with the *cis*-form predominating[53]. Pyruvate esters also consist of mixtures of the *cis*- and *trans*-conformers but with the *trans*-form predominating[54]. This difference is apparently due to the fact that the *cis*-forms of the esters of fluorine-containing α-ketoacids are less polar than the *trans*-forms, whereas in the case of the esters of hydrocarbon α-ketoacids the *trans*-form is less polar:



The amide of trifluoropyruvic acid has been obtained by the reaction of the corresponding acid fluoride with ammonia[38,40,43]:

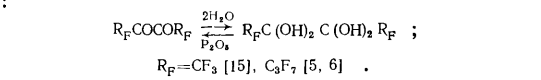
Hydrolysis of the amides of carboxylic α,α-diaminofluoroacids leads to the hydrates of the amides of α-ketoacids[35]:

The synthesis of the dimethylamides of carboxylic fluoro-α-ketoacids by the reaction of the chlorides of carboxylic perfluoroacids with dimethylformamide in the presence of triethylamine has been described[55,56] (without triethylamine, the yields are much lower[55,56]):



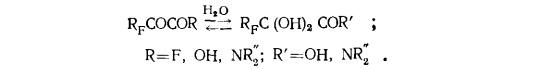
III. CHEMICAL REACTIONS

1. Anionoid Reactions



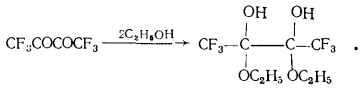
The majority of the studies in the chemistry of the fluorine-containing α-DCC have been associated with the investigation of anionoid reactions; they lead to different valuable α-DCC derivatives and make it possible to synthesise compounds with practically useful properties.

(a) The Interaction of α-DCC with Hydroxy-compounds

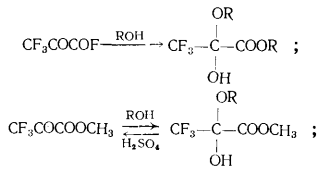


Fluorine-containing α-diketones with a fluoroalkyl substituent at one of the carbonyl groups and bis- α-diketones with an aliphatic fluorine-containing chain between the α-dicarbonyl groups combine with one molecule of water to form *gem*-ketodiols[10,57]. The site of addition has not been rigorously demonstrated but, by analogy with asymmetric β-diketones for which the addition of water to the carbonyl group linked to the fluorine-containing substituent has been established by ^1H, ^{19}F, and ^{13}C NMR, one can assume that in the case of the α-diketones water also reacts with the carbonyl group adjoining the fluorinated substituent[58]:

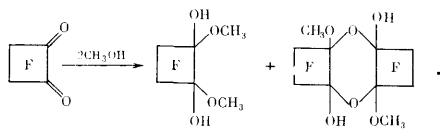
α-Diketones in which the fluoroalkyl groups are linked to both carbonyl groups combine with two water molecules to form tetraols[5,15]. The tetraols are stable compounds and give up water only on heating with phosphorus pentoxide[5,6] or 20% oleum[15]:



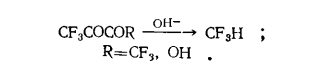
Fluorine-containing α-ketoacids[32,33,35,37], acid fluorides[37,38], and amides[35,55] also combine with a water molecule at the carbonyl group to form *gem*-dihydroxy-derivatives. The acid fluoride group is then hydrolysed to the carboxy-group:



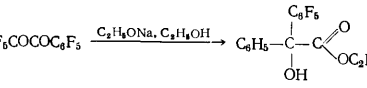
The derivatives of α,α-dihydroxy-acids are entirely stable compounds which give up water only on treatment with phosphorus pentoxide[47] or sulphuric acid[38], while the hydrocarbon α-ketoacids do not form stable hydrates.



On interaction with ethanol, perfluorodiacetyl gives rise to a stable bishemiketal[14]:

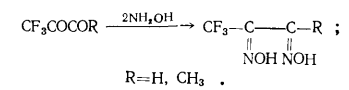


The methyl ester[37,60] and fluoride[61] of trifluoropyruvic acid react vigorously with alcohols, which leads to stable hemiketals. The hemiketal of methyl trifluoropyruvate can be decomposed by treatment with sulphuric acid[60]:

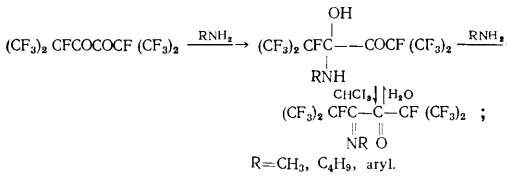


Perfluorocyclobutane-1,2-dione gives rise to a mixture of a bishemiketal and a dioxan on treatment with methanol[18]:

When aliphatic fluoro-α-diketones[14] and fluoro-α-ketoacids[33] are treated with aqueous alkali, they undergo the haloform decomposition with formation of trifluoromethane, like the fluorinated monoketones[59]:

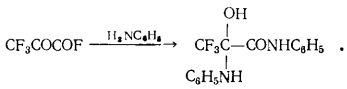


Fluorine-containing aromatic α-diketones in alcohol undergo a rearrangement in the presence of alkali metal alkoxides with migration of the pentafluorophenyl group[30]:



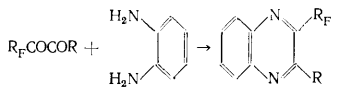
(b) The Interaction of α-DCC with Amino-Nucleophiles

The interaction of α-dicarbonyl compounds having one fluoroalkyl group with hydroxylamine yields dioximes, which readily form complexes with the nickel cation[8]:



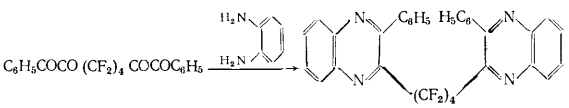
R=H, CH_3 .

Perfluoro-2,5-dimethylhexane-3,4-dione reacts with amines (with the reactants in proportions of 1:1) to form adducts which split off water on heating in chloroform and yield ketoimines[26]. However, on treatment with an excess of the amine, the α-diketone or its 1:1 adduct with the amine undergo the haloform decomposition with formation of 2-hydroperfluoropropane[26], which is apparently associated with the great stability of the leaving heptafluoroisopropyl anion:

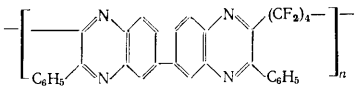


R=CH_3, C_4H_9, aryl.

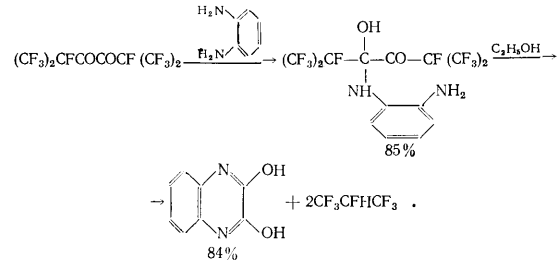
When trifluoropyruvyl fluoride was allowed to react with aniline the anilide of α-hydroxy-α-phenylaminoperfluoropropionic acid was obtained[46]:



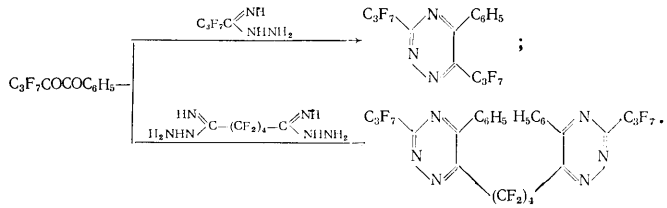
Fluorine-free α-diketones react with *o*-phenylenediamine (OPDA) to form 2,3-substituted quinoxalines[62]. This reaction has been studied vigorously also in the series of fluorine-containing α-DCC. Investigations showed that fluorine-containing α-diketones with fluoroalkyl substituents having a straight-chain structure and aromatic fluoro-substituents react with OPDA like the α-diketones of the hydrocarbon series and give rise to satisfactory yields of quinoxalines containing fluorinated substituents in the heterocyclic ring[5,8,10,14,30]. The reaction has been used successfully to identify fluorine-containing α-diketones, since the quinoxalines formed are readily purifiable crystalline substances.



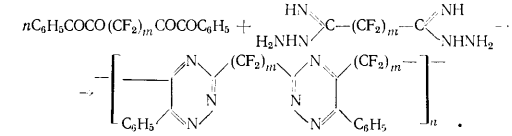
R_F=CF_3, R=H [8]; R_F=CF_3; R=CH_3 [8]; R_F=R=CF_3 [14]; R_F=C_3F_7, R=C_6H_5 [10]; R_F=R=C_3F_7 [5]; R_F=R=H$(CF_2)_4$ [5]; R_F=R=C_6F_5 [30] .



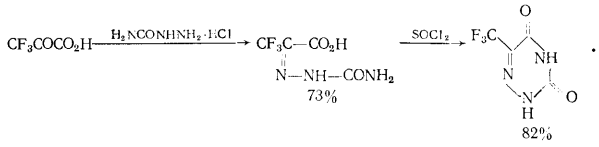
Fluorine-containing bis-α-diketones with an aliphatic fluorinated chain between the α-dicarbonyl groups also react with OPDA and give rise to bis-quinoxalines[57]:



This synthesis has been used to obtain polyquinoxalines by the reaction of bis-α-diketones with tetra-aminobiphenyl[57]:

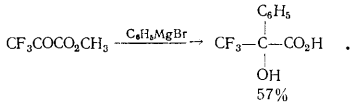


Perfluoro-2,5-dimethylhexane-3,4-dione reacts with OPDA in an unusual manner. Thus in acetonitrile at 0 °C the product is a 1:1 adduct, formed in 85% yield, which on heating in alcohol eliminates 2-hydroheptafluoropropane with formation of 2,3-dihydroxyquinoxaline[26,63]. This reaction pathway agrees also with the reactivity in relation to primary amines[26]; it too can be explained by the high stability of the leaving perfluoroisopropyl anion:

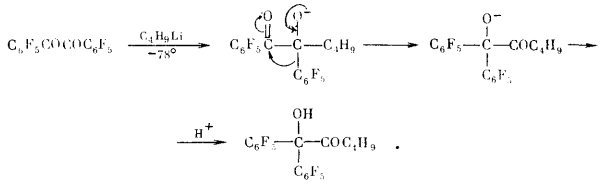


The interaction of fluorine-containing α-diketones with the imidoylhydrazides of carboxylic perfluoroacids, which leads to asymmetric triazines and bistriazines, has been described[10]:

If a bis-α-diketone and the bisimidoylhydrazide of a dicarboxylic perfluoroacid are introduced into the reaction, then fluorine-containing asymmetric polytriazines are formed[57]:

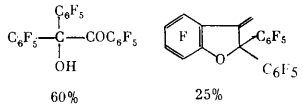


The interaction of trifluoropyruvic acid with semicarbazide hydrochloride in water yielded the semicarbazone of trifluoropyruvic acid, which is converted into 5-trifluoromethyl-6-azauracil on being refluxed with thionyl chloride[64]. The uracil has been used to synthesise nucleosides and nucleotides[64]:



It follows from the available literature data on the interaction of α-DCC with hydroxy- and amino-nucleophiles that the introduction of fluorine into the α-DCC molecule reduces the electron density at the carbonyl carbon atoms, as a result of which they are capable of forming stable adducts via one or both carbonyl groups, which is not characteristic of fluorine-free α-DCC. The structure of the fluorinated substituent also has a considerable influence on the reactivity of the α-DCC. Thus the introduction of perfluoroisopropyl groups gives rise to an increased tendency of perfluoro-2,5-dimethylhexane-3,4-dione to undergo the haloform decomposition in the presence of bases[36,63].

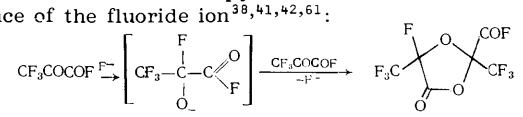
(c) The Interaction of α-DCC with Organometallic Compounds



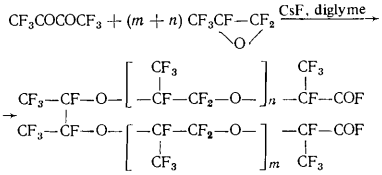
Treatment of methyl trifluoropyruvate with phenylmagnesium bromide and subsequent treatment of the reaction mixture with sulphuric acid and an alkali yielded α-hydroxy-α-trifluoromethyl phenylacetic acid[65]:

The reactions of alkyl- and aryl-lithium compounds with fluorine-containing aromatic α-diketones result in the formation of adducts, which undergo a rapid rearrangement with migration of the pentafluorophenyl group[30]. The structure of the final reaction products depends on the nature of the lithium derivative used. Thus, when decafluorobenzil was treated with butyl-lithium, 2-hydroxy-1,1-bis(pentafluorophenyl)-2-hexanone was obtained after acid hydrolysis[30]:

The interaction of decafluorobenzil with pentafluorophenyllithium leads to the formation of perfluoro-2-benzylbenzoin and perfluoro-2,2-diphenylbenzofuran-3-one (the latter is obtained as a result of the intramolecular nucleophilic substitution of the *ortho*-fluorine atom)[30]:



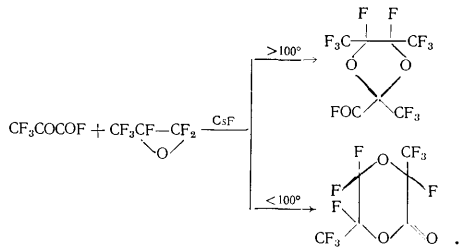
The reaction with pentachlorophenyl-lithium results in the formation of bispentafluorophenylmethyl pentachlorobenzoate[30]:



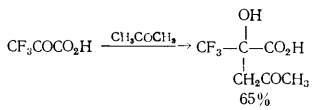
(d) Reactions with Participation of the Fluoride Anion

The reactions with participation of the fluoride anion are important for the chemistry of fluorinated carbonyl compounds[66,67]. However, hitherto only a limited number of reactions involving the fluoride ion in the series of fluorine-containing α-DCC are known.

The fluoride of trifluoropyruvic acid dimerises in the presence of the fluoride ion[38,41,42,61]:

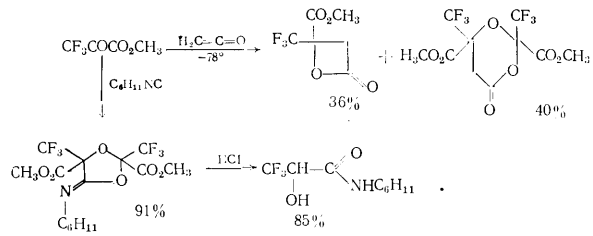


In the presence of caesium fluoride, perfluorodiacetyl reacts with epoxyhexafluoropropane in diglyme to form oligomeric products, both carbonyl groups of perfluorodiacetyl being involved in the reaction[69]:



The acid fluoride groups of this oligomer were then converted into fluoroalkyl groups by reaction with elemental fluorine[69].

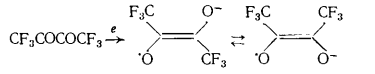
The interaction of epoxyhexafluoropropane with the fluoride of trifluoropyruvic acid and caesium fluoride leads to dioxolan or dioxan derivatives, depending on the temperature[38,40,43,44]:



(e) Other Reactions of α-DCC with Participation of the Carbonyl Group

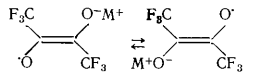
The condensation of trifluoropyruvic acid with acetone in water has been observed. The reaction in the formation of α-hydroxy-α-trifluoromethyl-γ-oxovaleric acid[32]:

When methyl trifluoropyruvate was allowed to react with keten, β-methoxycarbonyl-β-trifluoromethyl-β-propiolactone and 2,4-bis(methoxycarbonyl)-2,4-bis(trifluoromethyl)-1,3-dioxan-6-one were obtained[60]. Treatment of methyl trifluoropyruvate with cyclohexyl isocyanide in the same study[60] led to the isolation of a high yield of 5-cyclohexylimino-2,4-bis(methoxycarbonyl)-2,4-bis(trifluoromethyl)dioxolan, whose acid hydrolysis results in the formation of the cyclohexylamide of trifluorolactic acid:



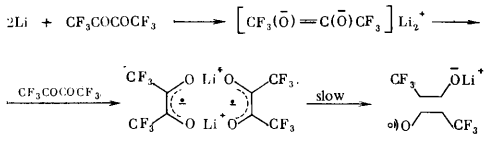
2. Oxidation-Reduction Reactions

The fluorine-free α-DCC are capable of undergoing oxidation-reduction reactions with participation of the carbonyl groups[70]. The oxidation-reduction reactions of polyfluoro-α-DCC with participation of the carbonyl groups (electrochemical reduction[71,72], interaction with metals and their salts[71,75], and interaction with phosphorus-containing reagents[77–86]) are also known.

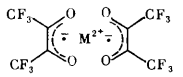


(a) Reduction of α-DCC

Like diacetyl, hexafluorodiacetyl is converted on electrochemical reduction in tetrahydrofuran (THF) (in the presence of an R_4N^+ cation) into a semidione radical-anion, which exists in the form of an equilibrium mixture of the *trans*- and *cis*-isomers (as shown with the aid of EPR).[71,72] The *trans/cis* ratio is 170 in THF and 120 in dimethyl sulphoxide (DMSO):[71,72]



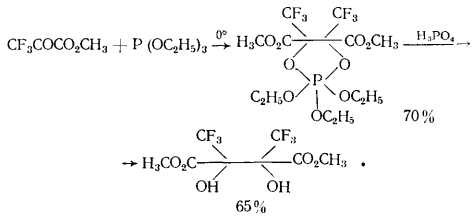
The *trans/cis* ratio for diacetyl in DMSO (in the presence of an R_4N^+ cation) is 35;[70] thus the introduction of fluorine shifts the equilibrium towards the *trans*-isomer.



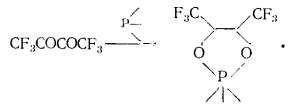
On interaction with alkali and alkaline earth metals in DMSO and THF, hexafluorodiacetyl is reduced to a radical-anion[71], which gives rise to several types of ion pairs with metal cations. If the counterions are Cs^+ and Rb^+, then the *trans*-isomer is formed preferentially (*trans/cis* = 150, DMSO, Rb^+; *trans/cis* > 200, THF, Cs^+);

The mechanism of the interaction of hexafluorodiacetyl with lithium has been established by EPR[71]:

The formation of ion pairs on reduction of perfluorodiacetyl with alkaline earth metals (Ca, Sr, and Ba) in THF was demonstrated in the same study[71]:

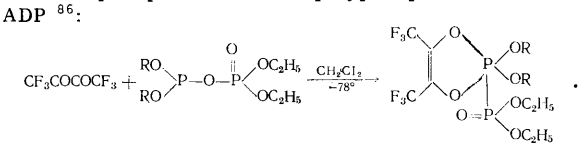


Hexafluorodiacetyl is also reduced on treatment with alkali metal iodides in solvents [in DMSO, hexamethylphosphoramide (HMP), and ethereal solvents] to a radical-anion, which forms ion pairs with alkali metal cations[72,74]. In DMSO and HMP the radical-anion exists mainly in the *trans*-form, (*trans/cis* > 100) and the ratio of the isomers is independent of the nature and the concentration of the counterion. The reduction takes place rapidly also in ethereal solvents when lithium iodide is used as the reductant[72], 1 : 1 ion pairs being formed. In the reaction involving treatment with sodium iodide, irradiation with light from a mercury lamp in a quartz cell is required[72]:

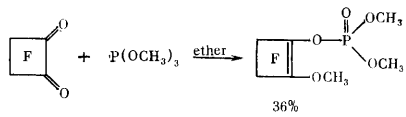


(b) The Interaction of α-DCC with Fluorine-Containing Reagents

The product of the reaction of methyl trifluoropyruvate with triethyl phosphite is a 2 : 1 adduct consisting of a cyclic phosphorane whose hydrolysis gives rise to a pinacone[60]:



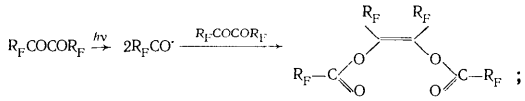
It is of interest that trifluoropyruvate reacts via one carbonyl group, like hexafluoroacetone, and not a diketone in which both carbonyl groups are reduced with formation of 1,3,2-dioxaphospholens[76].



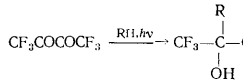
Numerous studies have been devoted to the investigation of the reactions of hexafluorodiacetyl with phosphorus(III) derivatives of different structure. A series of cyclic 1,3,2-dioxaphospholens have been obtained in this way with high yields[77–86]:

For example, hydroxyphosphoranes have been synthesised in this way from hexafluorodiacetyl and mixed anhydrides of phosphoric and phosphorous acids, which are models of the hypothetical intermediates formed in the addition of nucleophiles to the phosphorus atom in polyphosphates such as ATP and ADP [86]:

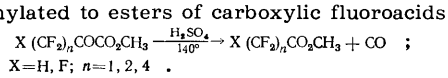
In reactions with phosphorus(III) derivatives, fluorine-containing aliphatic α-diketones behave mainly analogously to fluorine-free α-diketones[87]. It is of interest that the reaction of perfluorocyclobutane-1,2-dione with trimethyl phosphite yields dimethyl 3,3,4,4-tetrafluoro-2-methoxycyclobut-1-enyl phosphate[88].



3. Radical Reactions

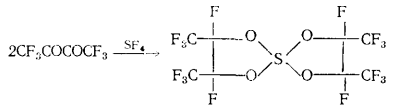


When hexafluorodiacetyl is irradiated with ultraviolet light in the vapour phase, it decomposes into trifluoromethyl radicals and carbon monoxide[89,90]. Irradiation of diacetyl at room temperature leads to the formation in the primary photochemical step of two acyl radicals, which then undergo a number of reactions[91]:



The study of the photolysis of hexafluorodiacetyl and tetrafluorodiacetyl in the liquid phase showed that the trifluoroacetyl radicals arising in the first stage can interact with the initial diketones to form diacetyl derivatives of enediols[4]:

When hexafluorodiacetyl is exposed to ultraviolet light in the presence of hydrocarbons, ketoalcohols and small amounts of CO are formed[90]:



When the methyl esters of polyfluoro-α-ketoacids are heated above 140 °C in the presence of sulphuric acid, they are decarbonylated to esters of carboxylic fluoroacids[51]:

One must note that the available literature data are insufficient to reach conclusions concerning the pathways followed in the primary photochemical processes in the photolysis of fluorine-containing α-DCC.

4. Interaction with Sulphur Tetrafluoride

The unusual formation of a spirosulphuran (in a quantitative yield) on interaction of hexafluorodiacetyl with sulphur tetrafluoride (reactant ratio 2:1) has been observed[92]. The compound obtained is a stable crystalline substance whose structure has been determined by ^{19}F and ^{13}C NMR and by X-ray diffraction[92]. It is of interest that products of the fluorination of the carbonyl groups of hexafluorodiacetyl were not detected in the reaction mass, whereas in the series of hydrocarbon α-DCC such compounds are formed in high yields[92-96]:

IV. APPLICATIONS

Perfluorodiacetyl has been recommended as an antibacterial and fungicidal agent and also for imparting water- and dirt-repellent properties to cotton textiles[13]. The use of perfluorodiacetyl as a photoinitiator in radical polymerisation and also for the treatment of fabrics has been patented[16].

The fluoride of trifluoropyruvic acid and its cyclic dimer are used as soil fumigants and insecticides, which evolve hydrogen fluoride on contact with water[39,41].

The amide of trifluoropyruvic acid can be used as a dispersing agent and exhibits surface-active properties[41].

The fluoride of trifluoropyruvic acid serves as the starting material for the synthesis of perfluoro-derivatives of cyclic dioxans and dioxolans, which are chemically inert and thermally stable solvents[41]. This compound is used as the starting material for the synthesis of monomers and then polymers employed as adhesive films and films with irreversible gas permeability[45]. The latter can be used to separate different gases.

Glyoximes, which are used as reagents for nickel(II), have been obtained from 1,1,1-trifluorobutane-2,3-dione and trifluoromethylglyoxal[8].

Polymers with quinoxaline and triazine rings in the chain have been obtained from fluorine-containing bis-α-diketones having an aliphatic fluorine-containing chain between the α-dicarbonyl groups[57]. Fluorine-substituted benzils are used as the starting materials for the synthesis of anaesthetics and antihistamine preparations[97].

Analysis of the present state of research into the chemistry, properties, and applications of fluorine-containing α-dicarbonyl compounds (α-diketones, α-ketoaldehydes, α-ketoacids, and their derivatives) permits the conclusion that methods have been developed in recent years for their synthesis and their properties of practical value have been discovered. However, hitherto many problems of the chemistry of α-dicarbonyl compounds have been virtually uninvestigated. Thus there are almost no data on their reactions with electrophiles and few studies have been made on the radical processes and physicochemical properties of substances in this series; such studies would yield additional information about the influence of fluorine atoms on the reactivity of organic compounds.

The Reactivity of 1,3,2-Diheterophospholans and 1,3,2-Diheterophosphorinanes with a Tetracoordinate Phosphorus Atom

R.A.Cherkasov, V.V.Ovchinnikov, M.A.Pudovik, and A.N.Pudovik

The present state of research into the reactivities of 1,3,2-diheterophospholans and 1,3,2-diheterophosphorinanes with a tetracoordinate phosphorus atom, containing in five- and six-membered rings, two identical or two different hetero-atoms (O, S, or N) together with the phosphorus atom, is described. Attention is concentrated on the differences between the reactivities of cyclic and acyclic organophosphorus compounds with the same ligand environment of the phosphorus atom. The influence of the introduction of a phosphorus atom into the ring on the reactivity of cyclic compounds is demonstrated. The bibliography includes 189 references.

I. INTRODUCTION

The last decade has been marked by increasing interest in cyclic esters, thioesters, amides, and amidoesters of phosphorus acids in which a tetracoordinate phosphorus atom is incorporated in a five- or six-membered ring—1,3,2-diheterophospholans and 1,3,2-diheterophosphorinanes. The importance of studies on organophosphorus compounds of this type is due primarily to the important role of cyclic phosphates in many biochemical processes. The considerable distortion of the geometry of the phosphorus tetrahedron in cyclic structures, particularly in five-membered structures, and the resulting changes in the nature of the intramolecular electronic interactions predetermine the known specificity of the reactivity of such molecules, differing significantly in many instances from the reactivity of their acyclic analogues. In addition, the rigidity of the cyclic fragment is responsible for certain limitations in the relative positions of the ligands at the phosphorus atom, imposing thereby its imprint on the stereochemical results of processes involving such molecules.

The aim of the present review is to examine and as far as possible describe systematically and survey the results of studies on the reactivities of 1,3,2-diheterophospholans and 1,3,2-diheterophosphorinanes having the general formula

R = 1,2- and 1,3-alkylene or 1,2- or 1,3-arylene; X, Y = O, S, NR'; Z = O, S, Se, NR'; A = = Alk; Ar, AlkO; ArO, AlkS, ArS, NR'_2, OH, SH, H .

Particular attention has been devoted to the deduction of the chemical consequences of the incorporation of a tetracoordinate phosphorus atom in the cyclic skeleton of the molecule; the reactivities of cyclic and acyclic compounds with the same ligand environment of the phosphorus atom have been compared.

Mainly synthetic aspects of the chemistry of 1,3,2-diheterophospholans and 1,3,2-diheterophosphorinanes have been considered in the available review literature[1]. Much attention has been devoted to studies of the stereochemical and conformational relations in these compounds[2-6] as well as the stereochemistry of nucleophilic substitution at the tetrahedral phosphorus atom in five-membered and six-membered phosphates and phosphonates[7].

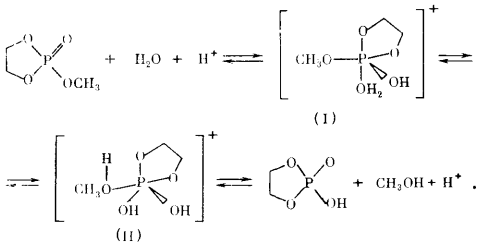
For this reason, the results of preparative and stereochemical studies are used in the present review only to the extent that they are necessary for the interpretation of the specific features of the reactivities of cyclic phosphorus compounds. Cyclic derivatives of enediol phosphates, to the chemistry of which a recently published review is devoted[8], are not considered.

The only publication of the review type published in 1972, which discusses the characteristics of the reactivity of phosphorus-containing cyclic molecules, embraces the results of studies carried out mainly in the 1960s and deals with various types of phosphorus-containing heterocycles[9]. This review is concerned with experimental data published during the last ten years.

II. NUCLEOPHILIC SUBSTITUTION AT A TETRAHEDRAL PHOSPHORUS ATOM

1. 1,3,2-Diheterophospholans

The results of kinetic, stereochemical, thermochemical, and quantum-chemical studies and the investigation of the composition of the products of the hydrolysis of phosphorus(V) acids made it possible to formulate[10-13] the concept of trigonal-bipyramidal intermediates with the hydroxyphosphorane structure (the "hydroxyphosphorane concept" [12]), which constitutes the basis of the modern interpretation of the mechanism of nucleophilic substitution at a tetrahedral phosphorus atom. The use of the hydroxyphosphorane concept proved to be extremely fruitful in explaining the very marked acceleration (by a factor of millions) of the hydrolysis of five-membered cyclic phosphorus esters compared with their acyclic analogues.



The hydrolysis of ethylene phosphate and its methyl ester takes place with the preferential opening of the five-membered ring; the exocyclic substitution product is formed in a smaller amount. However, both reactions are 10^6–10^8 times faster than the hydrolysis of trimethyl phosphate (see Westheimer's paper[10] and the literature quoted there). 2-Methoxy-2-oxo-1,2-oxaphospholan also hydrolyses very

rapidly and almost exclusively with the rupture of the endocyclic ester linkage, while the cyclic methyl tetramethylenephosphinate undergoes exocyclic hydrolysis at a rate close to that of the reactions of acyclic phosphorus esters.

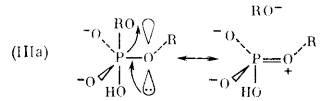
Whereas the ease of the endocyclic rupture of the bonds on hydrolysis can be explained by the decrease of the strain in the five-membered rings within the framework of the $S_N2(P)$ concerted nucleophilic substitution mechanism[7,10], for the rapid exocyclic elimination of ester groups a satisfactory explanation has been obtained only on the hypothesis of an addition–elimination mechanism. When the nucleophile attacks the phosphorus atom, metastable trigonal-bipyramidal intermediates are formed whose stability and decomposition are regulated by the rules of the hydroxyphosphorane concept[12, 14, 15].

According to these rules, the addition of a nucleophile to the phosphorus atom leads to the formation of a phosphorane in which the attacking and leaving groups occupy axial (apical) positions. The strained five-membered rings containing the phosphorus atom then occupy one axial (*a*) and one equatorial (*e*) positions whereby a decrease of strain is achieved. The disposition of the ligands in the phosphorane obeys the polarity ("apicophilicity" [14]) rule—electron-accepting groups prefer *a*-positions and electron-donating groups prefer *e*-positions. Finally, the phosphoranes undergo ligand reorganisation (pseudorotation and permutation isomerisation), which is determined by the strain and apicophilicity rules[16–18].

From these standpoints, the rapid exocyclic hydrolysis of ethylene methyl phosphate in an acid medium can be readily accounted for by the conversion of the intermediate (I) into (II) as a consequence of pseudorotation, which results in the transfer of the leaving methoxy-group to the *a*-position[10,13]:

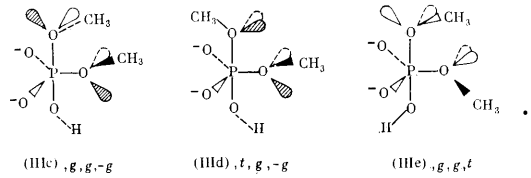
The endocyclic rupture of the bonds in the hydrolysis of the cyclic methyl propylenephosphinate is associated almost exclusively with the high energy barrier to the pseudorotation required to transfer the *e*-methoxy-group to the *a*-position; any permutation isomerisation causes the migration of an electron-donating endocyclic carbon atom to the *a*-position or the transfer of the five-membered ring to the *e*–*e*-position.

The slow hydrolysis of cyclic phosphinates is also due to the lack of pathways to the formation of low-energy hydroxyphosphoranes, because, as a result of pseudorotation, either the angle in the ring increases to 120° or one of the ring carbon atoms must substitute the oxygen atom in the *a*-position. The ring rupture on hydrolysis of ethylene methyl phosphate does not require pseudorotation, while substitution at the phosphorus atom can proceed via an intermediate resembling the transition state in a concerted S_N2 process†.



The main "driving force" of the rapid hydrolysis of ethylene phosphates is believed to be[10] ring strain. The heat of hydrolysis of ethylene phosphate exceeds by 20–25 kJ mol^{-1} that for acyclic phosphoric acid esters. On the other hand, the difference between the activation energies for the reactions of cyclic and acyclic phosphates reaches 40–45 kJ mol^{-1}, while the difference between the strain energies is 17–21 kJ mol^{-1} [19]; thus the high stabilisation (to the extent of almost 20–25 kJ mol^{-1}) of the cyclic transition state compared with the acyclic transition state (Fig. 1) cannot be explained solely from the standpoint of the strain in five-membered phosphorus-containing rings but is determined to a significant extent by stereoelectronic control or the orientation of the orbitals of the unshared electron pairs of the ligands[20].

Quantum-chemical calculations[20–22] of the potential energy cross-section of the model system



have shown that the reaction proceeds in two stages via intermediate (III) separated by activation barriers from the reactants and the reaction products. The energies of the transition state in both stages depend to a large extent on the conformations of the initial molecule of dimethyl phosphate and the molecule of the intermediate dimethoxyphosphorane and are subject to stereoelectronic control by the *e*-methoxy-group. This stereoelectronic effect is responsible for the selective weakening of the P–O ester linkages, which are in the *trans*-positions (antiperiplanar positions) relative to the unshared electron pairs of the adjacent oxygen atoms[21].

The nature of the stereoelectronic effect is explained within the framework of the anomeric effect[21,22]: the *a*-ester linkage P–OCH_3 is weakened in the molecule of compound (IIIa) for the *trans*-position (antiperiplanar position) of the orbital of the unshared electron pair of the *e*-oxygen atom. The *e*-ester linkage with the oxygen atom having the *trans*-unshared electron pair is stabilised. In other words, the resonance structure (IIIb) makes a significant contribution to the structure of the transition state:

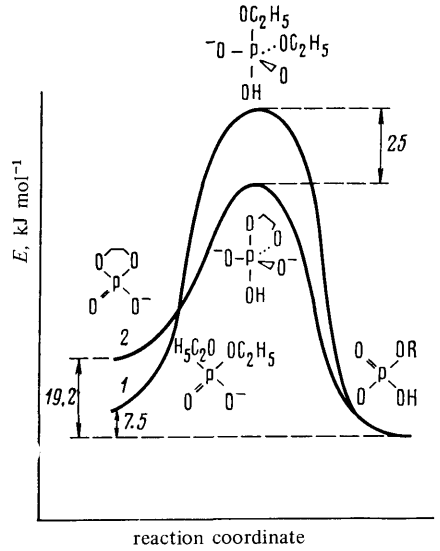
The addition of OH^- to the *gauche*, *gauche*-conformer of dimethyl phosphate leads to the intermediate (IIIc) (*g*, *g*, -*g*), while the ester in the *gauche*, *trans*-conformation can form the phosphoranes (IIId) (*t*, *g*, -*g*) and (IIIe) (*g*, *g*, *t*).

---

†Strictly speaking it is in principle impossible to draw a boundary between the $S_N2(P)$ and addition–elimination mechanisms in an endocyclic substitution reaction involving the inversion of the configuration at the phosphorus atom. Most probably in such situations we are dealing with the limiting cases of the same mechanism[7].

Calculation showed that the energy of the trigonal-bipyramidal transition state depends on the orientation of the *e*-ester linkage[20-22]. For the two-stage nucleophilic substitution process at the tetrahedral phosphorus atom, in which both stages are partly rate-determining[21], the rotation about the *e*-ester linkage during the reaction is significant. Whereas the *trans*-disposition of the unshared electron pair of the *e*-oxygen atom relative to the P–OH bond being formed is favourable for the attack stage [there is an energy gain of ~17 kJ mol^{-1} in structure (IIIe)], the *trans*-orientation of the unshared electron pair of the *e*-oxygen atom relative to the P–OCH_3 *a*-bond is required for the weakening of the bond between the phosphorus atom and the leaving group [there is an energy gain of ~45 kJ mol^{-1} in structures (IIIc) and (IIId)]. Only on rotation about the *e*-ester linkage in the course of the reaction can the stereoelectronic effect lower the activation barrier in both stages and hence the overall activation barrier. A necessary condition for such "stereoelectronic catalysis" [21] is the formation of intermediate pentacoordinate structures whose lifetime is sufficient for a single rotation.

In cyclic systems of the type of ethylene phosphate, where the favourable *trans*-disposition of the unshared electron pair of the *e*-oxygen and the *a*-ester linkage being ruptured is enforced in the potential hydroxy-phosphorane, the stereoelectronic effect ensures the stabilisation of the five-membered cyclic transition states (~25 kJ mol^{-1}) compared with the acyclic transition states, as shown in Fig.1.[20,21].



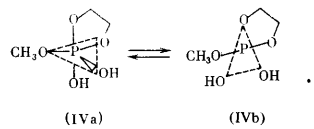


Figure 1. Reaction profiles of the OH^--catalysed hydrolysis of diethyl phosphate (curve *1*) and ethylene phosphate (curve *2*).[19]

The importance of the stereoelectronic control is confirmed by the considerable entropy contribution to the kinetic acceleration of the hydrolysis of five-membered cyclic phosphates[20]. Thus the entropy of activation for the latter is higher by almost 75 J mol^{-1} K^{-1} than for the acyclic ester[23]. Among all the possible conformations of the transition states in the hydrolysis of acyclic phosphates, only five undergo the interaction characteristic of *trans*-unshared electron pairs and the transition states of type (IIIc) or (IIId) are characterised by the lowest energy[20]. This requires the "freezing" of two rotational degrees of freedom about the acyclic ester linkages. The cyclic esters are already "frozen" in a suitable conformation with a low energy which is reflected in the difference between the activation entropies. The arrest of the free rotation about the ester linkages is responsible for the low negative entropies of activation for the acyclic esters (−143– −161 J mol^{-1} K^{-1}). In order to compensate for this unfavourable entropy, the stereoelectronic enthalpy gain must indeed be significant[20].

In the general case the reactivity of 1,3,2-diheterophospholans in nucleophilic substitution reactions at the tetrahedral phosphorus atom, the stereochemistry of these reactions (the retention or inversion of the configuration at the phosphorus atom), and the nature of the bond rupture (endocyclic or exocyclic) depend on many causes: on the presence or absence of catalysis (neutral, acid, or alkaline hydrolysis), on the type of heteroatoms linked to phosphorus, on the nature of the nucleophile and the leaving group, on the influence of the substituents in the five-membered ring, and on the nature of other electrophilic centres in the substrate molecule.

Kinetic studies and the investigation of the composition of the products of the hydrolysis as a result of the exocyclic and endocyclic substitution of the ester groups of ethylene methyl phosphate over a wide pH range in the medium[24] showed that the rate of reaction (Fig.2) and the *exo*/*endo* ratio (Fig.3) depend markedly on the nature of the catalysis.

If the ring rupture does not require pseudorotation, then the elimination of the methoxy-group is possible only after the conversion of the intermediate (IVa) into (IVb):

(IVa) (IVb)

In acid hydrolysis the intermediate phosphorane (IVa) is protonated by the *a*-oxygen atom[24], which prevents the conversion of compound (IVa) into (IVb), because the electronegative oxonium oxygen atom then migrates to the *e*-position. Therefore, with increase of the acidity of the medium, the fraction of the products formed as a result of ring rupture increases (Fig.3); the rate of reaction then varies linearly with the acid concentration (the left-hand branch of the curve in Fig.2).

The increase of the content of the cyclic product in dilute solutions (up to 50%, Fig.3) can be associated with the rate-determining pseudorotation in these instances[24]. In the regions where the pH is close to the value for a neutral medium, the rate of reaction is much lower and the fraction of the cyclic product reaches 25%.

In weak alkalis the intermediates exist in a monoanionic form with an anionic *e*-oxygen atom and pseudorotation giving rise to the anion of hydroxyphosphorinane (IVb) is in principle possible. The predominance of the endocyclic rupture in this instance can be accounted for by the fact that the rate of abstraction of the endocyclic *a*-oxygen atom is much higher than the rate of pseudorotation[24].

In a strongly alkaline solution the increase of the fraction of the cyclic product is most probably associated with the favourable energy of the permutation isomerisation of the

dianion of phosphorane (IVa) with an anionic α-substituent to the anion of the acid (IVb) in which both negatively charged oxygen atoms are located in the e-positions.

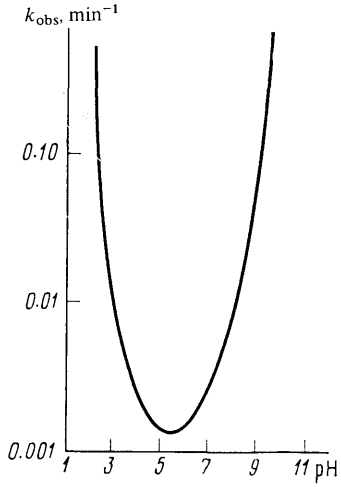

Figure 2. The rate of hydrolysis of ethylene methyl phosphate at 298 K.[24]

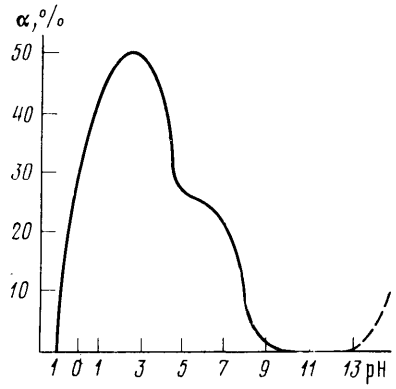

Figure 3. The pH profile of the hydrolysis products of ethylene methyl phosphate in water at 298 K;[24] α is the content of products formed as a result of exocyclic substitution.

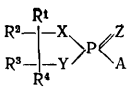
The retention of the 1,3,2-diheterophospholan ring on hydrolysis and alcoholysis is observed fairly frequently [compounds (V), (VI), (VIII), (IX), (XIV), (XVIII), (XX), and (XXV) in Table 1]. 1,3,2-Dioxaphospholans and their benzo-derivatives react in a neutral solution with a limited amount of water with the preferential elimination of exocyclic groups [compounds (XIV) and (VIII) in Table 1];[25-27] the hydrolysis of the benzodiheterophospholan ring is a secondary process. On the other hand, there are data[28] indicating the exceptional hydrolytic instability of the benzodioxaphospholan ring. Thus the alcoholysis of phenyl phenylene phosphate (XVI) with ring opening under the influence of isobutyl alcohol takes place very rapidly at room temperature; 2-ethylpropanol reacts in 5 min, while 2,4-dimethyl-3-pentanol reacts in 2 h. After standing for a long time at room temperature, the acyclic alcoholysis products recyclise to alkyl phenylene phosphates. An analogous situation has been observed in the reaction of the phenylene phosphate anion (XV) with α-chymotrypsin[29].

These results show that both the ring opening products and the exocyclic substitution products can be formed as a result of secondary reactions and the assessment of the nature of the substitution (exocyclic or endocyclic) must be performed with some caution.

The hydrolysis and methanolysis of acyl ethylene phosphate (VII) also proceed with retention of the ethylene phosphate ring[30]. It is striking that nucleophilic substitution is in this case directed to the phosphoryl and not the carbonyl centre, which is apparently due to the unfavourable energetic features of the intermediate with a pentacoordinate phosphorus atom, analogous to compound (I). The rate of reaction of compound (VII) is much higher than that of its acyclic analogue—acetyl dimethyl phosphate.



Preferential attack by nucleophiles on the phosphoryl rather than the carbonyl group has been observed in the alcoholysis, acidolysis, and aminolysis of 2,4-dioxo-1,3,2-diazaphospholans[31]. On the other hand, six-membered and acyclic acyl phosphates react with nucleophiles preferentially or fully via the acylation mechanism[32].

The relative ease of dissociation of the exocyclic and endocyclic ester linkages depends significantly on the degree of substitution of the ring carbon atoms. For example, in neutral media ethylene methyl phosphate hydrolyses almost completely with ring opening[24], while methyl tetramethylethylene phosphate (VI) forms methyl pinacolphosphoric acid under these conditions[33]. Alkaline hydrolysis takes place as a rule almost exclusively with the endocyclic rupture of ester linkages[24,33]. However, under these conditions too the dioxaphospholan fragment is ruptured preferentially at the P–O bond adjoining the least substituted carbon atom. Thus the endocyclic hydrolysis of compound (XVIII) takes place to the extent of 50% with rupture of the ester linkage involving the secondary carbon atom and to the extent of 20% with the rupture of the linkage involving the tertiary carbon atom[34].

It is most likely that the latter feature is associated with the fact that, on formation of the trigonal-bipyramidal intermediate, the oxygen atom linked to the least substituted (less electropositive and hence more apicophilic) carbon atom occupies preferentially the a-position for the a–e disposition of the five-membered ring. Naturally, this difference between the electronegativities of the ring carbon atoms is small and for this reason both ester linkages are ruptured.

Other conditions being equal, an increase in the number of alkyl substituents in the 1,3,2-diheterophospholan ring increases the hydrolytic stability of the cyclic skeleton of the molecule[35,36]. For example, it is known that the tendency of 1,3,2-dioxaphospholans to undergo reversible oligomerisation with ring opening is much greater for the unsubstituted cyclic compounds. The introduction of even one alkyl substituent at the ring carbon atoms sharply increases the stability of the molecules[37,38].

The greater stability of the substituted five-membered rings in hydrolysis reflects the tendency, common to small rings, to become stabilised with increase of the number of substituents[39,40], particularly in the presence of *gem*-dialkyl groups (the Ingold–Thorpe effect[41,42]).

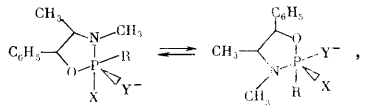
Note. α and β are the amounts of products formed as a result of the exocyclic and endocyclic ruptures respectively; the bond ruptured is indicated in brackets against the values of β.

*α = 17% and β = 83% (P—O) at pH 7 and α = 1% and β = 99% at pH 13 were obtained. **α = 100% was obtained for the 1:1 1,2-dimethoxyethane–H_2O system. ***Reaction does not occur. ****α = 10% and β = 90% (P—O) were obtained for the following conditions: $(CH_3)_2CHCH_2OH$, fast; $(C_2H_5)CHOH$, 5 min; $[(CH_3)_2CH]_2CHOH$, 2 h. *****t_{ki} = 20 min and α = 20% for the system comprising 3 moles of aqueous HCl in acetone.

If readily removed exocyclic substituents, for example aryloxy-substituents, are linked to the phosphorus atom, then the ring is retained and the rate of hydrolysis is described satisfactorily by the Hammett equation when the substituent in the leaving group is varied[44].



In the presence of unlike heteroatoms in the 1,3,2-diheterophospholan ring, nucleophilic substitution results in the preferential rupture of the bond between the phosphorus atom and the more apicophilic heteroatom or group. Alkaline hydrolysis of the cyclic phosphoramidate (XIX) and of the phosphonate (XXI) leads exclusively to the rupture of the endocyclic P—O bond, because the oxygen atom is more apicophilic than the NC_6H_5 group[34,43]. However, according to other data[45–47], the relative apicophilicities of the atoms can change following their incorporation in the heterocycle. The exclusive P—N rupture on alcoholysis of oxazaphospholans (XXIII)–(XXVIII) is attributed to the greater apicophilicity of the endocyclic nitrogen atom and the oxygen atom[45–47,51].

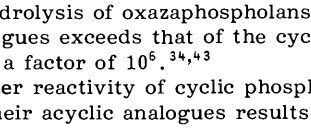
Thus the characteristic feature of cyclic aminoesters of phosphorus acids is the ease of the cleavage of the phosphamide linkages under the conditions of alkaline hydrolysis and alcoholysis. The alkaline hydrolysis of the phosphoramidates (XVII) and (XVIII) proceeds to the extent of 40 and 30% respectively with substitution of the amino-groups[34]. The base-catalysed hydrolysis of the phosphoramidate (XXII) [43] and the alcoholysis of the cyclic phosphorus derivatives (XXII)–(XXVI) based on (-)-ephedrine proceed wholly with dissociation of the P—N bond[45–48]. The rupture of the amide rather than the less stable thioester linkage has been observed in the hydrolysis[49] and alcoholysis[50] of the thiazaphospholans (XXVII) and (XXVIII), but the hydrolysis of compound (XI) in a neutral medium proceeds mainly with rupture of the P—S bond[26], while the exocyclic substitution of the phenoxy-group competes with the cleavage of the labile P—N bond in the oxathiaphospholan (X).

On the other hand, the acyclic amidoesters of phorphorus acids hydrolyse in alkaline solutions exclusively with liberation of the alcohol[34,44,51]. It has been suggested[52] that this difference is associated with the change in the nature of the P—N bond when it is incorporated in a rigid five-membered ring. The amino-group in acyclic phosphoramidates can "choose" the conformation in which there is maximum overlap of the orbital of the unshared electron pair of the nitrogen atom with the d orbitals of phorphorus, which strengthens the phosphamide linkage and lowers the electrophilicity of the phosphorus and the basicity of the nitrogen. When the P—N bond incorporated in a five-membered ring and the overlap weakens and hence the basicity of the nitrogen, the electrophilicity of the phosphorus, and the lability of the phosphamide linkage increase.

However, the interaction of alkyl(aryl)phosphonamidate, phosphinoselenoate, and phosphonamidothioate derivatives (XXIII), (XXIV), (XXVI), and (XXVII) of (-)-ephedrine

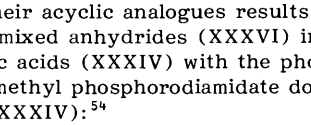
and (+)-pseudoephedrine with organolithium and organomagnesium compounds takes place with dissociation of the P–O and P–N bonds, the ratios of the reaction products depending both on the nature of the nucleophile and on the steric structure of the ring[7,51–53]. The difference from the reactions with oxygen-centred nucleophiles is associated with different barriers to the transformations of the intermediates (XXXII) and (XXXIII):

(XXXII) (XXXIII)



R=CH_3, C_6H_5; Y=O, S; X=OR, R, C_6H_5.

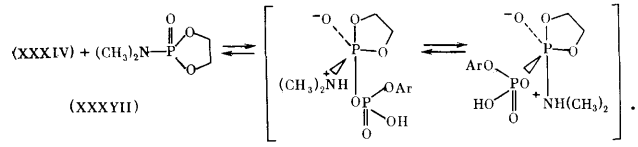
When X = OR, the pseudorotation (XXXII) ⇌ (XXXIII) is hindered, because the apicophilicity of the alkoxy-substituents is somewhat greater than that of the methyl or phenyl group; in such phosphoranes the α-elimination of the amino-group takes place. The apicophilicities of the group X (X = alkyl or aryl) and the equatorial substituents R are similar and pseudorotation and the subsequent heterolysis of the P–O bond compete with the endocyclic dissociation of the P–N bond. Furthermore, in many instances the nucleophile X can attack approximately equally readily the P–O and P–N groups from the rear. The interconversion energy of the intermediates is influenced by the nature and steric disposition of the ring substituents. In other words, there is a fine balance of all the factors which determine the nature of the rupture and the stereochemistry of the reaction involving substitution by organometallic nucleophiles[53].



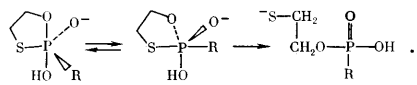
Acid hydrolysis of phosphoramidates takes place with substitution of the amino-group, because the nitrogen atom, being the most basic centre, is the first to be protonated, while the ammonium substituent is very readily eliminated. The insignificant contribution (5%) of the P–N dissociation in the hydrolysis of the phosphoramidate (XX) has been explained by general acid catalysis[44]. However, the exclusive P–N dissociation in the *N*-phenylphosphonate (XXII), where the nitrogen is less basic than in the *N*-methyl derivative (XXI), conflicts with this hypothesis. In order to account for this contradiction, a square-pyramidal structure of the intermediate has been proposed[43]. The full amides (XII) and (XIII) are not hydrolysed in a neutral medium.

The rate of hydrolysis of oxazaphospholans as well as their dioxa-analogues exceeds that of the cyclic phosphoramidates by a factor of 10^6.[34,43]

The much higher reactivity of cyclic phosphoramidates compared with their acyclic analogues results in the ready formation of the mixed anhydrides (XXXVI) in the reactions of arylphosphoric acids (XXXIV) with the phosphoramidate (XXXVI), while methyl phosphorodiamidate does not react with compound (XXXIV):[54]



(XXXIV) (XXXV)



(XXXVI)

It is of interest that ethylene *N,N*-dimethylphosphoramidate (XXXVII) is also inert in this reaction; this is apparently associated with the unfavourable energetic features of the intermediate (XXXVIII) (in which the ammonium group characteristically assumes an equatorial position) or its rotational isomer (XXXIX) (where the electronegative hydroxyphosphoryl group is equatorial):

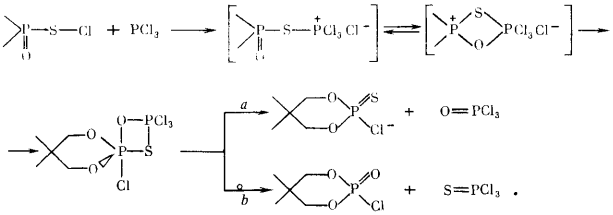
(XXXVII) (XXXVIII) (XXXIX)

A difference between the types of endocyclic dissociations has also been established in the series of oxathiaphospholans (XXIX)–(XXXI).[55–57] The alkaline hydrolysis of ethylene methyl phosphorothiolate (XXXI) involves, like that of the acyclic thiolo-esters of phosphorus acids[56], the substitution of the thioester group with formation of compound (XLII), while the hydrolysis products of the phosphorothioate anion (XXIX) and of the phosphonothioate (XXX) are the β-hydroxyethyl thiolo-esters of the corresponding acids. This can be explained by the different capacities of the intermediates (XL) for pseudorotation in the presence of different substituents R:

(XL) (XL1) (XLII)

A necessary condition for the P–S dissociation is the transformation of the bipyramid (XL) into (XLI), which is allowed only for R = OCH_3. Such pseudorotation is difficult for R = O [compound (XXIX)] and C_6H_5 [compound (XXX)] (the less apicophilic groups should migrate to the α-position) and it cannot compete with the endocyclic dissociation of the P–O α-bond.

2. 1,3,2-Diheterophosphorinanes



Nucleophilic substitution at the tetrahedral phosphorus atom incorporated in a six-membered 1,3,2-diheterophosphorinane ring does not involve a striking difference between the rates of reaction of cyclic and acyclic phosphorus acid esters of the kind observed in the series of 1,3,2-diheterophospholans. In contrast to the five-membered phosphorus-containing heterocycles, the six-membered heterocycles are more stable and in the presence at the phosphorus atom of a readily eliminated exocyclic group the substitution takes place with retention of the ring. The rate of exocyclic hydrolysis is very close to that of the analogous reactions of acyclic phosphates[7,10,58,59]. This is most probably associated with the absence of angular strain in the six-membered rings and with the similarity between the structure of the trigonal-bipyramidal intermediate, formed as a result of the addition of the nucleophile to the phosphorus atom, and the structure of the transition state in $S_N2(P)$ reactions (at any rate, in exocyclic nucleophilic substitution occurring with inversion of the configuration at the phosphorus atom[60]).

The formation of such intermediates presupposes that the six-membered ring is in the diequatorial position, which is energetically more favourable[11,12] than the *a–e* positions.

However, the arrangement in the phosphorane bipyramid of the six-membered rings in which a heteroatom is linked to the phosphorus atom is determined by the effect of the orientation of the unshared electron pairs of the heteroatom. The structure with the *a*–*e*-ring in the boat conformation has the lowest energy[7,60,61,62]. This conclusion agrees with the results of the X-ray diffraction analysis of the phosphorane containing the oxazaphosphorinane ring[61].

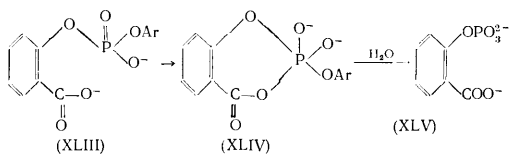
It has also been suggested that structures with the *e*–*e* and *a*–*e* disposition of the diheterophosphorinane ring have comparable energies[63,64]. On the other hand, the authors of recent investigations into the stereochemistry of nucleophilic substitution reactions of organophosphorus carbohydrate derivatives[65] question this claim on the grounds that the *a*–*e* disposition of the dioxaphosphorinane rings is thermodynamically preferred. This last factor is believed to be responsible[7,65] for the appreciably higher (by a factor ≥10) rate of ring opening in six-membered cyclic phosphates than was believed previously[10,58].

The *e*–*e* disposition of the six-membered ring is apparently the only one possible in the intermediate compounds in the reactions of cyclic phosphorylsulphenyl chlorides with phosphorus trichloride[66]. The reaction proceeds via the successive formation of quasi-phosphonium intermediates. The dicyclic phosphorane formed subsequently can decompose with abstraction of an oxygen atom from the four-membered ring or after the pseudorotation of the sulphur atom:

It is striking that acyclic phosphonosulphenyl chlorides undergo only deoxidation on treatment with phosphorus trichloride (pathway *a*). The lifetime of the phosphorane intermediate formed from the acyclic substrate is probably insufficiently long for the pseudorotation necessary for the occurrence of desulphurisation (pathway *b*).

It has been shown in a number of instances that, of the two enantiomeric 1,3,2-diheterophosphorinanes, the stereoisomer with the *a*-disposition of the P=X groups hydrolyses at a higher rate[20,60,67,68]. Thus 2-aryloxy-2-oxo-*trans*-5,6-tetramethylene-1,3,2-dioxaphosphorinanes with the P=O *e*-group hydrolyse 4–17 times more slowly than their epimers[60]. The difference between the energies of the ground states of the phosphorus-containing cyclic structures is responsible for this difference in behaviour: the P=O group occupies preferentially the *e*-position and the energy of isomers with this structure is lower by 6–8 kJ mol^{-1}. The difference between the energies of the transition states in these systems is very small (~0.8 kJ mol^{-1}). A similar difference between the reactivities of the stereoisomers has been observed in the hydrolysis of uridine 3,5-phosphates, where the difference between the energies of the ground states is ~3 kJ mol^{-1}.[69]

Endocyclic rupture occurs in 2-alkyl(aryl)-1,3,2-diheterophosphorinanes, in which the substitution of the exocyclic groups is impossible[7]. In those cases where a group difficult to eliminate is linked to the phosphorus atom, exocyclic cleavage competes with the ring opening[70,71]. In the series of *p*-substituted 5-chloromethyl-5-methyl-2-oxo-(phenoxy)-1,3,2-dioxaphosphorinanes the influence of the *p*-substituents on the reaction rate is not very significant, which is reflected in the constant $\rho = 0.95$ in the Hammett equation[7].

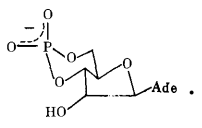


It has been suggested that the trigonal-bipyramidal intermediates formed initially in reactions with retention of the configuration at the phosphorus atom undergo pseudorotation[60,71,72]. An alternative explanation involves the formation of square-pyramidal intermediate structures[69,70].

As in the series of five-membered cyclic phosphates, the nature of the endocyclic dissociation of the phosphorus–heteroatom bonds in 1,3,2-diheterophosphorinanes depends on the nature of the heteroatoms in the ring and the substituents at the ring carbon atoms. The acid-catalysed hydrolysis of 1,3,2-oxazaphosphorinanes proceeds with dissociation of the P–N bond[7,73–75], while in reactions involving alkaline hydrolysis the stability of the P–N bond is intermediate between that of the stable acyclic amidoesters of phosphorus acids and that of the labile 1,3,2-oxazaphospholans[7,76,77].

The relative ease of the P–O and P–S dissociations in 1,3,2-oxathiaphosphorinane derivatives depends on the nature of the exocyclic substituents. Thus 2-ethoxy-2-oxo-1,3,2-oxathiaphosphorinanes undergo P–S cleavage in the CH_3ONa–CH_3OH system, while in the analogous methyl phosphonates the P–O bond is ruptured[7,70]. This result indicates an appreciable difference between the cyclic and acyclic phosphorus thiolo-compounds. As already stated, the acyclic thiolo-esters of phosphorus acids hydrolyse in the first place at the thioester linkage in all cases.

The influence of the substituents at the ring carbon atoms on the rate of nucleophilic substitution at a phosphorus atom incorporated in a six-membered ring has been studied in only a few instances[78–82]. The ester linkage with a secondary carbon atom is more labile in 1,3,2-dioxaphosphorinanes than the similar bond with a tertiary carbon atom[70]. The ease of ring opening in carbohydrate derivatives depends on the nature of the initial glucoside. In *trans*-joined 1,3,2-dioxaphosphorinanes derived from glucose the ring opening under the influence of Grignard reagents takes place under mild conditions; the *cis*-joined phosphate esters of galactose are fairly inert and react only after refluxing in benzene for 96 h.[78]



The acceleration of the reaction by a factor of 10^7–10^8 in the hydrolysis of aryl 2-carboxyphenyl phosphates (XLIII) in the region of pH 5, in which the *o*-carboxy group is ionised, has been explained by the intermediate formation of the phosphorane (XLIV), whose decomposition is responsible for the large effect in the formation of the monoaryl phosphate (XLV):[79]

(XLIII) (XLIV) (XLV)

The combined thermochemical, quantum-chemical, and stereochemical study[80–82] makes it possible to explain why the enthalpy of hydrolysis of six-membered cyclic adenosine 3′,5′-monophosphates (XLVI) is higher by ~33 kJ mol^{-1}

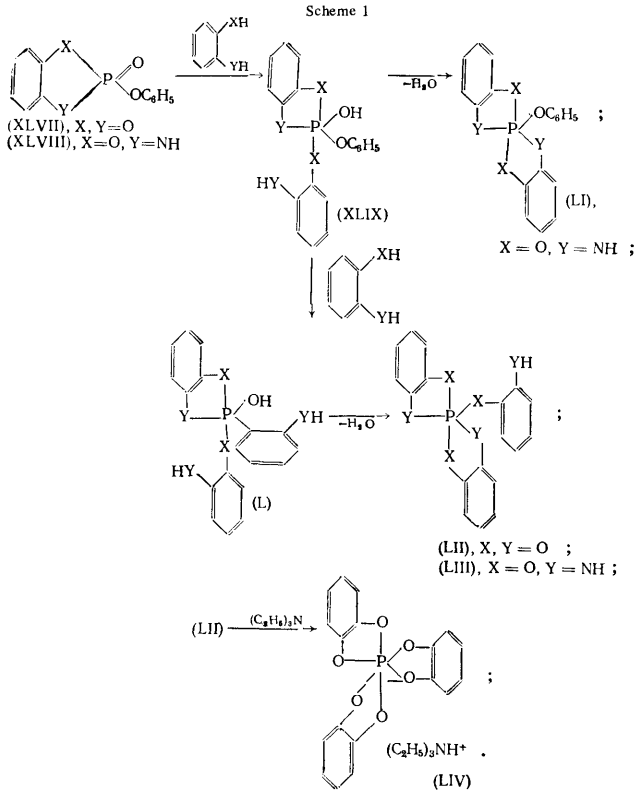
compared with trimethylene phosphate:

(XLVI)

It was established that ~21 kJ mol^{-1} corresponds to the strain induced by the ribofuranoside component of the molecule, *trans*-condensed relative to the phosphorus-containing ring. A definite proportion of the enthalpy difference (4.0–8.5 kJ mol^{-1}) is associated with the enforced fixation of the 5-alkoxy-substituent in the unfavourable *e*-position, which destabilises the system. Finally, 4–8 kJ mol^{-1} is due to the difference between the solvation energies of the reactants and products.

It has been shown that the enthalpies of hydrolysis of diethyl phosphate (~10.5 kJ mol^{-1}) and trimethylene phosphate (~16 kJ mol^{-1}) do not differ significantly[80].

The enthalpy of hydrolysis of cyclic phosphates can serve as a measure of the stability of the molecule in the synthesis of cyclic phosphates, for example, from the corresponding phosphorus acid dichlorides and diols[83]. The threshold of the enthalpy of hydrolysis above which cyclic phosphates lose their stability under the usual conditions (polymers and decomposition products are formed instead of the expected cyclic esters) is ~25 kJ mol^{-1}.



3. Nucleophilic Reactions with Increase of the Coordination Number of Phosphorus Atoms

A serious argument in support of the hydroxyphosphorinane concept was the detection of hydroxyphosphoranes formed in the course of the intramolecular and intermolecular nucleophilic substitution at a tetrahedral phosphorus atom. Direct evidence for the formation of hydroxyphosphorinane was obtained for the first time in a study of the interaction of phenyl phosphorodichloridate with catechol and *o*-aminophenol in the presence of triethylamine[84].

It was found that in the first case a salt of hexacoordinate phosphorus (LIV) is formed instead of the expected phenyl phenylene phosphate (XLVII). *o*-Aminophenol gives rise to small amounts of compounds (LI) and (LIII) with a phosphorane structure together with compound (LIV). The reaction of compound (XLVII) with catechol and *o*-aminophenol leads to analogous products. The formation of organophosphorus compounds with an increased coordination number is possible only as a result of the intermediate formation of the hydroxyphosphoranes (XLIX) and (L) via Scheme 1.

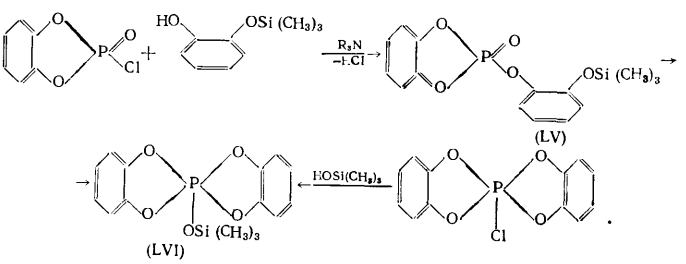
It was established subsequently that the formation of the phosphorane (LIV) is extremely characteristic of the reactions of catechol with 2-halogenobenzo-1,3,2-oxaphospholans containing an atom of tricoordinate, tetracoordinate, or pentacoordinate phosphorus in the ring[85,86].

Scheme 1

(XLVII), X, Y=O
(XLVIII), X=O, Y=NH

(XLIX)

(LI), X = O, Y = NH ;



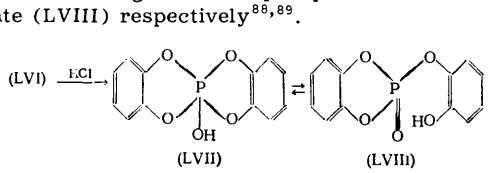
(L)

(LII), X, Y = O ;
(LIII), X = O, Y = NH ;

(LII) $\xrightarrow{(C_2H_5)_3N}$

(LIV)

The reaction of phenylene phosphorochloridate with *o*-trimethylsiloxyphenol[87] in the presence of triethylamine leads to the phosphate (LV), which fully isomerises in aprotic solvents to spirotrimethylsiloxydiphenylenephosphorane (LVI); the latter can be obtained by specific synthesis from spirochlorodiphenylenephosphorane and trimethylsilanol:



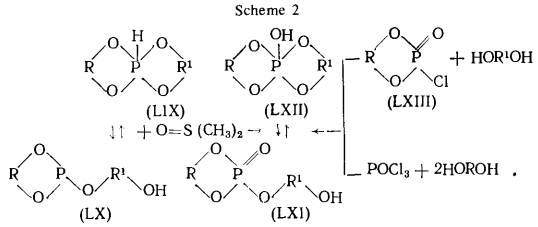
(LV)

(LVI)

The possibility of such silyl transfer apparently arises from the greater stability of the $(RO)_4P-O-SiR'_3$ system compared with $Ar-O-SiR'_3$.[87]

When silylphosphorane (LVI) reacts with anhydrous hydrogen chloride, a crystalline substance is formed, exhibiting features of a dynamic equilibrium in aprotic solvents: two signals in ^{31}P NMR spectra at −27 and +7 p.p.m. were assigned to the phosphorane (LVII) and the phosphate (LVIII) respectively[88,89].

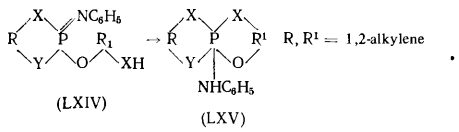
(LVI)



(LVII) (LVIII)

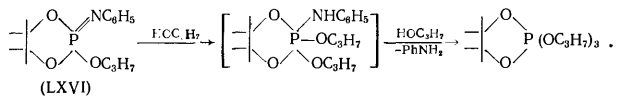
In the crystalline state this substance consists of the phosphate (LVIII). In acetonitrile at 225 K, the ratio of the quinquevalent and quadrivalent phosphorus forms $P^{V}:P^{IV}$ = 1.5:1, while in acetone it is 3:1.

The reaction of compound (LVIII) with diazomethane leads exclusively to methoxyspirodiphenylenephosphorane. Acylation yields 80% of 2-acetoxyphenyl phenylene phosphate and 20% of acetoxyspirodiphenylenephosphorane.

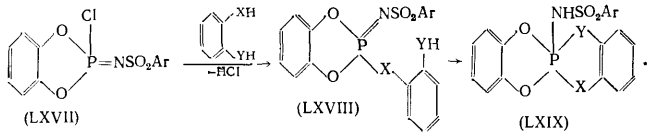


The phosphate–phosphorane tautomerism has been observed in the products of the oxidation of the prototropic system (LIX) ⇌ (LX) with dimethyl sulphoxide and also in the cyclic phosphates formed when alkylene phosphorochloridates (LXIII) or phosphoryl chloride react with diols[90–93] via Scheme 2:

Scheme 2

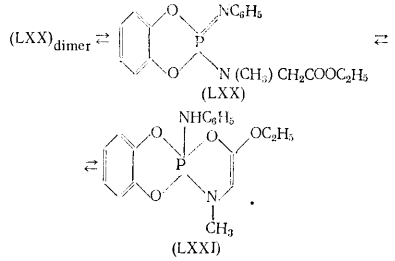


An increase in the number of substituents in five-membered rings and an increase of their electron-accepting capacity stabilise the phosphorus(V) form[93]. The equilibrium (LXI) ⇌ (LXII) shifts towards the hydroxyphosphorane with increase of the basicity of the medium[91].

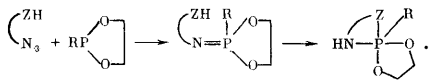


The intramolecular proton transfer from the functional group in the γ-position to the heteroatom in the P=X bond has been demonstrated in five-membered cyclic phosphorimidates[94,95]:

Although the phosphorimidate (LXIV), formed in the reaction of phosphites of type (LX) with phenyl azide, could not be identified, its transformation into compound (LXV) is modelled by the addition of an alcohol to the imide linkage of the phosphorimidate (LXVI):

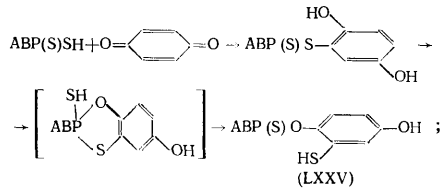


The interaction of 2-acylimino-2-chloro-4,5-benzo-1,3,2-dioxaphospholan (LXVII) with catechol, *o*-phenylenediamine, and *o*-aminophenol proceeds via a stage involving the formation of the phosphorimidate (LXVIII) with the subsequent intramolecular prototropic isomerisation to the spirophosphorane (LXIX):[96,97]

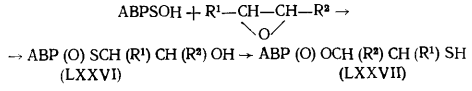


It was shown that the reactivity of the phosphorimidochloridate (LXVII) is higher than that of acyclic dialkoxychlorophosphazo-compounds[98].

An interesting case of reversible prototropic isomerisation was observed in the thermolysis of phosphoramidimidate (LXX), which is dimerised under the usual conditions (see below). When the dimer of the phospholan (LXX) is heated, it is converted into the monomeric form and then isomerises to the aminospirophosphorane (LXXI) with intramolecular proton transfer to the phosphorimide nitrogen atom[99]:



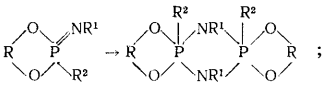
An analogous intramolecular prototropic process has been used to synthesise stable cyclic spirophosphoranes by the reaction of phosphites with bifunctional azides[100]:



The driving force of the intramolecular nucleophilic attack by the nucleophilic functional group in the γ-position on the phosphorus atom is spirocyclisation, leading to stable spirophosphoranes[14,89,94,101]. Acyclic organophosphorus compounds with a 2-hydroxy(amino, mercapto)ester group do not form hydroxyphosphoranes which would be sufficiently stable for identification[101]. This reflects the well-known sequence based on the decrease of the stability of phosphoranes; spirocyclic > monocyclic > acyclic.[102]

The isomerisation of *S*-(2-hydroxyalkyl) esters of phosphorus thioacids probably also proceeds via the hydroxy(mercapto)phosphorane stage. At any rate, the much greater ease of the isomerisation of the esters of cyclic ω-hydroxy(mercapto)phosphates compared with the acyclic compounds can be associated with the more favourable energetic features of the bicyclic intermediates[103–105]. Thus the product of the addition of alkylene phosphorodithioic acids to *p*-quinone isomerises to the corresponding phosphoromonothioate (LXXV) so rapidly that under the usual conditions the adducts (LXXIII) and (LXXIV) cannot be isolated, while *O,O*-dialkyl *S*-(2,5-dihydroxyphenyl) phosphorodithioates (LXXII) isomerise only at an elevated temperature[103]:

(LXXII)), A=B=Alko (LXXIII), AB=OC $(CH_3)_2C(CH_3)_2O$ (LXXIV), AB=$OCH_2C(CH_3)_2CH_2O$.

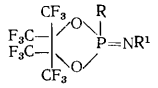


The stability of the products of the addition of phosphorus monothioacids to oxirans depends greatly on the nature of the substituents at the phosphorus atoms: whereas the acyclic *S*-(2-hydroxyalkyl) phosphorothioates (LXXVI) are fairly stable at room temperature, in the case of five-membered 2-hydroxyalkyl derivatives only the isomerisation products were detected—2-(2′-mercaptoalkyl)-2-oxo-1,3,2-dioxaphospholans (LXXVII). 2-Hydroxyalkyl phosphorothioates of the 1,3,2-dioxaphosphorinane series (LXXVI) can be detected by ^{31}P NMR.[104]

where AB = 1,2-dihydroxyalkylene. Evidently, the intermediate hydroxyphosphoranes with two five-membered rings have a lower energy than the intermediates with five- and six-membered rings, which are in turn more stable than the monocyclic phosphoranes.

It is striking that *S*-(3-hydroxyalkyl) phosphorothioates—the products of the addition of five-membered cyclic phosphoromonothioic acid to oxetans—are readily converted in ethereal solution into 3-mercaptoalkyl phosphates[105]. Derivatives of acyclic and six- and seven-membered cyclic acids do not isomerise under these conditions.

An increase of the coordination number of the phosphorus atom has been observed in the dimerisation of 2-imino-2-R-1,3,2-diheterophospholans and their 4,5-benzo-analogues[97,106] to 1,3-diaza-2,4-diphosphetidines:



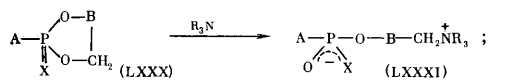
R = CH_2CH_2, *ortho*-C_6H_4 .

This process probably proceeds via a [2+2]-cycloaddition mechanism, but the dimerisation of the cyclic five-membered phosphorimidates obeys all the rules governing the nucleophilic substitution at the phosphorus atom. The presence of acyl groups at the nitrogen atom determines the stability of the monomeric form. If there is an aryl substituent at the nitrogen atom, then the capacity for dimerisation is determined by the nature of the substituents R^2: the dimethyl-amino-group attached to the phosphorus atom stabilises the monomer; weak electron-donating or electron-accepting groups at the phosphorus atom promote dimerisation. Acyclic phosphazo-compounds with the same environment around the phosphorus atom are monomeric[97].

A similar behaviour has been observed also in the series of 2-imino-4,5-benzo-1,3,2-dioxaphospholans[107,108]: regardless of the nature of the substituents at the phosphorus atom, the *N*-acyl derivatives are monomeric, while the *N*-aryl derivatives are dimeric. 2-Diethylamino-2-*N*-phenylimino-4,5-benzo-1,3,2-dioxaphospholan, which is involved in a monomer–dimer equilibrium in solutions, is an exception.

Evidently, the relative ease of the dimerisation of the five-membered cyclic phosphazo-compounds is ensured by the ring strain, which diminishes when the ring passes to the *a–e* position in the dimeric 1,3-diaza-2,4-diphosphetidine[106]. The greater tendency towards dimerisation by 4,5-benzo-derivatives can be accounted for by the greater strain in the condensed ring.

On the other hand, in the series of iminophospholan derivatives of perfluoropinacone (LXXVIII) the competing influence of the five-membered ring in the substituent at the phosphorus atom is manifested. Despite the presence of a bulky substituent in the imine fragment, which hinders dimerisation, compounds (LXXVIII) exist in the form of dimers, while the iminophospholan (LXXIX) is monomeric[109,110]:



(LXXVIII), R=F; R^1 = t-C_4H_9, $Si(CH_3)_3$;
(LXXIX), R=N [$Si(CH_3)_3]_2$; R^1=$Si(CH_3)_3$.

The imino-derivatives of the 1,3,2-oxazaphospholan[97] and 1,3,2-dioxaphosphorinane[111] types are monomeric. In the latter case this is probably associated with the absence of ring strain in the six-membered ring.

III. NUCLEOPHILIC SUBSTITUTION AT A CARBON ATOM

Apart from the tetracoordinate phosphorus atom or together with the latter, a ring carbon atom or a carbon atom in an exocyclic ester group can serve as a centre of nucleophilic attack. The site of nucleophilic substitution is determined by the nature of the nucleophile and of the substituents at the ring carbon atoms and the carbon atoms of the exocyclic group.

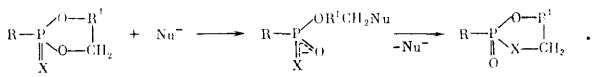
The interaction of tertiary amines with 2-oxo-2-thiono-, and 2-selenono-1,3,2-dioxaphospholans and the corresponding phosphorinanes (LXXX) leads mainly to the formation of the inner salts (LXXXI):[112]

(LXXX) (LXXXI)

X=O, S, Se; A=R, RO, Ar, ArO, R_2N; B=CH_2, $(CH_2)_2$, *ortho*-C_6H_4 .

The rate of reaction is greatly influenced by the electronic properties of the exocyclic substituents. Under the usual conditions, the reaction terminates after several days for A = C_6H_5O and *p*-$NO_2C_6H_4O$ and after several months for A = R_2N.[113]

The ease of formation of the inner salts depends on the degree of ring substitution and the nature of the amine. In the series of 2-oxo-2-phenoxy-1,3,2-dioxaphospholans[114] salts of type (LXXXI) are formed only in the case of unsubstituted rings. Monomethylphospholan does not form inner salts in the reactions with methylamine and dimethylamine; attack is mainly directed to the phosphorus atom. Nucleophilic substitution at a ring carbon atom is even less marked for rings with a large number of methyl groups. In these reactions with amines one can postulate an S_N2 mechanism, which leads to ring opening and the formation of aminoalcohol derivatives (LXXXI): the reaction with the strong bases $(CH_3)_2NH$ and $(C_2H_5)_2NH$ is faster, whereas that with bases of moderate strength, namely pyridine and aniline, is slower. This mechanism apparently operates also in the reactions of unsubstituted rings. However, the fact that in the reaction of monomethylphospholan the nitrogen atom is linked to the methylated carbon atom suggests that the S_N1 mechanism is preferred[114].

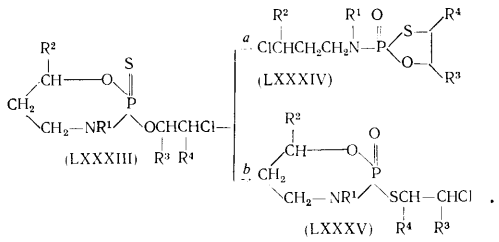


Exocyclic dealkylation by amines has been observed in 1,3,2-dioxaphospholan with alkoxy-substituents at the phosphorus atom[112,113]. Contrary to expectation, cyclic ammonium phosphates are formed also in the interaction of tertiary amines and pyridine with 4,5-dimethyl-2-oxo-2-phenoxy-1,3,2-dioxaphospholans and in the reaction of all the amines investigated with the phenyl ester of pinacone phosphate[114]. It has been suggested that in this case the amine attacks the phosphorus atom and the formation of phenylammonium cyclic phosphate is a result of a secondary disproportionation process arising in the first, phosphorane stage. Exocyclic dearylation also occurs when 5-chloromethyl-5-methyl-2-*p*-nitrophenoxy-2-oxo-1,3,2-dioxaphosphorinane reacts with sodium *p*-nitrophenoxide[115].

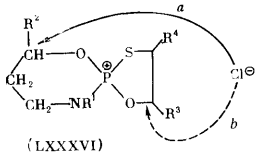
Thus an unsubstituted five-membered phosphate is attacked by amines at an endocyclic carbon atom. When the ring contains at least one methyl substituent, the reaction centre becomes either the carbon atom linked to the substituent or the phosphorus atom. A highly basic group attacks only the phosphorus atom; when the basicity is lower, there is competition between two electrophilic centres; interaction via the phosphorus atom can lead either to ring opening (in the case of strong bases) or to intramolecular disproportionation to ammonium phosphate[114]. The opening

of the phospholan ring under the influence of amines made it possible to develop a convenient method of synthesis of phosphorylcholines[116,117].

The endocyclic carbon atoms can undergo nucleophilic attack also by other nucleophiles, for example, by cyanide ions, with formation of 2-cyanoalkyl esters of phosphorus acid[118]. The substitution of the cyclic glycerol phosphates by phosphate anions has been used to synthesise glycerol phospholipids[119].



Nucleophilic substitution at a carbon atom in 2-selenono- and 2-thiono-2-R-1,3,2-dioxaphospholans and the corresponding phosphorinanes leads to selenone–selenol and thione–thiol isomerisation. The reaction proceeds via a stage involving the formation of the acyclic anions (LXXXII):

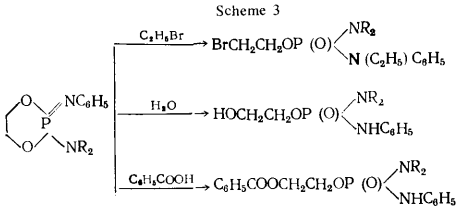


(LXXXII)

The isomerisation can take place under the influence of tertiary amines[113], tertiary phosphines[113,120], and iodide[121] and bromide[50] anions.

An interesting case of thermal thione–thiol isomerisation has been observed in the series of oxazaphosphorinanes with an exocyclic 2-chloroalkoxy-group (LXXXIII):

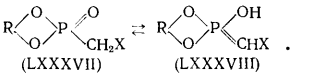
The reaction proceeds via two pathways (*a* and *b*) and leads to the products (LXXXIV) and (LXXXV), probably via the common intermediate (LXXXVI), which arises as a result of the intramolecular alkylation of the thiophosphoryl group:



(LXXXVI)

In those cases where $R^2 = CH_3$ and $R^3 = R^4 = H$, the attack by the chloride anion proceeds via pathway *b* and the isomer with the oxazaphosphorinane structure (LXXXV) predominates in the mixture of products. On the other hand, the introduction of the methyl substituent into the chloroethyl group favours pathway *a*, which leads to the opening of the six-membered ring and to an increase of the content of the oxathiaphospholan (LXXXIV).[122]

Nucleophilic substitution at a ring carbon atom in 2-alkylamino-2-phenylimino-1,3,2-dioxaphospholans is accompanied by the imide–amide rearrangement[97,106] in accordance with Scheme 3:

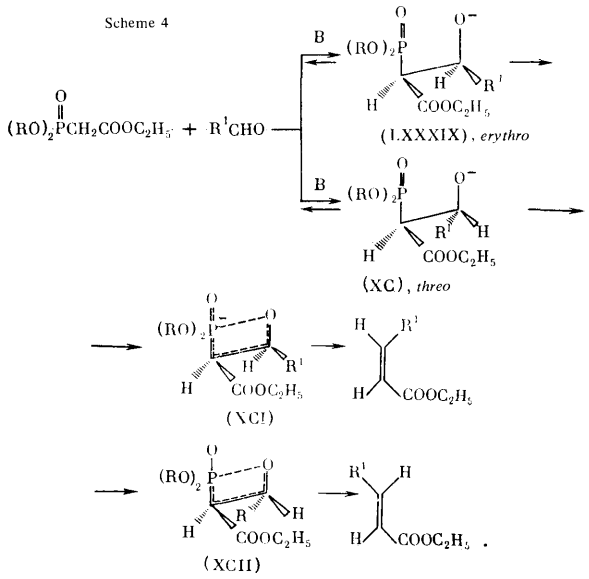


Scheme 3

Cyclic phosphorimidates are then more reactive than the acyclic derivative[97].

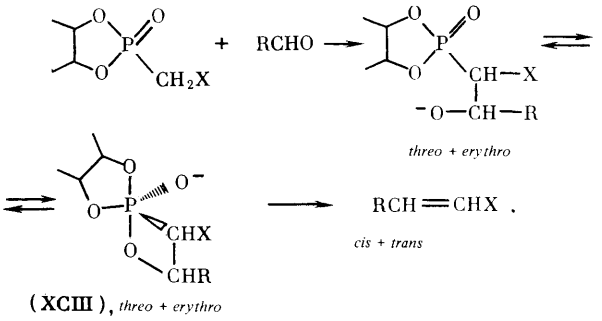
IV. COMPOUNDS WITH AN ACTIVE METHYLENE GROUP

Although the reactiviity of cyclic phosphonates with an active methylene group has been little studied[123], the available data indicate their unusual properties which are manifested both in their structures and in the characteristics of their reactions. Infrared spectroscopic and NMR studies on the phosphonates (LXXXVII) with $R = CH(CH_3)CH(CH_3)$ and $X = CN$ or $COOC_2H_5$ led to the discovery of the phosphonate–ylide tautomerism in the series of five-membered cyclic derivatives[124]:



(LXXXVII) (LXXXVIII)

The ylide structure (LXXXVIII) was detected from the characteristic absorption of the OH group in the infrared region (3420–3460 cm^{-1}); the isomer ratio is 4 : 1 in favour of compound (LXXXVII) according to ^1H NMR data[124]. These compounds are titrated like strong monobasic acids and vigorously interact with diazoalkanes. The presence of the ylide formed is associated with the pronounced electron-accepting effect of the dioxaphospholan fragment (see Section V). The acyclic and six-membered cyclic esters and nitriles of phosphonoacetic acid are not converted into ylides and do not exhibit acid properties[124].

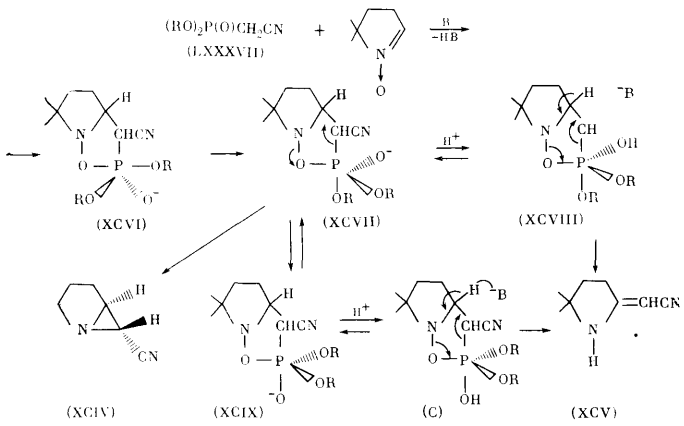


The incorporation of a phosphorus atom in the five- or six-membered rings of compounds (LXXXVII) alters appreciably the stereospecificity of the phosphonate modification of the Wittig reaction[125,126]. The reactions of acyclic organophosphorus compounds having an active methylene group with carbonyl compounds proceed preferentially with formation of *trans*-olefins[125–128]. This is attributed to the thermodynamic control of the reversible formation and interconversion of the *erythro*- and *threo*-betaines (LXXXIX) and (XC) and their decomposition to olefins.

In acyclic systems the stability of the intermediate monocyclic phosphoranes of type (XCI) and (XCII, R = alkyl) is apparently insufficient to prevent the epimerisation of the phosphonates (LXXXIX) and (XC) preceding them (Scheme 4):[126,127]

Scheme 4

The alkoxides (LXXXIX) and (XC) obtained from five-membered cyclic phosphonates (LXXXVII), rapidly form the more stable spirophosphoranes (XCIII), which should prevent the interconversion of the *erythro*- and *threo*-intermediates and hence should favour the formation of appreciable amounts of *cis*-olefins (the ratio of *cis*- and *trans*-olefins in reactions of five-membered cyclic phosphonates is close to 60:40 [126]). The study of ^{31}P NMR spectra of the reaction mixture of compound (LXXXVII), where R = $CH(CH_3)CH(CH_3)$ and X = $COOC_2H_5$, with benzophenone and aryl cyclopropyl ketones made it possible to demonstrate the formation of a spirophosphetan of type (XCIII):[129]



(XCIII), *threo + erythro*

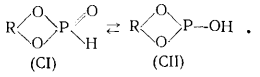
Phosphonates of the dioxaphosphorinane series also produce considerable amounts of *cis*-olefins in these reactions[128], but their content is appreciably lower, which may be attributed to the lower stability of the intermediate phosphoranes with a six-membered ring than that of the compounds with a five-membered ring (the effect of the five-membered ring).

The size of the phosphorus-containing ring in phosphonates with an active methylene group influences also the reactions with nitrones. The interaction of acyclic phosphonates with nitrones in aprotic solvents leads to the preferential or exclusive formation of the aziridines (XCIV), while in protic solvents this reaction proceeds to the enamines (XCV) whose content increases with the acidity of the medium[130–132]. These results have been interpreted on the hypothesis that the intermediate (XCVI) participates in the process. The formation of the reaction product requires the transfer of a carbon atom in compound (XCVII) to the *a*-position via permutation isomerisation; the decomposition of compound (XCVIII) leads to the formation of an aziridine. Protonation neutralises compound (XCVII) and 1,2-elimination from compound (XCVIII) gives rise to the enamine (XCV).

The reaction of the five-membered phosphonate (LXXXVII), where R,R = $CH(CH_3)CH(CH_3)$, proceeds via the intermediates (XCVII) and (XCVIII), whose stabilisation is improved by virtue of the *a–e* disposition of the two five-membered rings. The decomposition of compound (XCVII) also leads to a single product of the reaction of 2-cyanomethyl-3,4-dimethyl-2-oxo-1,3,2-dioxaphospholan, namely the aziridine (XCIV).[133] In the six-membered 5,5-dimethyl-1,3,2-dioxaphosphorinane derivative (LXXXVII), where R,R = $CH_2C(CH_3)_2CH_2$, the *a–e* position of the six-membered ring in the boat conformation[61,62] gives rise to the unfavourable non-bonding 1,4-interaction of the *gem*-dimethyl groups with the substituent at the phosphorus atom. For this reason, the intermediate (XCIX) with an *e–e* ring in the chair conformation, where the oxide anion occupies the *a*-position, is preferable. It is known that the oxide anion in the *a*-position is a stronger base[13] and is rapidly protonated to compound (C) with subsequent β-elimination of an enamine. Under these conditions, the weaker base (XCVII) remains in the form of an anion (in the reactions of the five-membered phosphonate) and decomposes to aziridine (Scheme 5).

Scheme 5

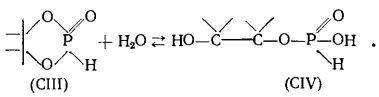
In the reactions of the phosphonate (LXXXVII), where R,R = $CH(CH_3)CH(CH_3)$ and X = CN, the formation of a spirophosphorane, which gives rise to high-field signals (−35 and −36 p.p.m.) in ^{31}P NMR spectra, was demonstrated[134].



V. CYCLIC PHOSPHORUS ACIDS

1. Alkylenephosphorous Acids

The principal data on the methods of synthesis, stereochemical features, and certain reactions of alkylenephosphorous acids are presented in a recently published review[135]. We shall therefore consider below only the result of later studies and those which permit inferences about the chemical consequences of the incorporation of the hydrophosphoryl fragment in a five- or six-membered ring.



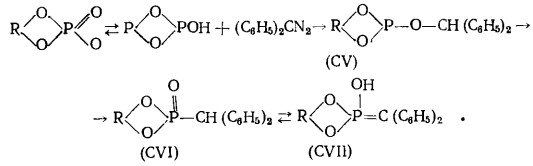
As in cyclic six-membered phosphates, among 1,3-alkylene phosphites, the stereoisomer with the P=O group in the *e*-position is more stable. Whereas in six-membered hydrophosphoryl compounds the conversion of the labile forms into stable forms takes place fairly readily, the analogous 1,3,2-dioxaphospholans do not tend to undergo the conversion readily[135].

The acid-base properties of alkylene phosphites and the influence of dihydroxyalkylene substituents on the diad tautomerism have been investigated:

The study of alkylenephosphorous acids in alcoholic[136] and aqueous alcoholic media[137] demonstrated the anomalously high acidity of the five-membered hydrophosphoryl compounds, which was explained by the presence of considerable amounts of the phosphite form (CII) and by the electron-accepting influence of the 1,2-dihydroxyalkylene groups. However, a detailed study of the acid–base properties of methyl pinacolphosphorous acid in aqueous organic solvents[138–140] made it possible to relate its high acidity to its ready

reversible hydrolysis to the monoalkyl phosphite (CIV), which is responsible for the highly acidic properties of the methyl pinacol phosphite:

(CIII) (CIV)



On the other hand, the reversibility of the hydrolysis of 2,3-butylene phosphite was not observed[139]; unusual ease of recyclisation is specific solely to the methyl pinacol phosphite derivative (the Ingold–Thorpe effect). A considerably smaller acidity has been found for 4,5-dimethyl-2-oxo-2-phenyl-1,3,2-dioxaphospholan[137]. Factors other than the contribution of structure (CIV) (for example, the CH acidity of the ring) probably play a role in this instance. The considerably smaller strength of methyl pinacol phosphorothious acid compared with the oxo-analogue is also striking (the pK_a in 50% ethanol are 4.76 and 2.37 respectively[141]); this difference is difficult to account for from the standpoint of hydrolysis, because the thiono-analogue of the acid (CIV) should be more acid or at least comparable in its acidity.

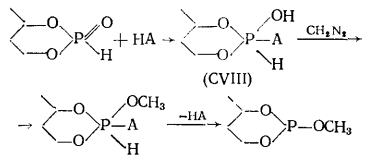
Possibly the protonated forms of compounds (CI) and (CII) contribute to the overall acidity of cyclic hydrophosphoryl compounds[137,141] and their formation is characteristic mainly of five-membered cyclic derivatives. The six-membered and acyclic hydrophosphoryl compounds have similar acid properties[137,139,141].

The contribution of the phosphite form to the equilibrium (CI) ⇌ (CII) involving five-membered alkylene phosphites is apparently less important than for the six-membered and acyclic derivatives[137]. In ethylene phosphoromonothiolite the content of form (CII) is estimated as ~30%;[142] catecholphosphorous acid exists in the condensed phase mainly in the phosphorus (III) form and both isomers are detected only in solutions[137].

The more marked tendency of five-membered alkylene phosphites to isomerise to the phorphorus(III) derivatives has been used to explain the characteristics of the chemical behaviour of these hydrophosphoryl compounds. Thus cyclic phosphorous and phosphorothious acids of the 1,3,2-dioxaphospholan series readily combine with sulphur in the absence of catalysts with formation of alkylenephosphoro-monothious and alkylenephosphorodithious acids[141]. Six-membered phosphorothioites combine with sulphur in the presence of bases[143]; this reaction is not characteristic of acyclic hydrothionophosphoryl compounds[144].

Fundamental differences between the reactivities of acyclic and cyclic hydrophosphoryl compounds have been noted for their reactions with diphenyldiazomethane. Whereas the former react with diazoalkanes only under severe conditions with formation of phosphorus–nitrogen derivatives[145,146], cyclic phosphates interact vigorously with diazo-derivatives, the reaction being accompanied by a rise of temperature and the evolution of nitrogen even in the cold[147]. The reaction proceeds via a stage involving the formation of diphenylmethyl phosphite (CV), which subsequently isomerises to the phosphonate (CVI) in equilibrium with the ylide (CVII):

(CV) (CVI) (CVII)

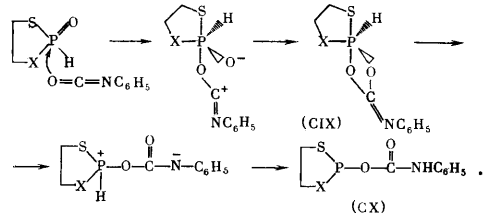


Kinetic studies of the two-stage formation of compound (CV) demonstrated the similarity of the mechanisms of the reactions of cyclic phosphites[148] and acids based on phosphorus in the highest oxidation state[149], which include the initial proton transfer and subsequent decomposition of the resulting ion pair:

$$HA + (C_6H_5)_2CN_2 \xrightarrow{k_1} HN_2C(C_6H_5)_2^+A^- \xrightarrow{k_2} \text{product.}$$

It was established that five-membered alkylene phosphites react faster by a factor of 3–12 than the six-membered derivatives and diphenyl phosphite, in conformity with the strengths of these acids. Measurement of the rate of consumption of the diazo-component and of the accumulation of nitrogen made it possible to compare the rates of the two stages. It was found that the rates of reaction measured by the two methods and the activation parameters are similar for the least reactive neopentyl- and diphenyl-phosphorous acids, i.e. $k_1 > k_2$. For the more acid 2,3-butylene phosphite, the rate of evolution of nitrogen is smaller by an order of magnitude than the rate of consumption of the diazo-compound[148]; in this case the slow stage of the process is the unimolecular decomposition of the ion pair ($k_2 > k_1$).

The intermediate formation of the diphenylmethyl phosphite (CV) has been demonstrated in the reaction of catechol phosphorous acid[147] and the capacity for the subsequent transformation into a phosphonate and an ylide was demonstrated in a study of compound (CV), obtained by the reaction of 2,3-butylene phosphorochloridite with diphenylmethanol.



We may note that the interaction of 1,3-butylene phosphite with diazomethane in protic media has been attributed to the involvement of the phosphorane adduct (CVIII):[150]

(CVIII)

However, this mechanism does not explain the non-catalysed reaction of alkylene-phosphorous acids and phosphorothioites in aprotic media[148].

The addition of five-membered alkylenephosphorous acids to unsaturated systems also proceeds with a decrease of the coordination number of the phosphorus atom. Thus phenyl isocyanate combines with ethylene phosphoromono-thioites and phosphorodithioites with formation of the phosphorus(III) derivatives (CX),[142] probably via a mechanism involving the nucleophilic addition of the acid to the tautomeric form with a tervalent phosphorus atom or the addition of their conjugate alkylene phosphite anions to the C=N bond of phenyl isocyanate. An alternative mechanism presupposes nucleophilic attack by the carbonyl oxygen atom of the unsaturated reactant on the tetrahedral phosphorus atom in the alkylene phosphite[135]. This course of the reaction involves the formation of the intermediate (CIX) with a high energy, which is due to the considerable angular strain in the dioxaphosphetan ring incorporating an sp^2-hybridised carbon atom:

(CIX) (CX)

Adducts with a phosphite structure are formed as a result of the non-catalysed addition of catechol phosphorous acid to styrene, anethole, and butyl vinyl ether[151]. Phosphites isomerise more or less readily to phosphonates. Intermediates with phosphorus(III) could not be detected in the reactions of 2,3-butylene phosphite and phosphorothioite with butyl vinyl ether. It is noteworthy that acyclic phosphorous acids do not undergo heterolytic addition to compounds whose double bond is nucleophilic[152,153].

2. Quinquevalent Phosphorus Acids. The Electronic Influence of Dihydroxyalkylene Substituents

In contrast to the types of organophosphorus compounds examined above in which the reactive centre is mainly the phosphorus atom, the reaction of phosphorus(V) acids  , where R = 1,2- or 1,3-alkylene and X,Y = O or S, are characterised by the involvement of the functional groups in the side chain, while the phosphorus-containing cyclic substituents exert a specific influence on them.

Cyclic phosphonic and phosphinic acids have on the whole acidities comparable to those of the acyclic phosphonates and phosphinates[154-159], although the strain in the five- and four-membered rings[154,155] leads to some enhancement of the acid properties.

However, a number of acids of the 1,3,2-dioxaphospholan and 1,3,2-dioxaphosphorinane series were found to exhibit appreciable differences from the phosphinate derivatives in aqueous alcoholic media in which potentiometric studies were carried out[158].

Comparison of the pK_a of substituted six-membered phosphoric acids in aqueous ethanol solutions, absolute ethanol, and nitromethane permitted the hypothesis[156,157,159] that there is a possibility of the specific solvation of the dihydroxyalkylene substituents at the phosphorus atom in aqueous organic media. Calorimetric and spectroscopic studies[160] of the solvation of isotypical cyclic and acyclic phosphorus and carbon compounds led to the discovery of a difference between the types of solvation of the cyclic compounds, on the one hand, and the acyclic compounds, on the other; no anomaly was found in water–alcohol mixtures. Nevertheless the available data are still insufficient to infer the nature of this difference.

Cyclic phosphoromonothioic acids[161] are stronger in aqueous alcoholic media than their acyclic analogues[162], which may be due to a more significant contribution to the tautomeric thione–thiol equilibrium by the thiolo-form of cyclic phosphorothioates[161]. This hypothesis is consistent with the results of the determination of the oxidation-reduction potentials of the latter compounds in these solutions[163]. In solvents with a lower polarity the thiono-forms of cyclic phosphoromonothioic acids predominate[136].

Cyclic phosphorodithioic acids also exhibit stronger proton-donating properties in benzene and anisole than the acyclic acids[164]. However, in absolute ethanol the values of pK_a of alkylene phosphorodithioates are higher than for their analogues with an open-chain structure. This anomaly of the acid properties was explained by the conformational characteristics of these cyclic compounds. Thus the *cis*-disposition of the exocyclic S–H and P–S groups in dioxaphospholan derivatives makes the proton less mobile and the effective positive charge on the phosporus is "quenched" as a result of the solvation by ethanol molecules which are of suitable size[165]. Such *cis*-orientation in the triad P(S)SH predetermines the possibility of the formation of intramolecular hydrogen bonds in the molecules of five-membered cyclic phosphorodithioates[166].

The removal of the acid centre from the phosphorodithioate substituent in acids of the type 

promotes a change in the mutual orientation of the functional groups and the manifestation of a greater electron-accepting capacity by 1,2-dihydroxyalkylene substituents compared with the alkoxy-substituents[167].

The study of the acid–base properties of the acids of phosphorus in the highest oxidation state is important for the determination of the electronic influence (σ^{ph}) of dihydroxyalkylene substituents at the phosphorus atom. However, the use of the ionisation constants of oxygen-based cyclic phosphates for the calculation of the σpH on the basis of Kabachnik's familiar standard series[168] proved to be impossible, because it was shown[156,157] that cyclic and acyclic phosphates are acids of different chemical types. Because of this, the values of σ^{ph} determined from this series do not exhibit the required constancy—they vary as the solvent is altered (Table 2, Nos.12–15).

Attempts have been made to determine the values of σ^{ph} of dihydroxyalkylene substituents from other reaction series: from the free energies of the association of cyclic phosphoryl compounds with *p*-fluorophenol[169], the basicity constants, ^{19}F NMR data for phosphorimidate compounds[170], and the stability constants of phosphinodithioyl complexes of cobalt[172]. Analysis of the results (Table 2) showed that invariant values of the σ^{ph} constants can be assigned only to alkylene (Nos.1 and 10) and dihydroxytetramethylene (No.20) substituents. For other 1,2- and 1,3-substituents, this is at present difficult to achieve.

One of the causes of the inadequately clear-cut quantitative ideas concerning the influence of these types of substituents at the phosphorus atom is the lack of exact views on the nature of the solvation and transolvation of the cyclic fragment containing a phosphorus atom. Admittedly, this factor cannot be decisive because the values of σ^{ph} for acyclic groups are fairly satisfactory in different reaction series and in media of different polarity[173].

One must also note the dependence of the σ^{ph} of the groups RX not only on the nature of the inductive and resonance components in the overall polar effect of substituents[173] but also on their steric influence[174-177]. This is apparently equally valid also as regards the groups X–R–Y at the phosphorus atom, although one cannot rule out the possibility that in the case of cyclic substituents hyperconjugation and field influences can be manifested together with the effects enumerated above.

On the other hand, there are data showing that the steric effect of dihydroxyalkylene substituents with sterically fixed configurations is less pronounced than the effect of two alkoxy-groups having the same number of carbon atoms[178].

Thus a realistic estimation of the relative contributions of the inductive, mesomeric, and structural components to the overall values of σ^{ph} for cyclic substituents at the phosphorus atom is at present fairly difficult. Only certain qualitative conclusions can be drawn from the available data (Table 2): the strained phospholan substituents have the most marked electron-accepting properties; the influence of the phosphorinane fragments is similar to the overall effect of two acyclic alkoxy-groups at the phosphorus atom.

It has been suggested that the enhancement of the electron-accepting effect of the 1,2-dihydroxyalkylene substituent at the phosphorus atom in a five-membered ring

Table 2. The values of σ^{ph} for cyclic substituents at the phosphorus atom.

Note. α, β, and γ are the values of σ^{ph} found from the thermodynamic characteristics of the hydrogen-bonded complexes of cyclic phosphoryl compounds with *p*-fluorophenol, the chemical shift $\delta(^{19}F)$ of fluorine-substituted arylimides of cyclic phosphorus acids, and the stability constants of the cobalt complexes of phosphorus dithioacids respectively.

*The value of σ^{pH} found from the pK_a for the acids ABPSOH is −1.65.[161]

**Found from the basicity constants of the arylimides of cyclic phosphorus acids.

***The value of σ^{ph} found from the basicity constants of the arylimides of cyclic phosphorus acids is −0.61.[170]

****Found from the correlation between the values of σ and the stretching vibration frequencies of the phosphoryl groups ν(P–O) in the compounds ABP(O)R.

is associated with the rigid fixation of the oxygen atoms, which weakens the p_π–d_π interaction of the unshared electron pairs of the endocyclic oxygen atoms with the *d* orbitals of phosphorus[179]. This increases the electron density deficit at the tetracoordinate phosphorus atom and reduces the basicity and nucleophilicity of the trivalent phosphorus atom in a 1,3,2-dioxaphospholan ring. We may note that the more pronounced electron-accepting properties of the 1,2-dihydroxyalkylene group compared with two alkoxy-groups are also attributed to the decrease of the endocyclic P–O–C angles, which alters the hybridisation of the oxygen atom from sp^2 towards sp^3, and to a decrease of the π character of the ring P–O ester linkages[180].

The reactivity of phosphorus(V) acids has been studied more extensively in relation to phosphorus dithio-acids. In the general case, cyclic phosphorodithioates are more reactive than their acyclic analogues. Thus their reaction with diphenyldiazomethane is accompanied by a greater heat change[181], they add faster to acrylonitrile[182], and they are more reactive in the protodemetallation reaction of tetra-ethylstannane[184]. This is mainly associated with the greater strength of the cyclic dithio-acids compared with the acyclic analogues.

On the other hand, the complexes of transition metal ions nickel(II), cobalt(II), silver(II), and zinc(II) with cyclic phosphinodithioyl ligands are less stable than the complexes with dialkoxyphosphinyl ligands[172,185,186], which can be naturally accounted for by the greater electron-accepting capacity of the cyclic ligands. For the same reason, the alkylation of salts of cyclic dithio-acids[183] is much slower than that of the acyclic acids[187].

The kinetics of the addition of cyclic phosphorodithioates to α-substituted styrylphosphonates and ethyl acrylate are unusual[188,189]. Whereas acyclic phosphorodithioates interact with these unsaturated reagents via the bimolecular nucleophilic addition mechanism with 1,4-orientation of the dithio-acid with respect to the system of multiple bonds of the unsaturated reactant, in the case of the stronger cyclic dithio-acids the rate of reaction is described by a third-order equation: of first order with respect to the unsaturated reactant and of second order with respect to the acid. In the first stage a hydrogen-bonded complex of the dithio-acid with a protophilic centre of the unsaturated compound (P=O or C=O) is formed and then a second molecule of the cyclic phosphorodithioate adds to the multiple bond.

* * *

The data presented in this review demonstrate the wide variety of the reactivities of 1,3,2-diheterophospholans and 1,3,2-diheterophosphorinanes, expressed both in the anomalous rates of reaction and in the unusual pathways followed in the interactions, which are not characteristic of their acyclic analogues. The fairly considerable ease of the change in the coordination number of the phosphorus atom, $P^{IV} \rightleftharpoons P^{V}$–$P^{VI}$, due to the favourable thermodynamic features of the trigonal and tetragonal bipyramids of penta-coordinate and hexacoordinate phosphorus compounds containing five-membered heterocycles, has been demonstrated in relation to cyclic and particularly five-membered organophosphorus compounds. The study of the reactivity

of cyclic derivatives of phosphorus acids established the important role in chemical reactions of intermediates containing phosphorus atoms in the highest coordination states. This made it possible in its turn to consider the fine details of many biochemical processes occurring with participation of phosphate esters. On the other hand, the available information about the interconversion of phosphorus compounds with different coordination numbers revealed and explained the unity and wide variety of the chemistry of organophosphorus compounds.

The Strain Energy, Geometrical Structure, and Spin-Spin Coupling Constants of Cyclic Hydrocarbons

M.P.Kozina, V.S.Mastryukov, and E.M.Mil'vitskaya

The thermochemical data and spin-spin coupling constants (SSCC) are compared with the geometrical parameters of molecules investigated in the gas phase by electron diffraction and microwave spectroscopy. Cycloalkanes C_nH_{2n}, cycloalkenes C_nH_{2n-2}, cyclo-1,3-dienes, bicyclo[n.1.0]alkanes, and bicyclo[$n.m$.1]alkanes have been chosen as objects of investigation. Using the method of least squares, 13 empirical equations, relating the strain energy and the SSCC, on the one hand, to the internuclear distances and the valence and dihedral angles, on the other, have been fitted. The equations can be used to estimate the characteristics of compounds which have not been investigated.
The bibliography includes 170 references.

III. Conclusion 782

I. INTRODUCTION

Two features are characteristic of the concept of strain, which is widely used in organic chemistry. On the one hand, the fundamental postulates of the concept are intuitively understood and permit easy qualitative predictions; on the other hand, quantitative estimates are difficult and are of a conventional kind, because the concept of "strain" has no rigorous definition[1].

It has come to be assumed that the molecule has a certain excess energy if its geometrical parameters differ from those characteristic of the "unstrained" system, adopted by convention as the starting point for calculations, the reference system, or standard. In order to discover individual types of strain in the molecule, it is sometimes sufficient to inspect its structural formula. In other cases it is necessary to construct three-dimensional models or to carry out special calculations. We shall describe as an example several molecules whose geometry is known.

For example, angular strain can be specially readily deduced in the spiropentane (I).[2] The deformations of the internuclear distances are less evident, but it can be assumed that the common bond in bicyclo[2.2.0]hexane (II) [3] must be extended if it is supposed that the molecule is formed from cyclohexane by the insertion of a bond between the 1- and 4-positions. Bicyclo[2.2.2]octane (III) may serve as an example of a molecule with a dominant torsional strain (the presence of eclipsed conformations).[4] Finally, repulsive van der Waals interactions between non-bonded hydrogen atoms have an appreciable influence on the conformation of a molecule such as that of bicyclo[3.3.1]nonane (IV).[5]

(I) (II) (III) (IV)

Thermochemical data constitute the experimental basis for the quantitative estimation of the strain energy E_S. Information about the geometrical structure of the molecules has been most frequently resorted to for their interpretation, although quantitative correlations have not been analysed[6-10]. On the other hand, an appreciable parallelism between the changes in E_S and molecular characteristics such as, for example, spectroscopic properties[11] and Compton profiles[12] has also been noted.

Comparison with the geometry is widely used also in the analysis of the spin–spin coupling constants (SSCC); the correspondence between the structure factors, the strain in the molecules, and the SSCC has been frequently pointed out in NMR studies.

For a number of reasons, cyclic hydrocarbons constitute the most promising objects for the search for a correlation between the above parameters:

$$E_s\text{-molecular geometry-SSCC.} \qquad (1)$$

Firstly, cyclisation of a hydrocarbon is as a rule accompanied by considerable changes in its geometry, which lead sometimes to the appearance of strain amounting to several tens of kcal mol^{-1}. Secondly, cyclic hydrocarbons are the most important structural units in organic chemistry, forming sequences of molecules with similar structures gradually increasing in complexity, which are being actively investigated by thermochemical and NMR methods. Accurate geometrical data obtained in the gas phase are available for many compounds. This is very important because only in the gas phase is the molecular geometry closest to the equilibrium geometry as a consequence of the absence of intermolecular interactions[13].

In the present review an attempt is made to compile and survey the experimental data published up to 1979 and characterising the strain energy, the geometrical structure, and the SSCC of cyclic hydrocarbons and to analyse the relation between these parameters using a minimum number of assumptions. It was found that the relations between the parameters can be analysed only in relation to cycloalkanes, cycloalkenes, cyclo-1,3-dienes, bicyclo[n.1.0]alkanes, and bicyclo[$n.m$.1]alkanes, which have been most thoroughly investigated on the lines indicated. We confined ourselves to the consideration of only unsubstituted hydrocarbons, since little information is available about substituted cycloalkanes and it is non-systematic. An exception has been

made for hydrocarbons of the cyclopropane series in order to survey the numerous thermochemical data which have been published in the last decade.

1. Calculation of the Strain Energies

The strain energy E_S of a cyclic compound is understood as the energy of the molecule in excess of that of the corresponding acyclic chain. The quantitative estimation of E_S presents considerable difficulties and is of a conventional kind[1,10,14]. The energies E_S can be estimated from the experimental enthalpies of combustion (ΔH_c°) or formation (ΔH_f°) and the enthalpies of hydrogenation (ΔH_h°) with the aid of additive computational schemes and by methods of calculation based on a mechanical model of the molecule and approximate quantum-chemical calculations.

Approximate quantum-chemical calculations of E_S are performed comparatively rarely and are of interest for an approximate estimation of ΔH_f°.[15] In calculations on complex molecules by this method, it is necessary to introduce many approximations, which leads to a considerable freedom in the selection of parameters and discrepancies between the results obtained by different workers[16].

Within the framework of the mechanical model of the molecule[9] (the term "molecular mechanics" is used in the foreign literature[17,18]), the energies E_S are calculated as sums of the individual contributions of the energies associated with the deformations of the bond lengths and angles (compared with ideal molecules), the torsional strain, and the interaction of atoms not linked by valence bonds. The method of molecular mechanics has been examined critically by Engler et al.[18] (see also other communications[19-21]).

The values of E_S obtained by comparing the experimental ΔH_f° with quantities calculated assuming additivity for hypothetical unstrained molecules with the same number and types of bonds are used in the present study. Hence it follows that the values of E_S depend both on the reliability of the experimental thermochemical data and on the selected method for their calculation for the chosen unstrained reference molecules, which are usually open-chain analogues (as in structural studies).

Not all compounds with an open chain of carbon atoms are free from strain. In branched acyclic molecules repulsive interactions inevitably arise between non-bonded atoms (mainly *gauche*-interactions). In estimating E_S one must therefore employ only computational schemes (based on the additivity of the bond energies or group contributions) in which the contribution of the *gauche*-interactions is isolated and highly branched acyclic molecules (for which interactions of another type are characteristic) are not considered. Table 1 presents the values of E_S for cyclo-alkanes obtained by computational schemes of this type[10,22-24].

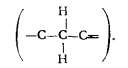
It follows from Table 1 that there are discrepancies between the values of E_S even when isotypical computational schemes are used. For a comparison of the E_S, it is therefore desirable to employ the same computational scheme for all the compounds considered. In the present study the E_S were evaluated by an additive scheme[22] in which the group contributions were obtained not only for hydrocarbons but also for their derivatives, which extends its applicability. The strain energy is defined as the difference between the experimental and calculated enthalpies of formation ΔH_f°:

$$E_s = \Delta H_{f(G),e}^\circ - \Delta H_{f(G),c}^\circ \qquad (2)$$

where $\Delta H_{f(G),c}^\circ$ is equal to the sum of the group contributions.

Table 2 presents only those group contributions which we used to calculate the $\Delta H_{f(G)}^\circ$ for hypothetical unstrained molecules corresponding to the hydrocarbon considered.

Table 1. The strain energies of cycloalkanes (E_S, kcal mol^{-1}) at 298 K.



n	1 [22]	2 [10]	3 [23]	4 [24]	n	1 [22]	2 [10]	3 [23]	4 [24]
3	27.6	28.1	28.0	27.5	7	6.4	7.7	7.3	6.3
4	26.6	27.3	27.1	26.5	8	9.9	11.3	10.9	9.7
5	6.0	6.9	6.7	5.9	9	12.8	14.4	14.0	12.6
6	0.2	1.3	1.0	0.1	10	12.6	14.4	13.9	12.4

Notation: n is the number of carbon atoms in the ring and the numerals 1, 2, 3, and 4 denote computational schemes. Note. The numbers in square brackets in this and other Tables as well as in the formulae in the text denote references (Ed.of Translation).

Table 2. The group contributions to $\Delta H_{f(G)}^\circ$ (kcal mol^{-1}) at 298 K*.

Group	Contribution	Group	Contribution
$C-(C)_2(H)_2$	−4.95	$C-(C_d)_2(H)_2$	−4.29
$C-(C)_3(H)$	−1.90	$C_d-(C)(H)$	8.59
$C-(C)(C_d)(H)_2$	−4.76	$C_d-(C_d)(H)$	6.78

*The designations of the groups are the same as in the review of Benson et al.[22] For example, $C-(C)(C_d)(H)_2$ means that the group contains a saturated carbon atom C linked to one similar carbon atom (C), to one carbon atom involved in a double bond (C_d), and to two hydrogen atoms $(H)_2$, i.e. it represents the group

The extent to which E_S is arbitrary depends on the possibility of selecting an unstrained system (computational scheme), as mentioned above, and on the different influences (not taken into account when any computational scheme is employed) of (a) temperature, (b) zero-point energy (i.e. the energy of nuclear movement), and (c) the energy $p\Delta V$ on the $\Delta H_{f(G)}^\circ$ for the real cyclic molecule and the hypothetical molecule assumed to be unstrained.

It is necessary to estimate the limits within which the values of E_S can vary as a result of the influences of the three factors.

(a) The heat capacities of acyclic hydrocarbons can be assumed to be additive. For example, the contribution of the group $[C-(C)_2(H_2)_2]$, i.e. of $-CH_2-$, to C_p is 5.5 cal mol^{-1} K^{-1}.[11] The contribution of the $-CH_2-$ group obtained from the experimental C_p (25.40 cal mol^{-1} K^{-1}) for cyclohexane[22] is 4.2 cal mol^{-1} K^{-1}. Owing to the difference between the values of C_p per $-CH_2-$ group in the ring and in the hypothetical unstrained molecule, the value of E_S for a six-membered ring is too low by more than 2 kcal mol^{-1} at 298.15 K.

(b) The vibrational energy in n-alkanes can also be regarded as additive (on average, 17.50 kcal mol^{-1} corresponds to the $-CH_2-$ group[25-27]). A specific vibrational energy different from that of a hypothetical unstrained molecule is characteristic of each cyclic compound, but the difference should not be large, because the main contribution to the zero-point energy comes from the vibration frequencies of the C–H bonds, which are comparatively insensitive to molecular structure. For the majority of hydrocarbons considered, the zero-point energy cannot be calculated because the complete set of vibration frequencies is unknown. Quantitatively this can be illustrated in only a few examples: the vibrational energy for cyclohexane, calculated as $N\sum_i \frac{1}{2}h\nu_i$ (where N is the Avogadro number, h the Planck constant, and ν_i the frequencies of the fundamental vibrations) is 104.5 kcal mol^{-1},[26] while the value estimated from the group contributions (6×17.50) is 105.0 kcal mol^{-1}; the corresponding values for cyclopentane are 86.0 and 87.5 kcal mol^{-1} and those for cyclobutane are 67.3 and 70.0 kcal mol^{-1}. Consequently, according to these data, the value of E_S may be too high owing to failure to take into account the difference between the zero-point energies, for example, by 3 kcal mol^{-1} for cyclobutane. According to the results of another study[14], the energy E_S for cyclobutane is too high by 4.6 kcal mol^{-1} and the corresponding errors for three-, five-, and six-membered rings are 4.2, 3.7, and 3.4 kcal mol^{-1}.

Table 3. Changes in the strain energy (ΔE_S, kcal mol^{-1}) on passing from a three-membered to a six-membered ring obtained from different thermodynamic quantities*.

n	ΔE	ΔE_0	ΔE_{298}	ΔE_S
3–4	1.0	0.9	1.4	1.4
4–5	20.8	19.8	19.9	19.9
5–6	6.4	5.7	6.1	6.1

*Notation: ΔE are the differences between the strain energies obtained from the internal atomisation energies in the hypothetical equilibrium state at 0 K and 298 K; the ΔE_S were obtained from the enthalpies of atomisation at 298 K; n is the number of carbon atoms in the ring.

The mutually compensating influences of the thermal (a) and zero-point (b) energies result in the approximate constancy of the differences in the E_S on passing from one ring to another regardless of whether the thermal and zero-point energies are excluded or taken into account in the calculations. Table 3 presents the differences between the E_S for several cycloalkanes according to Nelander and Sunner[14]. Consequently, in order to compare the E_S for a specific series of compounds, one can also employ other available quantities, such as ΔH_f° (298 K); here the error of the E_S compared is 1–2 kcal mol^{-1} (provided that the same additive scheme is used to calculate the ΔH_f° of the unstrained molecules).

(c) The difference between the contributions of the energies $p\Delta V$ to ΔH_f° for the cyclic compound and for the corresponding unstrained compound can be readily found from the relation $\Delta H_{f(G)}^\circ = \Delta U_{f(G)}^\circ + (1 - 1/2m)RT$ for compounds having the general formula C_nH_m. The difference between the $p\Delta V$ is incorporated in the E_S, where it is not constant (0.6 kcal mol^{-1} for cycloalkanes and 1.2 kcal mol^{-1} for bicycloalkanes) and will be eliminated in comparing the E_S in a given series of compounds.

Next, a comparison will be made of the conventional values of E_S, obtained as differences between the experimental and calculated $\Delta H_{f(G)}^\circ$ [see Eqn.(2)] or calculated with the aid of a mechanical model[17,18] in the few instances when no experimental ΔH_f° are available.

The experimental values of ΔH_f° and the strain energies E_S presented below are expressed in kcal mol^{-1} and refer to 298.15 K. The errors in ΔH_f° are expressed in terms of a 95% confidence interval and are given in round brackets. For example $\Delta H_{f(G)}^\circ$ for cyclopropane is 12.74(12) kcal mol^{-1}, i.e. in this case the error of the determination is 0.12 kcal mol^{-1}. In those cases where there are no experimental enthalpies of evaporation ΔH_v°, they were estimated from the Klages relation[28] in order to obtain ΔH_f° for the gaseous state (the latter quantities are listed in the Table without an indication of the error).

2. Geometrical Parameters of the Molecules

The steric disposition of the atoms in the molecules can be described unambiguously by specifying the internuclear distances r (the less rigorous term "bond length" is frequently used), the valence angles α, and the dihedral angles τ. The most accurate measurements of these molecular parameters are made in the gas phase by electron diffraction[13,29] and microwave spectroscopy[13,30]. The two methods yield geometrical parameters having a different physical significance and different indices and differing by an amount greatly exceeding the experimental error[31-33]. X-Ray diffraction analysis yields a third variety of geometrical parameters; therefore, in comparing data obtained by different methods, account must be taken of these differences.

However, even within the limits of each of the first two methods—electron diffraction and microwave spectroscopy—there exist a wide variety of parameters having a different significance. Readers wishing to make independently accurate comparisons of the internuclear distances should refer to the literature indicated above on the stereochemistry[13,30-33] and to the original studies. A rigorous comparison implies the employment of geometrical parameters of only one type within the limits of a given physical method.

In electron diffraction studies the final data are not presented in a unique manner and the authors quote distances designated by the symbol r_g or r_a. They are related by the equation

$$r_g = r_a + u^2/r_a ,$$

where u is the amplitude of the vibrations of pairs of atoms. The correction term u^2/r_a can be usually readily calculated and it amounts to 0.002 and 0.006 Å for the C–C and C–H bonds respectively. Tables 4–9 (see below) present data taken directly from original communications without indication of the type of distance. The only exception has been made for cycloalkanes, in which all the distances have been recalculated on the r_g basis to ensure a consistent comparison.

The distances designated by the symbols r_0 and r_s can be obtained from microwave data. They are not simply related and there are no simple relations between them and the electron diffraction parameters r_g and r_a.

The valence angles quoted in electron diffraction studies are believed to be the most reliable if they have been calculated taking into account the correction for the contraction effect[31]. Neglect of this correction can distort the valence angles by several degrees. The corrections are calculated on the basis of the theory of vibrations, provided that the force field of the molecule is known (for references to the last studies in this field, see Mastryukov and Dorofeeva[34]). The valence angles corrected for the contraction effect are designated by the symbol Φ_α in order to show that they refer to a geometrically self-consistent r_α structure, in contrast to the r_g and r_a structures.

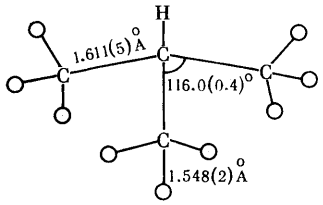
We shall now proceed to the description of the comparison of the geometrical parameters carried out to find correlations with E_S. For this purpose, it is desirable to employ a simplified equation for the calculation of the strain energy E_S within the framework of the mechanical model (for more complex versions of the equation, see the relevant communications[18-21]):

$$E_s = E(r) + E(\alpha) + E(\tau) + E_{nv} = \\ = \frac{1}{2}K_r(r - r_0)^2 + \frac{1}{2}K_\alpha(\alpha - \alpha_0)^2 + \frac{1}{2}K_\tau(1 + \cos 3\tau) + E_{nv} \qquad (3)$$

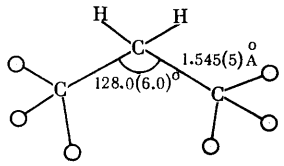
Here each term refers to individual components of the strain mentioned previously: the deformation of the distances (r), the valence angles (α), and the dihedral angles (τ) and also the energies of non-valence interactions E_{nv}. The reference values are designated by the subscript 0.

It follows from Eqn.(3) that the strain energy is a complex function of many variables and by an empirical comparison one can only hope to find a parameter (or parameters) on which the E_S for a series of molecules with similar structures depend preferentially. For this purpose, it is necessary to analyse three pair combinations: E_S–r, E_S–α, and E_S–τ. We shall not consider the non-valence interactions in quantitative terms and shall confine ourselves to referring to the system of van der Waals radii[35], which are usually resorted to for comparisons of this kind.

Inspection of Eqn.(3) shows that, for example, in the case of internuclear distances a linear correlation is to be expected in terms of the variables E_S and $n(r - r_0)^2$, where n is the number of deformed bonds. This is also true of the valence angles. However, tests have shown that the simplest relations of the type E_S–$(r - r_0)$ and E_S–$(\alpha - \alpha_0)$ are much more convenient and we shall henceforth employ these.



The second general observation about Eqn.(3) concerns the choice of the reference values of r_0 and α_0. In the mechanical model these quantities are empirical parameters without physical significance and are selected to ensure the best agreement between the calculation and experiment. We prefer to employ geometrical data for the reference molecules investigated. Admittedly in most instances such choice is not of fundamental importance, since the relative changes in $r - r_0$ and $\alpha - \alpha_0$ are necessary only for a qualitative derivation of a correlation with E_S, and the final quantitative characteristics, i.e. the correlation equations, have been usually derived not for the relative but for the absolute values of the geometrical parameters. The correlation equations make it possible in their turn to estimate independently certain values of r_0 and α_0 (see Section III).



The selection of the reference values for the dihedral angle τ, which should be 60° for the *gauche*-orientation and 180° for the *trans*-orientation in acyclic systems, presents a special difficulty[36]. However, cyclisation distorts these values so much that they become of little practical use for a comparison. Furthermore, in the majority of structural studies there is simply no explicit information about the dihedral angles. For these reasons, we confined ourselves to comparing certain dihedral angles in repeating fragments of similar molecules.

As already mentioned, the most suitable standard for saturated hydrocarbons is a normal chain with the *trans*-disposition of all the C–C bonds, although at the usual temperatures there is also a considerable amount of other conformers. Electron diffraction studies on alkanes ranging from ethane to n-heptane established that the average parameters of these molecules are appreciably constant and we shall use them henceforth for the comparison: the average distance r_g(C–C) = 1.533(1) Å† and the average valence angle ∠C–C–C = 112.6(0.1)°.[37,38] More detailed information about the structures of different hydrocarbons can be found in the book of Volkov et al.[13]

A recent investigation[39] showed that the above constancy of the C–C bond lengths breaks down on passing to higher alkanes. Thus the distance for n-$C_{16}H_{34}$ is 1.542(4) Å, which has been attributed to the influence of non-valence interactions. A reinvestigation of n-C_4H_{10} [40] taking into account the contraction effect led to a more accurate C–C–C valence angle, equal to 113.8(0.4)°. We shall use the previous average value if only because in the majority of studies on cyclic hydrocarbons quoted here such corrections were not introduced.

Since the entire subsequent data refer to cyclic hydrocarbons, in conclusion of this section we shall present examples of strained acyclic molecules as an illustration. In such systems the strain increases with increasing branching of the chain, which is particularly notable for the t-butyl group. When two such groups are linked together, the distance between them is significantly increased and reaches 1.582(10) Å.[41] The greatest C–C distance (1.611 Å) has been recorded in the $(t\text{-}C_4H_9)_3CH$ molecule[42] and in the similar molecule of $(t\text{-}C_4H_9)_2CH_2$ [43] the C–C–C angle is appreciably increased. The structural data for these two unusual molecules are presented below (the methyl group is illustrated by a circle).

†As in the representation of the thermochemical data, here and henceforth the experimental errors referring to the last decimal places are given in round brackets, i.e. in this instance r_g = 1.533 ± 0.001. A more detailed form of notation is usually employed for angles, i.e. 112.6(0.1)°, although a formulation of the type 112.6(1)° can also be encountered in the literature.

The strain has also distorted the conformational characteristics of the butyl and methyl groups for which the deviations of the dihedral angles $\Delta\tau$ from the staggered orientation, which serves as the starting point of the calculation ($\tau = 0°$), are presented:

Molecule	$(t\text{-}C_4H_9)_3CH$	$(t\text{-}C_4H_9)_2CH_2$
$\Delta\tau$ (C_4H_9)	10.8 (0.5)°	15.1 (6.0)°
$\Delta\tau$ (CH_3)	18.0 (6.0)°	13.2 (7.0)°

3. The Spin–Spin Coupling Constants

In the literature on the NMR spectroscopy of organic compounds a considerable number of publications (including review publications) are devoted to the discussion of the question of the correspondence between the spin–spin coupling constant (SSCC) and the structural, conformational parameters of the molecule[44–74]. The influence of molecular structure on the SSCC between the nuclei of like and unlike atoms, both linked directly and separated from one another, has been investigated. In connection with the development of ^{13}C NMR spectroscopy, there has been a growth of interest in recent years in the study of the SSCC between the carbon nuclei constituting the skeleton of an organic molecule. These constants are significantly smaller than the corresponding SSCC for protons, but this deficiency is compensated by the simplicity of the observation of the J_{C-C}.[71,75–77].

At the same time one should note that few systematic data, enabling one to trace the "geometry–SSCC" relation for a series of structurally similar compounds, are available. Among cyclic hydrocarbons, the SSCC for vicinal protons $^3J_{H-H}$ (the coupling constants of the ^1H nuclei via three bonds) and the coupling constants for the ^{13}C and ^1H nuclei via one bond $^1J_{^{13}C-H}$ (obtained either from high-resolution ^{13}C NMR spectra or by analysing the ^{13}C satellites in proton spectra), for which definite correlations with the structure have been established (see below), constitute an exception in this respect.

In this review we shall not be concerned with the theoretical aspects associated, in particular, with the mechanism of the spin–spin coupling, to which due attention has been devoted in the series of reviews quoted here. We shall only note that the true cause of the changes in the SSCC is still not altogether clear. They can be caused by an alteration of the *s* character of the corresponding orbital and hence can serve as a measure of the *s* character of the bond. (Minimum values of the $^1J_{^{13}C-H}$ constant are characteristic of carbon atoms with sp^3, sp^2, and *sp*-hybridisations, amounting to ~125, 156, and 250 Hz respectively.) Formulae linearly relating the degree of *s* character of the hybrid orbital of the carbon atom in the C–H bond to the $^1J_{^{13}C-H}$ constant have been proposed and have been frequently revised[44,78–86]. At the same time there exists the view that it would be premature to establish a quantitative correlation between the constant $^1J_{^{13}C-H}$ and the degree of *s* character and that it would be more correct to regard $^1J_{^{13}C-H} \cong 125$ Hz as a characteristic of tetracoordinate carbon with a tetrahedral environment[86,87].

The change in the SSCC may be a consequence of the change in the length of the corresponding bond caused by the deformation of the angles and the diminution of repulsive interactions[86]; in particular, an increase of the constant $^1J_{^{13}C-H}$ should then be expected. However, certain experimental and calculated data have shown that there is no direct relation between these quantities[48,58,67,68,79]. Despite the difficulty of interpretation, the correlation between the SSCC and the deformation of the structure is believed to have been reliably established[70]. However, one must not forget the definite (known) inaccuracy of the relations established is due to the fact that one of the parameters compared (SSCC) characterises the substance in the liquid state and the other (structural parameter) characterises the substance in the gaseous (or crystalline) state. One must also take into account the influence of the steric interactions of the neighbouring groups on the SSCC and hence the possibility of employing the observed correlations only within the limits of a series of isotypical compounds.

In this study we have analysed the "geometry–SSCC" relation on the basis of new experimental results or results which have been revised in recent years. We used mainly the constants $^1J_{^{13}C-H}$ and $^3J_{H-H}$, whose values for cyclic hydrocarbons are most systematic, as mentioned above. Certain bridged bicyclic hydrocarbons are an exception; successive changes in the SSCC between vicinal protons ($^2J_{H-H}$) and between protons via four bonds ($^4J_{H-H}$) have been described for these compounds.

II. CORRELATION BETWEEN THE STRAIN ENERGY, THE GEOMETRICAL PARAMETERS, AND THE SPIN–SPIN COUPLING CONSTANTS

1. Cycloalkanes

(a) Correlation between the Strain Energy and the Structural Parameters

The structural data for cycloalkanes and the strain energies E_S are listed in Table 4. The following dimensions are used in Tables 4–9 and in the text: kcal mol^{-1} for E_S, Å for the internuclear distance, degrees (°) for the valence and dihedral angles, and Hz for the SSCC.

The conformational characteristics of these hydrocarbons are distinguished by their wide variety and are not susceptible to analysis on a single basis. Indeed, cyclopropane is a rigid system, cyclobutane is bent by an angle of 26°#, there is pseudorotation in cyclopentane, and cyclohexane exists in the chair conformation with a torsional angle of 54.5°. The conformations of cycloheptane, cyclooctane, and cyclodecane are also comparatively unrelated to the conformations of the preceding homologue. Since it is difficult to put forward a single scheme for the comparison of the dihedral angles in the above molecules, we shall confine ourselves to the consideration of the internuclear distances r_g(C–C) and the C–C–C valence angles. These geometrical parameters will be considered in much more detail for cycloalkanes than for other cyclic compounds, firstly in order to illustrate the approach employed, which is to a large extent repeated in the subsequent sections of the review and, secondly, because of the unusual nature of the results obtained for the cycloalkanes themselves.

#The view has been established in the literature that the four-membered ring of cyclobutane is bent by an angle of ~35°.[104,105] In the latest electron-diffraction study it has been shown that allowance for the pendulum shifts of the methylene groups (for a more detailed description of this effect, see Mastryukov et al.[106]) leads to a significant decrease of the non-planarity of the cyclobutane ring, which confirms the results of non-empirical quantum-chemical calculations[107].

Table 4. The enthalpies of formation, strain energies, structural parameters, and SSCC of cycloalkanes*.

Molecule	ΔH_f°(L) (expt)	ΔH_f°(G) (expt)	ΔH_f°(G) (calc.)	E_s	r_g (C–C)	r_g (C–H)	∠C–C–C,	∠H–C–H	Ring shape	$^1J_{^{13}C-H}$

*The experimental values of ΔH_f° were taken from Pedley and Rylance[88].

**In this and subsequent Tables the references indicated for one of the geometrical parameters refer to all the structural data presented.

***The content of the main conformer was 76 ± 6%.

****The content of the main conformer was 49 ± 3%.

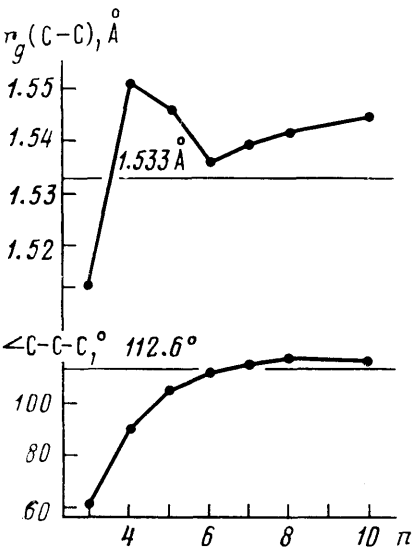

Figure 1. Variation of the C–C internuclear distances r_g and the C–C–C valence angles in the cycloalkanes C_nH_{2n} with ring size n. The horizontal lines correspond to reference values.

The distances r_g(C–C) and the valence angles in the cycloalkanes investigated are illustrated in Fig. 1. The range of variation of the distances (1.512–1.551 Å, i.e. ±2.5% relative to the average value) is significantly smaller than the range of variation of the valence angles (60–116.6°, i.e. ±64% relative to the average value). However, the variation of the internuclear distances is more complex, while the variation of the valence angles has the simpler form of curves with saturation§. The variation of the geometrical parameters of cycloalkanes expressed in this direct form has no analogy whatever with the variation of the E_S for these compounds illustrated in Fig. 2.

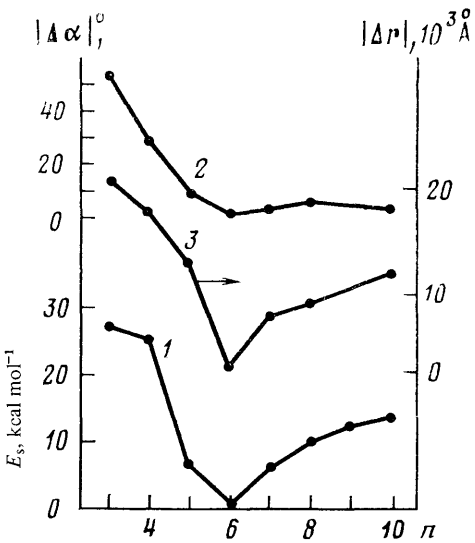

Figure 2. Variation of the strain energy E_S (curve 1) and of the differences $\Delta\alpha = |112.6° - \alpha|$ (curve 2) and $\Delta r = |1.533 - r| \times 10^3$ (Å) (curve 3) in the cycloalkanes C_nH_{2n} with ring size n.

§It is of interest to note that the introduction of a heteroatom into the cyclic system does not alter significantly the features found for hydrocarbons[108].

As mentioned above, the strain energies E_S must be compared with the deviations of the geometrical parameters of the molecule under consideration from the reference values. Since the symmetrical deviations from the reference values must make the same contributions to the E_S (in the mechanical model this phenomenon is described by Hooke's law), the absolute differences are employed for the comparison with the E_S: $\Delta r = |1.533 - r| \times 10^3$ Å for the C–C distances and $\Delta\alpha = |112.6° - \alpha|$ for the C–C–C angles. These differences are in fact illustrated in Fig. 2. It is quite evident that even such relative geometrical parameters reproduce correctly in qualitative terms the decrease of E_S on passing from C_3H_6 to C_6H_{12} with a subsequent increase on further ring expansion.

Fig. 2 shows that the curve illustrating the variation of the internuclear distances closely imitates the form of the E_S curve. A direct confirmation of this observation follows from the correlation equations

$$E_s = -5.74 + 1.56\ \Delta r\ , \qquad (4)$$

$$E_s = 6.19 + 0.48\ \Delta\alpha\ , \qquad (5)$$

obtained by the least squares method and presented in a graphical form in Figs. 3 and 4. These relations clearly show that the values of E_S for cycloalkanes are very closely related to the changes in the internuclear distances in these molecules.

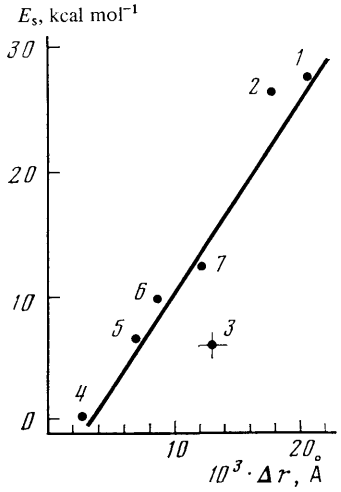

Figure 3. Variation of the strain energy E_S with Δr for different hydrocarbons: *1*) C_3H_6; *2*) C_4H_8; *3*) C_5H_{10}; *4*) C_6H_{12}; *5*) C_7H_{14}; *6*) C_8H_{16}; *7*) $C_{10}H_{20}$. The error in the measurement of the internuclear distances (±0.001 Å) and the approximate error in the estimation of E_S (±1.5 kcal mol^{-1}) for cyclopentane as an example are indicated by horizontal and vertical lines; straight line—calculation by Eqn. (4).

As a consequence of the satisfactory linear relation between E_S and Δr, Eqn. (4) can be used for quantitative estimates of the C–C distances in the hydrocarbons for which only thermochemical data are available. For example, the rg(C–C) = 1.545 Å distance has been estimated from E_S in C_9H_{18}¶.

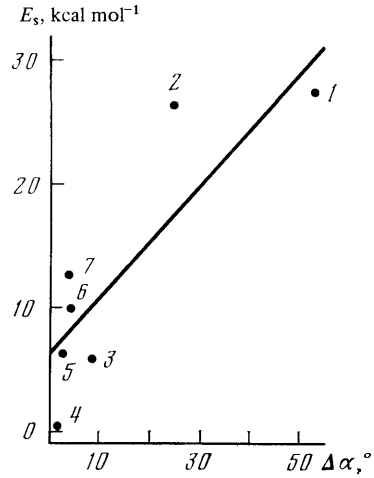

Figure 4. Variation of the strain energy with $\Delta\alpha$: *1*)–*7*) see Fig. 3; straight line—calculation by Eqn. (5).

The preferential correlation of E_S with the deformations of the internuclear distances rather than the valence angles conflicts with the generally accepted hypothesis that the values of E_S for cycloalkanes are mainly determined by the angular Baeyer strain. The same conflict obtains also in the mechanical model: a change in distances is believed to be so unfavourable energetically that in some calculations this effect is simply neglected[9].

In more accurate calculations[17–21] it is assumed that a 10% deformation of the C–C distances (for example, a change from 1.54 to 1.70 Å) is accompanied by a change in the strain energy by only 3.1 kcal mol^{-1}.[18] The result obtained in the above study shows that the changes in the C–C distances in the range 1.512–1.551 Å are satisfactorily correlated with the changes in E_S in the range 0.2–27.6 kcal mol^{-1}. It is noteworthy that the cyclopropane molecule does not deviate from this relation, although it has the shortest bond. The minimum C–C distance in this compound has been interpreted by some workers within the framework of the special concept of "bent bonds".[13,109]

We do not believe that the above contradictions indicate deficiencies of the computational procedure based on the mechanical model, because our treatment is extremely limited and empirical, as already mentioned. Attention need only be drawn to the fact that the analysis of the direct dependence of E_S on the geometrical parameters of cycloalkanes

¶The structural data for C_7H_{14} have been published only recently[94] and the initial version of Eqn. (4) was therefore derived without taking them into account and had the form $E_S = -6.37 + 1.59\ \Delta r$. On substituting the value of E_S for cycloheptane in this expression, it is possible to calculate rg(C–C) = 1.541 Å, which is larger than the experimental value only by 0.001 Å.

can yield an interesting and unusual result, which was not discussed previously and which can be used to estimate internuclear distances from thermochemical data (or conversely). Cycloalkanes occupy a special position, because the strain energies of cycloalkanes and bicyclic hydrocarbons are better correlated with the deformation of the valence angles (as will be seen from the exposition below).

We shall not deal with the H–C–H angles whose deformation also contributes to the strain energy, because the angles ∠C–C–C (α) and ∠H–C–H (β) vary in a concerted manner[110] in accordance with the linear equation

$$\beta = 126.1 + 0.17\,\alpha \ .$$

As a result of this relation, the behaviour of the difference $\Delta\alpha$ illustrated in Fig. 4 should reflect correctly the overall deformation component of the strain energy in cycloalkanes.

As already mentioned in the introduction, substituted cyclic hydrocarbons will not be considered systematically. The only exception was made for hydrocarbons of the cyclopropane series. In recent years extensive experimental data have accumulated for the ΔH_f° of cyclopropanes which have not been surveyed. Using these data, we considered the influence of the introduction of substituents of different types on the E_S for the three-membered ring. The data in Table 5, which lists the values of ΔH_f° and E_S for substituted cyclopropanes and cyclopropenes, show that E_S is constant (27–28 kcal mol^{-1}), within the limits of the error of the determination, for all saturated hydrocarbons with the exception of the seventh and eighth compounds†. The strain energy E_S of alkenyl derivatives of cyclopropane with the double bond separated from the ring by a σ-bond is close to E_S for cyclopropane itself, which indicates either the absence of an effect of $p-\pi$ conjugation or its very small magnitude. The introduction of an exocyclic or endocyclic double bond greatly increases E_S for the three-membered ring.

The estimated strain energy per trigonal atom in cyclopropene, evaluated as half the difference between the values of E_S for cyclopropene and cyclopropane, is 13.1 kcal mol^{-1}. Subsequent calculation of E_S for methylenecyclopropane, defined as the sum of E_S for cyclopropane and 13.1 kcal mol^{-1}, leads to 40.7 kcal mol^{-1}, which fully agrees with the value calculated from the experimental $\Delta H_{f(G)}^\circ$ for methylenecyclopropane (Table 5). This agreement suggests that the contributions of the trigonal carbon atom (*endo*- or *exo*-) to the strain energy in the systems considered are approximately the same.

Thus the data presented show that the introduction of the substituents into the molecule hardly alters the overall strain energy. At the same time in approximate quantum-chemical calculations[116] a relatively strong steric interaction between the CH_3 groups is postulated.

(b) Correlation between the Structural Parameters and the SSCC

On the basis of the changes in the constants $^1J_{^{13}C-H}$ in the series of cyclic saturated hydrocarbons (ranging from cyclopropane to cyclododecane), a linear correlation was observed as early as 1963 between the SSCC and the angle ∠C–C–C, described by the equation[44]

$$^1J_{^{13}C-H} = 203 - 0.720\,\alpha \ . \qquad (6)$$

Using Foote's data[44], Mislow[57] derived a correlation equation expressing the dependence of the constants $^1J_{^{13}C-H}$ not on the angle α but on the interorbital angle α_{orb} (which reflects the state of hybridisation and is determined from the relation $\alpha_{orb} = 0.1340\alpha + 94.83$).[57] However, calculation of the above constant by Eqn. (6) using modern values of the geometrical parameters (Table 4) yields values of $^1J_{^{13}C-H}$ which differ appreciably in many instances from the experimental values.

**Turner et al.[115] determined the enthalpies of hydrogenation of methylmethylenecyclopropane, ethylidenecyclopropane, and 1,2-dimethylcyclopropene in solution in acetic acid at 25 °C. We did not calculate the values of $\Delta H_{f(G)}^\circ$ from these data, because the differences between the enthalpies of evaporation and solution are unknown.

***S.M.Pimenov's data (Candidate's Thesis in Chemical Sciences, Moscow State University, Moscow, 1982).

†The ΔH_f° for 1,1,2-trimethyl- and 1,1,2,2-tetramethylcyclopropanes and vinyl-cyclopropane should be redetermined.

Fig.5 presents the changes in the constant $^1J^{13}C-H$, the C–C–C valence angles, the C–C internuclear distances, and the E_S (the data from Table 4) for the series of compounds considered on passing from cyclopropane to cyclododecane (the geometrical parameters of cyclononane have still not been determined). It shows that the SSCC vary almost in parallel with the variation of the C–C–C angle only.

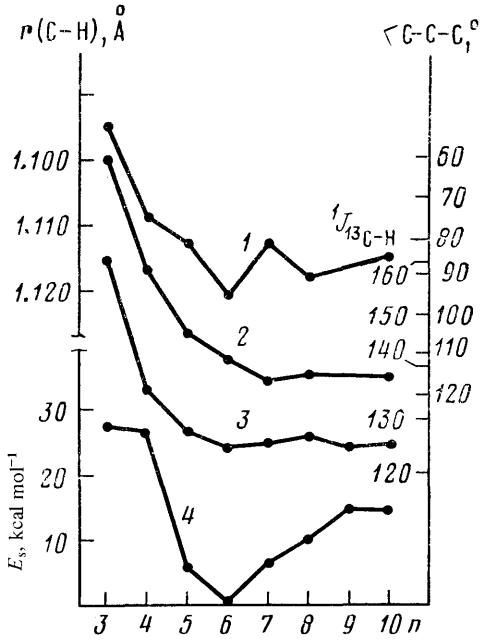

Figure 5. Variation of the C–H internuclear distances (curve *1*), the C–C–C valence angles (curve *2*), $^1J^{13}C-H$ (curve *3*), and E_S (curve *4*) in cycloalkanes with ring size *n*.

On the basis of the data presented, a linear relation was obtained between $^1J^{13}C-H$ and the C–C–C angle (α) for cycloalkanes ($^1J^{13}C-H = 195.7 - 0.632\alpha$), which, however, is characterised by a relatively small but appreciable scatter of the points. If the data corresponding to cyclopropane are disregarded in the calculation, then the above relations for the series of saturated cyclic hydrocarbons ranging from cyclobutane to cyclohexane fit satisfactorily on a straight line. The relation between $^1J^{13}C-H$ and ∠C–C–C for the series of cycloalkanes is best described by the parabolic equation (Fig.6)

$$^1J_{^{13}C-H} = 0.0073\,\alpha^2 - 1.963\,\alpha + 251.715 \quad . \qquad (7)$$

On the basis of the observed relation between E_S and the C–C distance [Eqn.(4)], the unknown average internuclear distances in cyclononane were estimated previously. Using Eqn.(7), it is also possible to find the average C–C–C angle in this hydrocarbon; it amounts to 111° (in agreement with the data in Table 4). Eqn.(7) satisfies the corresponding parameters of propane[117] and, which is particularly interesting, strained compounds such as bicyclo[2,2,1]-heptene and bicyclo[2,2,1]hepta-2,5-diene (for the $^1J^{13}C(7)-H$ and the corresponding angles, see Table 9 below).

2. Cycloalkenes

(a) Correlation between the Strain Energy and Structural Parameters

The structural data and the strain energies E_S for cycloalkenes are presented in Table 6. *cis*-But-2-ene serves as a suitable standard for comparisons in this series of compounds[131]. The required parameters of this molecule are the C–C distance [1.506(2) Å], the C = C distance [1.346(3) Å], and the C–C = C angle [125.4(0.4)°]. We shall consider initially the C–C and C = C distances. Comparison with the distances in the standard reveals the following features: cyclopropene should be just as strained as cyclohexene, but both these compounds are less strained by a factor of ~1.5 than cyclo-octene. The data presented in no way agree with the E_S curve in Fig.7.

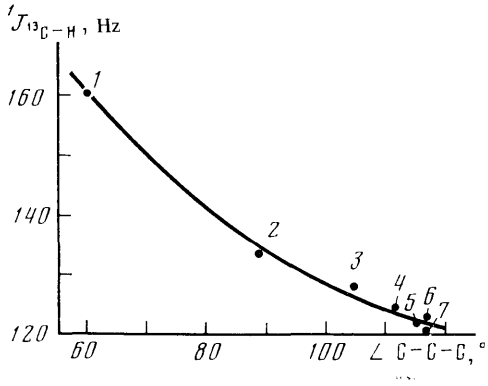

Figure 6. Variation of $^1J^{13}C-H$ with the C–C–C angle for cycloalkanes: *1*)–*6*) see Fig.3; *7*) C_9H_{18}; curve—calculation by Eqn.(7).

On the other hand, there is a satisfactory agreement between this curve and the variation of the C–C = C (α_1) ($\Delta\alpha_1 = 125.4 - \alpha_1$) and the C–C–C ($\alpha_2$) ($\Delta\alpha_2 = 112.6 - \alpha_2$) angles, illustrated in Fig.7. Since the differences $\Delta\alpha_1$ and $\Delta\alpha_2$ have non-alternating signs, the conclusions are independent of the type of standard within the limits of a single sequence of molecules. In this case it is more useful to find correlation equations using the geometrical parameters themselves rather than the above differences#. For the above angles, the equations assume the following form:

$$E_S = 111.2 - 0.895\,\alpha_1 \quad . \qquad (8)$$

$$E_S = 100.6 - 0.894\,\alpha_2 \quad . \qquad (9)$$

Their graphical representation is illustrated in Fig.8. The parallel arrangement of the straight lines obtained on the basis of Eqns.(8) and (9) is striking. Thus, in contrast to cycloalkanes, a correlation of the strain energy only with the deformations of valence angles is characteristic of their unsaturated analogues.

#We shall adhere to a similar approach henceforth; for a qualitative determination of correlations involving E_S, the relative changes in the geometrical parameters are usually employed, but in the final equations the structural parameters are used directly.

Table 6. The enthalpies of formation, strain energies, structural parameters, and SSCC of cycloalkenes.

Note. Here and henceforth the atoms are numbered in accordance with data obtained in structural studies. The experimental values of ΔH°_f were taken from Pedley and Rylance[88]. The dihedral angles in this and subsequent tables are presented in a dual form. The first has the usual significance, for example, $\tau(1-2-3-4)$ denotes the angles between the planes drawn through the 1—2—3 and 2—3—4 carbon atoms. The second designation is in the form of a fraction in which the planes between which the angle is measured are indicated in the numerator and denominator.

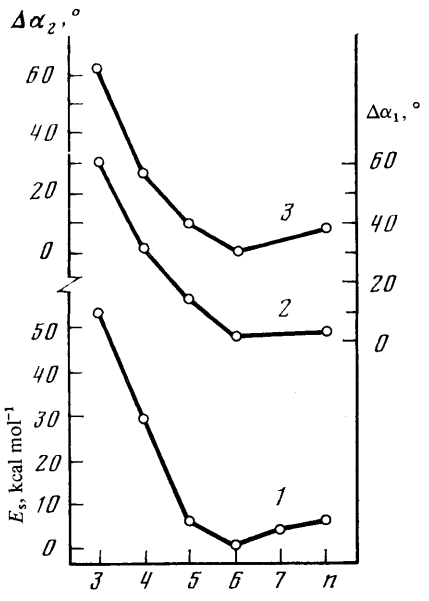

Figure 7. Variation of the strain energy E_S (curve 1) and the differences $\Delta\alpha_1 = 125.4° - \alpha_1$ (curve 2) and $\Delta\alpha_2 = 112.6° - \alpha_2$ (curve 3) in the cycloalkenes C_nH_{2n-2} with ring size n.

(b) Correlation between the Structural Parameters and the SSCC

It is known that in the series of *cis*-cyclo-olefins there exists a definite relation between the SSCC of the vinyl protons and the ring size[45—48,50,56,68]. The change in the constant $^3J_{H-H}$ is more likely to be due to the local geometry about the double bond[45,46] (the C = C interatomic distances and the C = C—C and C = C—H angles) rather than the overall strain energy of the molecule. The empirical correlations derived by different investigators between the above constants and the C = C interatomic distances are similar and correspond to an increase of the constant $^3J_{H-H}$ by ~0.6—0.7 Hz as the C = C bond length diminishes by 0.02 Å.[68] The comparisons of the above relations with experimental data have shown, however, that there is no direct relation between the constants $^3J_{H-H}$ and the C=C bond length[48,49,68]. Thus the change in the C = C internuclear distance from 1.342 Å in cyclobutane to 1.332 Å in cyclo-octene should have corresponded to an increase of the constant $^3J_{H-H}$ by ~0.3 Hz, while in reality the difference between the constants is ~7.5 Hz.

The relation between the constants $^3J_{H-H}$ and the C = C—H angles has been shown by the analysis of the study of Cooper and Manatt[48] to be close to the predicted theoretical relation[55], the sensitivity of the SSCC to the change in ∠C = C—H being particularly notable for angles close to 120°. The C = C—H angle is found from the C = C—C angles, which

are more readily determined experimentally, using the relation $\angle C = C-H \cong (360 - \angle C = C-C)/2$. Calculation of the dependence of the constants $^3J_{H-H}$ on the C = C–C and C = C–H angles for *cis*-buta-1,3-diene (for changes in the angles from 108° to 123° and from 114° to 124° respectively) showed that the size of the angles has an appreciable influence on the constant; the dependence of $^3J_{H-H}$ on the C = C–C angle is more explicit than that of the C = C–H angle[68].

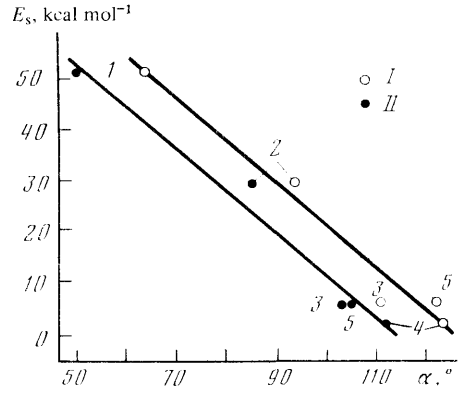

Figure 8. Variation of the strain energy with the C–C = C (*I*) and C–C–C (*II*) valence angles for different hydrocarbons: *1*) C_3H_4; *2*) C_4H_6; *3*) C_5H_8; *4*) C_6H_{10}; *5*) C_8H_{14}; *I*) calculated by Eqn.(8); *II*) calculated by Eqn.(9).

Comparisons have also been made between the structural parameters of cyclo-olefins and the constants $^1J_{^{13}C-H}$.[52,54,72] A linear relation has been established between the constant $^1J_{^{13}C-H}$ and the C = C–C angle for a series of unsaturated compounds of different types[54]. (However, the points corresponding to cyclobutene and cyclopentene do not fit on the resulting straight line.)

Fig.9 presents the variation of $^1J_{^{13}C-H}$, $^3J_{H-H}$, the C = C–C angles, the C = C distances, and the strain energies E_S (according to the data in Table 6) in the series of compounds investigated ranging from cyclopropene to cyclo-octene. It is seen that the SSCC and the C = C–C angle vary in parallel, the parallelism breaking down on passing from cyclopropene to cyclobutene. There is no correspondence whatever between the variations of both SSCC and the C=C bond length; nor is there a full correlation (particularly of the constant $^1J_{^{13}C-H}$) with the strain energies E_S.

The linear equations describing the relations between the SSCC and $\angle C = C-C$ (α) ($^1J_{^{13}C-H} = 277.5 - 1.014\alpha$; $^3J_{H-H} = -9.88 + 0.1556\alpha$) do not reflect the observed relation in a sufficiently clear-cut manner. (As for cycloalkanes, the linear correlation holds when data corresponding to the three-membered unsaturated ring are rejected in the calculation.) The dependence of the SSCC on $\angle C = C-C$ (α) has been studied most completely and in this instance is described by the parabolic equations (Figs.9 and 10)

$$^1J_{^{13}C-H} = 0.0195\alpha^2 - 4.720\alpha + 443.327 \quad , \qquad (10)$$

$$^3J_{H-H} = 0.0039\alpha^2 - 0.579\alpha + 22.465 \quad . \qquad (11)$$

The question of the reason for the deviations from the linear relation of the corresponding parameters of both saturated and unsaturated three-membered rings (if the accuracy of the determinations of the quantities compared is assumed to be adequate) still remains open. Owing to the lack of systematic, uniform data for a large number of the hydrocarbons considered (in the series of cycloalkenes the entire calculation is in fact based on the parameters for 4–5 compounds), it is difficult to reach a definite conclusion. Possibly the deviations are caused by the extremum values of the geometrical parameters or a significantly different hybridisation of the carbon atom in three-membered cyclic compounds, which occupy an intermediate position between saturated, unsaturated, and acetylenic hydrocarbons.

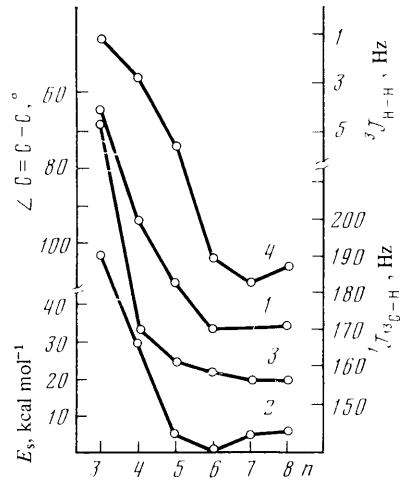

Figure 9. Variation of the C = C–C valence angles (curve *1*), E_S (curve *2*), $^1J_{^{13}C-H}$ (curve *3*), and $^3J_{H-H}$ (curve *4*) in cycloalkenes with ring size *n*.

It is noteworthy that Eqn.(10) is also characteristic of certain other unsaturated compounds, particularly of ethylene[117], cyclohexa-1,4-diene[67], cyclo-octatetracene[52], bicyclo[2,2,1]hept-2-ene[118], and bicyclo[2,2,2]octa-2-ene[48], while correlation (11) holds satisfactorily both for the above hydrocarbons and in addition for cyclopenta- and cyclohexa-1,3-dienes[67] and cycloheptatriene[68].

3. Cyclo-1,3-Dienes

Few data are available for cyclopolyenes and they are not susceptible to analysis on a common basis (Table 7). In agreement with previous observations, the strain energy E_S is a minimum for the six-membered ring, although the transition from the five- to the six-membered system is accompanied by only a slight decrease of E_S, amounting to 0.6 kcal mol^{-1} (the analogous decrements in the series of cycloalkanes and cyclo-olefins are 5.8 and 4.0 kcal mol^{-1} respectively).

It follows from Table 7 that the main internuclear distances (C = C, =C–C=, and =C–C–) in the dienes considered are equal within the limits of experimental error. The only

notable change occurs in the valence angles on ring expansion. For example, the C = C–C(=) valence angle§ increases in the series of compounds considered (109.21°, 120.13°, 129.1°, and 129.0°), which does not agree with the variation of E_S. Thus, for the given class of compounds, it is so far impossible to discover the geometrical parameter which is most closely related to the changes in E_S or the SSCC $^3J_{H-H}$ of vinyl protons).

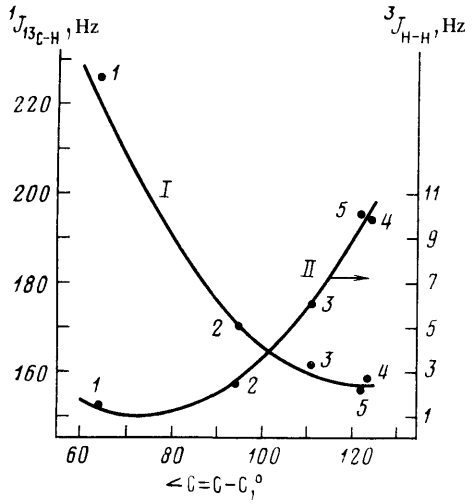

Figure 10. Variation of $^1J_{^{13}C-H}$ (curve *I*) and $^3J_{H-H}$ (curve *II*) with the C = C–C angles for C_nH_{2n-2} cycloalkenes; *1*)–*5*) see Fig.8; *I*) calculation by Eqn.(10); *II*) calculation by Eqn.(11).

4. Bicyclo[*n*,1,0]alkanes

(a) Correlation between the Strain Energy and the Structural Parameters

Thermochemical and geometrical data for bicyclo[*n*,1,0]-alkanes are compiled in Table 8. In their molecules there are several types of C–C distances which differ slightly from one another. The small differences between the C–C distances can be found accurately only by microwave measurements or by means of a combination of electron diffraction and spectroscopic data. The most interesting geometrical parameter in the above series of compounds is undoubtedly the length of the common C–C bond. The results of its measurement are available only for the first three representatives of the series, but they do not exhibit an appreciable correlation with the changes in the E_S of these compounds (Fig.11). This also applies to other individual C–C distances in these molecules.

The C–C–C valence angles in bicycloalkanes differ from those in the compounds considered previously by the presence of a tertiary carbon atom. The value of this angle for isobutane (110.8°) [154] was adopted as the reference value. The sum of the differences $\Delta\alpha = (110.8° - \alpha_1) + (110.8° - \alpha_2) + (110.8° - \alpha_3)$ was adopted as the measure of the strain in the three C–C–C angles around the tertiary carbon atom. The choice of the angles α_1, α_2, and α_3 is explained below in relation to bicyclo[1,1,0]butane:

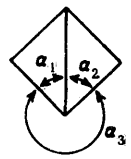

Fig.11 shows that the deformation of the angles about the tertiary carbon atom and the strain energy vary similarly in the series of condensed hydrocarbons and Fig.12 presents the variation of E_S as a function of the average angle $\angle C-C-C_{av} = \alpha_{av} = (\alpha_1 + \alpha_2 + \alpha_3)/3$. The corresponding equation is

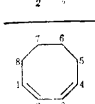
$$E_s = 168.2 - 1.374\,\alpha_{av}\,. \qquad (12)$$

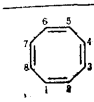
An analogous relation is obtained when account is taken of the C(1)–C(2)–C(3) valence angles (α) in a large ring, which are 60°, 89.5°, and 100.9° respectively according to calculations for the first three compounds in Table 8. The corresponding correlation equation is

$$E_s = 110.5 - 0.706\,\alpha\,. \qquad (13)$$

The dihedral angles θ at which the plane of the three-membered ring is inclined relative to the plane of the ring condensed with it have also been measured for the hydrocarbon investigated. The variation of these angles is not consistent with the variation of the E_S, as can be seen from Fig.13. Nor has a correlation been observed between E_S and the average C–C distances, which amount to 1.498, 1.529, 1.524, and 1.535 Å respectively for the saturated hydrocarbons of the bicyclo[n,1,0] series investigated (Table 8).

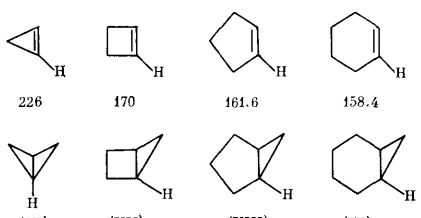
(b) Correlation between the Structural Parameters and the SSCC





Few data are available for the SSCC for condensed bicyclic systems containing a three-membered ring. The geometrical and thermodynamic parameters of bicyclo[*n*,1,0]alkanes have been determined only for the first four members of the series. Fig.13 presents the dependence of the constant $^1J_{^{13}C-H}$ (C is the common atom of the two rings) on E_S and the angle θ. All the quantities in the range indicated vary in parallel but E_S increases more appreciably (than $^1J_{^{13}C-H}$ and θ) on passing from bicyclo[3,1,0]hexane to bicyclo-[2,1,0]pentane, but changes little on passing from the latter to bicyclo[1,1,0]butane. Nor is there a full correspondence between the changes in E_S and the changes in the $(C-C-C)_{av}$ angle. At the same time the constant $^1J_{^{13}C-H}$ varies linearly with the angle θ, a geometrical parameter of the bicyclic condensed molecule, which can be expressed by the equation

$$^1J_{^{13}C-H} = -176.0 + 3.123\,\theta\,. \qquad (14)$$



It is of interest to discover how $^1J_{^{13}C-H}$ changes when the double bond in the cycloalkene is replaced by a three-membered ring.

§The reference value of this angle, obtained[140] for butadiene, is 123.3(0.5)°.

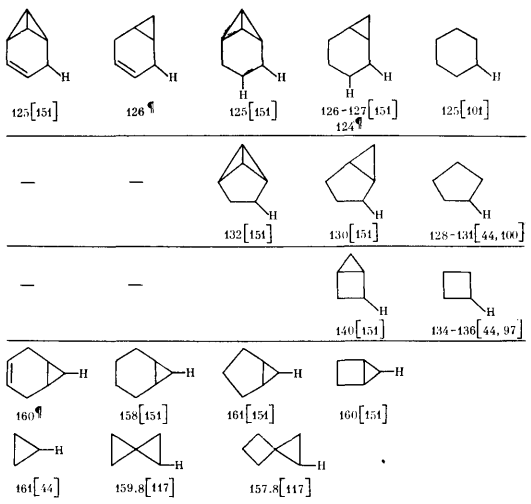
Note. All the experimental values of ΔH°_f were taken from Pedley and Rylance[88] except $\Delta H^{\circ}_{f(G)}$ for cyclo-octa-1,3-diene which we calculated from the enthalpy of hydrogenation obtained in acetic acid solution at 25 °C.[7] We assume that the calculated value is reliable because the corrections disregarded in the calculation (the differences between the ΔH of solution and evaporation of cyclo-octa-1,3-diene and cyclo-octane) are in this case small. This follows from a comparison of the enthalpy of hydrogenation of its isomer cyclo-octa-1,5-diene obtained in acetic acid solution[7] with the value calculated from the enthalpies of combustion of cyclo-octa-1,5-diene (ΔH°_c = −1186.46 ± 0.31 kcal mol^{-1} [132]) and cyclo-octane[88].

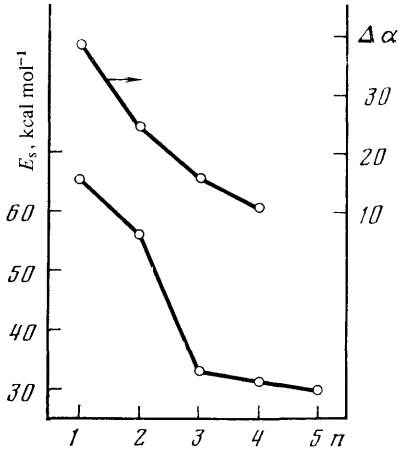


It is found that the bicyclic hydrocarbons (VI)–(IX) have higher constants than the corresponding cycloalkenes, the difference decreasing on passing from compound (VII) to (IX). The bicyclobutane (VI), for which $^1J_{^{13}C-H}$ is smaller than for cyclopropene, is an exception. The constants $^1J_{^{13}C-H}$ of the more complex polycyclic strained compounds (X)–(XII), whose composition includes the bicyclobutane fragment, are known.

Their geometrical and chemical parameters are unknown, but one can postulate that in the above series of compounds the strain energy E_S and the dihedral angles θ in the bicyclobutane fragment will diminish on passing from compound (X) to (VI), i.e. in conformity with the variation of the constant $^1J_{^{13}C-H}$.[151]

It is of interest to compare the values of $^1J_{^{13}C-H}$ for certain mono-, bi- and tri-cyclic hydrocarbons. Whereas the corresponding SSCC for the carbon atom common to both rings varies significantly with increase of the size of the larger ring and varies linearly with the dihedral angle θ (Fig.14), the constant $^1J_{^{13}C-H}$ for the nuclei of the "non-bridging" carbon atoms retains the specific value characteristic of the given ring and changes only slightly from compound to compound (the values of $^1J_{^{13}C-H}$ are given

under the formulae of the compounds below):



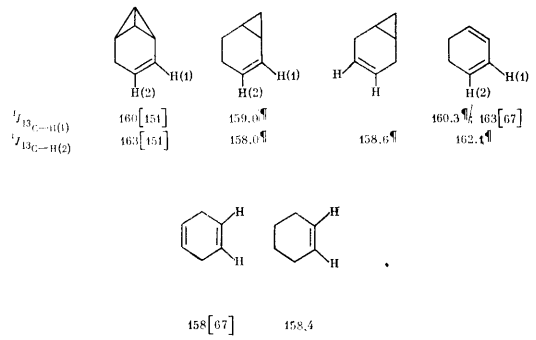


Figure 11. Variation of the strain energy E_S and $\Delta\alpha$ involving the tertiary carbon atom in bicyclo[n,1,0]alkanes: *1*) bicyclo[1,1,0]butane; *2*) bicyclo[2,1,0]pentane; *3*) bicyclo[3,1,0]hexane; *4*) bicyclo[4,1,0]heptane; *5*) bicyclo[5,1,0]octane.

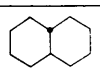
It is also noteworthy that virtually identical values of $^1J^{13}C - H$ (involving the double bond) are characteristic of the unsaturated hydrocarbons presented below. The constants $^1J^{13}C - H(2)$ of tricycloheptene and the conjugated cyclohexadiene are somewhat larger:

5. Bicyclo[n,m,1]alkanes

(a) Correlation between the Strain Energy and Structural Parameters

The geometrical features of hydrocarbons of this class have been more thoroughly investigated than their thermochemistry†. We shall therefore carry out only a qualitative comparison of the geometrical parameters, using partly the calculated strain energies taken from Allinger et al.[17] and Engler et al.[18] (Table 9 and Fig.15).

Several hydrocarbons in this series have been reinvestigated but only in the case of norbornane were the errors of previous studies revealed by an electron diffraction investigation[163]. The situation is much less clear for bicyclo[1,1,1]pentane[158,159] and bicyclo[2,1,1]hexane[160,161]: for each of these compounds, Table 9 presents two sets of geometrical parameters. It is difficult to make a choice between them. The results for the bicyclo[2,1,1]hexane are striking: the author of a later study[161] claimed that his data were more accurate than the results of previous measurements[160]. Nevertheless his results[161] seem to be anomalous on the corresponding plots, deviating from the general relations. We therefore decided not to include them in the derivation of the correlation equations (16) and (17); they are shown in Fig.16 for comparison (see the filled circles).



We shall consider how individual geometrical parameters vary, namely (a) the internuclear distances, (b) the valence angles, and (c) the dihedral angles.

(a) The most common geometrical element in the given series of hydrocarbons is the $-HC-CH_2-CH-$ bridge. The exact measurement of the C–C distances in the bridge involves a number of difficulties because the contributions of these distances to the overall diffraction patterns diminish significantly with increasing complexity of the molecule. We preferred to employ in this case the average distance $(C-C)_{av}$, which has been determined more accurately and which characterises the strain in the molecule as a whole. The variation of this parameter is illustrated graphically in Fig.15.

¶These data have been obtained by Yu.N.Luzikov in the Laboratory of NMR Spectroscopy of the Faculty of Chemistry of Moscow State University.

†Most thermochemical studies have been made on compounds of the norbornane series. Some compounds have been reinvestigated in different laboratories[155]. The results do not agree fully with one another and require further experimental confirmation.

Table 8. The enthalpies of formation, strain energies, structural parameters, and SSCC of the bridgehead C–H bond in bicyclo[*n*,1,0]alkanes.

Note. The experimental values of ΔH_f° for the second, fourth, and fifth compounds were taken from Kozina[141] and those for the remaining compounds are from Pedley and Rylance[88].

(b) The valence angle ∠C–C–C (α) involving the bridging carbon atom in the symmetrical bicyclo[*m*,*n*,1]alkanes increases linearly on expansion of the rings on either side of the bridge, which is described by the following equation[5]:

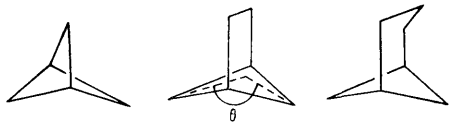
$$\alpha = 0.836 + 18.282p^\circ , \qquad (15)$$

where $p = m + 3$. When this relation is recalculated in terms of the deviation from the standard angle 112.6°, another plot is obtained, which is also shown in Fig. 15.

(c) The geometrical parameters considered above vary almost linearly on expansion of the rings, while E_S varies non-linearly. The parameter which exhibits the best correlation with E_S proved to be the dihedral angle θ; it is shown below for bicyclo[1,1,1]pentane and bicyclo[2,1,1]-hexane.

The dependence of the angle on E_S is illustrated in Fig. 16 and is described by the equation

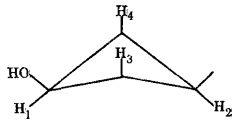
$$E_S = -1173.2 + 10.55\,\theta . \qquad (16)$$



Bicyclo[*n*,1,1]alkanes, containing a four-membered fragment occupy a special place. The individual characteristics of these molecules are presented in Fig. 17; the data for cyclobutane have been included for comparison. Evidently, in contrast to the preceding case, the best correlation is observed between E_S and the ∠C–C–C (α) involving the secondary carbon atom in the four-membered ring (Fig. 18), which is described by the following empirical equation:

$$E_S = 430.5 - 4.550\,\alpha . \qquad (17)$$

(b) Correlation between Structural Parameters and SSCC



There are virtually no systematic data on the geometry and the SSCC for bridged hydrocarbons. The successive changes in the above parameters can be illustrated only in

relation to the three bicyclic hydrocarbons (XIII)–(XV):

(XIII) (XIV) (XV)

Each of these contains the cyclobutane fragment[53]. One of the characteristic parameters in the NMR spectra of compounds of this kind is the SSCC of the *exo, cis* protons via four σ-bonds, for which one can postulate a dependence on the dihedral angle θ in the four-membered ring (Table 9). The series of compounds considered can be logically completed by cyclobutane itself. The exact value of the constant $^4J_{H-H}$ of this compound is unknown but it is close to zero according to Meiboom and Snyder[167]. [$^4J_{H(1)-H(2)} = -0.01$ and $^4J_{H(3)-H(4)} = +0.01$ for cyclobutanol[168].]

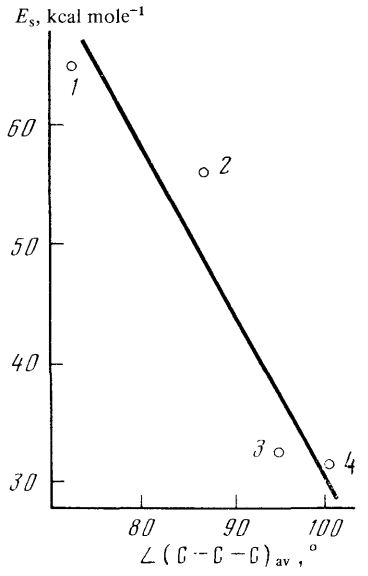


Figure 12. Variation of E_S with the average $(C-C-C)_{av}$ valence angle involving the tertiary carbon atom in bicyclo[n,1,0]alkanes: *1*)–*4*) see Fig.11; straight line—calculated by Eqn.(12).

Figs.19 and 20 (based on the data in Table 9) illustrate the changes in the constant $^4J_{H-H}$ and the angle θ for the hydrocarbons (XIII)–(XV) and cyclobutane as well as the linear relation between them, described by the equation

$$^4J_{H-H} = -0.285\,\theta + 44.026 \quad (18)$$

In determining the above correlation, bicyclo[1,1,0]butane should have been included, but two experimental values of the constant $^4J_{H-H}$, differing significantly from one another, are indicated in the literature: 10 Hz [86] and 5.9 Hz [150] (the latter agrees with theoretical values[152]). According to the relation established [Eqn.(18)], $^4J_{H-H}$ = 10 Hz should correspond to a dihedral angle of 122.4° for bicyclo[1,1,0]butane; however, when account is taken of the specific features of the structure of a system with two condensed three-membered rings, then the agreement with the data of Wiberg et al.[36] cannot apparently serve as a criterion of their validity.

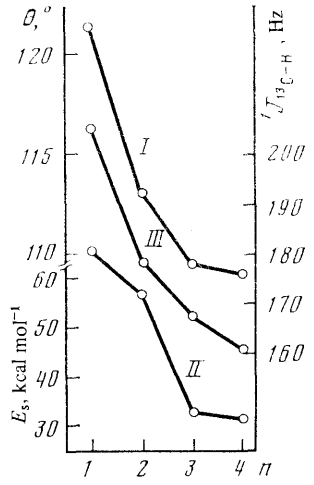

Figure 13. Variation of the dihedral angles θ (curve *I*), E_S (curve *II*), and $^1J_{^{13}C-H}$ (curve *III*) in bicyclo[n,1,0]-alkanes with the size of the larger ring: *1*)–*5*) see Fig.11.

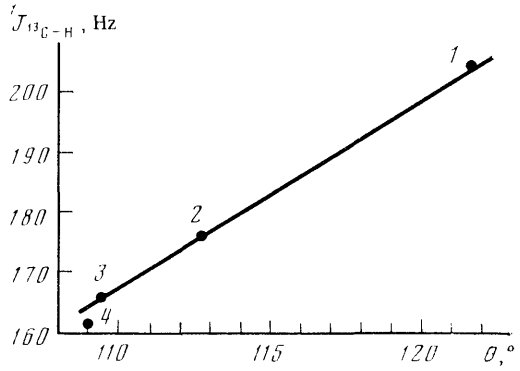

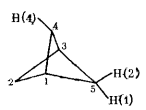

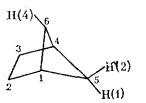

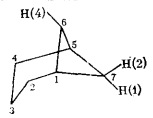

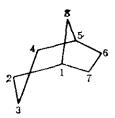

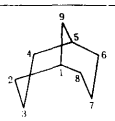

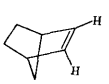

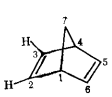

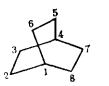

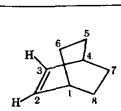

Figure 14. Variation of $^1J_{^{13}C-H}$ with θ for bicyclo[n,1,0]-alkanes: *1*)–*4*) see Fig.11; straight line—calculated by Eqn.(14).

It is possible to quote examples of successive changes in $^3J_{H-H}$ in a series of bridged hydrocarbons where five- or six-membered unsaturated rings are the repeating

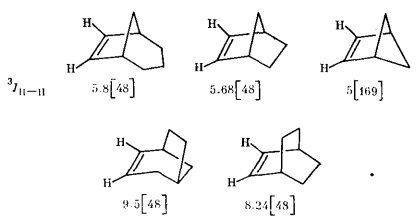

Table 9. The enthalpies of formation, strain energies, structural parameters, and SSCC of bicyclo[*m*,*n*,*k*]alkanes.

elements[48]:

The values of E_S for both series increase from left to right, i.e. in conformity with the decrease of the SSCC of the vicinal protons. Probably $\angle C = C-C$ varies in the same sequence (analogously to the variation of the corresponding parameters for cycloalkenes).

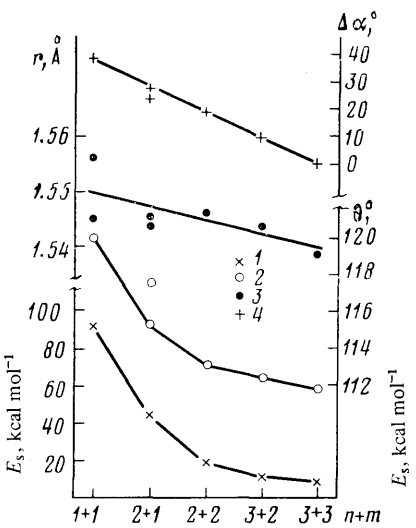

Figure 15. Variation of the strain energy E_S (*1*), the average $(C-C)_{av}$ internuclear distance (r) (*3*), the difference $\Delta\alpha = 112.6° - \alpha$ (α is the C–C–C angle in the bridge) (*4*), and the dihedral angle θ (*2*) in bicyclo[n,m,1]alkanes with the size of the ring; bicyclo[1,1,1]pentane and bicyclo-[2,1,0]hexane were investigated twice.

III. CONCLUSION

The most general comment which can be made on the basis of the data considered concerns Eqn.(1). The experimental data presented in Section II show that in fact two separate relations exist:

$$E_s\text{-molecular geometry and SSCC-molecular geometry.} \qquad (1')$$

They cannot be combined in terms of geometrical data because in most cases different geometrical parameters are involved in the quantitative relations.

The only deviation from this rule arises in the case of cycloalkenes [see Eqns.(8), (10), and (11)]. However, one should note that, despite the absence of quantitative relations, the SSCC vary in parallel with E_S. In those cases where deviations are observed from such parallel variation [for example in the cyclo-octane–cyclononane (Fig.5) and cyclohexene–cycloheptene (Fig.9) transitions], an experimental test of the corresponding parameters would be desirable.

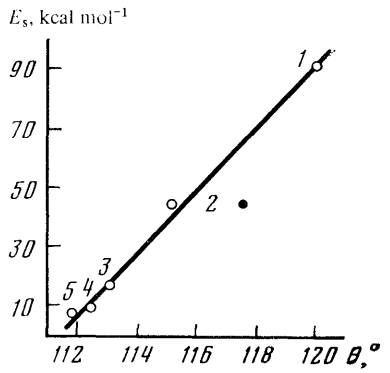

Figure 16. Variation of the strain energy with θ for different bicyclic hydrocarbons: *1*) bicyclo[1,1,1]pentane: *2*) bicyclo[2,2,1]hexane; *3*) bicyclo[2,2,1]heptane; *4*) bicyclo[3,2,1]octane; *5*) bicyclo[3,3,1]nonane; straight line—calculated by Eqn.(16); filled circle—Chiang's data[161].

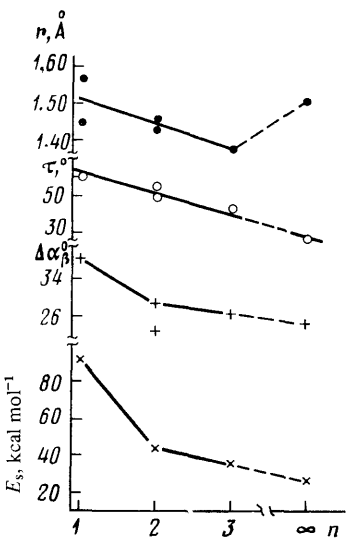

Figure 17. Variation of the strain energy E_S, the average $(C-C)_{av}$ internuclear distance (r), the dihedral angle in the four-membered fragment γ, and the difference $\Delta\alpha = 112.6° - \alpha$ (α is the C–C–C valence angle at the secondary carbon atom in the four-membered fragment) in bicyclo[n,1,1]-alkanes and cyclobutane (the convention is adopted that for this compound $n = \infty$).

For each series of the cyclic hydrocarbons considered, there is a definite correlation between the SSCC and the angular parameters of the molecule; no dependence on the

internuclear distances has been observed. One can postulate on the basis of the available (limited) data, that such correlations between the SSCC and the angular parameters of the molecule can be found also in other series of hydrocarbons when the amount of the relevant experimental data is sufficient.

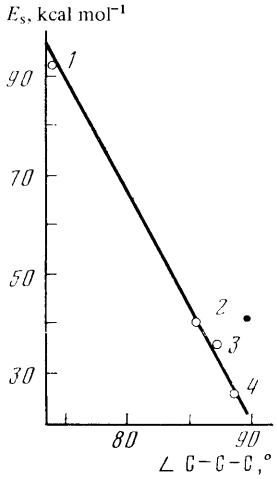

Figure 18. Variation of the strain energy with the C–C–C valence angle in the four-membered fragment in different bicyclic hydrocarbons: *1*) bicyclo[1,1,1]pentane; *2*) bicyclo[2,1,1]hexane; *3*) bicyclo[3,1,1]heptane; *4*) cyclobutane; straight line—calculated by Eqn.(17); filled circle—Chiang's data[161].

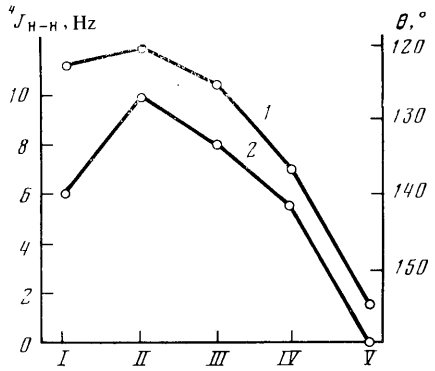

Figure 19. Variation of the dihedral angle θ in the four-membered fragment (curve *1*) and $^4J_{H-H}$ (curve *2*) in bicyclo[*n*.1.1]alkanes (*II–IV*), bicyclo[1,1,0]butane (*I*), and cyclobutane (*V*).

If the variation of E_S in the series of compounds considered as a function of the number of carbon atoms *n* is followed {for bicyclo[*n*,1,0]alkanes, *n* is the number of carbon atoms in the larger ring and for symmetrical bridged hydrocarbons it is the number of carbon atoms in each ring} (Fig.21), it is found that the nature of the variation of E_S in the series of bicyclo[*n*,1,0]alkanes and cycloalka-1,3-dienes is approximately the same, the values of E_S for rings with *n* between 5 and 8 being similar. In each series of compounds hydrocarbons containing six-membered rings have the smallest values of E_S regardless of which structural parameters (bond length, valence or dihedral angles) are mainly used to determine E_S. Bicyclo[*n*,1,0]alkanes, where the minimum is displaced to the hydrocarbon with the larger seven-membered ring, are an exception, but in this case there are grounds for recommending the redetermined values of ΔH_f° for bicyclo[5,1,0]octane#.

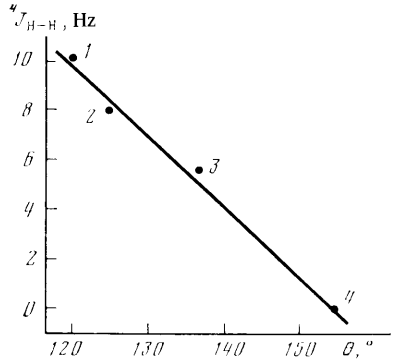

Figure 20. Variation of $^4J_{H-H}$ with θ: *1*)–*4*) see Fig.18.

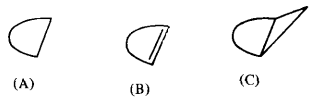
The introduction of a correction for the contribution of the energy $p\Delta V$ to E_S does not alter the nature of the curves, which are merely displaced by 0.6 or 1.2 kcal mol^{-1}.



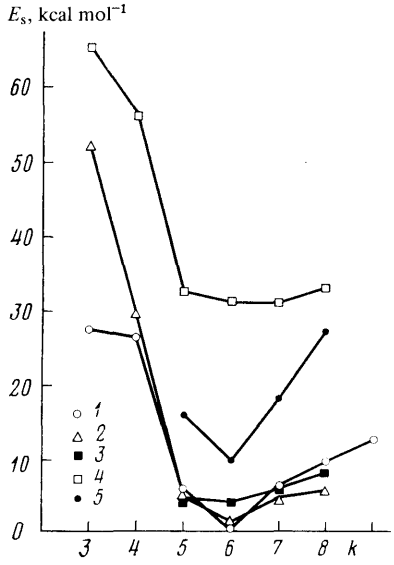
The strain energies E_S of cyclohexane, cyclohexene, cyclohexa-1,3-diene, and bicyclo[2,2,2]octane per six-membered ring are −0.2, 1.1, 4.2, and 4.9 kcal mol^{-1} respectively. The conformation of the six-membered ring in these hydrocarbons varies as follows: chair → half-chair → flattened half-chair → boat. However, one should note that the above values of E_S cannot be used to estimate the energy of the chair → half-chair → boat conformational transition for a six-membered ring, since the values of E_S reflect the overall strain energy and not the conformational energy.

We examined above how E_S is related explicitly to the geometrical parameters and the SSCC and how it varies in a specific series of compounds with the number of carbon atoms. It is also of interest to trace the variation of the

---

#The value of ΔH_f° for bicyclo[4,1,0]heptane quoted by Dashevskii[16], whose results we have employed, differ from the other literature values by 2.3 kcal mol^{-1}. In this connection, the enthalpy of combustion of bicyclo[5,1,0]-octane has been redetermined. The following values (in kcal mol^{-1}) have been obtained at 298 K: $\Delta H_{c(L)}^\circ$ = −1218.80 ± 0.45; $\Delta H_{f(L)}^\circ$ = −11.82 ± 0.47; $\Delta H_{f(G)}^\circ$ = −1.42 ± 0.51; E_S = 32.1. This value of E_S is presented in Fig.21 (the experimental work has been carried out by L.P.Timofeeva).

relative values of E_S characterising the transition from cycloalkanes (A) to the corresponding cycloalkenes (B) and the bicyclo[n,1,0]alkanes (C):



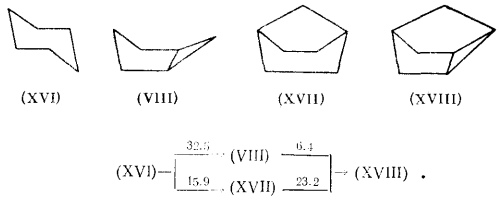


Figure 21. Variation of E_S in the series of cycloalkanes (*1*), cycloalkenes (*2*), cycloalkadienes (*3*), bicyclo[n,1,0]alkanes (*4*), and symmetrical bridged bicycloalkanes (*5*) with the number of carbon atoms in the ring for (*1*), (*2*), and (*3*), with the number of carbon atoms in the larger ring for (*4*), and with the number of carbon atoms in one of the rings for (*5*).

Fig. 21 presents the variation of E_S for each of these series and Fig. 22 presents the differences $\Delta E_S^{(1)} = E_S(B) - E_S(A)$ and $\Delta E_S^{(2)} = E_S(C) - E_S(A)$. Each of the quantities $\Delta E_S^{(1)}$ or $\Delta E_S^{(2)}$ considered separately corresponds to the additional strain in the cycloalkane molecule which appears as a consequence of the introduction of a double bond or a three-membered ring respectively. Comparison of the two sequences of the values of $\Delta E_S^{(1)}$ and $\Delta E_S^{(2)}$ demonstrates the approximately identical nature of their variations in series (B) and (C). It is known[145] that there are analogies between the conformations of the carbon ring in these hydrocarbons determined by the absence of internal rotation relative to the double bonds in series (B) or the common bond in the bicyclic systems (C).

It is of interest to trace the changes in E_S on passing from monocyclic to bicyclic and tricyclic hydrocarbons in the series below:

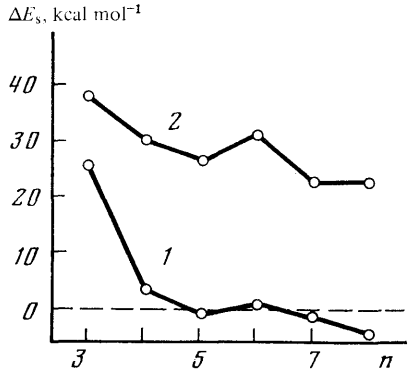

Figure 22. Variation of the differences $\Delta E_S^{(1)} = E_S(B) - E_S(A)$ (curve *1*) and $\Delta E_S^{(2)} = E_S(C) - E_S(A)$ (curve *2*).

(Unfortunately such examples are limited owing to the insufficient amount of experimental data.) The greatest change in E_S corresponds to the introduction of a three-membered ring into the system. The methylene bridge linking the first and fourth carbon atoms causes smaller changes in E_S, particularly when the trimethylene ring is already in the molecule. The overall change in E_S on passing from cyclohexane to the nortricyclene (XVIII) via compound (VIII) or (XIV) is virtually the same, which confirms the validity of the quantities used in the calculations.

On the basis of the empirical equations relating E_S to different geometrical parameters which have been derived, a slightly different meaning can be given to the reference values of r_0 and α_0. We recall that we adopted these values from data for the molecules with the minimum E_S, associated with the given geometrical parameter. For example, saturated hydrocarbons ranging from methane to n-heptane, *cis*-butene, and isobutane have been used as standards. With the aid of the above correlation equations, we can now carry out a kind of test of these values by determining them from the condition for the equality of E_S to zero. The values obtained from the empirical equations (we shall designate them by r_0' and α_0' respectively) can be regarded as generalised constants satisfying sets of molecules and related directly to E_S.

The values of r_0 and α_0 used previously are compared below with their analogues r_0' and α_0' calculated from empirical equations (4), (8), and (9):

C–C bond	$r_0 = 1.533$ (1) Å	$r_0 = 1.537$ Å	calc. by Eqn.(4),
C=C–C angle	$\alpha_0 = 125.4$ (0.4)°	$\alpha_0' = 124.5°$	calc. by Eqn.(8),
C–C–C angle	$\alpha_0 = 112.6$ (0.1)°	$\alpha_0' = 112.5°$	calc. by Eqn.(9).

It is noteworthy that the reference values of the angular parameters which we used above and the values calculated by Eqns.(8) and (9) are very similar. Evidently this shows that the selected acyclic systems are indeed free from angular strain, which arises in cyclo-olefins and is described by Eqns.(8) and (9). The discrepancy of 0.004 Å between r_0 and r_0' may not be fortuitous and may have a perfectly definite significance, because $r_0' = 1.537$ Å is virtually identical with the C–C distance in cyclohexane (1.536 Å), for which E_S is close to zero. The increase in the length of the C–C bond in cyclohexane may arise as a consequence of inevitable *gauche*-interactions[13]. Similar *gauche*-interactions in acyclic systems with a short-carbon chain are much less appreciable[39].

Analogous calculations using other empirical equations do not yield interesting results, which may be due to the specific features of the geometrical parameters considered or the inadequate number of experimental data [for example, the average angle $(C–C–C)_{av}$ in Eqn.(12)].

The Electronic and Steric Effects in Heterolytic Intramolecular Cyclisation Reactions

R.Valters

Data concerning the influence of the electronic and steric effects of substituents as well as the structure of the connecting units on the rate and equilibrium constants for cyclisation reactions, occurring as intramolecular nucleophilic addition to a trigonal carbon atom, are examined. The general characteristics permitting the prediction of the ease of ring closure and the stability of the heterocycles are specified.
The bibliography includes 166 references.

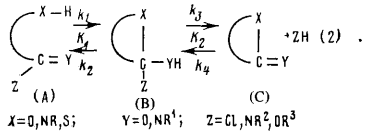
I. INTRODUCTION



The assessment of the influence of structural factors on intramolecular cyclisation reactions makes it possible to predict the ease of formation and the stability of heterocycles[1-3]. Factors promoting ring closure act similarly in the recyclisation reactions of heterocycles[4], in intramolecular catalysis[5-10], in the migration of acyl and other groups[8,10-12], and in other reactions which proceed with formation of cyclic transition states or cyclic intermediates. Studies of the mechanisms of enzymatic reactions[8,9,13-15], of the formation of chelates[16], and of the intramolecular hydrogen bond[17-19] are closely related to the problem of the influence of structural factors on intramolecular cyclisation.

The aim of the present review is to examine the influence of the electronic and steric effects of substituents at the reacting groups and the structure of the unit connecting them (the carrier system) on the relative stabilities of the heterocycles formed (represented by $\lg K$, where K is the ring–chain equilibrium constant) or on the ease of their formation (represented by $\lg k$, where k is the rate constant for the cyclisation reaction).

We shall confine ourselves to the consideration of the intramolecular nucleophilic reactions involving the addition of the O–H, N–H, and S–H groups to the multiple polar bonds C=Y [reactions (1)] occurring with subsequent elimination [reactions (2)] or without it, i.e. with retention or cleavage of the tetrahedral intermediate; there is yet another limitation, i.e. only the closure of the so-called[2] normal, i.e. five-membered, six-membered, and seven-membered, heterocycles will be considered†. The molecular fragment which constitutes the carrier system for the groups reacting with one another is designated by a half-circle in Eqns.(1) and (2).

(1)

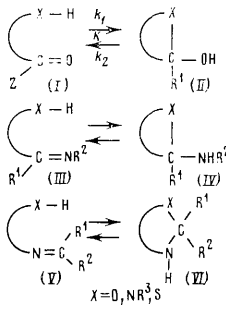
(2)

This choice makes it possible to employ the accumulated data on the ring–chain isomerism of organic compounds[20-23]; it is dictated primarily by the availability of quantitative literature data precisely for such reactions.

In reaction (1) the thermodynamic stability of the ring will be characterised by the ring–chain equilibrium constant K or the free energy difference ΔG, which is proportional to the logarithm of K. It is most rational to examine the influence of the relevant structural factors precisely on the equilibrium constant K. However, one must then take into account the fact that small changes in structure very frequently displace the system from the state of tautomeric equilibrium[12,23] and the possibility of employing the equilibrium constant for comparative purposes is lost. The use of the enthalpy and entropy components (ΔH and ΔS) of the free energy difference is limited by the comparatively small amount of experimental data. The use of ΔH and ΔS involves a number of uncertainties which are difficult to overcome and which have been examined by Jencks[9] (p.246). Among these, the impossibility of applying corrections for solvation effects is most important for reactions in solutions.

The energetic aspect of intramolecular reactions with separate analysis of the enthalpy and entropy contributions and their comparison with intermolecular reactions have been described in a review[24]. It is easy to show that the estimation of the individual components of the difference between the potential energies of the open-chain and cyclic structures, which are due to changes in bond lengths, the deformation of valence angles, the non-bonding and electrostatic interactions, steric strain, solvation, and the formation of hydrogen bonds, is difficult to achieve experimentally.

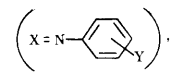
†The influence of structural factors on cyclisation reactions with formation of large rings has been examined in a recently published review: G.Illuminati and L.Mandolini, Acc.Chem.Res., 1981, **14**, 95.



The use of the cyclisation rate constant k_1 for the estimation of the ease of formation of the ring is associated with another type of uncertainty. The transformation (A) → (B) [Scheme (1)] consists of three stages: the abstraction of a proton from the group X–H, the formation of the X–C bond, and the addition of a proton to Y. The sequence of these stages is determined by the acidity of the groups X–H and Y–H and also by the protolytic properties of the medium and is not the same for different systems[23]. The ease of formation of the ring is characterised by the constant k_1 (or the corresponding activation energy $\Delta G^{\neq}$) only when the ring closure stage, i.e. the formation of the X–C bond, is slowest and the transition state has a cyclic structure. However, this is not always the case, because it has been shown experimentally for certain ring–chain tautomeric systems that the rate is limited by the proton transfer stage[25–27].

The suitability of thermodynamic and kinetic characteristics of the second group of reactions [reactions (2)] for the estimation of the stability and ease of formation of heterocycles is limited by the presence of the stage involving the cleavage of the tetrahedral intermediate. The equilibrium (B) ⇌ (C) is usually displaced to the right, but it is necessary to take into account the fact that the equilibrium constant $K = [B]/[A] = k_1/k_2$ and k_2 can be determined experimentally only by an indirect method.

The employment of the kinetically determined rate constant for the transformation (A) → (B) for our purposes is also correct (when account is taken of the considerations presented above) only when $k_1 < k_3$.

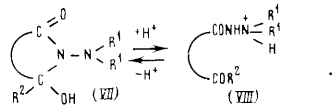


II. ELECTRONIC EFFECTS OF SUBSTITUENTS AT THE REACTING GROUPS

Inspection of a large number of ring–chain equilibrium systems of the type (I) ⇌ (II), (III) ⇌ (IV), and (V) ⇌ (VI) [23] permits the conclusion that the stability of the cyclic form, produced as a result of the intramolecular nucleophilic addition of the group X–H to a polar multiple bond, increases in the sequence of atoms X = O < N < S (naturally, other structural conditions being equal or similar).

This sequence agrees with the equilibrium constants for intermolecular reactions involving addition to the C=O bond[28] and can be accounted for both by the increase of the nucleophilicity of the atom X and by the smaller strain energy[24] in sulphur-containing heterocycles compared with the oxygen- and nitrogen-containing heterocycles.

The influence of the nucleophilicity of the atom X on the stability of the cyclic isomer can be traced in the series of amino-derivatives with different substituents at the nitrogen atom. Thus the introduction of electron-donating substituents Y into the phenyl group at the nitrogen atom



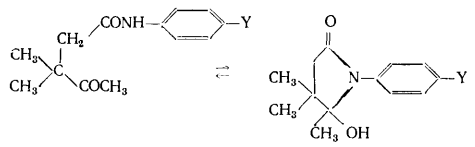
shifts the equilibrium towards the cyclic form, while electron-accepting substituents shift the equilibrium in the opposite direction[29,30]. The foregoing is confirmed by the negative value of the constant ρ,[30] obtained from the correlation between the ring–chain equilibrium constants for *N*-arylamides of 3,3-dimethyl-levulinic acid and the polar constants of the substituents Y (Table 1).

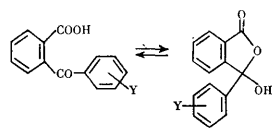
N-Methylated derivatives (X = NCH_3) almost always exhibit a greater tendency towards cyclisation than their analogues unsubstituted at the nitrogen atom (X = NH).[38–48] Several exceptions can be explained[44–46] by the steric influence of the methyl group, which destabilises the cyclic structure. As the length and degree of branching of the alkyl substituent at the nitrogen atom increase, its electronic influence cannot be estimated, because the steric effects are much stronger.

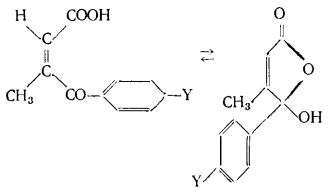
The cyclic structure is also destabilised by the decrease of the nucleophilicity of the nitrogen atom as a result of the introduction of aryl or acyl substituents at this atom[23].

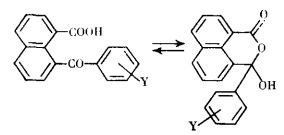
The protonation of the dialkylamino-group in the cyclic isomer of the *N,N*-dialkylhydrazide of a 3-acylcarboxylic acid proceeds with ring opening [(VII) → (VIII)], while deprotonation is accompanied by the reverse process[47,48]. This phenomenon can be explained by the influence of the strong $-I$ effect of the substituent $N^+HR_2^1$, which reduces the nucleophilicity of the second nitrogen atom.

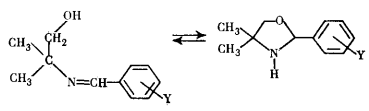
The higher ring–chain equilibrium constants in solutions for 2-acylmercaptoperimidines compared with 2-acylmercaptobenzimidazoles have been explained[49] by the greater basicity of the perimidine nitrogen atom compared with the benzimidazole nitrogen atom.

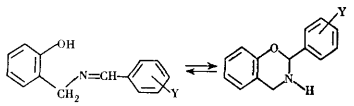


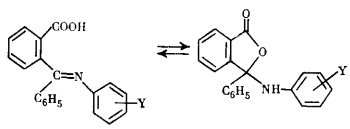


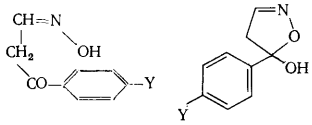












In the series of 3- and 4-acylcarboxylic acid [(I) ⇌ (II), X = COO] it is easy to trace the influence of the structure of the substituent on the ring–chain equilibrium constants. A pronounced shift of the equilibrium towards the cyclic form in the series of substituents aryl < alkyl < H is observed[21,23]. The enhanced stability of the open-chain isomers of aroylcarboxylic acids is caused not only by the reduced electrophilicity of the carbon atom of the group ArCO but also by the gain of the conjugation energy.

For tautomeric systems producing the cyclic form as a result of intramolecular addition to the C=N bond, the pattern of the influence of the electronic effect of substituents at this bond is more complex[50].

For hydroxyaldehyde imines [(III) ⇌ (IV), X = O, R^1 = H], the equilibrium is much more displaced towards the cyclic form than for hydroxyketone imines [(III) ⇌ (IV), X = O, $R^1 = CH_3$].[51] Similarly the *N*-(2-hydroxyalkyl)hydrazones of aldehydes show a greater tendency towards cyclisation compared with the *N*-hydroxyalkylhydrazones of ketones[50,52]. However, in this case the electronic effect of the alkyl group, which reduces the electrophilicity of the carbon atom in the C=N bond, is overlapped by the stronger steric effect of the alkyl substituent, which destabilises the cyclic structure[50–52].

The opposite effect has been observed[53] in the series of *N*-(2-mercaptoalkyl)hydrazones of aromatic aldehydes: on passing from a benzaldehyde derivative to an acetophenone derivative, the ring–chain equilibrium shifts towards the

Table 1. Examples of the linear correlation of the ring–chain tautomeric equilibrium constants $K = [B]/[A]$ and the polar constants of the substituents Y in the benzene ring at the reaction centre.

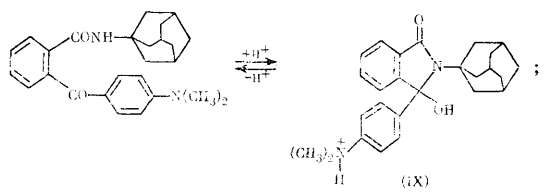
Note. K_0 is the ring–chain equilibrium constant for the unsubstituted derivative (Y = H), K the constants for substituted derivatives, n the number of compounds with different substituents Y, and r the correlation coefficient. The signs of the constants ρ are quoted in accordance with the condition $K = [B]/[A]$. Sheiman et al.[30] and Paukstelis and Lambing[34] calculated the equilibrium constants from the formula $K = [A]/[B]$.

*Infrared spectroscopy. ** Ultraviolet spectroscopy.

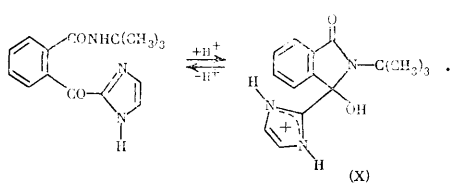
cyclic form, which has been explained by the influence of the breakdown of the conjugation $\rangle N-N=\overset{|}{C}-Ar$ in the open-chain isomer after the introduction of the methyl group.

The *N*-(2-hydroxybenzyl)imines of aromatic aldehydes exhibit a smaller tendency towards cyclisation than the corresponding derivatives of acetone or cyclohexanone[35] owing to the gain in the conjugation energy in the open-chain isomer.



An increased stability of the cyclic form has been observed in the *N*-arylimines of 5-hydroxypentanal compared with the *N*-alkylimines[51,54,55]. The authors explain this remarkable effect by the energy gain in the $p-\pi$ conjugation of the unshared electron pair of the nitrogen atom with the arene ring in the cyclic isomer compared with the $\pi-\pi$ conjugation,

which is disrupted, according to the authors, by the non-coplanarity of the C=N–Ar system in the open-chain isomer.

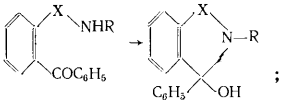


The introduction of an acyl group at the imine nitrogen atom in the imines of 2-benzoylbenzenesulphonamides stabilises the cyclic structure of 3-acylamino-3-phenylbenzoisothiazoline 1,1-dioxides[56]. The introduction of electron-accepting substituents Y in the phenyl groups of the C=O or C=N bonds [R^1 and R^2 in compounds (I)–(VI)] as a rule shifts the equilibrium towards the cyclic form, while electron-donating substituents act in the opposite direction. This conclusion confirms the examples of the linear correlation of the ring–chain tautomeric equilibrium constants for aroylcarboxylic acids and their *N*-arylimines, *N*-(2-hydroxybenzyl)- and *N*-(2-hydroxyalkyl)aldimines, and 3-aryl-1-hydroxyimino-3-propanones with the polar constants of the substituents Y ($\rho > 0$), which are presented in Table 1.

In addition, for certain systems, for example, for *N*-t-alkyl-2-aroylbenzamides, the introduction of electron-accepting substituents in the aroyl group made it possible to obtain cyclic isomers of compounds which did not undergo cyclisation in the absence of such substituents[57,58]. The rate constants for the interconversions of the isomers then increase and the equilibrium shifts towards the cyclic form[59].

An interesting example of the stabilisation of the cyclic form of *N*-t-alkyl-2-(4-dimethylaminobenzoyl)benzamides (IX) and 2-(2-imidazoylcarbonyl)benzamides (X) by the protonation of the dimethylamino-group or the imidazole ring has recently been observed[60–62].

(IX)



(X)

The protonation of the nitrogen-containing substituent increases its $-I$ effect, which enhances the electrophilic properties of the carbon atom of the C=O group and displaces the equilibrium towards the cyclic form. Deprotonation is accompanied by the reverse process.

Numerous qualitative and quantitative data[20–23] confirm the following general rule: the influence of the electronic effects of substituents on the relative stabilities of cyclic isomers formed as a result of the intramolecular nucleophilic addition of the group X = H to the polar multiple bonds C=O, C=N, etc. can be predicted by estimating the influence of these substituents respectively on the nucleophilic and electrophilic properties of the atoms between which the bond is formed on ring closure. As the nucleophilic properties of the atom X are enhanced and (or) with increase of the electrophilicity of the carbon atom in the groups C=O, C=N, etc., the equilibrium shifts towards the cyclic form.

This rule applies not only to the substituents R^1, R^2, and R^3 in compounds (I)–(VI) but also to the electronic influence of the structure of the connecting unit and the substituents incorporated in this unit. Thus it has been shown that 2-benzoylbenzenesulphinamides are capable of intramolecular cyclisation [(XI) ⇌ (XII), X = SO],[63] whereas the analogous reaction for 2-benzoylbenzenesulphonamides (XI, X = SO_2) is not feasible[64]. This phenomenon can be explained by the reduction of the nucleophilicity of the nitrogen atom on passing from the sulphinamide to the sulphonamide group.

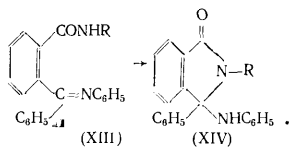
(XI) (XII)

X = SO, SO_2 .

However, the estimation of the electronic influence of the structure of the connecting unit on the reacting groups is associated with difficulties due to the overlap of the electronic effects with the steric effects, which alter the geometry of the mutual approach of the reacting groups.

The influence of the electronic effects of the substituents on the ring–chain equilibrium constants can be effectively predicted in conformity with the principle of the linearity of the variation of the free energies in those cases where the substituents are introduced into aryl groups at the reaction centres.

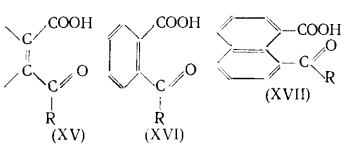
When the substituents R^1, R^2, or R^3 in compounds (I)–(VI) are varied in the sequence H, alkyl, aryl, their electronic influence is much more difficult to estimate, because it is then necessary to take into account also their steric effects, the gain in the stabilisation energy of the corresponding isomers as a result of the conjugation of the C=O and C=N bonds or the *p* electrons of the nitrogen atom with the aryl substituents, the stabilisation of the individual isomers as a result of the formation of intramolecular and intermolecular hydrogen bonds, or various solvation effects.



An estimate[23] of the thermodynamic stabilities of cyclic isomers from the changes in the nucleophilic and electrophilic properties of the reaction centres aroused objections[65], because a kinetic characteristic was used to estimate thermodynamic quantities. Although the stabilities of the corresponding cyclic isomers are usually satisfactorily correlated with the O < N < S nucleophilicity series in relation to the electrophilic carbon, one may agree that, in comparing different atoms X acting as nucleophilic centres, it is necessary to take into account also factors such as the different strains in the rings formed, the different capacities for the formation of hydrogen bonds, etc. However, under the influence of substituents, the difference between the free energies of the isomers varies in proportion to the difference between the free energies of activation, i.e. the polar constants of the substituents are correlated both with the equilibrium constants and with the reaction rate constants[66].

In other words, the changes in the structures of the carbonyl compounds are reflected similarly in the rates and equilibria of non-catalysed reactions involving addition to the carbonyl group, because both the transition state and the final product are destabilised by electron-accepting substituents to a smaller extent than the initial carbonyl compound[28].

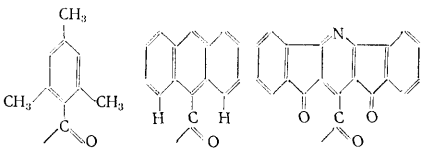
III. STERIC EFFECTS OF SUBSTITUENTS AT THE REACTING GROUPS



In order to estimate the steric influence of substituents at the reacting groups on the relative stabilities of cyclic isomers, the influence of the substituents on the possibility of the optimum intramolecular mutual approach of the reaction centres is usually considered. A more profound approach involves the calculation or empirical estimation of the difference between the energies of the non-bonding interactions between the substituent and the remainder of the molecule in the open-chain and cyclic isomers.

An increase in the length and branching of the alkyl substituent at the nitrogen atom in aminocarbonyl compounds [(I) ⇌ (II), X = NMe > NEt > NPr-iso > NBu-t] destabilises the cyclic structure. There exist examples of such influence on the ring–chain isomerism of *N*-monosubstituted amides of acylcarboxylic acids[21,23,56,67–69], *N*-alkyl-*N'*-(3-oxoalkyl)-thioureas[70], *S*-(2-oxoalkyl)dithiocarbamates[71], and other compounds[23]. Similar features have also been observed for reactions involving intramolecular addition to the C=N bond. Increasingly severe conditions are required for the isomerisation (XIII) → (XIV) in the presence of the series of substituents R = Pr, $PhCH_2$, iso-Pr, or t-Bu at the nitrogen atom[72]. The reverse reaction—the thermal isomerisation of the aminolactam [(XIV) → (XIII)]—has been achieved for the first time in the case of *N*-t-butylamide[73,74]:

Branching of the alkyl substituent at the keto-group [R^1 in formulae (I) and (II)] in different systems has the opposite influence on the stability of the cyclic form:



(1) If the connecting unit contains a double bond or an aromatic ring conjugated with the keto-group, as happens in *cis*-3-acylacrylic acids (XV),[75] 2-acylbenzoic acids (XVI),[76] and 8-acylnaphthoic acids (XVII),[33] then an increase in the bulk of the alkyl substituent R in the sequence Me < Et < iso-Pr < t-Bu shifts the equilibrium (I) ⇌ (II) (X = COO) towards the cyclic form:

With increase of the bulk of R, the keto-group "unscrews itself" from the plane of the double bond or the aromatic ring and assumes the conformation most suitable for intramolecular addition; furthermore, the electrophilicity of the carbonyl carbon atom increases owing to the decrease of the effect of conjugation as coplanarity breaks down. All these factors destabilise the open-chain structure. In the series of 8-acylnaphthoic acids (XVII)[33] the ring–chain equilibrium constants are satisfactorily correlated with the Taft steric substituent constants E_S [$\lg(K/K_0) = -0.60\,E_S$, $r = 0.977$].

(2) If the connecting unit forms a conformationally mobile chain, the opposite effect is observed: an increase in the bulk of the substituent R destabilises the cyclic structure. Thus, on branching of the substituent, the content of the cyclic form decreases in the series of *S*-(2-oxoalkyl)dithiocarbamates[71], 2-acylmethylmercaptobenzimidazoles[49,77], 2-acylmethylmercaptoperimidines[49], and 1-(2-oxoalkyl)-3-phenyltriazenes[29]. This effect is less clear-cut than the first effect and there are exceptions. For example, the influence of the branching of the alkyl substituent at the keto-group on the ring–chain equilibrium constants for 3-alkyl-1-hydroxyimino-3-propanones[37] is extremely complex and is not correlated with the steric substituent constants E_S.

The 2,6-dimethylphenyl and 9-anthryl residues as well as the analogous condensed systems exert a specific steric influence on the keto-group:

The plane of these substituents has "become detached" from the plane of the keto-group and therefore the *o,o'*-methyl groups of the mesityl substituent, the *peri*-protons of the anthryl substituent, and the oxygen atoms of the condensed dibenzoylenepyridine system prevent the intramolecular nucleophilic attack by the XH group directed at right angles to the plane of the C=O bond. For this reason, the amides of 2-(2,4,6-trimethylbenzoyl)-,[78] 2-(9-anthroyl)-,[79] and 2-[2,3(CO),6,5(CO)-dibenzoyleneisonicotinoyl]-benzoic acids[80] have an open-chain structure regardless of the structure of the substituent at the nitrogen atom and do not cyclise under the conditions of alkaline catalysis. Similar examples are known also for carboxylic acids—2-(2,4,6-trimethylbenzoyl)benzoic and 8-(2,4,6-trimethylbenzoyl)-naphthoic acids[81] and also for the substituted carbinols $2\text{-}R^1COC_6H_4CR_2OH$, where R = Me or Ph and R^1 = 2,4,6-trimethylphenyl[82] or 9-anthryl[83], and for 2-hydroxy-1,4-di-(2,4,6-trimethylphenyl)butane-1,3,4-trione[84].

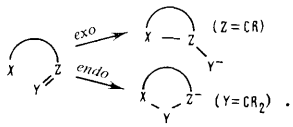
An increase in the length and branching of the alkyl substituents at the azomethine linkage [R^1 and R^2 in formulae (III)–(VI)] also destabilise the cyclic structure. For example, the ring–chain equilibrium constants for the *N*-(1-hydroxy-1-phenyl-2-propyl)-*N*-methylhydrazones of aliphatic aldehydes[85] decrease with increase of the bulk of the alkyl substituent in the sequence Me < Et < iso-Pr < t-Bu. The same behaviour is observed also for the *N*-2-hydroxy-[50] and 2-mercapto-alkylhydrazones of aldehydes and ketones[53,65] and for the *N*-alkylimines of hydroxycarbonyl compounds[51,55].

IV. THE INFLUENCE OF THE STRUCTURE OF THE CONNECTING UNIT

In order to elucidate the influence of the structure of the connecting unit, systematic studies on the equilibria and rates of the intramolecular reactions between the same two functional groups, while the structure of the carrier system is varied within wide limits, are necessary. Unfortunately, few such investigations, embracing a large set of different structures, have been described in the literature. The ring–chain equilibrium constants have been determined in different investigations under different conditions and by different methods[23], which reduces the value of the information obtained on comparing them.

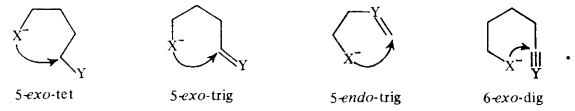
The problem of the estimation of the influence of the structure of the connecting unit on the ease of formation of the ring and its stability is extremely complex. Two approaches are possible: (1) estimation of the structural possibilities for the mutual approach of the reacting groups in the steric orientation optimum for the intramolecular reaction; (2) assessment of the structure from the standpoint of the entropy and enthalpy contributions (deformation of the bond lengths and angles, non-bonding and electrostatic interactions, strain, etc.) to the energy of formation of the ring[24].

The aim of the expansion of research on these lines was to create a model system whereby one could explain the enormous rates of enzymatic reactions compared with the usual



bimolecular reactions. New concepts such as "stereopopulation control"[86-90] and "orbital steering"[91-93] appeared in this connection.

According to the concept of stereopopulation control, the very considerable acceleration of the lactonisation reactions of *o*-hydroxyhydrocinnamic acids, observed after the introduction of methyl groups into the chain and into the benzene ring, can be explained by the increase of the content of the reactive conformer in which both reaction centres have the optimum orientations. It was shown later[94,95] that this effect cannot ensure such a large increase of the rate of reaction and that the increase of the strain energy in the open-chain structure after the introduction of the methyl group plays the most significant role in this phenomenon.

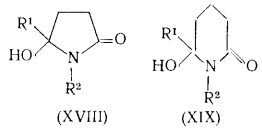


The concept of orbital steering explains the enormous increase of the rate of intramolecular lactonisation of hydroxyacids, achieved by a specific alteration of the structure of the connecting unit, by creating steric conditions for the optimum mutual angular orientation of the reacting centres. This concept has been criticised[96-98] for simplifying the complex pattern of enzymatic reactions and for the clear overestimate of the factor associated with the optimum geometrical orientation of the reacting groups.

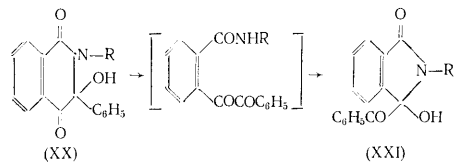
Another approach to the solution of this problem[27,99-101] is based on the use of X-ray diffraction data for the crystal structures of specially selected bifunctional compounds in order to elucidate the optimum geometry of the mutual approach of the reacting groups for the minimum-energy reaction. Thus it has been shown on the basis of X-ray diffraction studies on a series of aminoketones that the optimum angle at which the nucleophilic nitrogen atom approaches the C=O bond ($\angle N...C=O$) in nucleophilic addition to the keto-group is ~107° and not 90° as was suggested previously. For the oxygen atom as a nucleophile, this angle is in the range 100–110°.[102]

On the basis of simple considerations concerning the stereochemical requirements of intramolecular reactions, simple empirical laws governing the preferential occurrence of different types of cyclisation have been proposed[103-107]. A convenient classification of such reactions was introduced. The formation of the smaller of the two possible rings is called *exo*-cyclisation and the formation of the larger ring is *endo*-cyclisation:

The prefixes "tet", "trig", and "dig" denote tetrahedral, trigonal, and digonal geometries of the carbon atom attacked by the nucleophile and the numeral denotes the number of members in the ring formed, for example:

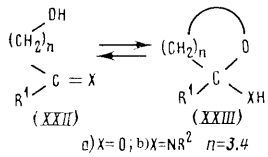


If X is an atom of an element in the Second Period, then 3-, 4-, 5-, 6-, and 7-*exo*-tet-, 3-, 4-, 5-, 6-, and 7-*exo*-trig-, 6- and 7-*endo*-trig-, 5-, 6, and 7-*exo*-dig- and 3-, 4-, 5-, 6-, and 7-*endo*-dig-cyclisation processes are favourable. The 3-, 4-, and 5-*endo*-trig- and 3- and 4-*exo*-dig-cyclisation processes are unfavourable but nevertheless feasible under certain conditions[103].



Clearly these rules are most general and the possibility of their practical application is extremely limited, because in the determination of whether or not the cyclisation process is favourable no account is taken of important factors such as the structure of the connecting unit, the presence of the substituents in it, and the nature of the reacting groups. Table 1 presents an example of an unfavourable 5-*endo*-trig-cyclisation, which nevertheless occurs as a ring–chain tautomeric process: aromatic aldehyde *N*-2-hydroxyalkylimine ⇌ oxazolidine#[34].

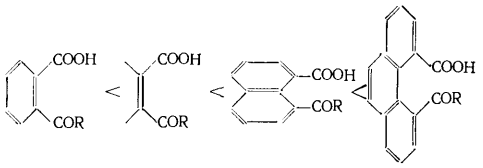
The rate of formation and higher stability of the five-membered or six-membered cyclic system depend on the nature of the reacting functional groups and the structure of the unit connecting them.



With an appropriate choice of substituents R^1 and R^2, the amides of 3-acylpropionic acids form stable five-membered hydroxylactams (XVIII),[39,108] while it is altogether impossible to obtain the six-membered hydroxylactams (XIX) from similarly substituted amides of 4-acylbutyric acids:

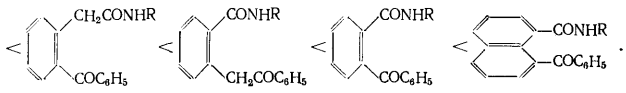
The higher stability of five-membered hydroxylactams compared with the six-membered compounds is confirmed by their ready isomerisation with ring contraction: (XX) → (XXI):[109,110]

On the other hand, in the series of 3-acylpropanols and 4-acylbutanols [(XXIIa) ⇌ (XXIIIa)], the ring–chain equilibrium constants are higher[111] for the closure of the six-membered ring. This also applies to their *N*-alkylimines [(XXIIb) ⇌ (XXIIIb)]:[51]



It is seen from a comparison of the rate constants for a large set of cyclisation reactions (see Table 13 in the monograph of Capon and McManus[7]) that a five-membered ring is formed more readily than a six-membered ring in the intramolecular substitution at a tetrahedral carbon atom when the connecting unit consists of sp^3-carbon atoms. The relative ease of closure of the six-membered ring increases after the introduction of sp^2-carbon atoms in the chain and also for reactions involving intramolecular addition to a trigonal carbon atom.

A series of acyl-substituted carboxylic acids, in which the stability of the cyclic form increases for identical substituents R in each respective instance have been proposed[33];



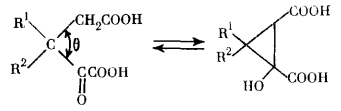
#An example of the faster "unfavourable" 5-*endo*-trig-cyclisation compared with the "favourable" 6-*endo*-trig-cyclisation process has also been observed by J.B.Lambert and M.V.Majchrzak (J.Amer.Chem.Soc., 1980, **102**, 3588).

the ring–chain equilibrium constants have been published in a monograph[23] (Table 3):

An increase in the stability of the cyclic form in an analogous series has been observed[23,38] for the amides of 3- and 4-benzoyl-substituted carboxylic acids:

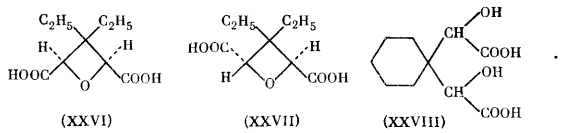
$C_6H_5CO(CH_2)_3CONHR < C_6H_5CO(CH_2)_2CONHR <$

The influence of the structure of the connecting unit on the equilibrium and rate constants for the lactonisation and thiolactonisation reactions of hydroxy- and mercapto-acids has been examined (Table 2)[92,93]; these data have been compared with the rate constants for the corresponding intermolecular reactions. It can be easily shown that insignificant changes in the structure of the connecting unit can have an enormous influence on the rate and equilibrium of the intramolecular reaction. Comparison of lactonisation and thiolactonisation (Table 2) shows clearly that the same structure of the carrier system has different effects on the rates of these reactions: the ratio of the lactonisation and thiolactonisation rate constants varies within the limits of two orders of magnitude, although the overall trend is maintained.



It is seen from the examples presented that the ease of formation and the stability of the cyclic form (the heterocycle) increase with increase of the rigidity of the connecting unit, i.e. with decrease of its conformational mobility, provided that the possibility of the mutual approach of the reacting groups in space and their optimum mutual orientation are maintained. Thus, in the structures of carboxylic ketoacids and their amides which have been examined, the keto-group is capable of free rotation about the C–CO bond and of assuming a conformation in which the nucleophile (O or N) can approach its plane in a perpendicular direction. The failure of this condition in the molecules of anthraquinone-1-carboxylic acid[116] prevents cyclisation.

The elucidation of the general characteristics of the influence of the structure of the connecting unit on the rate and equilibrium constants for the intramolecular reactions is difficult owing to the difference between the steric requirements of different reacting groups. The examples considered and the data in Table 2 show that there are no direct correlations between the structure of the connecting unit and the $\lg K$ and $\lg k$ for intramolecular reactions when pairs of reacting groups are replaced.

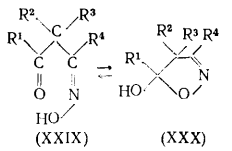


V. STERIC EFFECTS OF SUBSTITUENTS IN THE CONNECTING UNIT

1. The Thorpe–Ingold Effect

The introduction of alkyl groups at carbon atoms in the chain between the reacting groups and particularly the introduction of two groups at the same atom increase the rate of cyclisation and shift the equilibrium in the direction of the cyclic structure. This effect is usually called the "*gem*-dimethyl", "*gem*-dialkyl", or "Thorpe–Ingold" effect[1,2,7–9,16]. The first theoretical explanation has been given by Thorpe and Ingold[117,118], who observed the effect in a ring–chain isometric system which they suggested involved the (XXIV) ⇌ (XXV) transformation. A sharp increase of the content of the cyclic isomer was observed after the introduction of two alkyl groups R^1 and R^2 and the increase of their bulk[119]. The authors explained this phenomenon by the decrease of the valence angle θ.

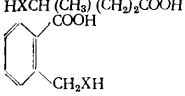
(XXIV) (XXV)

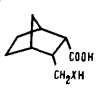


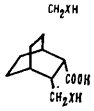
(XXVI) (XXVII) (XXVIII)

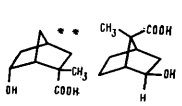
However, structures (XXIV) and (XXV) were later disproved by ^1H NMR and the corrected structures (XXVI)–(XXVIII) were proposed in their place[120,121]; this greatly reduced the popularity of Ingold's concept. The study of the intramolecular hydrogen bond in 2-substituted propane-1,3-diols by infrared spectroscopy showed[18] that, after the introduction of substituents at the middle carbon atom, the C–C–C angle decreases somewhat, but this decrease cannot play a significant role in the closure of five- and six-membered rings.

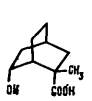
Hammond[1] saw a more important cause of the influence of the *gem*-dialkyl group on the cyclisation reaction in the restriction of the free rotation about the C–C–C bonds in the open-chain isomer after the introduction of two bulky groups at the middle carbon atom and hence in the appearance of entropy factors favouring cyclisation. As a development of this idea, a thermodynamic concept based on a comparison of the enthalpies and entropies of linear and cyclic structures was proposed[122]. It has been shown for hexanes and cyclohexanes that, in the presence of alkyl substituents, there is a smaller number of non-bonding *gauche*-interactions in the rings than in open chains. This implies that the enthalpy factors favour cyclisation of the methyl-substituted chain to a greater extent than the unsubstituted chain. Furthermore, branching reduces the entropy of open-chain compounds by restricting the internal rotation, but cannot alter significantly the entropies of cyclic compounds, because they are capable of free internal rotation. The decrease of ΔH and the increase of ΔS for the cyclisation reactions of pentane and hexane in the gas phase after the introduction of two methyl groups at the same carbon atom lead to an increase of the equilibrium constant by 2–3 orders of magnitude[7] (p.59).

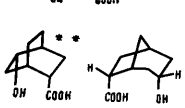


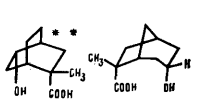












In a study of the ring–chain tautomerism of 1-hydroxyimino-3-propanones [(XXIX) ⇌ (XXX)], it was observed[37] that in solutions of 3-methyl-4-spiropropano-5-hydroxy-5-phenyl-Δ^2-isoxazoline [XXX, R^1 = Ph, R^2, $R^3 = -(CH_2)_2$, R^4 = Me] and the corresponding 4,4-dimethyl derivative (XXX, R^1 = Ph, $R^2 = R^3 = R^4$ = Me) the open-chain tautomeric form is absent within the limits of the sensitivity of the infrared spectroscopic and ^1H NMR methods. Since the equilibrium (XXIX) ⇌ (XXX) has been observed for the 4-unsubstituted derivative, this finding disproves Ingold's concept, since $(CH_2)_2C\langle$ angle has not been reduced and has even been increased conpared with the $H_2C\langle$ angle. The stabilisation

of the cyclic isomer (XXX) on spirocyclopropane substitution in the 4-position can be accounted for only by the restriction of the freedom of rotation or by the appearance of steric strain in the open-chain isomer of isoxazoline (XXIX):

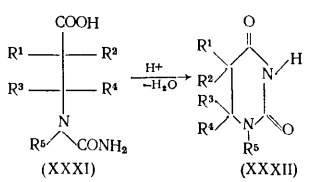
(XXIX) (XXX)

Table 2. The influence of the structure of the connecting unit on the equilibrium and rate constants for the lactonisation of carboxylic hydroxy- and mercapto-acids under the conditions of acid catalysis[92,93].

Carboxylic hydroxy- or mercapto-acid	X = O		X = S	
	K	$\lg k_{rel}$	K	$\lg k_{rel}$
$CH_2CH_2XH + CH_3COOH$ *	$7\cdot10^{-2}$	0.00	$6.6\cdot10^{-4}$	0.00
$HX(CH_2)_2COOH$	6.15	1.90	2.44	2.58
$HXCH(CH_3)(CH_2)_2COOH$	11.13	2.07	—	—
	—	2.50	—	2.97
	2810	3.82	110	1.95
	—	5.14	63	3.67
	12740	6.01	>100	5.91
	—	2.44	—	—
	—	2.94		
	—	4.99		
	—	3.96		
	—	5.68		

*The rate constants adopted as unity actually amount to $k = 1.09 \times 10^{-3}$ litre mol^{-1} min^{-1} for X = O and $k = 3.2 \times 10^{-6}$ litre mol^{-1} min^{-1} for X = S.

**These structures shown in brackets proved to be erroneous in a reinvestigation[112–115]; the corrected structures are shown next to them.

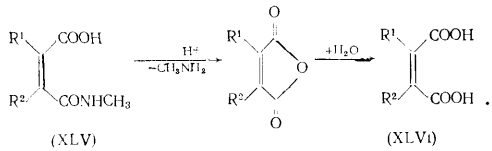


The positive influence of alkyl substituents in the connecting unit on the rate and equilibrium constants has been observed in the conversion of succinic acids[123] and their *N*-phenyl monoamides[124] into anhydrides [and imides respectively?], the lactonisation of 4-hydroxybutyric and 5-hydroxyvaleric acids[125], in the ring–chain tautomerism of levulinic acids[126], many other ring–chain tautomeric systems[20, 23,50], addition reactions with intramolecular cyclisation[127], intramolecular catalysis proceeding via a cyclic transition state[5–9], and the formation of an intramolecular hydrogen bond[17].

The influence of alkyl substituents on the rate and equilibrium constants for cyclisation reactions depends on their bulk, their position in the connecting unit, and the conformational mobility of the connecting unit itself. If the reacting groups are separated by a chain of three sp^3-carbon atoms, the introduction of alkyl substituents at the middle atom has the greatest influence[125,128]. The methyl groups at the carbon atom in the α-position relative to the reacting group, particularly the C=O group, can have the opposite influence owing to the steric shielding of the reaction centre. The influence of the position of the methyl substituent can be followed in relation to the cyclisation of methyl-substituted 3-ureidopropionic acids [(XXXI) → (XXXII)] (Table 3)[129].

Table 3. The influence of methyl substituents on the rate constants for the cyclisation of 3-ureidopropionic acids [(XXXI) → (XXXII)].[129]

R^1	R^2	R^3	R^4	R^5	$\lg k_{rel}$
H	H	H	H	H	0.00
Me	H	H	H	H	0.07
H	H	Me	H	H	0.45
erythro-Me	H	Me	H	H	−0.08
threo-Me	H	H	Me	H	0.47
Me	Me	H	H	H	−0.46
H	H	Me	Me	H	1.25
H	H	H	H	Me	1.66

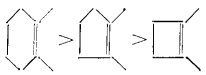


The introduction of two methyl groups in the α-position relative to the carboxy-group actually retards cyclisation, while two methyl groups at the β-carbon atom greatly accelerate it.

(XXXI) (XXXII)

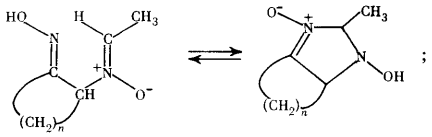
The destabilisation of the cyclic structure after the introduction of the methyl group at the carbon atom in the α-position relative to the C=O group has been observed in the ring–chain tautomerism of *N*-(3-oxoalkyl)-*N'*-substituted thioureas[70] and 3-aryl-1-(2-oxoalkyl)triazenes[29].

The influence of alkyl substituents at an sp^3-carbon atom intensifies following the increase of the conformation rigidity of the connecting unit, which is readily seen in relation to the lactonisation reactions (XXXIII) → (XXXIV) and (XXXV) → (XXXVI) (Table 4)[130].



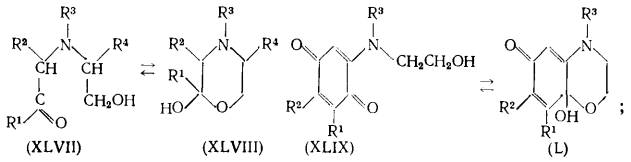
(XLV) (XLVI)

Table 6. The influence of alkyl substituents at the sp^2-carbon atoms on the ring–chain equilibrium constants K for *cis*-3-acetylacrylic acids [(XLIII) → (XLIV)] [143] and the hydrolysis rate constants k_{rel} for *N*-methylmaleamic acids [(XLV) → (XLVI)]. [142]



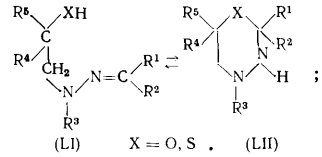
R^1	R^2	$\lg K$ (XLIII) ⇄ (XLIV)	$\lg k_{rel}$ (XLV) → (XLVI)
H	H	1.2	0.00
Me	H	1.9	1.49
H	Me	3.6	—
Me	Me	5.2	4.37
	$(CH_2)_4$	—	2.73
	$(CH_2)_3$	—	−4.38
	$(CH_2)_2$	—	−5.38

On passing to cyclopentene and cyclobutene systems, the catalytic effect of the carboxy-group disappears, which can be explained by the alteration of the valence angles in the sequence



which is unfavourable for the formation of a cyclic transition state.

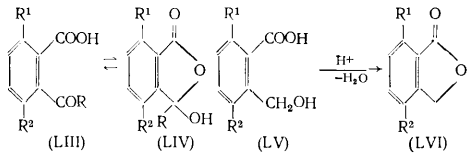
An analogous influence of ring size has been observed [144] in the ring–chain tautomerism of *N*-(2-hydroxyiminocycloalkyl) nitrones:



$n = 5$, $K > 100$; $n = 4$, $K = 9$; $n = 3$, $K = 0$.

The introduction of an alkyl group at the nitrogen atom in the connecting unit leads to a marked stabilisation of the cyclic structure (Table 3), which has been demonstrated in relation to the ring–chain tautomerism of *N*-alkyl-*N*-(2-hydroxyalkyl)-*N*-(2-oxoalkyl)amines [(XLVII) ⇌ (XLVIII)], [145, 146] 2-*N*-alkyl-*N*-(2-hydroxyethyl)amino-1,4-benzoquinones [(XLIX) ⇌ (L)], [147] and *N*-alkyl-*N*-(2-hydroxy- or 2-mercapto-alkyl)hydrazones of aldehydes and ketones [(LI) ⇌ (LII)]: [50,52,53,65,148,149]

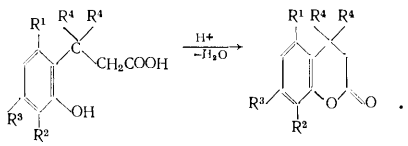
(XLVII) (XLVIII) (XLIX) (L)



(LI) X = O, S . (LII)

The introduction of alkyl substituents R^3 and the increase of their bulk displace the equilibrium towards the cyclic form, while in the absence of a substituent at the nitrogen atom (i.e. for $R^3 = H$), compounds (XLVII), (XLIX), and (LI) exist preferentially in the stable open-chain form and a tautomeric equilibrium is not observed.

Potekhin and Bogan'kova [149] suggest the weakening of the intramolecular hydrogen bond X–H...NR^3 as one of the possible causes of the destabilisation of the open-chain structure (LI) with increase of the bulk of the substituent R^3 in addition to the entropy factor, but they do not present any experimental evidence for this hypothesis.



2. The "Supporting" or Steric Cooperation Effect

If the reacting groups are in the *ortho*-positions in an aromatic ring, then the neighbouring alkyl or other substituents give rise to a steric strain, which favours intramolecular cyclisation [150]. Such influence is called the "supporting" or steric cooperation effect. Table 7 presents the quantitative characteristics of this effect for the ring–chain tautomerism of 2-acetylbenzoic [151] and 2-benzoylbenzoic [152] acids [(LIII) ⇌ (LVI)] and also for the lactonisation of 2-hydroxymethylbenzoic acid [(LV) → (LIV)], [153]

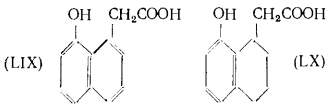
(LIII) (LIV) (LV) (LVI)

and 3-(2-hydroxyphenyl)propionic acid [(LVII) → (LVIII)]: [86,87]

(LVII) (LVIII)

The gradual introduction of methyl groups into the molecule of 3-(2-hydroxyphenyl)propionic acid (LVII) makes it possible to discover the influence of the location of the methyl substituents on the lactonisation rate constants under the conditions of acid catalysis; the maximum acceleration attained under these conditions is by 11 orders of magnitude. The main driving force of the acceleration of lactonisation after the introduction of methyl substituents is steric strain in the ground state of the initial molecule and from this standpoint there is no fundamental difference between the Thorpe–Ingold effect [as in compound (LVII, R^4 = Me)] and the steric cooperation effect [as in compound (LVII, $R^1 = R^2$ = Me)].

It is seen from Table 7 that the accelerating effect depends on the bulk of the substituent in the *ortho*-position with respect to the position where the methyl group is to be introduced. The introduction of the methyl group in the

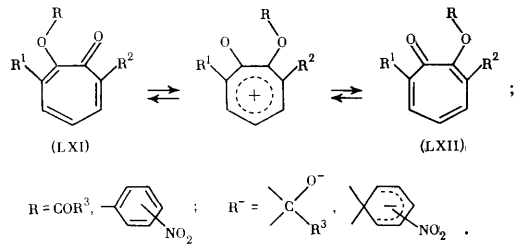


ortho-position with respect to the OH group or the introduction of two methyl groups in the *ortho*-positions with respect to the OH and CH_2CH_2COOH groups accelerates lactonisation by a factor of 3–7, while the methyl group in the *ortho*-position with respect to the CMe_2CH_2COOH group accelerates the lactonisation reaction by 7 orders of magnitude. The extremely high acceleration of the lactonisation reaction (LVII) → (LVIII) has been explained by the fact that the methyl substituents R^1, R^2, and R^4 restrict the freedom of rotation about the C–C bonds and favour the preferential formation of the conformation in which both reacting groups are in the optimum position for reaction between them[86,87].

Table 7. The steric cooperation of the *ortho*-substituents in cyclisation reactions.

R^1	R^2	K ((LIII) ⇄ (LIV))		$\lg k_{rel}$ ((LV)→(LVI)) [153]	$\lg k_{rel}$ ((LVII)→(LVIII)) [86,87]	
		R=Me [151]	R=Ph [152]		R^4=H	R^4=Me
H	H	3.2	<0.1	0.00	0.00*	3.65*
Me	H	16	2.85	1.19	—	10.93**
H	Me	0.52	0.22	1.72	—	4.22*
Me	Me		13.3	2.50	0.83**	11.41*
						11.53**

*R^3 = H.
**R^3 = Me.



It has been shown[94] that such high acceleration of cyclisation on passing from compound (LVII, $R^1 = R^2 = R^3 = R^4 = H$), i.e. compound (LVIIa), to the trimethyl-substituted compound (LVII, $R^1 = R^2 = R^4 = Me$, $R^3 = H$), i.e. compound (LVIIb), which is by a factor of 10^{11}, cannot be caused solely by the presence of the optimum conformation (this has been confirmed by X-ray diffraction analysis[90]); the steric strain in the initial molecule plays a more significant role here. Comparison of the rate constant for the lactonisation of the acid (LVIIa) with the lactonisation constants for 8-hydroxynaphthylacetic acid (LIX) and 8-hydroxy-1,2,3,4-tetrahydronaphthylacetic acid (LX),

(LIX) (LX)

which model the fixed most favourable conformation for the lactonisation reaction ($k_{(LIX)}/k_{(LVIIa)} = 2.1 \times 10^4$; $k_{(LX)}/k_{(LVIIa)} = 1.5 \times 10^2$) shows that acceleration by a factor of only 10^4 is ensured by the most favourable conformation. The remaining contribution to the acceleration of the cyclisation reaction on passing from compound (LVIIa) to (LVIIb), amounting to a factor of ~10^7, is due to the enthalpy effect of the steric strain in the initial molecule, which has been confirmed by empirical force field calculations[95].

The steric cooperation effect is clearly manifested in the acylo- and arylo- tropic tautomerism of the tropolone system [(LXI) ⇌ (LXII)]:[12,154–156]

The introduction of methyl or benzyl substituents in the 3- and 7-positions in the tropolone ring has a favourable steric effect on the formation of a cyclic dipolar transition state or intermediate and accelerates the migration of acyl or aryl groups. In the presence of only one methyl substituent (R^1 = Me, R^2 = H, R = Me_2NCO), the equilibrium (LXI) ⇌ (LXII) is displaced towards the sterically less encumbered tautomer (LXII) (K = 4).[156]

It is seen from the examples considered (see also Capon and McManus[7]) that the influence of the alkyl substituents in the connecting unit on the cyclisation reactions depends on many factors and is difficult to predict quantitatively. Progress in this field resulting from the employment of computational methods has been noted recently.

A satisfactory linear correlation (r = 0.932–0.993) between the free energies of activation for the cyclisation reactions of methyl-substituted ureidopropionic acids [(XXXI) → (XXXII)] and also a number of previously investigated anhydride formation reactions of succinanilic[124] and succinic[123] acids, the hydrolysis of p-bromophenylglutarates [(XLI) → (XLII)],[131] and the lactonisation of 4-hydroxybutyric and 5-hydroxyvaleric acids[125], on the one hand, and the energies of the steric strain estimated on the basis of the enthalpies of formation of homomorphous hydrocarbons[157], on the other, has been observed recently[129].

Empirical force field calculations[150,158–163] have been used successfully for the quantitative prediction of the acceleration of the lactonisation of carboxylic hydroxyacids when the structure of the connecting unit is altered and methyl substituents are introduced[95,164].

The possibilities of the computational methods have been satisfactorily demonstrated[165,166] for the cyclisation reactions of bromoalkylamines and their derivatives substituted by alkyl groups in the chain. A satisfactory agreement between the calculated and experimental rates of cyclisation was observed; the enthalpies of activation were calculated by the empirical force field method and the entropies of activation were obtained from the analogous formal cyclisation reactions of homomorphous alkanes.

It has been confirmed by computational methods that the driving force of the Thorpe–Ingold effect is mainly the enthalpy factor and not the entropy factor as was believed previously[86,87].

Spectroscopy of Intermolecular Field Interactions in Solutions

A.E.Lutskii, V.V.Prezhdo, L.I.Degtereva, and V.G.Gordienko

Methods of interpreting data on the effect of the solvent on the spectral characteristics of molecules are critically compared. It is shown that the effect of field-induced intermolecular interaction in solutions on molecular spectra can be calculated in terms of the London-Debye-Keesom pair potential. 145 references.

I. INTRODUCTION

Condensed media, in which the distance between molecules is smaller than in gases, invariably show substantial interaction between molecules with saturated chemical bonds (intermolecular interaction, IMI). The features of the IMI determine the thermodynamic properties of liquids and the kinetics and mechanisms of the elementary chemical acts: the IMI also control the formation of donor–acceptor complexes, and are responsible for the formation of colloidal systems. In biological systems intermolecular forces control the stability of all the compounds which are essential to life.

Intermolecular interactions can be studied experimentally by a variety of methods[1], mostly spectroscopic[2]. The interactions reveal themselves in the spectra of molecules in different ways (shifts in the absorption and in the emission bands, changes in intensity and shape of the bands, appearance of new bands). Information on the nature of the IMI can be obtained also from measurements of the polarisation and dipole moments of molecules[3,4].

All the different types of IMI can be classified into two main groups. Terenin[5] subdivides intermolecular forces into physical (determined by the physical characteristics of the interacting molecules) and chemical (responsible for the formation of directional chemical or quasi-chemical bonds between molecules). Other workers[6,7] classify the IMI into volume interactions (in which each molecule is bound to surrounding molecules by a force inversely related to distance) and local interactions (in which two or more molecules are held together fairly strongly but the bonds between these groups of molecules have only secondary importance). Others[8-10] distinguish between short-range and long-range order when classifying intermolecular forces. The former involves interactions described in terms of the physical parameters of the molecules, whereas the latter involves valency or chemical forces arising from overlap of the electron clouds of the interacting molecules. Bakhshiev[2] suggests classifying the IMI not according to their forces or radii of action, but according to the "generality of their occurrence". He classifies all types of IMI as universal or specific. The former operate between molecules in all systems, without exceptions, and are determined by the physical parameters of the molecules: they describe the collective influence of the surrounding molecules on the properties of one particular molecule. The specific IMI do not occur in all systems: they are individual manifestations, confined to a particular pair of interacting molecules. They have a quasi-chemical (exchange) origin and a high degree of selectivity towards certain molecules, leading to the formation of a definite bond which can be strong or weak[2].

In spite of these differences in terminology, and in the light of the physical meaning of the term IMI, we shall use the following classification of the IMI into two groups: the first group includes the van der Waals interactions, which are additive and non-directional (attractive forces due to orientation, induction, and dispersion effects, and repulsive forces arising from the mutual impenetrability of molecules), and the second group includes all forms of interaction of donor–acceptor origin and showing the typical attributes of a chemical bond (saturability and directionality).

The interaction energy of two molecules can be expressed as the sum $U_{tot} = U_{or} + U_{ind} + U_{dis}$, where the terms in the right-hand side denote the energies arising from the orientation, induction, and dispersion interaction of the molecules, given by the London–Debye–Keesom formulae[11] as

$$U_{or} = -\frac{2\mu_1^2\mu_2^2}{3kT\bar{R}^6},$$

$$U_{ind.} = -(\alpha_1\mu_2^2 + \alpha_2\mu_1^2)/\bar{R}^6, \quad U_{dis} = -\frac{3}{2}\frac{I_1I_2}{(I_1+I_2)}\frac{\alpha_1\alpha_2}{\bar{R}^6}.$$

In these expressions $\bar{R}$ is the average distance between the molecules, μ_1 and μ_2 are the (constant) dipole moments, α_1 and α_2 are the isotropic polarisabilities, and I_1 and I_2 are the first ionisation potentials of the molecules.

A strict solution of the intermolecular interaction problem (and an exact calculation of U_{tot}) are possible by using quantum mechanics. This calculation (so far attempted only for the simplest molecules) yields the interaction energy of the molecules as a function of the intermolecular distance $\bar{R}$. For more complex molecules the quantum-mechanical calculation becomes unacceptably laborious, and empirical models of the intermolecular potential are used to calculate the IMI energy. Depending on the properties of the system, the Lennard-Jones, Morse, Kihara, Stockmaier, Buckingham, and other potentials have all been widely used. For example, the well-known Lennard-Jones potential

$$U(r) = E\left[\left(\frac{\sigma}{r}\right)^{12} - \left(\frac{\sigma}{r}\right)^{6}\right]$$

(where E is the minimum potential energy of the pair of molecules, σ is the distance for which U is a minimum, and r is the Onsager radius of the molecule) ignores many-particle interactions and does not explicitly allow for the parameters I, α, and μ, which (together with the structural parameters $\bar{R}$ and $\bar{Z}$, the number of nearest neighbours) determine the value of U.

In this review we shall attempt to generalise the large amount of published data on the determination of the IMI energy by using the theoretically well-justified London–Debye–Keesom potential for the pair interactions between

molecules in a liquid in order to study the spectral characteristics of molecules in solutions.

II. EFFECT OF THE MEDIUM ON THE I.R. SPECTRA OF MOLECULES AND COMPLEXES

1. Methods of Calculating the Effect of the Medium on the I.R. Spectra

Two types of relationship between the spectral characteristics and the properties of the solvent are generally used to allow for the IMI effects of a universal type on the characteristics of the vibrational spectra of molecules in solutions: those involving macroscopic parameters such as the dielectric constant ε and the refractive index n, and those involving molecular parameters such as the dipole moment μ, the polarisability α, and the ionisation potential I. The first group includes relationships based on potentials for the collective interation between solvent and solute molecules. Kirkwood[12], and Bauer and Magat[13], used the Onsager reactive field model[14] to derive the widely used expression (KBM formula)

$$\frac{\Delta\nu}{\nu_s} = \frac{\nu_s - \nu_{gas}}{\nu_{gas}} = -C\,\frac{\varepsilon - 1}{2\varepsilon + 1}\ .$$

Buckingham[15] replaced ε by n^2 in this formula, converting the KBM formula into

$$\frac{\Delta\nu}{\nu_s} = \frac{\nu_s - \nu_{gas}}{\nu_{gas}} = -C\,\frac{n^2 - 1}{2n^2 + 1}$$

where ν_{gas} is the stretching vibration frequency of the isolated molecule, ν_S is the vibration frequency in the medium, $\Delta\nu$ is the frequency shift, C is a constant depending on the properties of the solute molecule, and ε and n are the dielectric constant and the refractive index of the solvent respectively.

However, these expressions have had only limited success with both polar[16,17] and non-polar solvents[18], and they cannot be applied to systems in which $\nu_S > \nu_{gas}$ to calculate the vibration frequency of groups able to form H-bonded complexes[2].

The KBM theory was further developed by Pullin[19], who examined the effect of the solvent on the spectrum of the solute in terms of ε, n, the molar volume of the solvent, and the molar volume of the solute. However, in Pullin's expression

$$\frac{\Delta\nu}{\nu_0} = C + \frac{A}{R}\,\frac{n^2 - 1}{n^2 + 2} + B\,\frac{\varepsilon - 1}{2\varepsilon + 1}$$

(where A and B are constants, and R is the radius of a sphere circumscribing the molecule) the physical significance of the constants is not clear, and the ratio A/R is found to depend on the nature of the medium.

The work of Buckingham, based on quantum-mechanical considerations, is especially interesting[20]. By using first- and second-order perturbation theory he obtained an expression for the relative frequency shift of the absorption corresponding to the transition between levels with vibrational quantum numbers m and n,

$$\frac{\Delta W_{m,n}}{W_{m,n}} = \frac{B_e}{hcW_e^2}\left[\bar{U}'' - 3\,\frac{A}{W_e}\,\bar{U}'\right]\ ,$$

where B_e is the rotational constant, A/W_e is the anharmonicity constant of the vibration, and U' and U'' are the first and the second differential of U (the interaction energy of the solute molecule with the solvent molecules) with respect to the vibration coordinate.

By applying the Onsager reactive field theory Buckingham[20] arrived at the following expressions for the relative frequency shifts in non-polar solvents,

$$\frac{\Delta\nu}{\nu} = C_1 + \frac{1}{2}\,C_2\left(\frac{\varepsilon - 1}{2\varepsilon + 1}\right) + \frac{1}{2}\,C_3\,\frac{n^2 - 1}{2n^2 + 2}\ ,$$

and in polar solvents,

$$\frac{\Delta\nu}{\nu} = C_1 + C_2\,\frac{\varepsilon - 1}{2\varepsilon + 1} + C_3\,\frac{n^2 - 1}{2n^2 + 2}\ ,$$

where C_i are constants determined by the microscopic characteristics of the molecules in solution (polarisability, dipole moment, etc.).

The most important attribute of these expressions is the fact that the physical meaning of their constants is relatively clear, though their application is limited to diatomic molecules. Attempts to apply them to polyatomic molecules[21] by calculating all the C_i values from experimental $\Delta\nu$ values are physically meaningless. This is especially true of the expressions which include a fourth term ($C_4\sigma^*$) to allow for the specific interactions of the molecules in solution[18,22].

From the Onsager model Bakhshiev obtained[2] the following expression for the shift in vibration frequency:

$$H\Delta\nu = -\Delta R\left[\frac{\mu_0\left(\frac{\partial\mu_0}{\partial R}\right)_{R_{s,d}}(F_1 + F_2)}{1 - \alpha_0(F_1 + F_2)}\left(\frac{\partial\alpha}{\partial R}\right)_{R\,equil} F_3\right];$$

$$F_1 = \frac{2}{a^3}\left(\frac{\varepsilon - 1}{2\varepsilon + 1} - \frac{\varepsilon_\infty - 1}{2\varepsilon_\infty + 1}\right);\quad F_2 = \frac{1}{a^3}\left(\frac{\varepsilon_\infty - 1}{2\varepsilon_\infty + 1}\right);$$

$$F_3 = \frac{3}{2a^3}\,\frac{I_s I_d}{I_s + I_d}\left(\frac{n^2 - 1}{n^2 + 2}\right)\ ,$$

where H_ν is the energy, and the subscripts 0, s, and d denote the gas phase, the solvent, and the dissolved substance (throughout this paper). This expression includes, in addition to macroscopic properties of the medium, also parameters which characterise the properties of the solute molecules. However, the relationship is difficult to apply, even to diatomic molecules[2,23,24]. In the case of more complex molecules the difficulties in determining the molecular parameters and in defining rationally the Onsager radius of the mole (a) become almost insuperable. Furthermore, the presence of macroscopic parameters of the solvent in the expression destroys the clarity of the presentation of the dependence of $\Delta\nu$ on the molecular properties of the solvent and makes it impossible to correlate $\Delta\nu$ with the basic characteristics of the molecular structure of the liquid.

The limited possibilities of all expressions which include generalised parameters of the solvent led to the belief that the universal IMI are always accompanied by specific interactions, or even that their effect is negligible and limited to the formation of low-stability complexes. The former point of view is implicit in the Caldow and Thompson expression[22]

$$\Delta\nu = C_1 + C_2\,\frac{\varepsilon - 1}{2\varepsilon + 1} + C_3\,\frac{n^2 - 1}{n^2 + 2} + C_4\sigma^*\ ,$$

where σ^* allows for the inductive or resonance effect of the substituents in the solvent molecule. The latter point of view is expressed in the work of Bellamy[25-27], who studied the correlation of the $\Delta\nu/\nu$ values for different vibrators in the same series of solvents. These workers assumed[22,25-27] that specific interactions can occur in non-polar as well as in polar solvents.

These views were further developed[28,29] in the cell theory of liquids. Using the terminology of that theory, strong specific interaction can be related mainly to the formation of donor–acceptor complexes in systems of the "polar solute–polar solvent" type, and weak non-specific interaction to the formation of collision complexes in systems of the "polar solute–non-polar (or weakly polar) solvent" type. This treatment excludes from the start any possibility of revealing characteristic dependences of the solvent effect on the composition and structure of the molecules for different types of IMI.

Another group of expressions for calculating the effect of IMI on $\Delta\nu$ relies on the pair interaction potential concept. The first expression of this type was proposed by Vol'kenshtein[30], who calculated the potential energy of the van der Waals interaction between solvent–solute pairs of molecules in the approximation of the London–Debye–Keesom potential:

$$U = \frac{1}{\bar{R}^6}\left(\frac{2}{3kT}\mu_s^2\mu_u^2 + \mu_s^2\alpha_d + \mu_d^2\alpha_s + \frac{3}{4}I\alpha_s\alpha_d\right).$$

Solution of the equations of motion leads to the following expression for the normal vibration frequency of the system:

$$\Delta W = WW_0 = -\frac{1}{2}\frac{B}{mW_0} \pm \frac{A}{mW_0},$$

where m is the reduced mass, and A and B are the sums of coefficients describing the orientation (o), dispersion (α), and induction contribution (i) to the pair interaction:

$$A = A_o + A_i + A_\alpha;\ B = B_o + B_i + B_\alpha .$$

The frequency shift is given by the factor B/mW_0, the line broadening by A/mW_0, with

$$B_0 = \frac{4}{3kT\bar{R}^6}\left[\mu^2\left(\frac{\partial\mu}{\partial q}\right)^2 + \mu^3\frac{\partial^2\mu}{\partial q^2}\right];\ B_\alpha = \frac{3}{4}\frac{I}{\bar{R}^6}\alpha\frac{\partial^2\alpha}{\partial q^2};$$

$$B_i = \frac{2}{\bar{R}^6}\left[\alpha\left(\frac{\partial\mu}{\partial q}\right)^2 + \alpha\mu\frac{\partial^2\mu}{\partial q^2} + \mu^2\frac{\partial^2\alpha}{\partial q^2}\right].$$

In these expressions $\bar{R}$ is the distance between dipoles, q is the relative displacement from the equilibrium position, μ is the dipole moment of the molecule, $\partial\mu/\partial q$ is the effective charge on the dipole, and $\partial^2_\mu/\partial q^2$ is the electrical non-linearity of the dipole.

Vol'kenshtein and coworkers[31] included not only the dipole–dipole inductive and dispersion interaction energy in their calculation of the IMI in terms of pair interaction energies, but also the repulsive energy of the molecules. The energy of the interaction between two molecules was identified with the sum of the pair interactions between bonds[32]. In this way, ignoring the second differential with respect to the vibration coordinate, we can arrive at the following expression for $\Delta\nu$ in the case of solutions of a polar substance in a non-polar solvent:

$$\Delta\nu = -\frac{3K_{11}}{8\pi^2c^2M_2V}\left[\frac{\alpha'_d}{\alpha_d} - 6\frac{R'_{s,d}}{R_{s,d}} + \frac{I'_d}{I_d} - \frac{I'_d}{I_d+I_s}\right]E_{disp} \qquad (1)$$

and for a polar solute in a polar solvent

$$\Delta\nu = -\frac{3K_{11}}{8\pi^2c^2M_2V}\left\{\left[\frac{\alpha'_d}{\alpha_d} - 6\frac{R'_{s,d}}{R_{s,d}} + \frac{I'_d}{I_d} - \frac{I'_d}{I_d+I_s}\right]E_{disp} + \right.$$

$$\left. + \frac{2\mu'_d}{\mu_d}E_{disp} + \left[\frac{\mu'_d}{\mu_d} - 3\frac{R'_{s,d}}{R_{s,d}} + \frac{I'}{I}\right]E_{or} - \left[\frac{a'}{a} - b'R_{s,d}\right]E_{rep}\right\}, \qquad (2)$$

where α', I', and μ' are the differentials with respect to the vibration coordinate of the polarisability, the ionisation potential, and the dipole moment respectively, $R_{s,d}$ is an orientation factor, a' and b' are the constants in the exponential expression for the repulsive energy, c is the velocity of light, M is the reduced mass of the molecule, ν is the frequency, and K is the force constant.

Acceptably precise calculations of $\Delta\nu = \nu_s - \nu_{gas}$ for quite simple molecules present almost insuperable difficulties in the evaluation of the pair interaction potential (as in the case of the potentials based on the collective interaction of molecules in solution). This explains the growing practice of correlating $\Delta\nu$ with various empirical parameters of the solvent[16,33]. However, the main advantage of using the pair interaction potential is the explicit presence in this type of expression for E_{in} of the molecular properties of the solvent (μ_s, α_s, I_s) as well as those of the solute, and also the explicit presence of characteristics of the molecular structure of the solution (Z and $R_{s,d}$). Unlike the expressions relying on collective interactions, the pair interaction relationships make it possible to study the dependence of $\Delta\nu$ on various specific properties of both the solvent and the solute molecule, and also its dependence on $\bar{Z}$ and $\bar{R}_{s,d}$. Thus, by using Eqns.(1) and (2) we can calculate E_{or} from the Keesom expression for the orientation interaction averaged over all configurations ($E_{or} \cong \mu_s^2\mu_d^2/\bar{R}^6$) instead of the expression for the local interaction, which makes it unnecessary to calculate I. Since α'_d is negligibly small, and α_d is almost independent of the nature of the solvent, but μ'_d varies with μ_d, we can expect that for a given solute in a series of solvents with similar values of I_s and $\bar{R}_s$ (and therefore similar values of $\bar{R}_{s,d}$) the combined contribution to $|\Delta\nu|$ from all the effects associated with the change of solvent will be quite small [Eqns.(1) and (2)] in comparison with the contribution from the energy of the pair interactions. For such a series of solutions with $\mu_s = \mu_d = 0$ we can expect $|\Delta\nu| \propto E_{disp} - E_{rep}$, whereas with $\mu_s \neq 0$ and $\mu_d = 0$ we have $|\Delta\nu| \propto E_{disp} + E_{ind} - E_{rep}$, and with $\mu_s \neq 0$ and $\mu_d \neq 0$ we have $|\Delta\nu| \propto E_{IMI} = E_{disp} + E_{ind} + E_{or} - E_{rep}$.

Since at ordinary temperatures and pressures the $\bar{R}_{d,s}$ values averaged over the whole volume vary between 5 and 8 Å, the contribution from E_{rep} to the IMI energy is negligible in comparison to that from E_{attr}, as confirmed by the small values of $\Delta\nu$ for many vibrators even at relatively high pressures[31]. If $E_{rep} \ll E_{attr}$ we can expect that in a series of solutions of a non-polar substance in non-polar solvents of the same type

$$|\Delta\nu| \propto E_{disp}. \qquad (3)$$

In the case of solutions of a polar substance in a series of non-polar solvents

$$|\Delta\nu| \propto E_{attr} = E_{disp} + E_{ind}. \qquad (4)$$

On the other hand, for solutions of polar substances in a series of polar solvents of the same type we have

$$|\Delta\nu| \propto E_{attr} = E_{disp} + E_{ind} + E_{or}. \qquad (5)$$

2. Effect of Intermolecular Interactions in Solutions on the Vibration Frequency of Functional Groups in Molecules

Expressions of the type of (3)–(5) have been used[34] to interpret data on ν_{max} for the stretching vibrations of different groups of polar or non-polar molecules. In that work the E_{attr} value (as a function of the molecular properties and of characteristics of the molecular structure

of the solution such as $\bar{Z}$ and $\bar{R}_{s,d}$) was fitted to a London–Debye–Keesom potential for condensed media[35,36]:

$$E_{attr} = \overline{const} \cdot \sum_k \left(\frac{\bar{Z}}{\bar{R}^6_{s,d}}\right)_k \left[\frac{3}{2}\frac{I_s I_d}{I_s + I_d}\alpha_s\alpha_d + \mu_s^2\alpha_d + \mu_s^2\alpha_s + \frac{2\mu_s^2\mu_d^2}{3kT}\right].$$

In studies of the behaviour of a single vibrator in a series of solvents of the same type we can write

$$|\Delta\nu| \propto \sum_k \left(\frac{\bar{Z}}{\bar{R}^6_{s,d}}\right)_k \left[\frac{3}{2}\frac{I_s I_d}{I_s + I_d}\alpha_s\alpha_d + \mu_s^2\alpha_d + \mu_d^2\alpha_s + \frac{2\mu_s^2\mu_d^2}{3kT}\right]. \quad (6)$$

By using Eqn.(6) we can recognise special features in the dependence of $\Delta\nu$ on the characteristics of the solution ($\bar{Z}$ and $\bar{R}_{s,d}$) and on the properties of the vibrator molecule and of the solvent molecule (μ, α, I). It follows from Eqn.(6) that for a given non-polar substance ($\mu_d = 0$) dissolved in a series of non-polar solvents ($\mu_s = 0$) having similar values of I_s we can write

$$\Delta\nu_s \propto C_1 \sum_k \left(\frac{\bar{Z}}{\bar{R}^6_{s,d}}\right)_k \alpha_s \qquad \left(C_1 = \frac{3}{2}\frac{I_s I_d}{I_s + I_d}\right)\alpha_d. \quad (7)$$

For a polar solute ($\mu_d \neq 0$)

$$\Delta\nu_s \propto C_2 \sum_k \left(\frac{\bar{Z}}{\bar{R}_{s,d}}\right)_k \alpha_s \quad (C_2 = C_1 + \mu_d^2). \quad (8)$$

In a series of non-polar solvents with similar values of I_s and α_s and T = const. containing a single non-polar solute ($\mu_d = 0$) we have

$$\Delta\nu_s \propto C_1 \sum_k \left(\frac{\bar{Z}}{\bar{R}^6_{s,d}}\right)_k \alpha_s + C_3 \sum_k \left(\frac{\bar{Z}}{\bar{R}^6_{s,d}}\right)_k \mu_s^2 \quad (C_3 = \alpha_d). \quad (9)$$

For a polar solute

$$\Delta\nu_s \propto C_2 \sum_k \left(\frac{\bar{Z}}{\bar{R}^6_{s,d}}\right)_k \alpha_s + C_4 \sum_k \left(\frac{\bar{Z}}{\bar{R}^6_{s,d}}\right)_k \mu_s^2 \quad \left(C_4 = \alpha_d + \frac{2}{3kT}\mu_d^2\right). \quad (10)$$

In these expressions C_i are quantities whose variation in a series is slight in comparison to that of the quantities under the summation sign.

We have tested[37] Eqns.(7)–(10) by measuring the ν(C–Cl) absorption for CCl_4 and $\nu(OH)_{free}$ for ethanol in polar and in non-polar solvents. Our results (Fig.1) show that, as required by Eqns.(7)–(10), the ν(C–Cl) and $\nu(OH)_{free}$ values decrease almost linearly with the parameter

$$Y \equiv \bar{Z}\frac{I_s I_d}{I_s + I_d}\frac{\alpha_s}{\bar{R}^6_{s,d}}$$ (i.e. that $\Delta\nu = \nu_s - \nu_{vap}$ increases with Y). This is confirmed by a large amount of published work. For many non-polar solvents of this type the ratios $\bar{Z}I_s/(I_s + I_d)$ and $\alpha_s/\bar{R}^6_{s,d}$ vary in the same sense: this also explains the often reported correlation between $\Delta\nu$ (or ν) and the $\alpha_s/\bar{R}^6_{s,d}$ value in a series of solvents[29,39,40]. The existence of this correlation is confirmed by the large deviation from the straight-line plot of ν or $\Delta\nu$ observed (point 6 in Fig.1) when H-bonded complexes or charge transfer complexes can be formed between the solute molecules and those of the non-polar solvent[41].

Dispersion and inductive interaction can cause a large decrease in ν_s, often of the same order as in polar solvents, which cannot form complexes with solute molecules[40,41]. A large contribution from inductive interactions in the case of polar vibrators in non-polar solvents can be recognised by comparing the $\Delta\nu$ values of the same vibrator for compounds of different polarity in the same non-polar solvents[22,31]. In the case of solvents which cause large deviations from Eqns.(7) and (8) we can calculate the contribution from complex formation or $\pi-\pi$ interaction of the solute and solvent molecules. On the other hand, a study of the contributions from dispersion and inductive IMI has shown that CCl_4 and CS_2 molecules do not take part in complex formation with molecules containing A–H groups[42,49].

The validity of these expressions for intermediate values of α_s, $\bar{Z}_s$, and $\bar{R}_{s,d}$ suggests a volume (as opposed to a local) mechanism for the interaction between molecules in solutions of this type. A volume mechanism can also explain the fact that the $\Delta\nu$ values in non-polar solvents having different but relatively small molecules all lie approximately on the same straight line. Similarly, the strong temperature and pressure dependence of the dispersion and inductive interactions is also consistent with a volume mechanism. An increase in temperature produces a large increase in $R_{s,d}$, and therefore a decrease in $\Delta\nu$.[44] An increase in pressure has the opposite effect on $\Delta\nu$.[31]

In a series of polar solvents with similar values of I_s and α_s (Fig.2) the $|\Delta\nu_s|$ values increase almost linearly with $\bar{Z}\mu_s^2/\bar{R}^6_{s,d}$, as required by Eqns.(9) and (10).

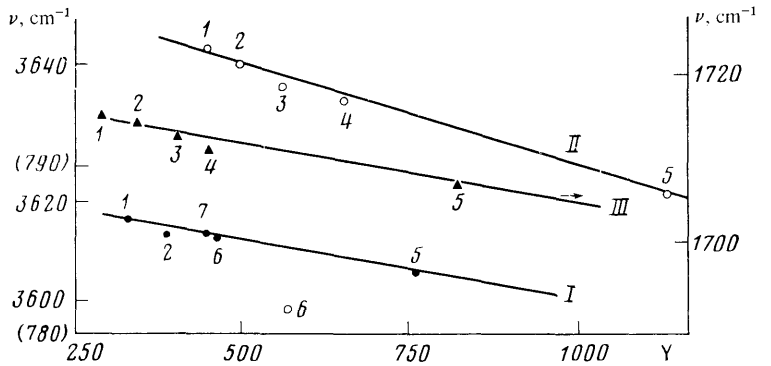

Figure 1. Dependence of ν(C–Cl) on $Y = \bar{Z}\frac{I_s I_d}{I_s + I_d}\frac{\alpha_s}{\bar{R}^6_{s,d}}$ for CCl_4 (*I*), and dependence of ν(O–H) for ethanol[37] (*II*) and of ν(C=O) for benzaldehyde[44] (*III*) in non-polar solvents: *1*) hexane, *2*) cyclohexane, *3*) CCl_4, *4*) C_2Cl_4, *5*) carbon disulphide, *6*) benzene, *7*) dioxan.

An analysis of the above expressions has revealed the following features of the field-induced (dipole–dipole and inductive) interaction of molecules in solutions (in comparison to the specific interactions accompanying the formation of complexes by the same molecules):

a) $|\Delta\nu_S|$ is usually smaller than the usual values for specific interaction between a vibrator molecule and a solvent;

b) the dipole–dipole interaction effect can take place even when the access of the solvent molecules to the proton-donor A–H group is blocked by steric hindrance;

c) the dependence of $|\Delta\nu_S|$ on the chemical composition and structure of the solvent molecules is different from (and almost opposite to) the effects observed during the specific interaction of a vibrator with a solvent[45]. For example, dipole–dipole interaction causes a decrease in $|\Delta\nu_S|$ rather than the increase expected from the decreasing *s*-character of the orbitals of the heteroatom in the solvent molecule [$CH_3CN > C_5H_5N > (C_2H_5)_3N$; $(CH_3)_2C{=}O > (C_2H_5)_2O$]. For solvents which include elements from the same period as heteroatoms, $|\Delta\nu_S|$ decreases in the following sequence: $RCN > RNO_2 > R_2CO > R_2O > R_3N$, which is the inverse of the series describing the tendency of solvents to form H-bonded complexes;

d) in the case of large differences in the size and nature of the solvent molecules (from both the aromatic and the aliphatic series) the $|\Delta\nu_S|$ values for a given vibrator lie on different straight lines if the interaction is of the dipole–dipole type;

e) if the solvent molecules are complex (with several polar functional groups) the $|\Delta\nu_S|$ values are determined by the molecule as a whole rather than by individual dipole moments or by the moment of the most polar group.

3. Effect of the Medium on the Vibrational Spectra of Molecules with Intramolecular and Intermolecular Hydrogen Bonds

In ternary systems [solvent, RAH, and BR', including the RAH...BR' complexes (K)] the vibrational spectra of the A–H group (which forms intermolecular hydrogen bonds) are affected both by changing the solvent and by changing the $c_{BR'}/c_{RAH}$ ratio[16,17,35]. The type of change is not very different from that of a vibrator not involved in hydrogen bond formation. The calculation of these solvent effects merely in terms of macroscopic characteristics such as ε and n,[47–49], or by using empirical relationships[16,46], has been criticised by several workers[2,47,50,51]. One of us[38] has examined the possibility of calculating the effect of the medium on the properties of the A–H group (involved in complex formation) by assuming proportionality (in the case of solvents of the BR' type with similar values of I_S and α_S) between $\Delta\nu_S$ and the parameter $\bar{Z}\mu^2_{BR}/\bar{R}^6_{K,BR'}$, which reflects the change in dipole–dipole interaction of the complex K with the excess of BR' molecules[37,45,52]. The proton-acceptor solvents BR' are chosen so that the changes in $\bar{Z}\alpha_S/\bar{R}^6_{S,d}$ are much smaller than those in $\bar{Z}\mu^2_S/\bar{R}^6_{S,d}$.

An analysis of the absorption spectra revealed the following features in the influence of the medium on the properties of the A–H group in H-bonded complexes. In relation to ν_{max} and $\Delta\nu_{1/2}$ the effect of the medium is relatively unimportant (as compared with the formation of the hydrogen bond itself). On changing from low-polarity ($\mu_{BR'} \leq 1.2$ D) to high-polarity solvents ($\mu_{BR'} > 1.2$ D) the sign of $\Delta\nu_{max}$ changes from positive to negative, and that of $\Delta\nu_{1/2}$ changes in the opposite sense[37]. We should note that when $\mu_{BR'} > 1.2$ D the effect of the medium on all the absorption characteristics is the same as the effect of complex formation. Under these conditions $\Delta\nu_S$(OH) for the complex is always much greater than $\Delta\nu_S$ for the free molecule.

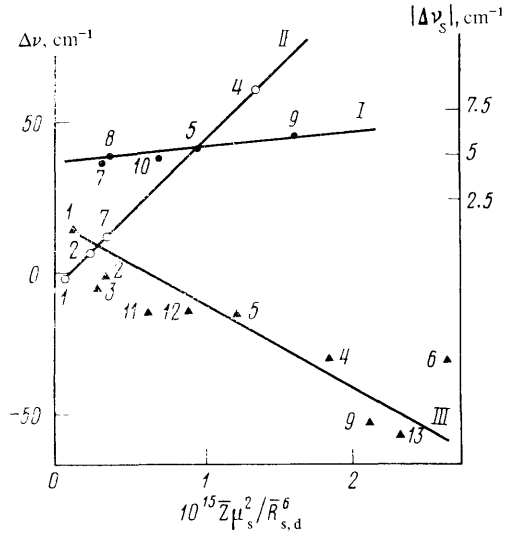

Figure 2. Plots of $\Delta\nu = \nu_{CCl_4} - \nu_{BR'}$ for CCl_4 (*I*), $\Delta\nu$(OH) for *o*-nitrophenol (*II*), and $\Delta\nu = \nu_{BR'} - \nu_{CCl_4+BR'}$ for ethanol (*III*) against $\bar{Z}\mu^2_S/\bar{R}^6_{S,d}$ in polar solvents[37]: *1*) $(C_2H_5)_2O$, *2*) C_4H_9Cl, *3*) $CH_3COOC_2H_5$, *4*) CH_3NO_2, *5*) $(CH_3)_2CO$, *6*) CH_3CN, *7*) CH_3COOCH_3, *8*) $HCOOC_2H_5$, *9*) $HCON(CH_3)_2$, *10*) CH_3COCl, *11*) $HCOOCH_3$, *12*) $CH_3COC_2H_5$, *13*) $(CH_3)_2SO$.

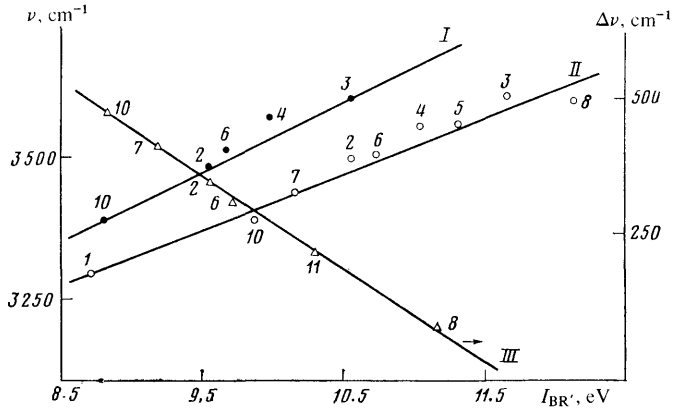

Figure 3. Plots (against the ionisation potential) of the ν(OH) values for ethanol in the ternary ($C_2H_5OH + CCl_4 + BR'$) system (*I*) and in the binary ($C_2H_5OH + BR'$) system (*II*), and of $\Delta\nu_S(OH) = \nu_{CCl_4} - \nu_{BR'}$ for *p*-nitrophenol (*III*),[37] where BR' is: *1*) $(C_2H_5)_3N$, *2*) $(C_2H_5)_2O$, *3*) $n\text{-}C_4H_9Cl$, *4*) $HCOOCH_3$, *5*) $CH_3COOC_2H_5$, *6*) $(CH_3)_2CO$, *7*) $HCON(CH_3)_2$, *8*) CH_3NO_2, *9*) CH_3CN, *10*) $(CH_3)_2SO$.

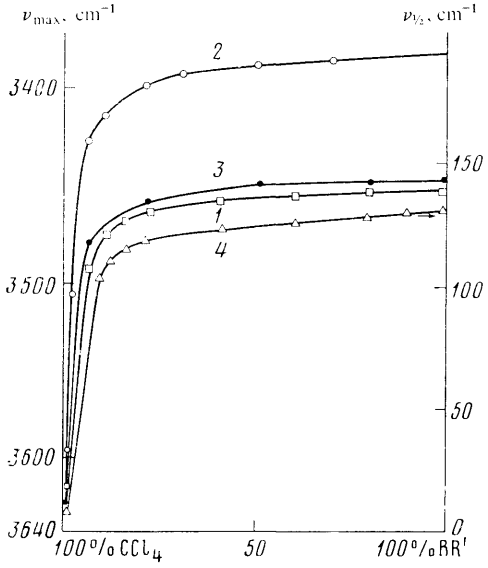
The ν_{max} (or $\Delta\nu_{max} = \nu(OH)_{free} - \nu(OH)_{h.b.}$] values for the ν(OH) band in the complexes of ethanol and *p*-nitrophenol with BR′ are inversely proportional to $I_{BR'}$ (Fig. 3), as required by the electronic model of the hydrogen bond[38]. The only exceptions are molecules with a proton-accepting power much lower than that of ethanol and a large dipole moment (for example, CH_3NO_2 and CH_3CN). On the other hand, the $\Delta\nu(OH) = \nu(OH)_{bin} - \nu(OH)_{tern}$ values are almost linearly related to $\overline{Z}\mu^2_{BR'}/\overline{R}^6_{RAH,BR'}$, a parameter which characterises the dipole–dipole interaction between the BR′ molecules and the complex (Fig. 2). This justifies the assumption that the main contribution to the change in vibrational frequency caused (for high values of $c_{BR'}/c_{RAH}$) by the displacement of surrounding molecules of non-polar CCl_4 by molecules of polar BR′ comes from the increased dipole–dipole interaction between the complex and the medium.



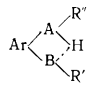


Figure 4. Spectral characteristic ν_{max} of the ν(OH) band against the solvent concentration ratio[37] for *1*) ethanol [BR′ = HCON$(CH_3)_2$]; *2*) ethanol [BR′ = $(CH_3)_2$SO]; *3*) *p*-nitrophenol (BR′ = CH_3NO_2); *4*) is the $\nu_{1/2}$ value of the ν(OH) band of phenol (BR′ = CH_3CN).

In ternary systems the dependence of ν_{max} on $\overline{Z}\mu^2_{BR'}/\overline{R}^6_{RAH,BR'}$ (and hence, for a given value of $\mu_{BR'}$, on $\overline{Z}$ and on $\overline{R}_{RAH,BR'}$) follows from the nature of the change in the spectral characteristics with $c_{BR'}/c_{CCl_4}$.[53–55] The steep increase of ν_{max} (Fig. 4, from Ref. 38) at low values of the ratio $c_{BR'}/c_{CCl_4}$ is due to the formation of a complex with BR′. The more gradual change in ν_{max} is due to the increase in Z caused by the replacement of molecules of non-polar solvent from the first coordination sphere of the complex by excess molecules of the polar compound BR′. The subsequent, even slower, change in ν_{max} is ascribed to the interaction of the complex with BR′ molecules from the outer coordination spheres, for which the interaction energy is very low (because of the large increase in $\overline{R}_{s,d}$).

The spectra due to the formation of intramolecular hydrogen bonds in compounds such as

(where Ar is an aryl group, and R′ and R″ are other parts of the molecule, attached to the atoms A and B) differ in several ways in the ν_s(A–H) absorption region from the spectra corresponding to the formation of an intermolecular hydrogen bond by the *para*-isomer[56,57]. For *o*-nitrophenol[58] and *o*-nitroacetanilide[54] these features are observed also in the effect of the medium on ν_{max} for ν_s(A–H) band of the intramolecular hydrogen bond. In different polar solvents of the BR′ type the ν_{max} value for this band increases in the opposite sense to the normal sequence for the ν_s(A–H) band of the intermolecular hydrogen bond. In solvents having a high proton-accepting power we find an additional band whose maximum usually lies at frequencies higher than the maximum of the ν_s(A–H) band for the intermolecular hydrogen bond[54,58–60].

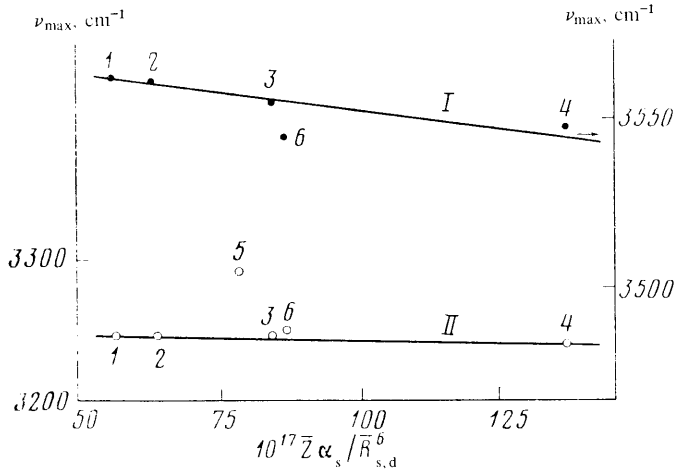

Figure 5. Plots against $\overline{Z}\alpha_s/\overline{R}^6_{s,d}$ of ν_{max} for the ν(OH) bands of guaiacol (*I*) and of *o*-nitrophenol (*II*) in non-polar solvents; *1*) hexane, *2*) cyclohexane, *3*) CCl_4, *4*) hydrogen sulphide, *5*) dioxan, *6*) benzene[58].

These effects of the medium have not yet been fully explained. Some workers[59,60] ascribe them to the breaking of an intramolecular hydrogen bond, with formation of complexes with molecules of the solvent, while others[61] postulate a three-particle complex with a forked hydrogen bond. Some published papers[62,63] explain the increase in ν_{max} in compounds with intramolecular hydrogen bonds in terms of dipole–dipole interactions, which lift the BR′ group from the plane of the aryl ring or displace the bridging proton. In an attempt to solve the problem more strictly[38], the spectral behaviour of molecules with intramolecular or intermolecular hydrogen bonds, and of molecules with a strong or a weak intramolecular hydrogen bond, has been compared as a function of $c_{BR'}/c_{CCl_4}$. The difference $\Delta\nu_{max} = \nu_{CCl_4} - \nu_{BR'}$ was found to increase with the

dispersion interaction energy[64]. This is confirmed by the fact that ν_{max} has about the same dependence on $\overline{Z}\alpha_s/\overline{R}^6_{s,d}$ as $\nu(OH)_{free}$ (see Fig.5, from Ref.38). In ternary systems containing *o*-nitrophenol only the $\nu_s(OH)$ intramolecular hydrogen bond band is observed. The high stability of this bond in *o*-nitrophenol is shown by the slight increase in $\nu_{max}(OH)$ caused by small additions of strong proton acceptors, followed by a steep fall, whereas additions of weak proton acceptors produce a continuous increase in ν_{max} towards the value for the pure BR′ compound (Fig.6),[38] i.e. the strong proton acceptors can break the intramolecular hydrogen bond and displace the equilibrium towards the formation of complexes involving intermolecular hydrogen bonds. On the other hand the increase in ν_{max} for the (A–H) band of the intramolecular hydrogen bond is probably due to non-specific interactions between molecules which contain intramolecular hydrogen bonds and the surrounding medium[65].

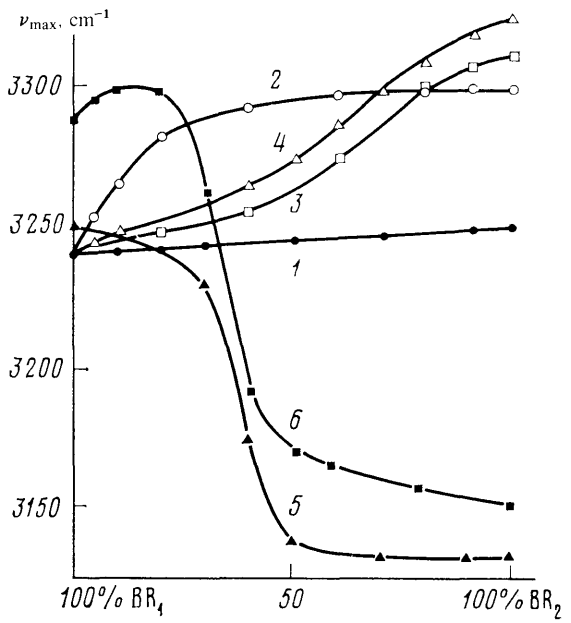

Figure 6. Plots of ν_{max} of the ν(OH) band for *o*-nitrophenol against the solvent concentration ratio (c_{BR_1}/c_{BR_2}) in ternary systems of the *o*-nitrophenol + BR_1 + BR_2 type. The BR_1 + BR_2 combinations are: *1*) CCl_4 + n-C_4H_9Cl, *2*) CCl_4 + CH_3NO_2, *3*) CCl_4 + CH_3CN, *4*) CCl_4 + $CH_3COC_2H_5$, *5*) n-C_4H_9Cl + $(CH_3)_2SO$, *6*) CH_3NO_2 + $(CH_3)_2SO$.[63]

III. INTERMOLECULAR FIELD INTERACTION AND THE CHEMICAL SHIFT OF PROTON SIGNALS

Ever since the first report of its use in studies of the hydrogen bond[66] the proton magnetic resonance (PMR) method has been one of the most useful and successful means of identifying and characterising intermolecular interactions. This is because the PMR spectra reflect both the nature and the extent of the participation of a proton in various interactions. The quantity δ_H (the chemical shift of the signal from hydrogen nuclei) in the PMR spectrum is determined to a first approximation by three independent factors[67]: the state of the electron shell surrounding a particular H atom (i.e. its shape and size), the effect of the surrounding atoms and functional groups in the molecule, and the effect of different kinds of IMI. Thus the quantity δ_H is defined by the structure of the molecule, by the interaction between atoms and functional groups within the molecule, and by the interaction with neighbouring molecules in a pure liquid or in a solution.

The change from the gaseous to the condensed state causes large changes in δ_H(A–H), where A = O, H, C, S. etc. The increment $\Delta\delta_H$(A–H) caused by the medium can be divided into five independent contributions[68–71]:

$$\Delta\delta_H(A\cdots H) = \delta_{vol} + \delta_{an} + \delta_{disp} + \delta_{pol} + \delta_{sp}. \qquad (11)$$

where δ_{vol} is the contribution from the volume susceptibility of the sample, δ_{an} is that due to the non-zero average anisotropy of the magnetic susceptibility of the solvent molecules, δ_{disp} is due to the dispersion interactions between solute molecules and solvent molecules, δ_{pol} is due to polarisation interaction between the molecules, and δ_{sp} is the contribution from specific interactions between molecules of the solvent and of the solute.

Most of the PMR studies of intermolecular interaction published so far are aimed at the contribution δ_{sp}, for two reasons: 1) this contribution is by far the largest, and 2) it can potentially give information on the genesis of intermolecular complexes involving a redistribution of electron density, which are currently of great interest. Since in most cases δ_{sp} is greater than the combined contribution from the other terms in Eqn.(11) it is not unusual to find the whole of the shift $\Delta\delta_H$ caused by the solvent ascribed to intermolecular association effects, the non-specific (field) interaction between solute and solvent molecules being completely ignored.

It is difficult to isolate one of the terms in Eqn.(11) for special study, even with carefully chosen series of solutes and solvents. If the change in volume susceptibility (and hence in δ_{vol}) is allowed for, and the contributions δ_{an} and δ_{sp} can be ignored, the observed increment $\Delta\delta_H$(A–H) should be determined only by field interactions of the molecules (dispersion effects, δ_{disp}, and polarisation effects, δ_{pol}).[67]

The quantity δ_{disp} is determined by two effects[67]: a) the interaction between molecules of the solute and of the solvent causes a loosening of the electron cloud surrounding the nuclei of the solute molecules, leading to a decrease in the diamagnetic screening effect (long-range interaction), and b) the interaction can perturb the symmetry of the electron clouds in the solute molecule (in the *s*-state), giving rise to a paramagnetic contribution in the screening constant (short-range interaction, temperature-dependent).

A quantum-mechanical calculation of the effect of dispersion interaction on the screening constant of the hydrogen atom has shown[72] that van der Waals forces lower the screening and shift the signals towards lower fields. Experimental measurements of the contribution δ_{disp} involve some serious difficulties. The direct method of isolating the contribution δ_{disp} involves comparing the δ_H values for a series of structurally similar non-polar compounds in the gas state and dissolved in non-polar isotropic solvents[82,83]. However, in practice the NMR spectroscopy of gaseous samples is far from straightforward.

To calculate the contribution of dispersion interaction to the magnetic screening of protons in solutions several models have been proposed: the "continuous" dielectric model, the lattice model, and the statistical model. Theoretical calculations of the contribution of the constant G_{disp} to δ_{disp} are also very difficult. The "excess" chemical shifts in the spectra of liquid systems consisting of magnetically isotropic molecules were first explained[74] in terms of dispersion forces. The model developed in that work[74] gives

$$G_{disp} = -\frac{3B\alpha_2 I_2}{2R^6} \qquad (12)$$

where B is the bond parameter ($B = 0.74 \times 10^{-18}$ for the hydrogen atom[75]), and α_2 and I_2 are the polarisability and the ionisation potential of the perturbing solvent molecule.

The "continuous dielectric" model, proposed earlier by Linder[77] for determining the potential energy of the dispersion interaction in pure liquids, has also been used in these calculations[76]. Starting from experimental values of the shift caused by the interaction in a solution of the solute 1 in the solvent 2 (at infinite dilution) Howard and coworkers[76] arrived at the expression

$$G_{disp} = -\frac{3B(2n^2-2)h\nu_1\nu_2}{4(2n^2+1)a^3(\nu_1+\nu_2)} \qquad (13)$$

where n is the refractive index of the solvent, a is the radius of the solute molecule, and $h\nu$ is the excitation energy. A similar model was used in Ref.73. The "continuous" dielectric model led to the conclusion[76] that the contribution of G_{disp} can be described by the expression

$$G_{disp} = -6\left[\frac{(n_2^2-1)^2}{(2n_2^2+1)(n_2^2+2)}\right]_{soln.} \cdot \left[\frac{K_1 B\Delta E_1}{\alpha_1}\right]_{solute}$$

where ΔE_1 is the energy of formation of the transition complex, which can be equated to twice the ionisation potential of this complex, and K_1 is a factor determined by the location of the proton and depending on the geometry of the solute molecule. However, in experimental tests of the expressions for δ_{disp} based on collective interaction concepts[73,74,76] the theoretical values of G_{disp} were inconsistent with measured values.

Calculations of G_{disp} by the "continuous" dielectric model rely on measurements of the characteristic frequencies of the solvent and of the solute (ν_1 and ν_2). These frequencies can be obtained by the formula $\nu = I/h$, which follows from the London approximation[78], where I is the ionisation potential of the molecules. Another formula for calculating the characteristic frequency[77,79] is

$$\nu = -4m_e c^2 \chi_m / hN\alpha \qquad (14)$$

where m_e is the mass of the electron, c is the velocity of light, N is Avogadro's number, α is the polarisability, and χ is the molar susceptibility of the molecules. Lastly, the characteristic frequencies have been calculated[80] by the Lorentz–Lorenz formula for the refractive index.

A calculation of G_{disp} for a large number of systems[81] has given very different results for given systems, depending on the method used to determine ν. A rational choice of the preferred method of calculation among those used in Ref.81 cannot yet be made. It has been suggested[82] that the influence of the medium on the chemical bond arises from the interaction of a solute molecule with the nearest molecules of the solvent "lattice", i.e. that $G_{disp} = Z \cdot G_{disp}(pair)$, where Z is the number of nearest solvent molecules in the "lattice" and $G_{disp}(pair) = -3B\alpha_2 I_2/R^6$ (by analogy with the formula given in Ref.74). The parameter Z was obtained[82] by dividing the area of a sphere passing through the centres of the molecules in the first coordination sphere $[4\pi(r_1+r_2)^2]$ by the effective cross-sectional area of the solvent molecules $(2r_2)^2$. Putting $R = r_1 + r_2$ we find

$$G_{disp} = -\frac{3\pi B\alpha_2 I_2}{(r_1+r_2)^4 r_2^2} \qquad (15)$$

where r_1 and r_2 are the radii of the solute and solvent molecules respectively.

With a suitable choice of series of compounds this model gives δ_{disp} values in good agreement with experiment: however, the results are less reliable when the same approach is used for molecules differing in size, shape, or chemical composition. Better agreement with experiment was obtained[86] by introducing into the formula the factor S_6^g, determined by the location of the resonating proton, and the additional empirical factor K_6^c, depending on the temperature and on the configuration of the solvent and solute molecules:

$$G_{disp} = -K_6^c \frac{3\pi B\alpha_2 I_2}{(r_1+r_2)^4 r_2^3} S_6^g .$$

An alternative approach was developed[83] by studying the effect of the medium in gaseous systems. The contribution from G_{disp} was calculated[83] in terms of binary collisions between the molecules only. The average contribution to the chemical shift from dispersion interactions was determined by using the Lennard-Jones intermolecular potential, and the following formula was obtained:

$$G_{disp} = -\frac{\pi NB\alpha_2 I_2 H_6(X)}{V_2 r_0^3 X^4} \qquad (16)$$

where V_2 is the molar volume of the solvent, $H_6(X)$ is a function tabulated in Ref.84 [$X = 2(\varepsilon/kT)^{1/2}$], ε/kT and r_0 are the force constants in the Lennard-Jones potential, and N is Avogadro's number.

The method[83] is essentially a semi-empirical statistical method, which has proved successful when applied to gases and gas solutions. Other workers[85,86] applied it to liquids, and obtained an expression not very different from (16). However, the model is relatively crude. Firstly, the calculated G_{disp} values are in qualitative rather than quantitative agreement with experiment, even when empirical coefficients are added to the formula. Secondly, the model cannot distinguish between the solvent effects on chemically non-equivalent protons in complex solvent molecules. The theory of pair collisions in gases was later modified[86] in order to apply it to liquids. The van der Waals interaction field $\langle\overline{E}^2\rangle$ near the peripheral protons of the solute molecule was shown to be different from the $\langle\overline{E}^2\rangle$ value at the centre of the molecule, and a correction to allow for the position of the proton in the molecule was added to the formula. The possibility of introducing a term for the repulsive effects into the expression for G_{disp} was examined, but the correction was found to be negligible. The formula finally proposed to describe quantitatively the contribution of dispersion interaction to the chemical shift also includes a temperature factor, to allow for the temperature dependence of G_{disp}:

$$G_{disp} = -(1.46 \pm 0.0064t)\cdot 1.36 \cdot 10^6 \frac{\alpha_2 I_2 H_6(X)}{V_2 r_0^3 X^4} S_6^g . \qquad (17)$$

The parameters S_6^g and $H_6(X)/X^4$ are tabulated in Ref.86. The physical nature of the temperature factor is not stated. Experimental tests of Eqn.(17) were on the whole satisfactory.

In a study[87–90] of various contributions from the medium to the chemical shift a linear combination of terms (including one due to dispersion interaction) was used to express the

chemical shift. The dispersion term was written as a product of contributions from the solvent and the solute respectively. By using this method the authors were able to determine experimentally the G_{disp} contribution for a number of systems. The experimental results were compared with theoretical calculations by the formulae of the collective interaction model[76,77], or by a formula obtained[85,86] from the statistical theory of pair collisions. The agreement in both cases was surprisingly good, and a critical analysis of the two methods of calculating G_{disp} was thought unnecessary.

The two sets of calculations (Refs.76, 77 and 85, 86), though differing in detail, have a great deal in common. First of all they both rely on generalised collective parameters, and therefore they cannot be used to study the dependence of δ_{disp} on the microscopic parameters of the interacting molecules. In spite of its relative success in calculations of G_{disp}, formula (17) (which was obtained from the theory of pair collisions in gases) has a number of shortcomings. The model is not applicable to large molecules, which require replacement of the one-centre Lennard-Jones potential by a many-centre potential force field. This is a serious limitation of all the models discussed above, especially in the case of aromatic solvents. The reliance on physical constants which are not always available creates further obstacles to the use of this working formula. Thus, though G_{disp} values have been successfully calculated, the method is not suitable for day-to-day use in the laboratory.

Allowance for polarisation effects is needed when one of the components of the solution is polar. This contribution is usually small[113], and can be described by the formula

$$\delta_{pol} = \delta_{disp} \frac{2\mu_2^2}{3\alpha_2 I_2}$$

where μ_2 is the (constant) dipole moment, α_2 is the polarisability, and I_2 is the ionisation potential of the solvent molecule. However, for small solvent molecules with large dipole moments the contribution from δ_{pol} becomes comparable to δ_{disp}.[103] An approximate calculation[60] has shown that for a proton of the A–H group the screening component associated with the external electric field is $\sigma_E = -AE_z - BE^2$, where A and B are constants and E_z is the component of the electric field E in a direction parallel to the A–H bond. The shift of the proton signal caused by the electric field is explained by the repulsion experienced by the excess charge on the proton, which lowers the electron density on the 1s orbital of the hydrogen and the screening constant[91]. Furthermore, the presence of an electric field hinders the diamagnetic current circulation within the hydrogen atom, which again lowers the screening constant and shifts the proton signal towards lower fields[92].

A polar molecule added to a solution polarises the surrounding medium, and its nuclei experience the reactive field of the medium. Starting from the Onsager model[14], and identifying E_z with the reaction field, Linder[77] obtained the following formula for δ_{pol}:

$$\delta_{pol} = -\text{const} \cdot \left(\frac{\varepsilon - 1}{2\varepsilon + n^2}\right) \frac{\mu \cos\varphi}{2} \qquad (18)$$

where ϕ is the angle between $\vec{\mu}$ and the C–H bond.

According to formula (18), in a binary solution the solute is characterised by the refractive index n, the dipole moment μ, and the polarisability α, and the solvent is characterised only by one macroscopic property: the dielectric constant ε.

Diehl and Freeman[93] made some improvements in Buckingham's theory to allow for the polar contribution, and proposed a slightly different model, which takes account of the shape of the solute molecule. They arrived at a modified formula for the reaction field, which reduces to the formula given by the Onsager model in the case of spherically symmetrical molecules. However, the expression obtained in Ref.93 is not very different from Eqn.(18). Better correlations have been obtained[94] by using formula (18) for the internal (or relative) shift between two non-equivalent protons in a molecule rather than for the chemical shift of any one proton. This should allow all effects to be excluded except the reaction field effects. This assertion was tested[95] with a series of methyl-substituted nitrobenzenes in 13 different solvents. It was found that only by limiting the choice of solvents to those having carefully chosen properties could good correlations be obtained with experimental data on the internal chemical shift, calculated by the reaction field theory based on the Onsager model.

If the polar component is the solvent, the influence of the electrostatic field created by its dipoles on the solute molecule is almost equivalent to the reaction field calculated by Buckingham[68], whose linear effect causes a change in the polarity of the A–H bond. It is clear from formula (18) that solutions of a polar solute in a series of solvents having different ε values should be described by the expression

$$\Delta\delta_H(\text{A}-\text{H}) \sim \frac{\varepsilon - 1}{2\varepsilon + n^2} \cdot \qquad (19)$$

However, expressions for the polar contribution to the chemical shift of protons in a solute molecule in terms of the macroscopic properties of the solution[68,96,97] are not precise enough for use in PMR.

In many polar (and in some non-polar) solvents the chemical shifts are very different from those calculated by formulae such as (19). Thus, according to Buckingham[68] solvents like n-hexane, nitromethane, acetonitrile, and acetaldehyde do not follow the correlation (19); carbon tetrachloride, acetone, acetonitrile, etc.[97], and dimethylsulphoxide, *N*,*N*-dimethylformamide, etc.[98,99] are also found to behave abnormally. On the other hand, as a result of the use of generalised properties of the components in these correlations it is impossible to study directly the dependence of the chemical shift $\Delta\delta_H$(A–H) on the physical properties and on the structure of the solute and solvent molecules and on the different types of intermolecular interaction. This led to various attempts to relate the $\Delta\delta_H$(A–H) values to other properties of the components, such as the polarity constant of the solvents[96], the dipole moment of the solute molecules μ_d,[98–100] the ratio of the dipole moment to the molar volume μ_d/V,[69] etc.

The calculation of the effect of dispersion and polarisation field interactions on the chemical shift of protons in the interacting molecules has also been examined from a different aspect[101]. A physically more justifiable set of equations was obtained[101] by assuming proportionality between the chemical shift due to field interactions and the energy of the pair interactions between the solute and the solvent molecules ($\Delta\delta_{field} \propto |U_{s,d}|_{pair}$). The parameter $|U_{s,d}|$ was calculated in the dipole approximation[8]: $|U_{s,d}|_{pair} = |E_{s,d}|_{disp} + |E_{s,d}|_{pol} + |E_{s,d}|_{el.st.}$, using the London, Debye, and Keesom potentials respectively for the additive contributions to the energy. In the case of dilute solutions, when the solute molecules are surrounded by solvent molecules only and no local interactions take place through the overlap of electron clouds, we can write[8]

$$\Delta(\delta_{disp} + \delta_{pol}) \propto |U_{s,d}|_{pair} = \frac{1}{R^6_{s,d}} \left\{ \frac{3}{2} \frac{I_s I_d}{I_s + I_d} \alpha_s \alpha_d + \mu_s^2 \alpha_d + \mu_d^2 \alpha_s + \frac{2}{3} \frac{\mu_s^2 \mu_d^2}{kT} \right\}. \qquad (20)$$

Formula (20) has a number of advantages over those given above. It shows explicitly the relationship between the chemical shift due to field interactions and the microscopic properties of the interacting molecules. The expression contains one of the most important parameters of IMI: the distance between the interacting molecules, which does not appear in formulae based on Onsager concepts. Furthermore formula (20) suggests a suitable methodology for studying the dependence of $\Delta\delta_{H,field}$ on molecular properties: by the strict selection of series of compounds related by particular characteristics. Thus, it follows from Eqn.(20) that the expression

$$\Delta(\delta_{11})_{disp} \sim \alpha_s/\bar{R}^3_{s,d} \qquad (21)$$

can be applied to solutions of a given non-polar substance ($\mu_d = 0$) in a series of non-polar solvents ($\mu_S = 0$) with similar values of I_S (i.e. in the presence of dispersion interaction only between molecules of the components).

Similar relationships apply to the chemical shifts of solutions of a given polar substance in a series of non-polar solvents with similar values of I_S, and also to solutions in a given non-polar solvent of a series of polar substances for which μ_d = const but with widely different values of α_S. For solutions of a given non-polar or polar substance in a series of polar solvents with similar values of I_S, α_S, and $\bar{R}_S$ (a condition easily satisfied by isoperiodic solvents with molecules of similar shape) we find the correlation[101,102]

$$\Delta\delta_{11}(A-H) \sim \mu_1^2/\bar{R}^6_{s,d} \qquad (22)$$

or, for a series of solvents selected more critically in respect of molar volume and molecular shape, we find the expression

$$\Delta\delta_{11}(A-H) \sim \mu_s^2 \ . \qquad (23)$$

These expressions have been tested[102] against a large amount of experimental information from different laboratories. Many data for δ_H(A–H) are quoted[102], but only for A=C (ring protons, protons in CH_3 groups, etc.) does comparison between calculation and result confirm the validity of Eqns.(21)–(23) when applied to different series of binary solutions of aromatic or aliphatic compounds. Calculation of δ_{disp} and δ_{pol} by Eqn.(20) shows that δ_H(C–H) is determined by interactions between solute and solvent molecules which are not local in character but are averaged over all possible orientations of the interacting molecules. Under these conditions the proton can become unscreened either as a result of proton withdrawal effects due to the electric field or as a result of the displacement towards the carbon atom of the electrons in the C–H σ-bond, also due to the electric field[83]. The change in the charge on the carbon atom[104] due to the redistribution of the electron density in the remainder of the molecule (other than the C–H group) under the influence of the field may also have a part to play.

A field interaction (of the volume type) with the surrounding molecules may also explain the change in the spectra of complexes in solution[102]. As Fig.7 (taken from Ref.102) shows, the change in the chemical shift of the bridging proton signal in the spectra of phenol and chloroform complexes with the proton acceptor BR′ caused by interaction with the medium is linearly related to the parameter $\bar{Z}_S\mu_S^2/\bar{R}^6_{S,d}$ (except in the case of very weak proton acceptors). This relationship also accounts for the change in chemical shift caused by varying the ratio of the concentrations of the proton acceptor solvent (BR′) and of the non-polar solvent in ternary systems (Fig.8, from Ref.102).

Thus the London, Debye, and Keesom potentials for pair interactions of the field type between component molecules can be used to calculate the effect of the solvent on the magnitude and direction of the chemical shift of the proton signal in solutions where complex formation cannot take place.

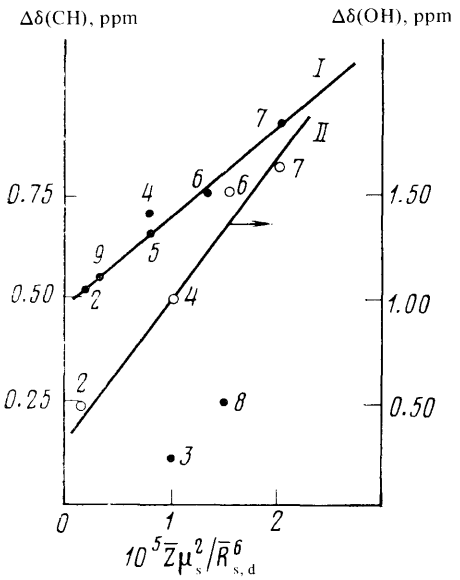

Figure 7. Plots of $\Delta\delta_H = (\delta_H)_{BR'} - (\delta_H)_{CCl_4+BR'}$ against $\bar{Z}\mu_S^2/\bar{R}^6_{S,d}$ for δ(CH) of chloroform (*I*) and δ(OH) of phenol (*II*) and different BR′: *1*) CCl_4, *2*) $(C_2H_5)_2O$, *3*) n-C_4H_9Cl, *4*) $(CD_3)_2CO$, *5*) $CH_3COC_2H_5$, *6*) $HCON(CH_3)_2$, *7*) $(CD_3)_2SO$, *8*) CH_3NO_2, *9*) $CH_3COOC_2H_5$.[102]

IV. EFFECT OF THE SOLVENT ON THE BASIC CHARACTERISTICS OF THE ELECTRONIC SPECTRA OF MOLECULES

1. Comparison of Methods of Calculating the Effect of the Medium on the Electronic Spectra of Molecules

Several studies of the influence of solvents on the basic characteristics (ν_{max} and the oscillator strength *f*) of the electronic spectra of molecules have been reported[105–109]. The parameter ν_{max} is usually obtained from universal expressions in terms of the generalised properties of the solvent *n* and ε.[2,108].

Bayliss[110] proposed the concept of a "general red shift", determined by the interaction with the medium of the dipole moment associated with the transition of the molecule. The shift $\Delta\nu$ is given by the formula

$$\Delta\nu = -cf\frac{n^2-1}{2n^2+1} \ , \qquad (24)$$

where *f* is the oscillator strength of the band, *c* is a constant, and *n* is the refractive index of the solvent.

Bayliss and Rae[111], using the Franck–Condon principle, arrived at a general scheme describing the effect of the solvent on electronic absorption spectra which allows

(qualitatively) for the main types of IMI. According to this treatment the displacement of the absorption band of a compound in solution relative to the spectrum of the same compound in the vapour phase is due to the difference between the energy of the interaction with the surroundings of the molecule in the ground and in the excited electronic state. Under these conditions the stabilisation energy for different electronic levels should be determined in each particular case in terms of the nature of the interaction between the molecule under study and the solvent molecules.

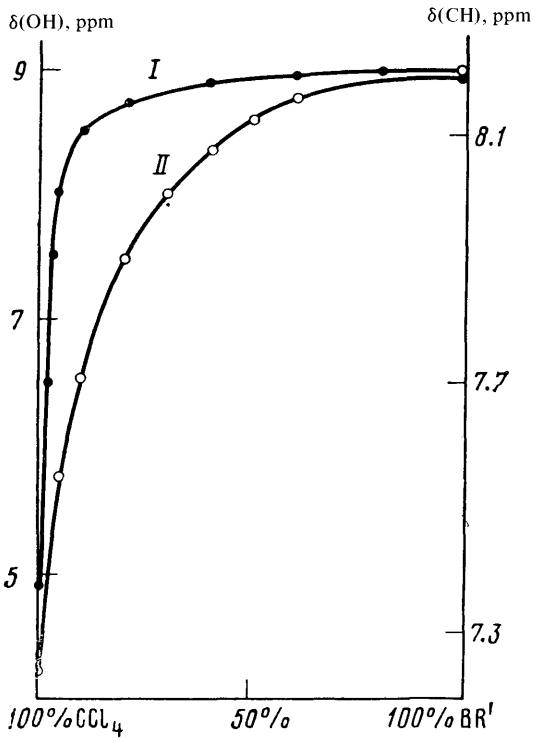

Figure 8. Plots of δ_H for the δ(OH) band of phenol (*I*) and of δ(CH) for chloroform (*II*) against the concentration ratio of CCl_4 and BR' [BR' = $(CD_3)_2CO$ for (*I*) and $HCON(CH_3)_2$ for (*II*)].[102]

An attempt has been made[112] to calculate the stabilisation energy of the electronic levels of molecules in solutions by assuming IMI of the dipolar type only. The stabilisation energies of the various levels were calculated from the basic characteristics of the interacting molecules, allowing for the changes in some of these characteristics caused by the absorption of a light quantum. The shift in the spectrum is treated essentially as due to the statistical averaging of the set of interactions between the solute molecule and the nearest-neighbour solvent molecules, and quantitative expressions are obtained by using the Onsager model.

A theoretical discussion[113] of the effect of the solvent on fluorescence spectra has shown that in general the shifts in the absorption and the emission band of any molecule undergoing a phase transition should be different. Two explanations are suggested: firstly, that the configuration of the solvent molecules around the solute molecule is different for solute molecules in the ground and in the excited state, and secondly that this configuration is not changed by the electronic transition (as required by the Franck–Condon principle).

A theoretical analysis of the effect of dipole–dipole interactions on the frequency of bands in the electronic spectra of solutions is given in Ref. 114. A simple electrostatic model yields expressions relating the frequency shifts in absorption and emission spectra to the parameters n and ε of the solvent. A theory of the effect of van der Waals interactions on the electronic spectra of molecules has been developed[115] from both semi-classical and quantum-mechanical foundations: the two approaches give qualitatively consistent results.

Important advances have been made in the application of computers to the analysis of experimental results[113–119]. The use of Kosower's Z parameter[119], an empirical characteristic of the polarity of the medium or (according to Kosower[119]) a microscopic measure of the type and strength of the interaction between solute and solvent molecules, has given interesting results in the analysis of experimental data on band shifts in electronic spectra. The same author has developed a method of determining the H-bond energy and the dipole moment in the excited state from absorption spectra by using the Z parameters.

The current state of spectroscopic research on intermolecular interactions has been systematically reviewed by Bakhshiev[2], who also showed[120] that intermolecular interactions in condensed media can affect, in general, not only all the physicochemical properties of the molecule of interest but also the field strength associated with a light wave acting on the molecule and inducing transitions between energy levels. He derived a general expression for the change in integral intensity of a band caused by the transfer of the molecule from the gas to the condensed state, which includes the correction factor $\bar{\theta}_\uparrow$ to allow for all the effects of the difference in field strength of the light wave between the condensed medium and a vacuum.

The first attempt to determine the form of the factor $\bar{\theta}_\uparrow$ by using the Lorentz model gave an expression[121] (applicable to dilute solutions) of the form

$$\bar{\theta}_\uparrow = 9n/(n^2+2)^2 \,. \qquad (25)$$

On the other hand, by using the Onsager model the following expression was obtained[131] for $\bar{\theta}_\uparrow$:

$$\bar{\theta}_\uparrow = n\left(\frac{2n^2-1}{3n^2}\right)^2 . \qquad (26)$$

The following formula was also obtained[123]:

$$\bar{\theta}_\uparrow = \frac{(2n^2+1)^2}{9n^3}\left(1-\frac{\bar{\alpha}}{a}\frac{2n^2-2}{2n^2+2}\right)^2 , \qquad (27)$$

where $\bar{\alpha}$ is the mean value of the real part of the complex polarisability of the molecule of interest, and a is the Onsager radius of the molecule.

A quantitative theory of the shift in electronic bands produced by universal intermolecular interactions is developed in Bakhshiev's papers, with full allowance for the different types of IMI. According to Bakhshiev the contribution from universal IMI is given by the formula $\Delta\nu^0 = C_1^a F(\varepsilon,n)$, where C_1^a is a characteristic of the properties of the solute molecule, and the universal interaction function $F(\varepsilon,n)$ characterises mainly the properties of the solvent. The function

$$F(\varepsilon,n) = \left(\frac{\varepsilon-1}{\varepsilon+2}-\frac{n_D^2-1}{n_D^2+2}\right)\frac{2n^2+1}{n^2+2} + P\frac{n^2-1}{n^2+2} \equiv A + PB \qquad (28)$$

is determined by the dielectric constant ε and the refractive index of the solvent (n_D for the visible region of the spectrum and n for the spectral region which includes the band of interest). The parameter P depends mainly on the change in polarisability of the solute molecule caused by the electronic excitation.

This method has been used[124,125] to separate the contributions ($\Delta\nu^0$) of the universal IMI from those ($\Delta\nu$) due to the formation of intermolecular hydrogen bonds (the $n \to \pi^*$ absorption bands of some aliphatic ketones). Though the Onsager model yields relatively simple expressions, readily tested experimentally[2,108], in both the quantum-mechanical and the classical approach, its application has been shown[126] to be severely limited. In addition to the well-known approximations implicit in the Onsager model, the Stark effect is ignored in the universal functions, and the parameter which characterises the size of the hole in the liquid structure is not expressed with adequate precision. Therefore the universal functions $f(\varepsilon)$, $f(n)$ and $f(\varepsilon,n)$, which rely on the generalised properties of the solvent, depend also on a number of features of both the solution structure and the various types of IMI.

Because of this, the effect of solvents on the ν_{00} value of absorption bands has been studied[126] by the model of pair interactions between molecules. The resulting expression explicitly includes the role of one of the most important factors in IMI: the distance between solvent and solute molecules. The expression is

$$\Delta\nu = \nu_s - \nu_{vap} = \frac{\bar{Z}\bar{\varphi}}{\bar{R}^6_{s,d}}\left\{\frac{3}{2}\left(\frac{I_d^{FC}\alpha_d^{FC}}{I_s^{gr}+I_d^{FC}} - \frac{\alpha_d^{gr}I_d^{gr}}{I_s^{gr}+I_d^{gr}}\right) I_s^{gr}\alpha_s^{gr} + [(\mu_d^{FC})^2 - \right.$$
$$\left. -(\mu_d^{gr})^2]\alpha_s^{gr} + [\mu_s^2(\alpha_d^{FC}-\alpha_d^{gr})] + \frac{2}{3kT}[\mu_d^{gr}\mu_d^{FC}\cos\beta - (\mu_d^{gr})^2]\mu_s^2\right\}, \quad (29)$$

where $\bar{\varphi}$ is a correction for non-additivity of the pair interactions and for the inaccuracy of the expressions for the various contributions to the potential, the superscripts "gr" and "FC" denote parameters of the ground state and the Franck–Condon state respectively, and β is the angle between the vectors $\vec{\mu}^{gr}$ and $\vec{\mu}^{FC}$.

For a given non-polar or polar solute undergoing a given electronic transition in a series of non-polar solvents the following expression was obtained[126]:

$$\Delta\nu = \bar{Z}\bar{\varphi}\left\{\left[\left(\frac{A}{I_s^{gr}+I_d^{FC}} - \frac{B}{I_s^{gr}+I_d^{gr}}\right)+C\right]\frac{\alpha_s}{\bar{R}^6_{s,d}}\right\}, \quad (30)$$

and for a series of polar solvents

$$\Delta\nu = \bar{Z}\bar{\varphi}\left\{\left[\left(\frac{A}{I_s^{gr}+I_d^{FC}} - \frac{B}{I_s^{gr}+I_d^{gr}}\right)-C\right]\frac{\alpha_s}{\bar{R}^6_{s,d}} + D\,\frac{\mu_s^2}{\bar{R}^6_{s,d}}\right\}, \quad (31)$$

where A, B, C, and D are constants. If the I_s^{gr} values are similar, if the product $\bar{Z}\bar{\varphi}$ is constant, and if no complexes are formed between molecules of the components, we find $\Delta\nu \propto \alpha_s/\bar{R}^6_{s,d}$ in the case of non-polar solvents, whereas in polar solvents with similar values of $\bar{R}_{s,d}$ and α_s but relatively large differences in μ_s we find $\Delta\nu \propto \mu_s^2/\bar{R}^6_{s,d}$ (or even $\Delta\nu \propto \mu_s^2$).

Many workers have tried to establish a relationship between the intensity of the absorption band and the solvent effect[126–130]. Thus, Chako proposed a formula[127] based on the classical theory of dispersion interaction which sets out the relation between f_s and f_{vap} but does not take account of the properties of the solute molecule:

$$\frac{f_s}{f_{vap}} = \frac{(n^2+2)^2}{9n^2}. \quad (32)$$

The changes in the field of the light wave in the dielectric have also been studied in detail by the Onsager model by Schleyer[128], who proposed a method of calculating the ratio of the molar extinction coefficients for the solution and the gaseous state. Abe[130] obtained the following expression:

$$\frac{f_s}{f_{vap}} = \frac{(n^2+2)^2}{9n^2}\,\frac{E_s}{E_{vap}}, \quad (33)$$

(where E is the energy of the transition), based on the Onsager model, which takes account of not only the effect of the solvent but also the properties of the solute molecule.

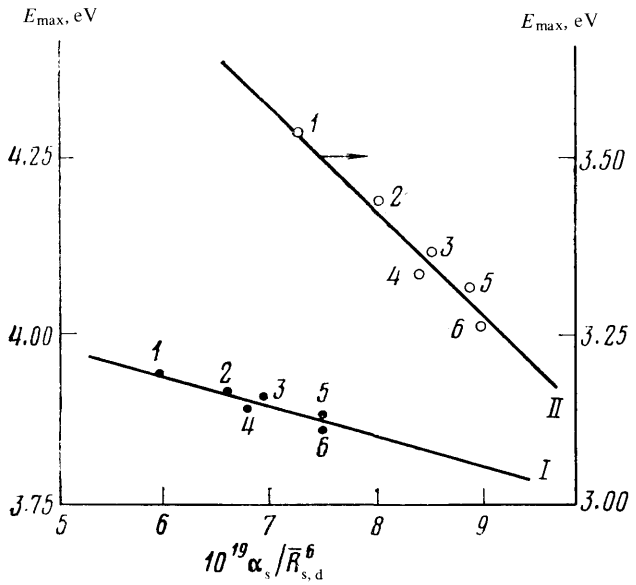

Figure 9. Plots against $\alpha_S/\bar{R}^6_{S,d}$ of the E_{max} values of the bands for the $\pi^* \leftarrow \pi$ transition in azobenzene (*I*) and the $\pi^*_{NO_2} \leftarrow n_{N(CH_3)_2}$ transition in *p*-nitrodimethylaniline (*II*). Solvents: *1*) hexane, *2*) cyclohexane, *3*) CCl_4, *4*) *p*-xylene, *5*) mesitylene, *6*) benzene[132].

2. Effect of Field Interactions on the Characteristic Absorption Bands of Substituted Benzenes

The effect of field interactions between solvent and solute molecules has been studied[131,132] in order to test the expressions (28)–(31). Fig.9 (from Ref.132) shows the dependence of E_{max} on $\alpha_S/\bar{R}^6_{S,d}$ for a number of substances. In the series of non-polar solvents the variation (increase) of E_{max} with $\alpha_S/\bar{R}^6_{S,d}$ is almost linear, both for the $\pi^* \leftarrow \pi$ band of the transition in azobenzene and for the $\pi^* \leftarrow n$ charge transfer bands of the other aromatic compounds. Fig.10 (from Ref.133) shows plots of E_{max} against $\mu_S^2/\bar{R}^6_{S,d}$ for two solutes in a series of polar solvents having the same (or similar) numbers of atoms of elements from the same period. In this case E_{max} decreases linearly with $\mu_S^2/\bar{R}^6_{S,d}$.

Thus we may conclude that the interaction between solute and solvent molecules is of the field type, i.e. that dispersion, dipole–dipole, and inductive interactions take place between the molecules. The contribution from inductive interaction in non-polar solvents depends on the difference in dipole moments, and in the case of polar solvents it depends also on the difference in polarisability of the solute molecules in the Franck–Condon and in the ground state.

Some special features of the effect of solvents on the oscillator strength f of the absorption bands of a range of compounds have been pointed out[132]. Starting from the formula (given in Ref.130) $f_S/f_{vap} = \frac{(n^2+2)^2}{9n^2}\frac{E_S}{E_{vap}}$ we find that for a given electronic transition in a solute molecule in a non-polar solvent $f = \text{const}\,\frac{(n^2+2)^2}{9n^2}E_{S,max}$. Fig.11 shows that this expression is reasonably well-obeyed. In Fig.12 (from Ref.132) we note that the parameter f decreases almost linearly with increase in $\alpha_S/\bar{R}^6_{S,d}$ in non-polar solvents.

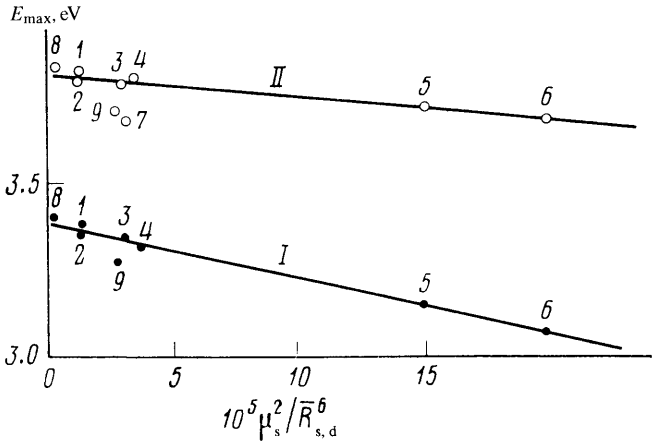

Figure 10. Plots against $\mu_S^2/\bar{R}^6_{S,d}$ of the E_{max} values of the bands for the $\pi^*_{NO_2} \leftarrow n_{N(CH_3)_2}$ transition in *p*-nitrodimethylaniline (*I*) and the $\pi^*_{CHO} \leftarrow n_{N(CH_3)_2}$ transition in *p*-dimethylaminobenzaldehyde (*II*). Solvents: *1*) $(C_2H_5)_2O$, *2*) $(C_2H_5)_2NH$, *3*) $n\text{-}C_4H_9Cl$, *4*) CH_3COOCH_3, *5*) $HCON(CH_3)_2$, *6*) $(CH_3)_2SO$, *7*) $iso\text{-}C_3H_7OH$, *8*) $N(C_2H_5)_3$, *9*) $n\text{-}C_3H_7OH$.[132]

3. Intermolecular Interaction with Hydrogen Bond Formation

The electronic spectra of H-bonded complexes are discussed in several papers, but the type and extent of the influence of complex formation on the electronic spectra (or, more exactly, on the E_{max} and f values) are not yet fully understood. From the fact that ΔE_{max} (and $\Delta\nu_{max}$) are described by the universal functions $f(\varepsilon)$ and $f(\varepsilon,n)$ [134,135] some workers conclude that specific interactions are weak, or absent, in the electronic spectra of compounds forming complexes with a solvent[2]. The main contribution to ΔE_{max} during complex formation has been ascribed[136–139] to the difference in energy of the hydrogen bond in the ground and the excited state. However, a more widely held view[140,141] is that E_{max} under these conditions is equal to the sum of two contributions: the van der Waals interaction and the ΔE_2 value for the formation of the hydrogen bond, and either of these contributions can be predominant under suitable conditions. Attempted calculations of these contributions in terms of universal functions[124,125] yielded functions which proved both cumbersome and inaccurate. Because of the approximations implicit in the derivation of universal functions based on the Onsager model, and because the interaction with solvent molecules affects the complex as a whole (and not the separate molecule of solute[64]), the influence of the solvent on hydrogen-bonded complexes has been studied[133] in terms of the potentials of pair interactions between the molecules[126].

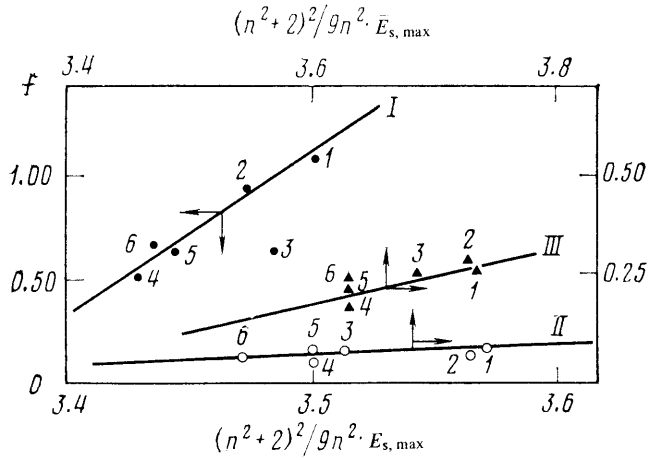

Figure 11. Plots of f against $(n^2+2)^2/9n^2 \cdot E_{max}$ for the absorption bands of azobenzene (*I*), *o*-nitroanisole (*II*), and *p*-nitroanisole (*III*). Solvents: *1*) n-hexane, *2*) cyclohexane, *3*) CCl_4, *4*) *p*-xylene, *5*) mesitylene, *6*) benzene[132].

Both in compounds which contain no proton-donor groups and in compounds able to form hydrogen-bonded complexes the E_{max} value decreases linearly with $\alpha_S/\bar{R}^6_{S,d}$ in non-polar solvents, and with $\mu_S^2/\bar{R}^6_{S,d}$ in polar solvents. This suggests that the predominant contribution to the solvent effect in the formation of the intermolecular hydrogen bond comes from ΔE_1 rather than from ΔE_2. Methods of calculating the separate contributions to ΔE_{max} from ΔE_1 and ΔE_2 have been suggested[132].

4. Effect of Solvents on the Electronic Spectra of Molecules with Conjugated Chains of Different Length

The optical absorption of these compounds has been studied in a large number of solvents[142,143]. Kuhn and Schweig[144] have calculated the shifts in the absorption and fluorescence bands of polar molecules of organic dyes under the influence of solvents. We have examined[145] the dependence of E_{max} (for the absorption bands) on $\alpha_S/\bar{R}^6_{S,d}$ and $\mu_S^2/\bar{R}^6_{S,d}$ in a series of compounds with conjugated chains of different length of the NO_2ZNR_2 type (where Z is an aryl group containing different numbers of π bonds).

The E_{max} value of the long-wave band with appreciable charge transfer, of the $\pi^*_{NO_2} \leftarrow n_{NR_2}$ type, was exactly described by the proposed expression[145] in every case, whatever the size of the solute molecule: it decreases linearly as the parameter $\alpha_S/\bar{R}^6_{S,d}$ increased. In polar

solvents also the E_{max} value of both absorption bands decreases as $\mu_S^2/\bar{R}_{S,d}^6$ increases. As the number of π bonds in the aromatic ring increases, the E_{max} value decreases almost linearly, and the slope of the linear plots increases slightly. For all the NO_2ZNR_2 compounds examined in polar solvents the dependence of f on $\mu_S^2/\bar{R}_{S,d}^6$ (produced by varying the size of the group Z) was accurately linear.

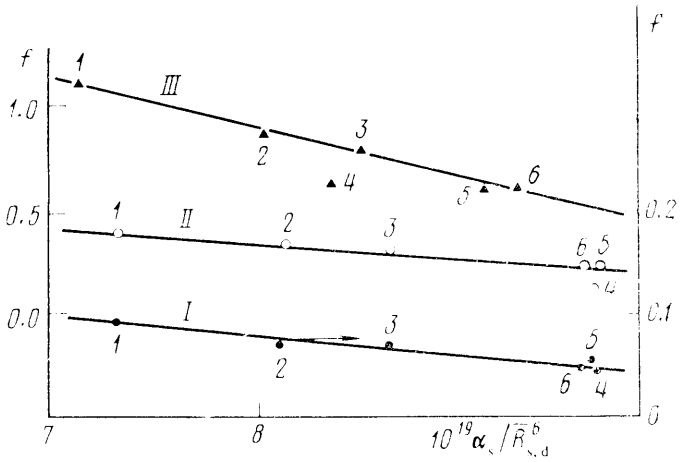

Figure 12. Plots against $\alpha_S/\bar{R}_{S,d}^6$ of the parameter f for the absorption bands of *o*-nitroanisole (*I*), *p*-nitroanisole (*II*), and *p*-dimethylaminobenzaldehyde (*III*). Solvents: *1*) n-hexane, *2*) cyclohexane, *3*) CCl_4, *4*) *p*-xylene, *5*) mesitylene, *6*) benzene[132].

Thus in a series of non-polar solvents with similar values of the ionisation potential the difference in the effect of the solvent on ν_{max} is due to $\alpha_S/\bar{R}_{S,d}^6$, whereas in polar solvents with similar values of $\bar{R}_{S,d}$ and α_S it is due to the parameter $\mu_S^2/\bar{R}_{S,d}^6$.

We have shown that the effect of intermolecular interactions in solutions on the spectral characteristics of molecules can be calculated by using the London–Debye–Keesom pair interaction potential for condensed media. The main advantage of this method is that it leads to expressions for the interaction energy containing in an explicit form the molecular properties of both the solute and the solvent (dipole moment, ionisation potential, polarisability) as well as parameters which characterise the molecular structure of the solution (Z and $\bar{R}_{S,d}$).

The expressions apply both to compounds which do not form hydrogen bonds and experience only intermolecular interactions of the field type and to compounds able to form hydrogen bonds with the solvent.

We have also shown that the relative contributions to the intermolecular interaction energy from field interaction effects and from complex formation by hydrogen bonds can be calculated approximately.

Surface Ionisation of Organic Compounds

E.Ya.Zandberg and U.Kh.Rasulev

The equilibrium thermal emission of positive ions of organic compounds from the surfaces of heated solids is examined. The possibilities of employing this phenomenon in the physical and analytical chemistry of organic compounds are illustrated.
The bibliography includes 75 references.

I. INTRODUCTION

Surface ionisation (SI) consists of the formation of ions in the course of the thermal desorption of species from the surface of a solid. In the general case surface ionisation includes three consecutive stages: the arrival of the species on the surface; the establishment of thermal and charge equilibria between the adsorbed species and the solid; evaporation of the species from the surface of the solid. In the last stage the single solid–species system breaks up into two subsystems over distances from the solid (x_{cr}) of the order of magnitude of atomic dimensions and the final charge state of the desorbed species is established. It depends on the probability of the isoenergetic electron exchange between the species and the solid. In a simplified form, this is illustrated in Fig.1: the species can become a positive ion if its valence electron can occupy a vacant level in the solid; conversely, if the electron of the solid can pass to a vacant orbital of the species, the latter can be desorbed in the form of a negative ion.

Surface ionisation was discovered by Langmuir and Kingdon in 1923:[1] a current comprising positive ions passed through a vacuum diode with an incandescent tungsten wire when caesium vapour was admitted. Langmuir and Kingdon obtained an expression for the degree of surface ionisation of atoms α within a closed uniform metallic cavity at a temperature T (Kingdon and Langmuir[2]) (the Saha–Langmuir formula):

$$\alpha = A \exp[e(\varphi - V)/kT], \quad (1)$$

where $\alpha = n^+/n^0$ is the ratio of the equilibrium concentrations of the ions and atoms within the cavity, A the ratio of

the statistical weights of the ionic and neutral states of the atoms ($A = 1/2$ in the case of Cs), $e\phi$ the electron work function of the wall of the cavity, V the ionisation potential of caesium, k the Boltzmann constant, and e the electronic charge.

It was established in subsequent years that positive atomic ions of the majority of elements and the negative ions of many elements can be obtained by surface ionisation. Ion sources for different purposes and detectors of atomic fluxes have been devised on the basis of surface ionisation. A general theory of the phenomenon has been developed. It describes the formation of positive and negative ions on ionisation of the atoms of any elements, not only within closed cavities but also on open surfaces which are both uniform and non-uniform as regards emission; the influence on α of external electric fields, which accelerate ions, has been examined.

The most complete theory of the phenomenon is described in a monograph[3]. It is based on the ideas of statistical thermodynamics and leads to explicit expressions for the current densities in different cases of ionisation. The possibility of the experimental determination of the parameters in these expressions from the measured current has become the basis of the development of a new application of surface ionisation—its employment as a method for the physicochemical investigation of many properties of solids, ionisable atoms, and the characteristics of the interaction of atoms with a solid.

More than twenty such methods have been developed recently, in particular, those for the determination of ionisation potentials, electron affinities, the lifetimes of atoms and ions on the surface, the heats of desorption of atoms and ions, and the emission characteristics of solids, for the study of phase transitions in adsorbed layers, for the determination of the activities of catalysts in heterogeneous dissociation reactions, etc.[3-5]. Evidently the surface ionisation of molecules, radicals, and complexes can yield valuable information about the properties of these species and also about their interaction with a solid.

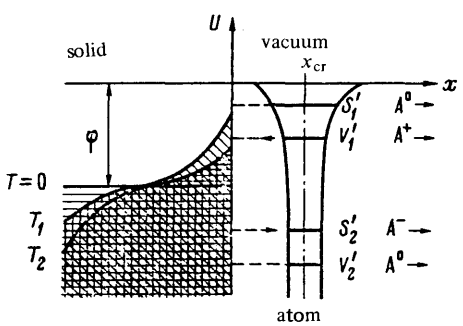

Figure 1. Illustration of the charge state of the desorbed species; $T < T_1 < T_2$.

Experimental studies on the surface ionisation of organic compounds (polyatomic species) have been begun recently. The possibility of the thermal desorption of organic ions was first indicated in studies carried out towards the end of the 1950's and the beginning of the 1960's;[6-10] some of these yielded elaborate mass spectra of the ions obtained on ionisation of the residual gases and vapours in the mass spectrometer[8-10], which can be accounted for only by the ionisation of organic compounds, for example, the vapours of the oils seeping from the pumps. Next, a change in the conductivity of flow-type diodes with an incandescent platinum or a molybdenum anode when specific organic compounds (the vapours of hydrocarbons, alcohols, ethers, and ketones) mixed with air or oxygen at atmospheric pressure were passed through them was observed[11-14]; however, it was not possible to observe the ionisation of the same compounds with the aid of the mass-spectrometric technique[10].

A number of studies on the surface ionisation of organic compounds involving the formation of negative ions have been performed by Page and coworkers using a magnetron technique. A systematic account of these studies has been published[15]; the electron affinities of many molecules and radicals have been determined with the aid of surface ionisation. However, subsequent mass-spectrometric studies established that the composition of the negative ions put forward in Page's studies did not correspond to reality[16,17] and that the ions were most probably formed not by surface ionisation but via some other mechanisms in secondary and tertiary side reactions associated with the emission of thermal electrons from the emitter[17]. Thus certain electron affinities are incorrect and it is regrettable that they are still quoted in the reference literature (for example, by Kondrat'ev[18]).

Systematic studies on the surface ionisation of organic compounds were begun in 1965 at the Ioffe Physicotechnical Institute of the USSR Academy of Sciences. Initially their aim was to discover the classes of organic compounds capable of ionising on heated surfaces. In the course of these studies it was found that, apart from the equilibrium thermal ionisation, non-equilibrium thermal ionisation also occurs, for example, in those cases where the energy evolved on decomposition of the molecule on the surface participates in the ionisation of the fragments[19-21]. Certain organic peroxides ionise in this way; the SI emission relations cannot be used to describe the ionisation of this type. As regards surface ionisation with formation of negative ions, hitherto it has been possible to obtain only the ions of small molecular fragments as a consequence of the small (as a rule) electron affinities of organic molecules and radicals and the requirement that the emitters of ions have high temperatures[17].

Extensive data have already accumulated on the surface ionisation of individual organic compounds with formation of polyatomic positive ions; the classes of ionisable compounds have been found, the principal rules governing the phenomenon have been established, and a number of its applications have been developed. These problems are considered in the present review.

II. CHARACTERISTICS OF THE SURFACE IONISATION OF ORGANIC COMPOUNDS

The theory of surface ionisation does not impose limitations on the composition of the ionising species. These can be polyatomic species, which includes both species incident on the surface and species formed from them as a result of chemical reactions in the adsorbed layer. The only important factor is that thermal and charge equilibria are established on the surface during the lifetime of the species.

If the molecule on the surface of the emitter can be converted into i types of new species, the incident flux of molecules ν can be conveniently represented as one

comprising i effective fluxes ν_i, each of which forms species of only one kind. There is then a relation between ν_i and ν:[22]

$$\nu_i(T, E) = \gamma_i(T, E)\nu, \quad (2)$$

where $\gamma_i(T, E)$ is a coefficient, which depends, for a given molecule–emitter pair, on the emitter temperature T and the electric field strength E at its surface. It defines the concentration of the ith species in the adsorbed layer as a result of all the processes occuring in it[23]. The ionisation of each kind of species can be treated independently of the ionisation of species of another type.

When the ion current is generated on the surface, the ratio of the charged component of the evaporating flux to its uncharged component $\alpha_i = \nu_i^+/\nu_i^0$ is given by the following formula for a surface uniform with respect to the electron work function ϕ in weak electric fields:

$$\alpha_i = A_i \exp\{e[(\varphi - V_i) + (eE)^{1/2}]/kT\}. \quad (3)$$

For polyatomic ith species, V_i is the first adiabatic ionisation potential and $A_i = Q_i^+/Q_i^0$ is the ratio of the total partition functions (translational, rotational, vibrational, nuclear, and electronic) for the charged and neutral species at the temperature T.[20] By definition, $0 < \alpha_i \leq \infty$.

As in the ionisation of atoms, a convenient characteristic is the ionisation coefficient

$$\beta_i = \nu_i^+/\nu_i, \quad (4)$$

which by definition lies in the range $0 \leq \beta_i \leq 1$.

Under steady-state conditions (when the effective flux ν_i is equal to the evaporating flux, i.e. $\nu_i = \nu_i^+ + \nu_i^0$), α_i and β_i are linked by the relation

$$\beta_i = (1 + 1/\alpha_i)^{-1}. \quad (5)$$

The current due to ions of the ith type is

$$I_i = e\nu_i^+ F = e\nu_i\beta_i F = e\nu\gamma_i\beta_i F, \quad (6)$$

where F is the area of the emitting surface. We obtain from Eqns.(3), (5), and (6)

$$I_i = e\nu\gamma_i F \Big/ \left\{1 + \frac{1}{A_i}\exp\left[\frac{e}{kT}(V_i - \varphi - (eE)^{1/2})\right]\right\}, \quad (7)$$

In two cases common in practice Eqn.(7) simplies significantly.

1. The case of difficult ionisation: $e[V_i - \phi - (eE)^{1/2}] \gg kT$. Only a small proportion of the incident species are ionised under these conditions; we obtain from Eqn.(7)

$$I_i \simeq e\nu\gamma_i F A_i \exp\left[\frac{e}{kT}(\varphi + (eE)^{1/2} - V_i)\right]. \quad (8)$$

The relation between I_i and T may be exponential or more complex owing to the relation between γ_i and T.

2. The case of easy ionisation: $e[\phi + (eE)^{1/2} - V_i] \gg kT$. We then obtain from Eqn.(7)

$$I_i(T, E) \simeq e\nu\gamma_i F, \quad (9)$$

i.e. virtually every species produced on the surface ionises.

If the emitter is non-uniform with respect to ϕ (for example, is polycrystalline), then, when the contact potentials of the spots on its surface are compensated by the external electric field (electric field strengths in the range $E \simeq 10^3$–10^4 V cm^{-1} are usually sufficient for this), the ionic current is equal to the sum of the currents from the individual spots. In this case the ionisation within narrow temperature ranges can be represented as occurring on a uniform surface; it is characterised by the effective parameters ϕ^*, A_i^* (Zandberg and Ionov[3]), and γ_i^*. The form of Eqns.(7)–(9) then remains unaltered.

III. EXPERIMENTAL TECHNIQUE

The methods used to investigate the surface ionisation of organic compounds must ensure the following conditions: (1) reliable identification of the ions; (2) the possibility of elucidating the problem of the thermal equilibrium in the adsorbed layer of the species; (3) the application of ion emitters with a high work function (the values of V for organic compounds exceed 7–8 eV [18]), which is stable in time; (4) the possibility of measuring T and ϕ under working conditions.

Special high-vacuum mass-spectrometric devices have been constructed at the Ioffe Physicotechnical Institute for the investigation of the surface ionisation of organic compounds[19,20,24]. The ionic currents due to the thermal ionisation of the vapours of the residual substances are virtually absent in these devices. Vacuum distillation of the substances introduced is used and the surface ionisation and electron ionisation mass spectra are compared at different stages of the distillation process (for this purpose, there is an additional source of ions with electron ionisation). If the sample contains impurities, it is possible to establish by this procedure to which substances the ions obtained refer and this is important in view of the selectivity of the surface ionisation with respect to V: a small amount of impurity with a smaller value of V can mask the current due to the main substance [for example, for two substances with $V_1 > V_2 > \phi$ and $V_1 - V_2 = 2eV$, we obtain from Eqn.(8) $I_2/I_1 \simeq 10^9$ at 1000 K].

The problem of the thermal equilibrium is studied by analysing the energies of the ions on the basis of the normal components of the initial translational velocities[3]. In principle, such analogy is insufficient in the case of polyatomic species, since all types of internal motion in the latter must also correspond to equilibrium. However, one can assume that in the adsorbed layers of the species there is the same sequence in the attainment of equilibrium by different forms of motion as in the gas phase, i.e. that the vibrational processes are slowest[25]. The thermal equilibrium in the translational motion of species indicates equilibrium in their vibrational motion. Since the energy of the bond between the chemisorbed molecules and the solid is of the same order of magnitude as the energy of the bonds between the atoms in the molecule, the equilibrium distribution of ions with respect to kinetic energy may indicate also the attainment of equilibrium with respect to all types of motion of the adsorbed species.

The search for the most effective emitters in order to obtain the ions of organic compounds led to oxidised metals exhibiting a catalytic activity in relation to the dissociation of the molecules and higher values of ϕ.[8,26,27]. Under the influence of organic compounds, the emission properties of oxidised metals vary with time[27], so that, in order to increase their continuous operation time, the vapours of the test substances are admitted only until the attainment of a pressure of approximately 1×10^{-5}–1×10^{-4} Pa. In view of the non-uniformity of the oxidised metals with respect to ϕ,[26,28] provision is made for the measurement under working conditions of both the effective electron work function ϕ_e^* and the effective ion work function ϕ_i^*. A Knudsen cell with a substance difficult to ionise, for example, bismuth ($V = 7.287$ eV) is present in the surface-ionisation ion source in order to measure ϕ_i^*.

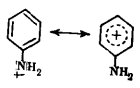
At the surface of the emitter the strength of the external electric field $E \simeq 10^3$–10^5 V cm^{-1}, this is sufficient to compensate for the contact fields of the spots but is much smaller than required for the desorption of the ions by the field[29].

The search for substances capable of surface ionisation has been carried out among compounds of different classes. Simple hydrocarbons, alcohols, ethers, ketones, nitrocompounds, and nitriles do not ionise[19,30]. Amines, hydrazines and their various derivatives, phosphines, arsines, and certain oxygen-containing substances (phenols, organic acids, and benzene derivatives) do ionise. Compounds containing Group VA elements, which form polyatomic radicals containing these heteroatoms, ionise with the greatest efficiency.

IV. CHARACTERISTIC FEATURES OF THE FORMATION OF IONS BY ORGANIC COMPOUNDS CONTAINING GROUP VA HETEROATOMS

The surface ionisation of approximately 70 compounds of different classes[30] (mainly the effectively ionisable amines[30-35], hydrazines[36], and their derivatives[34,37,38]) has now been investigated, mainly on emitters consisting of oxidised tungsten[26] and also on tungsten, molybdenum, nickel, rhenium, and iridium, oxidised molybdenum and nickel, and nichrome emitters[27,28,30].

In all cases the initial kinetic energy of translation of the ions desorbed from the surface of the emitter corresponded to equilibrium with the temperature of the emitter[24,31]. The currents due to molecular ions and the ions derived from the dissociation products of the molecules on the surface of the emitter depended linearly on the vapour pressure of the test substance, while the currents due to the associated species $(M + H)^+$, obtained on ionisation of primary and secondary amines and phosphines, depended on the square of the vapour pressure[39].



In virtually all publications the surface ionisation mass spectra are presented in the form of tables such as Table 1, where the following parameters are indicated in addition to the mass number m: the maximum ionic current density j (A cm^{-2}) referred to the vapour pressure $p = 1.33 \times 10^{-5}$ Pa, measured with an ionisation gauge calibrated against nitrogen†, the corresponding emitter temperatures, the postulated chemical structures of the ions (for this purpose, the surface ionisation of labelled compounds has been studied in a number of instances[35,36]), and the ionisation potentials of the ionising species estimated by SI methods.

In the ionisation of *alkylamines*[30-33] (the SI mass spectra of which are presented in Table 1), the following features were discovered.

1. The products of the chemical reactions of the molecules of the initial amines (mainly dissociation reactions) ionise on the surface of the emitter and not the molecules of the initial amines themselves.

2. In the SI mass spectra the number of lines is small. They may contain, regardless of the material of the emitter, lines due to ions within the set $(M - H)^+$, $(M - Alk)^+$,

Table 1. The surface-ionisation mass spectra of a series of amines.

Notation. M is the molecular weight of the substance, V_M its ionisation potential, m_i the mass of the ion, and j the current density.

†In this calibration of the gauge, there is an error in the determination of the vapour pressure p of organic substances resulting in an overestimate. Therefore the values of j presented are correspondingly too low.

$(M + H)^+$, $(M - H - nH)^+$, and $(M - Alk - nH)^+$.

3. As a rule, all the ions formed in the surface ionisation of alkylamines have an even number of electrons and they can be represented as ions containing quadrivalent positively-charged nitrogen atoms with sp^3-, sp^2-, or sp-hybrid orbitals. The current density due to such ions greatly exceeds that of radical-ions.

4. The ionisation potentials of the radicals (M - H) and (M - Alk), as well as the associated species (M + H) are as a rule lower than the V_M for the initial molecules. Therefore if the ions M^+ are in fact formed via surface ionisation under the conditions of the experiment, they cannot be detected against the background of a significantly more intense line due to the isotopic ions of the $m + 1$ radicals (M - H).

5. The current densities of isotypical radical and associated species depend on the nature of the groups attached to the nitrogen atom: the current density increases significantly as the hydrogen atoms in the amino-group are substituted by alkyl groups.

6. The efficiency of the surface ionisation of alkylamines, particularly secondary and tertiary amines, is high. Thus the overall ion current density in the ionisation of tertiary alkylamines on oxidised tungsten reaches approximately 0.1 A Pa^{-1} cm^{-2}, i.e. each 2–5 molecules of the amine arriving on the surface of the emitter lead to the formation of one ion on average.

7. The temperature variations of the ion currents of each species are characteristic (Fig.2), which is due to the difference between the temperature variations of the yields of the reaction involving the formation of ionisable species of each kind; reactions leading to the formation of associated species proceed at lower temperatures than the dissociation reactions; the temperature threshold of the reaction resulting in the formation of the (M - Alk) species is much higher than for the reaction in which the hydrogen atom is abstracted; the threshold ionisation temperatures for the (M + H) and (M - H) species are determined by the threshold surface ionisation temperature[30,39] and those for the (M - Alk) species are determined by the temperature threshold of the reaction[23,30].

8. The species (M + H) are formed on the surface of the emitter as a result of the association of the adsorbed molecules via hydrogen bonding and of the subsequent decomposition of the associated species[39].

The influence of substituents in the molecules of amines on the composition of their SI mass spectra and on the ionisation efficiency has been demonstrated for the SI of trimethylamines of the type $(CH_3)_2N-CH_2-R$, where $R = CH_3$ (I), $CH = CH_2$ (II), $N(CH_3)_2$ (III), CN (IV), C_6H_5 (V), or p-$C_6H_4NO_2$ (VI).[34,35] The SI mass spectra of these substances consist of lines due to the ions $(M - H)^+$ and $(M - R)^+$. The efficiency of the formation of the ions $(M - H)^+$ depends significantly on the electronegativity of the substituent R: the current densities of the ions $(M - H)^+$ vary over five orders of magnitude (from approximately 2×10^{-2} to approximately 2×10^{-7} A Pa^{-1} cm^{-2}) and are qualitatively correlated with the Taft substituent constants.

The radicals (M - R) derived from the above trimethylamines are identical, namely $(CH_3)_2N\dot{C}H_2$; on surface ionisation, they give rise to the stable ions $(CH_3)_2N^+CH_2 \rightleftharpoons (CH_3)_2NC^+H_2$, stabilised by the presence of an unshared electron pair at the nitrogen atom and the electron-donating methyl groups. However, the current densities of the ions derived from these radicals and the form of the relations between j and T for ionisation on the same emitter differ appreciably (Fig.3). This is associated with the difference between the $\gamma-T$ relations. The current density of the ions $(M - R)^+$ produced by tetramethyldiaminomethane ($j \gtrsim 5 \times 10^{-2}$ A Pa^{-1} cm^{-2}) and the absence of a dependence of j on T over a wide temperature range lead to the conclusion that the ionisation potential of this radical $V < \phi_i^*$. Here $\beta \cong 1$ (Zandberg and Ionov[3]) and it follows from Eqn.(9) that the $I-T$ relations in all the remaining cases reproduce the $\gamma-T$ relations, while the ratios of the values of j are the same as the ratios of the γ.

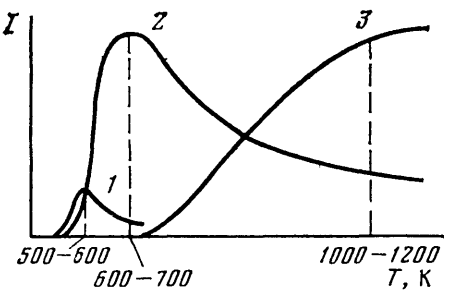

Figure 2. Temperature variation of the currents in the surface ionisation of alkylamines on oxidised tungsten[43]: *1*) $(M + H)^+$ ions; *2*) $(M - H)^+$ ions; *3*) $(M - R)^+$ ions.

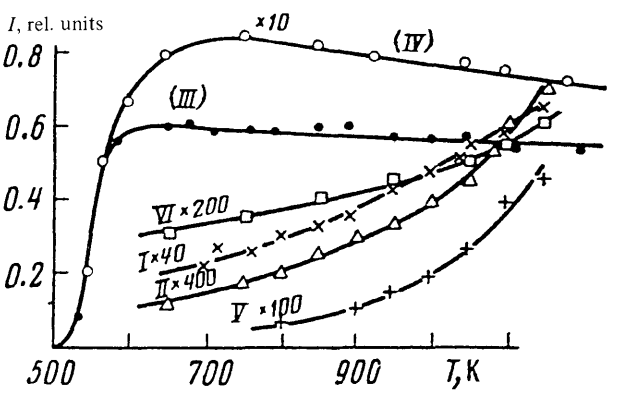

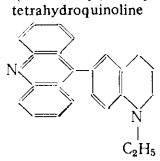

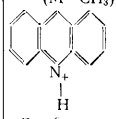

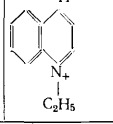

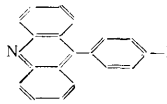

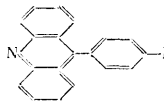

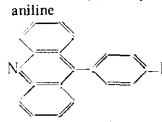

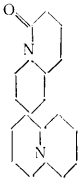

Figure 3. Temperature variation of the currents due to the $(M - R)^+$ ions in the ionisation of the substituted trimethylamines (I)–(VI).[34]

A qualitative correlation between the yield on the emitter of the products of the reactions involving the formation of the radicals (M - R) and the energy of formation of the radical R can be traced. The lower the latter, the higher the current density due to the ions $(M - R)^+$. It is noteworthy that the overall density of the currents due to all the ions in the surface ionisation of substituted trimethylamines is high and changes only slightly on passing from one compound to another. Thus the overall current density is in the range ~10^{-2}–10^{-1} A Pa^{-1} cm^{-2} for compounds (I)–(V).[34]

The ionisation of more complex bases such as acridinyltetrahydroquinolines and acridinylanilines with different substituents at the nitrogen atom, benzimidazoles, the alkaloid allomatrine, etc. (the SI mass spectra of some of these represented in Table 2) obeys the same rules governing

the formation of ions as in the surface ionisation of simple amines[37]; in particular their mass spectra consist of the same characteristic set of lines due to the ions $(M + H)^+$, M^+, $(M - H)^+$, $(M - R)^+$, and $(M - H - 2nH)^+$.

Table 2. The parameters of the mass spectra of certain *N,N*-heterocyclic compounds[37].

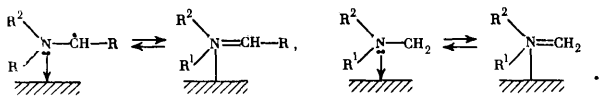
Simple rules for the formation of ions have been formulated on the basis of the analysis of the SI mass spectra of amines and their derivatives whereby one can predict the composition of the ions in the SI mass spectra of the amines and estimate the ion current densities[37,43]. These rules can be accounted for by the high selectivity of the surface ionisation in relation to the ionisation potentials *V* of the ionising species, the favourable energetic features of the formation of ions with saturated bonds, which in the case of amines can be represented by ions with a quadrivalent positively-charged nitrogen atom having hybrid orbitals, and by the dependence of *V* for the ionising species on the electronegativities of the substituents. Thus the ionisation of the amine $R^1R^2N\text{-}CH_2R$ always results in the formation of ions derived from the radicals (M - H) and (M - R), obtained on dissociation of the β-bond (relative to nitrogen) in the adsorbed molecules. The current density of the ions $(M - H)^+$ is determined by the electronegativities of the substituents R^1, R^2, and R. In the case of alkylamines, $j \cong (10^{-6}\text{–}10^{-4})$ for primary amines, $\sim 10^{-3}$ for secondary amines, and $\sim(10^{-2}\text{–}10^{-1})$ A Pa^{-1} cm^{-2} for tertiary amines[30]. The current density of the ions $(M - R)^+$ depends on the electronegativities of the substituents R^1 and R^2 and also on the energy of formation of the radical R. If R^1 and R^2 are alkyl groups, then the current density of the ions $(M - R)^+$ is $\sim(10^{-2}\text{–}10^{-1})$ A Pa^{-1} cm^{-2}.[30,32–34]

The lines due to the ions $(M - H - 2nH)^+$ and $(M - R - 2nH)^+$, which are formed on ionisation of the dehydrogenation products of the molecules on the surfaces of oxidised metals (when metallic emitters are used, these ions are hardly detected), should be observed in the SI mass spectra on ionisation of molecules with alkyl substituents. The intensity of the lines due to these ions on ionisation of amines with linear alkyl substituents is lower than the intensity of the lines of the ions $(M - H)^+$ and $(M - R)^+$ and decreases with increase of *n*. In the mass spectra of alicyclic compounds with the nitrogen atom in the ring, the intensity of the lines due to the ions $(M - H - 2nH)^+$, in which the ring has been aromatised, may be considerable and may increase the intensity of the lines due to the ions $(M - H)^+$.[37]

The lines of the ions $(M + H)^+$, formed on ionisation of the complexes (M + H), should be always present in the SI mass spectra of primary and secondary amines at low temperatures of the emitter; the complexes are obtained as a result of the self-association of the molecules on the surface of the emitter[39]. The ions $(M + H)^+$ can be detected also in the ionisation of tertiary amines; however, in this case the complex formation is due to the presence of polar molecules, for example, H_2O, in the residual gas within the mass spectrometer[32,34].



Points due to molecular ions M^+ which are susceptible to measurement can be obtained in those cases where the ionisation potentials of the molecules do not exceed the work function of the emitter by more than approximately 2 eV and during their lifetime in the adsorbed state the molecules must not be fully converted into species of another chemical composition. This happens, for example, in the case of aromatic amines and nitrogen-containing heterocyclic compounds[37,42]. However, even if the above conditions are fulfilled, the lines due to the ions M^+ can be more readily detected, as already mentioned, on ionisation of substances which do not form the ions $(M - H)^+$ effectively.

The rules governing the formation of ions, common to all the amines and their derivatives and independent of the material of the emitter, have been used to elucidate the mechanism of the adsorption of amine molecules and their reactions on the emitter[20,43]. One may conclude that the amines are adsorbed as a result of the formation of a coordinate bond with the adsorbent; the withdrawal of the electron pair to the emitter which occurs under these conditions leads to the formation of a partial positive charge on the nitrogen atom:

This causes a significant weakening of the β-bonds relative to the nitrogen atom[44] and explains the formation of the

radicals (M - H) and (M - R) on the surface of the emitter:

Measurements of the average lifetimes on the surface of the emitter have shown that such species persist on the emitter for a long period[23] (see below), reach thermal and charge equilibrium with the latter, and, on desorption, ionise via the surface ionisation mechanism.

Apart from the reactions examined, other reactions leading to the appearance of both ionising molecular fragments [for example, the products of the dehydration of the molecules—the species (M - H - 2*n*H) and (M - R - 2*n*H)] and non-ionising molecular fragments, can occur on adsorption of amines. However, the high efficiency of the formation of the ions $(M - H)^+$ and $(M - R)^+$ observed in many instances shows that the reactions involving the formation of the species (M - H) and (M -R) on adsorption of amines predominate and can take place with yields close to unity.

The above pattern in the adsorption of amine molecules is supported also by the low threshold temperatures for the ionisation of the radicals (M - H), which are even lower than the threshold temperatures for the ionisation of fluxes of Cs atoms having the same density[23]: if the adsorbed amine molecules were bound to the surface via many atoms, the species would have been desorbed at much higher temperatures.

The study of the surface ionisation of a series of *alkylhydrazines*[30,36] on emitters consisting of oxidised tungsten and molybdenum showed that, although the introduction into the molecule of the second heteroatom with formation of the >N–N< bond leads to some differences in the rules governing the formation of ions compared with amines, for example, it results in the formation of the ions M^+ [as a consequence of the decrease of the values of V_M for the molecules and the mutual approach of the ionisation potentials of the molecules and the radicals (M - H) compared with amines] and to the absence of lines of the ions derived from the associated species (apparently as a consequence of the conjugation between the heteroatoms), it does not alter the principal characteristics of the ionisation of nitrogen-containing organic compounds: mainly ions with saturated bonds are formed; they can be represented by ions with a quadrivalent positively-charged nitrogen atom having hybrid orbitals (Table 3). The efficiency of the ionisation of alkylhydrazines is higher; for example, the current density of the ions $(M - H)^+$ is approximately 10^{-2}–10^{-3} A Pa^{-1} cm^{-2} for trimethyl-, tetramethyl-, and dibutyl-hydrazines.

Comparison of data for the surface ionisation of a series of hydrazine derivatives[38], whose constituent atoms form the linkages >N–N=C< (hydrazones) –N=N– (azo-compounds) and >N–N=N–N< (tetrazenes), with data for the surface ionisation of alkylamines and alkylhydrazines shows that the ionisation efficiency of the radicals (M - H) decreases in the sequence amine > hydrazine > hydrazone > azo-compound [in the SI mass spectrum of tetramethyltetrazene the lines due to the ions $(M - H)^+$ are totally absent]; on the other hand, the ionisation efficiency of the molecules increases in this sequence (the mass spectrum of the primary ions of tetramethyltetrazene consists only of the lines due to the ions M^+). In contrast to hydrazines, the lines of $(M - Alk)^+$, caused by the ionisation of the species obtained on dissociation of the molecules at the N–C bond, are absent from the mass spectra of hydrazine derivatives. These differences can be accounted for by the decreased yield of reactions on the surface of the emitter which yield the above radicals rather than by the decrease in the ionisation potentials V_M of the molecules in the given series of compounds and the increase in the ionisation potentials of the radicals (M - H) and (M - Alk).

The presence of a double bond in the molecules and the possible conjugation between the π-electrons and the electrons of the unshared pairs of the nitrogen atoms can result in the formation of a bond between the molecule and the emitter surface not only via the unshared pair of the nitrogen atom, as in the case of amines, but via the entire conjugated system of the electrons in the unshared pairs of the nitrogen atoms and the π -electrons. The adsorption of these molecules does not therefore entail a weakening of the β-bonds, as in the case of amines, and the yield of reactions with formation of the species (M - H) and (M - Alk) is correspondingly lower than in the adsorption of amines and their threshold ionisation temperatures are higher.

We may note that, although the surface ionisation efficiencies of hydrazine derivatives are smaller than those of the amines and hydrazines, they are nevertheless fairly high. Thus ionic current densities of approximately 10^{-4} A Pa^{-1} cm^{-2} can be obtained as a result of the surface ionisation of these substances.

The following differences between the characteristics of the surface ionisation of a series of *alkyl derivatives of phosphorus and arsenic* relative to amines have been discovered[47]:

1. The ionisation efficiencies of phosphines and arsines are much lower than those of amines and decrease in the series of compounds with heteroatoms in the sequence N > P > As. Thus, whereas in the ionisation of triethylamine the current density of the ions $(M - H)^+$ is $\sim 3 \times 10^{-2}$ A cm^{-2} Pa^{-1}, for triethylphosphine $j \cong 3 \times 10^{-4}$ A cm^{-2} Pa^{-1} and for tripropylarsine it is only 7×10^{-8} A cm^{-2} Pa^{-1}.

2. The decomposition of adsorbed molecules with formation of the radicals (M – R), which is characteristic of amines, does not occur in the case of phosphines and arsines: the intensity of the lines of the ions $(M - R)^+$ in the mass spectra of phosphines is low, while in the mass spectra of arsines the lines are altogether absent.

3. In the ionisation of phosphines and arsines the current of the ions M^+ is close in magnitude to that of the ions $(M - H)^+$, which indicates either a small difference between the ionisation potentials of the molecules and the radicals or a low yield of the reaction involving the formation of radicals in the adsorbed layer.

The characteristics of the surface ionisation of phosphines and arsines, relative to that of amines, enumerated above are associated with the difference between the electronic structures of the heteroatoms in these molecules. The orbitals of the unshared electron pair of the P and As atoms have a more pronounced *s* character than in the nitrogen atom, which should lead to a decrease of the probability of the formation of ions with an sp^2-hybrid structure. Furthermore, the P and As atoms have unoccupied *d* orbitals with relatively low energies, as a result of which they are capable of accepting electrons. Therefore in the adsorption of phosphines and arsines the withdrawal of the unshared pair of the heteroatom to the emitter can be accompanied by the capture of electrons from the emitter in the unoccupied *d* orbital. The latter should weaken the negative inductive effect of the adsorbed molecules and decrease the probability of their dissociation at the β-bonds.

V. THE FORMATION OF VIBRATIONALLY-EXCITED IONS IN THE SURFACE IONISATION OF ORGANIC COMPOUNDS AND THE CHARACTERISTIC FEATURES OF THEIR UNIMOLECULAR DECOMPOSITION REACTIONS

The mass spectra of almost all compounds contain, together with the narrow lines due to the primary ions which have been desorbed from the surface of the emitter and which have "reached" the collector of the mass-spectrometer, also broadened lines due to fragment ions—the products of unimolecular decomposition reactions of primary ions during their movement within the space of the mass-spectrometer.

A pair of lines due to fragment ions in the SI spectrum corresponds to each decomposition of the primary ions $m^+ \rightarrow m_1^+ + m_2$ (Fig.4): the decomposition of ions in the acceleration region within the ion source leads to the appearance of lines corresponding to the mass of fragment ions m_1, which have broadened in the direction of low masses or low energies of the ion; the same decomposition within the field-free region of the mass-spectrometer, between the accelerating electrodes of the source and the magnetic field zone, leads to the appearance in the mass spectrum of broadened lines due to ions with an apparent mass $m^* = m_1^2/m$.[48] The decomposition process can be unambiguously identified on the basis of the pair of lines recorded. By virtue of the high intensity of the lines due to the primary ions and the small number of lines in the SI mass spectra, it is therefore possible to identify the lines of the fragment ions whose intensity is many times smaller (by a factor of up to approximately 10^6) than the intensity of the lines due to the primary ions.

The ions obtained by surface ionisation obey the Boltzmann energy distribution as a function of the emitter temperature *T*; the energy is determined by *T* and the number of vibrational degrees of freedom of the ionising species [in the classical approximation the total vibrational energy stored in the species on the surface of the emitter before evaporation is $(3N-5)kT$, where *N* is the number of atoms in the species]. Some of the ions, whose total vibrational energy exceeds the energy of a decomposition reaction, can dissociate in the course of their travel through the mass-spectrometer.

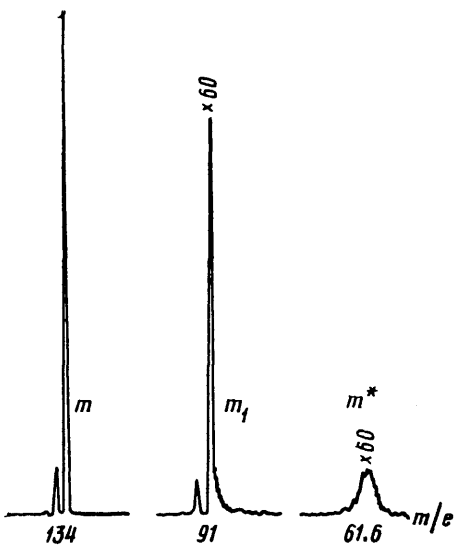

Figure 4. The lines due to the primary and fragment ions in the SI mass spectrum of benzyldimethylamine.

The unimolecular decompositions of the ions formed via surface ionisation are slow processes; the lifetimes of the ions are such that before decomposition they are able to execute more than 10^6–10^7 internal vibrations[34], which suggests that the decomposition reactions of the ions after their desorption from the surface of the emitter take place as a result of a statistical redistribution of the excitation energy within the ion; the energy being concentrated in such a way that a specific configuration of the activated complex, leading to its dissociation, is attained; the statistical theory of mass spectra can be applied to the description of such decomposition reactions[49].

The temperature variations of the ratios of the currents of fragment ions to the current of the parent ions make it possible to find the activation energies ε* for decomposition reactions which occur after the ions have moved for a specific time[24] (Fig.5). The true activation energy for the decomposition reactions or, in the case of direct decompositions, the bond dissociation energy in the ion can be determined from the values of ε* with the aid of the statistical theory of mass spectra[50,51].

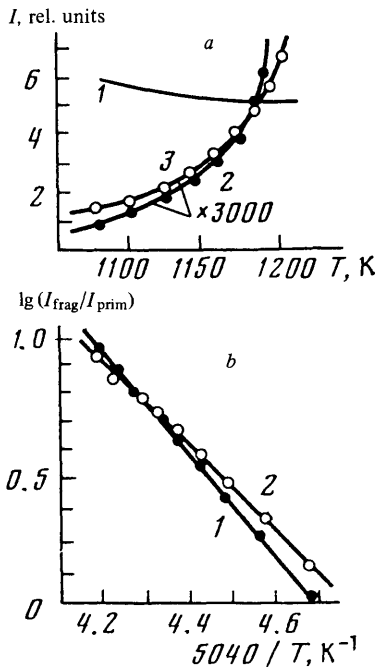

Figure 5. *a*) Temperature variation of the currents in the ionisation of diethylamine [*1*) for primary $(M - H)^+$ ions; *2*) for fragment ions with $m_1 = 44$ a.u.; *3*) for fragment ions with $m^* = 26.9$ a.u.; *b*) Arrhenius plots for the ratios of the fragment ion currents [*1*) m_1; *2*) m^*] to the primary ion current[32].

All the known types of unimolecular decomposition reactions of ions can be traced in the SI mass spectra: direct decompositions, decompositions with rearrangement, and multistage decompositions. In most cases the decomposition reactions of the ions obtained by surface ionisation belong to the type with rearrangements and to the multistage type and lead to the formation of stable fragments, which as a rule do not have unpaired electrons (Fig.6).

The mechanisms of the fragmentation of ions of different classes of organic compounds which have been deduced and the discovery of the characteristics of their decomposition pathways[33,36,38,47] are important for the purposes of the surface ionisation mass-spectrometry of organic compounds, since the primary ion can be "assembled" from the fragment ions (Fig.6).

Comparison of the decomposition reactions of ions obtained by surface ionisation (reliably identified experimentally), for which theoretical calculations have been made, with the decomposition reactions of the excited ions formed in collisions with electrons (with the mass spectrum generated as a result of ionisation by the electrons) can serve as a definite criterion of the applicability of the quasi-equilibrium theory to the description of the electron ionisation mass spectra[36,52] and in many instances can help in the determination of the pathways leading to the decomposition reactions on ionisation by electrons[38,52].

VI. SURFACE-IONISATION MASS-SPECTROMETRY OF ORGANIC COMPOUNDS

The set of results described constitutes the physicochemical basis of the method of the surface-ionisation mass-spectrometry (SIMS) of organic compounds. At the present

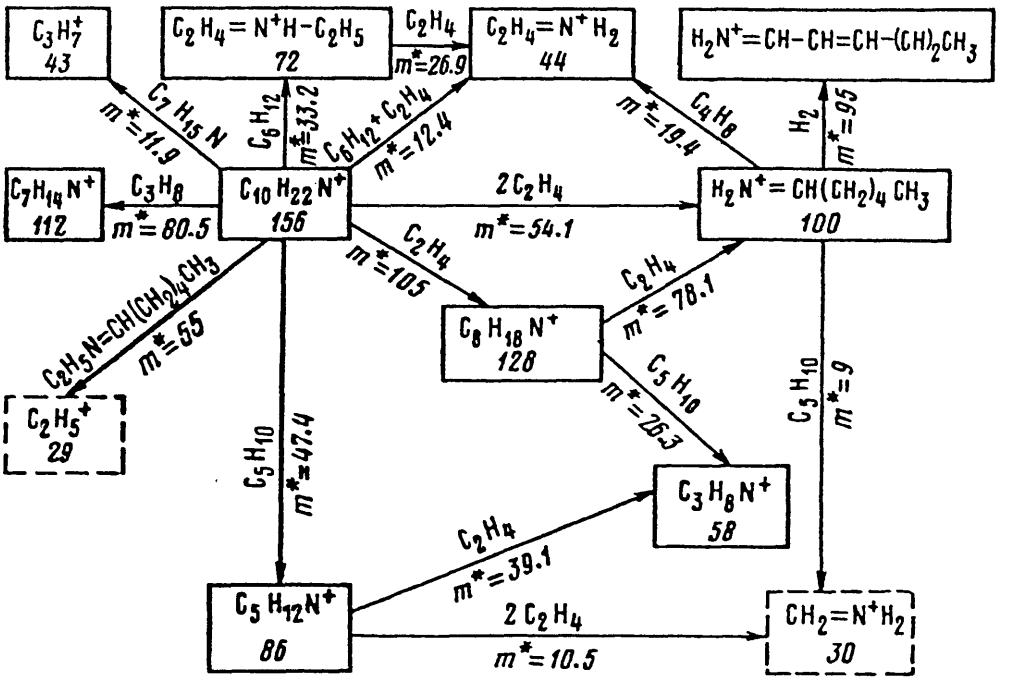

Figure 6. Unimolecular decompositions of the diethylhexylamine ions $(M - H)^+$.[33]

time SIMS can be applied only to specific classes of organic compounds with Group VA heteroatoms. However, the abundance and importance of these compounds are considerable. Certain fields of application of SIMS are examined below.

1. Application in Physicochemical Research

The following applications of SIMS are possible at the present time:

1. For the generation of fluxes of ions derived from organic compounds with considerable ion densities (up to 10^{-1}–10^{-2} A Pa^{-1} cm^{-2}). Their characteristic feature is a small scatter of the initial energies as a consequence of the Maxwell velocity distribution of ions as a function of the temperature of the emitter. The energy of the vibrational excitation of the ions can be readily regulated by altering the temperature of the emitter, which can be used in many problems, for example in the study of the influence of the vibrational excitation of ions on the kinetics of ion–molecule reactions.

2. For the detection of heterogeneous reactions from the chemical composition of the ions. The γ_i–T relations can be found by Eqns.(7)–(9) from the I_i–T relations for known $\beta_i(T)$ functions together with the concentration relations as a function of T for the ith species on the surface proportional to $\gamma_i(T)$. It is also possible to discover certain reactions with rearrangement on the surface, as can be seen from the ionisation of the molecules of ethyl-n-pentylamine, which have been partly converted into the molecules of *N*-ethylpiperidine[53].

3. For the estimation of the lifetimes of the vibrationally-excited ions with respect to unimolecular decomposition[34] and also for the determination of the activation energies ε for such decomposition reactions involving ions[24,50,51]. So far as we are aware, there are at present no other experimental methods for the determination of ε for reactions involving ions which would not require the knowledge of the thermochemical constants of the ions.

4. For the determination of the kinetic characteristics of the thermal desorption of species. We shall consider this problem in greater detail since it was not considered previously.

The kinetic characteristics of thermal desorption, namely the average lifetimes $\tau(T)$ of the adsorbed species relative to the desorption of ions and neutral species, the activation energies E^+ and E^0 for the desorption of these species, and the pre-exponential factors C and D in the equation for the flux of desorbed species $\nu^+ + \nu^0 = N[C \exp(-E^+/kT) + D \exp(-E^0/kT)] = N/\tau$ (N is the concentration of species on the surface) are the most important characteristics of the interaction of the species with the solid. The non-stationary processes ($\nu^+ + \nu^0 \neq \nu$), in which N varies with time, are used for their determination. The measured ionic currents are proportional to N.

The study of the ionisation of polyatomic organic molecules and radicals under non-stationary conditions is complicated by the simultaneous presence on the surface of the emitter of species of different composition, involved in reactions via many channels, which causes an additional variation of N_i as a function of time.

The present authors and their coworkers[23,54,55] analysed the possibility of determining the kinetic characteristics of the desorption of polyatomic species taking into account the reactions in the surface layer and using two isothermal methods for creating non-stationary conditions, which are explained in Fig.7: by modulating the potential at the surface of the emitter[56] (for $\beta_i > 0.1$) and by modulating the density of the incident molecular flux[57]. The solutions of the differential equations describing the time variation of N_i in each method made it possible to elucidate the significance of the measured characteristics, including those for the ionisation of molecules on inhomogeneous surfaces. As a rule τ is determined by the decrease of the number of species on the surface as a consequence of the processes occurring on the latter and is thus a quantity of practical importance. In many special cases it is possible to isolate $\tau_i^+(T)$ and $\tau_i^0(T)$ and correspondingly E_i^+ and E_i^0. In the case of non-uniform surfaces, all the parameters determined are effective; their magnitude approaches that of the characteristics of the desorption from the sections of their surface with the highest values of ϕ.

The quantities $\beta_i' = \beta_i/\{1 + [k_d/(k_0 + k_+)]_i\}$, where k_d, k_0, and k_+ are the rate constants for the dissociation and thermal desorption of the neutral ith species and the thermal desorption of their ions respectively, which are similar to the ionisation coefficients β_i, can be found from Fig.7 under conditions corresponding to the modulation of the potential with respect to the currents I_{i2} and I_{i1}. Evidently $\beta_i' < \beta_i$ and it is therefore possible to estimate the upper limit of the possible values of V_i from the β_i' with the aid of Eqns.(3) and (5). These estimates of V_i are more accurate than those based on the stationary currents defined by Eqns.(6) and (7) and do not require the knowledge of many quantities entering into these formulae which are difficult to determine.

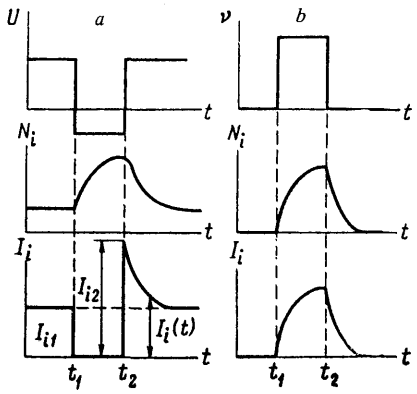

Figure 7. Illustration of the potential modulation method (*a*) (the rectangular waveform of the ion-arresting potential is switched on for the period from t_1 to t_2; ν = const.; T = const.) and of the flux density modulation method (*b*) (the molecular flux is introduced during the period from t_1 to t_2; U = const.; T = const.).

Table 4 presents the effective kinetic characteristics of the desorption and the values of β' obtained by the potential modulation method for several radicals formed from triethylamine, tributylamine, and tetramethyldiaminomethane when they are ionised on oxidised tungsten wires. These were the first determinations by the SI methods for species of such complex composition. Evidently the activation energy for the desorption of the ions is small. Because of this, the threshold temperatures for the ionisation of the radicals on oxidised tungsten wires are low; they are lower than for the ionisation of the corresponding fluxes of Cs atoms.

The quantities τ in the experimental temperature (T) ranges amount to tens–hundreds of milliseconds; such times are sufficient for the attainment of full thermal equilibrium in the adsorbed layer of species.

5. For the determinations or estimates of the ionisation potentials of species forming positive ions. The potentials V of species undergoing surface ionisation can be determined in different ways: (1) from the slopes of the plots of $\lg I_i = f(1/t)$ when the $I_i - T$ relation is exponential [Eqn.(8)] and the $\gamma_i - T$ relation may be disregarded[36,42]. It is then assumed that the ratio of the partition functions A_i is virtually independent of T. The error associated with this assumption is of the order of magnitude of $\sim kT$, which has been confirmed by the determinations of V for the molecules of aniline[42] and other compounds whose ionisation potentials had been determined by other methods[30]: (2) from the maximum current density and the corresponding temperature T. The value of β_i is found by Eqn.(6) and from it V_i is determined using Eqns.(3) and (5); it is then assumed that $\gamma_i(T) = 1$ and ν is found from the vapour pressure of the test substance in the apparatus. If the pressure is measured with an ionisation gauge calibrated with respect to nitrogen, then the experimental values of β are smaller than the true values and the ionisation potentials are correspondingly larger than the true values. Since the ionisation potentials V of radicals with Group VA heteroatoms are as a rule unknown[18], even estimates of their possible limiting values are of interest. The majority of the estimates have been made by this method. (3) From the values of β' obtained by the potential modulation method which is feasible for $\beta' \geq 0.1$.

Table 4. Kinetic characteristics of the thermal desorption of certain nitrogen-containing radicals from oxidised tungsten wires non-uniform with respect to emission.

Table 5 presents the values of V determined or estimated by the surface ionisation method. Evidently many radicals derived from nitrogen-containing compounds have relatively low ionisation potentials.

2. Applications in the Analytical and Structural Chemistry of Organic Compounds

The characteristic nature of the SI mass spectra of organic compounds and the simple rules governing the formation of ions and permitting the prediction of their composition in the mass spectra and the estimation of the current densities corresponding to the lines indicate the possibility of employing the SIMS in the analytical and structural chemistry of organic compounds. We shall examine certain possibilities of the analytical method based on the use of SIMS.[30,59]

The molecular weight of the substance analysed can be determined from the lines of the ions $(M - H)^+$ and, more rarely, from those of the ions M^+ and $(M + H)^+$. In all cases the characteristic form of the $I-T$ relations for each of these types of ions helps in their identification (Fig.2): the current of the ions M^+ as a rule increases with increasing temperature[30,36,47]. The mass numbers of the radicals R^i can be found from the $(M - R^i)^+$ lines; the current densities of the ions $(M - H)^+$ and $(M - R^i)^+$ yield information about the electronegativities of the substituents R^i; the $(M - H - 2nH)^+$ and $(M - R^i - 2nH)^+$ lines make it possible to assess the degree of saturation of the hydrocarbon substituents R^i. Finally, information about the structure of each primary ion can be obtained from the lines of its fragment ions (Fig.6).

Table 5. Ionisation potentials of certain molecules and radicals with Group VA heteroatoms.

The small number of lines in the mass spectra facilitates the analysis of mixtures of substances. The degree of coverage of the emitter by the molecules of the test substances at temperatures above the threshold value for ionisation is low and the molecules in the adsorbed layer do not interact. Therefore the mass spectra of mixtures of different amines, hydrazines, and their derivatives are the sum of the mass spectra of the individual components[30,32]. The characteristic form of the $I-T$ relations for ions of each type makes it possible to distinguish, for example, the ions $(M_1 - H)^+$ from the ions $(M_2 - R)^+$ having identical masses. The high selectivity of surface ionisation can be used to determine minute trace amounts of amine impurities in mixtures of substances which are non-ionisable or weakly ionisable by surface ionisation. For example, tertiary alkylamines and their derivatives, present in amounts of $\geq 10^{-7}-10^{-8}$%, can be analysed with the aid of SIMS.[30]

The high efficiency of the surface ionisation of amines, hydrazines, and derivatives of substances of these classes is responsible for the high sensitivity of the analysis by the SIMS method, which significantly exceeds the sensitivity of the analysis using electron impact mass spectrometry. Thus, in the surface ionisation of tertiary amines and their derivatives, it is possible to obtain from an oxidised tungsten emitter having an area of 1 cm^2 currents of approximately 10^{-1} A Pa^{-1}, whereas currents of approximately $10^{-4}-10^{-6}$ A Pa^{-1} are obtained in the ion sources of mass spectrometers with electron ionisation. In this connection SIMS is promising for the analysis of bio-organic substances whose isolation even in microamounts requires as a rule the processing of a large amount of the initial material of biogenic origin. The study of the surface ionisation of the alkaloid allomatrine, vitamin B_2, riboflavin, and the acetylcholine mediator makes analysis simpler when SIMS is employed and its sensitivity is significantly higher than for mass spectrometry with ionisation by electrons[30,37]. The likelihood of SIMS being useful for the determination of the aminoacid sequence in peptides has been examined[30] and it has been concluded that, at least for relatively short peptides, the application of surface ionisation makes it possible to simplify the mass-spectrometric analysis and to increase significantly its sensitivity compared with the mass spectrometric analysis involving ionisation by electrons.

An important property of the ions obtained by surface ionisation, which distinguishes them from the ions formed using other ionisation procedures, is their definite energy characteristic: with equipartition of energy among the internal degrees of freedom, the ions have a Boltzmann distribution (as a function of the emitter temperature) with respect to the total internal energy. We believe that this property makes it useful to employ SIMS in the solution of one of the important problems of organic mass spectrometry—the determination of a relation between the reactivity of a compound and its mass spectrum.

The state of the knowledge of the characteristic features of surface ionisation of organic compounds and the possibility of employing the surface ionisation phenomenon for analytical and other purposes is at present sufficient to develop practical surface-ionisation mass spectrometry. The design of the surface-ionisation ion sources is simple; much experience has been gained in their development for mass spectrometers designed for isotope analysis. After a minor redesign of commercial mass-spectrometers (for example, by providing the mass spectrometer for isotope analysis with a system for the injection of the vapours of organic substances or by fitting the mass spectrometers for the analysis of organic compounds with a surface-ionisation ion source), they can be used also for the surface-ionisation analysis of organic compounds. The SI mass spectra of a series of cyclic amines obtained using the MI-1201 mass spectrometer[60,61]# can serve as an example of this.

VII. SURFACE-IONISATION DIODE DETECTORS OF ORGANIC COMPOUNDS

The high efficiency of the surface ionisation of amines, hydrazines, and their derivatives can be used for the sensitive and selective detection of microamounts of the above substances, for example, in air or in mixtures in the course of their chromatographic separation. It is then evident that detection can be achieved not only mass-spectrometrically but also with the aid of simple diode devices in which the overall ionic current between the emitter and the collector is measured[62,63].

The possibility of the practical realisation of surface ionisation in a diode device under the conditions of its separation not only *in vacuo* but also in air or in other gases has now been elucidated: ways have been found for the preparation of effective emitters operating in different media[27,64]; the designs of flow-type devices ensuring the virtually complete deposition of the substances analysed on the surface of the emitter have been developed[65,66]; the optimum operating conditions for diode detectors have been established[65,67]. The first surface-ionisation devices and highly selective methods for the detection of organic compounds belonging to the classes of amines, hydrazines, and their derivatives, which are unique as regards sensitivity, have been developed[64-67]. For example, with the aid of a diode surface-ionisation detector of simple design, it is possible to measure the content in air of tertiary alkylamines and their derivatives in an amount down to approximately $10^{-14}-10^{-15}$ litre^{-1}.[65]

The surface-ionisation detectors are designed for the following purposes.

1. For the monitoring of the contamination by gases of industrial premises as part of safety techniques. The "Valdai" surface-ionisation gas-analyser was developed in 1976 for the continuous monitoring of the contamination of industrial premises with gaseous diethylamine[68]. After appropriate calibration, it can be used also for the determination in air of microamounts of other secondary and tertiary alkylamines and their derivatives.

2. For the highly sensitive detection of leaks in hermetically-sealed compartments (containers, tubes, etc.). We may note that, when halogen leak-seeking devices are replaced by the more sensitive amine devices, the contamination of the upper atmosphere by Freon is prevented.

3. For gas chromatography. The surface-ionisation detector (SID) for gas chromatography has the following characteristics[65]: ionisation efficiency $\sim 4 \times 10^{-2}$ (with respect to triethylamine), background current $\sim 10^{-11}$ A, noise level $\sim(2-10) \times 10^{-14}$ A, threshold sensitivity $\sim 5 \times 10^{-15}$ g s^{-1} (with respect to triethylamine), linear range $\sim 10^4-10^8$, errors of readings $\leq \pm 5$% (with respect to triethylamine), continuous operation time ≥ 50 h, and selectivity with respect to hydrocarbons $\sim 10^5-10^8$.

#Unfortunately in the above investigations the authors, who obtained the mass spectra at an emitter temperature of approximately 2000 K, do not draw a distinction between the primary and fragment ions, which reduces the amount of information available from the SI mass spectra.

It is important that, in contrast to virtually all the existing selective detectors, the SID is selective with respect to the nature of the functional group containing the nitrogen atom and not with respect to the heteroatom itself[62]. It can therefore be used for the functional gas-chromatographic (GC) analysis of nitrogen-containing compounds[69]. Thus, using the simultaneous detection of the components at the outlet from the gas-chromatographic column by the SID and the flame-ionisation detector (FID), it is possible to determine the type of amino-group in aliphatic amines: when, for example, the Pye-Unicam FID is used, the SID/FID signal ratio is $\sim 10^3$–10^4 for tertiary amines, $\sim 10^2$ for secondary amines, and ~10 for primary amines[69,70].

The high SI efficiency with respect to tertiary alkylamines, significantly exceeding the SI efficiency for all other classes of organic compounds, can be used for the equisensitive detection with the aid of the SID of any organic compounds in mixtures in the course of their gas-chromatographic separation: by passing a tertiary alkylamine at a constant concentration together with the carrier gas through the gas-chromatographic column and by recording with the aid of the SID the variation of its volume concentration during the passage of the mixture components through the detector, it is possible to determine the volume concentrations of the components[71].

4. For the solution of any special problems in which the detection and identification of submicroamounts of amines and their derivatives is required, for example, of traces of toxic substances for the protection of the environment, for the identification of amines which are the active principles of an odour, for the determination of trace amounts of alkylamines and their derivatives in hermetically-sealed volumes, for the analysis of amines evolved by living organisms, etc.

In conclusion we may note that, when an additional initial stage involving the chemical conversion of the substances analysed into amines is used in the surface ionisation detection method, the latter can become universal and suitable for all substances capable of such conversion. For example, *N*-nitroso-compounds can be readily converted into amines by denitrosation; therefore the SID can be used for the determination of the contents of carcinogenic *N*-nitroso-compounds in food products and in the environment.

* * *

Thus it has only been recently established that organic compounds are capable of forming stable polyatomic positive ions via surface ionisation. As a result of the investigation of the characteristic features of this phenomenon for compounds with Group VA heteroatoms, extensive possibilities have arisen for the employment of surface ionisation in the physical and analytical chemistry of these compounds. The uniquely high sensitivity of the detection with the aid of surface ionisation of microamounts of many substances in the atmosphere and in other mixtures is of great practical importance.

There are already indications that compounds of other classes can also be ionised by surface ionisation[19,30,72–75]. There is no doubt that the further search for compounds capable of surface ionisation and the study of the characteristic features of their ionisation will significantly extend the applications of the phenomenon.

A New Class of Complex Water-soluble Polyelectrolytes

A.B.Zezin and V.A.Kabanov

The literature data on polyelectrolyte complexes (PEC), mainly non-stoichiometric PEC (N-PEC), are analysed. Interpolyelectrolyte reactions, leading to the formation of N-PEC as well as the methods of synthesis of these macromolecular compounds are examined. The structure of water-soluble N-PEC, which constitute a new class of complex water-soluble polymers, is discussed. A special section is devoted to the behaviour of N-PEC in aqueous salt media and to the description of the characteristics of the phase separation in such systems. The prospects for the development of the research into and the possible applications of this new class of polyelectrolytes are discussed.
The bibliography includes 64 references.

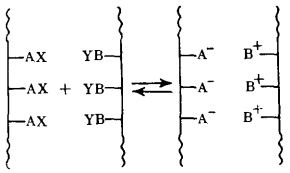
I INTRODUCTION

The increasing interest in the chemistry and physical chemistry of synthetic polyelectrolytes is due to the continuous expansion of their practical applications as highly effective flocculants, structure-forming agents and stabilisers for colloidal dispersions, ion-exchange materials, specific sorbents, biologically active compounds, etc. In addition, with their aid it is sometimes possible to simulate certain important features of the behaviour of biopolymers: enzymes and nucleic acids.

Polyelectrolytes belong to the class of reactive polymers. Among the reactions which they undergo, one of the most interesting is that between cationogenic and anionogenic macromolecules (polymeric acids, polymeric bases, and their salts) in aqueous solutions, leading to the formation of interpolymer salts or polyelectrolyte complexes (PEC), a term which is frequently applied to them. In a certain sense, this reaction has no analogies in the chemistry of low-molecular-weight substances, since the polymeric product (the PEC) is a compound whose stability is due mainly to entropy factors. Cationo- and aniono-genic macromolecules complement each other electrostatically. Therefore the interaction between them is fully analogous in the thermodynamic sense to the interaction between complementary biopolymers responsible for the self-assembly of the majority of biological structures.

As early as the 1930's, the attention of investigators was attracted to the fact that, when aqueous solutions of oppositely charged natural polyelectrolytes, characterised by a relatively low charge density on the macromolecules (for example, gelatines and gum arabic), are mixed, phase separation and the formation of living coacervates take place under certain conditions[1-4]. Subsequently the phase separation conditions were investigated[5-7]. On the other hand, the chemical and physicochemical aspects of the reactions between the macromolecules and particularly the structure of the PEC have not been investigated at the macromolecular level. The coacervates of natural polyelectrolytes still attract the attention of certain biochemists attempting to simulate the phenomena of prebiological evolution[8-10].

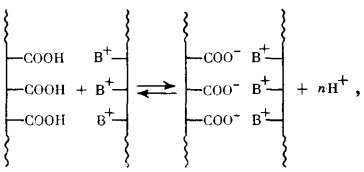


The next stage in the studies on the PEC refers to the 1960's [11-15] when strong polyelectrolytes with a high charge density on the chains became available as a consequence of advances in the synthesis of polymers. The interaction in solutions between electrostatically complementary polyelectrolytes, characterised by a high charge density, leads to the formation of PEC, which are usually precipitated from solution in the form of comparatively little solvated deposits. The ratio of the oppositely charged groups in these compounds is 1 : 1. Henceforth we shall refer to such PEC as stoichiometric (S-PEC). They are insoluble in any of the known solvents and are capable of limited swelling in water, resembling in some of their properties the well-known cross-linked hydrogels. The interest in the S-PEC is due mainly to the possibility of using them as membranes for the desalination of water[14-15], for haemodialysis[16-18], etc. A fairly large number of publications have been devoted to the formation reactions and properties of S-PEC (see, for example, Refs.19–27), a detailed description of which is outside the framework of our task.

The present review deals with a new field of research which has arisen as a result of the discovery of non-stoichiometric PEC (N-PEC). These interpolymer compounds are also the products of reactions between electrostatically complementary chains. However, in contrast to the S-PEC, when certain conditions are observed, they do not precipitate. Consequently they can be used like the usual soluble polyelectrolytes. At the same time, in contrast to the usual polyelectrolytes, the N-PEC also have a series of unique properties, which, as will be seen from the exposition below, make it possible to isolate them as a special class of water-soluble polymeric compounds.

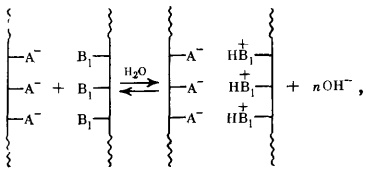
However, before proceeding to the description of the N-PEC, it is necessary to consider certain general characteristics of interpolyelectrolyte reactions and their products.

II. INTERPOLYELECTROLYTE REACTIONS



The reaction between polyelectrolytes can be represented schematically as follows:

(I)



Here -AX- is a unit of a polymeric acid or its salt and -BY- is a unit of the polymeric base or its salt. As a result of the reaction between the units of the macromolecule, salt bonds are produced. The formation of each bond is accompanied by the liberation into the surrounding medium of a pair of low-molecular-weight ions.

Evidently equilibrium (I) can be displaced in one direction or another by altering the activity of the low-molecular-weight reaction product. Accordingly, one of the methods for the investigation of equilibrium (I) is based on the measurement of the activities of the low-molecular-weight ions in the system. This can be done particularly simply when the reaction is accompanied by the liberation of protons or hydroxide ions, which happens when one of the macromolecular reactants is a weak polymeric acid or a weak polymeric base, and the second is a polymeric cation or a polymeric anion respectively:

(Ia)

where B^+ is, for example, a charged amino-group and

(Ib)

where A^- is an anionic group in the unit of the polymer chain and B_1 is, for example, a primary, secondary, or tertiary amino-group. Reactions of types (Ia) and (Ib) can then be investigated by the potentiometric titration method[19-23].

The typical pH profiles of such reactions are illustrated in Fig. 1 The degree of conversion θ represents the fraction of the intermacromolecular salt bonds formed relative to their maximum possible number. An equilibrium value of θ corresponds to each pH. The value of θ can be readily calculated from potentiometric titration data. It is determined as the ratio of the concentrations of the salt bonds (c_S) and the initial concentration of the functional groups of any of the polyelectrolytes (c_0)† provided that the PEC species remain stoichiometric over the entire range of θ.

†Here and henceforth the concentration of the polyelectrolytes will be expressed in terms of the molar concentration of their units and will be designated as follows: basic mol litre^{-1}.

Since the formation of each intermacromolecular salt bond is accompanied by the liberation of a proton [reaction (Ia)] or a hydroxide ion [reaction (Ib)] into the surrounding medium, the following equation can be used to determine c_S and hence also θ:

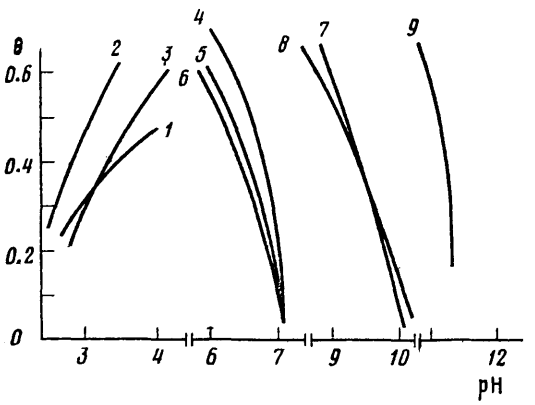
$$c_c = \theta c_0 = q_{alk}/V + [H^+], \quad (1a)$$

where q_{alk} is the amount of the added titrant (alkali), $[H^+]$ the concentration of protons in solution, V the volume of the reaction mixture, and

$$c_c = \theta c_0 = q_{ac}/V + [OH^-], \quad (1b)$$

where q_{ac} is the amount of added titrant (acid) and $[OH^-]$ the concentration of hydroxide ions in solution. Reactions whose θ–pH profiles have a positive slope correspond to equilibrium (Ia) and those with a negative slope correspond to equilibrium (Ib).

Fig. 1 shows that the profiles of reactions (Ia) and (Ib) are very steep, which is usually characteristic of cooperative transformations. The transformation of a mixture of macromolecules which have not interacted ($\theta = 0$) into the product of the completed reaction ($\theta = 1$) takes place over a fairly narrow pH range. Correspondingly the pH range in which the PEC formed is stable proves to be fairly wide.



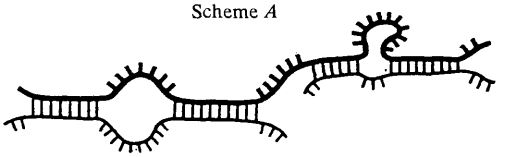


Figure 1. Dependence of the degree of conversion θ on the pH for reactions between polyelectrolytes: *1*) polyacrylic acid (PAA)–poly(dimethylaminoethyl methacrylate) hydrochloride (PDMAEMA.HCl); *2*) poly-L-glutamic acid–PDMAEMA.HCl; *3*) PAA–poly-L-lysine hydrobromide (PL.HBr); *4*) poly-4-vinylpyridine (PVP)–sodium polyphosphate (PP-Na); *5*) PVP–sodium polyethylenesulphonate; *6*) PVP–sodium polystyrenesulphonate; *7*) PDMAEMA–sodium polyacrylate (PA-Na); *8*) PDMAEMA–PP-Na; *9*) PL–PA-Na.[20]

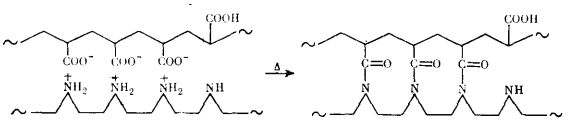
The results of the study of the equilibria of the reactions involving the formation of PEC have led to the idea that the PEC are polymers with a ladder structure in which more or less long sequences of pairs of units, linked via salt bonds, alternate with loops consisting of sequences of disconnected units[22,26,27] (Scheme *A*). The fraction of units incorporated in the ladder sequences increases with θ. The average length of the ladder sequences also increases,

as shown by the results of the analysis of equilibria (Ia) and (Ib) in terms of model *A*:[27]



Scheme *A*

The study of the properties of S-PEC, which are products of completed reactions, indicates the presence in the latter of a considerable number of defects, which are represented in Scheme *A* by loops. Because of the presence of the defects, which contain disconnected hydrophilic units of the electrostatically complementary chains, the S-PEC swell appreciably in water. The hydrophobic ladder sections limit the capacity of the S-PEC for swelling in aqueous media. The non-polar interactions of these units with one another lead to the compaction of the PEC species in dilute aqueous solutions[28,29]. The electron micrograph in Fig.2 illustrates typical globular PEC particles formed as a result of the reaction between poly-L-lysine and polyacrylic acid (PAA) in a dilute aqueous solution. Structures of this type were first discovered in 1959.[30] The coiling of the S-PEC species into compact globules is possible by virtue of the marked bending of the two-stranded formations at the sites of the defects (loops).

The presence of defects in the products of the completed reactions can be due to different causes. One of these is the "freezing" of the random intermolecular contacts arising in the early stages of the rapid ionic reaction. After the deposition of the PEC, its subsequent rearrangement, tending to "heal" the defects, probably proceeds very slowly. Thus certain non-equilibrium states are fixed in the system. This is indicated by data obtained in studies[28,29] in which the relaxation of the PEC formed as a result of the neutralisation of strong polymeric acids by strong polymeric bases was observed. On the other hand, if the conditions for the occurrence of non-equilibrium structures are excluded, for example, by employing matrix polymer reactions for the preparation of the PEC, then the resulting PEC can prove to be highly ordered[31-33].

However, in the general case one has to bear in mind also another important factor determining the defectiveness of the PEC: the absence of a steric correspondence between the electrostatically complementary chains. The majority of the PEC described in the literature are products of the interaction of sterically irregular macromolecules. Such PEC are amorphous as regards X-ray diffraction and contain at least 20–30% of pairs of disconnected units, i.e. units incorporated in defects. This is demonstrated convincingly by the results of the study of ion-exchange equilibria with a series of different PEC.[34] Even in the product of the complete reaction between linear polyethyleneimine (PEI) and atactic PAA, whose chains are characterised by a fairly satisfactory steric correspondence, 20% of the units of each type are in the defects. The infrared spectra of the PEC dialysed against water indicate the presence of ~20% of protonated carboxy-groups[35]. On the other hand, the two-stranded ladder sections in such PEC have an extremely ordered structure. This is indicated by the fact that, in the products of the interaction of PAA and PEI in the vitreous state, the intermolecular salt bonds are quantitatively converted into covalent amide bonds at elevated temperatures[35-37]:

(II)

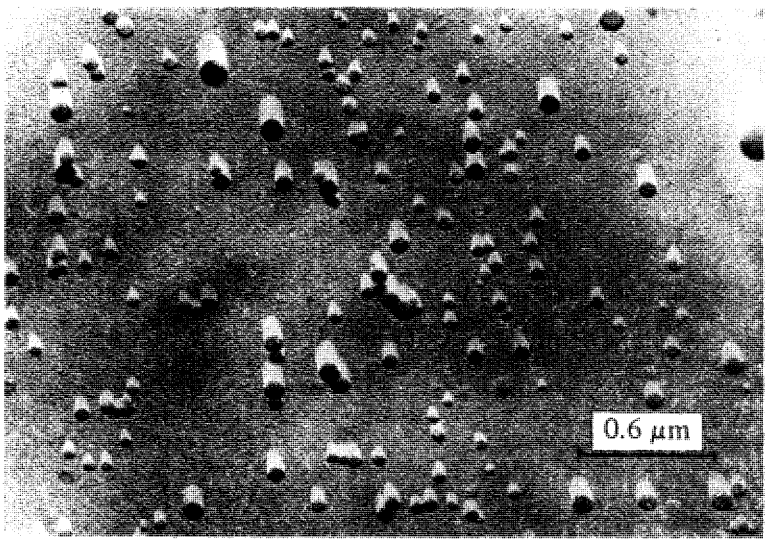


Figure 2. Photomicrograph of particles of the stoichiometric PEC formed as a result of the reaction between equivalent amounts of poly-L-lysine and polyacrylic acid at pH 4.2 and a concentration of polyelectrolytes of 10^{-5} basic M.[29]

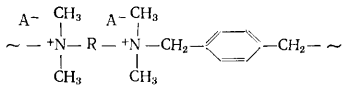
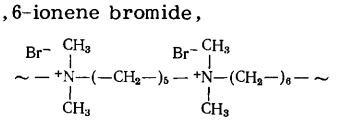
The units located in the defects do not enter into this reaction.

The foregoing does not imply that the presence of a considerable number of defects is characteristic of all the PEC obtained by the direct mixing of solutions of electrostatically complementary polyelectrolytes. Crystalline PEC, i.e. low-defect PEC, obtained, for example, from ionene, which is a product of the 1,4-polymerisation of 4-vinylpyridine,



and isotactic PAA [38] and also from ionene and a polyphosphate (PP),[39] have been described in the literature. However, presumably the stereoregularity and the satisfactory steric correspondence of the initial components are essential conditions for the formation of highly-ordered crystalline PEC.



III. SYNTHESIS OF WATER-SOLUBLE NON-STOICHIOMETRIC POLYELECTROLYTE COMPLEXES

In contrast to the S-PEC, the history of the study of which covers a period of approximately 20 years as already mentioned, detailed and systematic studies of the N-PEC began less than 10 years ago. The publications by Tsuchida et al.[40] and Gulyaeva et al.[41] are some of the first in which N-PEC were described. The ability of the N-PEC to dissolve in aqueous media was noted as their main characteristic in the above publications.

Tsuchida et al.[40] were the first to describe in detail the procedures for the preparation of non-stoichiometric water-soluble PEC. They showed that N-PEC are formed as a result of the mixing of aqueous solutions of aromatic ionenes

and sodium polystyrenesulphonate (PSS-Na) taken in non-equivalent proportions. It was observed that the PEC dissolve only when PSS-Na is present in excess relative to ionene. The complete dissolution of the PEC is observed in the presence of a threefold excess of PSS-Na. When excess amounts of ionene are introduced into PSS-Na solutions, a soluble PEC is not formed. In the latter case, insoluble S-PEC is produced and excess ionene remains in solution. These observations led the authors[40] to the conclusion that polymers of the series of ionenes have a special ability to form soluble PEC, which in their view is associated with the localisation of the charged groups in the chain of the main valences of the macromolecules. The authors[40] were unable to obtain water-soluble PEC from PSS-Na and polybenzylvinyltrimethylammonium chloride, i.e. from polyelectrolytes in which the ionogenic groups are localised in the side-substituents. It was soon shown[41], in relation to the reaction between the sodium polyacrylate (PA-Na) and 5,6-ionene bromide,

that aliphatic ionenes are also capable of forming water-soluble N-PEC. The above facts are seemingly consistent with the hypothesis of the exceptional properties of ionenes which, if one follows the reasoning of Tsuchida et al.[40], are due to the steric "accessibility" of the positively charged quaternary nitrogen atoms.

However it was shown later[42–45] that water-soluble N-PEC can be obtained from oppositely charged polyelectrolytes of a wide variety of chemical structures when certain conditions are observed. The examples of the water-soluble N-PEC known at present are presented in Table 1. Evidently N-PEC can be formed by pairs of strong polyelectrolytes, pairs of weak polyelectrolytes, and by mixed pairs. It is also seen that N-PEC can be obtained by the reaction of two electrostatically complementary polyelectrolytes in each of which the charged compounds are localised in the side-substituents and not in the chain of the main valences of the macromolecule, for example, PA-Na–poly(dimethylaminoethyl methacrylate) hydrochloride (PDMAEMA.HCl) or PA-Na–poly-*N*-ethyl-4-vinylpyridinium bromide (PVP.C_2H_5Br). The polyelectrolyte incorporated in the N-PEC in excess can be both negatively and positively charged. It follows from Table 1 that the structural-chemical limitation introduced by Tsuchida[40] is erroneous. As will be shown later, the necessary and sufficient conditions for the formation of soluble N-PEC are not associated directly with the chemical structure of the units of the electrostatically complementary polyelectrolyte components.

Notation: LPE and BPE are the lyophilising and blocking polyelectrolytes; s.(–), s.(+), and w.(+) are respectively strong and weak polyelectrolytes charged negatively and positively; PMAA = polymethacrylic acid; the notation used for the other polyelectrolytes and for the methods of preparation of the PEC is described in the text.

The data permitting the formulation of one of the necessary conditions for the formation of water-soluble N-PEC were first obtained by Kasaikin et al.[43]. In the synthesis of N-PEC, non-equivalent amounts of the initial polyelectrolyte components are introduced into the reaction. We shall adopt the convention that the overall condition of the reaction system is henceforth characterised by the quantity Z, which represents the ratio of the concentration of the units of the component present in a deficient amount to the concentration of the units of the component present in excess. Kasaikin[43] presents data for the solubilities of

the products of the interpolymer reaction in the PDMAEMA.HCl–sodium polyphosphate (PP-Na) system# as a function of the degree of polymerisation of the initial components P.

It follows from these data that the soluble products are formed only for $\bar{P}_1/\bar{P}_2 \gtrsim 1$. In all cases the reaction conditions correspond to a virtually complete shift of equilibrium (Ib) to the right, i.e. the degree of conversion θ, calculated with respect to the component present in a deficient amount, is close to unity. Consequently the soluble product is an N-PEC with the composition Z. If $\bar{P}_1 < \bar{P}_2$, the reaction product precipitates; analysis of the compositions of the coexisting phases showed that the precipitate is an S-PEC which incorporates the entire deficient polyelectrolyte. Only the superstoichiometric amount of the polyelectrolyte component introduced in excess remains in solution.

A completely analogous situation is observed in the same system with the "reverse" ratio of the PDMAEMA.HCl and PP-Na concentrations with an excess of polyanions instead of polycations. In this system N-PEC is formed only for $\bar{P}_1 > \bar{P}_2$. However, this requirement implies that the polyanions introduced in excess must be longer than the polycations[43].

Turning again to the studies[40,41,44] in which the N-PEC were first described, one should note that the condition $\bar{P}_1 > \bar{P}_2$ was in fact observed, since the N-PEC were obtained when the high-molecular-weight polyanions predominated over the relatively low-molecular-weight polycations (ionenes).

Thus the necessary condition for the formation of the N-PEC, concerning the ratio of the degrees of polymerisation of the electrostatically complementary polyelectrolyte pairs, is $\bar{P}_1 \geq \bar{P}_2$. To facilitate further exposition, we shall now introduce certain new definitions and characteristics. The relatively high-molecular-weight component present in the N-PEC in excess will be referred to as the lyophilising polyelectrolyte (LPE)§. The relatively low-molecular-weight component present in the N-PEC in a deficient amount will be called the blocking polyelectrolyte (BPE)¶.

Thus, by definition, the degree of polymerisation of the LPE ($\bar{P}_{LPE}$) is always greater than or equal to the degree of polymerisation of the BPE ($\bar{P}_{BPE}$). The composition of the N-PEC will be expressed in terms of the ratio of the number of units in the BPE to the number of units in the LPE incorporated in the N-PEC, designated by $\phi = [BPE]/.[LPE]$. Evidently ϕ can vary from 0 to 1. If the PEC is the product of a completed reaction, i.e. corresponds to $\theta \cong 1$ (such PEC will in fact be considered henceforth), the limiting value $\phi = 1$ corresponds to the transformation of the N-PEC into the S-PEC. Naturally $\phi = 0$ corresponds to a solution of the free LPE.

The condition $\bar{P}_1 \geq \bar{P}_2$ formulated above is insufficient for the formation of N-PEC on direct mixing of salt-free dilute aqueous solutions of oppositely charged polyelectrolytes. It is also necessary that the solution in which the reaction is carried out contains a certain amount of a low-molecular-weight electrolyte. This amount may be comparatively small. The required concentration of the 1:1-valent electrolyte, for example NaCl, can vary in the range 0.002–0.12 M, depending on the chemical nature of the polyelectrolytes and their ratio in the system. Generally speaking, the greater the excess of the high-molecular-weight component, i.e. the lower the value of Z, the lower the concentration of the low-molecular-weight salt necessary for the formation of the water-soluble N-PEC (Fig.3).

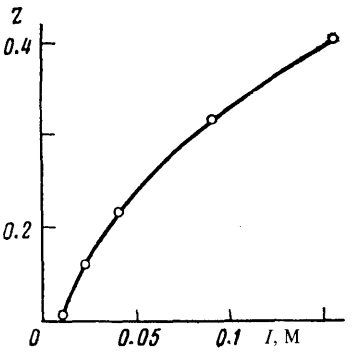

Figure 3. Dependence of the composition of a mixture of polyelectrolytes for which N-PEC dissolves in the sodium polymethacrylate (PMA-Na)–poly-*N*-ethyl-4-vinylpyridinium bromide (PVP.C_2H_5Br) system on the ionic strength of the solution I.[42]

For the complete dissolution of the product of the completed reaction between the BPE and the LPE, it is also necessary that their ratio in the system should not exceed a characteristic value: $Z \leq Z_{char}$. The characteristic composition of the N-PEC ($\phi_{char} = Z_{char}$) corresponds to this condition. If $Z > Z_{char}$, then the dissolved N-PEC with the characteristic composition ϕ_{char} and the corresponding amount of the insoluble S-PEC coexist in the reaction system. The value of ϕ_{char} for the majority of the systems studied varies in the range from 0.5 to 0.2 and depends mainly on the chemical nature of the polyelectrolytes constituting the PEC. It is still not altogether clear what determines the value of ϕ_{char}, but it presumably depends to a large extent on the steric correspondence of the units of the BPE and the LPE and also on the degree of hydration of the intermacromolecular salt linkages and the degree of binding of small counterions to the units of the LPE incorporated in excess in the PEC.

We shall now consider the specific procedures for the preparation of N-PEC. A general method for different pairs of polyelectrolytes whereby N-PEC can be synthesised consists in the direct mixing of solutions of fully ionised oppositely charged polyelectrolytes taken in appropriate proportions ($Z \leq Z_{char}$) and containing the necessary amounts of a low-molecular-weight salt (composition *a* in Table 1); such mixing can be achieved in two ways.

#Here and henceforth in the designation of the polyelectrolyte systems investigated we shall first indicate the component present in excess.

§In publications in English, for example in the book by Kabanov et al.[47], the term host-polyelectrolyte has also been adopted for LPE.

¶In the original publications[42,43,46,52,55] the BPE has also been called the reference polyelectrolyte and, in publications in English, the "guest-polyelectrolyte".[47]

Procedure *a'* consists in the gradual addition of a solution of the LPE to a solution of the BPE. The polyelectrolyte chosen as the LPE is then initially present in a deficient amount relative to the BPE. According to the above considerations, in this stage the N-PEC is not formed, since the reaction system is characterised by a ratio of the degrees of polymerisation of the reactants unfavourable for the formation of the N-PEC. Instead an insoluble S-PEC is formed and accumulated and the solution of the polyelectrolyte chosen as the BPE is in equilibrium with it. Fig.4*a* presents curves for the turbidimetric titration of a solution of 5,6-ionene bromide (BPE) with a solution of PP-Na (LPE) and for the titration of a solution of PP-Na (BPE) with a solution of PDMAEMA.HCl (LPE). The increase of turbidity with change in the composition of the mixture of polyelectrolytes is linear and corresponds to the accumulation of the insoluble S-PEC. The maximum turbidity corresponds to the equivalent proportions of the polyelectrolytes in the system ($Z = 1$). At the maximum both polyelectrolytes are quantitatively incorporated in the insoluble S-PEC. A further increase of the amount of the high-molecular-weight component chosen as the LPE is accompanied by a gradual, virtually linear decrease of turbidity.

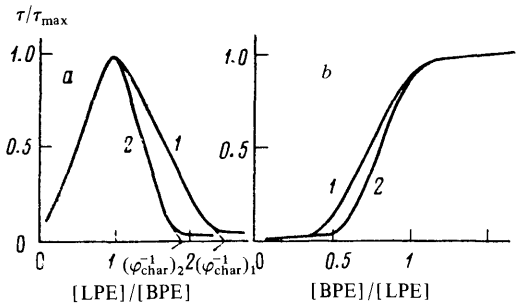

Figure 4. Turbidimetric titration curves: *a*) titration of an aqueous solution of 5,6-ionene bromide (BPE, $\bar{M}_w = 1.4 \times 10^4$) with a solution of PP-Na (LPE, $\bar{M}_w = 6.6 \times 10^4$) at pH 7.0 in 0.01 M NaBr (curve *1*) and of an aqueous solution of PP-Na (BPE, $\bar{M}_w = 1.7 \times 10^4$) with a solution of PDMAEMA.HCl (LPE, $\bar{M}_w = 6.3 \times 10^5$) at pH 4.5 in 0.1 M NaCl (curve *2*); *b*) ditto with the reverse order of mixing of the solutions; τ_{max}—maximum turbidity of the system[47].

Analysis of the composition of the coexisting phases shows that the concentrated phase contains the stoichiometric PEC. Its amount diminishes with increase of the excess of the LPE. The N-PEC accumulates in the dilute solution; its composition remains unaltered up to the complete dissolution of the precipitate and is specified by ϕ_{char}. The reciprocal ϕ^{-1}_{char} in Fig.4*a* corresponds to the intercept which the descending branch of the curve makes on the abscissa axis. Thus the procedure for the preparation of the N-PEC examined above virtually consists in the dissolution of the S-PEC under the influence of the excess of the LPE, i.e. in the transformation of the S-PEC into the N-PEC.

The second procedure (*a''*) leading to the preparation of the N-PEC consists in the addition of a solution of the BPE to that of the LPE. Fig.4*b* presents the corresponding turbidimetric titration curves for the same polyelectrolyte salt as in Fig.4*a*. Evidently the initial section of the curve corresponds to the homogeneous system. This is natural, since, in the given range of compositions of the polyelectrolyte mixtures, the condition $\bar{P}_1 > \bar{P}_2$, necessary for the formation of the soluble N-PEC, is satisfied; the LPE is present in excess at this stage. The system remains homogeneous over the entire range of compositions of the reaction mixture for $Z \leqslant Z_{char}$. Depending on the ratio $\bar{P}_{LPE}/\bar{P}_{BPE}$, the composition of the N-PEC can either vary within wide limits or can remain unaltered. The causes of this will be examined at the end of this Section.

A further alteration of the composition of the polyelectrolyte mixture is accompanied by the appearance and accumulation of a deposit of the S-PEC (up to $Z = 1$). In the range $Z_{char} < Z \leqslant 1$, the insoluble S-PEC coexists with the soluble N-PEC having the characteristic composition. Following the attainment of $Z = 1$, both polyelectrolytes are quantitatively incorporated in the particles of the insoluble S-PEC, after which further addition of the BPE no longer leads to such appreciable changes in the state of the system. The excess BPE simply accumulates in the solution. In this range of compositions the formation of the N-PEC is impossible, since we now have $\bar{P}_1 < \bar{P}_2$. In contrast to the previous method, this procedure presupposes the formation of the N-PEC in a homogeneous system and allows for the possibility of varying the composition of the N-PEC over a wide range.

The procedures described above consist in carrying out the reaction between wholly or almost wholly dissociated LPE and BPE taken in considerable proportions. The N-PEC are then formed immediately as products of the completed reactions ($\theta \cong 1$). However, other procedures are also possible whereby the N-PEC can be obtained from weak polyelectrolytes. They are based on the ability of pairs of polyelectrolytes, at least one of which is weak, to form the N-PEC for $\theta \ll 1$, i.e. under conditions where the interpolymer reaction is far from completion. Such N-PEC can be both soluble and insoluble in water. Insoluble S-PEC, formed in acid media by the reaction of PAA and polymethacrylic acid (PMAA) with various polymeric bases, have been described[24,44]. The virtually unionised units of the polymeric acid are incorporated in the N-PEC species in a 2–5-fold excess. It has been suggested that the solubility of these N-PEC is due to the compaction of their species. The compact conformations are stabilised by the hydrogen bonds formed by the excess carboxy groups. Non-polar interactions also play an important role in the stabilisation of these compounds.

Fig.5 presents curves for the potentiometric and turbidimetric titration of the PMAA–PVP.C_2H_5Br system with alkali (NaOH) for $Z = 0.2$. The degrees of neutralisation of the PMAA (α), calculated relative to the entire polymeric acid introduced into the reaction with the polycation, are plotted along the abscissa axis. The reaction product formed on mixing aqueous solutions of the polycation and free PMAA taken in a 5-fold excess was considered as the initial system. This reaction is accompanied by the liberation of protons into the solution [equilibrium (Ia)] and the formation of an insoluble N-PEC. Both polyelectrolytes are quantitatively incorporated in the species of the polymeric complex[45]. However, only ~25% of the units of the polycations functioning as the BPE form salt linkages with the macromolecules of the polymeric acid in the N-PEC formed. If alkali (for example, NaOH) is now added to the colloidal dispersion obtained, the reaction involving the formation of salt linkages between the BPE and the LPE is initially completed. The degree of ionisation of the PMAA then varies in the range between 0 and 0.2; at the same time there is a

slight increase of the pH to ~4, which is accompanied by an increase of the turbidity of the system. For $\alpha = 0.2$, an N-PEC in which virtually all the quaternary nitrogen atoms form salt linkages with an equivalent number of the charged carboxy-groups of the PMAA ($\theta \cong 1$) exists in the system.

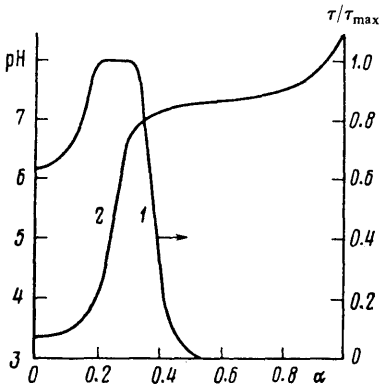

Figure 5. Curves for turbidimetric (curve *1*) and potentiometric (curve *2*) titration of an acid solution of a mixture of polymethacrylic acid (PMAA) (LPE, $\bar{M}_w = 2.6 \times 10^5$) and PVP.$C_2H_5Br$ (BPE, $\bar{M}_w = 2 \times 10^5$) having the composition $Z = 0.2$ with sodium hydroxide; [PVP.C_2H_5Br] = 2×10^{-3} basic M; α = degree of neutralisation[45].

However, such N-PEC is still insoluble in water, because the free PMAA units functioning as the LPE are not yet ionised and they do not therefore exhibit an adequate lyophilising capacity. The subsequent addition of alkali leads to the ionisation of the free carboxy-groups of the PMAA incorporated in excess in the N-PEC. After the attainment of $\alpha \cong 0.5$, the N-PEC dissolves. This follows from the form of the turbidimetric titration curve. On the other hand, the potentiometric titration curve exhibits a sharp rise, showing that the dissolution of the N-PEC is accompanied by a conformational transformation of its species: the compact conformations are converted into the uncoiled conformations characteristic of charged macromolecular chains. The degree of ionisation of the LPE necessary for the dissolution of the N-PEC is higher the smaller the excess of the LPE in the N-PEC species, i.e. the higher the value of ϕ. The dissolution of the N-PEC having the characteristic composition requires virtually complete charging of the units of the LPE chains. The method for the preparation of water-soluble N-PEC described above will henceforth be designated by *b'*.

An analogous procedure can be used also in cases where weak polymeric bases are used as the LPE. An example is provided by the PDMAEMA.HCl–PP-Na system[42]. When solutions of the polymeric components are mixed in an alkaline medium, where the amino-groups of the LPE are uncharged, the N-PEC formed initially is a product of the uncompleted reaction (but this time it is soluble). In the course of the subsequent titration of the reaction mixture with acid (HCl), the degree of completion of the interpolymer reaction θ increases to a value close to unity, but the excess free amino-groups of the LPE are still not protonated and the N-PEC formed in the intermediate titration range is precipitated. However, further addition of the acid leads to the charging of the free amino-groups of the LPE and to the formation of a soluble N-PEC. This method for the preparation of water-soluble N-PEC will be designated by *b''*.

Thus water-soluble N-PEC can be obtained in several ways. The possibility therefore arises of the solution of the fundamentally important problems of whether the water-soluble N-PEC are equilibrium compounds, i.e. whether their state depends on the way in which they have been obtained. In order to answer this question, it is necessary to compare the characteristics of the N-PEC formed by the same pair of polyelectrolytes having a fixed composition but prepared in different ways. Table 2 presents the weight-average molecular weights $\bar{M}_w$, the mean-square radii of inertia $(\bar{R}_g^2)^{1/2}$, the second virial coefficients of the solution A_2 obtained by the light scattering method, and the sedimentation coefficients S. It follows from Table 2 that the above characteristics of each of the N-PEC investigated are almost independent of the method of preparation. Consequently the soluble N-PEC must be regarded as equilibrium macromolecular compounds, which implies, in particular, that the methods widely used to investigate the usual polymer solutions, especially solutions of polyelectrolytes, can be employed for their investigation.

Table 2. Characteristics of the water-soluble non-stoichiometric PEC prepared by different methods[42].

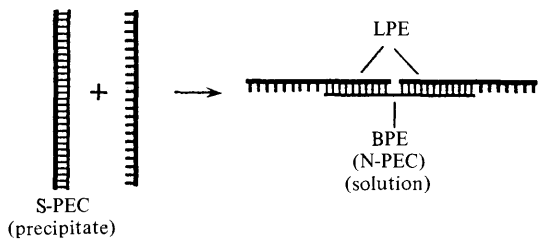
*$\phi = 0.25$; in the remaining cases $\phi = 0.33$.

Remarks: I = ionic strength of the solution; S = sedimentation coefficient (in Svedberg units) determined at a fixed concentration of the N-PEC (0.28 wt.%).

It was already noted above that in the reactions between polyelectrolytes, there is a possibility of the formation of both insoluble S-PEC and soluble N-PEC. Such situations are also observed when an insoluble S-PEC coexists with an N-PEC solution. It is significant that the characteristic composition of the N-PEC (ϕ_{char}) differs considerably from that of the stoichiometric polyelectrolyte. It has also been shown that, when an LPE is added to the S-PEC, the entire PEC gradually dissolves in the form of the N-PEC having

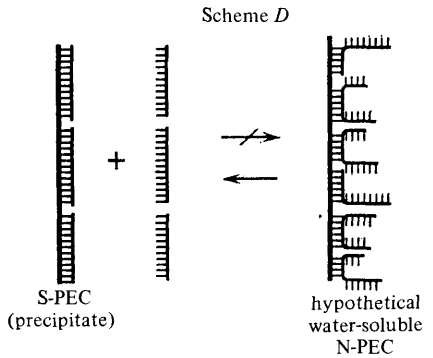
the characteristic composition[41]. In the case where $\bar{P}_{LPE} \gg \bar{P}_{BPE}$, this process can be represented by Scheme *B*.



Scheme *B*

It must be supposed that the driving force of the spontaneous formation of the water-soluble N-PEC after the addition of the LPE is the increase of the entropy of the system by virtue of the additional increase of the number of species in solution compared with the number of the LPE molecules introduced. The number of intermolecular salt linkages then remains unaltered.

However, the increase in the number of species in solution is apparently not the only factor determing the conversion of the insoluble S-PEC into the soluble N-PEC. This transformation occurs also when the degrees of polymerisation of the polyelectrolyte components are similar ($\bar{P}_1 \cong \bar{P}_2$), although the number of N-PEC species formed in this situation cannot exceed the number of macromolecules of all of the components added in excess to the system containing the S-PEC. The formation of the water-soluble N-PEC for $\bar{P}_1 \cong \bar{P}_2$ can be represented by Scheme *C*.



Scheme *C*

The number of interpolymer salt linkages remains unchanged after this transformation, as in the preceding case. However, reaction *C* can still be accompanied by an increase of the entropy of the system due to the transfer of the defects present both in the S-PEC and in the N-PEC from the precipitate to the solution. It was stated above that these defects, not illustrated in Schemes *B* and *C*, consist of loops made up of sequences of disconnected units of the electrostatically complementary chains (see Scheme *A*). The transfer of such loops from the concentrated to the dilute phase can be accompanied by an increase of the entropy of mixing of the system. The latter factor must naturally be taken into account also in considering processes described by Scheme (III). We may note that, for water-soluble N-PEC formed by chains with a similar degree of polymerisation, the concept of the LPE and BPE becomes degenerate. In this case the polyelectrolyte component present in excess actually plays the role of the LPE.

Finally, we shall consider the question why the water-soluble N-PEC are not formed when $\bar{P}_1 < \bar{P}_2$, i.e. why the excess of a polyelectrolyte having relatively short chains cannot lyophilise the oppositely charged long-chain polyelectrolyte. If one takes into account the fact that the PEC species acquires the ability to dissolve in the form of N-PEC only when its composition includes a considerable (at least two-fold) excess of LPE units, then the case under consideration may be reduced to Scheme *D*.

Scheme *D*

Evidently, the formation of the hypothetical N-PEC should result in a considerable decrease in the number of species in solution and the decrease should be greater the lower the degree of their polymerisation. When the total number of intermolecular salt contacts remains unchanged, this should be accompanied by a considerable decrease of the entropy of the system. Consequently process *D* can occur only from right to left, i.e. its occurrence from left to right is thermodynamically prohibited. An illustration of this situation is provided by the solubilities of the PEC and also the data in Fig.4*b*. It follows from Fig.4*b* that the introduction of an excess of the BPE into the reaction system relative to its content in the N-PEC for $\phi = \phi_{char}$ is accompanied by the formation of the S-PEC, which precipitates. After the attainment of the overall system composition $Z = 1$, a further addition of the BPE does not lead to any changes in the state of the insoluble S-PEC formed. The excess BPE simply accumulates in the solution over the precipitate.

Evidently the exact boundary between the polyelectrolyte pairs which are and are not capable of forming water-soluble N-PEC cannot be established exactly by an experimental procedure using only the average degrees of polymerisation of the electrostatically complementary polymeric components. This is due to the finite width of the molecular weight distribution of the fractions employed in the experiment. However, on the basis of the experimental data and their interpretation presented above, one can assume with an adequate degree of approximation that this boundary is in fact close to the ratio $P_1/P_2 = 1$. We may note that in all the examples considered the overall compositions Z were finite. One cannot rule out the possibility that, when a very large excess of even a relatively low-molecular-weight polyelectrolyte is used, it is possible to observe the spontaneous dispersion and peptisation of the PEC. However, the nature of such phenomena must be different and their consideration is outside the scope of our task.

In conclusion of this Section, we shall consider the question of the influence of the ratio $\bar{P}_{LPE}/\bar{P}_{BPE}$ on the characteristics of the compositions of the N-PEC formed. For this, it is sufficient to investigate two limiting cases: $\bar{P}_{LPE}/\bar{P}_{BPE} \gg 1$ and $\bar{P}_{LPE}/\bar{P}_{BPE} \cong 1$.

We shall consider the system PDMAEMA.HCl (LPE)–PA-Na (BPE). In the first of the versions investigated $\bar{P}_{LPE} = 3200$ and $\bar{P}_{BPE} = 150$, i.e. $\bar{P}_{LPE}/\bar{P}_{BPE} = 21 \gg 1$. Fig.6*a* presents sedimentation diagrams for mixtures of the above polyelectrolytes in the composition range $0.13 < Z < 0.5$ and also for free LPE. Evidently the peaks on the sedimentation

diagrams are symmetrical and fairly narrow, which indicates the inhomogeneity of the species of the water-soluble N-PEC as regards composition. The sedimentation coefficient S of the N-PEC decreases appreciably with decrease of the relative content of the BPE in the polymeric complex, i.e. as ϕ diminishes. When ϕ becomes sufficiently small ($\phi < 0.1$), the sedimentation coefficients of the N-PEC and LPE hardly differ. Thus, in systems where $\bar{P}_{LPE}/\bar{P}_{BPE} \gg 1$, the composition of the water-soluble N-PEC can be varied within fairly wide limits. The composition of the N-PEC then agrees with the overall composition of the mixture of polyelectrolytes, i.e. it can be readily specified in the experiments. The range of variation of the composition of the water-soluble N-PEC is determined by the inequality $\bar{P}_{BPE}/\bar{P}_{LPE} < \phi < \phi_{char}$.

In the second version $\bar{P}_{LPE} = 3200$ and $\bar{P}_{BPE} = 3500$ in the same system, i.e. $\bar{P}_{LPE}/\bar{P}_{BPE} \cong 1$. Fig.6*b* presents the corresponding sedimentation diagrams. Evidently the water-soluble N-PEC with the compoistion $\phi = 0.5$, which is the characteristic composition, is sedimented as an individual compound. The sedimentation diagrams show only a single peak whose sedimentation coefficient is significantly higher than the sedimentation coefficients of each of the initial components. A further enrichment of the system in PDMAEMA.HCl (LPE) leads only to its accumulation in the solution in a free state. This is evident from the appearance of a second peak on the sedimentation diagram, which corresponds to free PDMAEMA.HCl. Some decrease of the sedimentation coefficients of the excess polyelectrolyte with increase of its concentration in solution as well as the decrease of the sedimentation coefficient of the N-PEC are due to the increase of the viscosity of the medium. The area of the slowly sedimenting PDMAEMA.HCl peak steadily increases with increased content of this component in the system, i.e. with decrease of Z. Thus, in systems made up of polyelectrolytes having similar degrees of polymerisation, there is a possibility of the formation of only the N-PEC having the characteristic compositions ϕ_{char}. Variation of the overall system composition Z leads in this case to the appearance and accumulation in solution of an excess of the LPE which coexists with the N-PEC having the characteristic composition.

The behaviour, described above, for mixtures of oppositely charged polyelectrolytes having different ratios of degrees of polymerisation, is characteristic of an extremely wide range of polyelectrolyte pairs[43]. Thus one may conclude that, when $\bar{P}_{BPE}/\bar{P}_{LPE} < \phi_{char}$, the range of variation of the composition of the water-soluble N-PEC is determined by the inequality $\bar{P}_{BPE}/\bar{P}_{LPE} < \phi < \phi_{char}$. Evidently the composition of the species of the water-soluble N-PEC varies discretely with the overall mixture composition in the above range of ϕ by the amount $\bar{P}_{BPE}/\bar{P}_{LPE}$ or its multiple. On the other hand, if $1 \geq \bar{P}_{BPE}/\bar{P}_{LPE} > \phi_{char}$, then N-PEC with the characteristic composition only is always formed regardless of the overall mixture composition.

The above data on the methods of preparation of water-soluble N-PEC and the compositions of these macromolecular compounds are necessary for the correct choice of conditions in which their structures and properties can be usefully investigated.

IV. STRUCTURE OF WATER-SOLUBLE NON-STOICHIOMETRIC POLYELECTROLYTE COMPLEXES

In the first place we shall consider data obtained by light scattering[46,47]. We may note that solutions containing a single macromolecular component, namely N-PEC, have always been investigated. As stated above, in order to achieve this, the compositions of the corresponding polyelectrolyte mixture must satisfy the condition $\bar{P}_{BPE}/\bar{P}_{LPE} < Z < \phi_{char}$. The sedimentation diagrams for such mixtures are characterised by the presence of a single peak corresponding to the N-PEC. As a rule, light scattering measurements have been carried out in aqueous salt media (concentration of the low-molecular salt not less than 0.1 M) in order to suppress the polyelectrolyte effect. In order to be able to reduce the analysis of the experimental results to a canonical consideration of two-component polymer–solvent systems, in each series of experiments the activity of the low-molecular-weight salt in solutions of the N-PEC at different concentrations was kept constant. This was achieved by dialysing N-PEC in solution at different experimental concentrations against the same aqueous salt solution. The increment in the refractive index $(\partial n/\partial c)_I$ at an ionic strength I was measured making sure that the same requirements were satisfied[48].

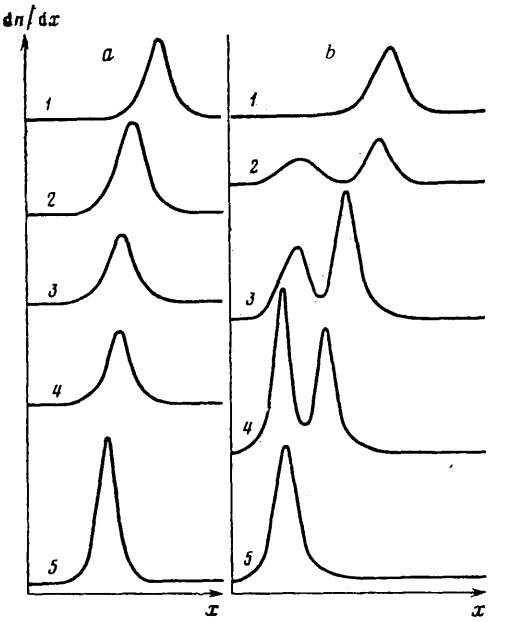


Figure 6. Sedimentation diagrams for mixtures of polyelectrolytes: *a*) PDMAEMA.HCl (LPE, $\bar{P} = 3.2 \times 10^3$) and PA-Na (BPE, $\bar{P} = 1.5 \times 10^2$) with different compositions Z [*1*) 0.5; *2*) 0.33; *3*) 0.2; *4*) 0.13; *5*) 0]; concentration of solutions 0.35 wt.%; time 100 min for a rate of rotation of rotor of 5600 min^{-1}; *b*) PDMAEMA.HCl (LPE, $\bar{P} = 3.2 \times 10^3$) and PA-Na (BPE, $P = 3.5 \times 10^3$) with different compositions Z [*1*) 0.4; *2*) 0.33; *3*) 0.2; *4*) 0.13; *5*) 0]; concentration of solutions 0.28 wt.%; time 70 min for a rate of spinning of 56000 min^{-1}. All the experiments were performed at pH 5.0 in 0.1 M NaCl at 20 °C.[43]

Fig.7 presents typical Zimm diagrams for N-PEC solutions obtained in the PDMAEMA.HCl–PP-Na systems for different ratios of the polyelectrolyte components. Evidently the double extrapolation plots do indeed have the form characteristic of normal polymer solutions. The relations between $(Kc/R_\theta)_\theta$ and c and between $(Kc/R_\theta)_c$ and $\sin^2(\theta/2)$ are

linear, which indicates the absence of polyelectrolyte swelling and dissociation of the N-PEC species into the initial components when the solutions are diluted.

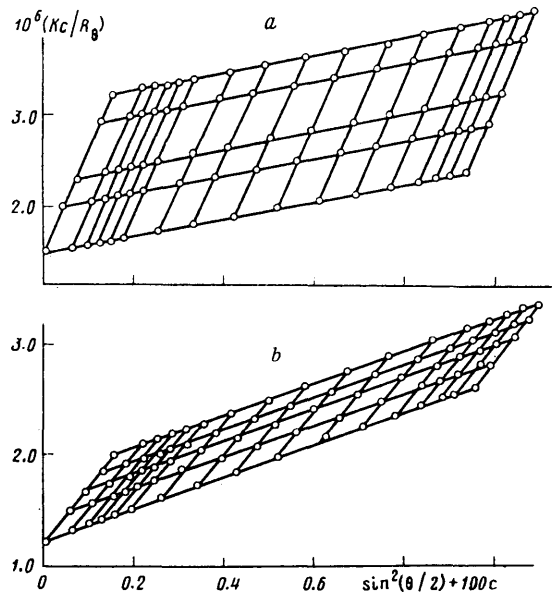

Figure 7. Zimm diagrams for solutions of the PDMAEMA.HCl ($\bar{M}_w = 6.3 \times 10^5$)–PP ($\bar{M}_w = 1.7 \times 10^4$) N-PEC at pH 4.0 in 0.1 M NaCl for different compositions ϕ: *a*) 0.13; *b*) 0.33.[46]

Table 3 presents the weight-average molecular weights $\bar{M}_w$ of a series of N-PEC having a fixed composition ϕ measured by the light scattering method. For comparison, the Table also includes the calculated molecular weights. In the calculation it was assumed that the N-PEC species have homogeneous compositions and that each contains only one LPE macromolecule and that the number of BPE macromolecules corresponds to the composition ϕ. Account was taken also of the fact that the formation of a single salt linkage between the LPE and BPE units is accompanied by the liberation of a pair of small ions present in solutions of the initial component as counterions. The degree of conversion θ relative to the BPE in the reaction involving the formation of the N-PEC was assumed to be unity. Next, assuming that the polyelectrolytes are monodisperse (relatively narrow LPE and BPE fractions were used by Kharenko et al.[46]) and that their true molecular weights are equal to the weight-average values listed in Table 3, we obtained the calculated M_{calc} from the formulae

$$M_{calc} = \bar{P}_{LPE}\bar{M}_{un}, \qquad (2)$$

where $\bar{M}_{un}$ is the average molecular weight of a unit of the N-PEC species, and

$$\bar{M}_{un} = \bar{M}_{(LPE)} + \varphi(M_{(BPE)} - M), \qquad (3)$$

where M is the molecular weight of the low-molecular-weight salt liberated on dissolution as a result of reaction (I). Table 3 shows that the measured values of $\bar{M}_w$ agree satisfactorily with those calculated by Eqns.(2) and (3), which convincingly demonstrate that the composition of each species of the N-PEC investigated does indeed incorporate in this instance a single LPE macromolecule and the corresponding number of BPE macromolecules ($\bar{n}_{BPE}$):

$$\bar{n}_{BPE} = \varphi(\bar{P}_{LPE}/\bar{P}_{BPE}). \qquad (4)$$

It will be shown below that the maintenance of specific conditions is necessary for the formation of such unassociated N-PEC. The results presented in Table 3 again confirm the conclusion that the N-PEC can be regarded as individual macromolecular compounds characterised by their specific molecular weights. It is seen from a comparison of the radii of inertia $(\bar{R}_g^2)^{1/2}$ for the N-PEC and the LPE that the dimensions of the N-PEC species are appreciably smaller than those of the charged chains of the corresponding LPE.

Table 3. Characteristics of the individual polyelectrolytes and the N-PEC formed from them and having the composition $\phi = 0.33$.[46]

(N-PEC)	$10^{-5}\bar{M}_w$ (LPE)	$10^{-5}\bar{M}_w$ (BPE)	pH	I, M	$10^{-5}\bar{M}_w$ N-PEC expt.	$10^{-5}\bar{M}_w$ N-PEC calc.	$(\bar{R}_g^2)^{1/2}$, Å	$10^4 A_2$

Remarks: The values in brackets refer to the LPE in the LPE–BPE systems.

It is also seen that the formation of the N-PEC is accompanied by a decrease of the second virial coefficient of the solution A_2. The causes of these changes will be examined below. Here we shall only note that the relative changes in the above parameters on formation of the N-PEC are not the same for different pairs of polyelectrolytes even if the polyelectrolyte complexes have the same composition expressed in terms of ϕ. It may be that this is associated with the characteristics of the structures of the initial polyelectrolyte, in particular, with the disposition of the ionogenic groups relative to the main chain and also with the ratio of the hydrophilic and hydrophobic groups in the units of the interacting polyelectrolyte components. The degree of the mutual steric correspondence of the polyions forming the N-PEC can apparently also play a definite role. These questions have not as yet been adequately investigated.

We shall now consider how the macromolecular parameters of the N-PEC in aqueous solution behave as a function of ϕ. Table 4 presents the results of a light-scattering study of N-PEC solutions obtained in the PDMAEMA.HCl—PP-Na system. Evidently, when the composition of the polyelectrolyte complexes ϕ is varied within a fairly wide range (from 0.5 to 0.067), their weight-average molecular weight hardly changes and is identical, within the limits of the error of the measurements, with the values calculated from Eqns.(2) and (3). Over the entire range of compositions, each PEC species contains a single LPE chain. The average number of BPE chains in each species, calculated from Eqn.(4), decreases from 10 to 1. Thus each N-PEC species, under conditions where it contains only one LPE chain, can be reasonably regarded as a kind of individual complex macromolecule whose composition with respect to the polyelectrolyte components can be readily varied within certain limits having specified their initial ratio Z. Clearly the constancy of the experimental molecular weights and the

slight variation of the calculated molecular weights, under the conditions of a 10-fold decrease of the population of the LPE chains by BPE chains is due to the compensation effect caused by the liberation of counterions into the solution as a result of the formation of the PEC.

Table 4. The influence of the composition of the N-PEC in the PDMAEMA.HCl ($\bar{M}_w$ = 6.3 × 10^{-5})–PP-Na ($\bar{M}_w$ = 1.7 × 10^{-4}) system on its molecular characteristics (pH 4.0 in 0.1 M NaCl at 20 °C).[46]

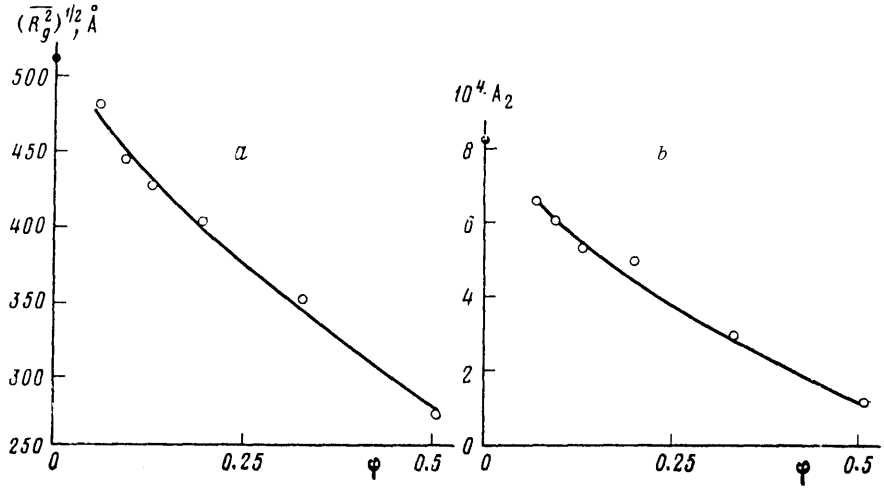
0.50	0.156	7.0	7.0	10	270	1.1	5.9

Notation: $\bar{n}_{BPE}$ = average number of macromolecules in the N-PEC species ($\bar{n}_{LPE}$ = 1); S = sedimentation coefficient (in Svedberg units) determined for [N-PEC] = [PDMAEMA.HCl] = 0.35 wt.%.

The mean square radius of inertia $(\overline{R_g^2})^{1/2}$ of the N-PEC is more sensitive to changes in composition than the molecular weight. In particular, $(\overline{R_g^2})^{1/2}$ of a complex macromolecule having the composition ϕ = 0.5 is almost a factor of two smaller than the $(\overline{R_g^2})^{1/2}$ of the macromolecule of the free LPE (Table 4). The dependence of $(\overline{R_g^2})^{1/2}$ of the N-PEC macromolecules on ϕ, based on the data in Table 4, is illustrated in Fig.8*a*. Evidently their average size decreases monotonically with decrease of the population of the LPE chains by the BPE chains, approaching the average size of the statistical coil of the free LPE in the same solvent. The results on the measurement of the radius of inertia of the N-PEC macromolecule as a function of composition are important for the justification of the general scheme for the structure of the N-PEC species assuming the existence of sufficiently long two-stranded ladder sections. This scheme was assumed above *a priori* on the basis of indirect data concerning the structure of the S-PEC in the solid phase already mentioned. It can now be shown that the adopted fundamental motif of the ladder-like relative distribution of the chains constituting the PEC has in fact no alternative.

Indeed Table 4 shows that the values of $(\overline{R_g^2})^{1/2}$ for the N-PEC macromolecules with composition ϕ = 0.067 and for the statistical coil of the free LPE differ by only 5–6%. At the same time, on average each 15th unit of the LPE chain of the N-PEC species having the composition ϕ = 0.067 is involved in the formation of a salt linkage with a unit of the BPE chain: for $\theta \cong 1$, each LPE chain with a length equivalent to ~3000 units is linked to a BPE chain with a length equivalent to ~170 units. If it is assumed that the two chains are randomly intertwined, then, on passing from the free LPE to the N-PEC, one would have to expect a much greater relative decrease of the radius of inertia, which follows, for example, from calculations by the Monte Carlo method of the change in the average dimensions of a model chain on random formation of irreversible intramolecular cross-links[49]. In particular, it has been shown that, even for a Gaussian chain comprising 100 segments and existing under θ-conditions, the relative decrease of the radius of inertia accompanying the formation of on average five fixed cross-links should be ~35%. Naturally, in the case of the N-PEC one is dealing with the formation of reversible salt linkages within its species. However, if the statistical weight of the randomly formed cross-links in the N-PEC structure had been considerable, the experimentally observed relative change in the average dimensions of the macromolecular coil on passing from the free LPE to the N-PEC would have been significantly greater.

Consequently, in the water-soluble N-PEC form the contour line of the fragment of the LPE chain is close to the contour line of the BPE chain interacting with it. In other



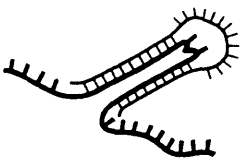


Figure 8. Dependence of the particle size $(\overline{R_g^2})^{1/2}$ (*a*) and of the second virial coefficient A_2 (*b*) for solutions of the PDMAEMA.HCl–PP N-PEC on the composition of the N-PEC (ϕ); for conditions, see caption to Fig.7.[46]

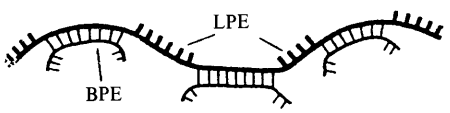
words, a structure in which both interacting chains are in the main distributed parallel to one another in all probability predominates in the N-PEC. At the same time, in the course of thermal movement, the BPE chains can in general migrate from one LPE section to another and different N-PEC macromolecules in solution can even exchange their constituent polyelectrolyte components†.

The two-stranded sections of the PEC species do not necessarily have the form of extended rods. On the other hand, by virtue of their increased hydrophobic properties, they should tend to fold at the sites of the "intraladder" loop-shaped defects already mentioned, forming drop-like clusters, as shown in Scheme *E*.

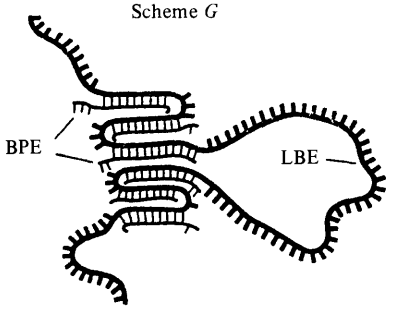


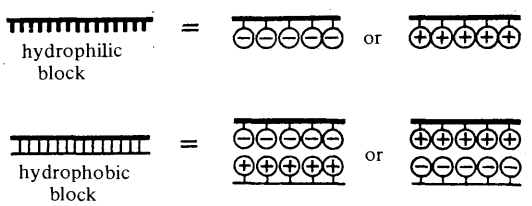
Scheme *E*

The conformation of the complex macromolecule of the water-soluble N-PEC illustrated in this Scheme appears probable also from general thermodynamic considerations. Conformations of this type for fixed values of ϕ and θ apparently correspond to the minimum free energy (maximum entropy), since they contain long sections of free LPE. By virtue of the reversibility of the formation reaction of the N-PEC, the system can "find" the optimum set of conformations by the method of "trial and error".

With increase of ϕ, i.e. with increase of the number of BPE chains incorporated in the N-PEC molecule, the number of two-stranded ladder sections in this molecule naturally also increases, as shown in Scheme *F*.

Scheme *F*





Each section of this kind constitutes a set of cooperatively interacting oppositely charged chain units. It exhibits an enhanced rigidity and relatively weak hydrophilic properties (i.e. relatively pronounced hydrophobic properties). This is why the N-PEC "overloaded" with the BPE for $\phi > \phi_{char}$ lose their solubility in water. The S-PEC are insoluble in water for the same reason. On the other hand, the BPE-free LPE sections in the N-PEC macromolecule are relatively flexible and hydrophilic. Consequently the N-PEC molecule can be regarded as a linear sequence of fairly long hydrophobic and hydrophilic blocks. In other words, the N-PEC constitutes a kind of block-copolymer. The hydrophilic blocks are carriers of properties typical for the usual linear polyelectrolytes. Water behaves as a good solvent in relation to one-stranded polyelectrolyte sequences and as a poor solvent in relation to two-stranded hydrophobic sequences. Consequently the hydrophobic blocks of the N-PEC macromolecules in an aqueous solution should collect together, i.e. should become segregated as a result of non-polar interactions.

†The question of the intramolecular and intermolecular dynamics of the PEC is of considerable interest and merits special study. Some primary information about this problem can be found in Kabanov's paper[21].

In fairly dilute solutions such segregation is intramolecular, which happens, in particular, in the systems presented in Table 4. The progressive decrease of the average dimensions, i.e. of the quantity $(\overline{R}_g^2)^{1/2}$, for complex N-PEC macromolecules as they become enriched in the BPE chains can serve as a quantitative measure of the intramolecular segregation. Scheme *G*, below, illustrates the intramolecular segregation of the hydrophobic blocks in water-soluble N-PEC,

Scheme *G*

A change in the composition of complex N-PEC macromolecules is also accompanied by a change in the thermodynamic characteristics of their solutions. It follows from Table 4 that the second virial coefficient of the solution A_2 increases with decrease of ϕ, i.e. with decrease of the fraction of LPE units incorporated in the hydrophobic blocks. With decrease of ϕ, the quantity A_2 tends to the value characteristic of the solution of the free LPE (Fig. 8*b*). The latter shows that the electrostatic repulsion between LPE units having like charges and forming one-stranded hydrophilic blocks makes the main contribution to the formation of the excluded volume in complex N-PEC macromolecules. According to the Donnan–Guggenheim theory[50], the contribution of the electrostatic repulsion of the polyion units to the overall second virial coefficient can be expressed as follows:

$$A_{2el} = 10^3 z^2/4M^2 I \ , \qquad (5)$$

where z is the effective charge of the polyion, M its molecular weight, and I the concentration of the low-molecular-weight (1:1) electrolyte. An important property of the parameter $A_{2,el}$ of an ordinary polyelectrolyte is its proportionality to the square of the degree of ionisation of the corresponding polyion. Evidently, for the N-PEC considered, this parameter can be varied within wide limits by altering the composition of the complex macromolecule ϕ. The effective charge on the N-PEC macromolecules in the pH range corresponding to the complete ionisation of the LPE units depends on the composition ϕ in the following manner:

$$z/M = \gamma(1-\varphi)/M_0 \ , \qquad (6)$$

where M_0 is the mass of the unit of the polyion and γ the degree of binding of the low-molecular-weight counterions. Thus the parameter $A_{2,el}$ should be proportional to the quantity $(1-\phi)^2$ for a solution of N-PEC block macromolecules, in which the hydrophobic ladder blocks are combined into a system of compact intramolecular clusters and the

charged hydrophilic blocks are on the periphery of the species and are responsible for the solubility of the N-PEC. The dependence of A_2 on $(1 - \phi)^2$ is plotted in Fig.9 on the basis of the data in Table 4. It is evidently linear. The parameter A_2 tends to the value for the solution of the free LPE as ϕ diminishes. For $\phi \to \phi_{char} = 0.56$, the quantity A_2 tends to zero. The data presented convincingly confirm the applicability of Scheme *G* to the description of the behaviour of water-soluble N-PEC.

Notation: see Table 4.

The dependence of the sedimentation coefficient S on the composition of the N-PEC macromolecule for a fixed concentration of the solutions is also in good agreement with the ideas developed above (Table 4). The coefficient S steadily decreases with decrease of ϕ, approaching the value of S for the solution of free LPE. It is evident that, since the molecular weight of the N-PEC depends little on its composition ϕ, the main factor determining the behaviour of S is the average size of the sedimenting particles, which increases with decrease of ϕ as a consequence of the increased degree of swelling of the particles caused by the mutual electrostatic repulsion of the excess positively charged LPE units in the complex macromolecules.

Scheme *G*, describing the structure of the water-soluble N-PEC, is fairly general. It is apparently valid for a wide range of N-PEC with different chemical compositions, provided that they are products of completed interpolymer reactions, i.e. for $\theta \cong 1$. Tables 5 and 6 present the characteristics of two other varieties of the water-soluble N-PEC measured by the light-scattering and high-speed sedimentation methods. The dependences of $(\bar{R}_g^2)^{1/2}$, A_2, and S on ϕ obtained are also fully consistent with the ideas described above.

Table 6. The influence of the composition of water-soluble N-PEC formed from PP-Na ($\bar{M}_w = 6.6 \times 10^4$) and 5,6-ionene bromide ($M_w = 1.4 \times 10^4$) on their molecular characteristics (pH 7.0 in 0.025 M NaBr at 20 °C).[46]

Notation; see Table 4.

The next important problem is that of the influence of the molecular weights of the LPE and the BPE on the macromolecular characteristics of the water-soluble N-PEC. Table 7 presents the values of $\bar{M}_w$, $(\bar{R}_g^2)^{1/2}$, and A_2 measured by the light-scattering method for the PDMAEMA.HCl–PP-Na N-PEC having the constant composition $\phi = 0.33$. The condition $\bar{P}_{LPE}/\bar{P}_{BPE} \gg 1$ holds for the entire series of systems. The systems differ from one another only by the molecular weights of the initial polyelectrolyte components. Table 7 shows that, when the ratio $\bar{P}_{LPE}/\bar{P}_{BPE}$ is varied within wide limits (from 5 to 20) by varying the values of both $\bar{P}_{LPE}$ and $\bar{P}_{BPE}$, only one LPE macromolecule is incorporated in the N-PEC species. In other words, in this case too the N-PEC species can be regarded as individual complex macromolecules in the dilute solution at fixed concentrations of the components and ionic strengths over the entire experimental range of molecular weights.

Table 7. The influence of the molecular weights of the LPE and the BPE on the molecular characteristics of the PDMAEMA.HCl–PP-Na N-PEC ($\phi = 0.33$; pH 4.0 in 0.1 M NaCl at 20 °C).[46]

$10^{-5}\bar{M}_w$ (PDMAEMA.HCl)	$10^{-4}\bar{M}_w$ (PP-Na)	$\bar{P}_1/\bar{P}_2$	$10^{-5}\bar{M}_w$ (N-PEC)	$\bar{n}$	$(\bar{R}_g^2)^{1/2}$, Å	$10^4 \cdot A_2$
1.64	1.7	5.1	1.9	1.7	—	2.9

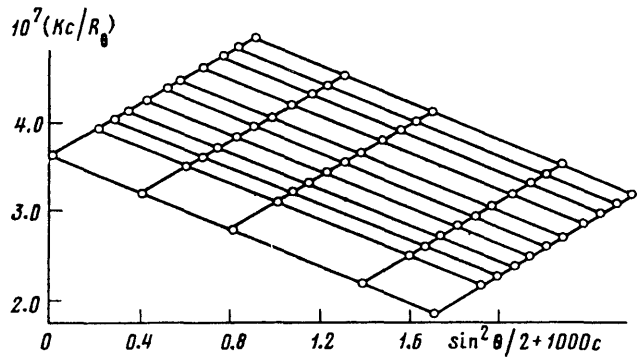
6.3	5.7	5.8	7.3	1.9	380	2.7
6.3	6.6	5.0	7.2	1.5	370	2.8

Notation: $\bar{n}$ is the average number of macromolecules in the N-PEC species; the values for PP are indicated, those for PDMAEMA.HCl being unity.

It is significant that the average dimensions of the N-PEC macromolecules and the second virial coefficients of their solutions with the specified values of $\bar{P}_{LPE}$ and ϕ are almost independent of $\bar{P}_{BPE}$. This agrees with ideas concerning

the structure of the complex macromolecules summarised in Scheme *G*. The segregation of the hydrophobic block in these macromolecules is again intramolecular. However, in other cases the change in the hydrophilic–hydrophobic balance in the N-PEC macromolecules with increase of ϕ and hence of the number of hydrophobic blocks can naturally lead also to their intermolecular segregation, i.e. to the formation of N-PEC species containing more than one LPE chain. Such species must be regarded as associated and consisting of individual N-PEC macromolecules.

At the beginning of this Section (Table 4) it was shown, in particular, that solutions of the N-PEC obtained from PDMAEMA.HCl and PP-Na with the composition $\phi \leqslant 0.5$ contain individual complex PEC macromolecules under the chosen conditions. However, when a comparatively small additional amount of the BPE, which is insufficient to cause phase separation in the system, is added to such a solution, the situation changes sharply. This is expressed primarily by a change in the Zimm diagram which assumes a form characteristic of solutions containing associated macromolecules (Fig.10). The double extrapolation plot shows that such associated species are entirely stable on dilution. The N-PEC species with the composition $\phi = 0.56$ has $\bar{M}_w = 2.8 \times 10^6$ according to light scattering data, which exceeds by a factor of four the $\bar{M}_w$ for the individual complex macromolecule with the composition $\phi = 0.5$. Consequently each such N-PEC species actually consists on average of four N-PEC macromolecules with the same composition ϕ.



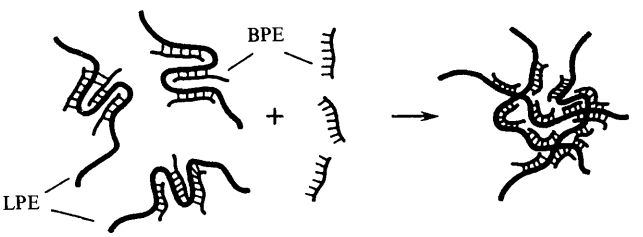


Figure 10. Zimm diagram for a solution of the PDMAEMA. .HCl–PP N-PEC having the composition $\phi = 0.56$ at pH 4.0 in 0.01 M NaCl at 20 °C; for the values of $\bar{M}_w$, see Fig.7.[52]

The association phenomena can be represented by Scheme *H*.

Scheme *H*

The formation of the associated species is accompanied by a sharp decrease of the second virial coefficient A_2 and its becoming negative ($A_2 = -4.5 \times 10^{-5}$). The species comprising associated N-PEC macromolecules with $\phi = 0.56$ is extremely compact and its average size $[(\bar{R}_g^2)^{1/2} = 270$ Å] is virtually identical with the average size of the N-PEC macromolecule of similar composition ($\phi = 0.5$). The behaviour described is characteristic of soluble N-PEC, which do not exhibit a great tendency towards association and give rise to associated species only in the vicinity of characteristic compositions defining their solubility limit. The association phenomena in solutions of such N-PEC resemble the pre-critical phenomena in solutions of ordinary high-molecular-weight compounds, which occur within narrow ranges of conditions near the phase separation points[51].

However, there exists an extensive group of soluble N-PEC which tend to form associated species over an extremely wide range of compositions[52]. In particular, such N-PEC include polyelectrolyte complexes formed by PA-Na and ionenes, for example, by PA-Na and 5,6-ionene bromide. Table 8 presents the characteristics of these N-PEC with the constant composition $\phi = 0.33$, which are formed by PA-Na fractions of different molecular weights. Knowing the molecular weights of the initial polyelectrolyte components and the N-PEC species, the average number of the LPE and BPE chains incorporated in the N-PEC species can be calculated with the aid of the procedures described above. Table 8 shows that, regardless of the molecular weight of the LPE, which was varied by more than an order of magnitude, the N-PEC associated species, formed under the experimental conditions, each incorporate three PA-Na macromolecules. The number of 5,6-ionene macromolecules per associated species corresponds to the composition $\phi = 0.33$ and increases in proportion to the molecular weight of the LPE. The second virial coefficient of the solution then remains virtually constant, while the size of the N-PEC species increases with increase of their mass. This shows that the structure of the species of the polyelectrolyte complex does not undergo qualitative changes with increased length of the LPE chains. Thus each N-PEC species in the systems described can be formally regarded as an associated species formed by three individual complex N-PEC macromolecules. The structure of such an associated species is represented on the right-hand side of Scheme *H*.

Table 8. The influence of the molecular weight of PA-Na (LPE) on the molecular characteristics of the PA-Na–5,6-ionene ($\bar{M}_w = 1.4 \times 10^4$) N-PEC ($\phi = 0.33$; pH 7.2 in 0.025 M NaBr at 20 °C; $n_{LPE} = 3$ [52]).

$10^{-4}\,\bar{M}_w$ (PA-Na)	$10^{-4}\,\bar{M}_w$ (N-PEC)	$\bar{n}$BPE	$(\bar{R}_g^2)^{1/2}$, Å	$10^3 \cdot A_2$

12	38	18.1	300	1.9
18	69	27.2	400	1.9
41	150	61.7	750	1.9

The phenomena involving the association of complex macromolecules in N-PEC solutions are analogous to the micelle-formation processes in solutions of the usual block-copolymers in selective solvents. The degree of association of the N-PEC for the specified composition ϕ is little sensitive to changes in the molecular weight of the LPE. It is determined primarily by the ratio of the numbers of the LPE units incorporated in the hydrophilic and hydrophobic blocks, i.e. by the composition of the N-PEC. It is known

that the degree of association of the macromolecules of the usual block-copolymer in solutions also depends little on their molecular weights. It is largely determined by the ratio of the lyophobic and lyophilic blocks[53]. The change in the composition of the N-PEC is accompanied in exactly the same manner by a change in the degree of association of their species. This follows from Table 9. It is seen that an increase in the relative content of the LPE units in the N-PEC species, i.e. a decrease of ϕ, leads to a gradual decomposition of the associated species into the individual complex macromolecules.

Table 9. The influence of the composition of the N-PEC on its molecular characteristics[52].

0.2	2.9	1	1	4.1
0.33	4.8	2	3.4	1.8

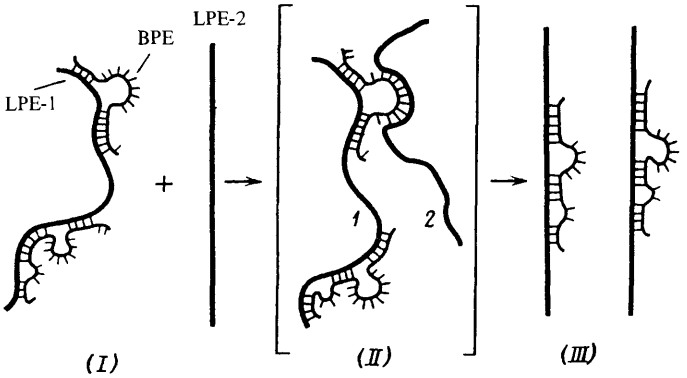
The N-PEC formed by high-molecular-weight sodium polymethacrylate (LPE) and PVP-C_2H_5Br (BPE) also exhibit a high tendency towards association[52]; the characteristics of their behaviour are analogous to those considered above.

As shown above, the processes involving the formation and decomposition of the N-PEC associated species can be controlled by altering the composition of the N-PEC. The degree of ionisation of the LPE units incorporated in one-stranded hydrophilic blocks exerts a significant influence on these processes. If the LPE is a weak polyelectrolyte, a decrease in the degree of ionisation is accompanied by a decrease in its lyophilising capacity and leads to a progressive association of the N-PEC macromolecules up to their precipitation from the solution. This is why the N-PEC in which a polycarboxylic acid plays the role of the LPE and which have nearly the characteristic composition are soluble only in alkaline media at pH > 7. Correspondingly the N-PEC incorporating weak polymeric bases as the LPE acquire a capacity for dissolution only in acid media at pH < 7. The degree of association depends also on the degree of binding of the counterions to the free sections of the LPE. Table 10 presents the characteristics, in the presence of 0.025 M NaCl and KCl, of the N-PEC formed from PA-Na and 5,6-ionene bromide ($\phi = 0.33$). Evidently the replacement of the Na^+ counterions by the K^+ counterions, which are less strongly bound to the carboxylate groups of the LPE, entails the decomposition of the N-PEC associated species.

The capacity for association is also determined by the chemical structure of the LPE and BPE constituting the N-PEC. This question has been hardly discussed in the literature partly owing to the insufficiency of rigorous experimental data. Nevertheless, the pairs of polyelectrolytes forming the N-PEC can apparently be divided into two large groups. The subdivision can be based on a comparison of the distances between the neighbouring ionogenic groups in the LPE and BPE chains.

The first group includes pairs for which the neighbouring ionogenic groups in the LPE are separated by larger distances than in the BPE, for example, PDMAEMA.HCl–PA-Na and PDMAEMA.HCl–PP-Na. The amino-groups in PDMAEMA.HCl are far from the main chain and hence from one another. In the PA and PP chains the negatively charged units are closer to one another. Presumably in the corresponding PEC the BPE chain "spreads" over the LPE chains, occupying the section of the latter containing a relatively smaller number of units than in the BPE. Some of the BPE units are then not included in the system of intermolecular salt linkages, i.e. they are, as it were, overlooked. The effective fraction of the units incorporated in the hydrophilic blocks can then prove to be greater than the values calculated on the basis of stoichiometry. In fact, in the case under consideration the hydrophobic blocks should include a smaller number of the LPE units than the BPE units. The reduced tendency of the complex macromolecules towards association for compositions differing from the characteristic compositions ($\phi < \phi_{char}$) may be a consequence of this. Another consequence is the relatively high values of ϕ_{char}, for example, for the N-PEC formed from PDMAEMA.HCl and PA-Na ($\phi_{char} > 0.5$, Table 5).

Table 10. The influence of the nature of the LPE counterion on the molecular characteristics of the PA-Na ($\bar{M}_w = 1.2 \times 10^5$)–5,6-ionene ($\bar{M}_w = 1.4 \times 10^4$) N-PEC ($\phi = 0.33$; pH 8.0; salt concentration 0.025 M; 20 °C).[52]



Salt	$10^{-5}\bar{M}_w$ (N-PEC)	$\bar{n}$LPE	$\bar{n}$BPE
NaCl	4.00	3	18.2
KCl	2.25	2	12.1

The second group of the N-PEC includes those for which the opposite condition holds, i.e. the distances between the neighbouring ionogenic groups in the LPE are smaller than in the BPE. Evidently such systems include particularly those which are symmetrical in relation to the systems examined above in which the LPE and BPE have changed places. Table 9 shows that the corresponding N-PEC have smaller values of ϕ_{char}. Presumably the number of units in the LPE section occupied by the BPE chain is greater than $\bar{P}_{BPE}$. The effective fraction of the LPE units incorporated in the hydrophilic blocks then falls, which actually implies a decreased lyophilising capacity of the LPE. A typical example of such a system is the PA-Na–5,6-ionene N-PEC examined in detail previously. The distance between the neighbouring quaternary nitrogen atoms in the BPE chain is much greater than the distance between the neighbouring COO^- groups in the LPE. Accordingly, the complex macromolecules formed by the above pair exhibit an enhanced tendency towards association.

In concluding this Section, we shall consider in broad outline the mechanism of the decomposition of the N-PEC associated species induced by a change in their composition. If the free LPE is added to solutions of the associated N-PEC, a gradual decomposition of the associated species is observed. For a certain ratio of the LPE and the BPE characteristic of each pair of the initial polyelectrolytes, the associated species decompose to the individual N-PEC complex macromolecules. This is illustrated by the data in Table 9.

The decomposition of the N-PEC associated species is accompanied by a redistribution of the BPE chains among a large number of the LPE chains. This leads ultimately to the formation of individual N-PEC species containing one LPE chain. However, their composition is significantly different from that of the initial associated species. The process described naturally presupposes the transfer of the BPE chains from one set of LPE chains to another. It is of interest that such transfer takes place in solutions from which free BPE macromolecules are absent. This is indicated by both light-scattering data and high-speed sedimentation data. Consequently the transfer of BPE takes place via the formation of intermediate macromolecular compounds, which then decompose to form the final products. The transfer can be represented by Scheme *I*.[21]

Scheme *I*

The intermediate polyelectrolyte complex (II) is formed via the addition of units of the free chain 2 to the section of the BPE chain incorporated in a defect of the N-PEC. The compound formed is unstable, since it possesses an increased electrostatic free energy. It therefore decomposes into two new N-PEC species having a different composition. This mechanism of the exchange of the BPE chains by the N-PEC species containing them is apparently fairly general for a wide variety of processes occurring with participation of polyelectrolyte complexes[54].

We emphasise yet again that the soluble N-PEC are macromolecular compounds formed as a result of reversible interpolymer reactions. This is why the reversible nature of the interaction of the macromolecules forming the N-PEC species presupposes the possibility of the interchange of the hydrophilic and hydrophobic blocks within such species and also between different species.

V. THE INFLUENCE OF LOW-MOLECULAR-WEIGHT SALTS ON THE BEHAVIOUR OF POLYELECTROLYTE COMPLEXES IN AQUEOUS SOLUTIONS

Certain properties of aqueous N-PEC solutions were briefly considered in the preceding two sections, mainly in connection with the factors altering the lyophilising capacity of the LPE. In particular, it was found that a decrease in the effective charge on the hydrophobic N-PEC blocks, which can be achieved by altering the pH of the solution or the nature of the LPE counterions, is accompanied by a change in the degree of association of the N-PEC species and ultimately by the loss of the solubility of the N-PEC. Situations were described where the precipitation of the PEC is not accompanied by a change in its composition.

However, the behaviour of the N-PEC in aqueous solutions of low-molecular-weight salts is of greatest interest. In the investigations summarised above mainly uni-univalent electrolytes—alkali metal halides and quaternary ammonium salts—were used[55]. Fig.11 presents as an example the curve for the turbidimetric titration of a solution of the PMA-Na–PVP.C_2H_5Br N-PEC having $\phi = 0.33$ with an NaBr solution. It is possible to distinguish three ranges of variation of the ionic strength of the solution to which regions I, II, and III in Fig.11 correspond.

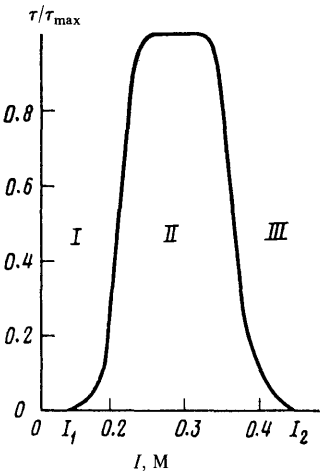


Figure 11. Curves for the turbidimetric titration of a solution of the PMA-Na ($\bar{M}_w = 2.6 \times 10^5$)–PVP.$C_2H_5Br$ ($\bar{M}_w = 6 \times 10^4$) N-PEC having the composition $\phi = 0.33$ with NaBr solution; at pH 7.5 and 20 °C.[55]

In region I an increase in the salt concentration in solution is not accompanied by a change in the phase state of the system—the latter remains homogeneous. After the attainment of a certain ionic strength I_1, the system begins to turn turbid and a further increase of the ionic strength is accompanied by a progressive increase of turbidity. In region II the system is of the heterophase type. A fairly broad range of variation of the salt concentration corresponds to this region. The right-hand boundary of region II is characterised by a decrease of turbidity. Finally, at an ionic strength of the solution $I = I_2$, the system again becomes homogeneous. Region III corresponds to ionic strengths $I > I_2$; here the system remains homogeneous.

The behaviour described is characteristic of all the N-PEC investigated at the present time. It can be illustrated in relation to examples of associated N-PEC, in particular PA-Na–5,6-ionene and PA-Na–PDMAEMA as well as non-associated N-PEC such as PDMAEMA.HCl–PP and PDMAEMA.HCl–PAA. However, one should note that the positions of the boundaries between regions I, II, and III, i.e. the values of I_1 and I_2, depend markedly on the nature of the polyelectrolytes forming the N-PEC and also on the nature of the low-molecular-weight salts inducing the transformations considered.

We shall follow in succession the changes in the state of the PEC in the above three regions corresponding to the variation of the ionic strength of the solution. For this purpose, we shall return to the PMA-Na–PVP.C_2H_5Br system. Fig.12

presents the results of the study by the light-scattering method of the corresponding aqueous salt solutions in region I (cf.Fig.11). It is seen that an increase in the ionic strength of the solution (an increase of the NaBr concentration) is not accompanied by a change in the molecular weights of the N-PEC associated species (curve *1*). In the range of ionic strengths indicated each associated species retains the composition $\phi = 0.33$ and each contains on average three LPE (PMA-Na) chains. The sedimentation diagrams for the solutions contain a single peak (see Fig.16 below). Thus, for $I < I_1$, the N-PEC investigated behaves like an individual macromolecular compound. On the other hand, an increase in the ionic strength of the solution in region I leads to a considerable decrease in $(\overline{R}_g^2)^{1/2}$, i.e. to a decreased average particle size (curve *2*). The second virial coefficient then also decreases and, as the boundary between regions I and II, i.e. the point $I = I_1$, is approached, it tends to zero, which indicates an impairment of the thermodynamic properties of the solvent.

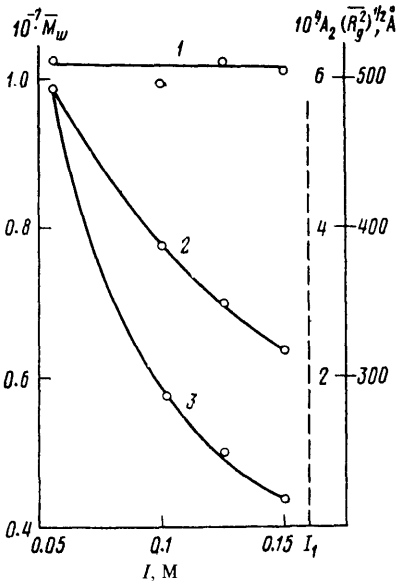

Figure 12. Molecular characteristics of the PMA-Na–PVP.C_2H_5Br N-PEC having the composition $\phi = 0.33$ as a function of the NaBr concentration in solution: *1*) $\overline{M}_w$ (N-PEC); *2*) $(\overline{R}_g^2)^{1/2}$; *3*) A_2; for conditions, see caption to Fig.11.[55].

Solutions of the unassociated N-PEC, an example of which may be provided by the PDMAEMA.HCl–PAA and PDMAEMA.HCl–PP systems, also behave analogously in region I. Such behaviour is typical for solutions of the usual flexible-chain polyelectrolytes. It is a consequence of the shielding of sections of the macromolecule by the counterions and of the decrease of the electrostatic repulsion between the LPE units with like charges incorporated in one-stranded hydrophilic blocks. The dependence of the second virial coefficients A_2 of solutions of different N-PEC on the reciprocal of the ionic strength is linear (Fig.13), which is also typical for the usual linear polyelectrolytes [see Eqn.(5)]. Thus the behaviour of the N-PEC in aqueous solutions containing comparatively low concentrations of low-molecular-weight salts is determined mainly by the properties of the charged one-stranded LPE blocks.

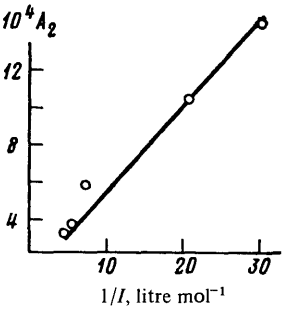

Figure 13. Dependence of the second virial coefficient A_2 for the PDMAEMA.HCl ($\overline{M}_w = 6.3 \times 10^5$)–PP ($\overline{M}_w = 1.7 \times 10^4$) N-PEC solution having the composition $\phi = 0.33$ on the reciprocal of the ionic strength of the solution $1/I$ (NaCl, pH 4.0 at 20 °C).[47]

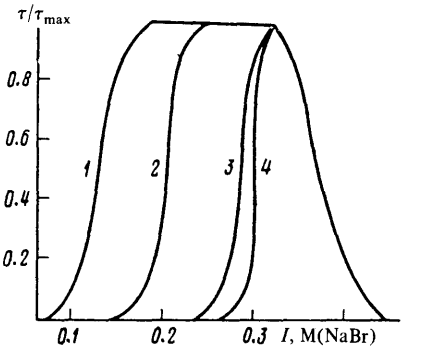

Figure 14. Curves for the turbidimetric titration of solutions of the PMA-Na ($\overline{M}_w = 2.6 \times 10^5$)–PVP.$C_2H_5Br$ ($\overline{M}_w = 6 \times 10^4$) N-PEC having different compositions ϕ [*1*) 0.4; *2*) 0.33; *3*) 0.25; *4*) 0.2] with an NaBr solution at pH 7.5 and 20 °C.[55]

The position of the boundary between regions I and II, i.e. the value of I_1, depends greatly on the composition ϕ of the N-PEC. This is shown in Fig.14 in relation to the PMA-Na–PVP.C_2H_5Br N-PEC. Evidently, with increase of the BPE content in the polyelectrolyte complex species. i.e. with decrease of the fraction of the free LPE units, the boundary between regions I and II shifts towards lower ionic strengths of the solutions. This is also true of the PDMAEMA.HCl–PP and PA-Na–5,6-ionene systems. However, for fairly low values of ϕ, the majority of the N-PEC investigated remain soluble over the entire range of ionic strengths (for $\phi < 0.15$). This result is natural, since a decrease of ϕ implies an increase of the relative content of the hydrophilic blocks made up of ionised LPE units. The ionic strength I_1 also depends on the chemical nature of the low-molecular-weight salt, more precisely on the nature of the LPE counterions.

Fig. 15 presents curves for the turbidimetric titration of the PA-Na–5,6-ionene N-PEC having a fixed composition by various salts. In the series of selected counterions, the ionic strength I_1 varies as follows: $Li^+ < Na^+ < K^+ < TMA^+$ (TMA^+ is the tetramethylammonium ion), i.e. increases with decrease in the constant for the binding of the counterions to the polymeric carboxylic acids[56]. At the same time, I_1 is independent of the nature of the low-molecular-weight LPE ion, whose charge has the same sign as that of the ionised LPE units. Evidently curves *2'*, *2''*, and *2'''*, which refer to cases where an increase of the ionic strength is attained by the addition of the corresponding sodium fluoride, chloride, and bromide, coincide. All the facts presented show that in region I the behaviour of the N-PEC is indeed mainly determined by the properties of the free LPE units. The position of the boundary between regions I and II depends strongly, other conditions being equal, on the chemical nature of the LPE and BPE constituting the complex[5]. However, the available experimental data are as yet insufficient to trace any consistent relations.

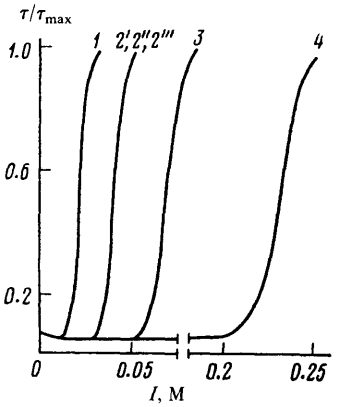

Figure 15. Curve for the turbidimetric titration of solutions of the PA-Na ($\bar{M}_w = 1.8 \times 10^5$)–5,6-ionene ($\bar{M}_w = 1.4 \times 10^4$) N-PEC having the composition $\phi = 0.33$ with solutions of LiCl (curve *1*), NaX [X: *2'*) F^-; *2''*) Cl^-; *2'''*) Br^-], KCl (curve *3*), and $(CH_3)_4NCl$ (curve *4*). Concentration of the N-PEC solution 0.01 wt.% at pH 8.5 and 20 °C.[55]

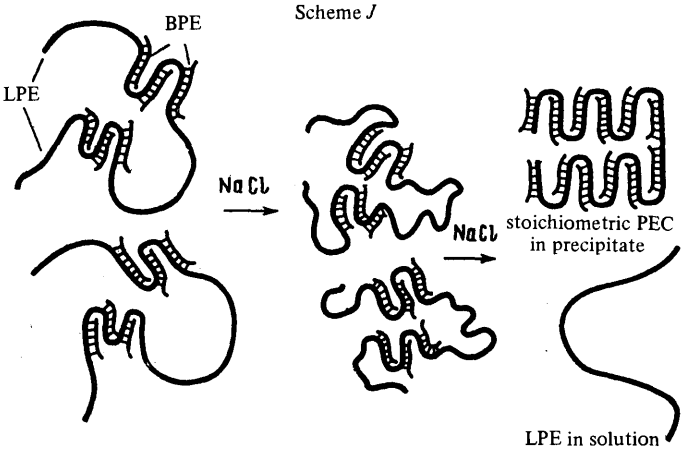
In region II ($I_1 < I < I_2$) the systems investigated are of the heterophase type for not unduly low values of ϕ. The soluble N-PEC must therefore be synthesised at ionic strengths of the solutions, not exceeding I_1. The behaviour of the PEC in region II differs significantly from the behaviour of the usual individual polyelectrolytes in aqueous salt media, for example, on salting-out. This is manifested primarily by a sharp difference between the compositions of the polymeric products in the coexisting phases. Table 11 presents the results of the analysis of the compositions of the dilute phase for the PDMAEMA.HCl–PP-Na system and the calculated compositions of the concentrated phase, i.e. the precipitate. It is found that, regardless of the composition of the initial system Z, for $\bar{P}_{LPE} \gg \bar{P}_{BPE}$, the S-PEC deposit coexists with a solution of complex macromolecules having the composition $\phi = 0.12–0.14$ (Table 11). For this composition, the N-PEC remains soluble over the entire range of ionic strengths. In the case where $\bar{P}_{LPE} \cong \bar{P}_{BPE}$ the S-PEC deposit coexists with a solution of free LPE (Table 11). Accordingly, the position of the turbidimetric titration curves for solutions of the N-PEC formed by electrostatically complementary polyelectrolytes with similar degrees of polymerisation is independent of the composition Z of the initial system.

Table 11. The composition of the phases coexisting in region II for the PDMAEMA.HCl ($\bar{P}_1 = 3200$)–PP-Na system at pH 4.0 at 20 °C.[55]



Z	$10^3 \cdot c_1$	$10^3 \cdot c_1'$	$10^3 \cdot c_2'$	φ

Notation: c_1 and c_1' are the PDMAEMA.HCl concentrations in the initial mixture and in the supernatant and c_2 and c_2' are the respective concentrations of PP-Na (in basic M) ($c_2 = 5.0 \times 10^{-3}$ basic M); ϕ is the composition of the PEC in solution; in the precipitate $\phi = 1$.

*Free PDMAEMA.HCl.

Thus, on passing from region I to region II, a distinct disproportionation phenomenon is observed, i.e. an inhomogeneous distribution of the BPE chains between the LPE chains. Disproportionation phenomena in interpolymer reactions are known[57]. In the cases considered here the disproportionation is due to the insolubility of the S-PEC. The transition from the uniform to the non-uniform population of the LPE chains by the BPE chains can be represented by Scheme *J*.

Scheme *J*

Evidently the entropy of the two-phase system where S-PEC is present in the concentrated phase (i.e. in the deposit), while in the dilute phase (i.e. in the solution) the N-PEC is depleted in the BPE or simply the free LPE is present, is

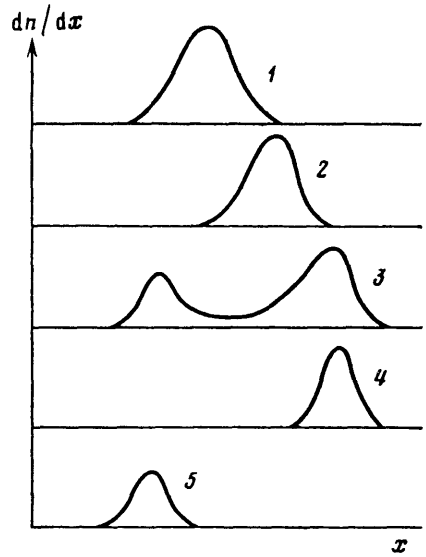
higher than the entropy of the system containing the N-PEC precipitate. For a constant total number of interpolymer salt linkages, a minimum in the free energy of the system should correspond to the first state.

The mechanism of the rearrangement of the N-PEC in aqueous salt media in region II is still not entirely clear. Presumably there are at least two pathways leading to disproportionation. One of these presupposes the preliminary salting-out of the N-PEC and its subsequent rearrangement in the concentrated phase with formation of the S-PEC and the liberation of the excess LPE into the solution. Another possible pathway consists in the formation of the S-PEC still in the solution as a result of the chemical reaction involving the transfer of BPE chains from one set of N-PEC species to another with subsequent precipitation of the S-PEC. In the case of associated N-PEC, the latter process can occur within the limits of each individual initial species. None of the postulated pathways excludes the other when applied to the given system—they can occur simultaneously. However, it must be emphasised that the characteristics of the behaviour of the N-PEC in region II are determined by the occurrence of two coupled processes: the physical process of phase separation and the chemical reaction involving the rearrangement of the PEC species.

The state of the species of the polyelectrolyte complex in region II varies with the ionic strength. An increase in the salt concentration is accompanied by the rupture of some of the interchain salt linkages as a consequence of ion exchange, i.e. as a consequence of the replacement of the "LPE unit–BPE unit" bond by two "chain unit–counterion" bonds[34]. For us, it is important that in region II the extent of the ion exchange is not sufficient for the dissociation of the PEC species into individual polyelectrolyte components. This is indicated particularly by the presence of the S-PEC deposit in the system.

Finally we shall consider the transition from the heterogeneous region II to the homogeneous region III. We may note in the first place that the position of the boundary between these regions, i.e. the value of I_2, depends little on the composition Z of the mixture of polyelectrolytes, in contrast to I_1 (Fig.14). The latter can be understood by taking into account the fact that, on passing from region II to region III and further, an increase in the ionic strength entails a far-reaching decomposition of the PEC. In fact I_2 is determined by the initial conditions for the separation of the polyelectrolyte components in the S-PEC, whose composition is naturally constant and independent of the initial ratio of the BPE and the LPE. In region III the fraction of the units θ linked by salt bonds greatly diminishes. There is a corresponding increase of the fraction of disconnected units. For the critical value of θ characteristic of each pair of polyelectrolytes, a sufficient number of hydrophilic sequences, i.e. loops incorporating disconnected units (see Scheme *A*), have accumulated in the S-PEC species. The precipitate then dissolves. The dissolution does not necessarily imply a complete separation of the electrostatically complementary chains in space. They can still be retained near one another by a relatively small number of salt linkages. However, with increase in the ionic strength in region III this number continuously falls. Finally, after the attainment of a sufficiently high concentration of low-molecular-weight salt, the polyelectrolyte complex dissociates completely into the individual polyelectrolyte components.

Fig.16 presents the sedimentation diagrams for the PMA-Na–PVP.C_2H_5Br N-PEC with the composition $\phi = 0.14$ in aqueous salt media. The polyelectrolyte complex having this composition is soluble over the entire range of experimental ionic strengths, i.e. the system is homogeneous at all the ionic strengths investigated. The characteristics of the behaviour of the N-PEC in the vicinity of the boundary between regions II and III and in region III are therefore particularly clearly manifested in relation to this system. Evidently, in the homogeneous system up to the ionic strength $I = 0.4$ M, the N-PEC species sediment with a single peak, i.e. they retain their individuality (curves *1* and *2*). However, on further increase in the concentration of the low-molecular-weight salt, the N-PEC dissociates into the free LPE and BPE. This is indicated by the appearance of two peaks on the sedimentation diagram (Fig.16, curve 3), corresponding to the individual initial polyelectrolyte components#. It follows from the data presented that the disproportionation phenomenon is not observed in the homogeneous system, i.e. that the disproportionation is indeed closely related to the phase separation occurring on transition from region I to region II. Hence it also follows that, after the attainment of I_2 (Fig.14), the S-PEC still does not decompose fully into the individual components and dissolves actually in the form of the products of the incomplete interpolymer reaction. The complete dissociation of the polyelectrolyte complex into the LPE and the BPE occurs only in region III at high ionic strengths corresponding precisely to the appearance of two peaks on the sedimentation diagram for the solution.



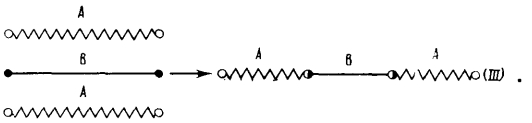


Figure 16. Sedimentation diagram for solutions of PMA-Na ($\bar{M}_w = 2.6 \times 10^5$)–PVP.$C_2H_5Br$ ($\bar{M}_w = 6 \times 10^4$) mixtures having the composition $Z = 0.14$ at different ionic strengths I(NaBr) [*1*) 0.2; *2*) 0.35; *3*) 0.48], PMA-Na (curve 4), and PVP.C_2H_5Br (curve 5). Concentration of solutions 0.3 wt.% at pH 7.5 and 20 °C. Time 60 min for a rate of spinning of 56000 min^{-1}.[55]

#In the experimental range of ionic strengths the individual polymeric components of the PMA-Na–PVP.C_2H_5Br system are not salted out, as happens, for example, in the sodium polystyrenesulphonate–polybenzylvinyltrimethylammonium chloride system[14].

The other pairs of the electrostatically complementary polyelectrolytes taken in non-stoichiometric proportions and capable of forming the N-PEC (i.e. for $P_1 \gg P_2$) also behave analogously in aqueous salt media. This behaviour is caused by the thermodynamic reversibility of the interpolymer PEC formation reaction.

VI. PROSPECTS FOR THE DEVELOPMENT OF RESEARCH INTO AND THE POSSIBLE APPLICATIONS OF THE NEW CLASS OF POLYELECTROLYTES

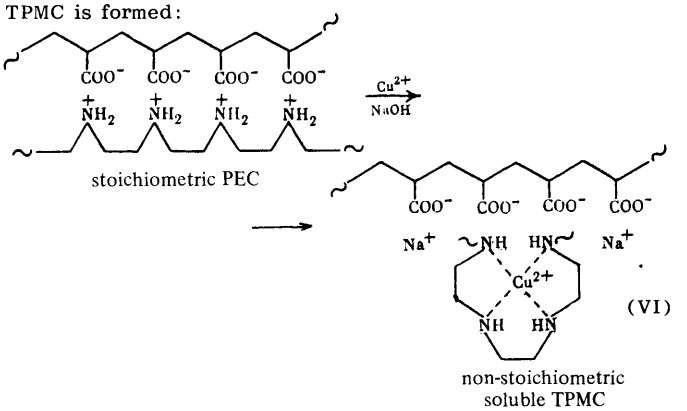
The experimental data and considerations described in the review make it possible to regard the water-soluble N-PEC as an unusual variety of block-copolymers. Its unusual nature is manifested in the very synthesis of the N-PEC. In the classical chemistry of polymers one of two approaches is used for the synthesis of block-copolymers. According to the first of these, one synthesises initially the individual blocks A and B with the reactive groups at the ends, which are then linked to one another by a covalent bond as shown in the following scheme:

The second approach consists of the preliminary synthesis of blocks of, for example, type B whose terminal groups are capable of inducing the polymerisation of the corresponding monomer and the growth of blocks of type A:

In contrast to this, a fundamentally different approach is used in the synthesis of N-PEC, consisting in the lateral pairing of chemically complementary chains of different lengths.

The N-PEC is formed as a result of a very rapid ion-exchange reaction on simple mixing of aqueous solutions of the initial polyelectrolyte components. The process terminates almost instantaneously even at very high dilutions. The synthesis of the N-PEC can be achieved without any experimental tricks in the same working system where it is intended to function subsequently. The unusual nature and simplicity of the synthesis of hydrophilic-hydrophobic block macromolecules naturally lead to their new practical applications.

This is not all. In the block-copolymer synthesised by the usual method, the sequence of the alternation of the blocks and their lengths, i.e. the primary structure of the block macromolecules, are specified at the synthesis stage. Subsequently the structure can no longer be altered without the rupture of covalent chemical bonds. The macromolecules of the usual block-copolymer therefore attain thermodynamically optimum states in their interaction with one another and with the surrounding medium only by a change in their conformations, i.e. in their secondary structure. The situation is different in the case of the block N-PEC. By virtue of the reversibility of the reactions between the LPE and the BPE, the BPE chains can migrate along the LPE chains and can even move from one chain to another. Such migration actually implies an alteration of the relative lengths and number of hydrophilic and hydrophobic blocks in the complex macromolecule, for example, in accordance with the scheme

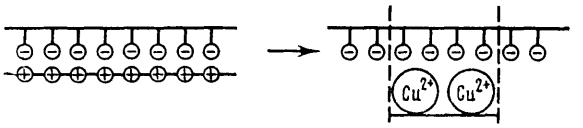


Consequently the complex block macromolecules of the N-PEC can "seek" thermodynamically optimum versions of the interaction with the surrounding medium not only by changing their secondary structure but also their primary structure. The unique ability of the N-PEC, which follows from this, which is to change as a function of the conditions its hydrophilic-hydrophobic balance and to become adjusted to the hydrophilic-hydrophobic balance of the surrounding species and surfaces, should also have important practical consequences, for example, in the solution of problems of flocculation or the stabilisation of colloidal systems.

The study of the structure and properties of N-PEC is extremely useful for the development of ideas concerning the behaviour of linear polyelectrolytes in classical highly disperse colloidal systems.

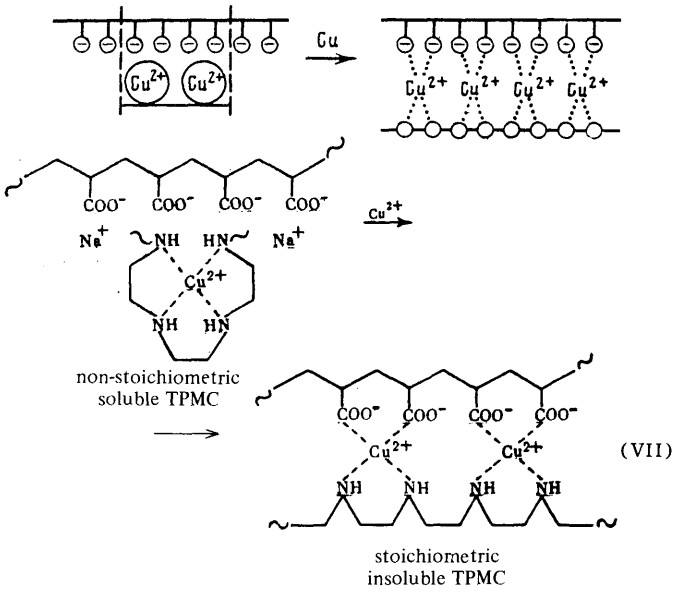
Non-stoichiometric polyelectrolyte complexes are of considerable interest also as the simplest model of polyelectrolyte complexes of biological origin, such as nucleoprotein, glycoprotein, etc. complexes. It has also been shown[47,58,59] that synthetic linear polyelectrolytes are capable of forming water-soluble complexes with oppositely charged proteins (albumin, globulins, etc.). Such complexes are characterised by a definite composition and molecular weight and are in many respects similar to the water-soluble N-PEC described above. They are of independent interest as fundamentally new biologically active macromolecular compounds, for example artificial antigens[60].

One rational explanation of the high physiological activity manifested by synthetic polyelectrolytes is based on the idea of their ability to interact cooperatively with oppositely charged biopolymers (nucleic acids, proteins, heparin, etc.) and also with cell membranes. Clearly, the polyelectrolyte complexes formed under these conditions can be both stoichiometric and non-stoichiometric.



The reversible interpolymer reaction leading to the formation of an N-PEC can find applications in the creation of most varied functional macromolecular systems. In particular, we shall consider an example in which the ability of the PEC to bind strongly transition metal ions such as Cu^{2+}, Fe^{2+}, Fe^{3+}, Ni^{2+}, Co^{2+}, etc. is used. The ternary polymer–metal complexes (TPMC) thus formed can be both stoichiometric and water-soluble and non-stoichiometric and can be interconverted. The TPMC of linear polyethyleneimine (PEI), PA-Na, and Cu^{2+} has been studied in greatest detail[61–63]. If an aqueous solution of a bivalent salt is added to the insoluble PAA–PEI S-PEC with $\theta \cong 1$, the deposit of the polyelectrolyte complex is coloured an intense blue. For the ratio $[Cu^{2+}]:[\text{polyelectrolyte unit}] \cong 1:5$, a water-soluble TPMC is formed:

Each Cu^{2+} ion in the TPMC is then bound by coordinate bonds to four non-protonated amino-groups belonging to four neighbouring PEI units. The TPMC can therefore be characterised as a polyelectrolyte complex formed by the negatively

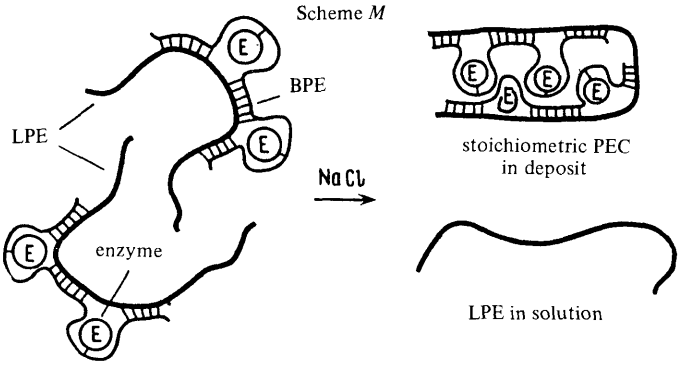


charged PA-Na chain and the positively charged chain of the copper complex of PEI. In the initial binary S-PEC there is one PEI unit per PAA unit. In contrast to this, in the TPMC for each two PAA units there are four PEI units, constituting the coordination sphere of the bivalent ion Cu^{2+}. Thus, on formation of the TPMC, the effective length of each PEI chain decreases. The PEI chains, as it were, "shrink" relative to the PA-Na chains. One-stranded sequences of the negatively charged PA-Na units are then liberated, as shown in Scheme *K*.

Scheme *K*

As a result, the TPMC acquires the block structure characteristic of the N-PEC and dissolves. However, if the addition of the copper salt to a solution of this TPMC is continued, then, for the ratio $[Cu^{2+}]/[\text{polyelectrolyte unit}] = 0.5$, phase separation occurs again. It is due to a rearrangement of the coordination sphere of the Cu^{2+} ion; in the presence of an excess of Cu^{2+}, only two PEI units remain in the TPMC molecule and two additional PAA units are incorporated. As a result, the TPMC acquires the continuous two-stranded structure characteristic of the S-PEC.[62] This is illustrated by reaction (VII) and Scheme *L*.

Scheme *L*



(VII)

The transformations of the TPMC as the concentration of transition metal ions in the surrounding solution is varied, described above, can be used, for example, for the creation of chemomechanical machines. The study of the above phenomena is of undoubted interest also for the creation of effective complex-forming ion-exchangers based on polyelectrolyte complexes.

Another example of functional macromolecular systems based on the N-PEC can be provided by the N-PEC–enzymes conjugated systems. The properties of penicillin amidase (*E*) from *E.coli*, incorporated in particles of the PMA-Na–$PVP.C_2H_5Br$ N-PEC, have been described[64]. The enzyme molecules were initially linked covalently to the BPE chains ($PVP.C_2H_5Br$) and then, using the procedures described above, the N-PEC was obtained ($\phi = 0.33$). The inclusion of the enzymes in the N-PEC species having an excess negative charge was accompanied by a considerable shift and distortion of the pH optimum in the enzyme activity induced by the Donnan exclusion effect. The activity of the enzyme hardly altered under these conditions. An important property of this three-component system is its ability to pass reversibly from the soluble to the insoluble state as the ionic strength of the solution is varied. The precipitation curve for the enzyme-containing PEC is very similar to the precipitation curve for the PMA-Na–$PVP.C_2H_5$ binary N-PEC having the same composition and presented in Fig.15.

The complete transition to the insoluble state takes place over a narrow range of salt concentrations (*I*), amounting to 0.01 M. The process is illustrated schematically in Scheme *M*.

Scheme *M*

The enzymes linked to the S-PEC formed are entrained together in the precipitate. It is remarkable that the formation of the deposit is accompanied by a virtually complete cessation of the enzymatic reaction. Since the phase separation process is reversible, it can be frequently repeated without loss of enzyme activity. Hence arises the possibility of creating self-regulating enzyme systems. If, for example, the enzymatic process involving the cleavage of the substrate leads to the formation of charged products, the ionic strength of the solution increases in the course of the reaction. After the attainment of an ionic strength I^* linked directly to the degree of conversion of the corresponding substrate, the N-PEC containing the enzyme is converted into the insoluble S-PEC. The enzymatic reaction should then stop independently. This has been demonstrated in relation to the hydrolysis of the sodium salt of benzylpenicillin by enzyme-containing N-PEC. The hydrolysis results in the formation of the sodium salt of 6-aminopenicillanic acid and the sodium salt of phenylacetic acid, which ultimately "stop" the reaction. By varying the initial ionic strength of the solution and (or) the composition of the N-PEC, it is possible to force the enzymatic reaction to stop automatically at any specified degree of conversion of the substrate.

* * *

The example presented naturally by no means exhaust all the theoretical and practical prospects for the employment of the N-PEC as a new class of water-soluble ionogenic macromolecular compounds. The very fact that the examples described refer to such varied and sometimes remote fields demonstrates convincingly the usefulness of further studies and research. Only the first steps have so far been taken in this direction.

Advances in the Chemistry of Sulphur-containing Macroheterocycles

M.G.Voronkov and V.I.Knutov

Data on the methods of synthesis and structures of macroheterocyclic sulphides as well as their complexes with alkali and transition metal ions are surveyed and described systematically.
The bibliography includes 185 references

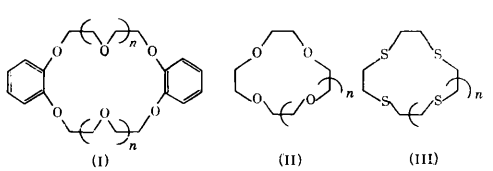
I. INTRODUCTION

The chemistry of macrocyclic compounds arose more than half a century ago as a result of the studies of Ruzicka, who synthesised macrocyclic ketones in order to discover the nature of the active principle of substances with the odour of musk[1,2]. The further development of this branch of organic chemistry was promoted by the fundamental studies of Ziegler[3-7], Hansley[8], Prelog[9], Stoll[10,11], Shemyakin[12-14], and others[15-18] carried out between 1930 and 1960.

At the present time, the chemistry of macrocyclic compounds is developing very vigorously, owing to the recently discovered extensive possibilities for the employment of macrocycles not only in chemical practice but also in biology, medicine and engineering[19-21]. The syntheses of catenanes and rotaxanes, crown-ethers and cryptands, cyclophanes, *ansa*-compounds, annulenes, etc. have attracted much attention.



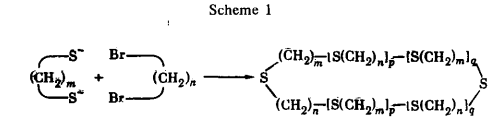
Macroheterocyclic compounds, namely crown-ethers, cryptands, and similar substances, whose study is closely related to the discovery of natural macroheterocyclic compounds, occupy a special place in the chemistry of macrocycles. The study of natural macroheterocycles—peptides, depsipeptides, and depsides—led to the discovery of their ability to form stable complexes with alkali and alkaline earth metals and to transfer these cations through natural and synthetic membranes. Such compounds have been called membranoactive complexones or ionophores[19]. The development of the chemistry of synthetic macroheterocyclic complexones is associated with the possibility of obtaining compounds whose properties are analogous to those of natural macroheterocycles. They can be regarded as simplified models of natural macroheterocyclic ionophores. Individual examples of synthetic macroheterocycles have been obtained by various groups of investigators[22-27], but the vigorous development of the chemistry of macroheterocycles has been stimulated by Pedersen's studies on the synthesis and complex formation reactions of macroheterocyclic polyethers with alkali and alkaline earth metal salts[28]. The vigorous development of the chemistry of macroheterocycles is indicated by the publication of recent monographs[19-21,29,30] and general reviews[31] and reviews devoted to individual classes of macroheterocycles: ethers[32], esters[33], amines[34], sulphides[35], heterocyclophanes[36], and other compounds of a similar type[37-40].

This review deals with studies on sulphur-containing macroheterocyclic compounds published in 1974–1980 (earlier investigations have been reviewed elsewhere[35]).

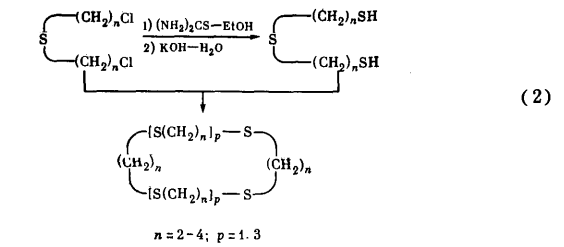
II. MACROHETEROMONOCYCLIC SULPHIDES

1. Macropolythiamonocyclanes

In 1967 Pedersen synthesised aromatic macroheterocyclic polyethers (I) and called them crown-ethers[28]. He observed that these compounds form stable complexes with alkali and alkaline earth metal cations as well as ammonium and silver cations. Crown-ethers are obtained by the condensation of 1,2-dihydroxyarenes with the corresponding α,ω-dichloro-derivatives in boiling 1-butanol in the presence of alkali metal hydroxides; in individual instances the yields reach 62%.

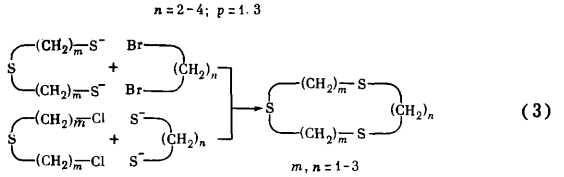


(I) (II) (III)



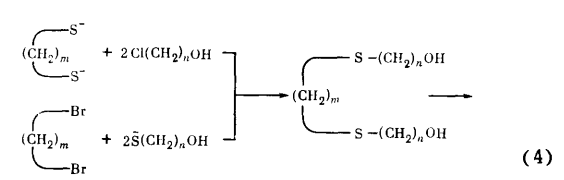
Instead of dichloro-derivatives, it is possible to employ ditosyl derivatives; heterocyclic polyethers of type (II) have been obtained from them in yields of 45%.[41-43,57] The high yields of crown-ethers can be accounted for by the "template" effect arising on coordination of alkali metal ions to the oxygen atoms in the cyclisation of the polyether.

Under analogous conditions, macropolythiamonocyclanes (III) are formed in only a low yield (less than 2%)[44] owing to the absence of the "template" effect because of the weak affinity of the sulphur atoms for alkali metal ions[45]. High dilution of the reaction mixture made it possible to improve the method of synthesis of macropolythiamonocyclanes[45,46]. The proposed methods (see Scheme 1) make it possible to synthesise macropolythiamonocyclanes in yields up to 35% (Table 1).

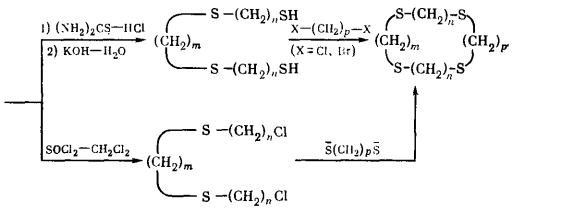


Scheme 1

$m, n = 3-5$; $p, q = 0,1$ (1)

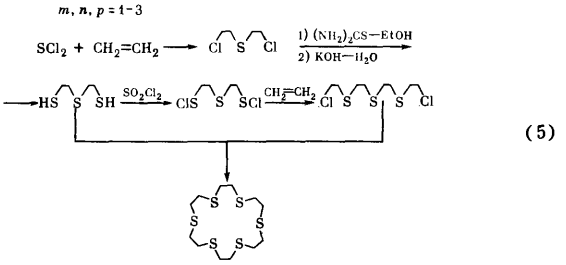


(2)



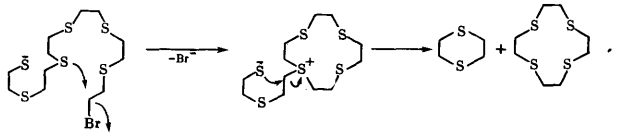
$n = 2-4$; $p = 1.3$

(3)



$m, n = 1-3$

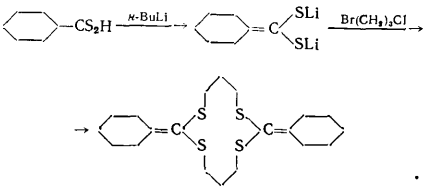
(4)



$m, n, p = 1-3$

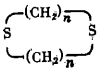
(5)

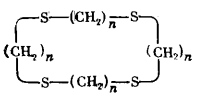
Method (1) is most suitable for the synthesis of tetrathia- and hexathia-cyclanes in which the sulphur atoms are separated by tetra- and penta-methylene bridges. On the other hand, methods (3) and (5) lead to the maximum yields of macropolythiacyclanes consisting of alternating SCH_2CH_2 units.

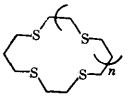


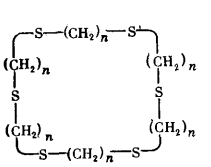
1,4-Dithiane and 1,4,7,10-tetrathiacyclododecane were unexpectedly obtained in reactions (1) and (3) together with 1,4,7,10,13,16-hexathiacyclo-octadecane. This is due to the formation of a cyclic sulphonium ion as a result of intramolecular cyclisation[45]:

When methods (2), (4), and (5) are used, the amount of side products is reduced to a minimum.



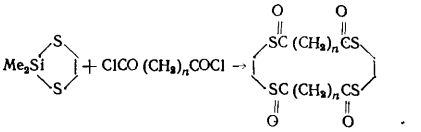






The kinetics of the formation of complexes by the Cu^{2+} ion with macrocyclic sulphides have been investigated and the influence of the solvent and the ring size has been considered[47-51]. The possibility of using these compounds as extractants for silver and mercury salts has been studied[52-55].

2,8-Bis(cyclohexylidene)-1,3,7,9-tetrathiacyclododecane (IV) has been obtained from cyclohexanedithiocarboxylic acid[56]:



(IV)

Table 1. Macropolythiamonocyclanes.

The interaction of the highly reactive 2,2-dimethyl-2-sila-1,3-dithiacyclopentane with dicarboxylic acid dichlorides has been used to synthesise macroheterocyclic thiolactones (V):[57,58]

$n = 3, 5, 7, 8$ (V)

Several sulphur-containing annulenes have been obtained by the oxidative coupling reaction of diacetylenic sulphides[60, 61]. The interaction of bis[(triphenylphosphonia)methyl] sulphide dibromide with *o*-ethynylbenzaldehyde led to the synthesis of the corresponding diacetylenic derivative whose

oxidation in the presence of copper acetate in pyridine resulted in the formation of the macroheterocycle (VI):

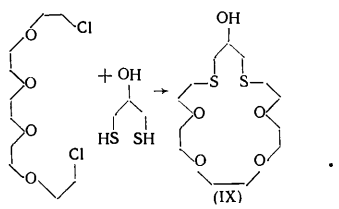
Compounds (VII) and (VIII) have been obtained analogously:

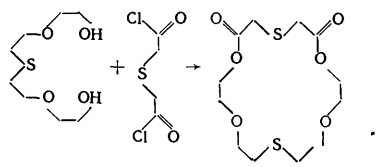
(VII)

(VIII)



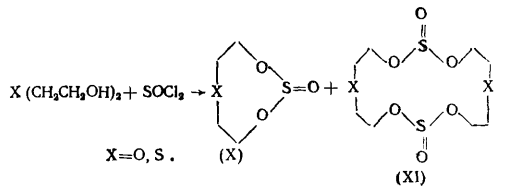
2. Macro-oxathiacyclanes

Crown-ethers containing sulphur atoms in the ring together with oxygen atoms were first synthesised by Pedersen[59,62], who also showed that, when oxygen atoms are substituted by sulphur atoms, the complex-forming properties of the crown-ethers in relation to potassium and sodium ions are weakened, while the complexes with silver ions are in fact strengthened. Thiacrown-ethers have been obtained by the condensation of aromatic 1,2-dithiols or *o*-mercaptophenol with aliphatic α,ω-dihalogeno-derivatives. The reaction of *o*-dihalogenoarenes with aliphatic α,ω-dithiols can also be used. *trans*-Cyclohexane-1,2-dithiol reacts with di(β-chloroethyl) ether analogous to 1,2-dithiols, forming 5,18-dioxa-2,8,15,21-tetrathiatricyclo[20,4,0,0^{9,14}]hexacosane:



The thiacrown-ethers synthesised are listed in Table 2.[62]

The reaction of aliphatic α,ω-dithiols with dichlorohydrins has also been used to synthesise thiacrown-ethers (Table 3).[63] For example, the macroheterocycle (IX) has been obtained (in 80% yield) by the reaction of 1,14-dichloro-3,6,9,12-tetraoxatetradecane with 1,3-dimercapto-2-propanol:



More than twenty thiacrown-ethers containing ester groups in the ring have also been obtained[64–68]. Sulphur-containing macroheterocyclic di- and tetra-oxa-esters have been synthesised by the interaction of oligo(ethylene thioglycols) or by the corresponding dithiols with the dichlorides of dicarboxylic acids under the conditions of high dilution (Table 3). The dichlorides of oxalic, malonic, succinic, and 3-thiaglutaric acids were used, for example:

Interest in macrolactones was aroused primarily by the possibility of using them as perfumes[33]. In connection with the discovery of the natural macrocyclic antibiotic valinomycin, containing carbonyl groups in the ring and exhibiting unique complex-forming properties in relation to alkali metal ions[19], nowadays these compounds attract attention as complex-forming agents. It was found that they exhibit a high complex-forming activity in relation to alkali and alkaline earth metal ions. Sulphur-containing macroheterocycles of this type form complexes with Na^+, K^+, Ag^+, Rb^+, Cs^+, and Ba^{2+} ions[69–72].

The reaction of diethylene glycol or β-thiodiglycol with thionyl chloride leads to the formation of heterocycles (X) of moderate size and macroheterocycles (XI):[73]

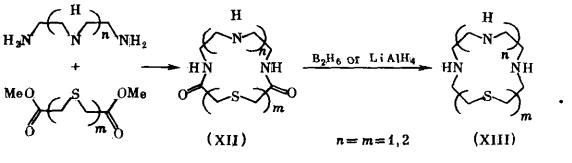
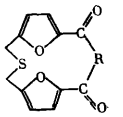
*An oil is formed.

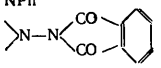


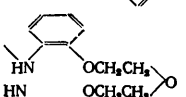
A series of sulphur-containing macroheterocycles have been synthesised using the dichloride of 5,5'-[thiobis(methylene)]-bisfuran-2-carboxylic acid as the key reagent[74]. A wide variety of diols (catechol, resorcinol, hydroquinone, monoethylene and triethylene glycols, 2,2-dimethylpropane-1,3-diol, propane-1,2-diol, 2,4-dimethyl-3-oxapentane-1,5-diol, *cis*- or *trans*-but-2-ene-1,4-diol, and but-2-yne-1,4-diol) as well as ethane-1,2-dithiol have been used as the second reagent (Table 4):

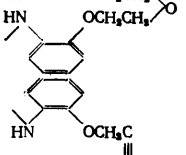
The reaction is carried out in the presence of lithium hydride in dimethylformamide with prolonged refluxing (20 h); the yields of the macroheterocycles are 11—77%.

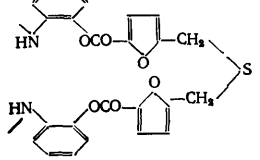


3. Macrothiazacyclanes









The general method of synthesis of macrothiazacyclanes is based on the aminolysis of the readily available dimethyl esters of thia-alkane-α,ω-dicarboxylic acids by polyethylenepolyamines and subsequent reduction of the resulting macroheterocyclic amides[75]:

Sulphur-containing macroheterocyclic diamides (XII) have been obtained in yields of 15.4—40.9% by heating the reactant for 3—7 days without high dilution or protection of the secondary amino-group. Successful cyclisation takes place by virtue of the different reactivities of the NH_2 and NH groups in the initial polyethylenepolyamines. The macrocyclic diamide can be reduced by lithium tetrahydroaluminate or diborane in tetrahydrofuran (THF), the yields of the corresponding macrothiazacyclanes (XIII) amounting to 60—80%.

Data on the synthesis of macroheterocycles containing alkyl, arylalkyl, or functional groups at the nitrogen or carbon atoms have been published with increasing frequency in recent years[32,40]. Such compounds have been used to form complexes with alkali and alkaline earth metal ions and to investigate complex formation kinetics, ion transfer through natural and synthetic membranes, and catalysis of interfacial transfer. Cryptands and their polymacroheterocyclic analogues have been synthesised from macroheterocycles with functional groups. Macroheterocycles with functional groups have been investigated as biologically active substances. After being immobilised in polymeric materials, such heterocycles are used as new heterogeneous catalysts. Finally they can be employed as reactive reagents in organic synthesis.

A new approach to the synthesis of open-chain and macroheterocyclic diamines with arylalkyl and functional group substituents has been discovered[76–80]. The synthesis of *N*-substituted open-chain diamines is based on the reaction of *N*-substituted aziridines with α,ω-dithiols. At 60 °C in methanol α,ω-dithiols react with two moles of aziridine, forming open-chain diamines (XIV). The analogous reaction in an aprotic solvent, for example, benzene, leads to the monoadducts (XV), which are oxidised by atmospheric oxygen to the corresponding disulphides (XVI) (Scheme 2):

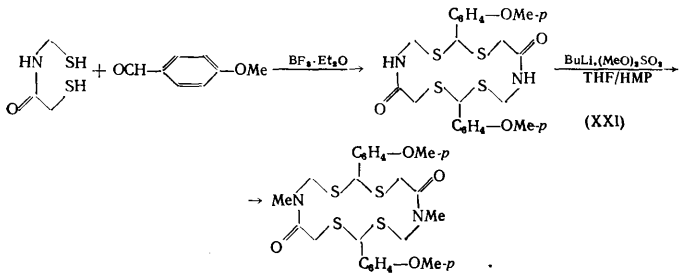
*An oil is formed.

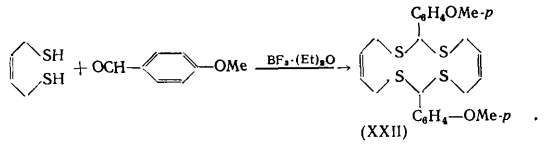
The cyclisation of the diamines (XIV) and (XVI) with dicarboxylic acid dichlorides has been investigated with the aim of synthesising macroheterocyclic compounds containing arylalkyl and functional groups at the nitrogen atom. The reaction is carried out in dry benzene at high dilution. The resulting *N*-unsubstituted macroheterocycles as well as the macroheterocyclic compounds (XVII) and (XVIII), containing

phenylethyl, methoxycarbonylethyl, and cyanoethyl groups are presented in Table 5.



The reaction of bis-*N*-ethyleneamides of azelaic and sebacic acids with an excess of hydrogen sulphide led to the isolation of the macrocyclic sulphides (XIX) and (XX) together with the bis(β-mercaptoethyl)diamides of the corresponding dicarboxylic acids[81]:

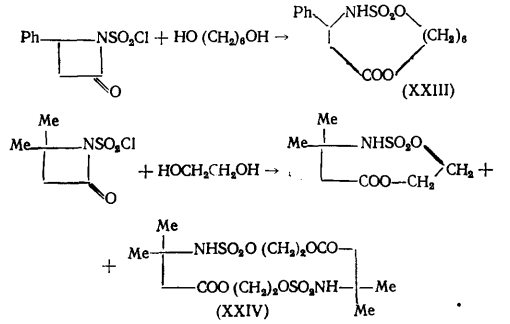
(XIX), $n = 7$; (XX), $n = 8$



The macrocyclic compounds are apparently the products of the intramolecular opening of the aziridine rings by the mercapto-group in the intermediate *N*,*N*-ethylene-*N*'-(β-mercaptoethyl)diamides of azelaic and sebacic acids. The cyclic sulphide (XIX) has also been synthesised by the reaction of the bis(β-chloroethyl)diamide of azelaic acids with sodium sulphide.

The reaction of the *N*-(mercaptomethyl)amide of thioglycolic acid with anisaldehyde leads to the formation of the macrocycle (XXI):[82]

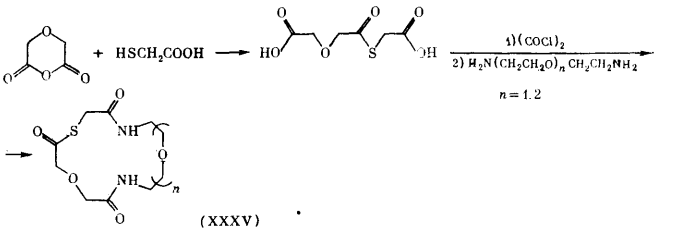
(XXI)



The macroheterocycle (XXII) has been obtained analogously by the reaction of 1,4-dimercaptobut-2-ene with anisaldehyde:

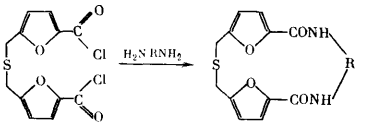
(XXII)

4. Macro-oxathiazacyclanes



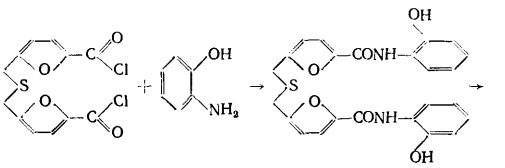
The reaction of *N*-chlorosulphonyl-β-lactams with glycols leads to the formation of the new macroheterocycles (XXIII) and (XXIV):[83-84]

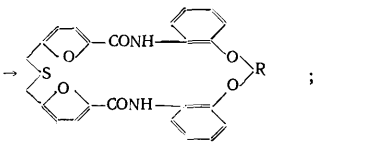
(XXIII)



(XXIV)

Oxygen- and nitrogen-containing macroheterocyclic sulphides have been synthesised from 5-oxo-3-oxa-6-thiahexanedicarboxylic acid, which is the product of the reaction of the anhydride of diglycolic acid with thioglycolic acid[85]. The dicarboxylic acid obtained was converted by treatment with oxalyl chloride into the corresponding acid dichloride whose reaction with 1,5-diamino-3-oxapentane or 1,8-diamino-3,6-dioxaoctane at high dilution leads to the macroheterocycle (XXXV) in 30–35% yield:



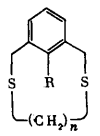


(XXXV)

The macroheterocyclic amides have been obtained analogously in higher yields using the dichlorides of 5,5'-[thiobis(methylene)]bisfuran-2-carboxylic acid and aliphatic or aromatic diamines (Table 4):[86]

R=$(CH_2)_2$, $(CH_2)_3$, $(CH_2)_6$, $(CH_2)_2S(CH_2)_2$, *o*-C_6H_4, *m*-C_6H_4, *p*-C_6H_4

R=$CH_2CH_2OCH_2CH_2$, $CH_2C{\equiv}CCH_2$, CO–  –CH_2SCH_2–  –CO

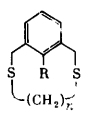


The reaction of the dichloride of 5,5'-[thiobis(methylene)]-bisfuran-2-carboxylic acid with o-aminophenol leads to the corresponding diamide, whose subsequent interaction with dichlorides (refluxing in the presence of potassium hydroxide for 25–30 h) leads to the formation of sulphur-containing macroheterocycles in 53–83% yields (Table 4).[87]

III. THIA- AND POLYTHIA-CYCLOPHANES

1. Sulphur-containing Cyclophanes

Cyclophanes are cyclic compounds containing one or several benzene rings connected by polymethylene bridges in the *ortho*-, *meta*-, or *para*-positions. Interest in these compounds arose in connection with the possibility of investigating the steric interaction of substituents, transannular effects, the dependence of the barrier to the rotation of the benzene rings on the length of the methylene bridge, etc.



A large series of dithiacyclophanes (XXVI), containing from 3 to 12 methylene groups in each aliphatic bridge incorporating a wide variety of intra-annular substituents in the benzene ring, have been synthesised (Table 6).

(XXVI)

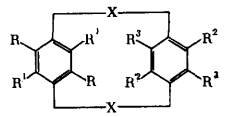
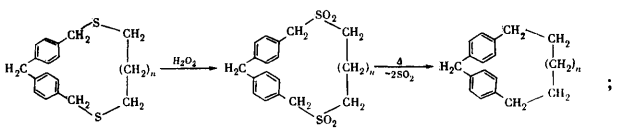
*An oil is formed.



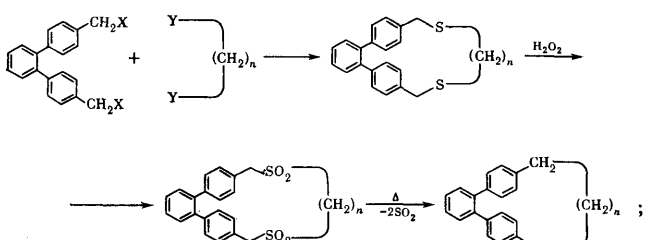
Cyclophanes with oxygen and sulphur atoms in the polymethylene bridges have also been obtained[88–91,111,117]. It has been shown by NMR that the steric requirements of an NO_2 group in these macrocyclic compounds are somewhat less stringent than those of a methyl group. CO_2Me and SO_2Me Groups are more bulky than NO_2 and SMe, but the bulk of an SMe group is greater than that of an OMe group. An SOMe group occupies an intermediate position between SO_2Me and SMe; the bulk of an NH_2 group is similar to that of a hydroxy-group. Both these substituents (NH_2 and OH) are more bulky than a fluorine atom linked to the aromatic ring, but are appreciably smaller than a chlorine atom or SMe and NO_2 groups. The general steric requirements of an iodine atom linked to an aromatic ring are more stringent than those of a chlorine or bromine atom but are comparable to those of an SMe group[88–91].

Dithiametacyclophanes containing intra-annular alkyl, alkenyl, and alkoxy-groups in the benzene ring have been synthesised[92,93]. They have been obtained by the interaction of 2,6-bis(mercaptomethyl)toluene with 2,6-bis(bromomethyl)-substituted benzenes; the yields of the macroheterocycles (XXVII) are 53–80%:



R = n-Pr, $CH_2CH{=}CH_2$, CH_2OMe. (XXVII)

Dithiaparacyclophanes containing bromine atoms, methoxy-groups, or cyano-groups in the benzene ring have been synthesised by the reaction of the corresponding 1,4-bis-(mercaptomethyl)benzenes with 1,4-bis(bromomethyl)-benzenes[94,95]:

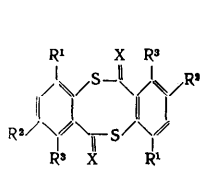


X = S, SO_2; R = R^1 = R^3 = H; X = S, SO_2; R = R^3 = H, R^1 = CN, R^3 = OMe; X = S, SO_2; R = R^3 = H, R^1 = CN, R^2 = OMe; X = S; R = Br, R^1 = R^3 = OMe, R^3 = H.

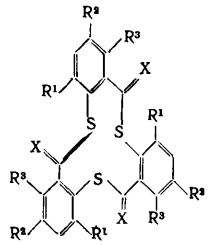
In recent years the pyrolysis of cyclic sulphones has been used widely for the synthesis of cyclophanes. The synthesis of sterically hindered paracyclophanes (XXVIII) has been achieved in this way[96]:

n=1–3. (XXVIII)

A series of cyclophanes containing two or three benzene rings in their molecules has been obtained[97–101]. The main method of synthesis of the initial dithiacyclophanes involves the reaction of the corresponding dibromides with dithiols (Table 7):



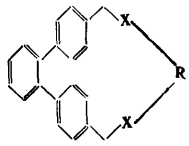
n=2–10, X=Br, SH, Y=SNa, Br.



An analogous method has been used to synthesise dithiabiphenylophanes[102–105], dithiabiphenylnaphthalinophanes[123–131], dithiaphenanthrenophanes, and dithiaphenanthrenonaphthalinophanes[136–138] (Table 8).

The homocyclisation of *o*-mercaptobenzyl chloride under the influence of sodium hydroxide and of methyl-substituted *o*-mercaptobenzoic acids under the influence of P_5O_{10} at a high

dilution proceeds with formation of both cyclic dithiaorthocyclophanes (XXIX) of moderate size and the macrocyclic trithiaorthocyclophanes (XXX) (yield 6.4–10%).[107,116,122]



(XXIX)

*Decomposition temperature.

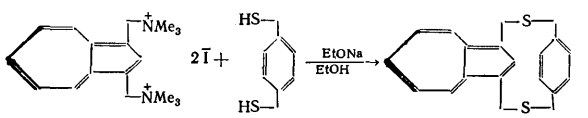
In order to investigate the effects of the internal rotation of the benzene rings in macrocyclophanes, dithiatriparacyclophanes (XXXIII) with various substituents in the *para*-position of the benzene ring have been obtained[109]:

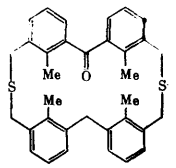
R = H, F, Cl, Me, OMe . (XXXIII)



They were synthesised by the reaction of sodium dithiolates with 1,2-bis(4-chloromethylphenyl)ethane in a benzene-alcohol solution at high dilution; the yields of the dithiacyclophanes (XXXIII) are 15–55%.

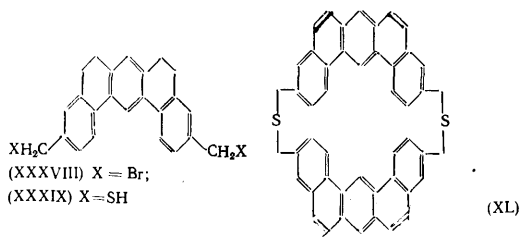
When the tetrasulphide (XXXIV) was treated with $Me_3\overset{+}{O}\overline{B}F_4$, the water-soluble tetrathiaparacyclophane (XXXV) was isolated[110]:

(XXXIV) (XXXV)



Using the high dilution technique, dithia-azulenoparacyclophane (XXXVI) was synthesised by the reaction of 1,3-bis(trimethylammoniamethyl)azulene di-iodide with 1,4-bis(mercaptomethyl)benzene (yield 40%):[114]

(XXXVI)

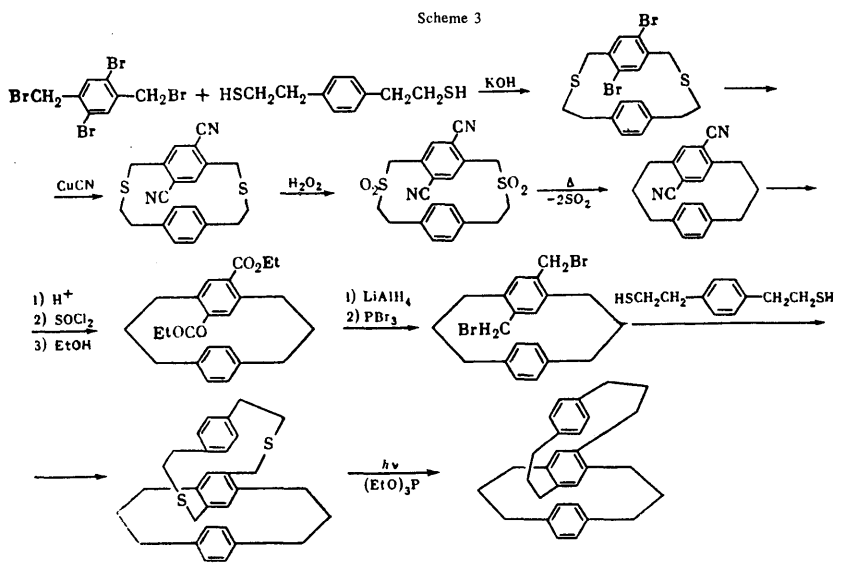


Two-layer and three-layer cyclophanes have been obtained in order to investigate the transannular interaction between the π electrons of the benzene ring[106,112,113,118–120,149]. The method of their synthesis is based on the pyrolysis of bis-sulphones or the photoextrusion of sulphur from bis-sulphides. The three-layer paracyclophanes are presented in Scheme 3.

Tetramethyldithiametacyclophane (XXXVII) has been obtained by the cyclisation of bis(3-bromomethyl-2-methyl)-benzophenone with bis(3-mercaptomethyl-2-methylphenyl)-methane in 80% yield[121]:

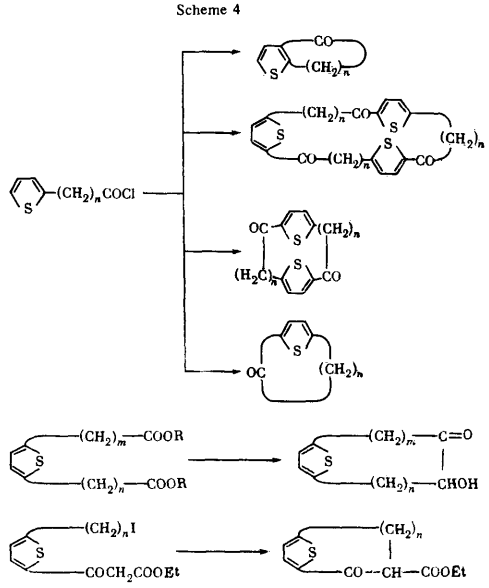
(XXXVII)

Sulphur-containing anthraceno- and anthraquinononophanes and pentaphenyleno-phanes have been described[132–135]. Dithiadibenzanthracenophane (XL) has been obtained by the reaction of bis(bromomethyl)dibenzanthracene (XXXVIII) with bis(mercaptomethyl)dibenzanthracene (XXXIX) (yield 55%):[139]



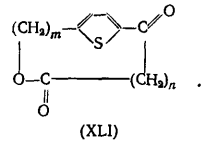
(XXXVIII) X = Br;
(XXXIX) X = SH (XL)

2. Thiophenophanes



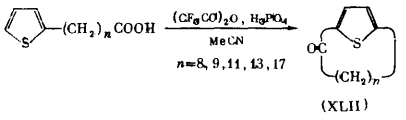
A method based on the intramolecular and intermolecular acylation of the chlorides of ω-thienylalkanecarboxylic acid, the acyloin condensation of 2,5-bis(alkoxycarbonylalkyl)-thiophens, and the intramolecular alkylation of ω-halogenoalkyl-substituted β-ketoesters of the thiophen series have

Scheme 3



been developed for the synthesis of macrocyclic compounds incorporating the thiophen ring[29,140,144,145,150–152,155,156] (Scheme 4).

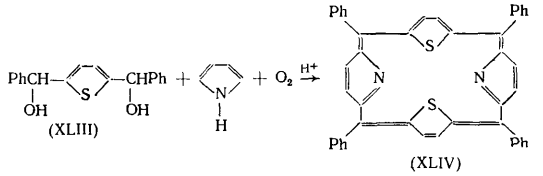
Scheme 4



These investigations have been reviewed[35].

The X-ray diffraction determination of the geometrical and conformational parameters of the isomeric *ansa*-ketolactones having the general formula (XLI) and incorporating the thiophen ring[141–143,146–148] made it possible to explain the different ease of formation of macrocyclic ketolactones depending on the position of the ester group in the *ansa*-bridge and also the characteristics of their spectra and physical and chemical properties:

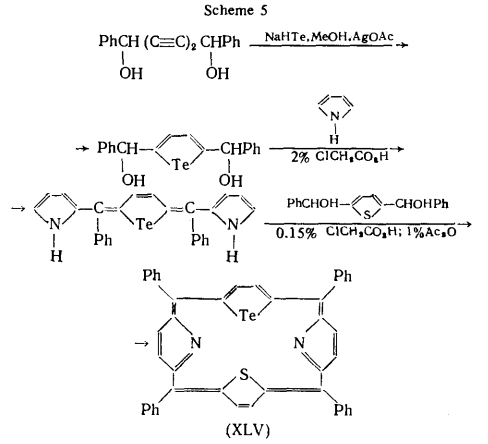
(XLI)



(2,5)-Thiophenophan-1-ones (XLII) have been synthesised by the cyclisation of ω-(2-thienyl)alkanecarboxylic acids in the presence of 85% phosphoric acid and trifluoroacetic anhydride in dry acetonitrile[153,154]:

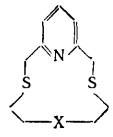
(XLII)

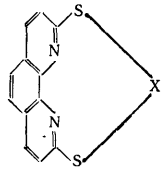
The yields of the macrocycles (XLII) increase from 9 to 66% with increase of the length of the polymethylene bridge.

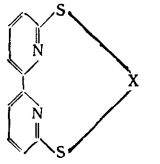


Tetraphenyl-21,23-dithiaporphyrin (XLIV) has been obtained by the reaction of 2,5-bis(α-hydroxybenzyl)thiophen (XLIII) with pyrrole (yield 10%):[157]

(XLIII) (XLIV)







A new tetraphenylporphyrin (XLV), containing sulphur and tellurium atoms together with nitrogen atoms, has been synthesised by the following scheme[185].

Scheme 5

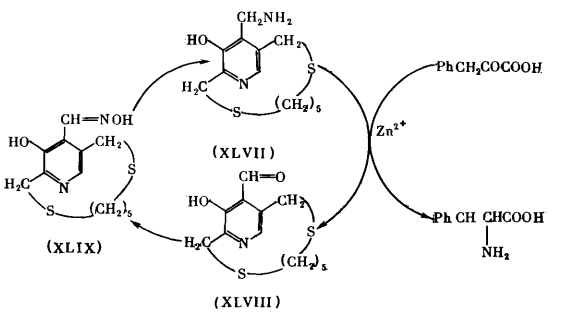
3. Sulphur-Containing Pyridinophanes

Pyridinophanes have been synthesised by the reaction of 2,6-bis(bromomethyl)pyridine with various α,ω-dithiols (Table 9). The pyridinophanes (XLVI) containing diamide

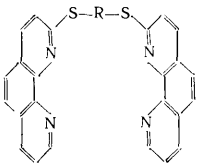
groups have been obtained by the reaction of the dichloride of pyridine-2,6-dicarboxylic acid with diamines[158]:



(XLVI)

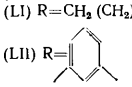
R=S, S—S .

The sulphur-containing pyridinophanes synthesised form crystalline complexes with the transition metal ions Ag^+, Fe^{2+}, Cu^{2+}, Ni^{2+}, Co^{2+}, Zn^{2+}, Hg^{2+}, Cd^{2+}, Pd^{2+}, Au^{3+}, and Pt^{4+} (yields 39–96%).

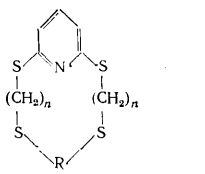


(−)-15-Aminomethyl-14-hydroxy-2,8-dithia[9](2,5)-pyridinophane (XLVII) has been used as a transaminating agent in the reaction with phenylpyruvic acid[115,159]. Zinc salts have been used as catalysts. Pyridoxamine (XLVII) has been obtained from the pyridinophane (XLVIII) by treatment with NH_2OH–HCl–AcOna–EtOH and subsequent reduction of the oxime (XLIV) with $NaBH_2S_3$ in THF. The transamination reaction is carried out by stirring a mixture of the pyridinophane (XLVII), sodium phenylpyruvate, and $ZnClO_4$. $.6H_2O$ at room temperature for 20 h in acetonitrile (Scheme 6); the maximum yield of phenylalanine is 83%:

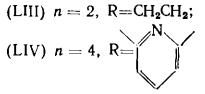
Scheme 6



(XLVII) (XLIX) (XLVIII)



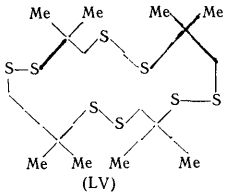
Macroheterocyclic phenanthrolines and dipyrinide (Table 9), in which the bridging sulphur atoms are linked directly to the pyridine ring, have been synthesised by the reaction of 2,9-dichloro-1,10-phenanthroline and 6,6′-dichloro-2,2-bipyridyl with α,ω-dithiolates in 3-methyl-1-butanol[160]. These macroheterocycles do not form crystalline complexes with alkali metal or alkaline earth metal ions, while among heavy metal ions complexes are formed only with silver and mercury ions. The open-chain ligands (L)–(LII) used for comparison readily form complexes with Co^{2+}. It has been suggested that the weak coordinating capacity of the macroheterocyclic ligand synthesised is associated with the shielding effect of the bridging chains[160].



(L) R=$CH_2CH_2XCH_2CH_2$ (X=O, S);
(LI) R=$CH_2(CH_2)_nCH_2$ (n = 3, 4, 9);

(LII) R=

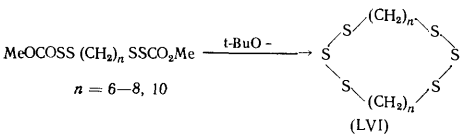
(LIII) n = 2, R=CH_2CH_2;



(LIV) n = 4, R=

The pyridinophanes (LIII) and (LIV) have been obtained by the reaction of 2,6-dihalogenopyridines with α,ω-dithiols[161].

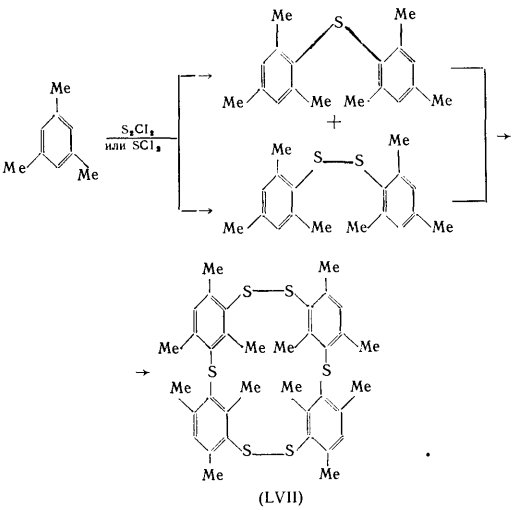
IV. MACROHETEROCYCLIC DI- AND POLY-SULPHIDES



The synthesis of the 16-membered polydisulphide (LV) by treating the isobutene–sulphur monochloride adduct with a solution of sodium hydrogen sulphide has been described[162].

(LV)

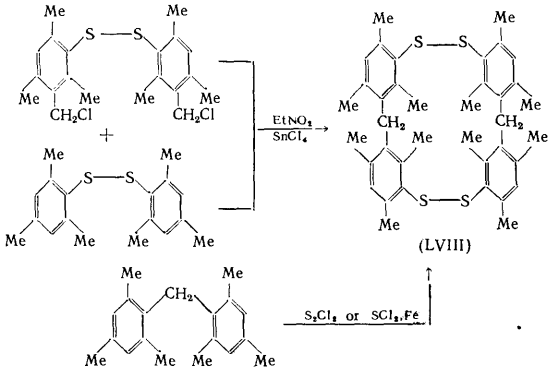
The same substance is formed by the reaction of 2-chloro-2-methylpropyl disulphide, methylallyl disulphide, or sodium methylallyl thiosulphate with sodium hydrogen sulphide; the maximum yield of compound (LV) is 45%.



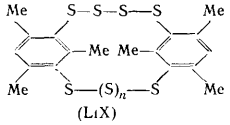
Macroheterocyclic trisulphides have also been formed as a result of the decomposition of polymethylenebis-sulphenyl thiocarbonates by alkoxides[163]:

(LVI)

The yields of the trisulphides (LVI) increases with increase of the length of the bis-sulphenyl thiocarbonate chain. Thus the yields are 16, 22, 50, and 86% respectively for n = 6, 7, 8, and 10.

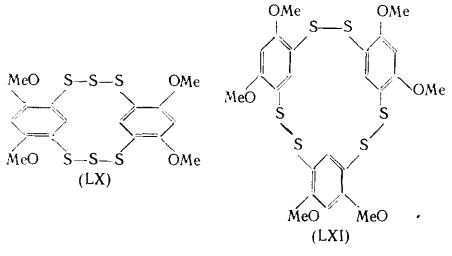


The synthesis of the polythiamacroheterocycle (LVII) has been achieved by the direct introduction of sulphur into mesitylene with the aid of sulphur monochloride or dichloride[164]:



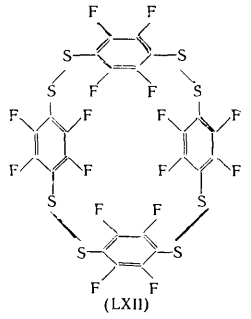
(LVII)

The reaction takes place when the mixture of the reactants is refluxed in chloroform in the presence of iron powder. When sulphur monochloride is used, the yield of compound (LVII) reaches 18%, while in the reaction with sulphur dichloride it does not exceed 3%. The interaction of dimesitylmethane with sulphur monochloride has been studied under analogous conditions and tetrathia[2,1,2,1]metacyclophane (LVIII) with alternating disulphide and methylene linkages



was isolated (yield 15%); in the reaction with sulphur dichloride, compound (LVIII) is formed in 3% yield[165]:

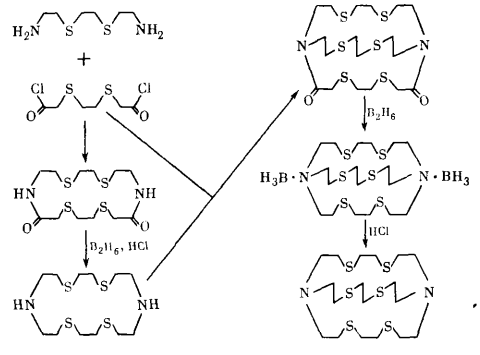
The formation of asymmetric macroheterocyclic polysulphides (LIX) in the reaction of mesitylene-2,4-dithiol with sulphur chlorides was entirely unexpected[166]. Their structure was confirmed by X-ray diffraction and NMR measurements:



The interaction of 1,3-dimethoxybenzene with sulphur chlorides, catalysed by iron, has been studied at normal dilution and using a high dilution technique[167–169]. In the former case, linear polysulphides were obtained, while under the conditions of high dilution a mixture of two macroheterocycles, (LX) and (LXI), is formed in yields of 6 and 1.5% respectively:

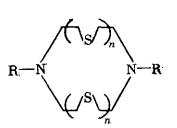
One of the methods of synthesis of macroheterocyclic polysulphides involves the oxidation of dithiols. It was stated previously that the oxidation of benzene-1,4-dithiols leads to the formation of polymeric disulphides[170–172]. However, macroheterocyclic compounds have been synthesised on treatment with iodine at high dilution in 30% yield[173]. The oxidation of naphthalene-1,4-dithiol in the presence of alkali metal hexacyanoferrates(III) also leads to a macroheterocyclic compound[174].

The oxidation of tetrafluorobenzene-1,4-dithiol in diphenyl sulphoxide yielded the macroheterocyclic tetrakisdisulphide (LXII) in 95% yield[175]. The ease of conversion of tetrafluorobenzene-1,4-dithiol into the macrocyclic polysulphide (LXII) is unique. On the other hand, when an attempt was made to oxidise benzene-1,4-diothiol, 2,5-dimethoxybenzene-1,4-dithiol, and tetramethylbenzene-1,4-dithiol under analogous conditions, only polymeric products were isolated. The oxidation of tetrachlorobenzene-1,4-dithiol has been investigated but the molecular weight of the entire product synthesised could not be determined owing to its low volatility and solubility[175].

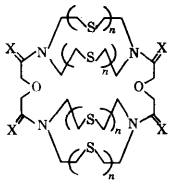


V. MACROHETEROBICYCLIC AND MACROHETEROTRICYCLIC SULPHIDES

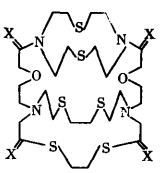
In 1969 Dietrich et al.[176,177] synthesised a series of macrobicyclic polyaminoethers which have been called cryptands. The main characteristic of compounds of this type is the stability of their complexes with a wide range of cations (Li^+, Na^+, K^+, Rb^+, Cs^+, Tl^+, Ag^+, NH_4^+, Ca^{2+}, Sr^{2+}, Ba^{2+}, Pb^{2+}, etc.). Cryptates—the complexes of macrobicyclic polyaminoethers—are readily soluble in water and organic media and their stability is superior to that of the complexes with macromonocyclic polyaminoethers.



Sulphur-containing cryptands have been obtained in the following way (Scheme 7).[178] The corresponding dichlorides of oxa- or thia-dicarboxylic acids were condensed with 1,8-diamino-3,6-dithiaoctane at high dilution. The diamides isolated were reduced with diborane and, after hydrolysis with hydrochloric acid, were converted into monocyclic diamines. The latter were again condensed with dicarboxylic acid dichlorides and the bicyclic diamides formed were converted, like the monocyclic compounds, into macrobicyclic sulphur-containing polyaminoethers (Scheme 7):

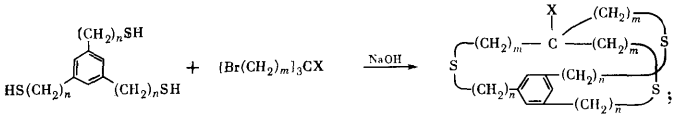


Scheme 7



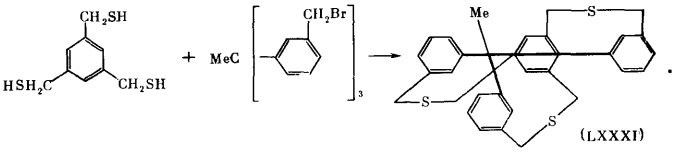
Macropolycyclic ligands can form polynuclear cryptates by incorporating two or more metal cations in the inner cavity within the molecule. Such systems are at present of great interest as models of polynuclear biological complexes and also as polynuclear catalysts. A general synthetic method has been developed[183,184] for the construction of cylindrical macrotricyclic systems which contain rings with different numbers of heteroatoms and different sizes of the inner cavity and a study has been made of their complex formation reactions with univalent and bivalent copper salts.

The sulphur-containing tetra-amide (LXX) has been synthesised by condensing the macroheterocycle (LXVI), containing reactive substituents at the nitrogen atoms, with the macroheterocycle (LXIII). Subsequent reduction of the tetra-amide (LXX) with diborane leads to the formation of the cylindrical macrotricyclic polythiatetra-amine (LXXI). The sulphur-containing macrotricyclic compounds (LXXII) to (LXXV) have been obtained analogously[183,184].



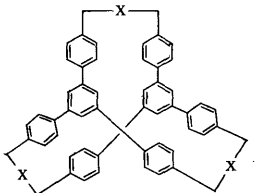
(LXIII): $n=1$, R = H;
(LXIV): $n=1$, R = Me;
(LXV): $n=1$, R = $COCH_2OCH_2COOH$;
(LXVI): $n=1$, R = $COCH_2OCH_2COOC_6H_4NO_2$-*n*;
(LXVII): $n=2$, R = Me;
(LXVIII): $n=2$, R = $COCH_2OCH_2COOH$;
(LXIX): $n=2$, R = $COCH_2OCH_2COOC_6H_4NO_2$-*n*

(LXX): $n=1$, X = O;
(LXXI): $n=1$, X = H_2;
(LXXII): $n=2$, X = O;
(LXXIII): $n=2$, X = H_2



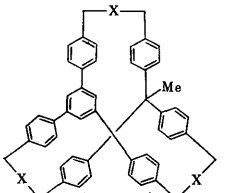
(LXXIV): X = O;
(LXXV): X = H_2

A single-stage method of synthesis of macrobicyclic sulphides[179] has been developed. The macrobicyclic compounds (LXXVI)–(LXXX) have been obtained by the reaction of 1,3,5-tris(mercaptomethyl)- or 1,3,5-tris(mercaptoethyl)-benzene with tris(bromoalkyl)methane or tris(bromoalkyl)-ethane in the presence of sodium hydroxide:



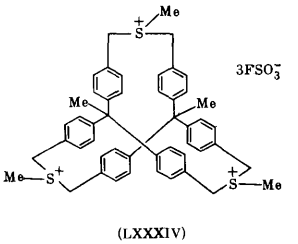
(LXXVI): $n=1$, $m=3$, X = H;
(LXXVII): $n=1$, $m=2$, X = H;
(LXXVIII): $n=2$, $m=3$, X = H;
(LXXIX): $n=2$, $m=2$, X = H;
(LXXX): $n=2$, $m=1$, X = Me.

1,3,5-Tris(mercaptomethyl)benzene has also been used to synthesise the symmetrical triply bridged [2,2,2]cyclophane (LXXXI):[180]

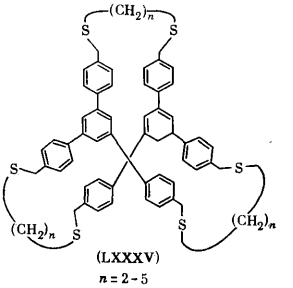


(LXXXI)

The triply bridged polythiacyclophanes (LXXXII)–(LXXXV) have also been synthesised[181]. Trithiatriphenylbenzophane has been produced by the reaction of 1,3,5-tris[(*p*-mercaptomethyl)phenyl]benzene with 1,3,5-tris[(*p*-bromomethyl)-phenyl]benzene in 31% yield:

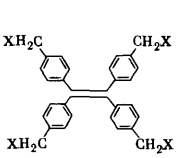


(LXXXII)
X = S, SO_2, $\overset{+}{S}Me \cdot \bar{F}SO_3$

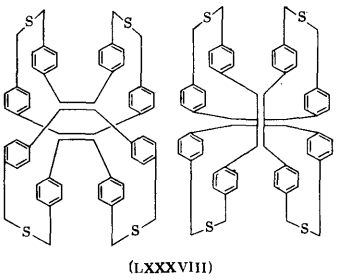


(LXXXIII)
X = SO_2, $\overset{+}{S}Me \cdot \bar{F}SO_3$

Compounds (LXXXV) have been obtained by the reaction of 1,3,5-tris[(*p*-bromomethyl)phenyl]benzene with different α,ω-dithiols:



(LXXXIV)



(LXXXV)
$n=2-5$

The reaction of equivalent amounts of the tetrabromo-compounds (LXXXVI) and the tetrathiol (LXXXVII) at high dilution leads to compound (LXXXVIII), with the four-sided bridged tetraphenylene system in the form of a mixture of two stereoisomers with parallel and orthogonal orientations of the central double bond (Scheme 8);[182] the yield of compound (LXXXVIII) is 4%.

Scheme 8

(LXXXVII): X = SH

(LXXXVIII)

---o0o---

Thus analysis of the literature data has shown that the chemistry of sulphur-containing macroheterocycles has been in recent years the subject of increasing attention of investigators. This is due primarily to the possibility of using macroheterocyclic sulphides as complex-forming agents and extractants for heavy metals. New studies in this field will undoubtedly promote their wider practical application.

Reactivity and Conformation of Systems containing a Three-membered Heterocycle Conjugated with an Unsaturated Group

A.V.Kamernitskii and A.M.Turuta

Steroidal epoxides, aziridines, and episulphides containing a vicinal unsaturated group (ketone or hydrazone) are used as examples to examine, systematise, and generalise reactions involving nucleophilic opening of a three-membered ring. The influence of an adjacent substituent on the structural and stereochemical trends of such reactions is discussed. A list of 107 references is included.

I. INTRODUCTION

The many reviews covering epoxides[1-5], aziridines[6,7], and episulphides[8,9] devote only insignificant space to the reactions of three-membered heterocycles conjugated with keto or other unsaturated group[1,7]. Often the general principles of the chemistry of three-membered rings cannot be used to foretell the direction of ring-opening in such systems, and it is difficult to predict and explain the results of reactions in any particular case[10]. Even in the relatively well-studied field of keto-epoxides definite correlations have not been established between substrate structure, reagent, and the conditions and direction of reactions: several views are held on the mechanism which best describes such reactions[3,10,11]. It may be supposed *a priori* that the direction of ring-opening will be determined by the concerted (or competing) influence of the nature of the heterocycle, the adjacent unsaturated group, and their relative arrangement (interaction). However, to determine the role of each of these factors in studying conformationally labile systems such as aliphatic epoxy(or epi-imino)-ketones is an almost hopeless task.

In fact the nature of the electronic interactions between three-membered ring (epoxy, epi-imino, cyclopropyl)† and neighbouring carbonyl group is usually described as conjugation resulting from orbital overlap of banana bonds of the ring and a *p*-orbital of the carbonyl group[12-14]. After Walsh had predicted[13] the geometrical requirements for such interaction, Cromwell[12] showed that maximum conjugation in such systems is achieved with the planes of carbonyl group and three-membered ring parallel and the keto-group on a bisector of the ring. Therefore the problem of reactivity and direction of ring-opening must, of course, be considered in connection with the conformation of the adjacent portion of the molecule.

The present Review represents an attempt to systematise scission reactions of three-membered rings with steroids as conformationally rigid models, in which the side-chain containing the unsaturated group adjacent to the three-membered ring is capable of rotating about the $C_{(17)}-C_{(20)}$ bond:

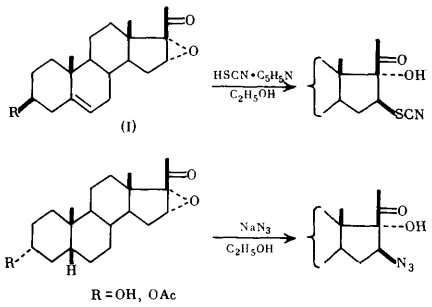
β-region (front) of molecule

X=O, NH, NAc, S Z=O, $NNHCO_2C_2H_5$ R=OH, OAc, Δ^5; O, Δ^4

α-region (rear) of molecule

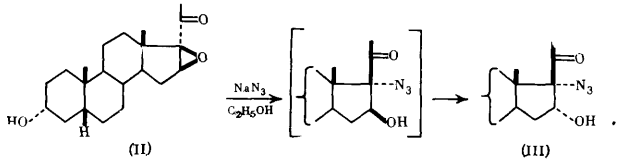
Because of structural and electronic features, however, the barrier to rotation is quite high, and the molecule is fixed in one of the preferred conformations depending on the nature of the heterocycle and its immediate environment[15-17]. This enables the relative influence of the above factors on reactivity and direction of reaction to be traced from stereochemically reliable data on ring-opening in such systems.

II. RING-OPENING IN EPIMERIC 16,17-EPOXY-20-OXO-STEROIDS



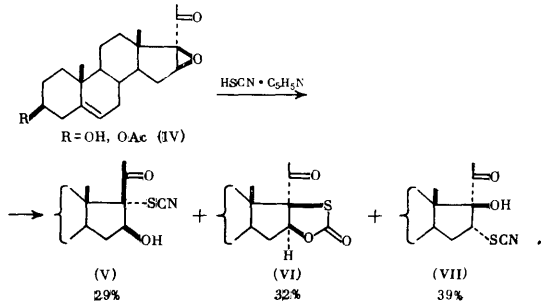
Among the 16,17-hetero-substituted 20-keto-steroids discussed only the epoxy-ketones have been widely studied; they showed clearly that the structural and stereochemical direction of ring-opening depends on the structure of the oxide, the nature of the reagent, and the reaction conditions. Most of the reactions studied are examples of acid-catalysed nucleophilic ring-opening. Exceptions are provided by the scission of 16,17-epoxy-20-ketones by highly nucleophilic reagents and by their aminolysis, which we shall consider first. In the former case solvation of the oxide ring by protons of the solvent provides electrophilic assistance to scission, and in the latter case the reagent itself acts as an alkaline catalyst.

1. Ring-opening under Neutral Conditions and Aminolysis



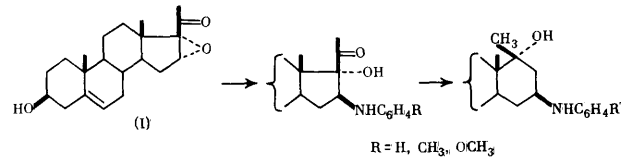
In neutral media 16,17α-epoxy-20-oxo-steroids (I) undergo exclusively *trans*-opening of the oxide ring at the more

†Episulphides containing a vicinal unsaturated group have not hitherto been studied.

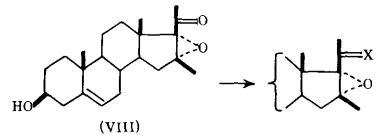


substituted carbon atom[18-20]:

A protic solvent undoubtedly helps to increase the reaction velocity, for in an aprotic medium the reaction, e.g. with thiocyanic acid, does not take place[19]. The analogous reactions of 16,17β-epoxy-20-oxo-steroids occur with the opposite structural selectivity. The only product of azidolysis of the 16,17β-epoxide (II) under identical conditions is that of attack by the azide ion at the tertiary atom with Walden inversion, epimerisation at the $C_{(16)}$ atom being regarded[20] as a secondary process:



Reaction of the 16,17β-epoxide (IV) with thiocyanic acid is not so selective[21,22]. The tendency to preferential but not exclusive attack at the tertiary centre is maintained. However, both *trans*- and *cis*-scission products (V) and (VI) are formed, with a total yield of 60–65%:[21]

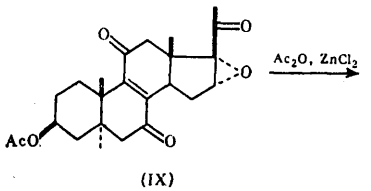


Attack at the secondary atom with formation of the *trans*-hydroxy-thiocyanate (VII) takes place to a lesser but appreciable extent (~40%).

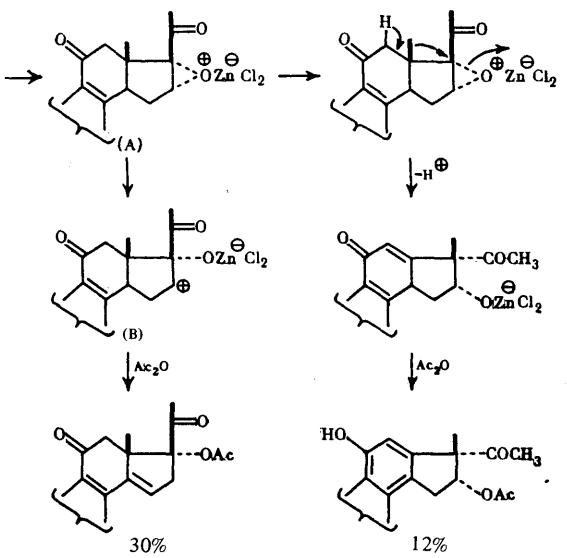
These results on the scission of 16,17β-epoxy-20-oxo-steroids by thiocyanic and hydrazoic acids, at first glance contradictory, become consistent on the assumption that formation of the 17α-azide (III) is a consequence of a retroaldol type of epimerisation[23] not of one, as had been assumed[20], but of two 17-azides, with α- and β-configurations of the azide function, formed in the reaction medium. Such epimerisation is, of course, completed by stabilisation of the thermodynamically more stable isomer (III) having β-orientation of the 17-acetyl group.

No information has been published on the aminolysis of 16,17β-epoxy-20-oxo-steroids, while results on the structure and configuration of products obtained with ring-opening of their 16,17α-epimers by amines are very few and contradictory[24]. A critical approach must be adopted to most of the early literature, mainly patents, with reference to the formation of 16-amino-17α-hydroxy-20-oxo-steroids on reaction with primary and secondary amines[25-27], since structures were assigned to the products without evidence. According to Frangulyan et al.[24,28,29] opening of the oxide ring of 16,17α-epoxy-20-oxo-steroids by aromatic amines (aniline, *p*-toluidine, *p*-anisidine) takes place with D-homoisomerisation, which implies initial formation of 16β-amino-17α-hydroxypregnanes, attempts to isolate which proved unsuccessful:

Even these few results show that, in the ring-opening of 16,17α-epoxy-ketones by bases, attack by the nucleophile is directed at the secondary centre, the β-position. When such attack is sterically hindered, as e.g. in the action of ammonia or a primary amine on the 16,17α-epoxy-16β-methyl-ketone (VIII), reaction takes place at the 20-oxo-group with elimination of water and without involving the oxide ring[30]:

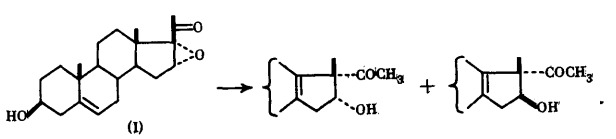


2. Acid-catalysed Ring-opening of Epimeric 16,17-Epoxy-20-oxo-steroids



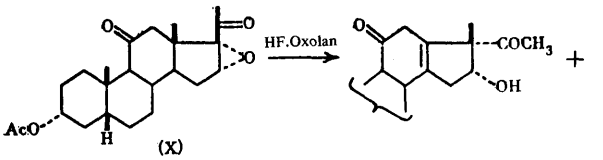
Reactions of this type include the ring-opening of 16,17-epoxy-20-oxo-steroids by hydrohalic acids (below) and the addition of water, acetic acid, methanol, thioacetic acid, hydrazoic acid, and other reagents catalysed by mineral or Lewis acids. They have been referred to many times in the literature, but with few exceptions the complete pattern of structural and steric trends has not been studied. The present Review is confined to published results, including a complete analysis of the reaction mixture. Protonation of the oxide ring or coordination with a Lewis acid is a necessary stage in these processes[3]. The direction of opening of the oxide ring depends both on the structure and stereochemistry of the initial oxide and on the nucleophilicity of the reagent.

In the acid-catalysed ring-opening of 16,17α-epoxy-20-oxo-steroids the tendency of the oxide to break at the tertiary centre closest to the keto-group increases in proportion to the decrease in nucleophilicity of the reagent. Incorporation of the nucleophile at the $C_{(17)}$ atom is observed only in exceptional cases and to an extremely insignificant extent. Stabilisation of the positive centre formed is usually completed by 1,2-migration of the angular methyl group. Thus in reactions of this type with weak nucleophiles or in their absence intermediate products are stabilised by rearrangements involving rupture mainly of the $C_{(17)}$–O and to a less extent the $C_{(16)}$–O bond[31], with the quantity of open-chain products apparently measuring the stability of the intermediates. A reaction of interest from

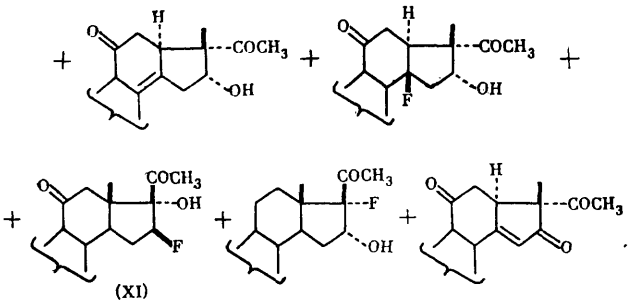


this point of view is that of the 16,17α-epoxide (IX) with acetic anhydride catalysed by zinc chloride[32], regarded as taking place by two competing routes, one of which involves a Wagner–Meerwein rearrangement by a synchronous mechanism with elimination of a proton from $C_{(12)}$ followed by enolisation and replacement of zinc chloride by an acylium ion:

(IX)

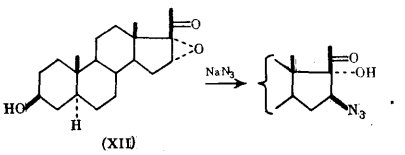


The alternative ring-opening of the intermediate A will give the 16-carbocation B, which is stabilised with elimination of a proton from the $C_{(15)}$ atom followed by allyl rearrangement of the $\Delta^{15,16}$ bond to a conjugated position. Apparently the relative contents of products formed with rupture of the $C_{(17)}$–O or $C_{(16)}$–O bond in reactions of this type depend to a considerable extent on the structure of the initial oxide and the catalyst used. Thus hydrolysis of the 16,17α-epoxide (I) in methanol catalysed by perchloric or sulphuric acid is 75–80% accompanied by a Wagner–Meerwein rearrangement with formation of an equilibrium mixture of epimers at the $C_{(16)}$ atom[33]:



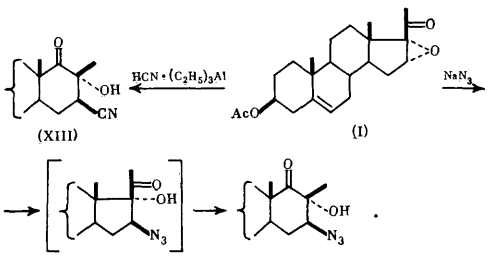
(I)

A similar structural trend is exhibited by the action of hydrogen fluoride on the epoxide (X), which differs from the reactions with hydriodic and hydrobromic acids[34–36] in involving rupture of the $C_{(17)}$–O bond and is usually completed by migration of the angular methyl group[37]; the expected *trans*-fluorohydrin (XI) is formed in only 2% yield:



(X)

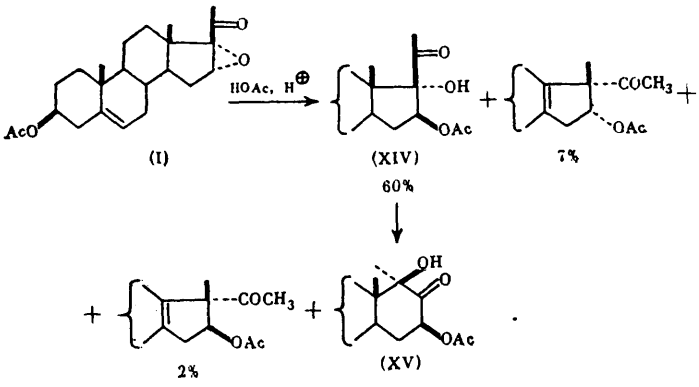
(XI)



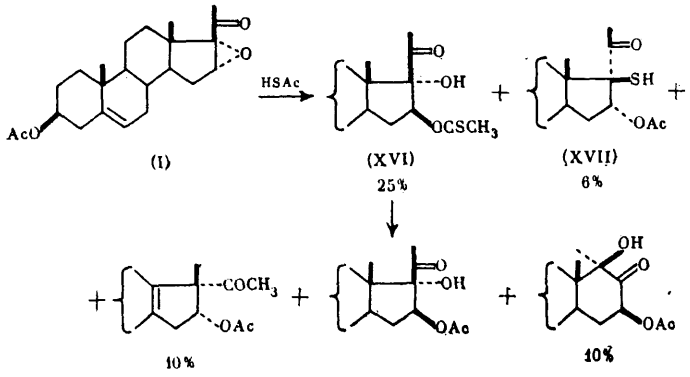
Ring-opening of 16,17α-epoxy-ketones with hydrobromic or hydriodic acid, which is most widely used in practice, is reported as yielding 30–70% of *trans*-products with rupture of the $C_{(16)}$–O bond and incorporation of the halogen at this position[34–36].

The acid-catalysed reactions of 16,17α-epoxy-20-oxo-steroids with such strongly nucleophilic reagents as e.g. azide and cyanide ions exhibit high stereo- and regio-selectivity. The course of the reaction of the epoxide (XII) with sodium azide in dimethyl sulphoxide (DMSO) catalysed by sulphuric acid is identical[38] with that described above in ethanol:

(XII)



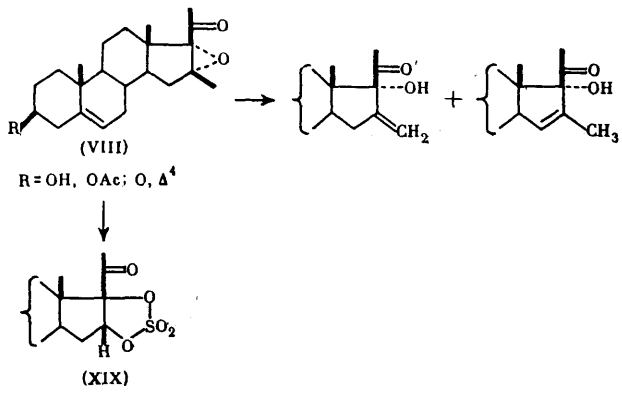
The same reaction is reproduced under identical conditions by the epoxide (I),[39] but a D-homostructure is attributed to the final product. It must be assumed that the absence of D-homoisomerisation in the preceding case is due to the greater stability of the D-ring in 5α-steroids. A similar result has been reported for scission of epoxide (I) by the hydrogen cyanide–triethylaluminium complex[40]; formation of the D-homoketone (XIII) is not unexpected, because of the Lewis nature of the reagent:



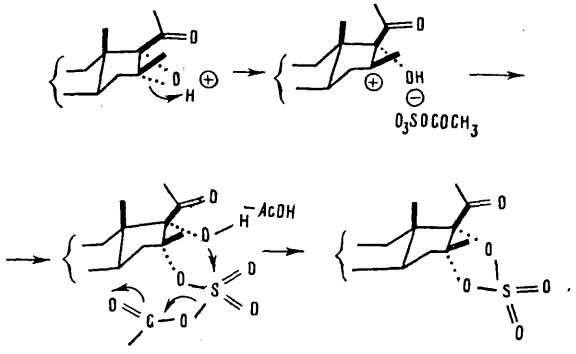
(XIII) (I)

Acetic and thioacetic acids, which are quite strong nucleophiles but considerably weaker than hydrazoic, thiocyanic, hydrobromic, and hydriodic acids, react with the oxide ring

of 16,17α-epoxy-20-oxo-steroids only in the presence of a mineral acid as catalyst. Such reactions are characterised not only by preferential *trans*-opening of the oxide at the secondary centre but also by rupture of the $C_{(17)}$–O bond[41,42]. The main direction in which 16,17α-epoxides are opened by acetic acid is *trans*-attack at the $C_{(16)}$ atom with formation of the 16β-acetate (XIV), which apparently isomerises into the D-homoketone (XV):[41]



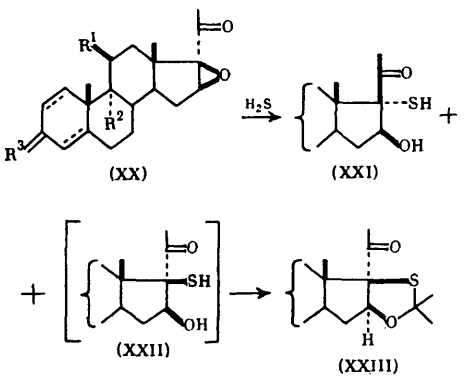
Rupture of the $C_{(17)}$–O bond followed by a Wagner–Meerwein rearrangement is observed to a considerably less extent. Such is the general direction in which the oxide (I) reacts with thioacetic acid in the presence of an inhibitor of free-radical addition and sulphuric acid as catalyst[42]. Thioacetic acid, which reacts in the *O*-form, attacks the $C_{(16)}$ atom to form the 16-O-thioacetate (XVI), which under the reaction conditions hydrolyses to the diacetate (XVIII):



A feature of the reaction is formation of the 17β-thiol (XVII), formally a product of *trans*-opening of the oxide by hydrogen sulphide with attack at the tertiary carbon atom. It must not be forgotten, however, that hydrogen sulphide ions are able to add to a carbonyl group[3,43], so that an alternative possibility is addition to the keto-group of hydrogen sulphide formed by decomposition of thioacetic acid, followed by intramolecular attack at the $C_{(17)}$ atom.

In the ring-opening of 16,17α-epoxy-16β-methyl-20-oxo-steroids by acidic reagents, in contrast to desmethyl oxides, incorporation of the nucleophilic reagent is not usually observed: reactions are completed by formation of unsaturated alcohols, the proportions of which vary with the reaction conditions (reagent, solvent), their formation being regarded as resulting from stabilisation of the $C_{(16)}$ carbocation by elimination of one of the neighbouring protons[44,45]. The direction of stabilisation is largely determined by the possibility of solvation of the 16-centre.

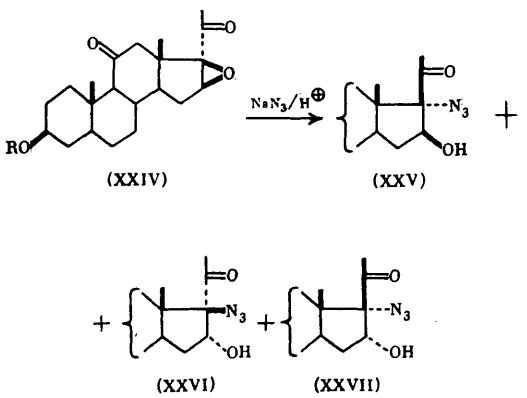
An extremely interesting reaction is the production of 16α,17α-cyclosulphates (XIX) in the ring-opening of the 16β-methyl oxide (VIII) by oleum in glacial acetic acid or by a mixture of acetic anhydride and sulphuric acid in acetic acid, formally involving *cis*-opening of the oxide ring and addition of sulphur trioxide[46]:



The postulated mechanism involves rupture of the $C_{(16)}$–O bond in the protonated form of the oxide by acetylsulphuric acid, apparently formed by interaction of acetic anhydride with sulphuric acid. Because of steric hindrance by the 13-methyl group, approach of the acetylsulphate ion to the $C_{(16)}$ atom takes place preferentially from the rear of the molecule:

Intramolecular acylation of the free hydroxy-group of the mixed anhydride of sulphuric and acetic acids is assumed to take place in the intermediate product, with formation of a cyclic sulphate[44]. The ease of such transesterification is explained by the close approach of the vicinal *cis*-substituents in the five-membered ring, and bears an analogy to the well-known 17 → 16 acyl migration[1].

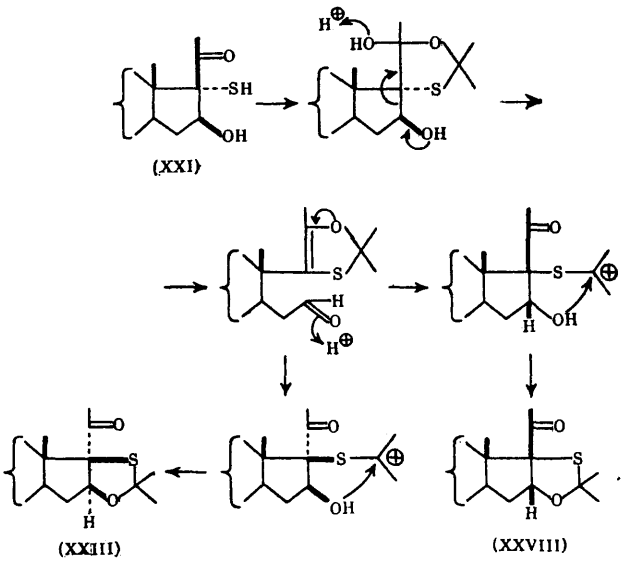
The structural direction of ring-opening in 16,17β-epoxy-ketones is less influenced by the reaction conditions: all the reported acid-catalysed reactions occur regiospecifically with rupture of the carbon–oxygen bond at the tertiary carbon atom closest to the carbonyl group. The subsequent behaviour of the resulting intermediate, however, depends to a considerable extent on the conditions: use of an acid catalyst and weakening of the nucleophilicity of the reagent favour isomerisation involving the $C_{(17)}$ centre. On interaction with strongly nucleophilic reagents such as hydrazoic acid[20,38,47], hydrobromic acid[48,49], and hydrogen sulphide[22,50] stabilisation of this centre is effected solely by addition of the nucleophilic species. *trans*-Opening of the oxide at the $C_{(17)}$ atom with incorporation of the nucleophile from the



rear of the molecule is the preferred but not exclusive direction of the reactions of 16,17β-epoxy-ketones, for which addition of the nucleophile at the $C_{(17)}$ atom from the β-region is also very characteristic. The stereochemistry of opening of the epoxide ring in (XX) with hydrogen sulphide and sodium azide is interesting. In the reaction of the epoxide with hydrogen sulphide in acetic acid catalysed by toluene-*p*-sulphonic acid the preferred product of *trans*-opening—the thiol (XXI)—is accompanied[22,50] by the *cis*-16,17β-isomer (XXII), identified as the acetonide (XXIII):

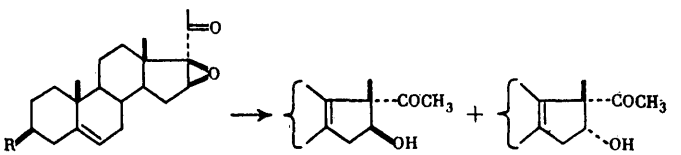
(XX) (XXI) (XXII) (XXIII)

R^1=H, OH, OAc;
R^2=H, F;
R^3=O, β-OAc, $\Delta^{1,4}$, Δ^4, Δ^5.



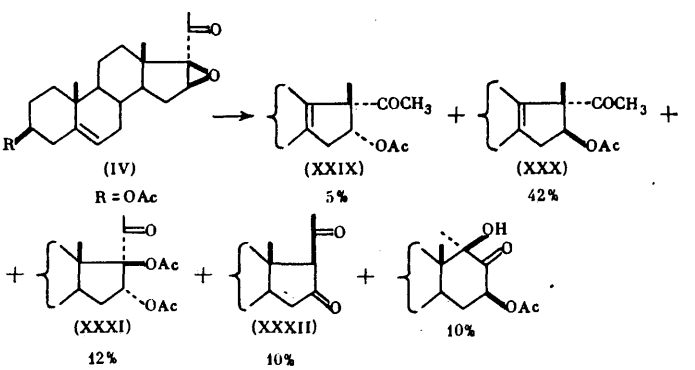
Reaction of the epoxide (XXIV) with sodium azide in the presence of sulphuric acid in DMSO involves formation of the three epimeric azides (XXV)–(XXVII), the proportion of the 16,17α-isomer (XXVII) increasing with the duration of reaction[38]:

(XXIV) (XXV) (XXVI) (XXVII)



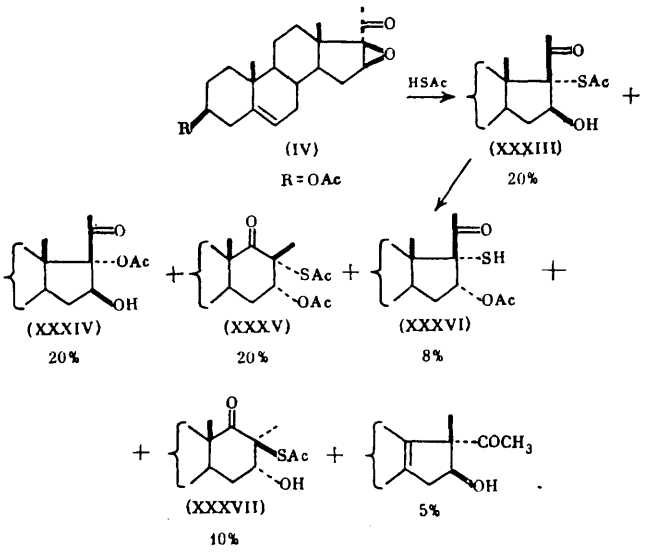
R=H, Ac.

The view[22,37] that a 17α-azido(or mercapto)-16β-ol is formed initially, and isomerises under the reaction conditions by a retroaldol mechanism, is supported by experiment. Thus the *trans*-thiol (XXI) condenses with acetone in the presence of an acid to give the oxathiolan (XXVIII) and its epimer (XXIII), whose formation can be represented



(XXI) (XXIII) (XXVIII)

Nevertheless, these results do not exclude the possibility of direct attack by the hydrogen sulphide or the azide ion from the front of the molecule at the $C_{(17)}$ atom. The tendency for the oxide ring to open at this atom from the β-region in the acid-catalysed reactions of 16,17β-epoxy-20-oxo-steroids is especially clearly evident in the hydrolysis of the epoxide (IV), which occurs solely with migration of the angular methyl group[33]:

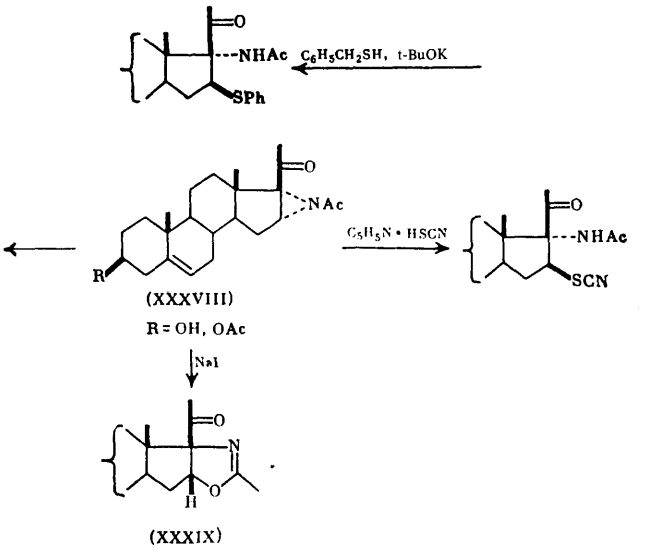


(IV)
R=OH.

Such a structural trend is maintained in the acetolysis of the β-epoxide (IV), when Wagner–Meerwein rearrangement products (XXIX) and (XXX) are accompanied by the *trans*-diacetate (XXXI), formation of this last compound being observed by attacking with the acetate ion from the β-region to neutralise the 17-carbocation and then epimerising and acetylating at $C_{(16)}$:[33]

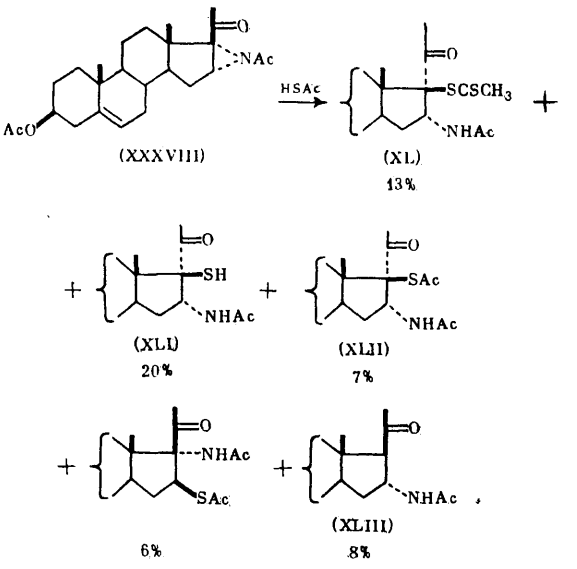
(IV) (XXIX) (XXX) (XXXI) (XXXII)
R=OAc 5% 42% 12% 10% 10%

The *S*-thioacetate (*O*-thioacetate) ion is more nucleophilic than acetate, which influences the action of thioacetic acid on the β-epoxide (IV), when incorporation of the nucleophile at the $C_{(17)}$ atom from the rear of the molecule is the main route[51,52]. The *cis*-isomer (XXXVI) is a secondary product of epimerisation of the 17α-*S*-thioacetate (XXXIII) formed initially, while the 17α-acetate (XXXIV) is a secondary product of hydrolysis of the 17α-*O*-thioacetate formed in the reaction:



Formation of the D-homoisomers (XXXV) and (XXXVII) is apparently a consequence of D-homoannelation of the primary products of ring-opening.

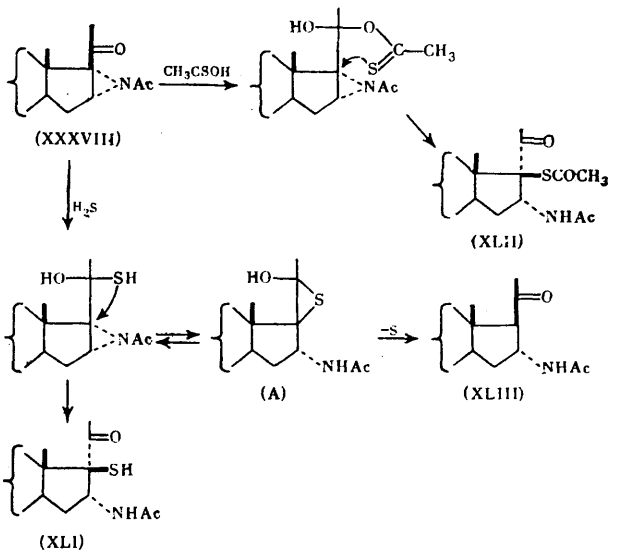
III. OPENING OF THE AZIRIDINE RING IN 16,17α-EPI-IMINO-20-OXO-STEROIDS AND THEIR *N*-ACETATES



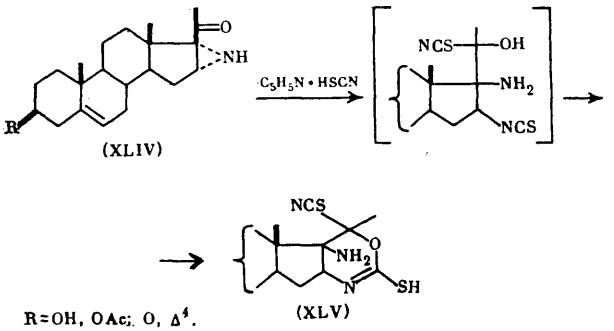
The chemistry of 16,17-epi-imino-20-oxo-steroids has not been developed so actively as that of the 16,17-epoxy-derivatives. Of the two epimeric 16,17ξ-epi-imino-ketones only the 16,17α-isomer has been prepared for study of its ring-opening reactions[53–59]. Existing results indicate firstly low reactivity not only of basic (NH) but also of activated# aziridines in ring-opening and secondly an enhanced tendency for the 20-oxo-group to undergo nucleophilic addition. Thus 16,17α-epi-imino-20-oxo-steroids and their *N*-acetates are inert under conditions under which the corresponding epoxides undergo ring-opening (under the influence of water, hydrazoic acid, acetic acid, methanol), and do not react with potassium thiocyanate in acetic acid[58]; under more severe conditions, in particular catalysis by mineral acids, a Wagner–Meerwein rearrangement takes place exclusively. 16,17α-Acetylepi-imines react only with such nucleophilic reagents as benzenethiol[65,56], pyridine–thiocyanic acid[58], and sodium iodide[57].

These reactions occur by paths characteristic of bio-molecular nucleophilic substitution with rupture solely of the $C_{(16)}$–N bond with inversion of configuration at this centre:

Formation of the 2′-methyl-[16,17α-*d*]oxazoline (XXXIX) by the action of sodium iodide on (XXXVIII) [39] must apparently be regarded as involving double Walden inversion–initial attack by the iodide ion at the $C_{(16)}$ atom followed by intra-molecular substitution of iodine by an internal nucleophile from the rear of the molecule.



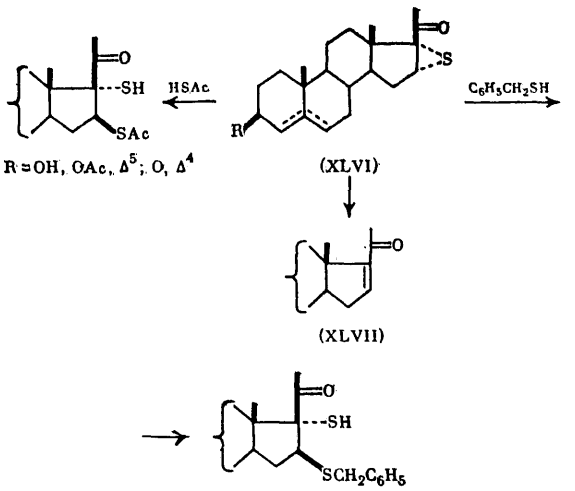
The course of reaction of the *N*-acetylepi-imine (XXXVIII) with thioacetic acid contradicts the general rule of orientation, and leads to preferential rupture of the tertiary $C_{(17)}$–N bond:



It could be included formally among acid-catalysed reactions of activated aziridines, which take place exclusively (above) with rupture of the $C_{(17)}$–N bond, completed by a Wagner–Meerwein rearrangement. Stabilisation of the $C_{(17)}$ centre should then lead not only to *trans*-addition of the *S*-acetate ion but also to migration of the angular methyl group, which has not been observed. The most acceptable explanation of the observed anomaly[59] is that the largest partial positive charge in the *N*-acetylepi-imine molecule (XXXVIII) is localised on the carbonyl $C_{(20)}$ atom, and this with the

#Activated aziridines have a substituent attached to the nitrogen atom, capable of stabilising the negative charge formed on the nitrogen in the transition state when the compound reacts with a nucleophile[6].

general inertness of the molecule creates favourable conditions for nucleophilic attack on this centre, the reactive species being thioacetatic either *S*- or *O*-acid:



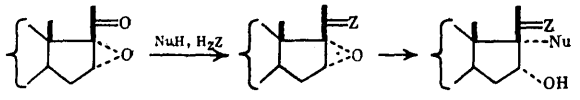
Subsequent intramolecular attack on the $C_{(17)}$ atom with synchronous rupture of the $C_{(17)}$–N bond is assumed to yield the amides (XLI) and (XLII), the former being acylated under the reaction conditions by thioacetic *O*-acid to give (XL). In terms of this scheme formation of the amide (XLIII) was regarded as involving the intermediate episulphide (A), which is desulphurised under acid conditions. This mechanism is consistent with the above tendency of hydrogen sulphide to add to the carbonyl group in epoxy-ketones[3] and also with that of thiocyanic acid to attack the keto-group in 16,17α-epi-imines (XLIV) to form (XLV) [60]

IV. REACTIVITY AND DIRECTION OF RING-OPENING IN 16,17α-EPITHIO-20-OXO-STEROIDS

Epithio-ketones as a class have remained almost unstudied, and no data on physicochemical properties or chemical behaviour are available other than those obtained for 16,17α-epithio-keto-steroids obtained in the Reviewers' laboratory[61,62]. 16,17α-Episulphides are intermediate in reactivity[22,61] between the corresponding oxygen and nitrogen compounds. They are inert under conditions under which the corresponding 16,17α-epoxides undergo ring-opening by such reagents as acetic, thiocyanic, and hydrazoic acids and methanol[62]. Raising the temperature or increasing the duration of reaction leads to elimination of sulphur with formation of the enone (XLVII) and subsequent addition of the nucleophilic reagent to the resulting double bond:

An exception is provided by the reactions of the episulphide (XLVI) with thioacetic acid and with phenylmethanethiol, which involve *trans*-opening of the ring at the less substituted atom $C_{(16)}$. Nucleophilic desulphurisation of the episulphide (XLVI) competes with nucleophilic ring-opening and in most cases predominates. Several aspects must be noted: (*a*) catalysis by a mineral acid (hence protonation of the episulphide ring) is not a necessary condition for elimination reactions [in a weak nucleophile—methanol, acetic acid—the epithio-ketone (XLVI) is stable in the presence of a mineral acid at 20 °C]; (*b*) the presence in the reaction medium of a strong nucleophile promotes desulphurisation even in the absence of a mineral acid (potassium thiocyanate in ethanol at ~80 °C); and (*c*) desulphurisation is equally promoted by a base. In contrast to epoxy(and epi-imino)-ketones the isomeric epithio-ketones (XLVI) apparently do not undergo reactions involving rupture of the $C_{(17)}$–S bond with stabilisation of the resulting electrophilic centre by 1,2-migration of the angular methyl group. If this bond is broken, the molecule is most probably stabilised by elimination of sulphur.

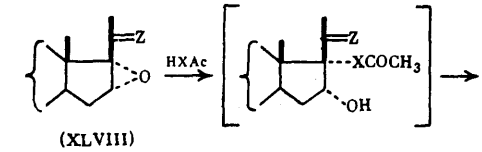
V. INVOLVEMENT OF A HYDRAZONE GROUP IN RING-OPENING IN 16,17-EPOXY(EPI-IMINO, EPITHIO)-20-OXO-STEROIDS



Replacing a keto-group by a hydrazone fragment increases markedly the reactivity of α-substituted ketones in elimination and substitution reactions, in which configuration is usually maintained[63]. This property of hydrazones has been thoroughly studied from both practical and theoretical points of view in a series of investigations undertaken in the Reviewers' laboratory on the involvement of the hydrazone fragment in opening the oxide[64–84], epi-imino[85–95], and episulphide[62,96] rings of 16,17-epoxy(epi-imino, epithio)-20-oxo-steroids. The resulting generalisations have been applied to the controlled modification of steroidal compounds. The stereochemical aspect and the mechanism have been studied in detail on 16,17-epoxy-ketones, with examination of the influence of the stereochemistry of the initial oxide on the stereochemical direction

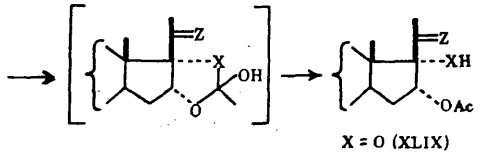
in which the oxide ring is opened by nucleophilic reagents[63,97].

1. Epimeric 16,17ξ-Epoxy-20-oxo-steroids



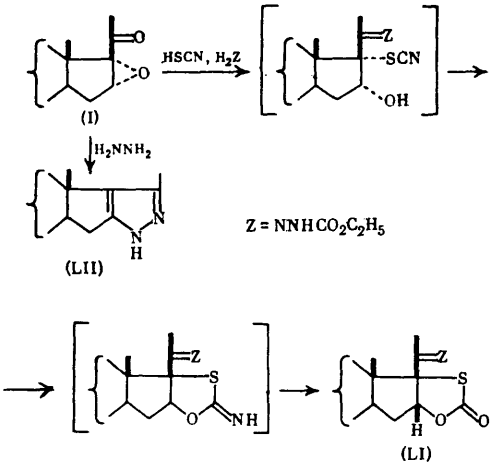
The presence of a reagent for the carbonyl group (a hydrazine) produces a marked change in the direction of ring-opening in 16,17-epoxy-ketones. In all cases regio-specific *cis*-opening of the ring is observed at the position closest to the hydrazone group; the general reactivity of the system towards ring-opening reactions is appreciably enhanced. Hydrazine plays a direct part in the reactions, adding to the keto-group by the stage preceding ring-opening[75,81,83] and forming the 20-hydrazone of the corresponding oxide[64,76-78]. With the above general structural direction of opening in 20-hydrazones of epimeric 16,17α-epoxy-ketones the final result is different and depends solely on the stereochemistry of the oxide ring.

The general scheme of ring-opening in 16,17α-epoxides in the presence of ethyl hydrazine carboxylate is

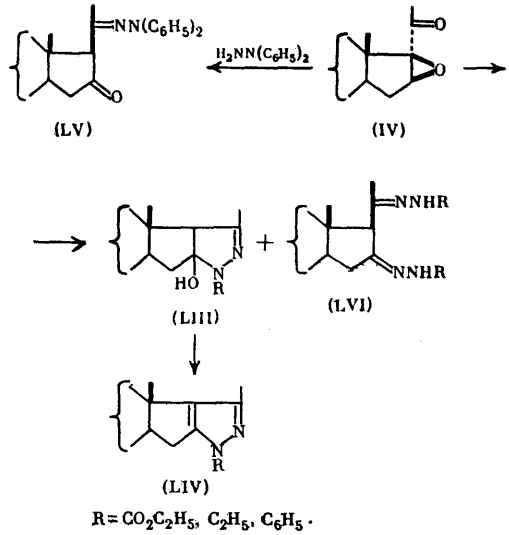


Nu = OH[65], OCH_3[67], OAc[64], SAc[71, 72], N_3[68-70], SCN[73, 74]
$Z = NNHCO_2C_2H_5$

where the reagents used for this purpose are enumerated. All the reactions take place stereo- and regio-specifically with *cis*-opening of the oxide ring at the tertiary carbon atom and incorporation of the reagent from the rear of the molecule. The *cis*-position of the resulting vicinal group quite often favours secondary cyclisation involving these substituents, a particular case of which is acyl migration. Thus reaction of the epoxide (I) with acetic and thioacetic acids under conditions of *cis*-opening[64,71,72] yields the 17α-hydroxy(or mercapto)-16α-acetates (XLIX) or (L), formed by the well-known route[97] via the orthoester intermediate:



(XLVIII)
$Z = NNHCO_2C_2H_5$, X = O, S

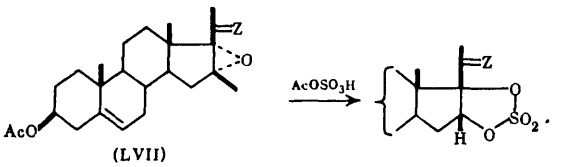


X = O (XLIX)
X = S (L).

The analogous reaction of the hydrazone (XLVIII) with thiocyanic acid yields the thiocarbonate (LI):

Exclusion of the nucleophilic reagent from the reaction medium directs the reaction of 20-hydrazones of 16,17α-epoxides towards cyclisation and formation of the pyrazole (LII).[83] This competes with the main reaction of (XLVIII) with thioacetic acid[72].

Incorporation of nucleophilic reagents is not observed in the ring-opening of 20-hydrazones of epimeric 16,17β-epoxides. Intramolecular cyclisation predominates, yielding the hydroxypyrazoline (LIII), which eliminates water to form the pyrazole (LIV):[78,79]

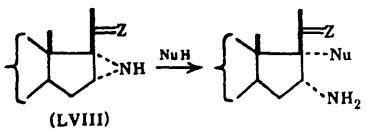


$R = CO_2C_2H_5$, C_2H_5, C_6H_5.

Use of diphenylhydrazine as reagent for a keto-group directs the process towards formation of a monohydrazone of the diketone (LV):[80,84] the second keto-group is not replaced by a hydrazone residue owing to steric hindrance. In several cases, e.g. in the presence of excess of ethyl hydrazinecarboxylate in acetolysis of the 16,17β-epoxide (IV), the dihydrazone (LVI) is formed together with the pyrazoline (LIII).[78] Complete elimination of deuterium in *cis*-ring-opening of the 16-deuterated 16,17β-oxide (IV) by acetic acid in dioxan indicates that these reactions occur with detachment of a proton from the $C_{(16)}$ atom and formation of the Δ^{16}-16-ol, which is then stabilised either by

intramolecular cyclisation involving the hydrazone fragment or by ketonisation[84].

The ditertiary 16β-methyl-16,17α-oxide (VIII) is an extremely interesting but little studied compound undergoing *cis*-ring-opening[46,98,99]. Both substituents adjacent to the epoxide, apparently involved in destabilising the carbocations formed when its ring opens, should promote cleavage of the epoxide bond in both directions. Nevertheless, the heterocycle in the epoxide hydrazone (LVII) is inert towards the ring-opening reactions of hydrolysis and acetolysis catalysed by mineral acids[98]. More severe conditions cannot be applied to the oxide 20-hydrazones owing to initial hydrolysis of the hydrazone group. Perhaps the only ring-opening reaction of the 16β-methyl oxide (LVII) that has been studied is the action of acetylsulphuric acid, which goes formally in the same direction as the corresponding reaction with the 16β-methyl-20-oxo-16,17α-oxide (VII):[46]

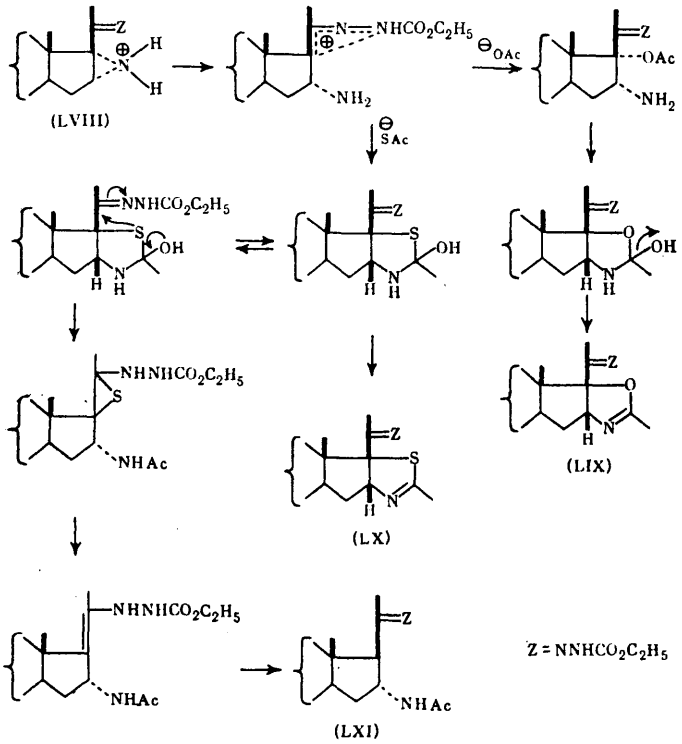


(LVII)

Z = $NNHCO_2C_2H_5$

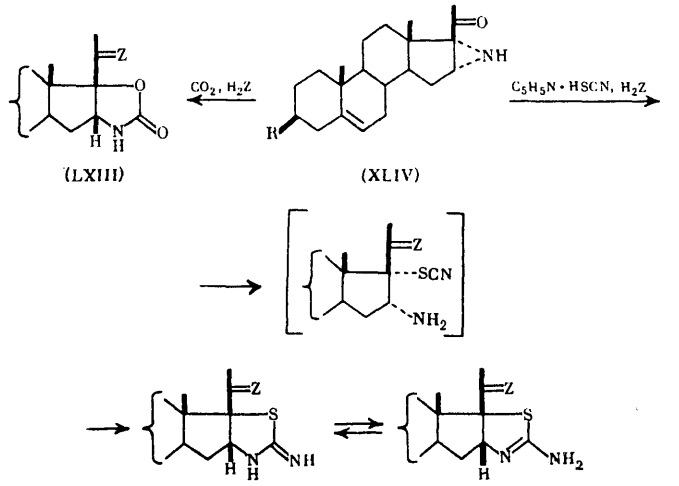
2. *cis*-Ring-opening of 20-Hydrazones of 16,17α-Epi-imino-steroids

The synthetic aspect of *cis*-opening has been extended significantly to 16,17α-epi-imino-20-oxo-steroids[85-95,100,101]. They exhibit several general features—(*a*) high reactivity, exceeding by several times that observed for the epoxy-analogues, (*b*) addition of hydrazine at the keto-group in the stage preceeding ring-opening, (*c*) exclusive stereo- and regio-specificity of ring-opening at the position adjacent to the hydrazone fragment, and (*d*) occurrence under the reaction conditions of secondary cyclisation processes involving the 16,17α-*cis*-group formed—independently of the presence or absence of an *N*-substituent. A mechanism of *cis*-opening suggested for 16,17-epoxy-steroids has been extended to reactions involving 16,17α-epi-imino-ketones, and used to explain the changes observed[100].



Exclusive incorporation of the nucleophilic reagent in the α-position to the hydrazone fragment from the rear of the molecule has been recorded in reactions of the 20-hydrazone (LVIII) with such reagents as hydrazoic acid[90,91,94], hydrogen fluoride[95], hydrogen chloride[88], water[87], and hydrogen sulphide[93], with formation of the 20-hydrazones of the corresponding products of *cis*-opening of the heterocycle:

(LVIII)

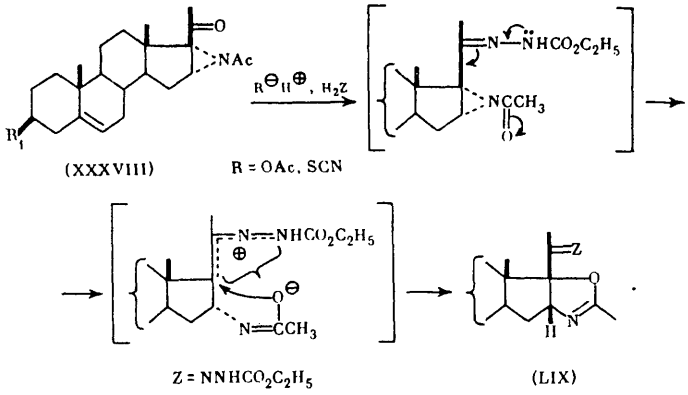


Z = $NNHCO_2C_2H_5$; Nu = N_3, F, OH, SH, Cl.

Attack by acetate (or *S*-thioacetate) ions at the $C_{(17)}$ atom in reactions of the epi-imine (LVIII) with acetic[85] and with thioacetic[86] acids is completed by cyclisation by the ortho-ester mechanism with formation respectively of the 2'-methyl-oxazoline (LIX) at the 2'-methylthiazoline (LX); water is eliminated at the stage of orthoester formation:

It is assumed that, in the action of thioacetic acid on the hydrazone (LVIII), stabilisation of the orthoester intermediate by intramolecular attack by sulphur at the $C_{(20)}$ atom in conformity with the above scheme leads to formation of the amide (LXI) as well as the thiazoline (LX).

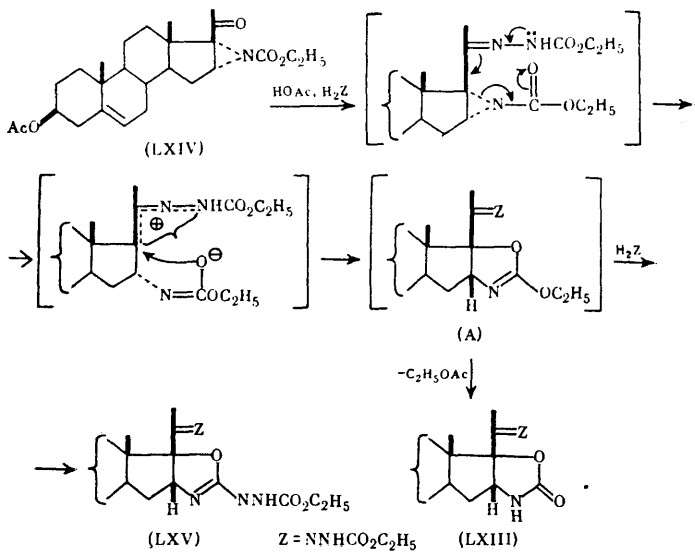
Thiocyanic acid acts on the epi-imine (XLIV) to produce *cis*-ring-opening in the general direction, leading to incorporation of the thiocyanate ion in the vicinal position to the hydrazone group followed by cyclisation to a 2'-iminothiazolidine in tautomeric equilibrium with the 2'-aminothiazoline form (LXII):[86]



(LXII)

R = OH, OAc; Z = $NNHCO_2C_2H_5$.

The stereochemical requirements of reactions involving expansion of a three-membered to a five-membered ring suggest initial *trans*-opening followed by cyclisation, so that such reactions are atypical in polycyclic systems. It is interesting in this connection that the epi-imino-ketone (XLIV) reacts readily with carbon dioxide in the presence of ethyl hydrazinecarboxylate to form the oxazolidinone (LXIII): i.e. the favourable stereochemistry of ring-opening makes this process entirely feasible[101].

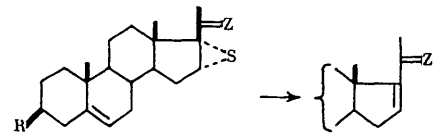


The general direction of ring-opening in *N*-substituted 16,17α-epi-imino-ketones in the presence of ethyl hydrazinecarboxylate does not differ fundamentally from that of their unsubstituted analogues, but stabilisation of the resulting 17-carbocation is effected not by incorporation of an external nucleophile but by intramolecular isomerisation involving an internal nucleophile. As a consequence, independently of whether an external nucleophile is or is not present, reaction with the *N*-acetylepi-imine (XXXVIII) results in formation of the oxazoline (LIX):

(XXXVIII) R = OAc, SCN

Z = $NNHCO_2C_2H_5$ (LIX)

The synthetic possibilities of the reaction can be extended by varying the *N*-substituent to obtain various new types of steroid heterocycles with a nitrogen atom attached to $C_{(16)}$. Thus formation of the oxazolidinone (LXIII) and its 2′-hydrazine derivative (LXV) in the reaction of the 16,17α-ethoxycarbonylepi-imine (LXIV) with ethyl hydrazinecarboxylate in acetic acid involves nucleophilic intramolecular cyclisation affecting the ethoxycarbonyl group[92,101]:



(LXIV) (A)

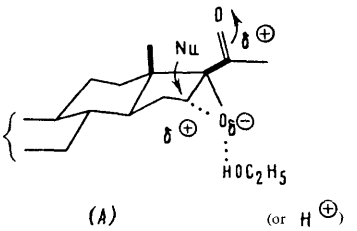
(LXV) Z = $NNHCO_2C_2H_5$ (LXIII)

It is assumed that the intermediate 2′-ethoxyoxazoline (A) reacts further by two independent paths: it either undergoes attack by the acetate anion with elimination of ethyl acetate or it condenses with a second molecule of ethyl hydrazinecarboxylate.

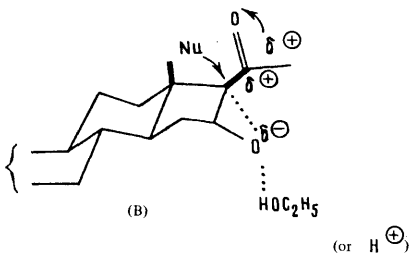
3. Opening of the Three-membered Ring in Ethoxycarbonylhydrazones of 16,17α-Epithio-steroids

Replacement of the oxo-group by a hydrazone fragment in 16,17α-epithio-20-oxo-steroids, in contrast to the above reactions of the 16,17α-epoxy(and epi-imino)-analogues, does not enhance the general reactivity of the episulphide ring. Moreover, the 20-ethoxycarbonylhydrazone of the 16,17α-epithio-ketone (LXVI) even exhibits some decrease in such reactivity, with an enhanced tendency to eliminate sulphur. It is sufficient to mention that, under the conditions of preparation (acetic acid and ethyl hydrazinecarboxylate at 20 °C), this hydrazone (LXVI) is converted partly—and to a greater extent with increase in exposure—into the alkene (LXVII):

(LXVI) (LXVII)



R = OH, OAc; Z = $NNHCO_2C_2H_5$.



Reactions of the hydrazone (LXVI) have been studied with a wide range of reagents—water, methanol, acetic, thioacetic, and thiocyanic acids, the pyridine complexes of thiocyanic acid and of hydrogen fluoride, hydrazoic acid, ethanethiol, and phenylmethanethiol—but in no case has incorporation of the reagent been detected[96]. The reaction of the hydrazone (LXVI) with ethanethiol is exceptional: nuclear magnetic resonance spectroscopy and elementary analysis show that the chromatographically difficultly separable mixture of reaction products contains, together with the alkene (LXVII) and products formed by subsequent addition of the thiol to it, also a compound resulting from addition of the mercaptide ion to the episulphide ring.

VI. FACTORS CONTROLLING OPENING OF A THREE-MEMBERED RING

The above facts show that in these keto-oxides the classic *trans*-scission of the oxide ring at the β-position to the carbonyl group is most often (not always) evident only among 16,17α-epoxy-20-oxo-steroids. It appears useful to discuss the results systematised above in terms of a "borderline" or "modified" S_N2 substitution mechanism[3], which has become the most acceptable theoretical model for describing the opening of epoxide rings. According to this mechanism reaction between the oxide and a nucleophilic reagent involves a termolecular transition state, in which almost synchronous action of the nucleophilic reagent and an electrophilic "accomplice" (solvent or catalyst) causes rupture of a carbon–oxygen bond. The transition state of a "modified" reaction having an S_N2 mechanism has longer partial bond lengths than has the classic S_N2 mechanism, with rupture of the carbon–oxygen bond in the oxide always more pronounced than formation of the new carbon–nucleophile bond. This is evident in the appearance in the transition state of a partial positive charge on the carbon

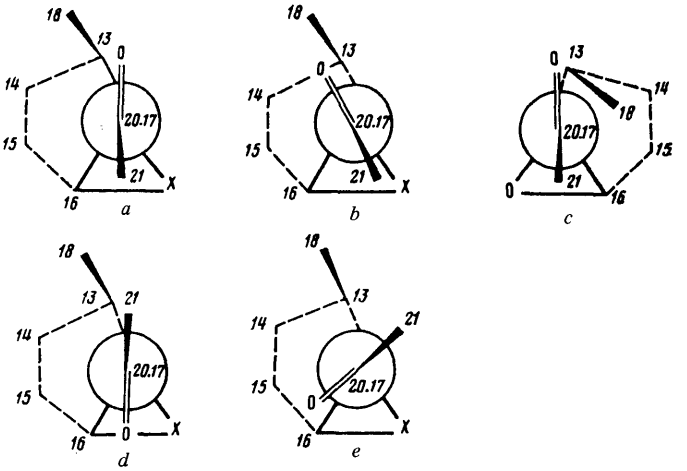
atom of the reaction centre, the possibility of whose stabilisation determines the principal direction of ring-opening. Hence *trans*-opening of 16,17α-epoxy-20-oxo-steroids must be described in terms of the transition states

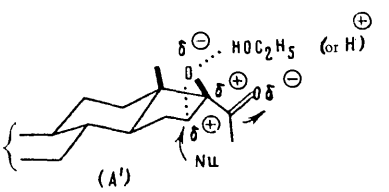
resulting from attack by the nucleophilic reagent from the front of the steroid molecule on the secondary and the tertiary centre respectively.

It can be assumed that transition state (A) is preferred not only because mutual repulsion between the two adjacent centres in (B) increases its activation energy[2] but also because the cationoid character of the $C_{(17)}$ centre in the latter is in some measure suppressed by the oxide ring in the preferred *S-trans*-conformation (Fig. 1*a*),[16,17,102] whose geometry satisfies the optimum requirements for conjugation of the keto-group with the oxide ring[7,12]. Furthermore, polar shielding by the neighbouring keto-function in the preferred conformation (*a*), and also the need for equatorial attack by the reagent in *trans*-opening of the oxide, do not favour realisation of transition state (B). The observed high stereo- and regio-selectivity of ring-opening reactions of 16,17α-epoxy-20-oxo-steroids with strong nucleophiles must then be explained by their occurrence via transition state (A), preference for which is due to concerted action of the conformational factor (*trans*-quasi-axial opening and attack from the opposite side of the oxide ring) and the electronic factor (electron-accepting influence of the keto-group when conjugated with the epoxide ring in the preferred *S-trans*-conformation).

Comparative analysis of steric factors in the intermediate species (A) and (B) does not support preference for either. Indeed, approach of the nucleophile to the $C_{(17)}$ and $C_{(16)}$ atoms is sterically hindered approximately equally by the angular and the $C_{(21)}$ methyl group in the *S-trans*-conformation, except that this involves respectively 1,3- and 1,2-interaction. This is why reactions with weak nucleophilic reagents take place in both directions, their result apparently depending on the relative rates of neutralisation of the two intermediate species. In particular, neutralisation of the carbocation centre at the $C_{(17)}$ atom by migration of the angular methyl group is more rapid than the alternative addition of a weak nucleophile (e.g. water) to the $C_{(16)}$ centre. In the absence of a nucleophilic reagent this becomes the sole reaction.

The geometry of ditertiary 16,17α-epoxy-16β-methyl-ketones differs from that of the desmethyl analogues. The preferred conformation of 16β-methyl-16,17α-epoxides is (*b*) (Fig. 1), in which the keto-group is oriented above the D ring in a skew position relative to the $C_{(13)}$–$C_{(17)}$ bond[17,102]. The general balance of steric and electronic factors changes in such a molecule (conjugation breaks down and the β-region of the molecule is strongly shielded), which by no means favours nucleophilic attack on the $C_{(16)}$ atom by an S_N2 mechanism. Therefore acid opening of the oxide ring in compounds of this type involves exclusively rupture of the $C_{(16)}$–O bond by a unimolecular mechanism with formation of a 16-carbocation, whose stabilisation is favoured by the 16-methyl group. Neutralisation is effected either by elimination of a neighbouring proton or by *cis*-opening of the oxide ring from the rear of the molecule[44].





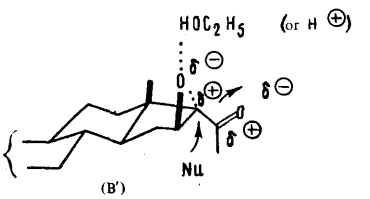


Figure 1. Newman projections of the conformations of 16,17-hetero-substituted 20-oxo-steroids, produced by rotation about the $C_{(17)}$–$C_{(20)}$ bond. The numerals denote carbon atoms.

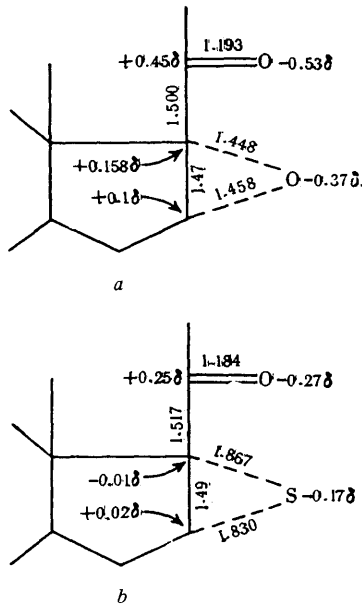
In 16,17β-epoxy-20-oxo-steroids the general balance of factors controlling the structural direction and the stereochemistry of opening of the oxide is changed. Examination on the same basis of molecular models and of the intermediate states

shows that the total of factors promoting attack at the $C_{(16)}$ atom remains unchanged, whereas the number of factors opposing attack at the $C_{(17)}$ atom diminishes. The most important and apparently decisive difference between transition states (A') and (B') is that the conformational factor—*trans*-quasi-axial attack at the $C_{(17)}$ atom—promotes opening of the 16,17β-oxide at the tertiary $C_{(17)}$ atom. Furthermore, approach of the nucleophilic reagent to $C_{(17)}$ from the rear of the molecule is sterically less hindered in (B')§. The thermodynamic factor is favourable also to formation of products with a β-configuration of the 17-acetyl group on ring-opening of 16,17β-epoxy-20-ketones. All these considerations make *trans*-attack by the nucleophilic reagent at the tertiary centre in the opening of 16,17β-epoxy-ketones logically understandable, but it is difficult in the general logic of the argument to explain their *cis*-opening at this centre, and also the Wagner–Meerwein rearrangement. It can therefore be supposed that the transition state of carbocation type (B') formed in the modified S_N2 mechanism is characterised more by breakage of the old bond than by formation of a new bond, with consequent smaller steric hindrance to attack from the β-region.

Most of the ring-opening reactions of keto-aziridines, both basic (including protonated) and activated, are classified as substitutions, in which S_N2 and S_N1 mechanisms compete depending on the structure of the aziridine and the reagent[6]. The observed *trans*-stereochemistry of the opening of 16,17α-epi-imino-ketones and their *N*-acetates indicates reactions of type S_N2. This applies equally to those involving rupture of the $C_{(17)}$–N bond, for an S_N1 substitution would be expected to yield not only products of a Wagner–Meerwein rearrangement but also those of attack at the $C_{(17)}$ carbocation from the rear, less hindered side of the molecule. Differences in reactivity between 16,17α-epi-imino-ketones and their structurally similar epoxy-analogues must apparently be explained, in terms of an S_N2 substitution mechanism, by the difference in their geometry shown in the Newman projections in Fig.1.[15,17,102] The *S*-cisoid conformation (*d*) is assumed for the aziridine (XLIV), with the keto-group and the *N*-proton involved in an intramolecular hydrogen bond. In the preferred conformation of the *N*-acetylaziridine (XXXVIII) the keto-group is displaced from conjugation with the ring and skew to the $C_{(16)}$ centre inside ring D, with both acetyl groups *cis*-oriented with respect to the plane of the aziridine ring (Fig.1*e*). The lower reactivity of the aziridine (XLIV) in ring-opening involving the $C_{(16)}$ centre than of epoxides, and its tendency to isolated addition both at the keto-group and at the aziridine ring, are explained by the difference in conformation between the initial molecules and the consequent change in balance of steric and polar factors[102]. This provides an explanation also of the low reactivity of the *N*-acetates (XXXVIII), in which strong polar shielding by the two carbonyl functions of the acetyl groups prevents approach of a nucleophilic reagent to the $C_{(16)}$ atom.

Epithio-ketones are far less reactive than their oxygen analogues, but still show a tendency to the same direction of ring-opening. The episulphide (XLVI) is a conformationally more labile model than the epoxy-analogues, but the conformational mobility of the 17β-acetyl group is restricted to conformations having *trans*-orientation of the keto-group and the heterocycle, with the *S-trans*-conformation (Fig.1*a*) showing minimum energy, and 30° deflection of the 21-methyl group towards coplanarity of the keto-group and the $C_{(17)}$–S bond energetically preferred to displacement in the opposite direction[103,104]. The factor stabilising the system in the preferred *trans*-conformation is apparently orbital interaction of the carbonyl with the delocalised electronic system of the episulphide ring. The difference in character between this interaction in the episulphide (XLVI) and in the epoxide (I) is evident from Fig.2, which illustrates the distribution of electron density obtained by quantum-chemical calculation in the energetically preferred conformations of the ground state of a fragment of the D-ring in (I) and (XLVI) with an indication of the bond lengths determined by X-ray structural analysis[16,103,104]. The episulphide shows diminished electrophilicity of the carbon centres at the points of attack and also diminished polarisation of its keto-group, the latter obviously due to displacement of the electron shell from the carbonyl group to a vacant *d*-orbital of the sulphur atom[105–107]. It may be supposed that these electronic differences together with the establishment of a conformation sterically favourable for elimination of sulphur, with anti-coplanar arrangement of keto-group and $C_{(17)}$–S bond, are responsible for the above behaviour of the episulphide in ring-opening reactions.



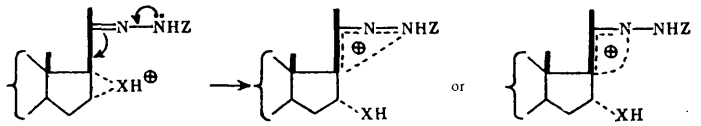


Figure 2. Distribution of electron density on atoms of the D-ring obtained by quantum-chemical calculation and interatomic distances (Å) determined by X-ray structural analysis for the: *a*) epoxide (I); *b*) episulphide (XLVI).

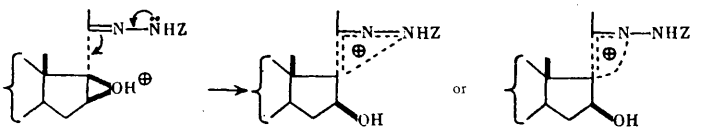
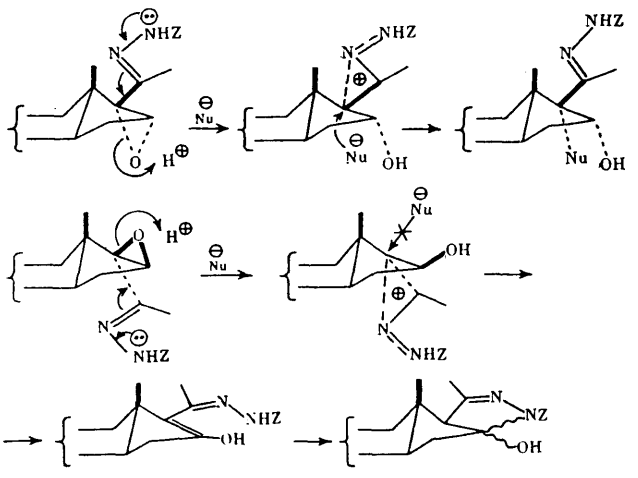


§By analogy with 16,17α-epoxides the preferred conformation of 16,17β-epoxy-20-oxo-steroids is taken to be (*c*) (Fig.1), with *anti*-orientation of the oxygen functions (oxo- and epoxy-groups).

Replacement of the keto-group by a hydrazone fragment apparently reverses completely the direction of polarisation of the system[63]. Under acid conditions reversible electronic displacement of the lone pair of the amino-nitrogen atom along the conjugated chain becomes more characteristic,

with a consequent loosening of the heterocyclic $C_{(17)}$–X bond (X = O, NH, $NCOCH_3$). At present, unfortunately, experimental information on the mutual steric arrangement of hydrazone group and three-membered ring is lacking. However, the fact that the configuration at $C_{(17)}$ is strictly maintained indicates rather preference for the *S*-transoid conformation. On the basis of the experimental facts it is suggested as intermediate species a non-classical cyclic ion stabilised in the configuration of the initial oxide or aziridine hydrazone:



X = O (XLVIII)
X = NH (LVIII)
X = NAc

Z = $CO_2C_2H_5$.

The question of whether both hydrazone nitrogen atoms are involved in this interaction or only that closer to the ring remains open[63].

Two factors—presence of a nucleophilic reagent and possibility of its approach to one side or the other of the non-classic cation—govern the subsequent fate of the latter. In the 20-hydrazone of the 16,17α-oxide the configuration of the cation requires approach of the reagent from the rear of the molecule. As a consequence, in the presence of a nucleophile the reaction is completed by its incorporation at $C_{(17)}$, and in the absence of such a reagent by elimination of a proton from the $C_{(16)}$ atom followed by intramolecular cyclisation involving the hydrazone fragment:

Z = $CO_2C_2H_5$, C_6H_5.

The reason for the observed course of the reaction in the latter case is the impossibility of any other way of satisfying the electronic requirements of neutralisation of the non-classical cation. The configuration of the cation of the 16,17β-epoxide 20-hydrazone requires that a nucleophile should attack from the side of the sterically-shielded β-region of the molecule. As a consequence, its neutralisation is effected not by addition of the nucleophile from the side of the β-epoxy-group but by elimination of a neighbouring proton with formation of a Δ^{16}-enol, which either rearranges into a ketone or cyclises into a pyrazolinol. But the latter role in the general direction of ring-opening reactions of oxide 20-hydrazones is apparently played by the geometrical arrangement of the hydrazone fragment relative to the plane of the three-membered ring, although this aspect has remained almost uninvestigated.

The anomalous behaviour of the 20-hydrazone of the 16,17α-epithio-ketone (LXVI) in ring-opening reactions suggests a different mechanism of interaction of the episulphide ring and the hydrazone fragment, without formation of an intermediate non-classical carbocation.

Advances in the Chemistry of α-Halogenoallenes

M.V.Mavrov

Results obtained on the preparation and reactions of α-halogenoallenes are critically surveyed, and the reaction mechanisms are discussed. A list of 224 references is included.

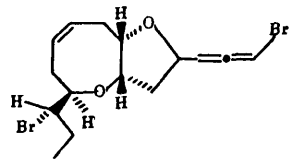
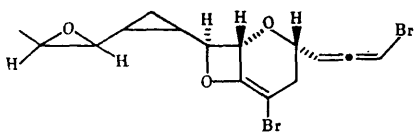
I. Introduction 887
II. Methods of preparation 887
III. Reactions and transformations 889



I. INTRODUCTION

α-Halogenoallenes are important examples of organic compounds having cumulative double bonds. As polyfunctional compounds they have an interesting structure, on whose basis various compounds can be obtained having properties useful in many fields of organic synthesis and practical application.



Individual members of this class, containing a terminal bromoallene group, have already been found in Nature. Thus the phenyl ether panacene

panacene

laurallene

okamurallene

has been isolated from the mollusc *Arlysia brasiliana*[1], and the bicyclic diethers laurallene and okamurallene have been obtained[2] from the marine red algae *Laurencia*.

During recent years research in this field has become more active and systematic, but the results have not yet been covered in reviews[3-6].

II. METHODS OF PREPARATION

Halogenoallenes can be obtained in various ways. In several cases these methods are based on elimination. However, most typically halogen substituents are introduced, and form the basis for various rearrangements of acetylenic compounds.

1. 1,2-Elimination

Practical methods for obtaining halogenoallenes by elimination are at present restricted to the dehalogenation and dehydrohalogenation of aliphatic compounds containing mainly halogens as substituents[4].

Mono- and di-fluoropropadienes have been prepared by the action of zinc in alcohol[7] or in dimethylformamide[8]. Debromination of 2,3-dibromo-1,1,3,3-tetrafluoropropene (with magnesium in oxolan) gives a 91% yield of perfluoroallene[9]. Butyl-lithium metallates 2-bromo-3,3,3-trifluoropropene at the bromine, which undergoes elimination when the temperature is allowed to rise from −90 to 20 °C, to give a 72% yield of 1,1-difluoroallene[10]:

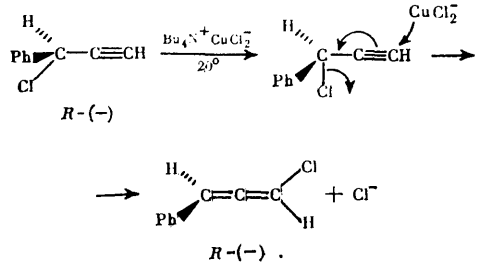
$$CF_3C(Br)=CH_2 \xrightarrow{BuLi,\ -90^\circ} CF_3C(Li)=CH_2 \rightarrow CF_2=C=CH_2 .$$

Deiodofluorination in the presence of copper powder at 200 °C has been used to obtain theoretical yields of perfluoro-1,2-dienes[11]:

$$CF_3CCl=C(R)CF_3 \rightarrow CF_2=C=C(R)CF_3 \qquad R=C_2F_5,\ n\text{-}C_3F_7,\ iso\text{-}C_3F_7 .$$

Various basic reagents–alkalis in a solvent[12-15] or in the solid state[16], sodamide in liquid ammonia[17,18], butyl-lithium[19]– are used to effect β′-elimination. This method can be employed to obtain trifluorinated[16], perfluorinated[12-14], perchlorinated[17], and perbrominated[18] allenes.

Dibromoalkenes containing substituents Y = COOR, COR, $PO(OC_2H_5)_2$, which activate an α-hydrogen atom, are readily dehydrobrominated by bases, including amines, to give satisfactory yields of allenes BrCH : C : CHY.[20-24] Potassium or lithium t-butoxide is used at low temperatures to prepare perhalogenoallenes containing electron-accepting groups[25,26]:



$$CCl_2=C(X)-CH(Cl)Y \xrightarrow{-70^\circ} CCl_2=C=C(Cl)Y \qquad Y=CO_2Et,\ CN,\ CONH_2 .$$

2. Prop-2-ynyl Rearrangements

Anionotropic conversion

Many reagents are able to convert 3-halogenoalkynes into 1-halogenoallenes, among which the most commonly used are copper(I) salts[27-29]. Although this process is reversible, it is often possible under appropriate experimental conditions to obtain entirely satisfactory yields (40–70%) of α-halogenoallenes[29-32]. Under the influence of the tetrabutylammonium chloride complex of copper(I) chloride(−)-phenylprop-2-ynyl chloride is converted with high stereospecificity into the optically active allene chloride[33]. In view of the first order a single-stage mechanism of S_N2' type with *anti*-attack by

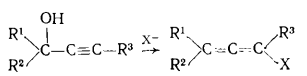
the reagent is assumed for this reaction:

R-(−) .

Prototropic isomerisation

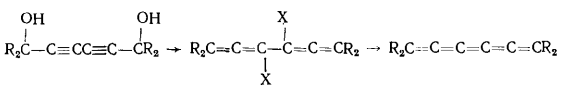
Only a few examples of the prototropic isomerisation of halogeno-compounds have been reported. Thus in the presence of sodium ethoxide a diacetylenic bromide isomerises into an allene[34]:

$$(RC{\equiv}C)_2CHBr \xrightarrow{EtONa} \underset{\displaystyle Br}{RC{\equiv}CC{=}C{=}CHR} \qquad R = t\text{-}Bu\ .$$



Isomerisation can be arrested at the stage of allene formation when electron-accepting groups activate the initial molecule. For example, halogenoallenecarboxylic esters are formed under very mild condtions[35,36], on brief shaking with dilute potassium carbonate solution at room temperature. Isomerisation is not observed in the absence of stabilising groups, as is clearly shown by the bromoprop-2-ynyl ester[35]:

$$BrC{\equiv}CCH_2\overset{\displaystyle O}{\overset{\|}{C}}OCH_2C{\equiv}CBr \xrightarrow{OH^-} BrCH{=}C{=}CH\overset{\displaystyle O}{\overset{\|}{C}}OCH_2C{\equiv}CBr\ .$$

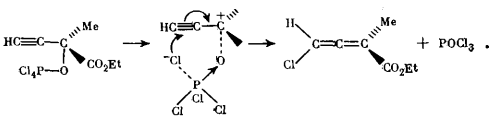


Prototropic isomerisation is possible under radical conditions[31,37]. A photochemically generated bromine atom leads to partial isomerisation of bromoprop-2-ynyl into bromoallenyl[37].

Anioniotropic rearrangements

It is well known that acetylenic compounds containing a group X = H, Hal, OH, MgZ, etc. in the prop-2-ynyl position are able to give an allene product on undergoing an S_N2' substitution[4,5]. Various α-halogenated allenes can be obtained from acetylenic alcohols as a result of this reaction:

Primary, secondary, and tertiary alcohols having a terminal triple bond and containing various types of alkyl groups near the reaction centre readily undergo the reaction[18,28,38–48]. It has acquired greatest value for the preparation of persubstituted halogenoallenes with aliphatic[43,47,49–51], aromatic[52–55], and alicyclic[56–58] substituents when the yields are 70–90%. Functional halogenoallenes—polyhalogenated[47,59–62], containing ester [63,64] and heteroatomic groups[65–68]—have also been obtained by this method, but side-reactions lower the yields. When two active centres are present, good yields can be obtained of dihalides having conjugated allene groups[51,56,59], which have found application in the synthesis of cumulenes[69,70]:

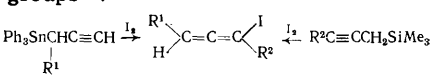


R = t-Bu, Ph, 2,2,6,6-$(CH_3)_4$-cyclo-C_6H_7;
X=Cl, Br .

The hydroxy-group is exchanged for a halogen atom when alcohols are treated with hydrohalic acids—hydrochloric[28,44,47,50], hydrobromic[39,40,43,47,59,60,67], and hydriodic[47,60]—phosphorus trichloride[49] and pentachloride[61,64] thionyl chloride[42,44–49,51–55,57,60,61,63], phosphorus tribromide[41,42,46,49,52,53,56,71], sulphuryl bromide[64], phosphorus pentabromide[64,71], and a mixture of triphenyl phosphite and iodomethane[38,68]. The detailed course of the reactions has not been studied, but qualitative observations show the possibility of varying and experimental conditions within each class to enable satisfactory results to be obtained. The yields differ somewhat, but under the most favourable conditions reach 70–90%.

Additional information on the chemistry of the reactions has been gained by the use of optically active substrates. Study of the action of three of the above reagents—thionyl chloride[45,72,73], hydrobromic acid[43], and phosphorus pentachloride[74]—on optically active acetylenic alcohols has shown high stereoselectivity of formation of halogenoallenes, usually with retention of configuration.

Intermediate products in all these reactions are probably chlorosulphite[63,73], a copper complex coordinated with hydroxyl and ethynyl groups[43], or a prop-2-ynyl cation solvated by phosphoryl chloride[74], which break down as a result of internal electron transfer: e.g.

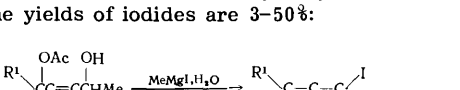


Thus the halogen is introduced as a consequence of *cis*-nucleophilic substitution by an S_Ni' mechanism.

Other reactions are known involving exchange of a prop-2-ynyl function for halogen. Thus the action of iodine on a 4-chlorobut-2-ynoic ester forms the 2-iodobutadienoic ester[75].

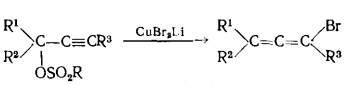
Iodoallenes have been obtained by reaction between prop-2-ynyl bromide and iodine in methanolic caustic potash[76,77]; all three hydrogen atoms may be substituted:

$$HC{\equiv}CCH_2Br \xrightarrow{I_2} IC{\equiv}CCH_2I \xrightarrow{I_2} I_2C{=}C{=}CHI \xrightarrow{I_2} I_2C{=}C{=}CI_2\ .$$



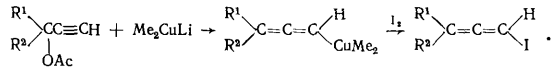
The suggested mechanism involved an intermediate allene carbanion. Similarly, phenylprop-2-ynyl chloride and *para*-substituted phenylprop-2-ynyl sulphide give 40–65% yields of the corresponding tri-iodoallenes[77]. Iodides are formed also by direct replacement of the triphenylstannyl[78] and trimethylsilyl groups[79]:

R^1=H, Me; R^2=C_6H_{13} .



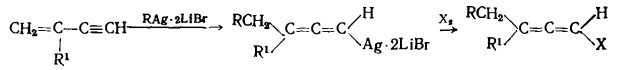
This method is suitable also for obtaining allenyl bromides[79].

Monoacetates of acetylenic t-glycols react with methylmagnesium iodide, but a mixture of products is formed, including allene iodides[80]; after hydrolysis of the reaction mixture the yields of iodides are 3–50%:



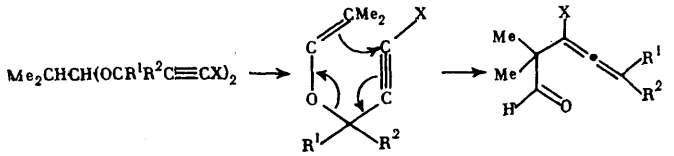
R^1, R^2=Alk, Ph .

Allene bromides are formed in ~60% yields also from prop-2-ynyl sulphonates by the action of the lithium copper(I) bromide complex in[81]:



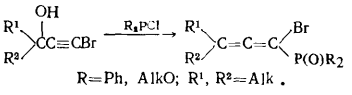
R=Me, *p*-Me-C_6H_4; R^1, R^2, R^3=H, Alk, Ph .

New methods of synthesis are based on reactions of allene organometallic compounds. Thus an organocopper intermediate, prepared regiospecifically from prop-2-ynyl acetates with lithium dimethylcuprate, reacts normally with iodine (at −78 °C) to give allene iodides[82]:



In the same way an allenylsilver salt (obtained by 1,4-addition of an alkylsilver(I)–lithium bromide complex to homologues of butenyne) is able to react with electrophiles (including halogens) to form brominated (iodinated) allenes[83], accompanied by a small quantity of an acetylenic isomer:

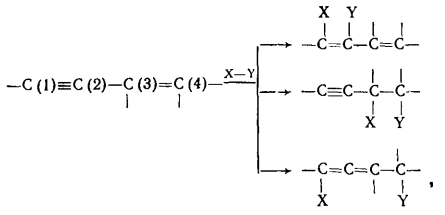
R = n-Bu, t-Bu, iso-Pr; R^1=H, Me; X=Br, I .



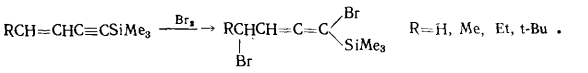
Other rearrangements

Bishalogenoprop-2-ynylacetals, when heated (to 80–115 °C) in the presence of toluene-*p*-sulphonic acid, rearrange *in situ* into halogenoallene aldehydes[84,85]. It is assumed that a Claisen-type rearrangement takes place with intermediate formation of a prop-2-ynyl vinyl ether:

R^1, R^2 = H, Alk; X = Cl, Br .



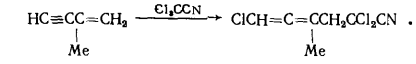
An analogous rearrangement occurs in the reaction between a halogenoprop-2-ynyl alcohol and a dialkyl chlorophosphite[86] or diphenylchlorophosphine[87,88] in the presence of a base, when a halogenoallene derivative is formed in 10–60% yield:



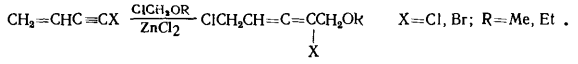
R=Ph, AlkO; R^1, R^2=Alk .

3. Addition to a Conjugated Butenyne System

Addition of molecules X–Y of halogens, hydrogen halides, and other active halogen compounds to conjugated enynes may take place in three main ways[4,89] among which only 1,4-addition yields allenes:

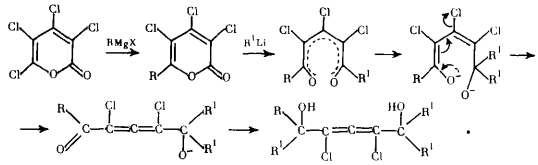


Addition of the different parts of the X–Y molecule obeys the general rule, so that, in conformity with the expected polarisation, the negative group goes to the $C_{(4)}$ atom of the ethylenic double bond. With bromine formation of compounds by 1,4-addition predominates over other directions to such an extent that such addition has preparative value[90–92]:

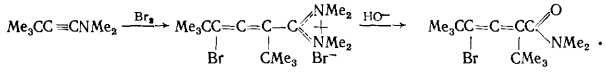


The direction of addition is little affected by the nature of the solvent, although there is a tendency for 1,4-addition to increase with alkenylacetylenes and to a greater extent with trimethylsilyl derivatives[93].

Methylbutenyne reacts with trichloroacetonitrile to give an allene derivative in theoretical yield[94]:



Several examples have been reported of the electrophilic addition of alkyl chloromethyl ethers[95,96] and hydrogen halides[97] to give 30–65% yields of halogenoallenes (although in these cases isomeric dihalides are formed at the same time):

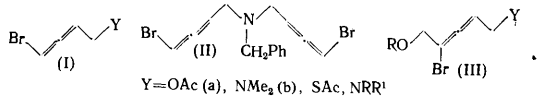


4. Other Methods

Perchloro-2-pyrone reacts with Grignard and then organolithium reagents to give tetra-alkyl-2,4-dichloropenta-2,3-diene-1,5-diols[98], most probably by the scheme

In the bromination of a 3,3-dimethylbut-1-ynylamine addition of a second alkynylamine molecule is observed with formation of the corresponding salt, which under alkaline conditions yields the dimethylamide of 4-bromo-2-t-butyl-5,5-dimethylhexadienoic acid[99]:

III. REACTIONS AND TRANSFORMATIONS

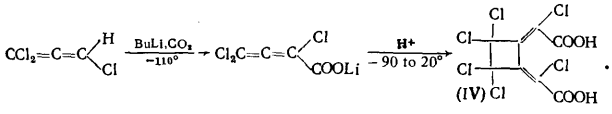


The known chemical reactions of halogenoallenes can be divided into three groups—those leading to functional transformation of substituents without affecting the allene group, cycloaddition, and linear substitution and addition with or without lengthening of the carbon chain.

1. Functional Transformations

Halogenoallenes are extremely sensitive to various reagents and to temperature, which cause a change in the allene bond. They can easily be converted into 1,3-dienes by prototropy[65,84]. It must therefore be borne in mind that the problem of

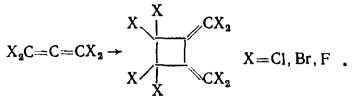
instability is present in all preparations of functional halogenoallenes.



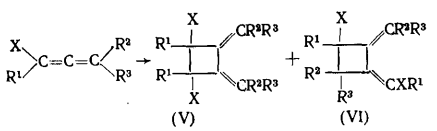
Substitution of the allyl bromine in 1,4-dibromobuta-1,2-diene (I: Y = Br)

Y=OAc (a), NMe_2 (b), SAc, NRR^1

by primary and secondary amines, potassium acetate and thioacetate, and thiourea under mild conditions gives positive results[67,100]. With benzylamine the reaction yields the bisbromoallene amine (II).[101] Functional derivatives of 5-alkoxy-4-bromopenta-2,3-dienes (IIIa,b) have been obtained similarly[96]. 1,4-Dibromobuta-1,2-diene is not hydrolysed under normal conditions: even mild bases (sodium hydrogen carbonate, calcium oxide, silver(I) oxide, etc.) eliminate hydrogen bromide. The alcohol (I: Y = OH) can readily be obtained in 60–70% yield from the acetate (Ia).[102] Trimethylsilyl and oxanyl protection is also readily introduced and removed[67].



In some cases halogenoallenes undergo deprotonation under the influence of organolithium compounds and form a resonance-stabilised allenylcarbenium ion. But the trichloroallenyl cation reacts in the usual way with carbon dioxide to give the lithium salt of the acid, thermal conversion of which yields (after hydrolysis) and cyclic dimeric product (IV):[19]



This salt reacts with cyclopentadiene (at −90 to 20 °C) to give in high yield (91%) the adduct of diene synthesis.

2. Cycloaddition Reactions

Dimerisation into four-membered cyclic compounds is a general reaction for the allene group, and is undergone also by halogenoallene derivatives. Indeed, polyhalogenoallenes such as the tetrachlorinated[17,103], tetrabrominated[18,104], and tetrafluorinated[12] propadienes are converted extraordinarily readily even at room temperature (which makes it difficult to obtain them in pure form) into 1,2-bisdihalogenomethylenecyclobutanes:

Thermal 2,2-cycloaddition takes place quite readily with unsymmetrical halogenoallenes, and in several cases (Table 1) yields a mixture of the possible isomers (V) and (VI):

(V) (VI)

The orientation of dimerisation undoubtedly depends on the positions of substituents. Experiment shows that halogenoallenes form four-membered rings head to head (V) and head to tail (VI) at the expense of the halogenated double bond preferably with vicinal methylene groups. Examples of the formation of 1,3-dimethylenecyclobutanes are fairly rare[110]. Nor has addition at both double bonds been reported.

Table 1. Examples of the 2,2-cycloaddition of halogenoallenes.

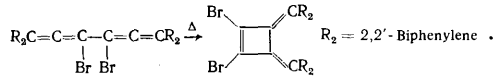
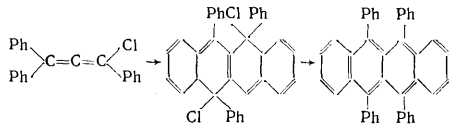
Mutual thermal isomerisation of the dimers has been noted in several cases[49,57,110], but the dimer of perfluoroallene in the presence of caesium fluoride isomerises quantitatively into perfluoro-2-methyl-3-methylenecyclobutene[115].

The stereochemistry of dimerisation also depends on the positions of substituents and the degree of substitution of the allene bond. Isomers having a *trans*-arrangement of ring substituents usually predominate in a mixture of stereoisomers[109,112]. Substituents in the two *exo*-methylene groups are arranged mainly in *cis*-positions[111,112]. According to Jacobs[105,111,112] the stereochemical nature of the products of dimerisation is consistent with a biradical mechanism.



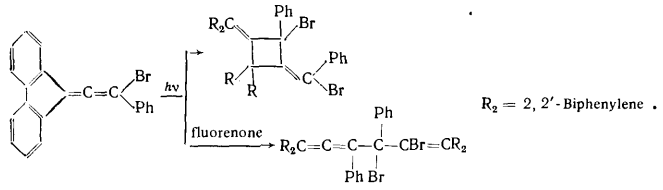
Study of the kinetics and the mechanism of the cyclodimerisation of perhalogenoallenes has shown[103] a second-order reaction. The rate of dimerisation to 1,2-dimethylenecyclobutane derivatives is very strongly dependent on the influence of substituents. Accumulation of electron-acceptors greatly destabilises the system: thus perchloroallene is stable only below −50 °C.[17] Kinetic measurements on a series of halogenoallenes of type $Cl_2C:C:CClX$ show that the rate of dimerisation increases in the sequence of substituents

$$X = H < Br < C_6H_5 \cong Cl < COOC_2H_5 < CN.$$



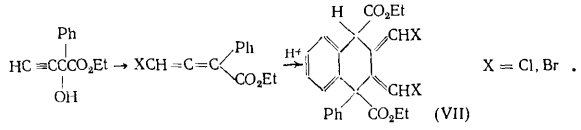
Among these trichlorobuta-2,3-dienenitrile is the most unstable of all allenes known at the present time[26].

Study of the thermodynamics of cyclodimerisation has revealed a low enthalpy of activation (35.2–62.8 kJ $mole^{-1}$) and high negative entropies of activation (−188 to −146 J $mole^{-1}$ deg^{-1}). No paramagnetic intermediate species were detected in the dimerisation of tetrachloroallene, and a non-synchronous two-stage mechanism was assumed[103].

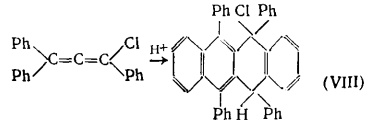


The conjugated 1,6-dibiphenylene-3,4-dibromohexa-1,2,4,5-tetraene when heated undergoes intramolecular cycloaddition with formation of a 3,4-dimethylenecyclobutene derivative[57]:

However, dimerisation of triphenylchloropropadiene takes place preferentially by a Diels–Alder type of reaction accompanied by elimination of hydrogen chloride to form rubrene[116]:



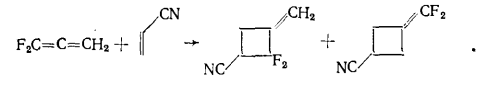
Depending on the conditions photochemical treatment yields various products, including those of 2,2-cycloaddition[111,117]. Thus exposure of 1,1-biphenylene-3-bromo-3-phenylallene in benzene to ultraviolet radiation yields a 1,3-divinylcyclobutane derivative[117]:



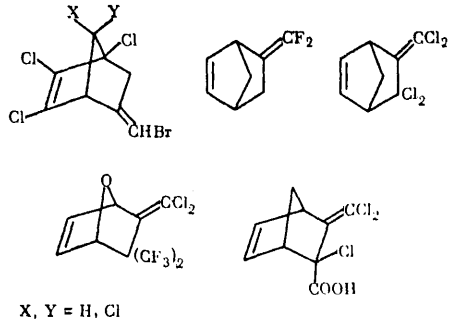
The action of ultraviolet radiation in the presence of fluorenone as sensitiser forms only a product of linear dimerisation of the bromoallene[117].

In several cases the reactions are complicated by interesting rearrangements of the resulting halogenoallenes under the influence of electrophiles. With a 2-hydroxy-2-phenylbut-3-ynoic ester the main product is the cyclic dimer (VII) as a mixture of geometrical isomers relative to the double bond[63,118]:

Formation of such a product can be explained by addition of the cation $XCH:C^{+}C(C_6H_5):C(OH)OC_2H_5$, formed by protonation of the ester group of the halogenoallene, to the central atom of another molecule of the latter followed by an electrophilic substitution type of cyclisation to an aromatic ring[118].



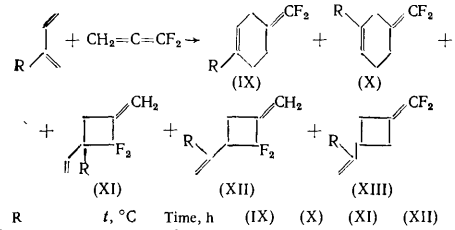
Under the influence of acids triphenylchloroallene undergoes cycloaddition to a tetracyclic compound (VIII):



The reaction is assumed to involve interaction of a delocalised carbenium ion formed by protonation of the central carbon atom[119].

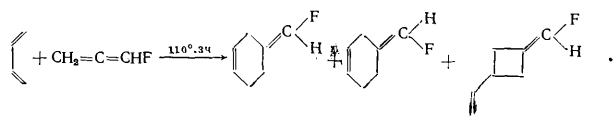
The possibility of the codimerisation of halogenoallenes with other dienophiles (X = Y) is strongly dependent on the position and the character of the substituent. The thermal codimerisation of perfluoroallene with hexafluorobutyne at 80–85 °C in the presence of a free-radical scavenger gives a 50% yield of perfluoro-1,2-dimethyl-3-methylenecyclobutene mixed with a dimer of allene (yield 42%) and other minor products[120].

With typical dienophiles (acrylonitrile, azodicarboxylic ester) 1,1-difluoroallene forms a four-membered rings predominantly by means of the fluorinated double bond[7,106]. In the case of acrylonitrile[7] the proportions of isomeric products are 5:1:



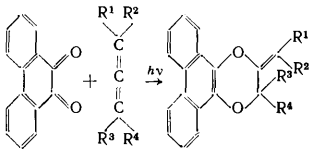
Halogenoallenes react quite well also with various 1,3-dienes, but in this case adducts of diene synthesis are formed primarily, together with 2,2-cycloaddition products[7,17,121]. The diene condensation has been reported of bromopropadiene[122], 1,1-difluoroallene[7,106], perchloroallene[17], trichlorobutadienoic acid[19], and 1,1-dichloro-3,3-bistrifluoromethylpropadiene[123] with cyclic dienes. These reactions always lead to the formation of only one of the isomers having an exocyclic halogenomethylene group

X, Y = H, Cl



and may be of synthetic value for their preparation.

Table 2.



R	*t*, °C	Time, h	(IX)	(X)	(XI)	(XII)
R=H	110	7	63	—	37	—
R=CH_3	110	7.5	29	35	26	10
R=$(CH_3)_3SiO$	140	5.5	23	23	37	17

Addition of fluoroallene to butadiene forms a mixture of isomers at the *exo*-fluoromethylene group (yield 57%), the proportions of the reaction products being 2:2:1:[7]

Addition of 1,1-difluoroallene to alkylated dienes is still less selective: the yield of the adducts (IX) and (XIII) fluctuates between 60% and 90% (Table 2).[121] It is interesting that in both cases[7,121] an appreciable difference is observed in the addition of fluoroallenes: whereas 2,4-adducts are formed solely with an exocyclic mono- or di-fluoromethylene group, 2,2-adducts appear almost exclusively with an endocyclic difluoromethylene group; the proportions are (XI) + (XII) : (XIII) = 20 : 1.

Cycloaddition often occurs in photochemical processes. For example, 2,4-cycloaddition of 9,10-phenanthraquinone to dimethylbromoallene[124] leads to a roughly equally probable mixture of structural and geometrical cycloadducts of type (XIV: $R^1 = Br$, 9%; $R^2 = Br$, 7%; $R^4 = Br$, 13%):

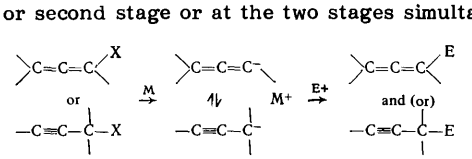
(XIV)

When bromopropadiene is used under the same conditions[125], only one bond is involved in the reaction, with formation of a methylene-containing isomer (XIV: $R^1 = R^2 = R^3 = H$ and $R^4 = Br$).

Similarly, 4-chloro(and bromo)methylenetetramethyl-1-pyrazolines have been obtained (in respective yields 18% and 28%) from diazopropane and 1-chloro(and bromo)-3-methylbuta-1,2-dienes. The orientation in these examples corresponds to a hindered mode of cycloaddition[126,127].

The photoinduced addition of dehydrobenzene to chloroallene with formation of a chloromethylenebenzocyclobutane has been reported, but the yield is low (12%).[128]

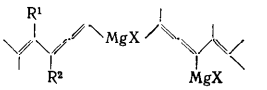
3. Substitution of Halogen



The ability of a halogen atom to be replaced by a nucleophilic species is directly dependent on the structure of the substrate. The presence of two electrophilic centres in a molecule is responsible for their peculiar reactivity, which depends in complicated fashion on the relative electrophilic properties of the centres, the nature of the nucleophilic, and solvolytic effects.

Subsequent discussions of α-halogenoallenes in nucleophilic reactions include consideration of parallel reactions of isomeric alkyne halides. This is necessary, since from the character of the changes they often lead to the formation of intermediate species that are resonance forms.

Reactions of halogenoallenes have been studied with water, alcohols, C–H acids, organometallic compounds, amines, metal hydrides, etc. The experimental results indicate that these reactions are governed by similar laws, and enable their most characteristic mechanisms to be examined.

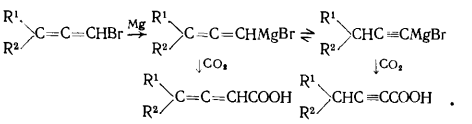


Organometallic derivatives

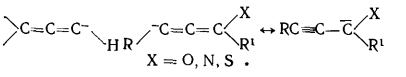
Halogenoallenes (and prop-2-ynyls) give with such metals as magnesium, zinc, aluminium, lithium, etc. organometallic derivatives, which then react with an electrophilic (E) with preservation and/or rearrangement of the initial molecule at the first or second stage or at the two stages simultaneously:

Reviews have recently appeared on this topic[129,130]. Not all the reactions have been discussed exhaustively, only the fundamental principles from the point of view of applying the especially valuable magnesium– and lithium–allene derivatives. It is considered at present that formation of Grignard reagents from halogenoallenes and the corresponding prop-2-ynyls is facilitated on the introduction of mercuric chloride or the addition of magnesium amalgam by the use of low temperatures (0–5 °C) and high-dilution technique[3,131,132].

1-Chloro- and 1-bromo-propadienes, as also the corresponding propynes, give with magnesium in ether a Grignard reagent, according to the infrared spectrum identical with the allene form but according to nuclear magnetic resonance data containing a greater proportion of the latter[3]. The preparation of α-deuteroallenylmagnesium bromide has been described[133]. Grignard reagents of vinylallenyl structure



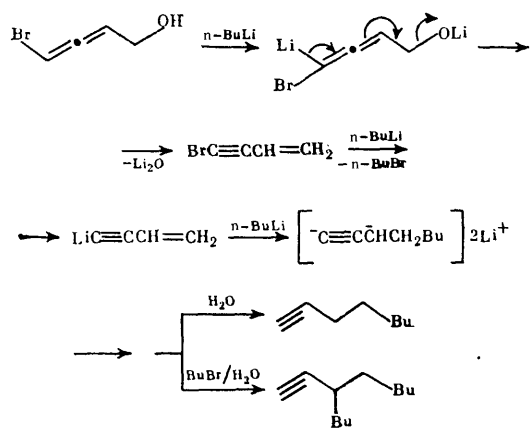
(XVa) (XVb)



can be obtained by the action of magnesium on conjugated[129,134] and non-conjugated[135,136] vinylprop-2-ynyl halides. This method has wide application for the synthesis of diverse systems, in particular of phenomones and jasminoids[134–136].

Substitution of organo-magnesium and -zinc derivatives of allene in reactions involving electrophiles (water, aldehydes, ketones, epoxides, carbon dioxide, etc.) leads to their functionalisation. Attack takes place in general either at $C_{(1)}$ or at $C_{(3)}$. The regioselectivity of these reactions is ambiguous, and variations can be observed in the dependence on the nature of the metal (aluminium, magnesium, zinc)[137] and in the effects of various steric and electronic factors[138].

Sometimes competing side-reactions also lead to the formation of allene and/or acetylene derivatives. For example, hydrolysis of allenylmagnesium halides always occurs with partial formation of dimers of the hydrocarbon part of the initial halide[131,132]. Carbon dioxide gives exclusively or preponderantly allenic acids[43,48,49,131], the formation of acetylenic acids being explained by a slow prototropic shift in the allenylmagnesium bromide formed[131]:

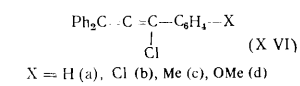


Lithiation of halogenoallenes gives good yields of lithium allenyls[59,139,140]; in many other cases the latter are generated by deprotonolysis[139–142], which occurs especially readily with hetero-substituted prop-2-ynyls:

In such reactions lithium reagents are especially attractive as synthons for organic synthesis. Reactions with diverse electrophiles clearly indicate the dual nature of the reagent, although in most cases they take place with retention of the allene structure[139–147].

A curious rearrangement takes place in the action of butyl-lithium on 4-bromobuta-2,3-diene-1-ol. The reaction produces not only buta-2,3-dienol (in ~25% yield) but also a mixture of acetylenic hydrocarbons. An intermediate bromobutenyne is formed, which then reacts with butyl-lithium to form a dilithium prop-2-ynyl derivative that is converted into

the final hydrocarbons[148]:

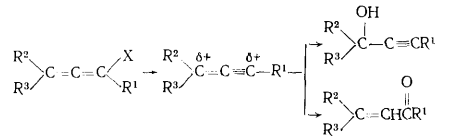


Hydrolysis (solvolysis) of allenyl halides

Allenyl halides, especially those containing electron-donor substituents in the α-position, tend to hydrolyse by an S_N1 mechanism via a cationoid allenyl intermediate, which is a resonance form of an alkynylcarbenium ion

The latter is formed also by heterolysis of the C–X bond in prop-2-ynyl substrates, and its structure has been reliably confirmed by the ^1H n.m.r. spectra of diarylalkynols in a strongly acid medium[149]. Jacobs and Fenton[52] were the first to suggest formation of an intermediate allenyl cation during hydrolysis.

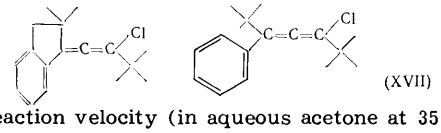
Finally, a fairly recent study of the solvolysis of various triarylchloroallenes



(XVI)

X = H (a), Cl (b), Me (c), OMe (d)

has shown that all these processes are unimolecular[54,150]. First-order kinetics has been established right up to 90% conversion, when reaction rates are independent of addition of a base. Solvolysis is characterised by a considerable accelerating effect of the ionic strength of the solvent [$m = 0.69$ and 0.77 for (XVIa) and (XVId) respectively] and a retarding effect of a salt having a common ion: the initial rate of solvolysis of triphenylchloroallene decreases by 29% in the presence of 0.1m lithium chloride[150]. The relative rates of reaction of the halogenoallenes (XVIa-d) in 80% aqueous acetone are 1 : 0.57 : 3.7 : 37.5. The element effect of the leaving group lies in the range $k_{Br}/k_{Cl} = 20$–58.

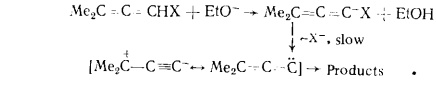


Similar rules have been illustrated by the solvolysis of a wide range of di- and tri-alkylated halogenoallenes with the alkyl groups in different positions (R^1, $R^2 = CH_3$, t-C_4H_9)[42,55]. The rate of solvolysis depends on the type and the number of substituents: on passing to bromopropadiene the rate constant decreases by a factor of 10^9.[151] The appearance of an element effect $k_{Br}/k_{Cl} = 20$–58, the reaction constant of arylated chloroallenes $\rho = -2.0$, and the entropy of activation of these reactions (−42 to +37 J mole^{-1} deg^{-1}) also agree well with substitution by an S_N1 mechanism.

In conformity with this the solvolysis of optically active 1-bromo-3-methylpenta-1,2-diene gives racemic products[152]. Finally, the effect of a salt on the observed solvolysis rate constant[152] and stereochemical data on recovery of the allenyl halide (complete retention of configuration)[153] indicate directly the possibility that the intimate ion-pair of the allenyl cation is involved in the transition state:

Substitution in allene derivatives by an S_N1 mechanism obeys different rules, since selectivity of attack is then determined by competition of the carbenium ion from two sides. The main products are acetylenic alcohols (yield 40–60%): i.e. preferential attack at the prop-2-ynyl centre of the cation is observed. Furthermore, addition takes place at the sterically less hindered carbenium centre, for unsaturated ketones are formed in the case of halogenoallenes having the substituents $R^2 = R^3 = t\text{-}C_4H_9$.[53,55]

An aromatic ring is more effective in influencing the rate of solvolysis when attached to $C_{(1)}$ than to $C_{(3)}$ (nine times as rapid)[55]. This is obviously due to the inability of such a ring at position 3 to attain a planar arrangement in order to act effectively on formation of a cationic centre and on its reactivity. It has been shown for the sterically fixed chloroallene



(XVII)

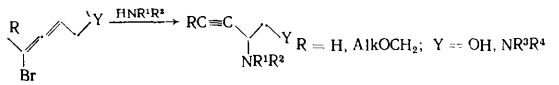
that the reaction velocity (in aqueous acetone at 35 °C) is higher than that of the open-chain analogue by a factor of 6800.[58]

An aromatic 3-substituent may be expected to have a greater influence in stabilising an allenyl than a vinyl cation. Stang[154] estimated this effect by comparing the reaction rate constants of triphenylallenyl and tri-p-methoxyphenylvinyl chlorides in 90% aqueous ethanol. The considerable kinetic effect of 10^6–10^9 in the rate constant can be explained by direct attachment of the aryl substituent to the carbon atom, which in a unimolecular process becomes a cation.

The influence of isotopes on reaction velocity has also been studied[42,155]. Replacement of α-hydrogen by deuterium in 1-bromo-3,4,4-trimethylpenta-1,2-diene lowers the rate, with an α-secondary isotope effect $k_H/k_D = 1.22$,[155] which far exceeds the usual isotope effect of hydrogen substitution in the solvolysis of alkyl bromides. Solvolysis of the above bromo-compound labelled with deuterium in the β′-position (CD_3) gave considerable secondary isotope effects (1.23). These results can be explained by additional stabilisation of the transition state and the intermediate carbenium ion by a greater contribution from the prop-2-ynyl structure.

The solvolysis of terminal halogeno allenes and prop-2-ynyl halides under conditions of catalysis by bases is of especial interest, since it enabled the possibility of substitution via an intermediate vinylidenecarbene—a zwitterion—to be demonstrated for the first time[156]. Mainly prop-2-ynyl substitution products are formed from a 3,3-dialkylated bromoallene:

There is no doubt about the mechanism of this reaction, at least in relation to the formation of vinylidenecarbene[157,158]. It is supported by physical and chemical tests: the reaction is not catalysed by bases when the acetylenic hydrogen is replaced by an alkyl group[159]; and the change in the activation volume indicates that water plays no part in the transition state. The positive but small activation volume

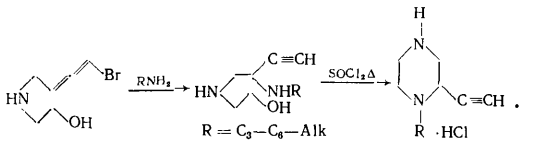


(+1.8 cm^3 $mole^{-1}$) is consistent with equally probable contributions by the two resonance structures[160].

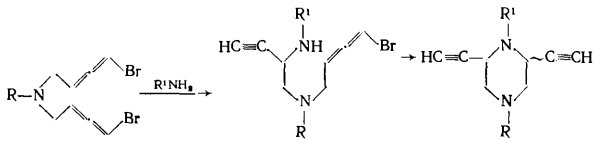
From data on recovery of the allenyl halide (with the use of 1,4-disubstituted adamantanes as stereochemical label) it was concluded that a carbene–anion pair was involved in the reaction[153].

A carbene mechanism has been attributed to other reactions of halogenoallenes—with amines[156,161] C–H acids[162,163], Grignard reagents[164]—mainly by analogy with the mechanism of solvolysis. These reactions also take place in basic media, which favour carbene formation, e.g. under conditions of phase-transfer catalysis[165]. However, because of inadequate study of these reactions, there is no complete certainty that a carbene mechanism is involved.

Substitution by amines



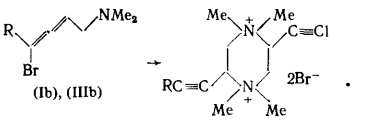
Replacement of halogen by an amine in a prop-2-ynyl halide is one of the most widely used methods for obtaining many aminoacetylenes, which show promise in research on physiologically active substances[166]. Halogenoallenes have been less investigated. It has proved possible to use these reactions, not with halogenoallenes themselves but with their functional derivatives. Examination of the reactions of allene bromides (I: R = H) and (III: R = AlkOCH$_2$)



(I), (III)

with primary and secondary amines have shown that the sole process is replacement of the bromine atom by an amino-group. Substitution takes place at the γ-position, i.e. with simultaneous allene–acetylene rearrangement, to give vicinal difunctional acetylenes in ~40–70% yields[100,167,168].

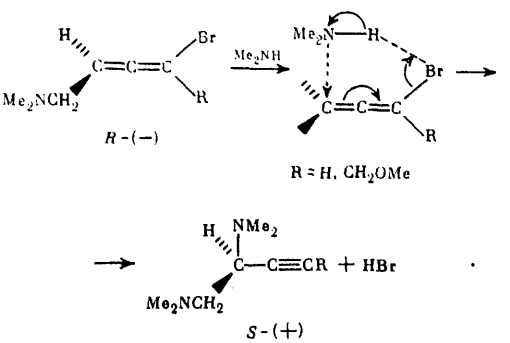
Aminoalkylation also occurs with 1-bromo-4-2′-hydroxyethylaminobuta-1,2-diene[169]; although yields are not high, the resulting acetylenic diamino-alcohols can be converted by simple transformations into 2-ethynylpiperazines, which are difficultly accessibled by other means (yield ~30%):



However, results for the heterocyclisation of *NN*-bis-4-bromobutadienylamines (II) are most interesting for preparative purposes; the only products are 2,6-diethynylpiperazines (an equimolecular mixture for *cis*- and *trans*-isomers) in 40–60% yield, apparently by intramolecular replacement of an atom in an intermediate diaminobromoallene[101,170]:

R=CH$_2$Ph, HOCH$_2$CH$_2$; R^1=C$_2$–C$_6$–Alk, CH$_2$Ph, 1-adamantyl .

This unusual, but smooth and obviously general reaction provides a good method for obtaining *C*-alkynyl derivatives of other heterocycles (nitrogen, oxygen, sulphur) and merits further study.



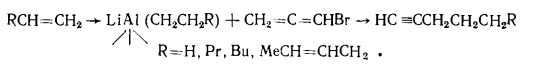
Finally, the dimerisation of bromo-*NN*-dimethylbuta-2,3-dienylamines (Ib, IIIb) (dimethylformamide at 20 °C) yields the corresponding salt of the quaternised 2,5-dialkynylpiperazine (which may be explained as both an intermolecular and an intramolecular process, in which a three-membered ring should be obtained)[170]:

(Ib), (IIIb)

The mechanism deserves special consideration. To elucidate the effect of the degree of substitution in the bromomethylene group on the direction, kinetics, and stereochemistry of substitution, two types of α-bromoallenes were used (Ib: R = H) and (IIIb: R = CH$_2$OCH$_2$). In the former case the reaction could occur via a carbene, and in the latter an allenyl cation could be formed. As noted above, the reaction is not complicated by secondary processes, gives the same regioselective substitution product in the two cases, and has overall second order (first with respect to the halogenoallene and first with respect to the amine)[171]. Even from these results it could be concluded that interaction with amines involves neither S_N1 alkylation nor a carbene stage.

Investigation of the stereochemistry of amino-substitution[172] involving optically active (–)-bromobuta-2,3-dienylamines (Ib) and (IIIb) has shown that the reaction with dimethylamine involves transfer of chirality with formation of (+)-acetylenic diamines†. Such constancy of structural, kinetic, and stereochemical relations indicates that the same type of transition state is involved in the two cases. From these facts a model of this complex was suggested with *cis*-orientation of entering and leaving groups, according to which aminoacetylenes should be formed with positive specific rotation for the *S*-configuration#:

Since the retroprop-2-ynyl rearrangement accompanying substitution involves essentially an S_Ni' mechanism, it is interesting that such reactions in the acyclic allyl system lead to predominance of the *cis*-isomer when the attacking nucleophile is neutral[173], and the *trans*-isomer if the nucleophile is ionic in character (RS^-).[174]



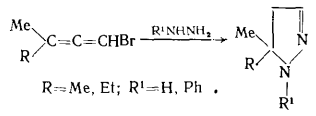
---

† The degree of stereospecificity of the analogous reaction of (–)-(Ib) with (–)-α-methylbenzylamine is ≥80% (according to capillary gas–liquid chromatography)[170].

Erroneously termed an *R*-configuration in Ref. 172.

Other nucleophiles

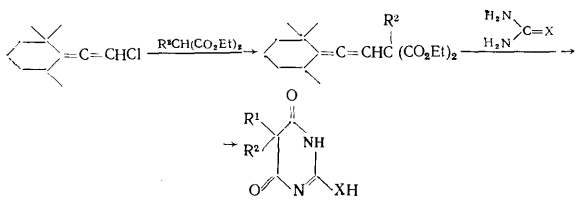
Individual studies have been made of the conversion of allenyl halides in the Meyer reaction[175] with metal phosphides and arsenides[176] and with lithium tetrahydroaluminate[177], leading to the formation solely of acetylenic derivatives§. A novel method for obtaining terminal acetylenes (in 50–60% yield) is based on the hydroalumination of bromopropadiene[178]:



Under similar conditions prop-2-ynyl bromide yields terminal allenes[178].

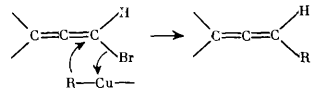
Halogen can be replaced by hydroxyl under suitable conditions[44,179]. A case has been reported of intramolecular substitution—rearrangement with formation of *trans*-2-ethynyl-3-phenyloxiran (yield 34%) from 4-bromo-1-phenylbuta-2,3-dien-1-ol in the presence of caustic potash[180]:

Substitution of dialkylallenyl bromides by hydrazines is accompanied by intramolecular cyclisation with formation of a 2-pyrazolines (yield 60–70%), reaction being facilitated by catalytic additions of copper(I)[181]:



Compounds containing active hydrogen can be used. With acetoacetic ester halogenoallenes are assumed to undergo reactions having S_N2 and/or S_N2' mechanisms[182,183]. Under these conditions the isomeric 1-bromoallene and 3-bromopropyne give a moderate yield of a like mixture of mono and disubstitution products and cyclic compounds formed from them[182,183]. From iodoallene (mixed with 25% of 3-iodopropyne) with formamidomalonic ester in the presence of sodium ethoxide as base are formed the corresponding prop-2-ynyl derivatives in 67% yield[162]:

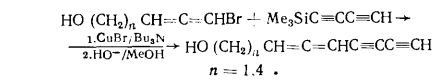
Similar reactions occur with alkylated halogenoallenes, but the proportion of isomeric allenic keto-esters[183] or diesters[162] increases with the steric hindrance of the halides.



Similarly, alkylmalonic esters react with sterically hindered allenyl halides in the presence of sodium ethoxide to form allenic diesters, from which several allenic barbiturates (and thiobarbiturates) have been obtained by the action of urea (thiourea)[163]:

R^1 = t-BuCH = C = CH, t-BuC (Me) = C = CH, (iso-Pr)$_2$ C = C = CH, $Et_2C{=}C{=}CH$; R^2=Et, n-Bu; X=O, S .

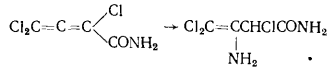
§ Reactions of iodoallenes with vinyl cuprates have been used also for the synthesis of dehydroarachidonic acids[224].



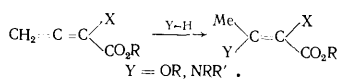
Halogenoallenes are converted by lithium dialkylcuprates[184,185] and copper cyanide[186] into allenic derivatives with replacement of the halogen via a four-centre transition state:

R = Alk, CN, $(AlkO)_2P(O)CH_2$.

The allenic structure is retained during cathodic reduction[187] and on reaction with lithium alkyls[188] and with a Grignard reagent in the presence of catalytic quantities of palladium chloride[189].

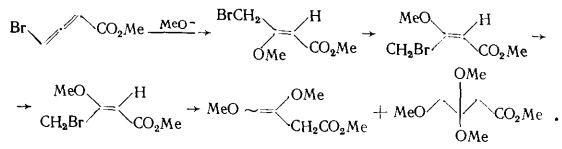


We note in conclusion that bromo- and iodo-allenes condense smoothly with terminal acetylene in the presence of copper salts and an amine (as a base) to form conjugated allene–acetylenes[67,190]. This process has been used to synthesise allene-diyne metabolites produced by micro-organisms[67]:

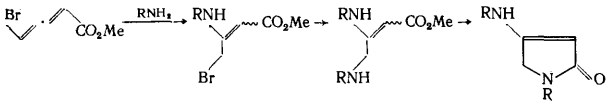


Under the influence of copper salts α-bromoallenes are converted into conjugated diallenes, the course of the reaction being strictly regioselective[191].

4. Linear Addition of Nucleophilic Reagents

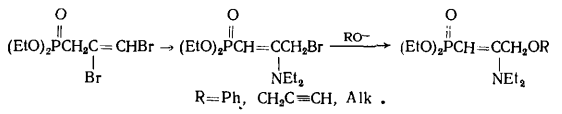


The allene group in α-halogeno-derivatives is usually resistant to attack by nucleophiles, and addition reactions have been little studied. Among them we may note firstly those of halogenoallenes containing electron-accepting substituents (alkoxycarbonyl, diethylphosphono, carbonyl). As might be expected, attack by the nucleophile (amine or alcohol) takes place exclusively at the carbon atom of the more electrophilic αβ-double bond, with formation of adducts corresponding to a protonated carbanion at the outer carbon atoms of the allene group. Adducts of crotonic type, being thermodynamically stable, may of course result also from prototropic isomerisation of vinylacetic adducts. 2,4,4-Trichlorobut-2,3-dienamide and ammonia form only the vinylacetic amino-derivative[26]:

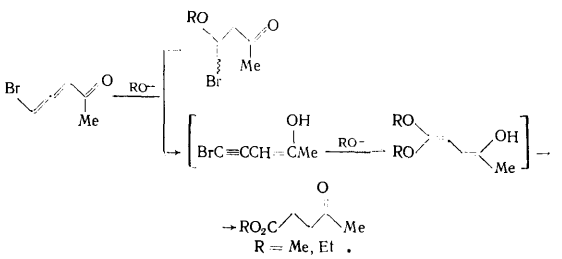


Primary and secondary amines and also alcohols (in the presence of an alkoxide) react smoothly with 2- [192] and 4-4-halogenobutadienoic esters[24,35,193] to give high yields of β-substituted derivatives of crotonic type:

However, involvement of γ-halogen in the reaction leads to formation of bisadducts. Thus mono-, di-, and tri-alkoxy-derivatives are formed with alcohols depending on the proportions of the components[193]: for the addition of methanol the reactions are

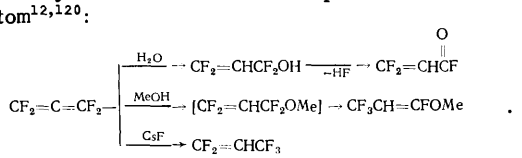


When excess of a primary amine is used, the resulting diaminocrotonic ester then undergoes cyclisation to form γ-alkylamino-substituted α-pyrrolinones, which cannot be obtained in other ways[35]:



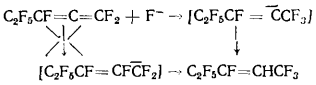
R=Et, n-Bu, t-Bu, CH_2Ph .

Several nucleophilic additions of amines and alcohols have been reported for βγ-dibromoalkenylphosphonates. The reactions involve an intermediate bromoallenylphosphonate. The method enables addition to be conducted selectively, and phosphonates to be synthesised to contain various functional substituents[21-23]:



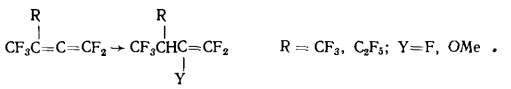
R=Ph, $CH_2C{\equiv}CH$, Alk .

The interaction of halogenoallenyl ketones with amines and alcohols has been studied considerably less. 5-Bromopenta-3,4-dien-2-one with alcohols gives only a small proportion of alkoxy-derivatives, the main reaction products being laevulinic esters. It is assumed that an intermediate ketenic acetal is formed by substitution at the *sp*-hybridised carbon atom[194]:

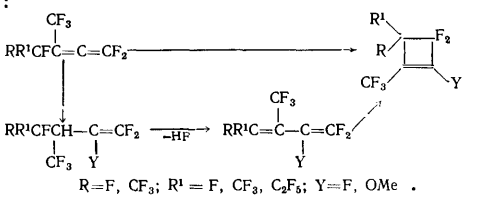


R = Me, Et .

Somewhat different rules are observed in the orientation of addition of nucleophilic reagents to perfluoroallene compounds, whose reactions have been widely studied. Tetrafluoroallene reacts with such reagents as water, methanol, and moist caesium fluoride under exceptionally mild conditions to give monoadducts. Elimination or rearrangement of the initial adducts can be observed at the same time, but the regioselectivity is such that the nucleophile adds to a terminal carbon atom[12,120]:

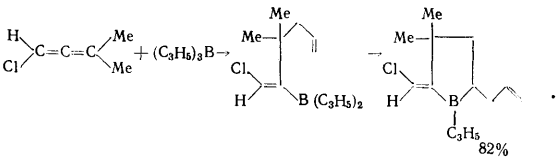


Similarly, perfluoropenta-1,2-diene gives monoadducts formed by attack at a terminal difluoromethylene group, with simultaneous formation of products of retroprop-2-ynyl rearrangement[195].

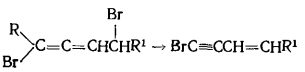


The orientation of nucleophilic addition to tetrafluoroallene and perfluoropenta-1,2-diene is directly opposite to that observed with halogenated buta-2,3-dienoic acids and related compounds discussed earlier. Such a course is not surprising, since attack by a nucleophile at the central carbon atom should produce an α-fluorocarbanion, which is unable to destabilise the positive charge on the fluorinated carbon atom[196]. In such cases only derivatives at a terminal carbon atom are formed: i.e. addition takes place at the double bond with formation of the most stable carbanion, stabilised by the perfluoroalkyl group:

Increasing the chain length of perfluoroalkyl-substituted allenes leads to a change in the orientation of addition. Their reactivity diminishes, but with increase in reaction time quantitative yields can be obtained even here[11]. The perfluorinated analogues of 1,1-methyl(alkyl)- and tetramethylallenes react with nucleophiles (methanol, caesium fluoride) to form monoadducts corresponding to regioselective attack at the central carbon atom[11,13,197]; hydrogen is directed solely to the end of the double bond substituted by the perfluoroalkyls:

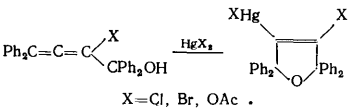


The monoadducts formed may undergo further changes, as e.g. in the reactions of 1,1-dialkylperfluoroallenes, when the resulting derivatives are dehydrofluorinated and spontaneously cyclised with high yields into the corresponding cyclobutenes[11]:



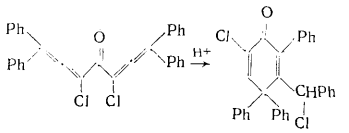
R=F, CF_3; R^1 = F, CF_3, C_2F_5; Y=F, OMe .

At 20 °C reaction takes place between triallylborane and dimethylchloroallene at the substituted double bond; the resulting diallylborane undergoes intramolecular cyclisation[198]:



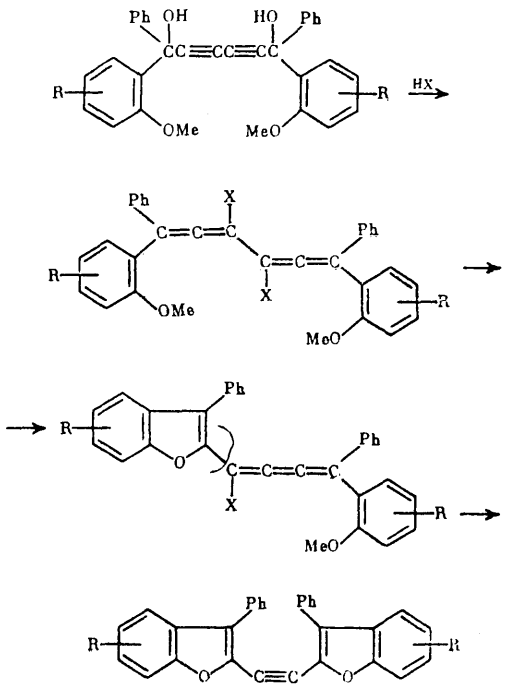
5. Other Reactions

Derivatised halogenoallenes exhibit specific properties towards several reagents in virtue of their structural features. Thus 1,4-dibromoallenes are sensitive to alkalis and readily undergo dehydrobromination involving the allyl bromine atom[90-92]:



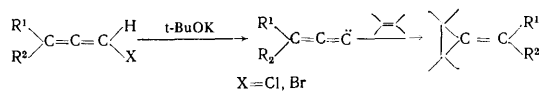
R=H, $SiMe_3$; R^1=H, Me, Et .

Treatment of halogenoallenes with acidic reagents[46,119,199,200] or with mercury salts[201] leads to unusual reactions, probably involving carbocation intermediates, which may be cyclised, depending on the presence of a functional group (hydroxy, phenyl), into derivatives of indene[46,119,201] or of dihydrofuran[199-201]:



X=Cl, Br, OAc .

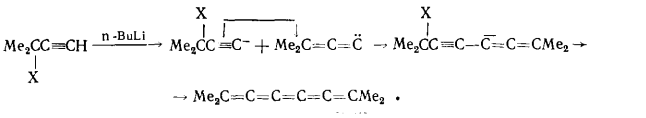
αβ-Unsaturated aldehydes and ketones are obtained under the same conditions[46,119,132]. Bis-3,3-diphenyl-1-chloroallenyl ketone is smoothly cyclised into cyclohexadienone in the presence of an acid[202]:



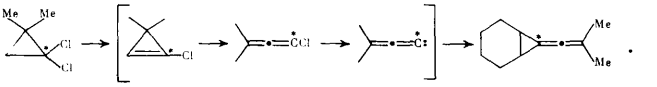
Symmetrical tetraphenylhexadiynediol under the influence of hydrogen halides undergoes two-stage cyclisation with formation of bisbenzofurylacetylenes[203]; study of this curious reaction showed the intermediate formation of a halogenobutatriene, which in the presence of activated alumina gives the final product in 35–45% yield:

R = H, Me, Cl, OMe; X = Cl, Br .

Under alkaline conditions halogenoallenes are able to eliminate a hydrogen halide containing the allenyl halogen atom. For example, heating bromoallenes with copper cyanide in dimethylformamide gives 45–65% yields of butenynes[39,204]. The most interesting is the 1,1-elimination of α-halogenoallenes. The method consists in acting on the latter with a strong base (usually potassium t-butoxide) with generation of a carbene; subsequent reactions with alkenes yield the corresponding cyclopropanes[205,206]:



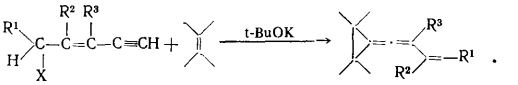
X = Cl, Br



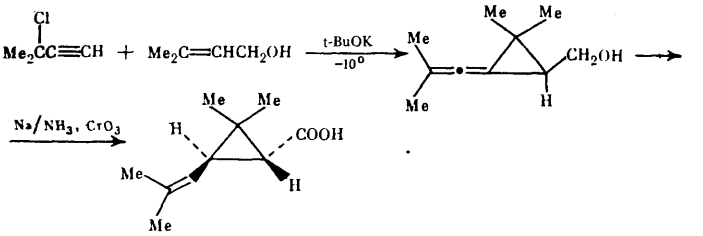
Better yields of carbene intermediates are observed if phase transfer is used in the presence of butyltriethylammonium chloride[165,166,207] or a crown ether[208,209].

Another method of generating carbenes consists in the intermediate formation of products of lithiation of halogenoacetylenes at the carbon-hydrogen bond. Under mild conditions isomerisation of the triple bond does not occur.

Above 25 °C, however, the lithium halogenoalkynides undergo unambiguous conversion into carbenes[210], which under the reaction conditions are often transformed into hetero-substituted (methylated, phenylated) hexapentaenes[47,211]:

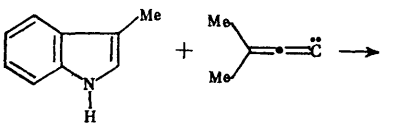


In a limited number of cases carbenes could be obtained from such compounds as 1,2-dibromo-3,3-diphenylallene (by the action of lithium alkyls[47]) and 3-alkyl-1-bromopropynes (by the action of alkoxides)[212,213]. The most interesting case was the preparation of dimethylvinylidenecarbene by the action of potassium t-butoxide (in Hexametapol) on dichlorocyclopropane (yield at most 6%), with intermediate formation of a chlorocyclopropene[214]:

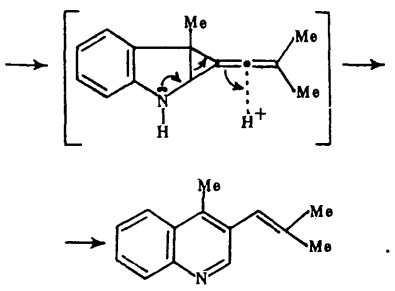


Such reactions constitute a special case, and can be used only for compounds analogous to those described above.

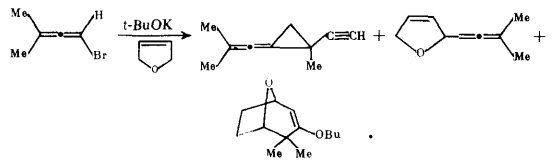
Towards alkenes allenylcarbenes behave as strong electrophiles, and undergo exclusively *cis*-addition, as has been demonstrated for dimethylvinylidenecarbene with *cis*- and *trans*-but-2-enes[209,215]. Study of the reactions of this carbene generated in different ways (from chloroprop-2-ynyl with potassium 2-butoxide or from bromoallene by the phase-transfer method) showed good agreement between the relative rate constants of the carbene with different alkenes[209].



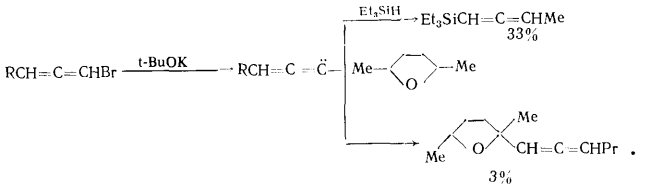
Various allenylcyclopropanes are readily formed, usually in satisfactory yield, also in the generation of allenylcarbenes from available halogenoprop-2-ynyl derivatives, which is of great value for their synthesis[216–218]. Analogous schemes are suitable also for the generation of vinylvinylidenecarbene[219]:

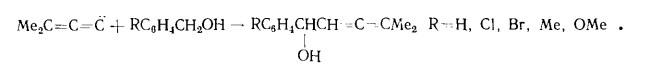


An interesting example is the stereospecific synthesis of *trans*-chrysanthemic acid by use of this carbene[220]:



1-Bromoallenes react in basic medium (via the carbenes) with methylindoles to give alkynyl(allenyl)-3*H*-indoles[221] and alkenylquinolines—products of the ring expansion of allene intermediates:





Dimethylvinylidenecarbene (generated from a halogenoallene by the action of potassium t-butoxide) reacts with dihydrofuran[222] to form, together with cyclopropanation products (yield 22%), also unsaturated compounds corresponding to incorporation of the carbene at a carbon-hydrogen bond:

The action of potassium t-butoxide on alkylallenyl bromides led to isolation of a carbene, which added to 2,5-dimethyloxolan and triethylsilane to give products involving incorporation at carbon-hydrogen and silicon-hydrogen bonds respectively[214]:

The action of dimethylvinylidenecarbene on alcohols (reaction between halogenoallenes and sodium ethoxide in alcoholic solution) usually gives satisfactory yields of products involving incorporation at a carbon–hydrogen bond, i.e. α-allenyl alcohols[223]:

---oOo---

As the above survey shows, α-halogenoallenes can be used to obtain many aliphatic, carbocylic, and heterocyclic functional derivatives belonging to various classes of organic compounds. Halogenoallenes can therefore be rightly regarded as effective and multipurpose starting materials for the synthesis of diverse compounds of theoretical and practical value.

Protection of the Amino-group in Peptide Synthesis

S.V.Burov and M.P.Smirnova

N-Protecting groups most widely used in peptides synthesis are examined. The possible mechanisms of the elimination of the protecting groups in acid and alkaline media are described and the methods of synthesis of the reactants for the introduction of certain protecting groups are considered.
The bibliography includes 65 references.

III. Alkali-labile protecting groups 906

I. INTRODUCTION

Two main trends may be isolated in the development of peptide chemistry: the improvement of methods for the formation of the peptide bond and the development of new more convenient protecting groups. The advances made in this field in recent times made it possible to simplify greatly the synthesis and to increase its effectiveness.

This review deals with the present state of the problem of the utilisation of *N*-protecting groups in the synthesis of peptides by the classical and solid-phase methods.

Despite the availability of deblocking methods such as catalytic hydrogenation, electrochemical reduction, treatment with sodium in liquid ammonia, irradiation with ultraviolet light, etc., the majority of protecting groups can be classified as either acid-labile or alkali-labile. Subsequently, we shall adhere to this conventional subdivision, considering other methods for the removal of protecting groups only in those cases where they are of special interest. The traditional protecting groups are described only briefly and some of these are not considered at all since their properties have been frequently discussed in the literature[1-5].

II. ACID-LABILE PROTECTING GROUPS

The first acid-labile protecting group, which has found extensive practical applications and which has exerted a great influence on the development of peptide synthesis, was the benzyloxycarbonyl group proposed in 1932 by Bergmann and Zervas[6]. The simplicity of the preparation and the ready availability of benzyloxycarbonyl derivatives, their high resistance to racemisation, and the wide variety of deblocking methods (treatment with hydrogen bromide in acetic acid, treatment with sodium in liquid ammonia, catalytic hydrogenolysis, and irradiation with ultraviolet light) are the main causes of the popularity of this protecting group.

New methods for the removal of the benzyloxycarbonyl protecting group, which have many advantages compared with the traditional methods, have been developed comparatively recently.

In 1977, Jackson and Johnstone[7] proposed a hydrogenation procedure involving hydrogen transfer, which proved convenient in the reduction of aromatic nitro-compounds. In the same year it was used to remove a number of protecting groups including the benzyloxycarbonyl group in classical peptide synthesis[8] and subsequently also in synthesis by the solid-phase method[9]. It was found that in this case the removal of the protecting groups is much faster and in addition it is possible to avoid the formation of side products in the deblocking of nitroarginine-containing peptides.

In the initial version, the hydrogenation with hydrogen transfer reduced to refluxing for several hours a solution of the protected derivative in ethanol in the presence of cyclohexene and palladium on charcoal or of palladium black. However, the refluxing of the peptide solution, which is itself undesirable, becomes particularly risky in the presence of protecting groups such as the t-butoxycarbonyl and t-butyl ester groups in view of the possibility of their being split off.

It has been shown[10] that these difficulties can be overcome when cyclohexa-1,4-diene is used as the hydrogen donor. In this case the deblocking is achieved at room temperature in 1.5–2 h in the presence of palladium and charcoal, while the use of palladium black permits the complete elimination of the protecting group in 5 min. The method proved convenient also for derivatives of certain sulphur-containing aminoacids, in particular methionine.

Yet another version of the hydrogenation reaction with hydrogen transfer was proposed in 1979, in which provision is made for the employment of formic acid as the hydrogen donor[11]. The benzyloxycarbonyl group is removed by treatment with a 4.4% solution of formic acid in methanol in the presence of palladium black in an atmosphere of nitrogen or by passing a solution of the protected derivative in methanol, containing 4.4% of formic acid, through a column containing palladium black. The time taken to eliminate the benzyloxycarbonyl group does not exceed 10 min in most cases; in addition this hydrogenation method greatly reduces the time taken to eliminate the *O*-benzyl groups.

Thus hydrogenation with hydrogen transfer makes it possible to remove rapidly and effectively the benzyloxycarbonyl group and a number of other protecting groups.

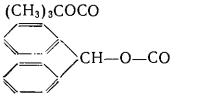
The t-butoxycarbonyl group, the parent of acid-labile groups eliminated under mild conditions, plays a no less important role in peptide synthesis. As a result of the appearance of this group[12], the possibilities of both the classical and solid-phase methods of synthesis of peptide have been greatly expanded.

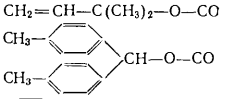
Either the Schanabel method[13] or the Schwyzer method[14], in which the amino-group is acylated by treatment with the corresponding azide, were used initially to introduce the protecting group. However, in subsequent years a tendency arose to search for more efficient methods and reactants for the synthesis of protected derivatives. Here one may mention the application of systems such as t-butoxycarbonyl azide–triethylamine[15], t-butoxycarbonyl azide–imidazole, and t-butoxycarbonyl azide–1,1,3,3-tetramethylguanidine-1,2,4-triazole[16]. In the last case the method is so effective that it makes it possible to obtain fully protected derivatives of insulin by the direct acylation of the natural hormone, the yield of the reaction product exceeding 90%.

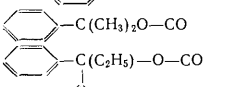
It has been suggested quite recently that the above protecting group be introduced using di-t-butyl pyrocarbonate[17]. The application of this reagent makes it possible to simplify greatly the method of synthesis and to increase the availability of the corresponding derivatives. Subsequent studies showed that the method is suitable also in the case of certain other protecting groups[18].

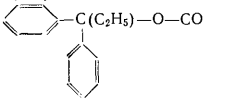
According to the method proposed by Pozdnev[17,18], the synthesis of aminoacid derivatives reduced to their treatment with di-t-butyl pyrocarbonate in the isopropyl alcohol–water system in the presence of triethylamine for 30 min at room temperature. The reaction takes place with a high yield (~90%) and the products formed do not as a rule require further purification.

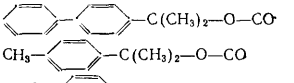
Since the introduction of the t-butoxycarbonyl protecting group, the development of the solid-phase peptide synthesis has in essence begun. The employment of the benzyloxycarbonyl protecting group enabled Merrifield to synthesise only short model peptides[19] because of the occurrence of a side reaction involving the branching of the peptide–polymer bond in the deblocking process at acid pH. At the same time in the case of the t-butoxycarbonyl protecting group, under conditions ensuring its virtually quantitative removal, the degree of cleavage of the *C*-terminal benzyl ester is 1–2%.[20] As a result of this, it was possible to achieve the stepwise synthesis of ribonuclease A (124 aminoacid residues) by the solid-phase method[21].

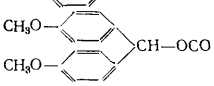


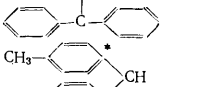


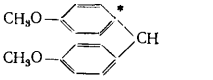












In the classical peptide synthesis the t-butoxycarbonyl protection of the α-amino-group in aminoacids is usually employed in combination with the following groups for the blocking of functional side groups in aminoacids: the nitro- or tosyl-group for the guanidino-group of arginine, the benzyloxycarbonyl group for the ε-amino-group of lysine, the benzyl group for the imidazole nitrogen of histidine and the sulphydryl group of cysteine, the benzyl ester groups for the carboxy-groups of glutamic and aspartic acid (and the *C*-terminal carboxy-group), and the benzyl ether groups for the hydroxy-groups of serine, threonine, and tyrosine.

Thus, after an appropriate choice of other protecting groups, the t-butoxycarbonyl group can be used successfully in the synthesis of peptides with a wide variety of aminoacid sequences by both classical and solid-phase methods.

Nevertheless, mention must be made of a series of specific difficulties arising in the employment of the protecting group. It is sufficient to note the problem of selectivity in the blocking of the α- and ε-amino-groups of lysine[22] and the t-butylation of the tryptophan-containing peptides, involving the removal of the t-butoxycarbonyl group[23–25]. It therefore became necessary to develop *N*-protecting groups more labile in acids than the t-butoxycarbonyl group and also groups which can be removed selectively in the presence of the t-butoxycarbonyl protecting group and the t-butyl ester groups used for the blocking of the functional side groups in aminoacids or the *C*-terminal carboxy-group.

The resistance of groups of this kind to the action of acids and the mechanisms of their elimination were investigated in detail in 1968.[26] It was shown in relation to various alkyl and urethane groups that the rate of their acidolytic cleavage depends on the stability of the carbonium ion formed and the acidity of the reaction medium. The rate of removal of certain protecting groups then proved to be 60000 times higher than that of the t-butoxycarbonyl group (Table 1). Unfortunately most of them are unsuitable for use in peptide synthesis owing to the instability of the azides or chloroformates used as the reagents for the introduction of the protecting group. The authors therefore decided to employ the diphenylisopropoxycarbonyl group[27], the rate of elimination of which is 3000 times higher than that of the t-butoxycarbonyl group. It has been suggested that this protecting group be introduced by the reaction of the corresponding azide or phenyl carbonate with aminoacid esters or salts. It proved possible to use dilute acetic acid and other weak acid reagents for the deblocking, which permits the retention of other acid-labile groups present in the growing peptide chain, particularly the t-butoxycarbonyl and t-butyl ester groups. By virtue of the large difference between the rates of elimination of the benzyloxycarbonyl and diphenylisopropoxycarbonyl protecting groups, it is then possible to solve the problem of selectivity for trifunctional aminoacids.

Table 1. The time of the 50% cleavage (τ_{50}) of $RHNCH_2COOY$ ($Y = C_2H_5$) with 80% CH_3COOH at 22–25 °C.[26]

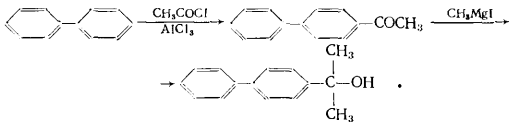
	28 days**
	~12 days

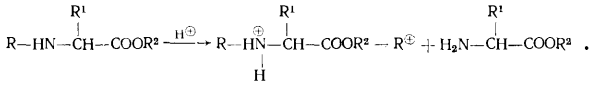
*Y = H.

**The degree of elimination was less than 0.1%.



The disadvantages of the protecting group considered may include, together with the low availability of the initial reagents, also the unduly high acid lability, as a result of which the corresponding aminoacid derivative must be stored in the form of dicyclohexylammonium salts. Theoretically, there is even the possibility of removing the diphenylisopropoxycarbonyl (DPOC) protecting group in the course of the formation of the peptide bond under the influence of the COOH group of the carboxy-component[28], which can lead to the doubling of the aminoacid residue introduced in accordance

with the scheme†

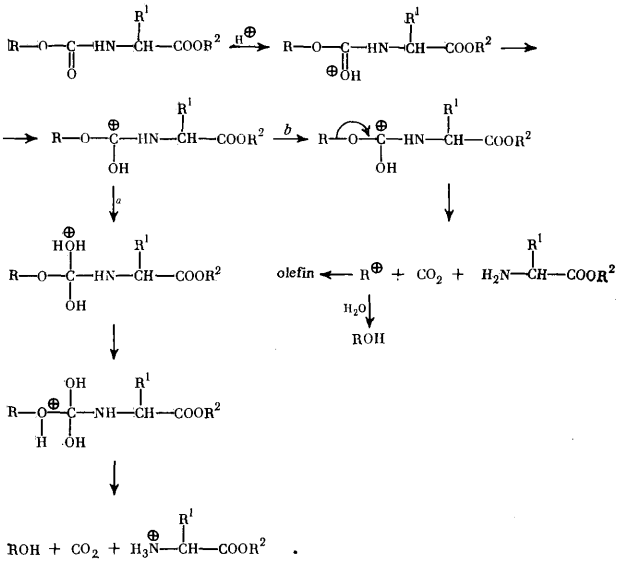


However, hitherto such cases have not been noted.

Since the diphenylisopropoxycarbonyl group is of undoubted interest from the standpoint of its employment in peptide synthesis, it is appropriate to consider the problem of the synthesis of the initial reagents for the introduction of this protecting group. In particular, the alcohol used as the starting compound in the synthesis of the corresponding azide or phenyl carbonate can be obtained as follows[29]:

We shall consider further the mechanism of the acid-catalysed elimination of alkyl and urethane protecting groups and the practical conclusions which follow from this.

In the case of alkyl groups, the cleavage under the influence of acids apparently proceeds via a mechanism involving the protonation of the nitrogen of the α-amino-group with the subsequent removal of the alkyl residue in the form of the corresponding carbonium ion:



This is also indicated by the finding that, in the detritylation of peptides by treatment with an ethanol solution of hydrogen chloride under anhydrous conditions, ethyl trityl ether is formed in addition to the hydrochloride of the corresponding peptide, while in the presence of water triphenylmethanol is formed[30].

Evidently in this instance the rate of elimination of the protecting group is determined by the stability of the carbonium ion formed. Among the known groups of the type considered, the trityl group is therefore most readily removed by acids. Despite this, the trityl protecting group has not found extensive applications in peptide synthesis for the blocking of the α-amino-group owing to the steric hindrance which it generates and the associated difficulties in the synthesis of the corresponding derivatives. However, it is used to block the functional groups in the side chains of aminoacids (mainly the mercapto-groups of cysteine).

There is apparently a possibility of using protecting groups with a smaller number of phenyl moieties containing electron-donating substituents in the ring (Table 1), while the replacement of the phenyl moiety by the methyl moiety permits the stabilisation of the carbonium ion as a result of the formation of an olefin. However, one cannot rule out the possibility that in the latter case the problem may arise of the stability and reactivity of the halogeno-derivatives used for the introduction of such groups.

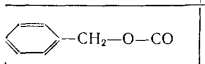
†CDI = dicyclohexylcarbodiimide.

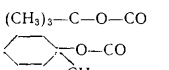
In the acid cleavage of protecting groups of the urethane type, there is a possibility of two reaction mechanisms[31]. Structures related to the benzyloxycarbonyl group react via a bimolecular mechanism, while those related to the t-butoxycarbonyl group react via a unimolecular mechanism:

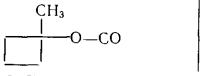
Hence it follows that groups of the first type are removed at a higher rate the greater the electron density in the benzene ring. Indeed, it has been shown[32] that the rate of cleavage of *para*-substituted derivatives of the benzyloxycarbonyl group by hydrogen bromide in acetic acid varies as follows:

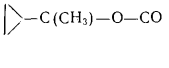
$$CH_3O > C_6H_5 \sim CH_3 > H > F > Cl > NO_2 \quad .$$

In the case of groups of the second type there is a correlation between the rate of elimination of the protecting groups and the rate of solvolysis of the corresponding tosylates[33,34]. The results are presented in Table 2.









Their investigation enabled the authors[34] to propose a new protecting group—the 1-methylcyclobutoxycarbonyl group, which is stable in 50% acetic acid and is eliminated by treatment with trifluoroacetic acid in less than 30 min. The enhanced stability in relation to aqueous acetic acid, usually employed as the solvent in the purification of higher peptides, imparts to this group certain advantages compared with the t-butoxycarbonyl protecting group.

Comparison of the data in Tables 1 and 2 permits the following conclusions: (1) the rate of the acid-catalysed elimination increases sharply on passing from the bimolecular to the unimolecular mechanism; (2) the introduction of substituents promoting the delocalisation or decrease of the positive charge of the carbonium ion formed increases the rate of elimination; (3) the presence of a methyl group at the carbon atom with a positive charge also increases the rate of elimination as a result of the stabilisation of the carbonium ion by the formation of an olefin.

It is noteworthy that the formation of carbonium ions in the removal of protecting groups of the type considered is a source of extremely undesirable side reactions, such as the alkylation of the methionine and tryptophan residue[35], in the peptide synthesised. For example, Wünsch pointed out that deblocking with hydrogen fluoride in both classical and solid-phase synthesis favours the occurrence of side reactions

involving tryptophan derivatives even in the presence of added substances which reduce the extent of such reactions[36]. It has also been stated in a number of communications that the employment of additives such as mercaptoethanol, anisole, thioanisole, ethane-1,2-dithiol, scatole etc. by no means always guarantees the absence of side reactions[37-39].

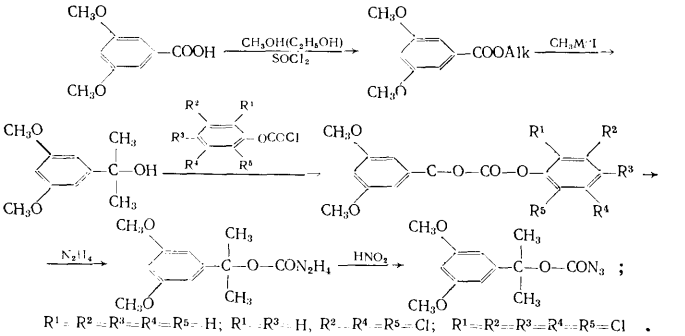
Table 2. The 50% cleavage times (τ_{50}) of various *N*-protecting groups in the deblocking of phenylalanine derivatives[34].

Protecting group	τ_{50} (25° C, min)		Protecting group	τ_{50} (25° C, min)	
	CF_3COOH	HCOOH		CF_3COOH	HCOOH
	300	—		1*	4
	40	—		1*	2
	2	—		—	1.5

*Total cleavage time.

Returning now to the consideration of the acid-labile *N*-protecting groups, we shall consider those among them which have not found extensive applications in peptide synthesis but which may prove extremely valuable for this purpose by virtue of particular advantages.

Here we may mention in the first place the o-nitrobenzenesulphenyl protecting group[40], which has been used successfully in the synthesis of oxytocin analogues[41]. The corresponding protected derivatives are usually obtained with the aid of o-nitrobenzenesulphenyl chloride, although it has recently been suggested that *o*-nitrophenyl thiocyanate be used[42]. The latter is more stable on storage and reacts with aminoacids in the presence of silver nitrate at pH 6–9, giving rise to satisfactory yields. In 1979 Cipens and coworkers developed a new method for the synthesis of *o*-nitrobenzenesulphenyl chloride and *o*-nitrobenzenesulphenylaminoacids[43]. It was found that, when di-(2-nitrophenyl) sulphide is chlorinated with sulphuryl chloride in methylene chloride at 40–45 °C, it is possible to avoid the formation of impurities.



The *o*-nitrobenzenesulphenyl protecting group can be removed selectively in the presence of t-butyl esters with the aid of a solution of hydrogen chloride in diethyl ether.

It has been suggested[44] that the adamantyloxycarbonyl group be employed[44]. The protecting group is introduced with the aid of adamantyloxycarbonyl chloroformate, which can be obtained from the corresponding alcohol by treatment with an excess of phosgene in benzene solution in the presence of pyridine. The reaction with aminoacids takes place on cooling or at room temperature over a short period. The protecting group is removed by treatment with trifluoroacetic acid in the course of 15 min, adamantane forming a stable carbonium ion which can react with an anion from the surrounding medium but is incapable of losing a proton to form an olefin.

The authors[44] also noted that the adamantyloxycarbonyl derivatives are ninhydrin-positive on heating to 100 °C. It is likewise of interest that adamantyloxycarbonyl chloride can be used as the condensing agent in the synthesis by the method of mixed anhydrides, but this method of formation of the peptide bond is not of special value.

The t-pentyloxycarbonyl protecting group was proposed in 1967.[45] In contrast to the t-butoxycarbonyl group, the corresponding chloroformate could be used to introduce it. The reaction is carried out with the aminoacid ester and the resulting derivative is hydrolysed or converted into a hydrazide. t-Pentyloxycarbonyl azide or di-t-pentyl pyrocarbonate can also be used as the reagents for the introduction of the protecting group. The group hardly differs in its properties from the t-butoxycarbonyl protecting group.

The possibility of using the 3,5-dimethoxy-α,α-dimethylbenzyloxycarbonyl protecting group has been investigated[46]. Subsequently this group was used widely in the synthesis of peptides by both classical and solid-phase methods[47,48]. A method of synthesis of 3,5-dimethoxy-α,α-dimethylbenzyloxycarbonyl azide and the corresponding mixed phenyl carbonates from 3,5-dimethoxybenzoic acids via the following scheme has been developed (the yields are not less than 80% in all the stages):

These reagents are introduced into the reaction with aminoacid salts and Triton B in anhydrous pyridine. The protecting group can be removed selectively in the presence of the t-butoxycarbonyl group and t-butyl esters by treatment with 1–5% trifluoroacetic acid in methylene chloride for 8–30 min. It was found that the rates of the acidolytic elimination of the t-butoxycarbonyl, 3,5-dimethoxy-α,α-dimethylbenzyloxycarbonyl, and 2-(*p*-biphenylyl)isopropoxycarbonyl groups are in the ratios 1 : 1400 : 3000. The proposed protecting group is also photolabile, which makes it possible to remove it by ultraviolet radiation. The protected derivatives are thermolabile and give a positive response to the ninhydrin test on heating to 100 °C. The use of the above group in the synthesis by the method of mixed anhydrides makes it possible to simplify greatly all the operations and in addition to avoid the side reactions noted in a number of instances for proline-containing peptides[49].

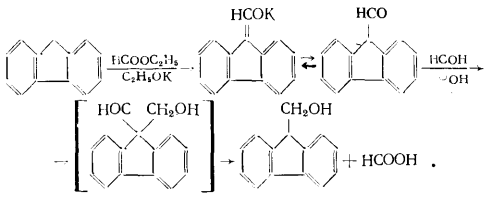
Among the latest developments in the application of acid-labile *N*-protecting groups, mention may be made of the 1,1-(1-adamantyl)-1-methylethoxycarbonyl protecting group[50]. The phenyl carbonate synthesised from adamantane-1-carboxylic acid is used as the reagent for the introduction of this group. The reaction with aminoacids is carried out in dimethylformamide at 50 °C. The deblocking is achieved by treatment with 3% trifluoroacetic acid in methylene chloride for 2–3 min.

Other acid-labile *N*-protecting groups have either not found extensive applications in peptide synthesis or are of purely theoretical interest.

In conclusion it should be noted that the protecting groups eliminated under mild acid conditions play an important role in the classical and particularly in the solid-phase peptide synthesis. Their application for the protection of the *N*-end in the synthesis of polypeptides permits the employment for the blocking of the functional groups in the aminoacid side

chains not only of comparatively stable groups such as the benzyloxycarbonyl groups but also of groups of the type of t-butoxycarbonyl and t-butyl esters. This simplifies both the operations in the course of the growing of the peptide chain and the deblocking stages.

III. ALKALI-LABILE PROTECTING GROUPS



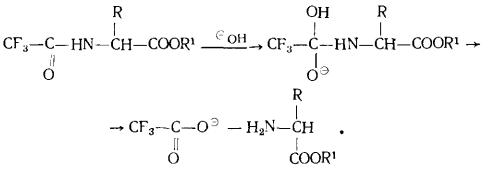
It is noteworthy that at the present time only a few alkali-labile groups of this type are used in peptide synthesis. However, the results show that the search for protecting groups eliminated under mild alkaline conditions constitutes an extremely promising development in peptide chemistry. Indeed, the appearance of such protecting groups would make it possible to avoid the difficulties arising in deblocking by acids of methionine- and tryptophan-containing peptides and their use in combination with the acid-labile protection for the functional groups in the side groups of aminoacids would greatly extend the scope of peptide synthesis.

The first step in this direction was the use of the trifluoroacetyl protecting group[51]. Trifluoroacetylaminoacids can be obtained by treating the aminoacid with trifluoroacetic anhydride in anhydrous trifluoroacetic acid or by the aminolysis of trifluoroacetate esters, while the protecting group can be eliminated by treatment with aqueous ammonia, sodium hydroxide, or barium hydroxide or by interaction with basic ion-exchange resins.

Unfortunately there is a possibility of a whole series of side reactions even in the course of the formation of the protected aminoacid derivatives and in addition under certain conditions rearrangements are observed with formation of azlactones, which leads to the racemisation of the protected aminoacid residue. Trifluoroacetyl derivatives are therefore used mainly only in gas-chromatographic analysis for the determination of the aminoacid sequence or of the degree of racemisation[52,53].

The 9-fluorenylmethoxycarbonyl protecting group, developed in 1970, is nowadays used to an increasing extent in peptide synthesis[54]. The authors introduced this group by means of the corresponding azide or chloroformate in aqueous dioxan in the presence of sodium bicarbonate or carbonate.

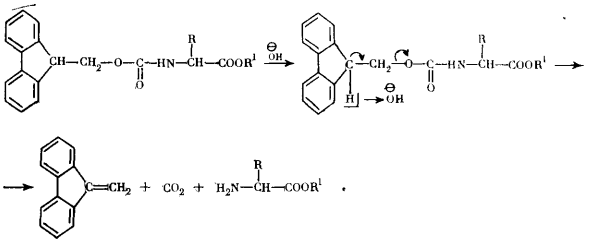
The starting compound for the synthesis of the reagents used to introduce the above protecting group is 9-fluorenylmethanol. The latter is a comparatively inaccessible compound but it can be readily obtained from fluorene in accordance with the following scheme[62]:



The yield of the final product was more than 67%. The intermediate 9-formylfluorene need not apparently be isolated in a pure form.

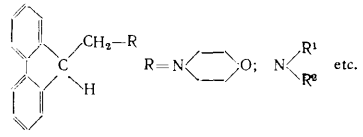
The protected aminoacids or peptides are deblocked by treatment with liquid ammonia, ethanolamine, morpholine, or similar bases. It has recently been suggested that piperidine bound to polystyrene[55] or other polymeric bases[56] be used for this purpose. According to Carpino and Han[54], the 9-fluorenylmethoxycarbonyl group is stable under the conditions where it is treated with hydrogen bromide or chloride in organic solvents and trifluoroacetic acid and also under hydrogenolysis conditions. However, a special study of the hydrogenation of protected derivatives in methanol in the presence of small amounts of acetic acid and 10% of palladium on charcoal showed that the side products are formed in this instance[57]. The authors explained the observed discrepancy in the results by the different qualities of the catalysts employed: a partially poisoned catalyst can be inactive in relation to the derivative considered.

In the classical peptide synthesis the 9-fluorenylmethoxycarbonyl protecting group has been used in the successive growing of the peptide chain by the method of activated esters[58] and also for the blocking of the α-amino-group in trifunctional aminoacids in combination with the t-butoxycarbonyl group and the t-butyl ester[59] groups for the protection of the functional side groups. Side reactions, leading to the dimerisation of the aminoacid residue introduced, have been noted in a few instances under these conditions.



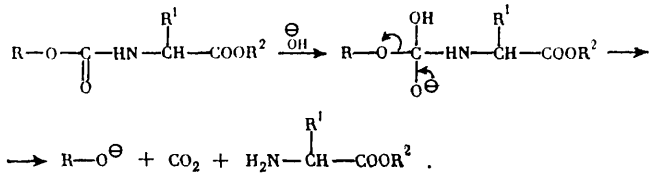
The possibilities for the employment of the derivatives under consideration in the solid-phase peptide synthesis have been investigated in detail[60,61].

In the study of the mechanisms of the elimination of alkali-labile groups, certain formal analogies can be drawn with the mechanisms of the elimination of the acid-labile protecting groups. Thus protecting groups related to the trifluoroacetyl group are removed in accordance with the following scheme:



The above reaction equation resembles formally the acid-catalysed elimination of an alkyl group and in both cases the protecting group is removed without fragmentation and with formation of the corresponding ion. In the instance considered the reaction rate is evidently determined by the fractional positive charge on the carbon atom of the carbonyl group.

Unique ideas concerning the mechanism of the removal of the 9-fluorenylmethoxycarbonyl protecting group have not so far been developed. The nature of the solvent is apparently significant in this instance. In aprotic solvents the process mechanism has not been established, while in water, methanol, and t-butyl alcohol it is close to the carbanionic mechanism[56]. To a first approximation, the elimination of the 9-fluorenylmethoxycarbonyl group can be represented by the equation



The character of this reaction is similar to that of the elimination of protecting groups of the benzyloxycarbonyl type—the group fragments in both instances and the process is not

accompanied by the formation of ions having an independent existence. In this instance the rate of cleavage is determined by the stability of the intermediate carbanion. The stabilisation of the carbanion derived from the 9-fluorenylmethoxycarbonyl protecting group is achieved by β-elimination, leading to the formation of dibenzofulvene. Depending on the reaction conditions and the reagents used in deblocking, an adduct with dibenzofulvene of the type

can be formed as a side product.

Continuing the comparison of the mechanisms of the elimination of the acid- and alkali-labile protecting groups, one may postulate the existence of a third pathway leading to the removal of the alkali-labile groups. The reaction must then proceed via a fragmentation stage with formation of independently existing ions, as happens in the case of the t-butoxycarbonyl group. The mechanism of this process can be represented by the equation

Evidently the rate of this reaction depends on the stability of the anion formed and hence on the electronic effects of the substituent R. The possibility of the operation of this mechanism is confirmed indirectly by the finding that, on passing from the benzyloxycarbonyl group to the phenoxy- and naphthoxy-carbonyl and related protecting groups, which might show a greater tendency towards the formation of anions on fragmentation, an increase of resistance to the action of hydrogen bromide in acetic acid is observed. The elimination under the influence of this reagent can be carried out only under severe conditions leading to the rupture of the peptide bond[63]. Apparently the introduction into the benzene ring of substituents promoting the stabilisation of the anion formed would make it possible to obtain alkali-labile protecting groups of the type considered. At the present time such *N*-protecting groups are not used in peptide synthesis.

A number of studies devoted to the search for new alkali-labile protecting groups and to the expansion of the applications of the already existing groups have been published in recent years. As early as 1970, the possibility of modifying the 9-fluorenylmethoxycarbonyl group in order to increase or decrease its sensitivity to bases was pointed out[54].

In 1978 Merrifield suggested that the 2-sulpho-9-fluorenylmethoxycarbonyl protecting group be used in the elimination of side products with a shortened aminoacid sequence from the peptides synthesised by the solid-phase method[64]. The 2-sulpho-9-fluorenylmethoxycarbonyl group is attached to the amino-group of the peptidylpolymer and the resulting derivative and other elimination products are separated on diethylaminoethyl-cellulose and deblocked. The protecting group is introduced using the corresponding chloroformate or the *p*-nitrophenyl ester of the aminoacid. The deblocking is carried out by treatment with aqueous morpholine or piperidine.

The possibility of using the *p*-substituted benzyloxycarbonyl group as an alkali-labile protecting group has been investigated recently[65]:

$$R-COO-C_6H_3(R^1)-CH_2-OCO-$$

$R = CH_3$, $R^1 = H$; $R = (CH_3)_2CH$, $R^1 = H$; $R = OC_2H_5$, $R^1 = H$; $R = (CH_3)_2CH-O$, $R^1 = H$; $R = C_2H_5S$, $R^1 = H$; $R = (CH_3)_2CH-NH$; $R^1 = H$; $R = (CH_3)_2N$, $R^1 = H$; $R = (CH_3)_2CH-O$, $R^1 = Cl$.

It was shown that groups of this type are more stable in trifluoroacetic acid than the benzyloxycarbonyl protecting group and can be removed selectively in the presence of the latter and the t-butoxycarbonyl group by treatment with H_2O_2 in ammonia.

Thus, despite the fact that the use of alkali-labile *N*-protecting groups in peptide synthesis is so far still fairly limited, the data obtained hitherto show that this trend will have a significant influence on its development.

Phosphorus Acid Azides

V.A.Gilyarov

Data on the synthesis and the chemical and physical properties of phosphorus acid azides are surveyed. The bibliography includes 100 references.

I. INTRODUCTION

Although the first phosphorus acid azides (PAA) were described in 1953,[1,2] the bulk of the studies on their synthesis and their properties have been carried out during the last 15–20 years. The synthesis of PAA has been greatly developed and the ready availability and in the vast majority of cases also the high stability of these compounds have been demonstrated, which constitutes their advantageous features compared with other azides, for example, aryl azides.

The chemical properties of PAA are very close to those of aryl, alkyl, and sulphonyl azides. PAA readily undergo the Staudinger reaction. Interaction of PAA with phosphorus(III) derivatives has led to the full availability of a new class of phosphorimido-compounds–substances containing the $\rangle P{=}N{-}P(X)\langle$ group, where X = O or S. The photolysis of PAA results in the formation of nitrenes capable of various reactions; in particular, in certain cases the groups attached to the phosphorus atom migrate to the nitrogen atom, i.e. a reaction analogous to the Curtius reaction takes place. PAA add to unsaturated compounds. On the other hand, the azide group in PAA exhibits the properties of a pseudohalogen and is capable of being substituted by other groups in reactions with nucleophiles. The study of the chemical properties of PAA established detailed differences between them and other azides, for example, sulphonyl azides. Thus, in terms of the number of reactions, PAA occupy one of the first places among phosphorus acid derivatives.

Recently one of the PAA, namely diphenyl phosphorazidate (diphenyl azidophosphate), has found extensive applications in organic synthesis, the synthesis of peptides, alkyl azides, etc.

There are a few reviews on PAA.[3–5] The first review[3] deals only with azides with a phosphorus–carbon bond. The last review[5] is the most complete but it covers the literature only up to 1973. The fundamental monographs[6,7] on organophosphorus compounds deal only briefly with PAA. It therefore became necessary to write the present review, which deals with the PAA synthesis, indicating the methods of synthesis, the yields, and the constants.

II. SYNTHESIS

The principal method of synthesising PAA involves the replacement of the chlorine atom in the corresponding chlorides by the azide group. The methods based on the employment of phosphorus acid anhydrides and hydrazides have been developed only slightly.

1. Synthesis from Phosphorus Acid Chlorides

Metal azides (principally sodium azide and more rarely lithium azide) or organoelemental azides in which the azide group is partly mobile (trimethylsilyl azide or PAA) are used to substitute the chlorine atom in phosphorus acid chlorides:

$$(RO)_2P(O)Cl + MN_3 \rightarrow (RO)_2P(O)N_3 + MCl,$$
$$(RO)_2P(S)Cl + MN_3 \rightarrow (RO)_2P(S)N_3 + MCl.$$

Various solvents have been proposed for sodium azide: acetone[1,8–10] (method *a*), pyridine[11–14] (method *b*), acetonitrile[9,15] (method *c*), DMF [16] (method *d*), water[2] (method *e*), ethanol[17] (method *f*), and methylene chloride[18] (method *g*). The reaction with lithium azide is carried out without a solvent[19], in acetonitrile[20,21] (method *h*), or in tetrahydrofuran (THF) [22] (method *i*). The most general method of synthesis of PAA proved to be the reaction with a concentrated solution of triethylammonium azide in chloroform[23,24] (method *j*). Tables 1–7 present the PAA synthesised with an indication of the method of synthesis, the yield, and the constants.

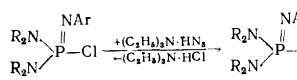
Table 1. Phosphorus(III) acid azides.

Formula	Method of synthesis	Yield, %	B.p., °C (mmHg)	M.p., °C	Refs.
$P(N_3)_3$	*c*	97	—	—	[25]
$[(iso\text{-}C_3H_7)_2]_2PN_3$	—	81	65–67 (0.01)	37–39	[26]
$(CF_3)_2PN_3$	—	—	—60 (1)	—	[19]
$(C_6H_5)_2PN_3$	*h*	—	—	13.6–13.8 (decomp.)	[20]

In the synthesis of diphenylphosphinic azide (I), the influence of the solvent on the rate of exchange of the chlorine atom was investigated:

$$(C_6H_5)_2P(O)Cl + NaN_3 \xrightarrow{\sim 20^\circ} (C_6H_5)_2P(O)N_3 + NaCl$$
(I)

The rate of reaction increases in the sequence benzene << dioxan < THF << pyridine[11].



Method (a). Phosphorus acid chlorides react with sodium azide in acetone at room temperature or on prolonged refluxing. It cannot be claimed that the method is universal; for

example, when it is employed, the chlorine atom in dibutylphosphinic chloride is incompletely substituted by the azide group[23].

Method (b). Pyridine is the most universal solvent for the synthesis of PAA. The completion of the reaction can be monitored by analysis for chlorine. The advantages of this method are the mild reaction conditions (the reactants are stirred at room temperature) and the comparative ease of isolating the PAA. A possible side reaction involves the alkylation of pyridine by the PAA containing the RO groups (particularly in the case of the lower esters), which makes it necessary to limit contact between the reaction product and pyridine. Limitations to the method have also been found: in the case of *N,N,N',N'*,tetra-alkyl-*N''*-arylphosphoroamidimdic chlorides it is impossible to achieve a complete substitution of the chlorine atom by the azide group[52]. Apparently the accumulation of nitrogen atoms at the phosphorus atom and the associated extensive delocalisation of the effective positive charge significantly reduce the capacity of the halogen for substitution.

Method (d). The use of dimethylformamide (DMF) proved to be convenient in the synthesis of dialkyl phosphorazidothioates[16]. However, the PAA obtained must not be soluble in aqueous DMF (at the end of the reaction the mixture is diluted with water and the PAA is extracted with an organic solvent). It is noteworthy that, when an attempt was made to synthesise diarylphosphinic azides by this method, negative results were obtained[12].

Method (j). As already mentioned, this is the most universal method. Indeed its employment makes it possible to obtain PAA (for example, compounds 1, 2, and 3 in Table 6) from acid chlorides in which the chlorine atom is relatively inert.

Triethylammonium azide may prove useful in the synthesis of other PAA, which are difficult to obtain by other methods. The lack of side reactions, the complete substitution of chlorine in the acid chlorides by the azide group, and the mild reaction conditions are undoubted advantages of this method.

When *N,N'*-dialkylphosphorodiamidic chlorides were treated with lithium azide in acetonitrile at 50 °C, *N,N'*-dialkylphosphorodiamidic azides (II) were obtained in a low yield, decomposition being observed on boiling the solution[37]:

$$(RNH)_2P(O)Cl \xrightarrow[CH_3CN]{LiN_3} (RNH)_2P(O)N_3\ (II)\ .$$

The employment of sodium azide in aqueous acetone also gives rise to a low yield of the azide (II).

2. Synthesis from Phosphorylpyrazoles

Certain PAA have been obtained from phosphorylpyrazoles in which the P–N bond is of the anhydride type[43]:

R=R'=OCH$_3$; R=OCH$_3$, R'=C$_6$H$_5$.

3. Synthesis from Phosphorus Acid Anhydrides

The reactions of phosphorus acid anhydrides with sodium azide, leading to the formation of PAA, can be illustrated schematically as follows[57]:

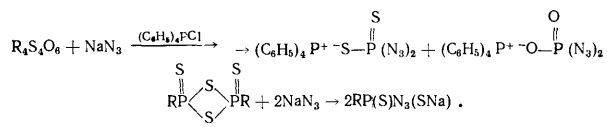


Table 2. Phosphoric acid azides.

4. Synthesis from Phosphorus Acid Hydrazides

The azides (II) have been obtained in a very low yield by the reaction of *N,N'*-dialkylphosphorodiamidic hydrazides with nitrous acid:

$$(RNH)_2P(O)NHNH_2 + HNO_2 \rightarrow (RNH)_2P(O)N_3 + 2H_2O \quad .$$
(II)

The use of the above reaction has not been extensively developed for the synthesis of PAA. Although the employment of dialkyl phosphorohydrazidothioates for the synthesis of dialkyl phosphorazidothioates has been described[58], methods *a* and *d* (from dialkyl phosphorochloridothioates) proved to be more convenient for their synthesis:

$$(RO)_2P(S)NHNH_2 + HNO_2 \rightarrow (RO)_2P(S)N_3 + 2H_2O \ ;$$
$$R = CH_3,\ C_2H_5,\ C_3H_7 \ .$$

When methyl hydrogen phosphorohydrazidate $CH_3OP(O).(NHNH_2)OH$ was treated with nitrous acid, only the evolution of nitrogen was observed; the expected azide $CH_3OP(O)(N_3).OH$ could not be obtained under these conditions[28].

5. Synthesis of Triazidophosphine and Phosphoric Triazide

The possibility of the formation of $P(N_3)_3$ and $PO(N_3)_3$ by the reaction of PCl_3 and $POCl_3$ with ammonium azide in liquid sulphur dioxide and the extremely high risk of their exploding were noted in the first communication[4] on the synthesis of these PAA. When $POCl_3$ is treated with ammonium azide in liquid SO_2 at −30 °C, a crystalline product is formed, but explodes when an attempt is made to isolate it.

In a later study[25] $P(N_3)_3$ and $PO(N_3)_3$ were obtained by the reaction of PCl_3 and $POCl_3$ with sodium azide in acetonitrile at −20 °C. After separating the precipitate by evaporating the filtrate at 0 °C, the azides were obtained in the form of readily hydrolysable liquids, which frequently explode on being heated to room temperature.

6. Phosphorus(III) Acid Azides

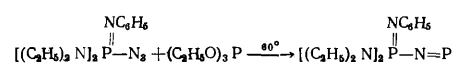
The azides of tervalent phosphorus acids are difficult to obtain. For this reason, the number of azides of this type isolated hitherto is small (Table 1). The azides are apparently formed readily from the corresponding chlorides and sodium azide or trimethylsilyl azide. The main cause of the difficulty of their isolation is their high reactivity, which

leads to the formation of cyclic and linear phosphonitriles as a result of self-condensation. Thus the use of trimethylsilyl azide in the reaction with chlorodiphenylphosphine under various conditions (variable temperature and solvents) did not yield azidodiphenylphosphine, but invariably led to the formation of its further transformation products[59]. The syntheses of the following azides are merely mentioned in the literature: $[(CH_3)_2N]_2PN_3$,[26] $(t\text{-}C_4H_9)_2PN_3$,[26] $\{[(CH_3)_3Si]_2N\}_2.PN_3$,[60] and $(C_6F_5)_2PN_3$.[61] Azidobis(diethylamino)phosphine[62] and *o*-phenylene phosphorazidite[63] were obtained in accordance with the following scheme:

These azides are stable only below 10–15 °C. The products of the self-condensation of *o*-phenylene phosphorazidite were obtained by the reaction of *o*-phenylene phosphorochlorodite with trimethylsilyl azide at 80 °C.[64]

III. CHEMICAL PROPERTIES

Two groups of reactions with participation of the azide group are most characteristic of PAA: reactions with phosphorus(III) compounds leading to the evolution of nitrogen, the formation of compounds with the fragment $\geq P=N-P(X)\leq$ (X = O or S) and the reaction in which the azide group reacts as a pseudohalogen (phosphorylation). Other reactions of PAA are noteworthy—pyrolysis, photolysis, and addition to unsaturated systems.



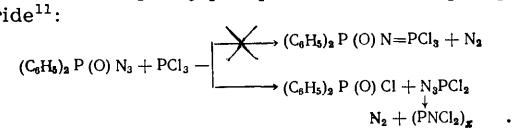
1. Reactions of PAA with Phosphorus(III) Compounds

The reactions of PAA with tervalent phosphorus compounds constitute an extension of the Staudinger reaction to PAA:

$$(RO)_2P(O)N_3 + (R'O)_3P \rightarrow (RO)_2P(O)N{=}P(OR')_3 + N_2 .$$

These reactions are general and, when the azide and the phosphorus(III) compounds are varied, many classes of phosphorimido-compounds, a considerable proportion of which cannot be synthesised by the Kirsanov reaction, can be obtained.

The rate of reaction depends on the structure of the reactants—of both the azide and the phosphorus(III) compound. Special kinetic studies of the influence of substituents in the azide molecule have still not been made, but it is known that *N,N,N',N'*-tetra-alkylphosphorodiamidic azides react with phosphorus(III) compounds more slowly than dialkyl phosphorazidates[35]. *N,N,N',N'*-Tetra-alkyl-*N''*-arylphosphorodiamidimidic azides react with particularly great difficulty, for example[52]:

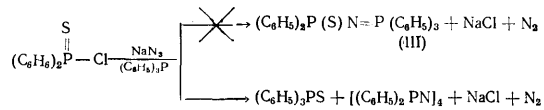


Azidobis(diethylamino)phosphine does not react with triethyl phosphite[63].

The mechanism of the reactions of PAA with phosphorus(III) compounds has not been investigated. By analogy with other azides (aryl azides and sulphonyl azides), the reaction presumably proceeds via triazenes, which decompose with evolution of nitrogen. The triazene has been isolated in only one instance and its heat treatment led to the formation of a phosphorimido-compound[52]:

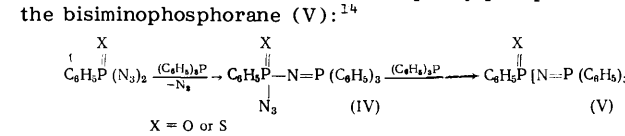
The structure of the triazene was not investigated; the proposed structure is analogous to that of the triazenes formed from aryl and sulphonyl azides. A somewhat reduced (compared with aryl azides) reactivity in the reactions of PAA with phosphorus(III) compounds is noteworthy. In the case of PAA, the reaction are usually carried out at 50–60 °C,[31] while aryl azides react even at room temperature.

If the phosphorus(III) chloride is an acid chloride (phosphorus trichloride, chlorodiphenylphosphine), then the azide group is exchanged for the halogen in the reaction with PAA.[11,21] Thus a phosphonitrilic chloride polymer is formed in the reaction of diphenylphosphinic azide with phosphorus trichloride[11]:



An analogous reaction is possible also in the case of chlorodiphenylphosphine[21]:

$$(I) + (C_6H_5)_2PCl \rightarrow (C_6H_5)_2PN_3 + (C_6H_5)_2P(O)Cl .$$

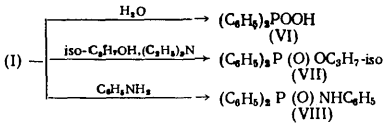


The main product proved to be $(C_6H_5)_2P(O)[N=P(C_6H_5)_2]_2Cl$ (yield 60%), whose formation can be represented as the result of a series of consecutive reactions of the azide (I) with $(C_6H_5)_2PN_3$ followed by the exchange of the N_3 group for Cl.

The reaction of diphenylphosphinothioic chloride with sodium azide and triphenylphosphine led to the isolation of the tetramer of diphenylphosphonitrile instead of the expected *N*-(diphenylphosphinothioylimino-*p,p,p*-triphenylphosphorane(III):[11]

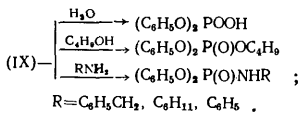
Diphenylphosphinothioic chloride is apparently initially converted into chlorodiphenylphosphine, which then reacts with sodium azide.

In the presence of two azide groups in the PAA a stepwise reaction with triphenylphosphine is possible. Thus the azide (IV) can react further with triphenylphosphine to form the bisiminophosphorane (V):[14]



The reactions of various PAA with a wide variety of phosphorus(III) compounds, namely triphenylphosphine[11,14], the bisphosphines $(C_6H_5)_2P-X-P(C_6H_5)_2$ (X = *p*-C_6H_4 or *p*-$C_6H_4C_6H_4$-*p*),[14] alkyl dialkylphosphinites[23], dialkyl phosphonites[23], trialkyl phosphites[16,30,31], dialkyl phosphoramidites[31,35], alkyl phosphorodiamidites[35], and phosphorous triamides[31,35]. The reactions of PAA with trialkyl phosphorothioites have not been described.

2. Reactions of PAA involving the Azide Group as a Pseudohalogen

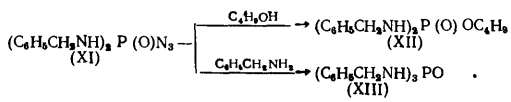


In the reactions of diphenylphosphinic azide with nucleophiles (water[11], isopropyl alcohol[11], and aniline[11,65]), its azide group is substituted with formation of diphenylphosphinic acid (VI), isopropyl diphenylphosphinate (VII),

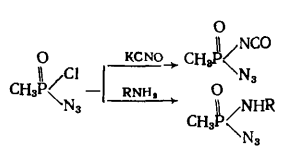
and diphenylphosphinic anilide (VIII):

N-(Azidophenylphosphinylimino)-*p*,*p*,*p*-triphenylphosphorane $(C_6H_5)_3P{=}NP(O)(C_6H_5)N_3$,[14] diphenyl phosphorazidate (IX),[66] and diethyl phosphorazidate $(C_2H_5O)_2P(O)N_3$ (X) [8] are capable of undergoing similar reactions involving the substitution of the azide group.

Comparison of the reactivities of the last two azides in reactions with nucleophiles permits the conclusion that the mobility of the azide group in the azide (IX) is much greater than in the azide (X). The azide (IX) interacts with water and butanol on boiling. The azide (IX) reacts with aliphatic amines with self-heating, while the reaction with aniline is terminated after 3 h on refluxing in alcohol[66]:



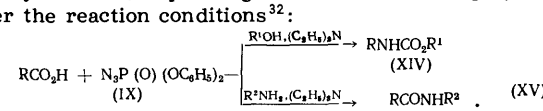
Diethyl phosphorazidate reacts with aniline under severe conditions (17.6 h at 185 °C). *N*-Phenylphosphoramidic acid $(HO)_2P(O)NC_6H_5$ was then isolated, evidently as a result of a secondary reaction involving the alkylation of aniline by the diethyl *N*-phenylphosphoramidate formed. Indeed, diethyl *N*-phenylphosphoramidate is rapidly converted into this acid on being refluxed in aniline[8].



The solvolysis of diethylphosphinic azide in methanol takes place comparatively readily, while sterically hindered azides (di-isopropyl- and di-t-butylphosphinic azides) do not react with methanol in the course of 17 h at room temperature[48].

Although solutions of diaryl phosphorazidates in pyridine are readily hydrolysed by water in pyridine, the pure azides are hydrolysed only slowly in 0.5 *N* NaOH. The resistance of PAA to hydrolysis is noteworthy. It makes it possible to obtain them in an aqueous medium (method *e*). The ready hydrolysability of dimethyl phosphorazidothioate has been noted[44]. The kinetics of the hydrolysis and ammonolysis (in reactions with butylamine and benzylamine) of methyl phosphorazidate have been investigated. The formation of the corresponding phosphoramidates in this process has been demonstrated[28].

The azide group in phosphorodiamidic azides is more resistant to the action of nucleophiles. Thus *N*,*N*′-dibenzylphosphodiamidic azide (XI) reacts with butanol and benzylamine under severe conditions (for example, refluxing in butanol for 18 h), forming the ester (XII) and the triamide (XIII) respectively[36]:

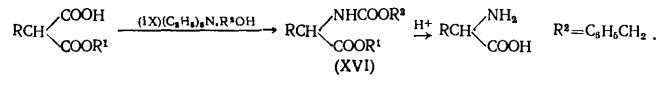


The azide group is less reactive than the chlorine atom in nucleophilic substitution reactions[42]:

PAA are more resistant to hydrolysis than the corresponding acid chlorides[44].

The reaction of the azide group as a pseudohalogen constitutes the basis of the modification of the Curtius reaction with participation of the readily available diphenyl phosphorazidate; this reaction has found extensive applications recently. Diethyl phosphorazidate was used initially[67], but the azide (IX) gave better results.

Thus the urethane (XIV) or the amide (XV) is formed from carboxylic acids, depending on the reactants employed under the reaction conditions[32]:



The urethanes (XIV) are obtained by refluxing equimolar amounts of a carboxylic acid, triethylamine, and the azide (IX) in the presence of a hydroxy-compound. This modification of the Curtius reaction† proved successful, since it is carried out under more or less neutral conditions and in the absence of oxidants (highly alkaline or acid media of the kind necessary for the Hofmann or Schmidt reactions are not required). In addition, it is possible to employ acids which do not enter into the Schmidt reaction (for example, pyridine-2-carboxylic acid). Table 8 presents certain results of the application of the azide (IX) in the syntheses of urethanes.

Table 8. The modified Curtius reaction involving the use of diphenyl phosphorazidate (R^1CH = t-C_4H_9OH).[68]

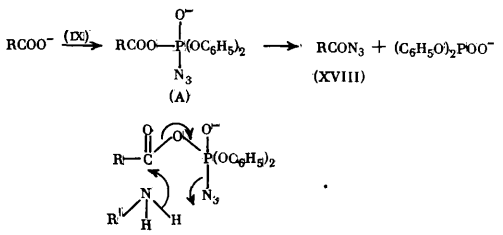
*R^1OH = C_2H_5OH.
**Diethyl phosphorazidate was used.

The attempt to convert the monoester of malonic acid into an aminoacid made it possible to obtain the ester (XVI) only when benzyl alcohol was used[69] and the latter must be added after refluxing a mixture of the azide (IX) and triethylamine for 1 h:

When a mixture of acid, the azide (IX), triethylamine, and alcohol is refluxed, the esters (XVII) are formed invariably[69,70]:



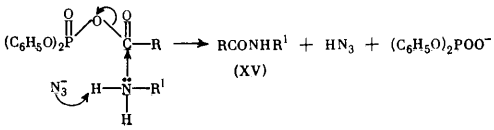
R^1 = t-C_4H_9, $C_6H_5CH_2$.

†The reaction under consideration is in a certain sense similar to the Schmidt reaction, but, from the standpoint of the mechanism (see below), the authors[68] regard it as a "modification of the Curtius reaction".

The mechanism of the reactions of substituted malonic acid monoesters with the azide (IX) and alcohols has been investigated and a scheme has been proposed whereby one can account for the different ways in which this reaction takes place[71].

Although the azide (IX) has found extensive applications, the mechanism of its reactions has not been established[72]. It may be that the intermediate (A) reacts intermolecularly with the amine or on dissociation gives rise to the acid azide (XVIII), which is converted into the amide (XV) as a result of bimolecular nucleophilic attack:

However, according to the authors of a review[5], the formation of the azide (VIII) has been insufficiently proved and the following mechanism can be considered for the formation of the amides (XV):



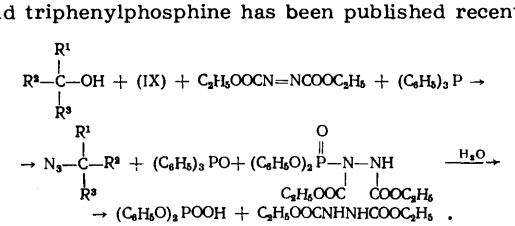


Table 9. The conversion of alcohols into azides using diphenyl phosphorazidate.

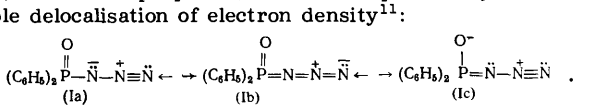
Alcohol	Azide	Yield, %
3β-Cholestanol	3α-Azidocholestane	78
Cholesterol	3α-Azido-5-cholestane	80—85
5α-Androsten-3β-ol-17-one	3α-Azido-5α-androsten-17-one	68
3α-Cholestanol	No reaction	—
5α-Androstan-17β-ol-3-one	No reaction	—
Cyclohexanol	Cyclohexyl azide	60
Decyl alcohol	Decyl azide	68
2-Menthol	(+)-Menthyl azide	90

The azide (IX) was used successfully to synthesise peptides in a high yield and without racemisation[32,68,73]. For example, the reaction of *N*-benzoxycarbonyl-L-leucyl-L-leucine with the hydrochloride of the methyl ester of L-valyl-L-phenylalanine has been achieved with a yield of 87%.[32]

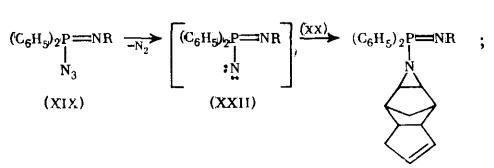


An elegant method of converting alcohols into azides by the reaction of the azide (IX), the diethyl ester of azodicarboxylic acid, and triphenylphosphine has been published recently[74]:

The reaction is stereospecific and makes it possible to obtain azides with high yields (Table 9).

3. Pyrolysis of PAA

The relatively high thermal stability of PAA, much higher than that of aryl and sulphonyl azides, has been noted. There is no satisfactory explanation of this phenomenon in the literature. The high thermal stability of diphenylphosphinic azide, for which different resonance structures (Ia–Ic) have been proposed, has been explained by the possible delocalisation of electron density[11]:



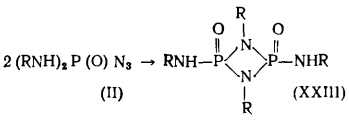
For thermally stable phosphorodiamidic azides, the possibility of a strong p_π–d_π conjugation between the α-nitrogen atom of the azide group and the phosphorus atom, has been noted[17].

Diphenyl phosphorazidate partly decomposes at 165 °C, darkens at 175 °C, and decomposes rapidly at 230 °C.[66] The extreme instability of the PAA in which there are several azide groups [triazidophosphine[4,25], phosphoric triazide[4,25], penta-azidophosphorane[25], and the azide $N_3P_3(N_3)_6$ [56]] should be noted.

Phenylphosphonic diazide and phenylphosphonothioic diazide decompose explosively above 80 °C,[14] while azidoperfluorodimethylphosphine explodes at 2–25 °C.[19] *N,N,N',N'*-Tetra-alkyl-*N''*-arylphosphorodiamidimidic azides decompose slowly at 150 °C with evolution of nitrogen[52]. For diphenylphosphinic azide, this temperature is above 137 °C.

Azidodiphenylphosphine decomposes at approximately 13.7 °C and is converted into the phosphonitrile $[(C_6H_5)_2PN]_x$. When attempts are made to vacuum distill (1 mmHg) diphenylphosphinothioic azide and diphenylphosphinoselenoic azide, they decompose[44]. All other PAA are stable on vacuum distillation and prolonged storage.

The evolution of nitrogen from the azide (XIX) has been noted only at 200 °C and in the presence of copper powder at 110 °C. In the presence of dicyclopentadiene (XX), a crystalline adduct (XXI) was obtained. It is formed when the nitrene (XXII) adds to dicyclopentadiene[75]:



R = $SO_2C_6H_4CH_3$-*p*.

Various insertion reactions are characteristic of the nitrene formed on pyrolysis of sulphonyl azide[76]. It is known[77,78] that arenesulphonyl azides react with aromatic compounds at 105–120 °C to form *N*-aryl substituted arenesulphonamides. Under these conditions and also in the presence of azobisisobutyronitrile, diphenylphosphinic azide does not undergo this type of reaction[11]. Nor does it enter into the reaction with pyridine characteristic of sulphonyl azides[78,79]. The reduced reactivity of the azide group at the phosphorus atom has also been manifested by the fact that the azide (I) does not undergo a reaction of the type of the Schmidt rearrangement on treatment with boron trifluoride in ethereal solution (refluxing for 48 h).[11]

The above insertion reactions could not be carried out for phosphorodiamidic azides either[36]. Prolonged heating of the azides (II) *in vacuo* or in the presence of inert solvents at 150–200 °C leads to the formation of the imido-amides

RNHP(O)=NR, which have been isolated in the form of the dimers (XXIII):[5,36]

(II) (XXIII)

On pyrolysis (1 h, 380 °C) of diphenylphosphinic azide, the phenyl group is seen to migrate from the phosphorus atom to the nitrogen atoms[80] (aniline was detected among the hydrolysis products), but the structure of the reaction product was not investigated in detail[3].

4. Photolysis of PAA

The aim of studies on the photolysis of PAA was the detection of nitrene, the investigation of its reactions involving insertion into a C–H bond, and its capacity for rearrangements.

The photolysis of diethyl phosphorazidate, diphenyl phosphorazidate, and *N,N,N',N'*-tetramethylphosphorodiamidic azide (XXIV)[81] was investigated [the resistance of the azide (XXIV) to ultraviolet irradiation in benzene had been noted previously[17]]. The photolysis of a 0.01 M solution of diethyl phosphorazidate in cyclohexane yielded diethyl *N*-cyclohexylphosphoramidate (yield 88%) and ethyl phosphoramidate (12%). Both products are formed as a result of the attack of diethylphosphorylnitrene on the solvent. No products indicating a rearrangement of the nitrene were detected.

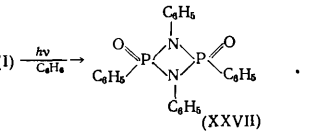
The results of the photolysis of phenyl azidoformate in cyclohexane are presented as a comparison—the yield of *N*-cyclohexylurethane, formed as a result of the insertion of the nitrene in a solvent molecule, was only 19%. The study of the products of the photolysis of the azides (IX) and (X) in 2-methylbutane showed that phosphorylnitrenes do not exhibit a very pronounced selectivity with respect to insertion in a C–H bond of the kind observed for nitrenes formed from $C_2H_5OC(O)N_3$, $t\text{-}C_4H_9C(O)N_3$, and $C_6H_5N_3$ (the products of insertion in a C–H bond involving a tertiary cation atom are formed preferentially in the last case)[81]:

$$(RO)_2P(O)\ddot{N} + (CH_3)_2CHCH_2CH_3 \rightarrow (RO)_2P(O)NHR^1;\ R=C_2H_5,\ C_6H_5;$$

(a) $R^1=CH_2CH(CH_3)CH_2CH_3$, (b) $R^1=(CH_3)_2CHCH_2CH_2$; (c) $R^1=(CH_3)_2CHCH(CH_3)$

(d) $R^1=CH_3CH_2C(CH_3)_2$.

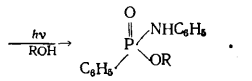
For example, in the case of the azide (X) the product ratios are (XXVd):(XXVc):[(XXVa) + (XXVb)] = 6.0:4.3:1.0.



The high reactivity and low selectivity of phosphorylnitrenes were also observed on irradiation of a solution of the azide (X) in t-butyl alcohol[81]. Whereas the photolysis of ethyl azidoformate in t-butyl alcohol gives rise only to the product of the insertion in the O–H bond on photolysis, the product of the insertion in the C–H bond, namely the amide (XXVI), was also detected in the photolysis of the azide (X):

$$(C_2H_5O)_2P(O)\ddot{N} + (CH_3)_3COH \rightarrow \underset{(XXVI)\ (35\%)}{(C_2H_5O)_2P(O)NHCH_2C(CH_3)_2OH} +$$

$$[+\ \underset{(33\%)}{(C_2H_5O)_2P(O)NHOC(CH_3)_3} + \underset{(27\%)}{(C_2H_5O)_2P(O)NH_2}\ .$$

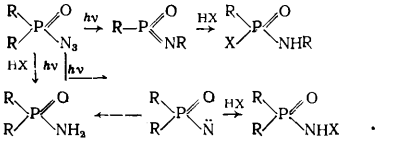


The phenyl[65], alkyl[48], and dimethylamide groups [in the photolysis of the azide (XXIV)][81] were found to migrate in phosphorylnitrenes from the phosphorus to the nitrogen atom, i.e. the photolysis of PAA is found to entail a rearrangement similar to the Curtius rearrangement. Derivatives of metaphosphonimidates# and an imidometaphosphate with the $O{=}\overset{|}{P}{=}N-$ fragment, which can dimerise or react with substances having a mobile hydrogen atom, are formed as intermediates.

Thus diphenylphosphinic azide gives rise to the diazadiphosphatidine (XXVII) on irradiation for 12 h (at 253.7 Å) in benzene:

(XXVII)

If the irradiation of the azide (I) is carried out in the presence of alcohols, then alkyl phenylphosphonanilidates are obtained[65]:



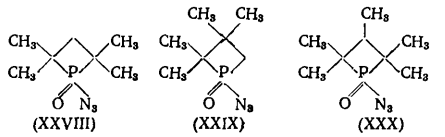
In other media the products of the addition of ethylene glycol, aniline, and methyl iodide to the metaphosphonimidate were obtained.

The photolysis of PAA has been studied in greatest detail in relation to di-t-butylphosphinic azide, di-isopropylphosphinic azide, and diethylphosphinic azide in various alcohols and in t-butylamine[48]. The results of the investigation are compiled in Table 10.

Table 10. Photolysis of dialkylphosphinic azides $R_3P(O)N_3$ in protic solvents[48].

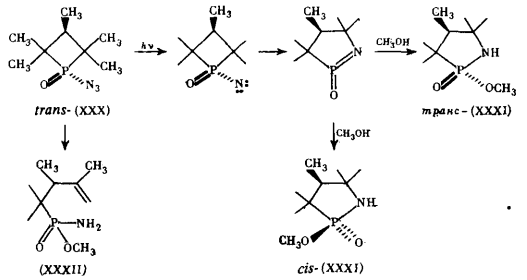
№	Azide	Solvent (HX)	Yield, %		Other products
			$RP(O)(X)NHR$	$R_2P(O)NH_2$	
1	$(t\text{-}C_4H_9)_2P(O)N_3$	CH_3OH	71	—	$(t\text{-}C_4H_9)_2P(O)NHOCH_3$ (8%)
2	$(t\text{-}C_4H_9)_2P(O)N_3$	C_2H_5OH	62	24	none
3	$(t\text{-}C_4H_9)_2P(O)N_3$	iso-C_3H_7OH	27	64	none
4	$(t\text{-}C_4H_9)_2P(O)N_3$	$t\text{-}C_4H_9OH$	63	6.5	$(t\text{-}C_4H_9)_2P(O)NHCO_4H_9\text{-}t$
5	$(t\text{-}C_4H_9)_2P(O)N_3$	$t\text{-}C_4H_9NH_2$	74	—	none
6	$(iso\text{-}C_3H_7)_2P(O)N_3$	CH_3OH	71	5	$(iso\text{-}C_3H_7)_2P(O)NHOCH_3$
7	$(iso\text{-}C_3H_7)_2P(O)N_3$	C_2H_5OH	38	46	none
8	$(iso\text{-}C_3H_7)_2P(O)N_3$	$(t\text{-}C_3H_7OH$	—	87	none
9	$(iso\text{-}C_3H_7)_2P(O)N_3$	$(iso\text{-}C_4H_9NH_2$	74	—	none

The reactions can be illustrated schematically as follows:



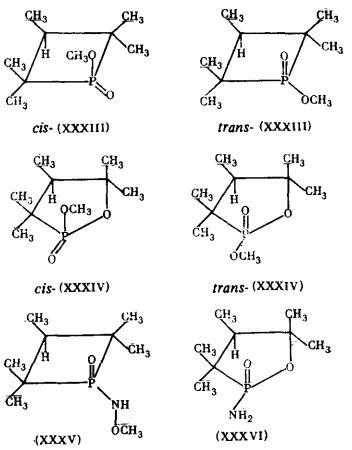
The addition of alcohols or t-butylamine to metaphosphonimidates results in the formation of alkyl *N*-alkylphosphonamidates or alkyl *N*-alkyl-*N'*-t-butylphosphonodiamidates. On passing from methanol to ethanol, the formation of dialkylphosphinic amides $R_2P(O)NH_2$ (compounds 2 and 7, Table 10) is observed, their yields increasing when the reaction is carried out in isopropyl alcohol (compounds 3 and 8), which can be accounted for by the ease of abstraction of hydrogen

#An analogy has been noted between the metaphosphonimidates and the isocyanates formed in the Curtius rearrangement of acyl azides[48].



from the latter alcohol; the rate of the decomposition of the azide is several times greater than in methanol.

The migration of the alkyl group from phosphorus to nitrogen has also been observed in the nitrenes formed on photolysis of 1-azido-2,2,4,4-tetramethylphosphetan 1-oxide (XXVIII),[49] 1-azido-2,2,3,3-tetramethylphosphetan 1-oxide (XXIX),[49,82] and 1-azido-2,2,3,4,4-pentamethylphosphetan 1-oxide (XXX),[49,82,83] in methanol:

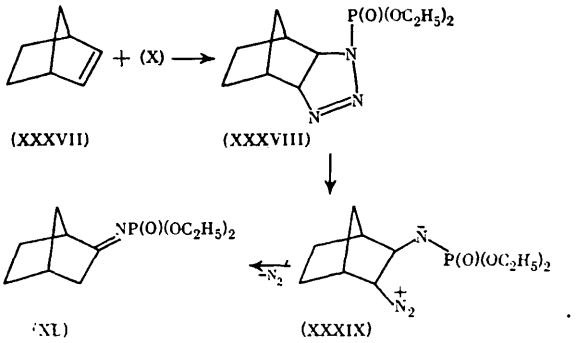


(XXVIII) (XXIX) (XXX)

The *trans*- and *cis*-isomers of compound (XXXI) and also compound (XXXII) have been obtained from the *trans*-isomer of compound (XXX):[49,82]

trans-(XXX) *транс*-(XXXI) (XXXII) *cis*-(XXXI)

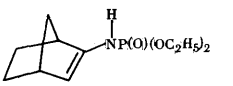
The formation of the *cis*- and *trans*-isomers of compounds (XXXI), (XXXIII), (XXXIV), (XXXV), and (XXXVI) was demonstrated in a more detailed study[83] of the products of the photolysis of the *trans*-phosphetan (XXX):



cis-(XXXIII) *trans*-(XXXIII) *cis*-(XXXIV) *trans*-(XXXIV) (XXXV) (XXXVI)

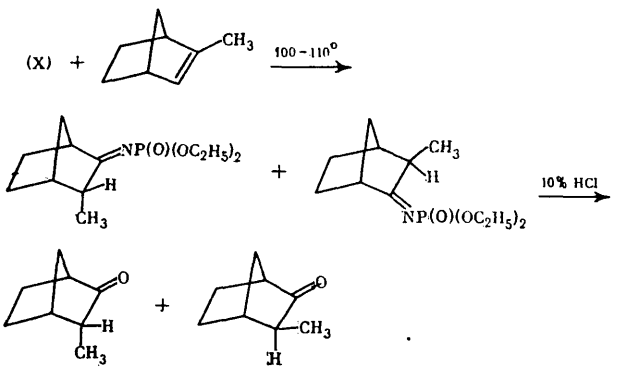
5. Reactions of PAA with Unsaturated Compounds (1,3-Dipolar Cycloaddition)

It has been shown in a number of studies[9,10,84-89] that PAA add to unsaturated compounds analogously to aryl azides and the azides of carboxylic acids.



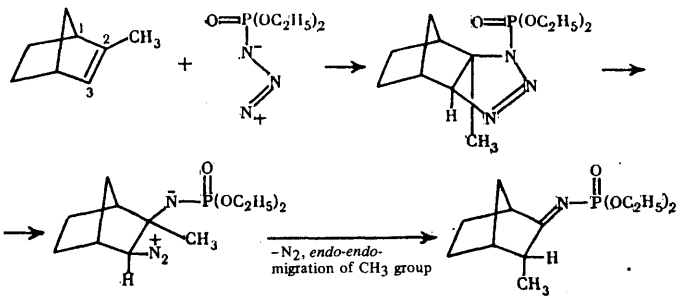
In relation to the addition of diethyl phosphorazidate to norbornene (XXXVII),[89] it has been suggested that the reaction proceeds via an intermediate triazoline (XXXVII), which is formed as the result of the 1,3-dipolar cycloaddition and is subsequently converted into the dipolar ion (XXXIX),

which decomposes with formation of *N*-(2-norbornylidene)-phosphoramidate (XL):

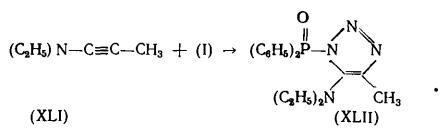


(XXXVII) (XXXVIII) (XL) (XXXIX)

A small amount (<5%) of the phosphoramidate

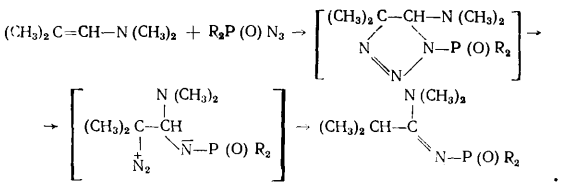


is also formed. The study of the reaction of norbornene deuterated in the 5- and 6-positions with the azide (X) led to the conclusion that the norbornyl skeleton does not rearrange. Dimethyl phosphorazidate reacts with compound (XXXVII) like the azide (X).[85]

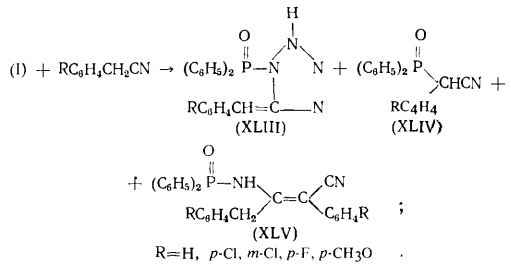


When the azide (X) adds to 2-methyl-2-norbornene, a mixture of diethyl *N*-(*endo*-3-methyl-2-norbornylidene)-phosphoramidate and diethyl *N*-(*exo*-2-methyl-3-norbornylidene)phosphoramidate is formed, but could not be resolved. However, after the hydrolysis of this mixture, *endo*-3-methyl-2-norbornanone (86%) and *exo*-3-methyl-2-norbornanone (14%) were isolated:

The intermediate triazolines were not isolated, since they are rapidly converted into phosphorylated imines as a result of the 3,2-*endo*-migration of the methyl group (the main reaction pathway) and the elimination of a nitrogen molecule[87]:



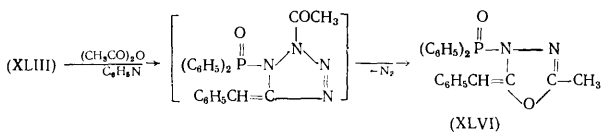
PAA react similarly with activated alkynes. Thus 1-(diethylamino)propyne (XLI) reacts with diphenylphosphinic azide in boiling benzene to form the triazole (XLII):[90]



(XLI) (XLII)

The reactions of PAA with enamines give rise to high yields of phosphorylated amidines[9]:

The interaction of the azide (I) with substituted phenylacetonitriles led to the synthesis of the phosphorylated tetrazoline (XLIII), the nitrole (XLIV), and the enaminonitrile (XLV):[86]



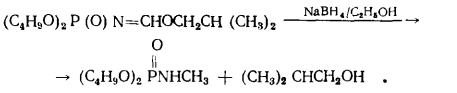
(XLIII) (XLIV)

(XLV)

R=H, *p*-Cl, *m*-Cl, *p*-F, *p*-CH_3O

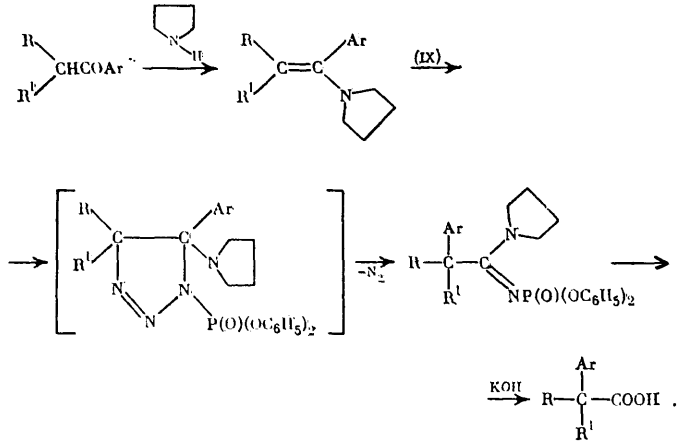
The acylation of compound (XLIII) and subsequent heating yielded the phosphorylated oxadiazoline (XLVI):

(XLVI)



The reaction of PAA with vinyl ethers led to the formation of *N*-phosphorylated imines (XLVII) and phosphorylated triazolines, which were not expected[10]:

$$R_2P(O)N_3 + CH_2{=}CHOR^1 \rightarrow R_2P(O)N{=}CH{-}OR^1 + CH_2N_2 \qquad \text{(XLVII)}.$$



Hydrolysis of compound (XLVII) under mild conditions leads to the formation of *N*-formylphosphoramidates (XLVIII) and alcohols:

$$\text{(XLVII)} + H_2O \rightarrow R_2P(O)NH{-}CHO + R^1OH \qquad \text{(XLVIII)}.$$

The structure of compounds (XLVII) was confirmed in a study of the reaction with sodium tetrahydroborate, which involves the dissociation of the C–O bond:

A method has been proposed for the conversion of alkyl aryl ketones into α-arylalkanecarboxylic acids using pyrrolidine and diphenyl phosphorazidate[91]. These reactions can be illustrated by the following scheme, in which the addition of the azide (IX) to the C=C double bond is postulated:

IV. PHYSIOLOGICAL ACTIVITY

Since the azide group in PAA has the properties of a pseudohalogen, the PAA fully satisfy the formula proposed by Schrader[92] for insecticides:

Indeed the first PAA [1,2] were patented as insecticides (dialkyl phosphorazidothioates—contact insecticides[1,93,94]; *N,N,N',N'*-tetramethylphosphorodiamidic azide—an effective systemic insecticide used against aphids).

Certain PAA exhibit a considerable toxicity for warm blooded animals. A strong miotic activity of diethyl phosphorazidate has been noted[8,30]. At the same time appropriate precautions made it possible to carry out an extensive research into this compound.

The toxicity and the anticholinesterase activity of certain phosphonamidic azides—derivatives of methylphosphonic acid have been investigated (Table 11).[42] The toxicity depends significantly on the structure of the amide component of the molecule—it has a maximum for the anilide group at the phosphorus atom.

Table 11. The toxicity and anticholinesterase activity of *N*-phenyl-*N*-alkoxycarbonyl-, and arylcarbamoyl-methylphosphonamidic azides[42].

Compound	Toxicity, mg kg^{-1}		I^*_{50}, moles
	LD_{50}	LD_{100}	
$CH_3P(O)(N_3)NHC_6H_5$	2.692	5	$4.5\cdot10^{-7}$
$CH_3P(O)(N_3)NHCOOCH_3$	1.39	5	$3.0\cdot10^{-6}$
$CH_3P(O)(N_3)NHCOOC_2H_5$	83.18	100	$8.0\cdot10^{-5}$
$CH_3P(O)(N_3)NHCOOC_3H_7$-iso	20.89	25	$4.0\cdot10^{-6}$
$CH_3P(O)(N_3)NHCONHC_6H_5$	851.1	1000	$1.0\cdot10^{-2}$
$CH_3P(O)(N_3)NHCONHC_6H_4Cl$-*p*	952.0	1000	$1.0\cdot10^{-2}$

*I_{50} represents the molar concentrations of the inhibitor which cause a 50% suppression of enzyme activity in 5 min.

The following series based on the dependence of the toxicity on the structure of the alkoxy-group has been observed for alkoxycarbonylamido-substituted PAA: methoxy > isopropoxy > ethoxy. Amido-substituted derivatives of ureidoazidomethylphosphonic acid exhibit a minimal toxicity.

V. PHYSICAL PROPERTIES

1. Infrared and Raman Spectra

PAA are characterised by an intense absorption band corresponding to the antisymmetric N–N stretching vibrations in the N_3 group. The band, which occurs at 2138–2195 cm^{-1} (3,25, 44–46) has a higher frequency than for organic azides (in the vicinity of 2130 cm^{-1})[95]. As for organic azides, the corresponding symmetrical vibrations have a much lower frequency and their absorption bands are much less intense.

Various types of vibrations characteristic of PAA have been examined in detail in a dissertation[45]. Some of them, localised either in the group of nitrogen atoms or in the group of phosphorus and nitrogen atoms, will be presented here.

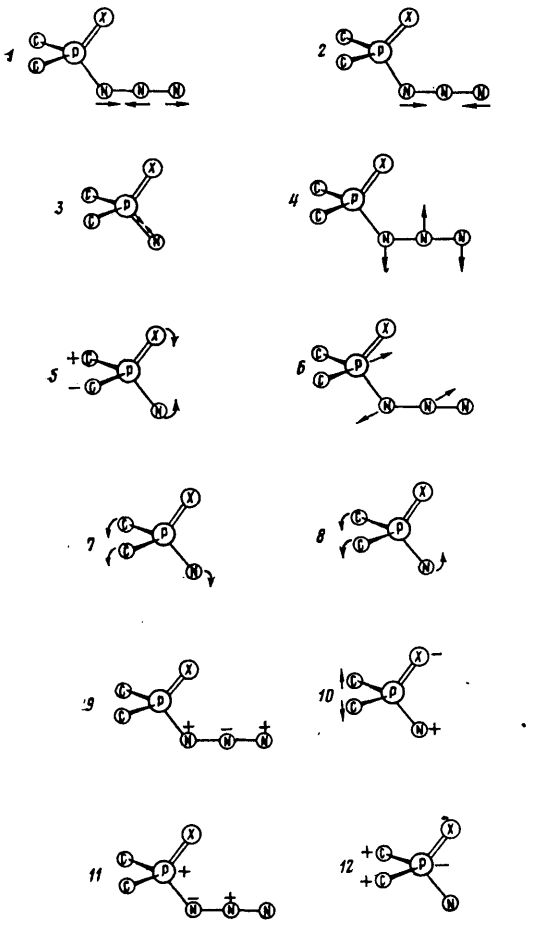


Figure 1. The types of vibrations of the $C_2P(X)N_2$ (X = O, S, or Se) fragment characteristic of PAA;[45] 1) $\nu_{as}(N_3)$; 2) $\nu_s(N_3)$; 3) ν(P–N); 4) $\delta(N_3)$; 5) $\delta[C_2P(X)N]$; 6) δ(P–N–N); 7) $\delta(C_2PN)$; 8) $\rho(C_2PN)$; 9) $\gamma(N_3)$; 10) $\tau[C_2P(X)N]$; 11) γ(P–N–N); 12) $\omega[C_2P(X)N]$.

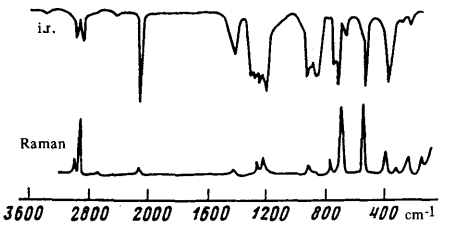
The first group (Fig.1, *1–8*) includes stretching and deformation vibrations symmetrical relative to the plane. They must be active both in the infrared absorption and Raman spectra; in the latter case they should give rise to polarised lines.

In the second group (Fig.1, *9–12*) the stretching and deformation vibrations are antisymmetric relative to the plane; they are also active in the infrared absorption spectra, while in the Raman spectra depolarised lines correspond to them.

Table 12 presents the infrared and Raman spectroscopic data for dimethylphosphinic azide[44]. The insignificant ν_{as} intensity in the Raman spectrum is noteworthy (Fig.2). The antisymmetric vibration characteristic of PAA can be used for analytical purposes. When PAA were allowed to react with phosphorus(III) compounds, the end of the reaction was inferred from the disappearance of the azide band in the infrared spectrum of the reaction mixture[31].

Table 12. The wavenumbers (ν, cm^{-1}) in the vibrational spectra of dimethylphosphinic azide[44].

i.r.	Raman	Assignment	i.r.	Raman	Assignment
3397 w.	—	$\nu_{as} + \nu_s(N_3)$	554 v.s.	552 v.s.	ν (P—N) + $\delta(N_3)$
2521 w.	—	$2 \times \nu_s(N_3)$	393 s.	399 m.	$\delta[C_2P(O)N]$
2143 v.s.	2150 m.	$\nu_{as}(N_3)$	317 v.w.	312 m.	$\omega(PC_2N)$
1268 v.s.	1269 m.	$\nu_s(N_3)$	260 m.	258 s.	$\rho[C_2P(O)N]$
735 s.	732 w.	ν (P—N)+ $\delta(N_3)$	—	142 s.	$\tau[C_2P(O)N]$



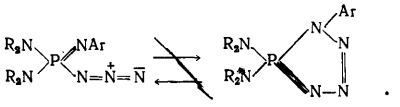


Figure 2. Infrared and Raman spectra of dimethylphosphinic azide[44].

The study of the infrared spectra of PAA confirmed their structure. The relative intensity of the azide absorption band at 2140 cm^{-1} in the spectra of *N,N,N',N'*-tetra-alkyl-*N''*-arylphosphorodiamidimidic azides is independent of the solvent (CCl_4, dioxan, and pyridine). This disproves the possibility of the azido-tetrazole tautomerism[52]:

A similar tautomerism has been ruled out for phosphinimidic acid azides $[(C_6H_5)_2P(=NR)N_3]$ [22,96,97] and diethyl phosphorazidate[8].

2. NMR Spectra and Mass Spectra

The chemical shifts of the signals in the ^1H, ^{13}C, and ^{31}P NMR spectra of PAA and the corresponding chlorides have been compared[28,44–46]. The ^{14}N NMR data for certain PAA and ^{15}N NMR data for isotope-substituted PAA have been published[98].

Mass-spectrometric data for PAA have also been published[44-46]. In the mass spectra of dimethylphosphinic azide $(CH_3)_2P(O)N_3$ and its deuterated analogue $(CD_3)_2P(O)N_3$, the fundamental peaks 77 $[(CH_3)_2PO^+]$ and 83 $[(CD_3)_2PO^+]$ correspond to the loss of the entire nitrogen $(M^+ - 42)$.[45] It is noteworthy that the fundamental peak in the mass spectrum of phenyl azide corresponds to the loss of molecular nitrogen $(M^+ - 28)$.[99]

3. The Atomic Refraction of the N_3 Group

The atomic refraction of the N_3 group in PAA has come to be assumed to be 9.61 cm^3 (calculated from the results of Gilyarov and coworkers[23,31]; the Eisenlohr numbers have been used for the atomic refractions of other elements), i.e. it is close to the atomic refraction of the N_3 group in alkyl and aryl azides[100].

---o0o---

The advances in PAA chemistry are evident. Like any vigorously developing field of study, the chemistry of PAA involves many unsolved problems, some of which have been formulated in this review. It has now become necessary to manufacture in the USSR diphenyl phosphorazidate, the employment of which in the "modified Curtius reaction" instead of nitrous acid will undoubtedly prove useful in organic synthesis.

It may be hoped that this review will stimulate interest in the chemistry of PAA and this will assist in its further development.

Advances in the Chemistry of Phosphorus(III) 1,3,2-Diheterophosphorinanes

E.E.Nifant'ev and A.I.Zavalishina

Studies on the synthesis and chemical reactions of 1,3,2-diheterophosphorinanes containing a tervalent phosphorus atom are examined for the first time within a single review. The influence of the heteroatoms surrounding the phosphorus atom on the properties of the phosphorinane system is analysed. The chemical features of mono- and poly-cyclic 1,3,2-diheterophosphorinane are compared and the ways of the practical utilisation of these substances are discussed.
The bibliography includes 338 references.

CONTENTS

I. Introduction 921
II. Monocyclic 1,3,2-diheterophosphorinanes 922
III. Polycyclic diheterophosphorinanes 932

I. INTRODUCTION

Phosphorus(III) 1,3,2-diheterophosphorinanes (DHP) constitute a large group of six-membered heterocycles whose molecules contain a tervalent phosphorus atom surrounded by other heteroatoms. Here one should include also the corresponding hydrophosphoryl, hydrothiophosphoryl, and hydroiminophosphoryl compounds, one of the tautomeric forms of which contains a tricoordinate phosphorus atom. The phosphorus–oxygen heterocycles, namely 1,3,2-dioxaphosphorinanes (DOP) have been investigated most thoroughly but in very recent years related systems have begun to be considered: diazaphosphorinanes (DAP), oxazaphosphorinanes (OAP), and dithiaphosphorinanes (DTP).

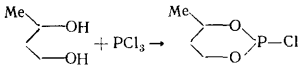
The first examples of DHP were synthesised in the Soviet Union[1] and in the United States[2] at the end of the 1940's. During this period, the reasons for the interest in these compounds were largely classified and the volume of work was therefore small. It was not until the 1970's that the chemistry of the DHP was sharply activated, in connection with the development of much interest during this period in the comparison of the stereochemistry and reactivity of cyclohexanes and saturated heterocycles. In addition, at this time realistic methods became available for the investigation of the electronic structure of the DHP and particularly the elucidation of the nature of the interaction of the electron pairs and orbitals of the triad $-\ddot{X}-P-\ddot{Y}-$, which is incorporated in six-membered rings with different degrees of rigidity. Finally, the development of the chemistry of DHP was stimulated by the publication of novel synthetic studies, including those leading to the solution of important applied problems. Ultimately the interests of specialists in organophosphorus synthesis, stereochemistry, spectroscopy, complex catalysis, bio-organic chemistry, and the chemistry of high-molecular-weight compounds coincided in the study of the DHP. Because of this, an extensive scientific field was established, the

principal achievements in which are discussed in the present review.

The chemical behaviour of DHP is mainly determined by two factors: the nature of the central functional group and the overall structure of the molecule. In dealing with the structure of the molecule, one must bear in mind whether the substance belongs to mono- or poly-cyclic systems, since the latter frequently have chemical properties which are not altogether usual. In this connection, we subdivided the entire contents of the review into two parts, devoted to the mono- and poly-cyclic systems.

In each section the synthesis and partly the stereochemistry are considered initially and then the chemical properties of the DHP.

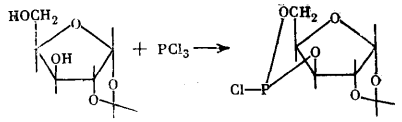
Since the appendix to the Russian translation of the book of Purdela and Vilceanu[3] gives a list of publications on phosphorus-containing heterocycles covering the literature up to 1969, in the present review attention has been concentrated only on studies of the latest period.



II. MONOCYCLIC 1,3,2-DIHETEROPHOSPHORINANES

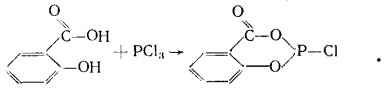
1. Synthesis

DHP can be obtained using two approaches. The first combines the phosphocyclisation of 1,3-glycols and similar 1,3-bifunctional compounds, i.e. reactions leading to the formation of six-membered phosphorus-containing heterocycles from linear systems. Data on this problem are discussed in this section separately for DOP, DAP, and DTP. The system adopted is dictated by the non-uniformity of the studies on different DHP and also by the fact that they are not always produced by general methods. The second approach is based on the exchange reactions of the substituents at the phosphorus atom already incorporated in the phosphorinane ring. The corresponding data are considered in the next section which deals with the chemical reactions of DHP. This procedure eliminates the possibility of repetitions and makes it possible to relate the problem of the synthesis of individual classes of DHP to their general chemical characteristics.

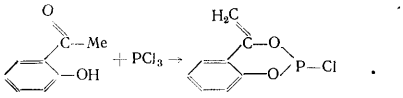


(a) 1,3,2-Dioxaphosphorinanes

When 1,3-diols react with phosphorylating agents having at least two leaving groups, it is possible to obtain different types of DOP. Phosphorus trichloride has been used as the phosphorylating agent in many investigations[1,2,4-8], for example:



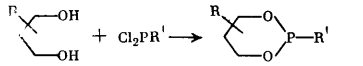
The reaction is usually carried out in a dry solvent. A tertiary amine is not always used to combine with the hydrogen chloride evolved. The hydrogen chloride is then removed from the reaction mixture by bubbling in a dry inert gas. This feature, apparently associated with the anomalously low basicity of cyclic phosphorochloridites, greatly simplifies the synthesis of chlorophosphorinanes and distinguishes it from the synthesis of dialkyl phosphorochloridites.



The condensation of phosphorus chloride has been widely investigated. A wide variety of halogenated glycols[9], the corresponding unsaturated systems[10], ethers[6,11,12], and nitro-compounds[13] have been made to undergo this condensation. In this case the possibility of a partial oxidation-reduction reaction, leading to nitrosoglycols and phosphoryl compounds, has been noted[13]. In addition, the cyclophosphorylation of the polyfunctional system of the antibiotic synthomycin[14] and 1,2-isopropylidenexylofuranose[15] has been achieved:

We shall consider the stereochemical aspect of the phosphorylation with phosphorus trichloride. A single stereoisomer, whose chlorine atom occupies an axial position, is as a rule formed in this case[15-20]. The reaction of phosphorus trichloride with 2-benzylglycerol, leading to a mixture of unequal amounts of two stereoisomers, is an exception[12]. Salicylic acid reacts with phosphorus trichloride similarly to β-glycols[21]:

As regards the chemical aspect, the analogous phosphorylation of acetylacetone and 2-acetylphenol, leading to unsaturated DOP, is of great interest[22]:



Unfortunately this synthesis has not yet been widely developed. Among other phosphorus trihalides, only phosphorus tribromide has been made to react with diols, 2-bromo-1,3,2-dioxaphosphorinane being obtained[18,23].

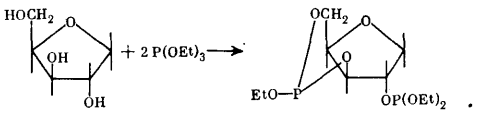
Numerous studies have been devoted to the cyclophosphorylation of 1,3-diols with tervalent phosphorus acid dichloride. In particular, a detailed study has been made of the interaction of glycols with Menshutkin acid chlorides in the presence of bases[6,7,15,24,25]. The cyclisation reaction[26]

is promising in many respects.

The dichloride of phosphorus acids react with 1,3-glycols similarly to the Menshutkin acid chlorides. This makes it possible to obtain interesting cyclic phosphonites albeit not always in high yields[24,27-30]:

We may also note that the condensation reactions with phosphonous acid dichlorides are of less universal importance than the corresponding reactions with phosphorus trichloride owing to the occurrence of side reactions[31].

In its stereochemical aspect, the phosphocyclisation with acid dichlorides differs from the cyclisation with phosphorus trichloride. When asymmetric glycols are used, not one but two interconvertible stereoisomers are formed, in which the axial position is preferred for the alkoxy-group.

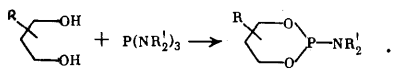


The reactions discussed above have attracted attention because of the outward simplicity of their mechanism and the availability of phosphorylating agents. Nevertheless, they do not always yield good results owing to the presence of hydrogen chloride, which is not completely bound by the acceptors employed. A significant factor for larger-scale syntheses is also the fact that many reactions involving

phosphorus chloride require the employment of large volumes of dry solvents. Bearing this in mind, alternative cyclophosphorylation methods have begun to be studied in many laboratories, including those dealing with applied problems. The transesterification method was the first to be studied in detail, for example:

It has been shown that various forms of glycols[4,9,18,33,34] readily interact with the simplest neutral phosphorus acid esters. It has been suggested that this reaction be used to simplify industrial polymer stabilisers[32].

The reaction of xylitan, which is an asymmetric triol, with an excess of triethyl phosphite merits special attention. The β-glycol group in xylitan ensures the selective formation of the phosphorinane ring; the second of the *trans*-vicinal hydroxyls is more passive and is phosphorylated without cyclisation:

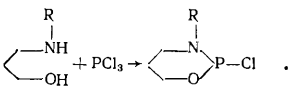


A similar regioselectivity has also been noted in the phosphorylation of 2,4-methylenexylitan[35].

Neutral phosphonites can also be transesterified with 1,3-glycols,[36,37] including those with other functional groups. As an illustration, we may quote the synthesis of the spirocyclo system[36]

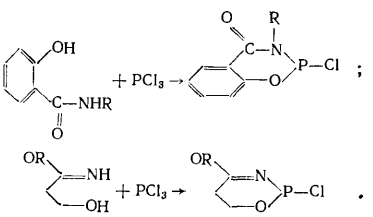
Dialkyl phosphites are also involved in transesterification with various β-glycols. This results in the formation of DOP belonging to the class of hydrophosphoryl compounds[4,12,38-42]. A mixture of two geometrical isomers of DOP is usually obtained as the technical product. One of them, which has the phosphoryl group in the equatorial position, crystallises out[38-40,43].

In the latest studies the phosphorylation of 1,3-diols is usually carried out using the triamides of phosphorus acid[34,38,39,42,44-47]:



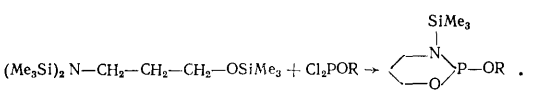
The reaction is carried out simply and under mild conditions in the absence of corrosive side products and is very productive. Because of this, it has found extensive preparative applications, particularly in a series of complex systems. Thus it has been used in the synthesis of aminophosphorinanomonoses[15,25,40] and nucleosides[47,48].

The problem of the configuration of the phosphorus centre in 2-amino-DOP has been discussed in the literature. From NMR data, it has been concluded that the position of the amino-group depends on the nature of the substituents at the nitrogen atoms[45,49-52]. The unusual equatorial disposition is probably promoted by the orbital interaction of the nitrogen and phosphorus; on the other hand, if the unshared electron pair of the nitrogen atom is delocalised over the structural elements of the amino-group, then the axial disposition of the substituent obtains more readily[52].

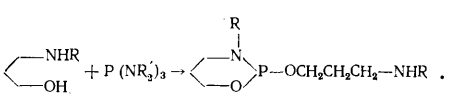


The diamides of alkylphosphorus[48,53], arylphosphorus[53], and phosphonous[54] acids are also effective phosphorylating agents. Many DOP, particularly those derived from sterically hindered phenols[53], sugars[25], and nucleosides[48], have been obtained on their basis.

(b) 1,3,2-Oxaphosphorinanes

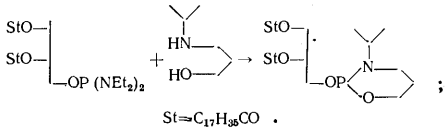


OAP have been vigorously investigated in the last ten years, mainly in connection with the requirements arising in the development of bio-organic chemistry. They are synthesised from β-aminoalcohols in different ways depending on the nature of the latter. *N*-Alkyl-[55-59] and *N*-aryl-propanolamines[55] react with phosphorus trichloride in the presence of triethylamine to form 2-chloro-oxazaphosphorinanes:



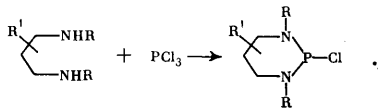
The amides of salicylic acid[60] and the iminoesters of β-hydroxypropionic acid[61] have been similarly condensed with phosphorus trichloride to form OAP with functional groups:

The phosphocyclisation is also carried out using the dichlorides of alkylphosphorous[57,60,62], phosphoramidous[57,63], and phosphonous[64] acids. The dichlorides of alkylphosphorous acid are condensed with *O,N,N*-tri(methylsilyl)propanolamine[65]:



The most frequently employed method of synthesis of OAP involves the interaction of 1,3-aminoalcohols or their derivatives with a tervalent phosphorus acid amides, unexpected results being obtained. The simplest instance of such cyclisation is the interaction of secondary aminoalcohols with the triamides of phosphorous acid. It has been stated in a patent[55] that, for an equimolecular reactant ratio, 2-amino-OAP are obtained. However, it was shown later[57] that, for different ratios of reactants, different substances are formed, namely 2-γ-aminopropyl-OAP:

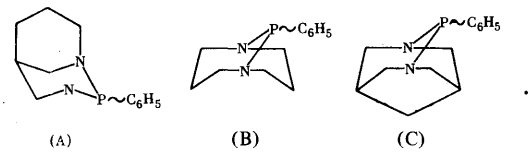
A similar type of phosphocyclisation has also been described for the phosphorylation of unsubstituted propanolamine with phosphorus acid triamides[66]. This result, i.e. double phosphorylation, is apparently associated with the higher reactivities of 2-amino-OAP, which are intermediates in this synthesis, than those of phosphorus acid triamides. Triamides of phosphorous acid readily phosphorylate *N*-acetylpropanolamine[67,68]. The absence of secondary phosphorylation is entirely logical, because the basicity of the phosphorus atom (the most important factor in reactivity) in 3-acetyl-2-amino-OAP is significantly reduced.



Phosphorodiamidites react with an equimolar amount of propanolamine[62,69,70], *N*-alkylpropanolamine[57,71,72], and *N*-acylpropanolamine[68] to form OAP of different types, including those which belong to the class of phospholipids as regards their structure, for example[72]:

St=$C_{17}H_{35}CO$.

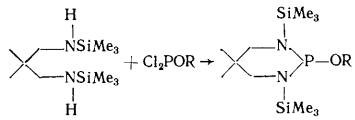
(c) 1, 3, 2-Diazaphosphorinanes



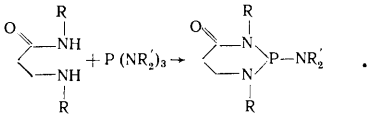
DAP began to be studied later than OAP but more extensively. Initially they were synthesised successfully by the reactions of secondary 1,3-diamines with tervalent phosphorus acid halides. Numerous studies have been devoted to phosphorylation with phosphorus dichlorides[73–78]:

A wide variety of chlorides of 1,3-alkylenephosphorodiamidic acid chlorides, which exist in the form of a single isomer in which the chlorine atom has the axial orientation, have been synthesised by the above methods[73,76,79]. 2-Chloro-4-methyl-1,3-diphenyl-DAP, which consists of two isomers, is an exception. Bearing in mind the results of Belov et al.[80], one may postulate that the chlorine atom in the systems considered occupies the axial position.

Experiments with secondary amides of β-alkylaminopropionic[81] and *N*-alkylanthranilic[82,83] acids have been described, but pure 2-chloro-4-oxo-DAP were not obtained. Nevertheless the technical products have been used successfully in further extremely complex reactions[83].

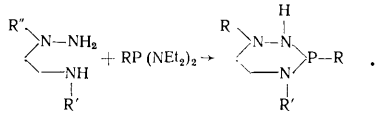


The dichlorides of alkylphosphorous[73,78], phosphoroamidous[73,76,78]†, and phosphonous[73,76] acids usually react with secondary 1,3-diamines to form various DAP. Together with linear diamines, their cyclic analogues began to be studied in the phosphorylation reaction, which makes it possible to synthesise "bulky" DAP of great stereochemical interest[73], for example:



(A) (B) (C)

The chemical shifts of the phosphorus atom in these derivatives are determined by the geometry of the molecules to a significant extent : 94.3 p.p.m. for (A), 103.6 p.p.m. for (B), and 180.8 p.p.m. for (C).



N-Silylated DAP are formed when Menshutkin acid chlorides react with bisdisilylated 1,3-diamines[84]:

The second method of synthesising the diazaphosphorinane ring is based on the transamidation of the amides of tervalent phosphorus acids. It is experimentally simple and is of great synthetic value. Thus the full amides of phosphorous acids phosphorylate extremely effectively secondary diamines[77] and aminoamides[81]:

We may note that the reaction of phosphorous acid triamides with secondary 1,3-diamines does not suffer from the limitation which we have considered for the reaction with propanolamines. This indicates some difference in the phosphorylation of related diamines and aminoalcohols and possibly amines and alcohols in general. The diamides of alkylphosphorous acid have been investigated in the reaction with primary 1,3-diamines, which made it possible to obtain the hitherto unavailable but very promising DAP without substituents at the nitrogen atoms[84]. The diamides of phosphonous acids have been made to react with aminohydrazines. Condensation resulted in the synthesis of the first representatives of 1,2,4,3-triazaphosphorinanes[85]:

It may be supposed that the proposed condensations will permit the synthesis in the immediate future of a large number of new DAP of interest for structural and synthetic research.

(d) 1, 3, 2-Dithiaphosphorinanes

This field of synthesis of DHP has been studied very much less than those already discussed, which reflects the overall picture showing that the thiol esters of tervalent phosphorus acids have been little investigated. Nevertheless, it has already been established that some of the simplest DTP are chemically very unusual; furthermore, they exhibit insecticidal and herbicidal activities[86].

1,3-Dithiols interact with phosphorus trichloride in the presence of tertiary amines to form 2-chloro-DTP.[86–88] The dichlorides of alkylphosphorous[89], alkylphosphorothious[88], phosphoroamidous[87], and phosphonous[88–93] acids, have also been used as phosphorylating agents. It has been noted[91] that DTP dimers are formed together with the DTP themselves. The problems of the stereochemistry of DTP have been examined in a number of studies[89,93–95]. Azathia- and oxathiaphosphorinanes have not so far been described in the literature.

2. Chemical Properties

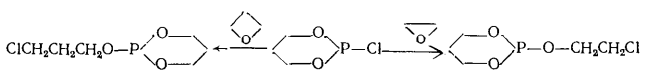
In writing this section of the review, the authors had two aims: to carry out a subject survey of synthetic studies and to examine the characteristics of the chemical behaviour of DHP determined by their cyclic structure. The latter aim presupposes in its turn the analysis of the electronic structure and intramolecular dynamics of DHP, which is at present difficult to achieve in the required detail despite the progress made, for example, in the study of Arshinova[96]. However, it is possible to make introductory remarks which will draw the reader's attention to the problem and will help him to become acquainted with the factual data.

† The reaction has no general importance and is very unusual in its chemical aspect. Its analysis will be described in the section dealing with the chemical properties of DHP.

An ordered orientation of the unshared electron pairs of the heteroatoms, which is absent from the corresponding acyclic systems, is characteristic of DHP [97–99] and presumably the n_P–n_O interaction is blocked in DOP by virtue of such order. This is confirmed by a comparison of photoelectron spectroscopic data and the chemical properties of acyclic and cyclic compounds. The problem of the involvement of the electron pairs of the nitrogen atoms of OAP and DAP in the n_P–n_N interaction is more complex, since in this case their orientation can generally speaking depend on the influence of the substituents present.

The orientation of an exocyclic substituent at the phosphorus atom plays a significant role in the chemical characteristics of monocyclic DHP. If the substituent having n or π electrons is axial, its electrons are less effectively delocalised than those of a similar equatorial substituent. This difference is probably associated with the blocking of an interaction of the n_P–n_X type on the assumption of the axial position.

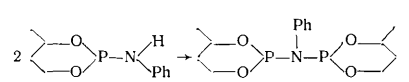
Another feature of the DHP consists in the somewhat small number of their conformational transitions[100]. The limited number of such transitions is thrown into particular relief when substituents are introduced into the hydrocarbon part of the ring or when an additional ring is condensed. Henceforth the possibility of synthesising in the series of DHP rigid systems in which the central and additional functional groups are located in space in such a way that they can ensure attack from unusual directions and hence also unusual types of reaction. Having outlined this situation, we formulated the principle of the stereochemical regulation of the reactivity in the series of cyclic derivatives of tervalent phosphorus acids. This principle has already been realised in the reactions of DHP.



Since numerous scientific articles and patents have been devoted to the reactions of monocyclic DHP, the relevant data are discussed separately in terms of classes of compounds.

Within each section the data are further subdivided on the basis of the principal structural-chemical features. The following characteristics are discussed in succession for the usual DHP: (1) substitution reactions involving an exocyclic substituent at the phosphorus atom; (2) protonation and oxidation reactions; (3) Arbuzov alkylation and related syntheses; (4) other processes. After this, the chemical properties of DHP, which are prototropic systems (hydrophosphoryl and thiohydrophosphoryl substances), are discussed in separate subsections.

(a) 1, 3, 2-Dioxaphosphorinanes

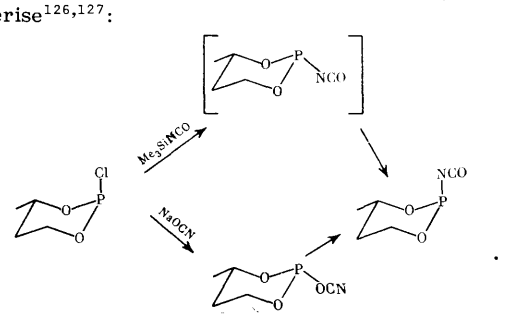


Substitution reactions at the phosphorus atom. The nucleophilic substitution of chlorine in 2-chloro-DOP has been studied in greatest detail. These compounds are readily converted into neutral phosphites in their reactions with alcohols[6,7,10,15,22,101–103], phenols[7,104,105], substituted glycerols[106,107], and sugars[15,107,108] in the presence of bases. The problems of the stereochemistry of the reaction and the characteristics of the steric organisation of the cyclic neutral phosphites obtained have been examined in a number of studies[101,102,107,109,110].

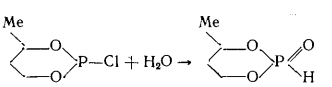
2-Chloro-DOP can be converted into the corresponding neutral phosphites even on treatment with oxirans and oxetans[111,112], for example:

Six-membered cyclic phosphorochloridites react with mercaptans to form phosphorothioites (see, for example, Okruszek and Stec[113]).

Numerous communications contain data concerning the interaction of 2-chloro-DOP with nitrogen-containing bases of different types. Arbuzov and Zoroastrova showed for the first time[114] that 1,3-alkylene phosphorochloridites react with a simplest secondary amides to form 2-amino-DOP. Subsequently this reaction came to be widely employed[10,12,15,34,102,115,116]. It was shown that, when amines are phosphorylated by asymmetric cyclic chlorides, a mixture of two isomers is always formed[19,51,102,110]#. Primary amines in general behave in this reaction analogously to secondary amines[49,50,114,118], although they yield less satisfactory results on a preparative scale. This is associated with the disproportionation, first investigated in relation to the anilide of 1,3-butylenephosphorous acid[118]:



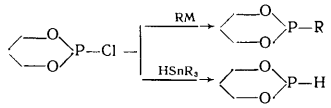
In the presence of bases, imines are also phosphorylated by 2-chloro-DOP in accordance with the general mechanism, for example[119]:



Instead of amines, it is possible to use their *N*-trimethylsilyl or magnesium derivatives.

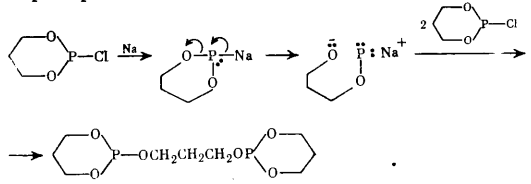
2-Chloro-DOP exchange the chlorine atom for many groups on interaction with salts of acids or their trimethylsilyl derivatives. Thus the reaction with antimony trifluoride yields fluorides[8], that with carboxylic and alkylcarbonic acid salts gives rise to acylates[120,121], the reactions with cyanotrimethylsilane[122], silver cyanate[123], or hydrocyanic acid in the presence of triethylamine results in the formation of cyanides[124], and the reaction with isothiocyanatotrimethylsilane yields isothiocyanates[125]. The reaction with cyanic acid derivatives is of special interest. *N*-Trimethylsilyl derivatives leads to phosphoisocyanates, while salts of cyanic acid result in the initial formation of the *O*-isomers, which then isomerise[126,127]:

2-Chloro-DOP react with sodium dialkyl phosphites to form asymmetric pyrophosphites (*O*-phosphorylation of the ambident phosphite anion[128]), while their reaction with *N*-trimethylsilylacetamide gives rise to acid cyclic phosphites[129]. The latter reaction probably involves the *O*-phosphorylation of the silyl derivative with formation of the phosphiminoacetate, which then decomposes splitting off acetamide.



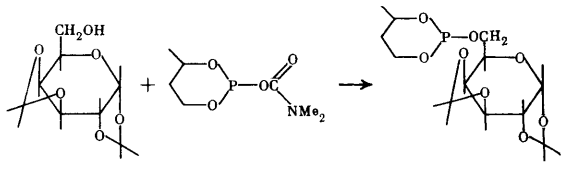
The hydrolysis of 2-chloro-DOP to cyclic hydrophosphoryl compounds has been studied in detail[7,10,12,15,33,117,130], for example:

This problem has been treated erroneously by Bodkin and Simpson[117].



The hydrolysis of asymmetric phosphorochloridites results in the formation of two isomers, the stable isomer, with an equatorial phosphoryl group, crystallising out[43,117]. The sulphydrolysis of 2-chloro-DOP leads to cyclic hydrothiophosphoryl compounds[130,131]. The problems of the stereochemistry of this reaction have been studied[131].

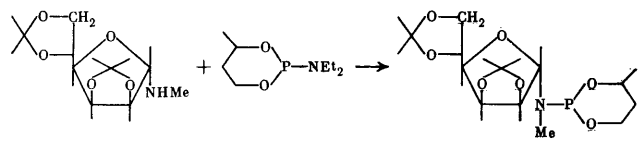
The consideration of the substitution of chlorine in the series of DOP will be completed by examining reactions with organometallic compounds and metals. It has been suggested that the following reactions take place with Grignard and Norman reagents[132] and with tin hydrides[110,133]:



The cyclic esters of hypophosphorus acid obtained are of definite interest as the parent members of the series of DOP. Using them, it is possible to determine the stereochemistry of phosphorus in various DOP by comparative ^{1}H and ^{13}C NMR.[110]

The 2-chloro-DOP do not react with alkali metals in an altogether usual manner[134]§. The process probably begins with one-electron transfer and involves the stage in which P-metallated DOP are formed. The latter decomposes owing to the concerted donor–acceptor action of the geminal substituents at the phosphorus atom. The polar intermediate undergoes further reduction and phosphorylation with formation of diphosphites:

If 2-chloro-DOP is treated with other metallating and even silylating agents, for example, triphenyl-lithiosilane, then a diphosphite is also obtained[134].

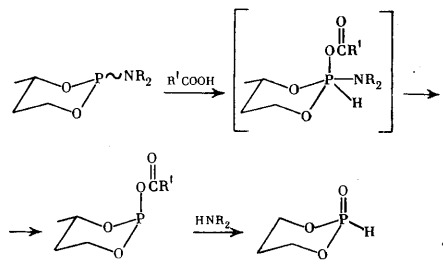


2-Acyloxy-DOP are similar to 2-chloro-DOP as regards reactivity. These compounds have found applications as phosphorylating agents and are used in the synthesis of certain cyclic phosphites[120,121]. Their advantage is that in the acylation of nucleophiles less corrosive carboxylic, alkylcarbonic, and carbamic acids are evolved instead of hydrochloric acid, as mentioned above. As an illustration of the foregoing, we may quote the following examples[136]:

The hydrolysis[128] and acidolysis[137] of the above cyclic acyl phosphites gives rise to hydrophosphoryl compounds. The same result has been noted in the decarboxylation of formyl phosphites[138].

Other popular reagents frequently used for the purposes of fine organophosphorus synthesis are the amides of 1,3-alkylenephosphorous acids. These compounds are readily available, convenient to work with, and exhibit the optimum reactivity in many reactions. When they are used in phosphorylation, the amine is evolved, but it does not as a rule complicate the process and is readily removed from the reaction mixture. 2-Amino-DOP readily phosphorylate alcohols[7,40,47,115,139–143], phenols[7,140,144], substituted glycerols[106,107], and sugars[15,107,108,145]. An important factor is the difference in the ease of interaction of the two geometrically isomeric amides with alcohols[139].

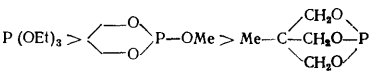
A series of studies has been devoted to the phosphorylation of amines by transamination[141,146]. Very recently transamination has been used to synthesise new systems—phosphoglycosylamines[147]:



The interaction of 2-amino-DOP with carboxylic acids has been described in the literature. If two moles of acid are consumed per mole of the phosphoramide, substitution takes place with formation of acyl phosphites; the other reaction product is the amine, which combines with the excess acid[148]. If one mole of acid is used, then the substitution at the phosphorus atom is supplemented by the cleavage of the acyl phosphite by the amine and an acid cyclic phosphite is obtained[38,39,40,42,44]. A significant factor in the synthesis is its stereospecificity[38,39,44]—the formation of a labile isomer with an axial phosphoryl group. A mixture of cyclic acyloxyaminophosphoranes, capable of ready interconversion by pseudorotation, is apparently formed initially. The most stable conformer subsequently decomposes with formation of only one axial acyl phosphite. The process terminates with deacylation, which does not involve the configuration of phosphorus (see below).

The conversion of 2-amino-DOP into acid cyclic phosphites is also possible via hydrolysis accelerated by acid catalysts[7,12,114]. Sulphydrolysis takes place similarly[131].

2-Amino-DOP are also capable of insertion reactions. Thus they react with carbon dioxide to form carbamoyl phosphites, for example[136]:

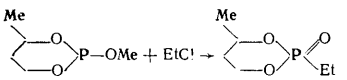


Fewer synthetic studies have been made on the conversion of neutral phosphite DOP into other compounds of this class. They can undergo selective hydrolysis[148,149] and alcoholysis[150] via the exocyclic substituent. 2-t-Butoxy-DOP [151] and its thio-analogue[152] undergo thermal decomposition to the corresponding hydrophosphoryl and hydrothiophosphoryl compounds and isobutene. According to NMR data, the equatorial substituent undergoes degradation at a higher rate than the axial substituent[151].

§ Erroneous results have been published[135].

Apart from the nucleophilic substitution at the phosphorus atom in the DOP system, radical substitution has also been described. In this case the geometrical isomers react at different rates and the process is accompanied by inversion at the phosphorus atom[153].

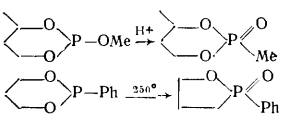
Addition reactions. An interesting feature of the chemical behaviour of DOP consists in the fact that the electron-donating capacity of the phosphorus atom is determined by the cyclic nature of the substances and the spatial orientation of the unshared electron pair of the phosphorus atom. At the beginning of this section we reported the characteristic features of the unshared electron pairs of the heteroatoms in DOP and in this connection one can conclude that the basicity of phosphites decreases in the sequence



This conclusion has been confirmed experimentally. Thus the ionisation potential of the highest level of the phosphorus atom increases appreciably in this series (8.99, 9.37, 9.95 eV).[97,98] At the same time the basicity, determined both in the gas phase by ionic cyclotron resonance[154] and in the liquid phase at −50 °C from the $^1J_{P-H}$ constants of the protonated esters[155–156], decreases¶. The Lewis basicity of acyclic, monocyclic, and bicyclic phosphites varies similarly. This problem has been analysed by studying the stability of the borane[157,158] and nickel[160] complexes and by infrared spectroscopy. Advances in the investigation of the electronic structure of monocyclic DOP are also manifested by the fact that the theoretical conclusion that the basicities of differently oriented unshared electron pairs at the phosphorus atom are different has been proved experimentally: the axial pair is more basic than the equatorial pair[154,156,157,161]. Investigations demonstrating the marked influence of the exocyclic substituent on the electron-donating properties of the phosphorus atom are also of interest. Thus the amino-group significantly increases the electron-donating properties of the phosphorus atom relative to the alkoxy-group and the chlorine atom[97,98].

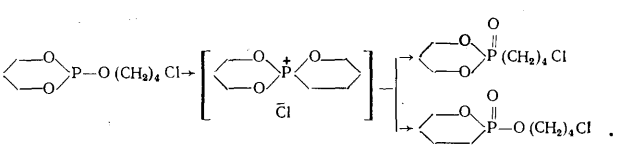
The study of the complex formation reactions between DOP and copper[1,162], boron[158,163], molybdenum[158,161,164], nickel[160, 165], cobalt[166,167], and palladium[168] derivatives has shown that the configuration at the phosphorus atom is retained in these reactions (X-ray diffraction has been used[158,160,161,163]). Complexes are synthesised in order to solve specific chemical problems. Adducts with the copper(I) salts are used for the identification of DOP.[1,114,162] The adducts with nickel salts[165] isomerise but-1-ene to a mixture of but-2-enes, while the corresponding rhodium[169,170] and palladium[168,171] derivatives are used as hydrogenation catalysts. In the latter case it has been shown that the configuration of the phosphorus ligand determines the activity and stereoselectivity of the catalysts. It has been stated that the formation of complexes of DOP increases their reactivity in organic synthesis[172]. Such studies are apparently very promising and merit vigorous development.

The electron-donating properties of the phosphorus atom in DOP are also manifested in their oxidation. This reaction has been widely used on a preparative scale and has involved cyclic hypophosphites[133], phosphites[7,46,48,106,145,173–179], phosphoramidites[15,48,50,158,273,180], phosphorimidites[119], phosphorocyanidites[123], phosphoroisocyanidites[126], phosphorochloridites[34], phosphorothioites[113], and phosphonites[27, 132]. The question of the stereochemistry of the oxidation reaction is being actively discussed in the literature, conflicting views being expressed. Under conditions excluding the interconversion of the different DOP formed, they are probably converted stereospecifically by the majority of oxidants into phosphoryl forms with retention of the configuration at the phosphorus atom. This is indicated by the conclusions reached in a series of studies[34,50,127,158,173,175,178, 181]. On the other hand, the possibility of the non-stereospecific oxidation has been indicated[113,176]. It has been suggested that the reactions of two geometrical isomers may not have completely identical mechanisms[182].



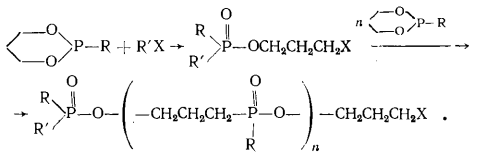
Sulphurisation†[7,25,53,106,107,113,126,133,145,175,179], selenisation [49,113,133,176,183,184], and imination[48,116,133] of DOP are carried out similarly to oxidation. Here too there is no complete unanimity in the stereochemical interpretation of the results. Both complete retention of the configuration at the phosphorus atom[127,158,179] and its partial inversion[113,176] have been noted.

Arbuzov alkylation and related syntheses. Neutral phosphite DOP undergo the usual Arbuzov alkylation[6,24,47,143,149, 162,175,187–189], for example:



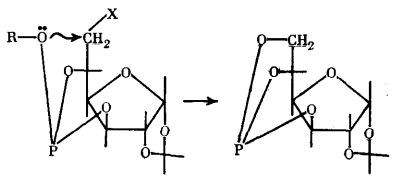
In the majority of cases the alkylation probably involves the retention of configuration at the phosphorus centre[158,162,175, 190] although its partial inversion can also occur[176]. However, one cannot rule out the possibility that the quaternisation of the DOP entails a partial inversion of the configuration of the initial substance, which in fact affects the final results. The reactivity of tripropyl phosphite has been compared with those of the corresponding dioxaphosphorinane and dioxaphospholan by differential thermal analysis. It has been shown that the reactivity diminishes in the above series[191].

The phosphite[192] and phosphonite[193] isomerisations, leading to phosphoryl compounds, are relevant to the data under discussion:



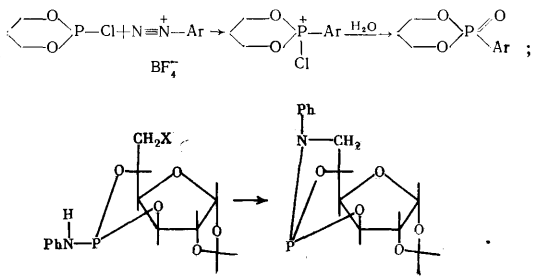
There exist data showing that the Arbuzov reaction can be accompanied by the opening of the dioxaphosphorinane system. This occurs when 2-methoxy-4,4,6,6-tetramethyl-DOP interacts with fluorosulphonic acid[194], when 2-butoxy-4-methyl-DOP interacts with bromotriphenylmethane[149], and in intramolecular interactions of the type[103,112,195]

¶ Mikolajczyk et al.[159] were the first to carry out a semi-quantitative comparison of cyclic and acyclic phosphates.



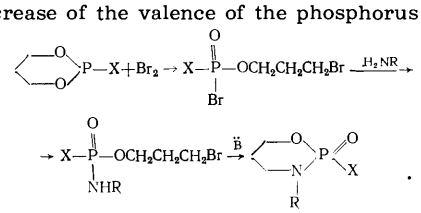
† Together with sulphurisation, other reactions involving the transfer of sulphur and occurring on treatment of elemental sulphur merit attention. Thus neutral cyclic phosphites of nucleosides are sulphurised with di-t-butyl disulphide[185] and 2-chloro-DOP is sulphurised by acetylsulphenyl chloride[156].

The competition between the endocyclic and exocyclic pathways in the decomposition of the quasi-phosphonium intermediates disappears on passing from phosphite to phosphonite derivatives. A fundamentally new method of synthesising polyphosphonates, which is impossible for acyclic systems, has been demonstrated in this instance. The method consists in treating the cyclic phosphonite with an insufficient amount of the alkylating agent. A γ-halogenopropyl phosphinate, which propagates the alkylation process via a relay mechanism, is formed in the first stage[27,196]:

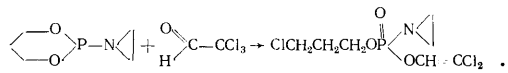


Japanese workers have reported an analogous polymerisation of cyclic phosphonites but in the presence of boron trifluoride[29].

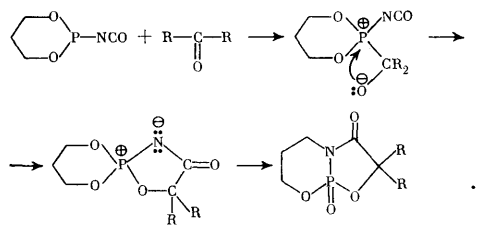
It has recently been possible to show that the intramolecular alkylation of stereochemically rigid DOP, in which an electrophilic carbon atom and the oxygen atom of an exocyclic alkoxy-group are in close spatial proximity, can be achieved. Such spatial disposition led to a reaction which is an alternative to the Arbuzov reaction, which demonstrated the possibility of steric regulation in the alkylation of neutral phosphites#[197]:



The intramolecular cyclisation of the anilide of the corresponding glycophosphorus acid takes place similarly. The possibility of the alkylation of the nitrogen atom in the amides of tervalent phosphorus acid was thereby demonstrated reliably for the first time[198] (see below).

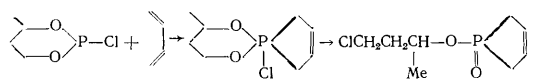


The arylation of certain DOP has also been described in the literature, for example[199]:

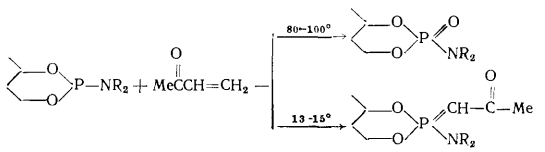


A series of reactions are related to the alkylation of DOP: interactions with hypochlorites[200], sulphenyl chlorides[188,201], and chloramines[102], which entails the formation of cyclic phosphates, phosphorothioates, and phosphoramidates. When account is taken of the stereoregularity of these reactions, conclusions can be reached concerning their preparative value. Data concerning the reactions of DOP with halogens have been published recently[111,202]. It has been established that, regardless of the type of substituent at the phosphorus atom, the reaction is accompanied by ring opening, which is unexpected. On treatment with primary amines, the acid halides formed give rise to amides, which readily cyclise. Thus here we have a transition from DOP to OAP with an increase of the valence of the phosphorus atom[202]:

The Perkow reaction also takes place with DOP, for example[203]:

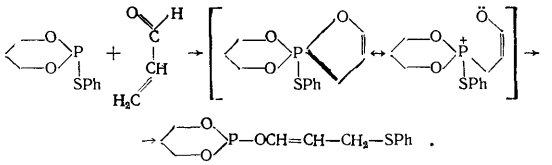


The interaction of 2-isocyano-DOP with electrophilic carbonyl compounds merits attention[204–206]:

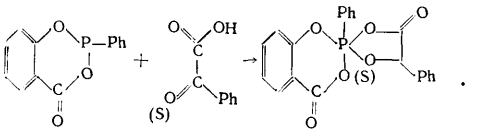


On the other hand, electrophilic carbonyl compounds with a halogen atom in the α-position react with 2-isocyano-DOP differently, namely via the Perkow mechanism, with opening of the phosphorinane ring and retention of the isocyano-group[207].

Other processes. The phosphorus atom in the dioxaphosphorinane ring is biphilic, as a result of which there is a possibility of the addition to DOP of dipolar or readily polarisable 1,3-homo- and 1,3-hetero-diene systems, for example[208]:

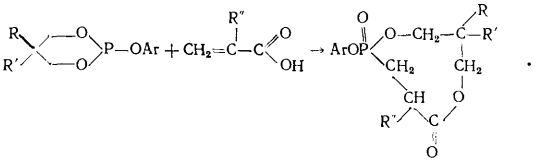


The substituent at the phosphorus atom influences the reaction significantly. Thus the amino-group prevents the addition of alkadienes. However, 2-amino-DOP can combine with polar substances, for example α,β-unsaturated ketones. Depending on temperature, different reactions take place in this instance[209]:



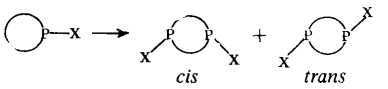
Next, the cyclic imide can react with the excess acrolein and be converted via the Wittig mechanism into 1,3-butylene phosphoramidate. It is of interest to note that 1,2-alkylene phosphoramidites react with methyl vinyl ketone to form only spiroisophospholen.

The cyclisation of the 3,5-cyclic phosphorochloridite of 6-tosyl-1,2-glucofuranose, which apparently takes place as a result of the mutual approach of the phosphorus and O(6) atoms, should also be noted[197].

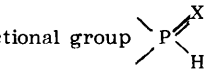


If there is an SR group at the phosphorus atom in the initial DOP, then the primary adduct reacts in an unusual manner[210]:

The cycloaddition may not be followed by a further chemical development when DOP containing the amino-group at the phosphorus atom§ or a hydrocarbon group are used, for example[212]:

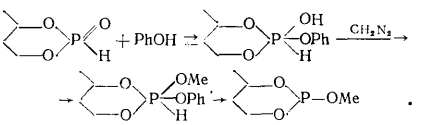


On the other hand, 2-aryloxy-DOP react with acrylic acids to form macrocyclic phosphonates[214]:

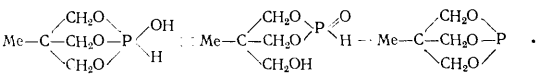


This outwardly unusual reaction has a rational explanation. The process begins with cycloaddition, after which the intermediate undergoes a reorganisation via the Arbuzov mechanism. Next, the acid cleaves the neutral phosphite to a hydrophosphoryl compound of the acyl phosphite type and the latter cyclises via a standard pathway with formation of a phosphorus–carbon atom.

An important feature of the chemical behaviour of DOP is their ability to undergo reversible condensation on storage. This process can lead to dimers, trimers, and in the general case oligomers. It is significant that the condensation leads at each stage to the appearance of pairs of isomers[215]:

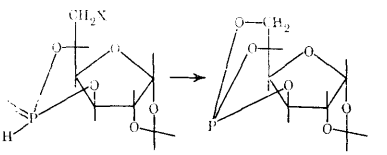


This interesting reaction was studied by NMR. According to the authors, such disproportionation is a catalytic process and is accelerated by admixtures of acid substances, frequently the hydrochlorides which usually contaminate DOP. If this is so, then disproportionation can be prevented by effective purification of the compound.



Reactions of hydrophosphoryl and hydrothiophosphoryl DOP. DOP containing the prototropic functional group  are being actively investigated, the research being accompanied by an acute controversy concerning the influence of the ring on chemical properties. Within the framework of this controversy, a special enhanced acidity has been attributed to these substances[216–219]. Reliable experiments on this subject have not been reported but it has been shown nevertheless that the hydrophosphoryl compounds in the series of DOP have certain characteristic features.

We shall consider initially the basic properties of the cyclic acid phosphites. Information on this question has been obtained in the study on the *p*-fluorophenol complexes. It has been shown that the axial orientation of the phosphoryl group ensures a higher basicity than the equatorial orientation, which is consistent with the general theoretical analysis of the systems considered at the beginning of this section. On the other hand, an approximate correspondence of the basicities of DOP and dialkyl phosphites has been established. Nevertheless the experiments performed have demonstrated a large difference between the cyclic and open-chain hydrophosphoryl compounds. The former, particularly those with an equatorial phosphoryl group, are significantly associated in solutions, while the latter are not[220]¶.



The interaction of hydrophosphoryl DOP with proton donors may apparently not consist solely in protonation. It has been shown that, after the addition of phenol or water, 1,3-butylene phosphite begins to react with diazomethane to form ultimately a cyclic neutral phosphite+[221]:

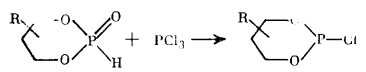
The above reaction is apparently related to the "anomalous" cyclisation of the monocyclic metriol phosphite[172,222]:

The spatial approach of the functional groups is probably an important factor in this case, since the benzyl ester of metriol phosphite also undergoes a similar cyclisation. The steric factor is undoubtedly manifested in the very easy intramolecular alkylation reactions, which are alternatives to the Michaelis–Becker synthesis[197,223]:

The reaction proceeds easily either in the presence of tertiary amines or when the substance is kept at a somewhat reduced pressure. Its chemistry resembles that of the intramolecular alkylation of bis(β-chloroethyl phosphite)[224] but takes place much more readily because the process is predetermined by steric factors owing to the rigidity of the initial system.

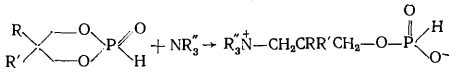
§ A similar final result has been noted in the case where two equivalents of electrophilic monocarbonyl compounds were used[213].

¶ The association may be accompanied by the condensation of these substances. Esters without substituents in the hydrocarbon part of the ring undergo oligomerisation particularly readily[42].



+ It has been stated that neopentylene phosphite reacts at 20–25 °C with diphenyldiazomethane to form diphenylmethyl-neopentylene phosphite, which immediately isomerises. The authors[218] attribute this observation to the anomalous acidity of the initial DOP. An alternative explanation of the experimental result is the scheme presented above.

Hydrophosphoryl DOP undergo intermolecular alkylation reactions (α-hydroxy- and α-amino-alkylation, etc.) which to a large extent correspond to the analogous reactions involving open-chain systems. We shall confine ourselves to quoting certain typical communications[225–227] and shall consider in greater detail the stereochemistry of these reactions. Soviet workers[228] were the first to show that the α-hydroxyalkylation takes place stereoselectively. Later Mosbo and Berkade supplemented this finding by data concerning the characteristics of the reaction in the presence of acids[226]. Finally, it has been shown quite recently[229] on the basis of the structure of the substances obtained that the reactions take place with retention of the configuration of the phosphorus centre. This conclusion leads to the possibility of the stereospecific synthesis of complex phosphorinanes. The kinetics of the reaction of isomeric forms of phosphorinanes with various carbonyl compounds have also been investigated and the dependence of the reaction rate on the configuration at the phosphorus atom in the initial substance has been established. This dependence is not constant for all aldehydes and ketones[229].

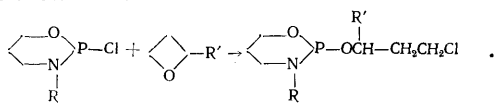


Like other acyclic analogues, hydrophosphoryl and hydrothiophosphoryl DOP can be modified oxidatively by the Todd–Atherton method as well as other procedures[5,12,110,133,230–234]. However, rigorous stereochemical features are characteristic of these substances. Thus they react stereoselectively with retention of the configuration at the phosphorus atom[117,228,235]. The problem has been discussed in greatest detail in a study[229] where both a difference between the reactivities of the geometrical isomeric forms of phosphites was demonstrated and the possible causes of the steric hindrance in the synthesis were analysed.

The report of the addition of sulphur to 1,3-alkylene phosphites[236], which takes place more readily than the corresponding reaction with dialkyl phosphites, is of undoubted interest.

Yet another valuable chemical feature of hydrophosphoryl DOP must be pointed out. It is known that, on reaction with phosphorus trichloride, dialkyl phosphites give rise to Menshutkin acid chlorides. In contrast to this, six-membered alkylene phosphites react with phosphorus trichloride retaining the fundamental molecular skeleton[237]:

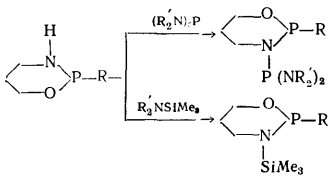
Hydrophosphoryl DOP can also react with the opening of the six-membered phosphite ring. Thus, on reaction with tertiary amines, they give rise to betaines[238]:



We may note that this alkylation proceeds under more severe conditions than the interaction of dialkyl phosphites with amines.

Among other reactions accompanied by a change in the six-membered ring, we shall mention cyclo-oligomerisation[42]. The presence of substituents in the hydrocarbon part of the ring prevents this process.

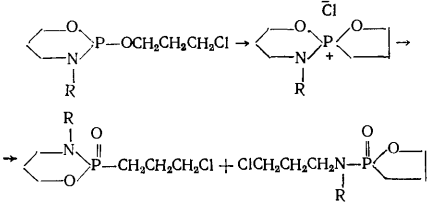
(b) 1,3,2-Oxaphosphorinanes



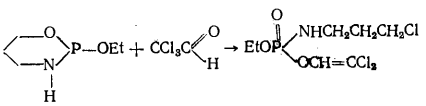
OAP have been less thoroughly investigated, but certain reactions of these compounds, which may be of interest to many specialists in the chemistry of organophosphorus compounds, have been achieved.

We shall consider initially the exchange of exocyclic substituents at the phosphorus atom. On reaction with secondary amines[57], carboxylic acid salts[60], tributyltin hydride[64], and water[239], 2-chloro-OAP exchange the chlorine atom for the corresponding groups in the usual way. The reaction with an equimolar amount of alcohol also takes place analogously[57,60,61,71,240]. We may note that the use of an excess of alcohol is inadmissible owing to the possibility of ring opening[62]. 2-Chloro-OAP are converted into esters also on treatment with oxetans[240]:

2-Amino-OAP can be made to exchange the amino-group for the hydroxy-group[239] or an alkoxy-group[57] by standard methods. In the reaction with 2-aminophenols the substitution is accompanied by addition[63].

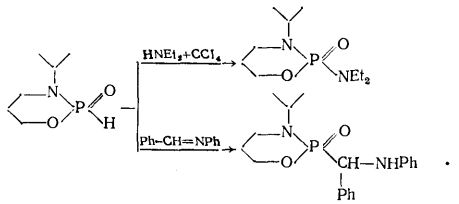


It has been shown that OAP with the endocyclic fragment $-NH-P\lessdot$ can be effectively phosphorylated[241] and silylated[70] at the nitrogen atom using mild reagents:



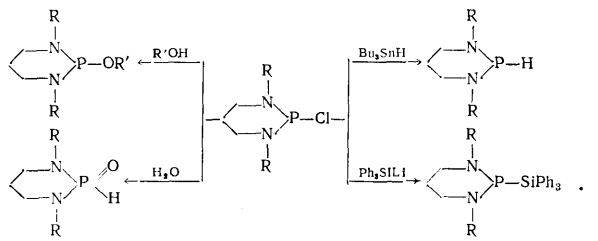
The ease of phosphorylation depends greatly on the chemical nature of the phosphoramide: the presence of electron-accepting groups at the phosphorus atom hinders the process, while the presence of electron-donating groups facilitates it[241].

OAP form complexes with transition metals, for example platinum, which are of interest for oncology[59]. OAP are oxidised[72,242] and sulphurised[67] in the usual way. The combination of the oxidation of glycerol-containing OAP with subsequent ring opening leads to a novel method of synthesis of phospholipids important for membranology[72].



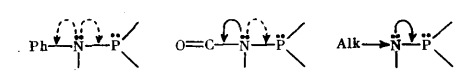
The alkylation of OAP and similar reactions have been little investigated. The intramolecular Arbuzov interaction of γ-chloroalkyl ethers of this series has been reported[240]:

The possibility of two pathways leading to the cleavage of the phosphoester bonds in the quasi-phosphonium intermediate was demonstrated in the above study. In another communication[69], devoted to the employment of the Perkow reaction for a series of OAP, only one version of the degradative stage is mentioned, which appears less probable:



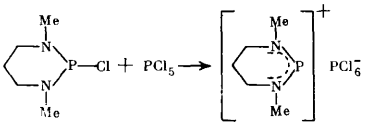
Hydrophosphoryl OAP enter into the usual oxidative phosphorylation and aminoalkylation reactions[239]:

(d) 1, 3, 2-Diazaphosphorinanes

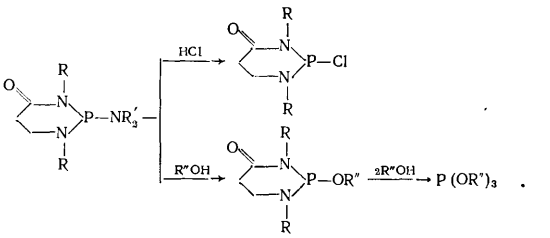


The reactions of DAP, like those of OAP, have still been little investigated, but the number of studies in this field is increasing and the scientific importance of the results obtained is growing.

A series of studies have been devoted to the substitution of the exocyclic groups at the phosphorus atom. On interaction with alcohols in the presence of bases, 2-chloro-DAP of different types give rise to ester-amides[73,75–78,81], the reaction with carboxylic acid salts produces mixed anhydrides[76,77], the reaction with tributyltin hydride affords cyclic amides of hypophosphorous acid[79,110,243], the reaction with triphenylsilyllithium leads to the formation of phosphoramidosilicides[134], and the reaction with water produces the corresponding hydrophosphoryl compounds[81,82,243]:

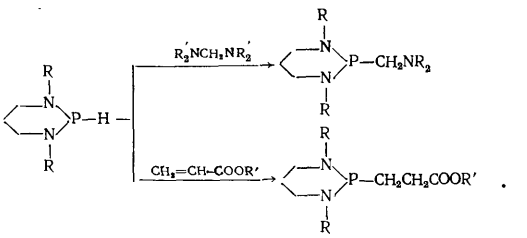


The reaction with secondary amines, which in the case of other DHP always leads to the usual results, proved to be more complex. 2-Chloro-1,3-diphenyl-DAP [78] and 2-chloro-1,3-dimethyl-4-oxo-DAP [81] react with secondary amines to give high yields of the full cyclic amides of phosphorous acid. On the other hand, 1,3-dialkyl-2-chloro-DAP behave differently in this reaction[75–77,141]. Thus the phosphorylation of aziridine and dimethylamine involves the expected nucleophilic substitution but the phosphorylation of diethylamine, which is only a little more basic, was unsuccessful. Furthermore, the attempt to synthesise the required cyclic triamide by another acid chloride method yielded an entirely unexpected result[76,77]#.

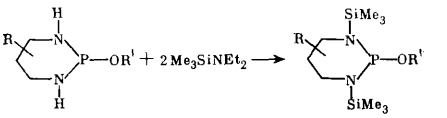


We believe that the observed difference in the phosphorylation reaction is associated with the different basicities of the expected reaction products. *N,N'*-Diphenyl derivatives and particularly compounds containing the carbonyl group are much weaker bases than the *N,N'*-dialkyl derivatives:

Compounds of the latter type therefore manifest relatively more basic properties than triethylamine and accept hydrogen chloride with the cleavage of the exocyclic P–N bond and the formation of 2-chloro-DAP. If this view is correct, then we may conclude that in the diazaphosphorinane ring there is a more pronounced electron-donating effect on the phosphorus atom than in the open-chain phosphorus tetraalkyldiamide systems. This hypothesis is confirmed to some extent by the results of a mass spectrometric study of 2-chloro-DAP and data for their interaction with phosphorus pentachloride[244]:



2-Amino-DAP have also been used in other substitution reactions, for example[78,81]:

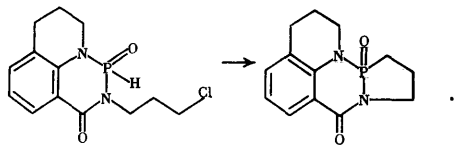


We may note that the reagents used must be measured in rigorously specified amounts, since degradation of endocyclic phosphoramide linkages is also observed in the presence of their excess.

Substitution reactions and similar processes have been described for 2-hydro-DAP:[245]

These reactions are of great interest for the synthesis of complex DAP and are apparently promising for synthetic purposes.

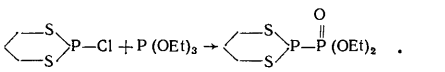
In conclusion of the consideration of the substitution reactions, we may point out the silylation of 1,3-dihydro-DAP at the nitrogen atom[84]:



DAP tends to enter into reactions involving an increase of the valence of phosphorus: oxidation[75,77], sulphurisation[77,78], and quaternisation[244]. Unfortunately the complex-formation reactions of DAP have not yet been investigated, which impoverishes the field of the chemistry of transition metal complexes of organophosphorus ligands.

Hydrophosphoryl DAP have been relatively widely investigated. The simplest of these compounds have been made to undergo the Todd–Atherton oxidative phosphorylation[77,81,243] and aminoalkylation[77,81]. Novel possibilities for the Michaelis–Becker alkylation (including intramolecular alkylation) of

The required triamides are obtained successfully by non-acid chloride methods[77].

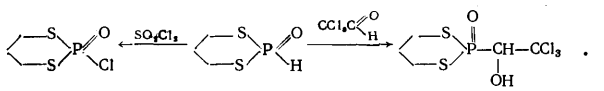


bicyclic and tricyclic DAP with formation of fairly complex systems have been recently demonstrated[83]:

(e) 1, 3, 2-Dithiaphosphorinane

DTP have been studied less thoroughly than other DHP, which, however, does not imply less chemical importance to these compounds.

Substitution reactions at the phosphorus atom have been studied mainly in relation to 2-chloro-DTP. Satisfactory results have been noted for the interactions with alcohols[86,87§], amines[87,246], mercaptans[88], and water[247]. The Arbuzov and Michaelis–Becker reactions have been carried out[248,249]:

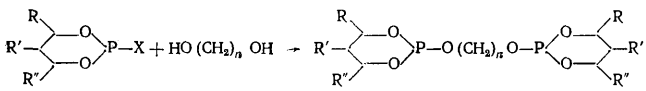


2-Amino-DTP react satisfactorily with dialkylphosphorodithioic acids to form mixed anhydrides[250]. However, they do not phosphorylate in the usual manner alcohols taken in equimolar amounts. In such cases a small amount of a secondary amine is produced and a trialkyl phosphite is obtained[87].

In contrast to other DHP, DTP are poorly oxidised and sulphurised[87,88,91,92,250]. Their complex formation reactions have not been studied.

The behaviour of hydrophosphoryl DTP merits special consideration[247]. Their physical and chemical properties differ sharply from those characteristic of other hydrophosphoryl DHP. Under the usual conditions, they are crystalline substances which are very sparingly soluble in the majority of solvents, apparently owing to their dimerisation due to their enhanced acidity.

It has been possible to achieve the chlorination and certain other reactions of these unusual hydrophosphoryl compounds, for example[247]:



III. POLYCYCLIC DIHETEROPHOSPHORINANES

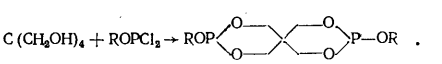
In terms of structural features, all the polycyclic DHP can be divided into three independent classes: systems with isolated rings, spirans, and condensed polycycles. Chemically, these classes are different from one another. In terms of their fundamental features, the first two resemble the monocyclic DHP and we shall therefore describe the problems of the chemistry of these substances only briefly. On the other hand, condensed polycycles are unusual systems and their synthesis and chemical properties are therefore analysed in detail in the present review.

1. Polydiheterophosphorinanes with Isolated Rings

This class of compounds has been studied only in relation to dioxaphosphorinanes. The six-membered cyclic diphosphites are of interest if only because they are more stable than their acyclic analogues. Alkylenebis-DOP have been obtained by the phosphorylation of diols with 1,3-alkylene phosphorochloridites[251], 1,3-alkylene, acyl phosphites[252], 1,3-alkylene phosphoramidites[253], or fluoroethyl phosphites[150]:

Together with the usual glycols, dihydric phenols[253] as well as systems with functional groups of substituents, for example dianhydrosorbitol[251], have been introduced into the reaction.

Among the phosphorylating agents enumerated above, amides are experimentally most convenient. These reagents have been used in the phosphorylation of novolac resins[254] and cellulose[255]. For this reason, high-molecular-weight poly-DOP have been obtained. The reactivities of di- and poly-DOP are very similar to those of the usual monocyclic compounds. They are readily oxidised and readily combine with sulphur[251,255] and are also alkylated via the Arbuzov and Perkow reactions[255].



2. Spiran Bisdiheterophosphorinanes

Hitherto only dioxaphosphorinane examples of the above class of compounds have been described in the literature. Despite their structural limitations, the number of relevant studies has been fairly large. This is due to the practical importance of the spiran bis-DOP, among which polymer stabilisers[256–260] and modifiers[261], plasticisers and oils[262], antipyrenes[111], and pesticides[263] have been found.

The synthesis of spiran bis-DOP is based on the employment of pentaerythritol. This readily available tetrol was made to react with phosphorus trichloride[264,265]:

Unfortunately in the published methods only a very brief description of the preparative aspect of the experiments is given and apparently they make it possible to obtain only an acid dichloride which is not altogether pure. The phosphorylation of pentaerythritol by Menshutkin acid chlorides has been described in the literature; in this case a tertiary amine must be used to bind hydrogen chloride[266]:

The second method of synthesis of a spirodiphosphite system involves the transesterification of neutral esters (usually triphenyl phosphite) by pentaerythritol for a molecular reactant ratio of 2 : 1.[18,256,257,266] Diethyl phenylphosphonite reacts similarly with pentaerythritol[37]:

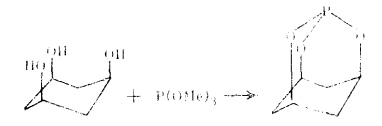
The steric organisation of spiro-di-DOP has begun to be studied in a series of laboratories. By measuring the dipole moment and Kerr constants[37,267,268], NMR experiments[18],

§ The reaction with t-butyl alcohol yields a hydrophosphoryl compound and isobutene[87].

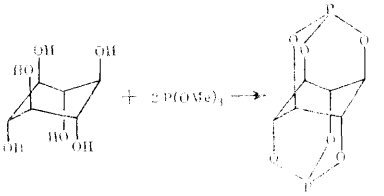
and X-ray diffraction[269], it has been shown that the molecules of these compounds contain two rings in the chair conformations, relative to which the alkoxy-group is in the axial position and the amino-group is in the equatorial position.

As regards chemical reactions, the chloride of pentaerythritol-diphosphorous acid has been studied in greatest detail. On treatment with alcohols[256,266], mercaptans[265], epoxides[211], sodium isocyanate[270], and amines[266], this compound exchanges the chlorine atom for the corresponding nucleophilic groups. The reaction with formic acid[138] or t-butyl alcohol[271] results in the formation of a bishydrophosphoryl compound, while the corresponding bisthiohydrophosphoryl compound has been synthesised by the sulphydrolysis of the corresponding acid dichloride[272].

The neutral phosphite spiro-bis-DOP and certain related compounds have been investigated in oxidation[266], sulphurisation[266,270], and Arbuzov alkylation[262,266] reactions. The last reaction has been recently proposed for the vulcanisation of fluororubbers[261].



3. Condensed Polydiheterophosphorinanes



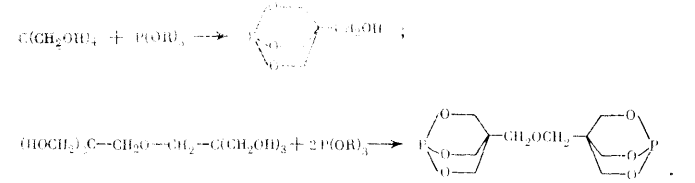
A large number of condensed poly-DHP, containing different as well as the identical structural elements, have been investigated at the present time. They can be usefully divided into four groups: 1-phospha-2,8,9-trioxa-adamantanes, 1-phospha-2,6,7-triheterobicyclo[2.2.2]octanes, and 1-phospha-2,7,8-heterobicyclo[3.2.1]octanes; the fourth group formally combines other systems which have so far been little investigated.

(a) 1-Phospha-2, 8, 9-trioxa-adamantanes

Two compounds of this group are known at the present time; phloroglucitol phosphite and scyllitol diphosphite. The molecules of these substances constitute systems bounded by dioxaphosphorinane rings in the chair conformation. This factor is responsible for the high stability of these substances and a number of their other features[273,274].

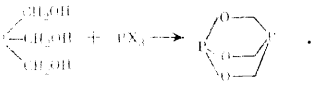
The transesterification method has been proposed to synthesise phloroglucitol phosphite and scyllitol diphosphite:

In the former case the yield is 93%[275] and in the latter only several per cent[276]. The low yield of scyllitol diphosphite is apparently due to the poor compatibility of the reactants in the phosphorylation reaction.



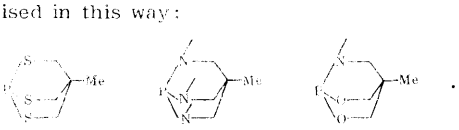
The chemical properties of the esters considered have been little investigated. It has been shown that phloroglucitol phosphite is protonated in the gas phase[154], forms complexes with palladium, platinum, nickel, copper, and silver[277], undergoes the Arbuzov reaction (it is possible to isolate the intermediate quasi-phosphonium compound),[275] and is oxidised by benzoyl peroxide to the corresponding phosphate[278]. The reaction of this phosphite with ozone has also been studied[274]. Finally, the hydrolysis of 1-phospha-2,8,9-trioxa-adamantane, consisting in the cleavage of one of the ester linkages with formation of a bicyclic hydrophosphoryl compound which forms metal complexes activating the phosphorus centre in nucleophilic reactions, has been considered in the literature[272].

(b) 1-Phospha-2, 6, 7-triheterobicyclo[2. 2. 2]octanes



This is the most numerous and most thoroughly investigated group of compounds among all the condensed poly-DHP. It includes phosphite, phosphorothioite, and phosphoramidite systems, which have a number of characteristic features. Unfortunately the extent to which the above types of bicyclic compounds have been studied are different and so far it is difficult to achieve a thorough comparison of their properties.

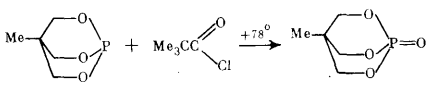
1-Phospha-2,6,7-triozabicyclo[2.2.2]octanes have been synthesised by the phosphorylation of 1,1,1-tris(hydroxymethyl)alkanes and related compounds. Phosphorus trichloride[279,280], the simplest neutral phosphites[281–283], phosphorous acid triamides[281], and acyl phosphites[252] have been used as phosphorylating agents. The simplicity of the methods of synthesis of these compounds and also the ready availability of the initial triols explain the interest of chemical engineers in 1-phospha-2,6,7-trioxabicyclo[2.2.2]octanes, particularly in the possibility of using them as stabilisers for different materials[281].



Pentaerythritol[266,279] and bispentaerythritol[285] are phosphorylated analogously, forming skeletal systems:

The above reactions have been extended in recent years to the phosphorylation of tris(hydroxymethyl)phosphine, which yielded the phosphinophosphite 1,4-diphospha-2,6,7-trioxabicyclo[2.2.2]octane[286]:

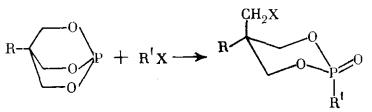
In addition, similar condensations have been achieved with tris(mercaptomethyl)ethane[287], tris(methylaminomethyl)ethane[183,288,289], and bis(hydroxymethyl)methylaminomethylethane[289]. Bicyclic phosphorinanes containing sulphur and nitrogen have been synthesised in this way:



Finally, 2,3,5,6,7,8-hexazabicyclo[2.2.2]octane, which is based on an inorganic skeleton, has been obtained from 1,2-dimethylhydrazine[288].

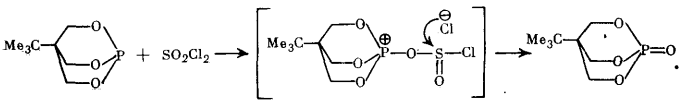
Structurally, phosphatriheterobicyclo-octanes are in many respects analogous to the phosphatrioxa-adamantanes examined above—in each individual instance the bulky molecules of the substances are bounded by 1,3,2-diheterophosphorinane

rings, which differ from one another. Thus the bonds are significantly eclipsed in phosphatriheterobicyclo-octanes, which results in different mutual orientations of the bonds of the P–O–C–H vicinal system in their molecules[273]. The spectroscopic properties of the complexes of the above compounds have been compared[273]. We shall now consider the chemical behaviour of 1-phospha-2,6,7-triheterobicyclo[2.2.2]octanes. The corresponding 2,6,7-trioxa-derivatives have been studied in greatest detail. They are appreciably weaker based than the monocyclic DOP and phosphatrioxa-adamantane. This conclusion is based on the study of the ionisation potentials by photoelectron spectroscopy[97,99,290], the proton affinities in the gas phase (ion–cyclotron resonance)[154], the stability of the complexes with phenol[291], and the spectroscopic properties of protonation products[156,158,292] and the borate[155] and nickel[160] complexes. All these data indicate a relatively pronounced s character of the unshared electron pair of the phosphorus atom in 1-phospha-2,6,7-trioxabicyclo[2.2.2]-octanes. Nevertheless these phosphites form complexes readily with many metals: copper and silver[277,293], molybdenum[164], manganese[294], rhenium[295], cobalt[166,167,296,297], nickel[165,296,298], iron[296,299,300], and platinum and palladium[277, 301].

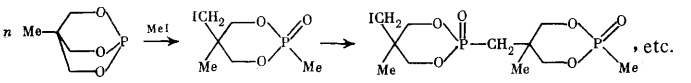


Some of the complexes enumerated above are of particular importance as stabilisers of olefins[164] or catalysts of the isomerisation and oligomerisation of unsaturated compounds[165, 302–304].

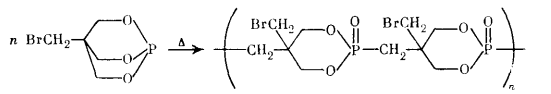
1-Phospha-2,6,7-trioxabicyclo[2.2.2]octanes are oxidised in the usual way to phosphates[266,278,279,305]. Several new observations have been made for this reaction, which has been thoroughly investigated in a series of neutral phosphites: it has been noted that hydrogen peroxide[279] and pivaloyl chloride[306] can be used as oxidants:



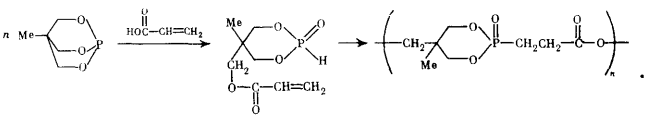
It has been established that metriol and etriol phosphites react with ozone to form stable ozonides, which decompose on heating with the corresponding bicyclic phosphates and singlet oxygen[274,305]. It was concluded that such ozonides are likely to be of preparative value[305]. Sulphurisation[266,307, 308], selenisation[308], and imination[286] have been studied together with oxidation.



The above neutral phosphites exhibit stereoselectivity in alkylation by the Arbuzov reaction[275]:



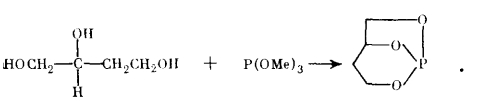
The reactions with sulphenyl chlorides[309], chloramines[309,310], bromine[172], chlorine, and sulphuryl chloride[172,309,310] proceed analogously. In the last case the possibility of a different reaction pathway was noted when a bicyclic phosphite with a tertiary butyl group in the C(4) position was used. This bulky group prevents the traditional attack by the anion on the key carbon atom and its attack is therefore directed to the sulphoxy-group with the ultimate formation of a neutral phosphite, i.e. oxidation takes place[311]:



The Arbuzov and related reactions have been suggested for the synthesis of non-combustible phosphorus-containing polymers. Thus the reaction of metriol phosphite with a catalytic amount of methyl iodide results in the formation of a polyphosphonate[312]:

Another polyphosphonate has been obtained in the autoalkylation of bromometriol phosphite[280]:

Pentaerythritol phosphite polymerises similarly and the resulting polyphosphonate hydrolyses to β,β,β-tris(hydroxymethyl)ethylphosphonic acid[313]. The copolymerisation of metriol phosphite with acrylic acid is of interest[314]:

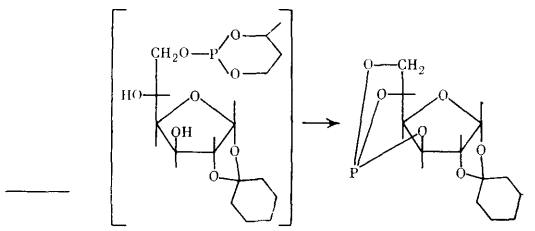


Much attention has been devoted in the literature to the hydrolysis of 1-phospha-2,6,7-trioxabicyclo[2.2.2]octanes and it has been shown that these substances are more resistant to hydrolysis and acidolysis than the usual neutral phosphites[41]. However, it has been possible to achieve the hydrolysis of metriol phosphite[172] and pentaerythritol phosphite[315]. In the former case the isolation of the hydrolysis products involves considerable difficulties and it has therefore been suggested that the reaction mixture be subjected to complete silylation with formation of two silyl phosphites[172]. Bicyclic phosphites are apparently not hydrolysed by the traditional Arbuzov mechanism, which emphasises yet again their unusual chemical behaviour.

Phosphabicyclo-octanes containing nitrogen instead of oxygen have so far been little investigated and data required for a reasoned comparison of their nature with that of the related systems are still being merely accumulated. Nevertheless we may point out that the results of an X-ray diffraction study[288], the dipole moments and NMR spectra[316], and photoelectron spectroscopic data[317] have been described. Oxidative[183], imination[318], and complex formation[319] reactions have been achieved.

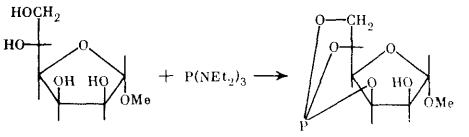
(c) 1-Phospha-2, 7, 8-triheterobicyclo[3. 2. 1]octanes

The study of this series of compounds was begun with the simplest phosphite and was later extended to complex phosphorylated hydrocarbons.



1,2,4-Trihydroxybutane and its 2,2-dimethyl derivatives are readily phosphorylated by phosphorus trichloride[320], trimethyl phosphite[320,321], or phosphorus hexaethyltriamide[284,320] with formation of 1-phospha-2,7,8-trioxabicyclo[3.2.1]-octanes, for example:

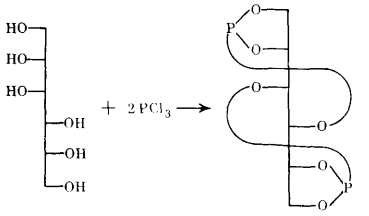
The structure and conformation of the phosphites have been investigated by ^{1}H NMR.[18,322]



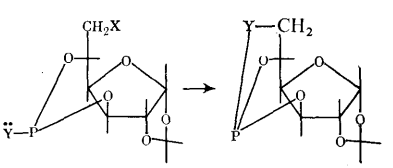
In later studies it was shown that 1,2-alkylideneglucofuranoses, whose molecules incorporate a 1,2,4-triol fragment are phosphorylated similarly to phosphorous triamides[284],

[323] and triphenyl phosphite[324]. The intramolecular transesterification

which takes place readily at 20 °C, constitutes a very novel synthesis[325]. The structure of such compounds has been demonstrated by X-ray diffraction[326], ^{1}H NMR, and ^{13}C NMR.[234]. An important outcome of this investigation was the establishment of a significant decrease of the OPO valence angles compared with the usual values.



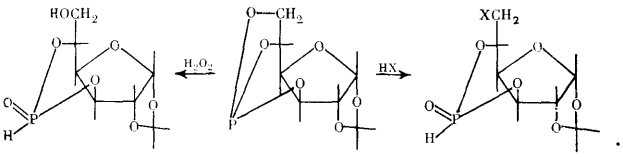
Apart from the carbohydrate triols mentioned above, a series of corresponding tetraols have been introduced into the reaction with phosphorus hexaethyltriamide and it was shown that, when the hexafuranose molecule contains hydroxyls in the C(3), C(5), and C(6) positions with the "glucose configuration", then these hydroxyls (and not the fourth hydroxyl) actually react[327]. This can be illustrated by the following synthesis:



The data presented permit the conclusion that the 1-phospha-2,7,8-trioxabicyclo[3.2.1]octane system, adapted to the structure of hexafluranoses, exhibits a special stability.

6-Alkyl(aryl)amino-6-deoxy-1,2-isopropylideneglucofuranoses, 3-benzamido-3-deoxy-1,2-isopropylideneglucofuranoses[328], and the corresponding mercapto-derivatives[329, 330] are phosphorylated analogous to the sugars mentioned above. A series of 1,2-isopropylideneglucofuranose derivatives of bicyclicphosphoramidites and bicyclicphosphorothioites were synthesised.

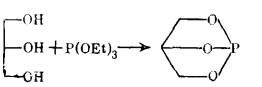
A more complex case of phosphorylation was noted in the interaction of a hexaol (sorbitol) with phosphorus trichloride. A bisbicyclicphosphite, whose molecules contain two 1-phospha-2,7,8-trioxa[3.2.1]octane fragments, was isolated as one of the products[331]:



A second method of synthesising bicyclicphosphites, bicyclicphosphoramidites, and bicyclicphosphorothioites derived from 1,2-alkylideneglucofuranoses consists in stereocontrolled condensations[197,198,330]:

As regards chemical reactions, the 1-phospha-2,3,7-trioxabicyclo[3.2.1]octanes considered are characterised by important features determined by their molecular geometry, namely by the decrease of the OPO valence angles contrary to the usual behaviour. As a consequence of this decrease, the amount of *s* character of the unshared electron pair of the phosphorus atom greatly increases, which reduces in its turn the basicity and nucleophilicity of this atom. The foregoing has been confirmed experimentally by comparing the Lewis basicities[160] and by protonating in the gas and liquid phases[154,156] various neutral phosphites. It is noteworthy that 1-phospha-2,3,7-trioxabicyclo[3,2,1]octanes are not oxidised by powerful oxidants[320,323,325], do not combine with sulphur[323], and undergo the Arbuzov alkylation with much difficulty[320,324,325]. On the other hand, they are very readily halogenated by chlorine and bromine[323]. The reaction proceeds via a stage involving the formation of an adduct with a pentacovalent phosphorus atom[323]. The very mild interaction with chloramines apparently proceeds in the same manner[320].

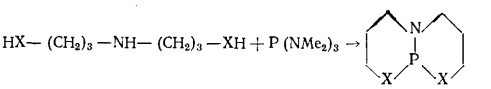
The bicyclic phosphites considered do not react with the usual strong acids, but readily undergo ring opening on treatment with hydrogen chloride and particularly hydrogen bromide in a non-polar medium and also on treatment with hydrogen peroxide[197]:



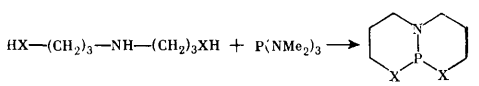
We may point out that other types of DHP are oxidised by hydrogen peroxide without ring opening, i.e. we may note instances of a significant influence of the geometry of the phosphite on its reactivity.

1,2-Alkylideneglucofuranose cyclicphosphoramidites and cyclicphosphorothioites have been little investigated. It has been shown that they readily undergo methanolysis with formation of trimethyl phosphite and the corresponding sugar [328,329,330]. The chlorination of phosphorothioites is of interest[329,330].

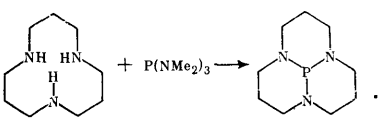
(d) Other Condensed Polydiheterophosphorinanes



It was shown that the transition from 1-phospha-2,6,7-trioxabicyclo[2.2.2]octanes to 1-phospha-2,7,8-trioxabicyclo-[3.2.1]octanes entails a decrease of the OPO valence angles and hence a significant alteration of the chemical properties of the substances. An even greater deformation of the phosphite valence angle should occur in 1-phospha-2,6,7-trioxabicyclo[2.2.1]heptanes. The simplest compound of this series has been synthesised by phosphorylating glycerol with triethyl phosphite[332]:



The structure of this substance has been recently confirmed by electron diffraction and it was shown that the C–O and P–O bonds in the bridged structure are longer than in the phosphorinane structure[333]. From this follows the conclusion that the bridge fragment is chemically more labile in reactions involving the opening of the cyclic system. However, this conclusion conflicts with data present in a communication[334] where the opposite opening of the bicyclic compound in the reaction with phosphorus trichloride is reported.



The OPO valence angles in the bicyclic glycerol phosphite are contracted compared with the angles in the bicyclic compounds examined above[333]. As a result of this, the bicyclic glycerol phosphite is a very weak nucleophile[278].

Unusual structural motifs may be manifested in the formation of condensed DHP whose molecules contain tervalent nitrogen atoms. The linear secondary aminodiols[335] and triamines[336] give rise to unusual bicyclic DHP on interaction with phosphorus triamides:

Tris(1,3-propylene)triamine is phosphorylated analogously[337]:

This reaction has been extended also to cyclic triamides[336,338].

---o0o---

Summarising, we may note two principal conclusions. The first concerns the availability of the substances considered and consists in the fact that at the present time simple methods have been proposed for the synthesis of various types and classes of DHP. This has led to a significant expansion of the synthetic and structural possibilities in the chemistry of tervalent phosphorus and a firm base has been created for the solution of problems of practical importance.

The second conclusion concerns the reactivity of DHP. The high synthetic value of DHP has been demonstrated and the fundamental differences between them and the corresponding acyclic derivatives have been established. It is known that dialkyl phosphorochloridites and phosphoramidites, as well as compounds of a similar type tend to disproportionate and satisfactory results have not therefore been obtained in all the reactions. The above factor as well as the unusual conformational features of DHP facilitate more promising quantitative studies of the reactivities of these compounds compared with their acyclic analogues. DHP can apparently be more correctly employed in the study of the electronic effect of substituents linked to the tervalent phosphorus atom and of other urgent problems of physical organophosphorus chemistry.

The Unpaired Electron in Transition Metal Complexes

E.R.Milaeva, A.Z.Rubezhov, A.I.Prokof'ev, and O.Yu.Okhlobystin

The present state of research into complex and organometallic compounds with an unpaired electron is described. Paramagnetic complexes of transition metals, differing in the position of the free-radical fragment and in the nature of the paramagnetic ligands are examined. The possibility of investigating the intramolecular electron transfer in the metal-ligand system and the formation of intermediate free-radical products in reactions of transition metal compounds is discussed.
The bibliography includes 201 references.

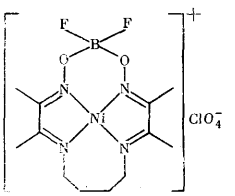
I. INTRODUCTION

The study of transition metal complexes carrying an unpaired electron presupposes two interrelated aspects. Firstly, the study of the possibility of intramolecular electron transfer in the metal–ligand system. Secondly, the elucidation of the question of what changes are undergone by the free radical while it is coordinated in the sphere of the metal. The first aspect is of interest in connection with the fact that there should exist an analogy between macromolecular biological systems responsible for electron transport and artificial models in which such transport is possible. The transition metal, capable of existing in various oxidation states, may play a decisive role in electron transport. On the other hand, the coordination of a free radical leads to a change in its fundamental characteristic, namely its reactivity. Furthermore, the free radical undoubtedly influences the electronic structure of the molecule of the complex.

The solution of the above problems has become possible as a result of the development of spectroscopic methods for the investigation of paramagnetic organometallic compounds. These compounds can be divided into three main types:

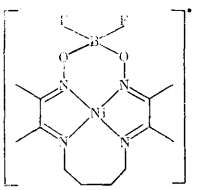
(1) Paramagnetic compounds whose properties are determined by the paramagnetism of the central metal ion, i.e. the so-called spin-unpaired complexes.

(2) Charged paramagnetic systems—radical-anions and radical-cations generated by one-electron reduction or oxidation and neutral radicals formed on photolysis, radiolysis, or chemical bond dissociation.



(3) Complexes with paramagnetic ligands.

Like any classification, such subdivision is to some extent arbitrary. Strictly speaking there exist two clearly distinguished limiting cases—transition metal complexes with an odd number of electrons in the *d* level and complexes with an unpaired electron located on the periphery of the ligand and virtually incapable of hyperfine interaction with the metal nucleus. Intermediate compounds are of greatest interest. In systems where there is a possibility of the delocalisation of an electron over the entire molecule, one may expect the occurrence of intramolecular electron transfer, which determines the functional similarity of such compounds with oxidation-reduction coenzymes.



An example of intramolecular electron transfer is provided by the process occurring in the cofactor NAD (nicotinamide-adenine dinucleotide). The reduction of the cation NAD^+ leads to NAD·. Kinetic data have shown[1] that in the initial stages an electron adds to adenine and is then rapidly transferred to the nicotinamide component of the molecule, a signal due to the nicotinamide radical appearing in the EPR spectra. This mechanism has been proposed by analogy[2] for biological systems containing a transition metal ion. Intramolecular electron transfer has been postulated for cytochrome *c*, the one-electron oxidation of which results in the formation of the ferrocytochrome *c* radical-cation (the unpaired electron is localised in the porphyrin ligand). There is then rapid electron transfer within the molecule with participation of the iron atom and ferrihaemoprotein is formed[2]:

$$Fe^{II}Cyt\text{-}c \xrightarrow{-e} [Fe^{II}Cyt\text{-}c]^{\ddagger} \rightarrow Fe^{III}Cyt\text{-}c \ .$$

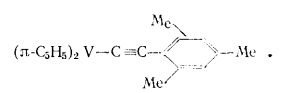
An interesting case of intramolecular electron transfer *in vitro* has been noted recently[3]; the nickel(II) complex

was obtained, its reduction by a one-electron reductant (cobaltocene) yielding a one-electron reduction product:

Two signals were observed in the EPR spectrum of this product in the frozen liquid-crystal phase: the first (g = 2.113) was assigned to a complex containing a paramagnetic nickel(I) ion and the second (g = 2.048) was

assigned to a radical-anion containing nickel(II). Thus there are two complexes in the first of which the unpaired electron is localised at the central nickel ion and in the second it is localised in the organic ligand. In other words the one-electron reduction of the nickel(II) complex with a macrocyclic ligand leads to the formation of two extreme forms of the reduced product, which are in equilibrium:

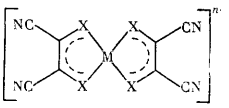
$$Ni^{II}(L^{\cdot-}) \underset{}{\overset{K=0.27}{\rightleftharpoons}} Ni^{I}(L) \ .$$



This example is an unusual instance of electronic tautomerism in solution and demonstrated the possibility of the artificial generation of metal-containing systems capable of effecting the intramolecular electron transfer. The search for and study of such systems may provide a key to the understanding of the most important catalytic and biochemical processes in which the transition metal and its chemical environment play a decisive role.

II. TRANSITION METAL COMPLEXES CONTAINING A PARAMAGNETIC CENTRAL ATOM

The first EPR data for paramagnetic transition metal complexes were obtained in 1957 [4,5] in studies of complex formation reactions. The method is applicable only to compounds containing a transition metal atom with an odd number of electrons in the *d* or *f* levels. The paramagnetism of the complexes is determined in this instance by the properties of the central ions with d^1, d^3, d^5, d^7, d^9, and f^7 configurations. Since numerous reviews and monographs have been devoted to studies of such complexes[6-14], they will not be considered in the present review. We should like to mention merely that the unpaired electron in such complexes may interact with the ligand environment. Fairly high constants for the hyperfine interaction (HFI) of the unpaired electron with the nuclei of the coordinating ^{14}N or ^{31}P atoms are characteristic of ligands containing heteroatoms (pyridine, isoquinoline, pyrazole, imidazole, triphenylphosphine, etc.).[15-17]

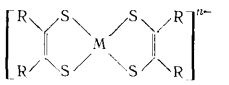


It has been shown[16] that the degree of delocalisation of spin density over the ligand depends on the geometry of the complex and increases on passing from an octahedral to a tetrahedral structure. The spin density can be delocalised via both π and σ metal–ligand bonds[18-21]. For π-complexes of the sandwich type, the interaction of the metal *d* orbitals with the π-electron system of the ligand leads to HFI with the ring protons; for example $a_H = 3.8$ G has been obtained for dinaphthalenevanadium(0).[22,23]

Cases of the formation of organic σ-complexes, in which a π-type transfer of spin density takes place, are also possible; for example, this happens in the following organometallic radical containing two unpaired electrons[24]:

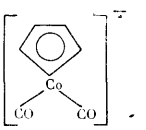
The degree of delocalisation of the spin density to the acetylenic ligand is significantly greater than to the π-cyclopentadienyl ligands.

However, in many instances it is fairly difficult to establish the factor which determines the paramagnetism of the molecules of the complex. A change in the oxidation state of the metal in complexes, associated with the appearance of an odd number of electrons in the *d* level, can be achieved by the one-electron reduction (or oxidation) of the corresponding initial compounds. However, this entails the reduction (or oxidation) of the molecule as a whole and the change in the effective charge of the metal by unity is not an obligatory consequence of the process[25-33]. Thus the electrochemical reduction of the nickel-subgroup metal dithiolate complexes yielded the corresponding d^9 complexes:



M = Ni, Pd, Pt; X = S, NH_2, $n = 1, 2$

It is believed[25] that the main process involves the one-electron reduction of the metal:



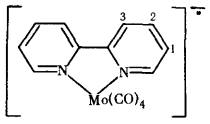
$$M^{II} \xrightarrow{-e} M^{I} \ .$$

The oxidation state of five, which is unusual for platinum and palladium, is attributed by the above investigators to the oxidised form of the dithiolene complexes of the quadrivalent metal formed in the reaction with bromine[26]:

M = Pd, Pt; R = CN, $n = 1, 2, 3$;
R = H, Alk, Ar, CF_3, $n = 0, 1, 2$.

The radical-anion of (π-cyclopentadienyl)cobalt(I)-dicarbonyl, formed as a result of γ-irradiation, has been called[30] a cobalt-centred radical:

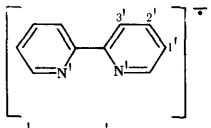
A number of studies[31-33] have been made on the oxidised form of cobalt complexes with macrocyclic ligands, which are structural models of vitamin B_{12}. EPR data suggest that the central cobalt(II) ion is paramagnetic.



In the general case the possibility of the delocalisation of the spin density over the entire molecule is influenced by the nature of the metal–ligand bond[34-42].

The electronic "conductivity" of substrates depends not only on the nature of the metal but also on its ligand environment and is a characteristic property of enzyme-like molecules. The study of metal complexes with ligands capable of undergoing ready and reversible one-electron transitions, involving only partly the valence shell of the metal, is particularly promising in this connection.

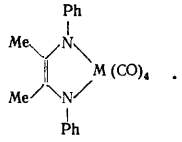
III. CHARGED AND NEUTRAL PARAMAGNETIC COMPLEXES



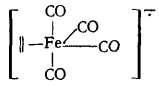
The first attempts to obtain and investigate organometallic radical-anions and radical-cations were made in the 1960's. At that time a series of communications by Dessy and coworkers[43-58] were published, describing the generation of charged paramagnetic species by the electrochemical oxidation (or reduction) of organometallic compounds. The study of the radical-anions of a series of chromium, molybdenum, tungsten, iron, and ruthenium complexes by various physicochemical methods enabled the authors of the above studies to reach conclusions, firstly, concerning the degree of delocalisation of the spin density by means of EPR studies, secondly, about the charge distribution (with the aid of the NMR method), thirdly, about the nature of the electric field gradient at the metal atom nucleus (with the aid of the Mössbauer method), and, fourthly, about the transmission of charged density via the metal atom (with the aid of infrared spectroscopy).

The constants for the hyperfine interaction of the unpaired electron with the ^1H and ^{14}N nuclei of bipyridyl coordinated in the bipyridylmolybdenum tetracarbonyl radical-anion and in the radical-anion of the free ligand have been compared[44]. The HFI constants (a, G) are smaller for aromatic protons in the radical-anion of the complex, while the constant for the HFI with the coordinating ^{14}N heteroatoms increases on passing from the free ligand to the complex. This permitted the conclusion that the organometallic group exhibits an electron-accepting effect in the redistribution of spin density.

$a_H^1 = 3.96$; $a_H^2 = 0.67$



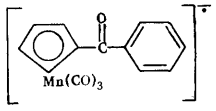
$a_H^3 = 1.2$; $a_N = 3.96$



$a_H^{1'} = 4.96$; $a_H^{2'} = 0.7$

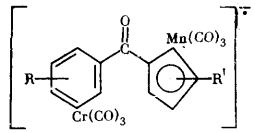
$a_H^{3'} = 1.4$; $a_N' = 2.48$

The change in charge density at the atoms of the organic ligand relative to the free ligand was estimated by NMR from the decrease in the chemical shift $\Delta\delta$ of the aromatic carbon atoms in the chromium, molybdenum, and tungsten complexes[57]:



It was found that the charge is almost wholly localised at the metal atom. Mössbauer spectroscopic data confirmed the increase of electron density at the metal atom following the formation of a complex. It has been shown in relation to olefin complexes of iron that the spin density is mainly concentrated in the ligand:

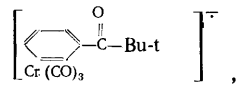
Mössbauer spectra yield a lower σ-electron density on the nucleus of the iron atom, which is due to the increase of the s-electron shielding caused by the ligand → metal π-electron donation. Electronic absorption spectroscopic data have shown that the electron occupies the π^* orbital of the ligand, but most of the charge is "withdrawn" via the metal to the carbonyl groups[45].



Thus the coordinated ligand in the L–M–CO system is an effective spin reservoir but a weak charge reservoir, i.e. the spin and charge are separated in the charged radical systems.

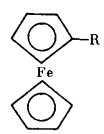
Chromium and manganese carbonyl complexes with ligands of the cyclopentadienyl and arene types have been investigated[59–61]. The benzoylcyclopentadienylmanganese tricarbonyl radical-anion has been obtained by reduction with metallic potassium:

Its EPR spectrum consists of six equal-intensity lines with $a_{^{55}Mn} = 7.68$ G. Each component of this sextet is split into a doublet (2.91 G) of triplets (1.03 G), which indicates the involvement of the ligand in the delocalisation of the spin density.



The electronic effects have been investigated for a series of substituted radical-anions obtained by the reduction of neutral complexes with metallic potassium in dimethoxyethane:

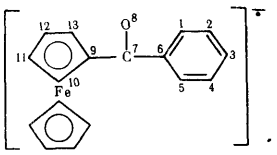
R = H, *o*-Me, *m*-Me, *p*-Me, *p*-OMe;
R' = H, α-Me, β-Me.



Signals due to the hyperfine interaction with the ^{55}Mn and ^{53}Cr nuclei and with the ligand protons have been observed in the EPR spectra of such radical-anions, $a_{^{55}Mn}$ depending on the positions of the substituents R and R'; the g-factor varies in the range 1.9989–2.0002; the constants $a_{^{55}Mn}$ range from 1.62 to 5.11 G; the constant a_{p-H} for the ligand protons is in the range 1.53–1.65 G, while a_{o-H} is in the range 0.78–2.70 G. Studies of the EPR spectra indicate an appreciable delocalisation of electron density over the entire chromium–benzoylcyclopentadienyl–manganese system, which can be accounted for solely by taking into account the appreciable π-overlap between the metal and ligand orbitals and also by the π-electron conjugation with the aromatic system.

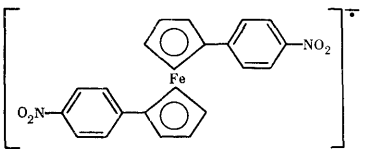
Comparison with the benzoylcymantrene radical-anion described above makes it possible to elucidate the principal effect of the $Cr(CO)_3$ group—the delocalisation of the spin density over the entire system, including the $Mn(CO)_3$ group. The conclusions reached agree with the results of studies of the complexes by ^1H NMR and infrared spectroscopy[62–69]. In the arene complex of chromium with a t-butyl substituent at the carbonyl group[64],

it was not possible to observe the hyperfine interaction with the ^{53}Cr nucleus, as in the case of the carbonyl complexes $(CO)_5MC(R)Ph$, where M = Cr, Mo, or W and R = OMe or Ph.[65]



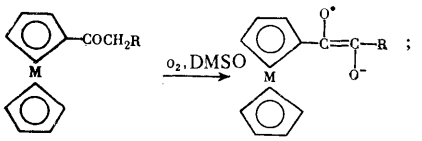
A large series of studies have been devoted to metallocenes, starting with the simplest representatives of compounds of this class—ferrocene[66] and its derivatives[67–72]:

R = Bz, CC_6H_4Me (O), NO_2, C_6H_4CN, CC_6H_4COOMe (O), $C_6H_4NO_2$.



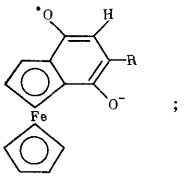
Comparison of the results of the calculation by the Hückel molecular orbital method with the observed hyperfine structure of EPR spectra[68] yields a quantitative distribution of the spin density in the radical-anion. Overall, the ferrocenyl group is destabilising compared with the phenyl group. In the presence of both groups in one molecule, the degree of delocalisation of the spin density is greater

in the direction of the benzene ring[69]:



The following values have been obtained for the phenyl group: $a_H^1 = 3.3$ G; $a_H^5 = 2.91$ G; $a_H^2 = a_H^4 = 0.89$ G; $a_H^3 = 4.3$ G. In the ferrocenyl group the delocalisation involves only one cyclopentadienyl ring ($a_H^{10} = a_H^{13} = 0.89$ G).

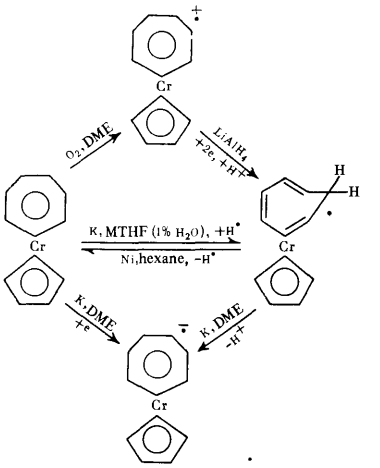
In complexes with *p*-nitrophenyl substituents of the type



the unpaired electron is located almost wholly in the nitrophenyl fragment by virtue of the high electronegativity of the nitro-group ($a_N = 10$ G, which is close to the value for the nitrobenzene radical-anion), while the constants for the HFI with the protons of the cyclopentadienyl rings are small ($a_H \leq 0.3$ G).[67]

Stable paramagnetic semiquinones of the metallocene series are formed on oxidation of ketones containing the α-methylene group[70,71]:

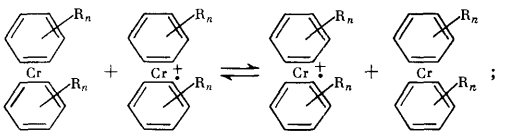
M = Fe, Ru; R = Me, Et, iso-Pr, iso-Bu, Ph;
a_H(ring) = 0.57 G, a_H(Me) = 3.4–4.4 G.



R = H, Me, Et, iso-Pr; a_H(ring) ≅ 0.4 G, a_H = 4.05 G, a_H(Me) = 3.47 G, a_H(Et) = 3.54 G, a_H(iso-Pr) = 3.35 G.

The ease of the one-electron oxidation of metallocene derivatives is confirmed by the formation of paramagnetic salts, where the anionic component may consist of the radical-anion derived from the organic one-electron acceptor tetracyanoquinodimethane (TCNQ):[73]

$$\{[Fe(C_5Me_5)_2]^+\}_2(TCNQ)_2^{2-}.$$

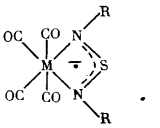


Such salts are in essence organometallic analogues of charge-transfer complexes.

An interesting cycle of one-electron transitions has been described for π-cycloheptatrienyl-π-cyclopentadienyl-chromium[74–76]†:

Lines due to the HFI of the unpaired electron with the ^{53}Cr nucleus have been observed in the EPR spectra of paramagnetic complexes of chromium ($a_{^{53}Cr} = 17.35$ G for the radical-anion, $a_{^{53}Cr} = 19.0$ G for the radical-cation, and $a_{^{53}Cr} = 19.7$ G for the radical). A change in $a_{^{53}Cr}$ is observed also for arene complexes of chromium[75].

The electron exchange in the arene π-complexes of chromium and their deuterated analogues has been investigated by EPR and ^1H NMR; the rate constants for the exchange have been measured and the influence on the latter by various substituents has been investigated[77,78]:



R_n = Me, 1,3-Me_2, 1,3,5-Me_3, 1,2,4,5-Me_4.

Paramagnetic complexes of chromium, molybdenum, and tungsten are formed also in the one-electron reduction of carbonyl complexes containing sulphur diimides as bidentate ligands[79]:

$$\{(CO)_4M[S(NR)_2]\}^{\bullet-};$$

R = t-Bu, Ph, 4-MeC_6H_4, 4-$O_2NC_6H_4$.

Analysis of the EPR spectra, calculations by the ENDO method, and comparison with the spectra of the radical-anions of the initial ligands $[S(NR_2)]^{\bullet}$ have led to the conclusion that the unpaired electron is localised in the ligand:

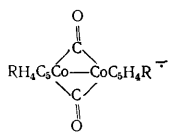
The radical-anions obtained are fairly stable; for example, the half-life of the chromium complex is 6 min.[79].

Cationic paramagnetic complexes of chromium containing carbenes as ligands can be obtained by one-electron oxidation. These paramagnetic compounds have been isolated as tetrafluoroborates[80].

The formation of radical-anions in the electrochemical reduction of clusters has been reported. Radical-anions have been generated from iron carbonyls and also from their ruthenium and osmium analogues[81]:

$$[Fe(CO)_{12-n}L_n]^{\bullet-}$$

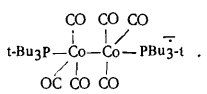
L = PPh_3, $P(OMe)_3$, $P(OPh)_3$, etc.



†In the formula below DME = 1,2-dimethoxyethane and MTHF = 2-methyltetrahydrofuran (Ed.of Translation).

The radical-anions of a tricobaltcarbon cluster have been obtained by electrochemical reduction[82]:

$$YCCo_3(CO)_9 \xrightarrow{+e} [YCCo_3(CO)_9]^{\cdot-} ;$$
$$Y = H, Me, Et, F, CF_3, CF_3CH_2, Cl, Br, Ph, p\text{-}FC_6H_4, COOH, p\text{-}HOC_6H_4, Me_3Si, \alpha\text{-}C_{10}H_7 .$$



The radical-anions produced are relatively stable and the g-factors are 1.9800–2.0210. The unpaired electron interacts with the substituent Y (a_H = 10 G, a_F = 10.8 G) and also with the three equivalent ^{59}Co nuclei (I = 7/2), which leads to the appearance of 22 lines in the EPR spectrum with the constants $a_{^{59}Co}$ = 34.2–37.1 G.

The preparation of dinuclear cobalt radical-anions has been described[83]:

$$R = H, COOMe, Si(Me)_3, Si(Ph)_2Me, CH_2COOMe .$$

Complexes of another type with tri(t-butyl)phosphine ligands have the following structure[84]:

It has been suggested[84] that the unpaired electron occupies the Co–Co σ^* orbital, involving at the same time the P–Co–Co–P chain of atoms. The uniform distribution of the unpaired electron density over the two Co atoms makes it possible to treat such a dinuclear paramagnetic complex either as a compound with "mixed" valence metal species $Co^0 - Co^+$ or as formally a compound of +0.5-valent cobalt[83]. In all probability both these hypotheses are arbitrary and are most probably concerned merely with terminology. Evidently the immediate ligand environment also participates in the distribution of spin density[85]:

$$[X_2Co_2(CO)_6]^{\cdot-}$$
$$X = H_2C_2, t\text{-}Bu_2C_2, Ph_2C_2, MeC_2SiMe_3,$$
$$PhC_2SiMe_3, CF_3C_2SiMe_3, (CF_3)_2C_2, P_2, As_2;$$
$$a_{^{59}Co} = 2.37\text{–}2.88 \text{ G}, \quad a_P = 3.74 \text{ G}, \quad a_{As} = 2.12 \text{ G}.$$

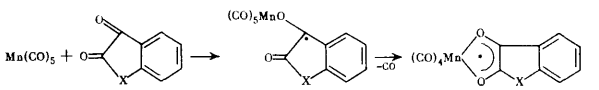
One of the common methods of generating free radicals is homolytic bond dissociation. This method is suitable for the preparation of paramagnetic products on ultraviolet irradiation of dinuclear complexes of transition metals[86]. The photolysis of bis(tributylphosphine)dimanganese octacarbonyl $Mn_2(CO)_8(PBu_3)_2$ (the reaction is carried out in the presence of an excess of tributylphosphine) or tris(triethoxyphosphino)dimanganese heptacarbonyl $Mn_2(CO)_7[P(OEt)_3]_3$ in heptane with periodic removal of the CO evolved leads to the formation of paramagnetic intermediates. The EPR spectrum of the frozen irradiated solution indicates the presence in the system of the radical $Mn(CO)_3(PBu_3)_2^{\cdot}$ (its structure consists of a tetragonal pyramid with *trans*-axial phosphine ligands). The radical formed reacts slowly with the solvent, the reaction involving the abstraction of a hydrogen atom, which is typical for active free radicals. The formation of all possible products as a result of the free-radical reactions can be represented schematically as follows:

$$Mn_2(CO)_8L_2 \overset{h\nu}{\rightleftharpoons} 2Mn(CO)_4L^{\cdot} ;$$
$$Mn(CO)_4L^{\cdot} + L \rightleftharpoons Mn(CO)_3L_2^{\cdot} + CO ;$$
$$Mn(CO)_3L_2^{\cdot} + Mn(CO)_4L \rightleftharpoons Mn_2(CO)_7L_3 ;$$
$$2Mn(CO)_3L_2^{\cdot} \overset{h\nu}{\rightleftharpoons} Mn_2(CO)_6L_4 ;$$
$$Mn(CO)_3L_2^{\cdot} + HR \overset{h\nu}{\rightleftharpoons} HMn(CO)_3L_2 + R^{\cdot} .$$

The EPR spectrum has a hyperfine structure with two equivalent ^{31}P nuclei (I = 1/2, $a_{\parallel}$ = 20 G, $a_{\perp}$ = 19 G) and with one ^{55}Mn nucleus (I = 5/2, $a_{\parallel}$ = 54.1 G, $a_{\perp}$ = 35.7 G); the g-factor is 2.040. A similar situation is observed also for triethyl phosphite derivatives of manganese[86].

Apart from the photolytic method of bond dissociation with formation of free-radical species, thermolysis is also employed[87]. Thermal decomposition of manganese complexes leads, like photolysis, to paramagnetic products, whose formation can be demonstrated by the spin trapping method using t-butyl nitroxide as the trapping agent:

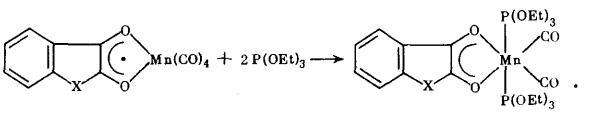
$$L_nM\text{—}ML_n \rightleftharpoons 2^{\cdot}ML_n; \quad {}^{\cdot}ML_n + R\text{—}N{=}O \rightarrow R\text{—}\underset{\underset{O}{|}}{N}\text{—}ML_n$$
$$R\text{—}\underset{\underset{O}{|}}{N}\text{—}ML_n \rightarrow \text{decomposition products;}$$
$$M = Mn, \ R = t\text{-}Bu, \qquad L = PPh_3, CO, PX_3, X = OMe, Et, Me, m\text{-}, p\text{-}MeC_6H_4, OEt .$$



It is sometimes possible to detect the intermediate free radical, as, for example, in the case of triphenylphosphine-manganese tetracarbonyl:

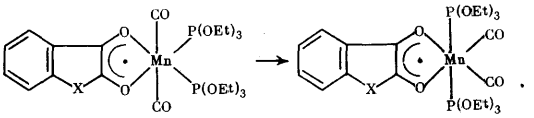
$$Mn_2(CO)_8(PPh_3)_2 \rightleftharpoons 2^{\cdot}Mn(CO)_4(PPh_3)$$
$${}^{\cdot}Mn(CO)_4(PPh_3) + ON\text{—}Bu\text{-}t \rightarrow (PPh_3)(CO)_4Mn\text{—}\underset{\underset{O}{|}}{N}\text{—}Bu\text{-}t.$$

Lines due to the hyperfine interaction with the ^{55}Mn, ^{31}P, and ^{14}N nuclei are recorded in the EPR spectra. Metal carbonyls of the type $M_2(CO)_{10}$, where M = Mn or Re, have been considered in some cases[88].



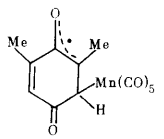
The irradiation of metal decacarbonyls in the presence of 1,2-dicarbonyl compounds[89] results in the formation of products of the addition of free radicals to diketones:

$$Mn_2(CO)_{10} \rightleftharpoons 2^{\cdot}Mn(CO)_5 ;$$

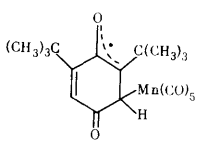


$$X = CO, NH, O, S .$$

The interaction of the resulting paramagnetic chelate with phosphines yields products of further reactions, but the paramagnetism of the molecule is maintained, an additional hyperfine interaction with the ^{31}P nuclei of the triethylphosphine ligands being observed:

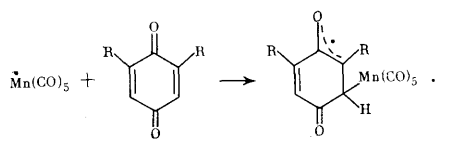


The authors[89] suggest that *cis–trans* isomerisation takes place in paramagnetic complexes of this type:

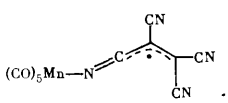


Chelates of the above type will be described below. The interaction with quinones and α-diketones of free metal-centred radicals, formed as a result of the thermal or

photolytic cleavage of the metal–metal bond in $Mn_2(CO)_{10}$, $Re_2(CO)_{10}$, $(Me)_3SnMn(CO)_5$, and $Me_2Sn[Mn(CO)_5]_2$ has been thoroughly investigated by EPR.[90] Dimethylbenzoquinone, phenanthrenequinone, etc. have been used as the trapping agents. The differences between the structures of the quinones employed have a significant influence on the nature of the paramagnetic products formed. When *para*-quinones are used, the compounds formed can be regarded as organometallic σ-radicals with a paramagnetic fragment of the allyl type in the ligand:

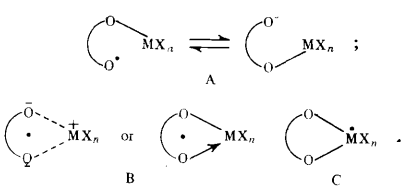


$a_H(Me) = 5.52$ G
$a_H(Mn) = 1.51$ G



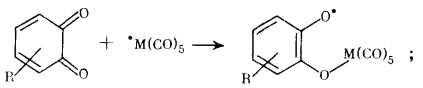
$a_H(Mn) = 3.38$ G .

The following scheme for the formation of these paramagnetic species has been proposed[90]:

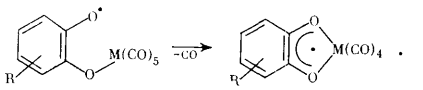


$$Q + (CO)_5MnMn(CO)_5 \underset{\text{or } \Delta}{\overset{h\nu}{\rightleftharpoons}} \left[Q^{\cdot-}(CO)_5\overset{+}{\dot{M}}n\dot{M}n(CO)_5\right] \xrightarrow{-Q^{\cdot-}} (CO)_5\overset{+}{\dot{M}}n\dot{M}n(CO)_5 \longrightarrow \dot{M}n(CO)_5 + \overset{+}{\dot{M}}n(CO)_5 \ ;$$

An analogous mechanism describes the reaction of $Mn_2(CO)_{10}$ with tetracyanoethylene, which results in the formation of an iminotricyanoallyl radical[91]:



When the metal carbonyl dimers interact with *ortho*-quinones, it is necessary to consider in this instance several probable structures of the products formed[92]: structures of the phenoxy-type with localisation of the organometallic fragment at one of the oxygen atoms (A), a structure of the semi-quinone or chelate type (B), and a metal-centred radical (C):



The addition of the fragment $^{\cdot}M(CO)_5$, formed on dissociation of the initial dimer, leads to structure (A), which is stable only at a low temperature. Slight heating results in the elimination of one CO group and the EPR spectra indicate the formation of structure (B), characterised by a symmetrical distribution of the spin density and a hexacoordinate manganese atom. The free radicals corresponding to structure (B) have been postulated for a series of quinones[93].

Overall, the reaction of dinuclear metal carbonyls with *ortho*-quinones can be represented by the following chain of transformations:

$$(CO)_5MM(CO)_5 \longrightarrow 2^{\cdot}M(CO)_5 \ ; \qquad (1)$$

(2)

(3)

The activation energy for the unimolecular reaction (3) (17.3 kcal mol^{-1}) and the rate constant ($k_{-20^\circ} = 0.07$ s^{-1}) as well as all the spectroscopic characteristics of the primary [reaction (2)] and secondary [reaction (3)] radicals have been published[92].

If homolysis does not precede the formation of the reaction products, it is possible to postulate a reaction pathway[94] where the interaction of $M_2(CO)_{10}$ with the acceptor A takes place in the first stage via one-electron transfer and is followed by a rearrangement in a cage:

$$(CO)_5MnMn(CO)_5 + A \xrightarrow{h\nu \text{ or } \Delta} [(CO)_5MnMn(CO)_5^{+} A^{\cdot-}] \xrightarrow{\text{fast}} \rightarrow [(CO)_5Mn^{\cdot}(CO)_5Mn{-}A^{\cdot}] \rightarrow (CO)_5Mn^{\cdot} + (CO)_5Mn{-}A^{\cdot} \ .$$

In the study of oxidation-reduction processes in organometallic chemistry, the problem arises of the formation of intermediate paramagnetic products and their subsequent reactions. A mechanism has been proposed[95] for electron transfer in the reactions of organoplatinum compounds having a Pt–C σ-bond with one-electron acceptors (hexachloroiridate and tetracyanoquinodimethane TCNQ):

$$R_2PtL_2^{+} \left\{ \begin{array}{l} \xrightarrow{\text{fast}} RPtL_2^{+} + R^{\cdot} \xrightarrow[-IrCl_5^{3-}]{IrCl_6^{2-}} RCl \ ; \\ \xrightarrow[-IrCl_5^{3-}]{IrCl_6^{2-}} R_2PtL_2Cl^{+} \ ; \end{array} \right.$$

$R = Me, Et$; $L = PPh_3$, PMe_2Ph .

The ease of one-electron oxidation decreases in the sequence $Et_2Pt(PMe_2Ph)_2 > Me_2Pt(PMe_2Ph)_2 > Et_2Pt(PPh_3)_2 > Me_2 . Pt(PPh_3)_2$.

The oxidation of R_2PtL_2 by TCNQ results in the formation of a radical pair; the TCNQ radical-anion is manifested in EPR spectra. Further reactions follow after the emergence of the radicals from the cage. Overall, the picture is identical with that in the decomposition of organometallic compounds of non-transition metals (Mg, Hg, Sn, Pb):[96]

$$R{-}MX \xrightarrow{-e} [R{-}MX]^{+} \rightarrow R^{\cdot} + MX^{+} \ .$$

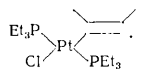
A characteristic feature of transition metal complexes is their ability to undergo a change in coordination number after a change in the state of oxidation. For this reason, there is a possibility also of another pathway involving transformation into quadrivalent platinum compounds; the two possibilities are approximately equivalent for *cis*-dimethylbis(triphenylphosphine)platinum:

$$cis\text{-}Me_2Pt(PPh_3)_2 \xrightarrow[MeCN]{} \left\{ \begin{array}{l} \xrightarrow{54\%} (Me)Pt(PPh_3)_2X_2 \ ; \\ \xrightarrow{46\%} (Me)Pt(PPh_3)_2X + MeCl \ ; \end{array} \right.$$

$X = Cl, IrCl_5(MeCN), MeCN$.

In contrast to the preceding example, dialkyl(bipyridyl)-iron gives rise on oxidation with bromine to a mixture of hydrocarbons—the products of the disproportionation or

dimerisation of the radicals R$^{\cdot}$:[97]



$$\left.\begin{matrix} R \\ R \end{matrix}\right\rangle Fe(bipy)_2 + Br_2 \left\{\begin{matrix} \longrightarrow R{-}R + Fe(bipy)_2 \\ \swarrow \longrightarrow 2RBr + FeBr_2(bipy)_2 \end{matrix}\right. ;$$

In this case the coordination number of iron atoms diminishes.

Aryl compounds of nickel decompose with partial coordination of a solvent molecule:

$$Ar_2NiL_2 \xrightarrow{-e} Ar_2NiL_2^{\ddagger} + S \xrightarrow{fast} Ar_2NiL_2(S)^{+} \xrightarrow{slow} \text{products}.$$

The formation of the alkenebis(triethylphosphine)platinum chloride radical has been noted[98]:

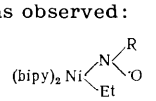
Paramagnetic palladium complexes of the π-allyl type, which exhibit a high catalytic activity, have been described as intermediates in the hydrogenation of nitro-compounds[99].

Nowadays the EPR method is widely used in the study of the paramagnetic complexes formed in catalytic processes[100]. Transition metal derivatives can behave as initiators of radical reactions of organic halogeno-compounds[101]. At any rate it is evident that many reactions in organometallic chemistry can proceed via the formation of free radicals. We shall consider some further examples.

On the basis of the study of the kinetics of the formal oxidative elimination reaction, it has been postulated that radical-cations are formed from iron complexes as an elementary stage of the reaction[102]

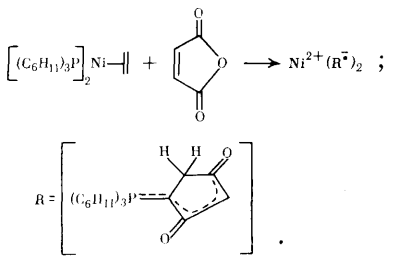
$$[Fe(CO)_3L_2] + I_2 \rightarrow [Fe(CO)_3L_2]^{\ddagger} + I^{\cdot} + I^{-} ;$$
$$[Fe(CO)_3L_2] + I^{\cdot} \rightarrow [Fe(CO)_3L_2]^{\ddagger} + I^{-} \text{ etc.}$$

The radical-cations formed were investigated by EPR.[102] The changes in the characteristics of the EPR spectra as a function of the electron-donating properties of the ligand L, where L = PPh_3, $AsPh_3$, $PMePh_2$, $P(NMe_2)_3$, $P(OPh)_3$, or $Ph_2PCH_2PPh_2$, have been traced. In all cases the EPR spectra indicate the occurrence of a hyperfine interaction with two equivalent nuclei of the donor heteroatom (P, As). For a full identification of the intermediate, the radical-cation was obtained by specific electrochemical synthesis:



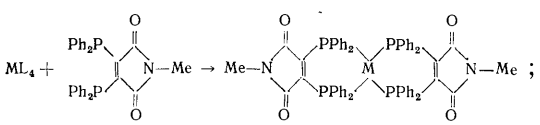
$$Fe(CO)_3L_2 \xrightarrow[\text{Pt electrode}]{-e} [Fe(CO)_3L_2]^{\ddagger} ,$$

and by interaction with a silver salt; in the presence of a halogen X the reaction proceeds with formation of a diamagnetic salt:



$$Fe(CO)_3L + AgPF_6 \xrightarrow{X_2} [Fe(CO)_3L_2][PF_6] .$$

The paramagnetic radical-cation $[Fe(CO)_3L_2]^{\ddagger}$ formed has the structure of a trigonal bipyramid with the *trans*-configuration.



In the study of the mechanism of the aldol condensation and oxidation-reduction processes in the presence of organic σ-complexes of nickel with the aid of the spin trapping method[103], the involvement of free-radical intermediates of the following type was observed:

The interaction of ethylenebis(tricyclohexylphosphine)-nickel with maleic acid anhydride proceeds in an unexpected manner[104]. It has been suggested that intermolecular ligand exchange (the replacement of ethylene by the anhydride in the coordination sphere of the metal) results in further reactions with formation of a radical-ion salt (see below). The description of the compound obtained as a complex with a radical-anion ligand is based on spectroscopic data (EPR, ultraviolet spectroscopy). The doublet of triplets in the EPR spectrum characteristic of the given radical-anion is due to hyperfine interaction with the ^{31}P nucleus (a_P = 13.1 G) and two protons (a_H = 2.04 G). In the visible region the spectrum contains a band characteristic of the nickel(II) cation[104].

Radical complexes with maleic acid derivatives have been obtained also for palladium and platinum[105]. The interaction of zerovalent palladium, platinum, and nickel complexes with diphosphine derivatives of maleic anhydride leads to a diamagnetic complex of the zerovalent metal, stable in air, only in the case of nickel:

L=PPh_3, M=Pd, Pt; L=CO, M=Ni .

The palladium and platinum complexes are paramagnetic products unstable in air. It may be assumed that the ligand becomes a radical-anion as a result of electron transfer from the metal:

$$M^0(PP)_2 \rightarrow M^I[(PP)_2]^{\overline{\cdot}} .$$

Signals due to the hyperfine interaction with the two ^{31}P and N nuclei and the hydrogen atoms of the methyl group [a_P = 9.6 G, a_N = 3.0 G, and $a_{H(Me)}$ = 0.68 G] have been recorded in the EPR spectra. The HFI constants obtained are close to those for the paramagnetic salt $PP^{\overline{\cdot}}K^{+}$.

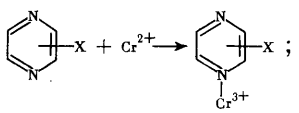
The photolytic interaction of cobalt complexes with sulphonyl chloride proceeds as the addition of the active free radical to the double bond, giving rise to paramagnetism in the ligand sphere of cobalt[106]:

$$RSO_2^{\cdot} + [R'R''C{=}CHCH_2CoL_2Py] \rightarrow$$
$$\rightarrow [RSO_2CR'R''CHCH_2CoL_2Py] \left\{\begin{matrix} \rightarrow RSO_2CR'R''CH{=}CH_2 \\ \rightarrow [Co^{II}L_2Py] \end{matrix}\right. .$$

An interesting example of the homolytic cleavage of the metal–ligand bond is the anaerobic photolysis of derivatives of cobaltoxime via the mechanism[107]

$$Co^{III}\text{—}R \xrightarrow{h\nu} Co^{II} .$$

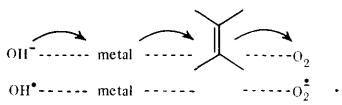
In the presence of oxygen a peroxide is formed in this reaction[108]:



$$Co^{III}\text{—}R \xrightarrow{h\nu} Co^{II}R^{\cdot} \xrightarrow{O_2} Co^{III}\text{—}O\text{—}O\text{—}R .$$

Paramagnetic organometallic compounds can also be formed as a result of interaction with an organic free radical[109]:

$$Ag + {}^{\cdot}CH_2CN \rightarrow Ag^{\overline{\cdot}}CH_2CN ;$$
$$Ag + {}^{\cdot}CH_2OH \rightarrow Ag^{\overline{\cdot}}CH_2OH ;$$
$$Ag^{+} + CH_3CN^{\overline{\cdot}} \rightarrow Ag\text{—}C(CH_3){=}N^{\cdot} .$$



There is also a possibility of the reduction of a ligand to a

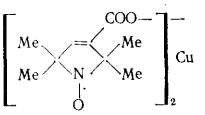
paramagnetic species with its simultaneous coordination to the reductant metal[110]:

X = Me, Cl, COOH, $CONH_2$.

An extremely interesting study[111] of metal-catalysed photochemical organic reactions of olefins involved simultaneously several important problems. A chain mechanism of the intramolecular electron transfer was postulated. The donor is the hydroxide ion and the final acceptor is oxygen:

Electron transfer proceeds via a chain with participation of a transition metal atom (Fe). The development of studies of this type can apparently elucidate the mechanisms of enzymatic oxidation reactions.

Thus a fairly large number of paramagnetic complexes are known whose magnetic properties are determined either by the electronic configuration of the central ion or by the appearance of an unpaired electron as a result of an oxidation-reduction process. An odd number of electrons in the *d* and *f* levels of the central ion in the first group of compounds does not cause qualitative changes in the nature of the metal–ligand bond and the structure of the complex and in essence such compounds differ little from their diamagnetic analogues. As regards charged paramagnetic compounds, it is rarely possible to obtain stable radicals; all the measurements are made at low temperatures and it is rarely possible to isolate the product.



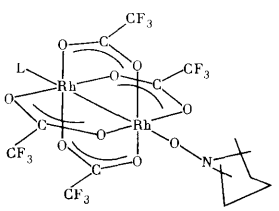
The essential requirements are, firstly, a relative simplicity of the synthesis and, secondly, the possibility of the preparative isolation of stable paramagnetic compounds. The development of the chemistry of free radicals made it possible to satisfy these requirements, which permitted the employment of stable organic radicals as ligands. Mainly stable nitroxy- and *ortho*-semiquinone paramagnetic ligands are used nowadays in the chemistry of transition metal complexes. In addition, a large number of examples of variable-valence metal complexes with nitric oxide[112] or its derivatives, coordinated via the N–O bond, have been described in the literature[113–124].

IV. STABLE NITROXY-RADICALS IN TRANSITION METAL COMPLEXES

The class of nitroxy-radicals is of considerable interest in view of their high stability[125]. These radicals have found extensive applications as spin labels and paramagnetic probes for the study of molecular dynamics and the structures of liquids in polymeric formations, biological systems, etc.[126].

Nitroxy-radicals are π-electron radicals. In aliphatic nitroxy-radicals the unpaired electron is localised almost wholly in the N–O fragment; after the introduction of aromatic substituents (R^1, R^2 = Ar), the spin density on the N and O atoms diminishes owing to the establishment of a conjugation system and a considerable proportion of the unpaired electron density is transferred to the aromatic rings[127,128].

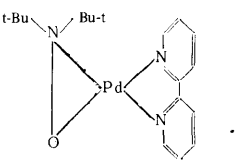
The synthesis of the copper salt of 3-carboxy-2,2,5,5-tetramethylpyrrolin-1-yloxy-radical was described for the first time in 1966:[129]



This compound was isolated in the form of a stable crystalline substance. In the solid state the salt does not give rise to an EPR signal, while in solution (in water and ethanol) a weak signal can be recorded.

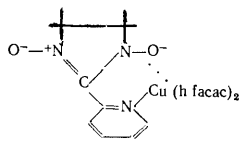
Thus it became possible to synthesise from derivatives of nitroxy-radicals complexes with ligands known to be paramagnetic beforehand. Nitroxy-radicals are, in principle, ambifunctional ligands and the complexes based on them can be divided into two classes in accordance with the type of ligand–metal coordination:

(1) Coordination via the N–O group carrying the unpaired electron; this leads to a spin–spin interaction between the nitroxy-fragment and the metal ion, provided that its isotope is paramagnetic.



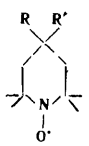
(2) Coordination via other functional groups of the ligand which show a greater tendency towards complex formation than the N–O group; there is then a possibility of exchange interactions of the radical centres with one another and with the metal ion.

The first case is of no particular interest because in compounds of this kind there is a possibility of the disappearance of paramagnetism; however, for example, in the EPR spectrum of the product of the addition of the nitroxy-radical to the rhodium trifluoroacetate dimer[130], the signal is split owing to the interaction with the ^{103}Rh nucleus ($I = 1/2$, $a_{Rh} = 1.7$ G).



In this case the unpaired σ-electron is donated by the nitroxy-group to the d_{z^2} orbital of rhodium and there is a reverse interaction of the d_{xy} orbital of the rhodium atom with the π* orbital of the NO group carrying the unpaired electron.

An unusual three-membered ring is formed in the complex of palladium with the di-t-butylnitroxy-radical[131]:



Complexes of other variable-valence metals have also been described[131–135]. It is difficult to draw a sharp boundary between compounds of the first and second types. There is a possibility of instances of coordination via a functional group accompanied by the simultaneous interaction of the metal ion with the nitroxy-fragment, which is in many respects determined by the structure of the complex. It has been shown[136–139] that the geometry of the complex influences the nature of the bond. In the series of compounds of copper, manganese, and vanadium with α-, β-,

and γ-pyridylnitronyl nitroxide, copper or vanadyl α-pyridyl-nitronylnitroxide bishexafluoroacetylacetonate is diamagnetic:

The occurrence of additional coordination of this type can be accounted for by intermolecular electron transfer from the $d_{x^2-y^2}$ orbital of copper or the d_{xy} orbital of vanadium to the $2p\pi$ orbital of the nitroxy-group and is based on the energies of the singlet–triplet cleavage.

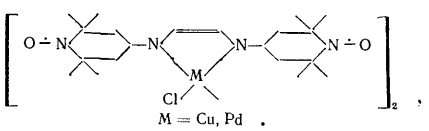
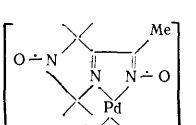
In the zinc compounds with a similar mode of coordination there is no direct interaction with the radical centre[140]. There are more numerous examples of transition metal complexes with coordination via the functional groups of the substituents in the radical ligands. In the main these are derivatives of 2,2,5,5-tetramethylpiperidin-1-yloxy-, 2,2,5,5-tetramethyl-Δ^3-imidazolin-1-yloxy-, and 2,2,5,5-tetramethylpyrrolin-1-yloxy-radicals. The types of complexes based on the piperidinyloxy-radical are presented in Table 1.

The magnetic properties of complexes with paramagnetic ligands have been investigated by determining the magnetic susceptibilities and by EPR.[149,150]. The magnetic susceptibility of the copper complex of the Schiff base[152]

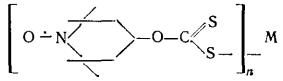


indicates the presence of three unpaired electrons in the molecule and is equal to the sum of the susceptibilities of three non-interacting or weakly interacting spins. However, the analogous complex differing by only one methylene unit in the ring of the radical proved to be diamagnetic in the crystalline state, which the authors explain by the formation of the coordinate bond $NO^{\cdot} \rightarrow Cu^{2+}$ in the polymeric crystal lattice:



The EPR spectra of the solutions indicate the occurrence of weak exchange interactions in the radical centres and Cu^{2+} ions.

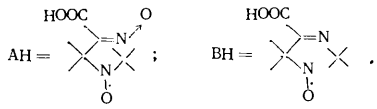
The nickel(II), palladium(II), and zinc(II) complexes of the 4-amino-4-carboxy-2,2,6,6-tetramethylpiperidin-1-yloxy-radical give rise to triplet spectra typical for nitroxy-radicals[141], which do not differ significantly from the spectra of the free radicals. A change of temperature also does not affect the nature of the spectra. For the palladium(II) and copper(II) complexes of the biradical ligand



M = Cu, Pd .

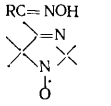
an EPR spectrum characteristic of free radicals with a weak exchange interaction between the radical centres was obtained: $I < a$, where a = 15 G is the constant for the hyperfine interaction of the unpaired electron in the ^{14}N nucleus and I the exchange interaction energy. The exchange interactions in dimeric complexes are manifested spectroscopically by additional lines in the EPR spectrum relative to the initial ligand. These data make it possible to confirm the structure of the dimeric complex with the aid of a spin label[153]:

For the cobalt(II) and palladium(II) complexes of the 4-amino-2,2,6,6-tetramethylpiperidin-1-yloxy-radical, it is possible to observe in the EPR spectrum a quintet corresponding to strong exchange between the radical centres, i.e. $I \gg a$. In the analogous copper(II) complex the unpaired electron of the radical ligand interacts with the copper ion, to which corresponds a broad signal in the EPR spectrum[154].



For the complexes with the paramagnetic xanthate ligands[146]

M = Zn (II), Hg (II), Co (III), Ni (II) ,



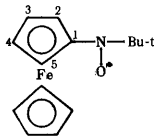
the g-factors are in the range 2.0075–2.0089, which differs little from the g-factors of the nitroxy-radicals. This can be explained by the fact that in the given complexes the metal ions interact only weakly with the radical centres. At room temperature the EPR spectra of the solutions are characterised by a triplet (a_N = 15–16 G). A weak intramolecular spin exchange between two radical centres is exhibited for zinc and mercury (the intensity of the biradical components is ~5% of the main signal).

Transition metal acetates containing paramagnetic fragments of the following type have been obtained[155]: $CoA_2.2H_2O$, $NiA_2.2H_2O$, $CuA_2.2H_2O$, $ZnA_2.2H_2O$, $PrA_3.3H_2O$, $EuA_3.2H_2O$, $CoB_2.4H_2O$, $CuB_2.4H_2O$, $ZnB_2.4H_2O$, and PdB_2.

A single broad line with a g-factor equal to the mean of the g-factors of the metal ion and the ligands is observed in the EPR spectra of the copper(II) complexes. In the copper(II) and nickel(II) compounds there is an exchange interaction between the paramagnetic centres; the zinc(II) and palladium(II) complexes give rise to quintets typical for biradicals; in praseodymium(III) and europium(III) acetates there is no exchange interaction between the paramagnetic centres, i.e. the usual triplet is observed in the EPR spectrum (a_N = 15.1 G).[156,157]

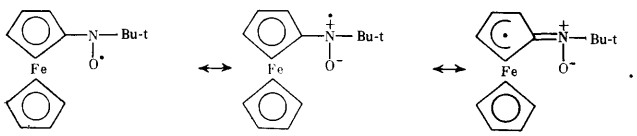
The 4-hydroxyiminomethyl-2,2,5,5-tetramethyl-Δ^3-imidazolin-1-yloxy-radical forms chelate rings with the copper(II), nickel(II), palladium(II), cobalt(III), and zinc(II) ions via the oxime group and the electron-donating ring nitrogen atom:

R = H, Me .



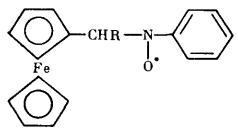
A quintet typical for biradicals has been recorded in the EPR spectra of such complexes[158,159].

The EPR spectra of solutions of the analogous copper(II), nickel(II), cobalt(III), and palladium(II) (R = Me) complexes[160] in chloroform have not been observed, which is a consequence of the strong exchange interaction between the metal ions and the paramagnetic ligands, which leads to a marked decrease of the electronic relaxation time. The EPR spectra of the cobalt(III) and palladium(II) chelates are quintets.



All the examples enumerated above permit the conclusion that there is only a weak interaction between the radical centre and the metal ion in complexes of the above type or that such interaction is altogether absent, which implies that the paramagnetic ligand hardly introduces any changes into the usual complexes, be they acetates, xanthates, or Schiff bases, and functions only as a paramagnetic label. This is due to the absence of a conjugation chain between the radical centre and the metal.

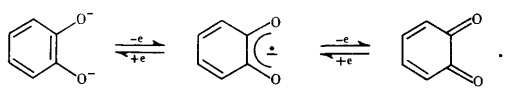
A completely different picture is observed in complexes in which the metal atom is involved in a conjugation chain with the paramagnetic fragment. Unfortunately such examples are extremely rare. However, it is clear that in cases of this kind the unpaired electron interacts with the orbitals of the metal atom.



In the stable nitroxyferrocenyl radical[161]

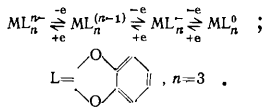
the spin density at the ^{14}N atom is smaller than in the di-t-butylnitroxy-radical ($a_{^{14}N}$ = 13.3 G) and the g-factor (2.0149 ± 0.0004) exceeds the g-factor for arylnitroxy-radicals (2.006). The HFI constant (0.8 G) corresponding to the second and fifth ring protons is smaller by a factor of 2.5 than the HFI constant for the remaining protons ($a_{O-H} \cong$ 2.0 G) in the aryl fragment of the phenyl-t-butyl-nitroxy-radical (PTN). The following mesomeric structures have been proposed[161] taking into account conjugation:

The constants a_N = 10.9 G and a_H = 2.95 G have been obtained for the nitroxy-radical separated from the ferrocenyl substituent by a carbon atom[162]:



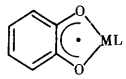
R = MeC_6H_4, Ph, Me .

V. TRANSITION METAL COMPLEXES WITH *ORTHO*-SEMIQUINONE LIGANDS

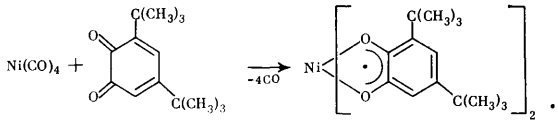


There has always been an extremely great interest in aromatic dicarbonyl compounds, starting with the first studies by Michaelis[163,164], who postulated the formation from quinones in biochemical reactions of the active forms of certain enzymes as radical species. Sufficient data concerning the role of quinone derivatives in oxidation-reduction enzymatic processes have now accumulated[165].

Compounds of the type of *ortho*-quinones[166] are characterised by the formation of the redox triad:



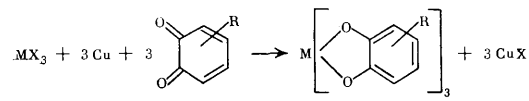
dianion *ortho*-benzosemiquinone *ortho*-benzoquinone



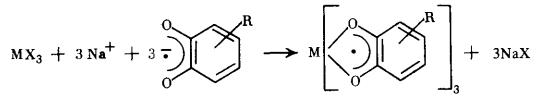
It was to be expected that a similar system, linked by one-electron transitions, is formed also by transition metal chelates:

In this series a complex is formed with the unpaired electron in the ligand:

The synthesis of a nickel complex by the reaction of nickel tetracarbonyl with 3,5-di-t-butyl-1,2-benzoquinone was reported in 1966:[167]

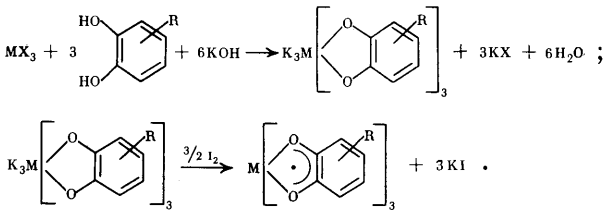


Chromium, molybdenum, and tungsten complexes based on *o*-chloranil were obtained in 1974.[168–171]

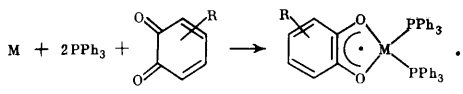


The chemistry of transition metal complexes with paramagnetic *ortho*-semiquinone ligands was developed to the greatest extent in the studies by Razuvaev, Abakumov, and coworkers[172–177]. Copper, silver, zirconium, hafnium, vanadium, niobium, tantalum, chromium, molybdenum, tungsten, iron, gallium, gadolinium, palladium, and nickel complexes with *ortho*-quinone fragments were obtained[173–177].

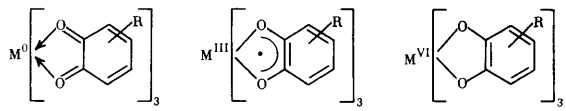
The methods of synthesis of complexes of tervalent metals can be combined in the following groups.



1. The interaction of metal halides and *ortho*-quinones in the presence of metallic copper:



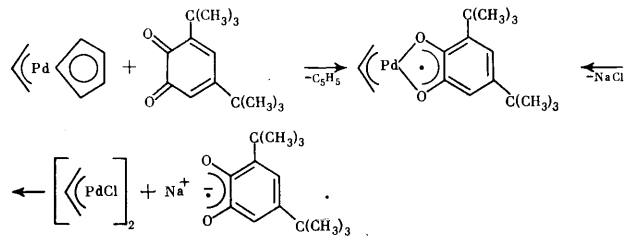
2. The reaction of transition metal halides with sodium or thallium *ortho*-semiquinolates:



3. The exchange reaction between a transition metal salt and the catechol dianion:

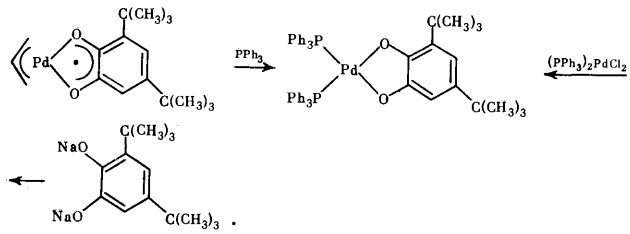
4. The monoligand copper and silver complexes can be obtained by the direct interaction of the quinone and the metal in the presence of a stabilised ligand, for example, triphenylphosphine[176]:

Complexes of different transition metals have been synthesised in this way. Of the three possible types of structures of the above complexes, structure B is believed to be closest to reality[176]:



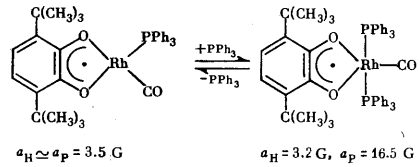
A-(quinone) B-(semiquinone) C-(catecholate)

M = Cr, Mo, W .



The term "quasi-radical ligands" has been proposed for the ligands of this type, implying the possibility of exchange interactions between the paramagnetic fragment and the metal ion[176].

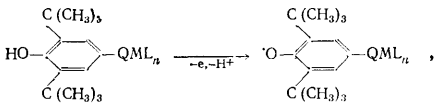
In the general case the distribution of spin density in the paramagnetic complex does not differ significantly from that in the *ortho*-semiquinone radical-anion. In the presence of stabilising ligands ER_3 (where E = P or As and R = Ph, Et, or OEt) in the molecule of the complex, the unpaired electron is seen to interact not only with the magnetic isotopes of the metal ion but also with the ^{31}P and ^{75}As nuclei of the extraneous [sic] ligand (a_P = 12–20 G).[169]



For example, the allyl group can serve as an extraneous ligand:

However, in this case it was not possible to observe the hyperfine interaction of the unpaired electron with the allyl fragment[175,176] owing to the great width of the HFS lines in the EPR spectra. The allyl complex can be converted into the corresponding triphenyl phosphine derivative:

The possibility of reversible conversion into a complex with a pentacoordinate rhodium atom (trigonal bipyramid) has been demonstrated in relation to the square-planar rhodium complex[177]:

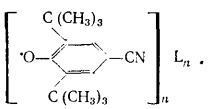


$a_H \simeq a_P$ = 3.5 G a_H = 3.2 G, a_P = 16.5 G

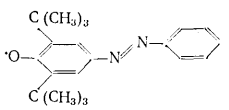
All the paramagnetic complexes obtained are relatively stable and they are also stable in the presence of oxygen[178,179].

Thus the data obtained demonstrate the possibility of introducing free-radical *ortho*-semiquinolate species into a molecule of the transition metal complex.

VI. PHENOXY-RADICALS IN PLATINUM METAL COMPLEXES

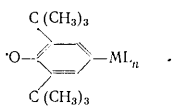


Another approach to the synthesis of paramagnetic complexes was followed when a series of stable phenoxy-radicals were used. A series of complexes based on sterically hindered phenols were obtained, their one-electron oxidation resulting in the formation of metal-containing free phenoxy-radicals[180–186]:

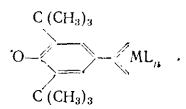


where Q is the coordinating group and M = Pd, Pt, or Ph.

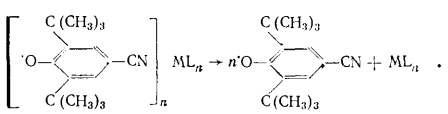
The compounds obtained can be divided into several groups in terms of the type of the metal–paramagnetic ligand bond (L = Cl, Br, I, PPh_3, acac, THF, or π-C_5H_5).



I. *n*-Donor coordination:

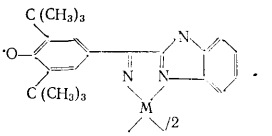


II. σ-Bond + *n*-donor coordination:



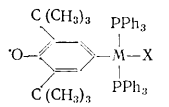
III. σ-Bond:

IV. π-Bond:



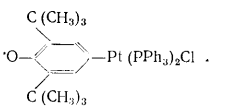
Group I free radicals are unstable and dissociate with liberation of the stable cyanophenoxy-radical into the solution:

The EPR spectra of Group II complexes are isotypical[180]; a hyperfine structure is observed, which can be explained by the interaction of the unpaired electron with the *meta*-protons of the phenoxy-ring (a_H = 1 G) and with two ^{14}N nuclei (I = 1, a = 2 G). At the same time the radical corresponding to the initial ligand is extremely unstable and decomposes rapidly even at 20 °C with liberation of molecular nitrogen, diphenoquinone, biphenyl, and their reaction products[187,188]. Its EPR spectrum is poorly resolved and yields virtually no information.



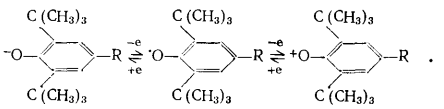
The fairly high stability of the organometallic azophenoxy-radicals in the range between −40° and +40 °C implies that the metal–carbon σ-bond, stabilised by the coordination to the nitrogen atom, is fairly stable, despite the presence of a paramagnetic fragment in the ligand, i.e. *ortho*-metallation and *n*-donor coordination (the formation of an organometallic ring) increase significantly the stability of the organic free radical. Furthermore, on formation of complexes, the spin conductivity of the azo-group increases, since in the ligand free radical the −N=N− unit is "non-conducting".

Phenoxy-radicals containing a heterocyclic fragment are also relatively stable[186]:



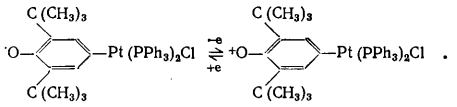
A triplet of triplets is observed in the EPR spectrum of the palladium(II) complex (a_H = 1.7 G, a_N = 4.8 G, a_{Pd} = 24 G); a septet is characteristic of the platinum(II) complex (a_H = 1.7 G, a_N = 3.4 G, a_{Pt} = 21.5 G).

The σ-bonded organometallic phenoxy-radicals obtained proved to be extremely stable[183]:



X = Cl, Br, I; M = Pd, Pt .

Their concentration does not decrease when the temperature is raised to 100 °C, they are stable for a long time in solutions, and they can be stored in evacuated bulbs for an unlimited period. A phenoxy-radical containing a platinum atom has been isolated in the solid state:



Its infrared spectrum does not contain the band corresponding to the vibrations of the OH bond and the band due to the stretching vibrations of the >C=O group appears in the region of 1640 cm^{-1}. The platinum-containing radicals are more stable than their palladium analogues. Depending on the nature of the halogen, the stability of the radicals decreases in the sequence Cl > Br > I. The unpaired electron interacts with the *meta*-protons of the phenoxy-ring, with the magnetic isotopes of the transition metal, and also with two equivalent ^{31}P nuclei (Table 2), which indicates a *trans*-geometry of the complex. The constants for the hyperfine interaction with the *meta*-protons in the palladium and platinum derivatives indicate the electropositive nature of the organometallic group. The high constant for the hyperfine interaction with the palladium and platinum nuclei and with the phosphorus nuclei of the triphenylphosphine ligands indicate a significant involvement of the *d* orbitals of the transition metal and the *p* orbitals of the phosphorus atom of triphenylphosphine in the distribution of spin density.

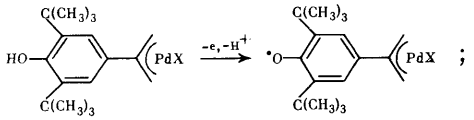
The free radicals exhibit a dual reactivity: in reactions with reductants they accept one electron and in reactions with oxidants they give up one electron:

The reduction of phenoxy-radicals to phenoxide ions constitutes a fairly trivial fact. Oxidation with formation of the phenoxylium cation has been described only for a limited number of organic derivatives[189,190]. In relation to stable σ-bonded derivatives, it proved possible to observe the reducing properties of organometallic radicals. The platinum-containing phenoxy-radical is oxidised by vanadyl chloride or tetracyanoquinodimethane to the phenoxylium

cation with retention of the metal–carbon bond:

Initially one observes in the EPR spectra a superposition of two spectra—that of the initial phenoxy-radical and that of the radical-anion $TCNQ^-$. After a time, the signal of the initial phenoxy-radical disappears and the spectra show only the signal due to $TCNQ^{\cdot}$. As the reductant is added, the signal of the radical-anion $TCNQ^-$ gradually disappears and the signal of the initial platinum-containing phenoxy-radical takes its place, which demonstrated the reversibility of the reaction.

Table 2. The EPR parameters of the σ-bonded derivatives of phenoxy-radicals (toluene, 25 °C).[183]



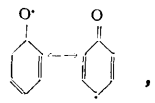
M	α*, %	I	a_H, G	a_{31P}, G	a_M, G	g-factor
Pt	33.7	1/2	1.2	16.0	94.0	2.0079
Pd	22.2	5/2	1.5	18.7	5.15	2.0051

*Natural abundance of the magnetic isotope.

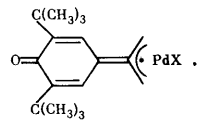
Table 3. The EPR parameters of the π-allylpalladium-containing phenoxy-radicals (toluene, 25 °C).[184]

X	a_H^{meta}, G	a_H^{all}, G	a_{Pd}, G	g-factor
Cl	1.8	0.9	12.2	2.0051
Br	1.8	0.9	11.5	2.0057
I	1.8	0.9	10.3	2.0076
PPh_3Cl	1.8	0.9	9.2	2.0052
acac	1.8	0.9	—	2.0043
C_5H_5	1.6	0.8	5.4	2.0038

Phenolic π-allyl derivatives have been used to generate π-allylpalladium-containing phenoxy-radicals[184]:



X = Cl, Br, I, PPh_3, acac, Cp .



The spectroscopic parameters of the radicals obtained are presented in Table 3. The unpaired electron interacts with the *meta*-protons of the phenoxy-ring, with the protons of the terminal methylene groups of the allyl ligand, and with the magnetic palladium isotope ^{105}Pd. The last interaction results in the appearance at the edges of the main signal of satellite lines whose intensity is ~20 times lower than that of the main signal. Table 3 shows that, on passing from the chloride to the cyclopentadienyl derivative, the $a_{^{105}Pd}$ diminishes, the greatest effect being observed for the π-cyclopentadienyl ligand. In the square planar complexes this quantity diminishes monotonically with increasing bulk of the substituent at the palladium atom (Cl, Br, I, PPh_3). In the formally octahedral π-cyclopentadienyl derivative a more pronounced decrease of $a_{^{105}Pd}$ is observed. If $a_{^{105}Pd}$ is adopted as a measure of the delocalisation of the spin density, then its variation as a function of the group X will reflect the influence of the π-allylpalladium-containing group as a substituent in the *para*-position of the phenoxy-radical. The electronic characteristics of this group as a substituent in an aromatic ring are known[191].

A satisfactory linear dependence of $\delta_{^{19}F}$ and $a_{^{105}Pd}$ on the electronegativity of the ligand X ($r = 0.996$) has been observed for square planar complexes; the slope of the straight line $\rho = -7.162$ ($\Delta\rho = \pm 1.883$) indicates a greater influence of the ligands X on the distribution of spin density compared with their influence on the distribution of electron density. On passing to the formally octahedral π-allyl-π-cyclopentadienylpalladium complex[186], the linear relation is somewhat impaired ($r = 0.966$); the straight line is inclined still more steeply relative to the coordinate axis on which the values of a_{Pd} have been plotted. Thus the spin density is in some way redistributed over the metal atom in the π-cyclopentadienyl derivative, in which the electron density in the 2-position is significantly reduced as a consequence of the strong electron-donating influence of the ligand π-C_6H_5.

The parallel variation of the distributions of the electron densities in the compounds investigated is striking in both instances. As shown previously[191], the electronic effects can be transmitted between the benzene ring and the π-allyl ligand only via an inductive mechanism. The question arises whether one can assume that the transmission of spin density also involves an analogous mechanism. However, the role of the inductive effect in the distribution of electronic charge, at least in the phenoxy-part of the molecule, should be significantly smaller than the role of the conjugation effect[187–191]. It is necessary to elucidate how the charge density of the unpaired electron, delocalised to the *para*-position in the phenoxy-radical via the conjugation chain, is then redistributed to the π-allyl fragment,

and then further to the palladium atom (provided that further conjugation with the central carbon atom of the π-allyl ligand is impossible). In other words, there is no resonance structure of the type

The above question can be answered as a result of the following observation; in diamagnetic complexes the signals of the *syn*- and *anti*-protons of the π-allyl ligand are observed in the NMR spectrum for different field strengths as a consequence of the different degrees of shielding. In the EPR spectra of the corresponding free radicals a pattern is observed which indicates the equivalence of all four allyl protons (a quintet, $a_H = 1$ G). Thus the *syn-anti* exchange, leading to the equivalence of all the protons in the usual allyl complexes and observed on the NMR time scale either with increase of temperature or when the system

contains a strong electron-donating ligand, also occurs in the paramagnetic analogues under the usual conditions.

The equivalence of the four allyl protons observed on the EPR time scale following the transition from the diamagnetic to the paramagnetic system shows that the energy barrier in the intramolecular rearrangements in free radicals is lower than in the corresponding diamagnetic compounds. In other words, in paramagnetic complexes a reversible metallotropic rearrangement can take place much more readily:

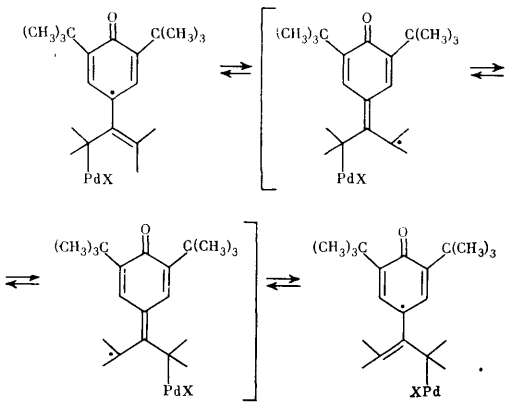


Table 4. Dependence of $a_{^{105}Pd}$ on the solvent (20 °C).[184]

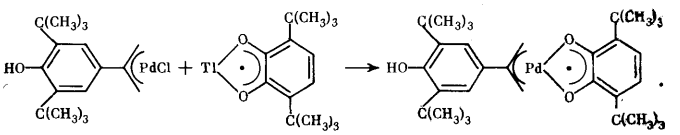
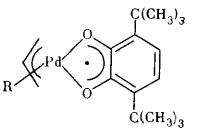


Solvent	$a_{^{105}Pd}$, G	Solvent	$a_{^{105}Pd}$, G
C_2H_5OH	14.6	Dioxan	13.2
$CH_3COC_2H_5$	13.6	Toluene	13.1

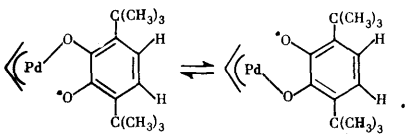
Table 5. Temperature variation of $a_{^{105}Pd}$ (toluene).[184]



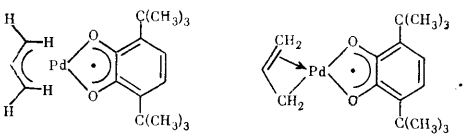
t, °C	20	0	−20	−40	−60
$a_{^{105}Pd}$, G	13.1	13.2	13.4	13.6	13.7

As a result of this, the system resembles the allyl compounds of non-transition metals, for which the decisive role of metallotropy has been demonstrated in dynamic processes, leading to the equivalence of the terminal hydrogen atoms[198].

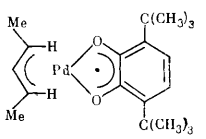
The EPR spectra of the paramagnetic palladium complex (X = Cl) have been studied in different solvents (Table 4) and at different temperatures (Table 5). The equivalence of the four protons of the allyl ligand is maintained in all cases. Consequently the driving force of the rapid dynamic processes occurring in the paramagnetic allyl complexes is the delocalisation of the spin density over the entire molecule. The question arises whether the dynamic state of the allyl system is preserved also in the case where the paramagnetic fragment is not linked directly to the allyl ligand. A study was therefore made[184] by the EPR method of the interaction of the π-allyl complexes of palladium with thallium 3,6-di-t-butyl-*ortho*-semiquinolate:



The unpaired electron interacts with two equivalent protons of the *ortho*-semiquinolate ring (a_H = 3.37 G), with the magnetic isotope ^{105}Pd (a_{Pd} = 2.35 G), and with two protons of the allyl fragment (a_H^{all} = 0.97 G). An analogous picture is observed also for other substituted π-allyl complexes.

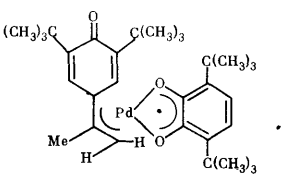


R = 2-H, 2-Ph, 2-$MeOC_6H_4$, 1-FC_6H_4 .

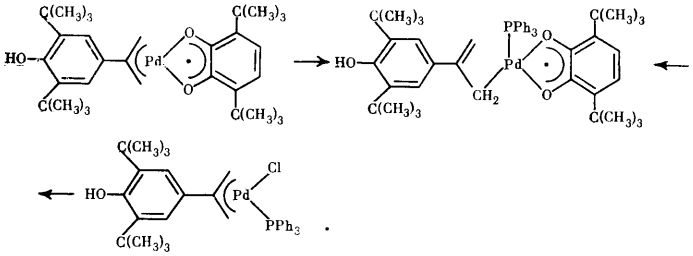


A triplet due to the two protons of the paramagnetic ligand and the two protons of the π-allyl ligand appears in all cases; each component of the triplet is split further into another triplet. The equivalence of the two protons in the *ortho*-semiquinolate ligand is a consequence of the rapid reversible migration of the palladium atom[199]:

The appearance in the EPR spectrum of the triplet due to the two equivalent protons of the π-allyl ligand can have two causes: firstly, the interaction of the unpaired electron solely with the *anti*-protons while retaining the π-allyl structure (A) and, secondly, the possibility of the freezing of the σ-structure (B):

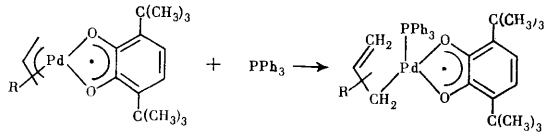


A 1,3-disubstituted allyl complex of the type

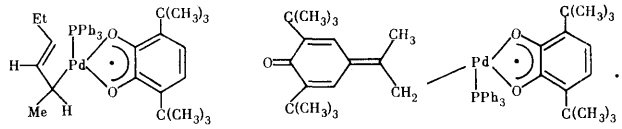


was used to solve this problem. The EPR spectrum of this radical contains a triplet caused by the interaction of the unpaired electron solely with the two *anti*-protons of the π-allyl ligand.

Analysis of the EPR spectra of an allyl complex with a quinonoid bond system leads to the same conclusion[185]:



In this case the unpaired electron interacts only with one *anti*-proton of the allyl group and the HFI constant is ~0.5 G, which is smaller approximately by a factor of two than in all the cases described above[181,184].

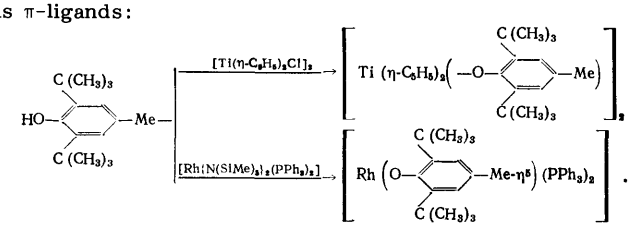


The formation of a σ-structure in the systems investigated was observed only in the presence of triphenylphosphine; the σ-complex was isolated on a preparative scale and has been obtained by specific synthesis:

An analogous transition, which led to an overall rearrangement of the bond system, has been studied spectroscopically for complexes with different substituents in the π-allyl ligand:

For R = 2-H, 2-C_6H_5, 2-$MeOC_6H_4$, or 1-FC_6H_4, a triplet due to the two protons of the terminal carbon atom is observed (a_H = 0.4–0.6 G); in addition the unpaired electron interacts with the ^{31}P nucleus ($a_{^{31}P}$ = 2.55 G). A doublet due to a single proton (a_H = 0.5 G) has been recorded in the EPR spectra of 3-ethyl-1-methylallyl-palladium *ortho*-semiquinolate, and a triplet due to two protons (a_H = 0.6 G) has been observed in the spectrum of the quinonoid complex[184]:

Thus the nature of the processes occurring in paramagnetic π-allyl complexes is determined to a significant extent by the position of the free-radical ligand relative to the allyl group. When the unpaired electron appears directly in the allyl ligand, the system becomes dynamic; on the other hand, for systems with an extraneous ligand, carrying the unpaired electron, the π character of the ligand–metal bond is retained, but the π–σ transition is significantly facilitated compared with the diamagnetic ligand corresponding to the allyl compounds.



Yet another fact drew attention in the study of the free radical generated by the oxidation of π-allylpalladium-substituted phenols. The radical corresponding to the initial ligand, namely 2,6-di-t-butyl-4-isopropylphenol, is extremely unstable[200], and cannot be detected by EPR. On the other hand, π-allylpalladium-containing phenoxy-radicals proved to be fairly stable over a wide temperature range (between −50° and +50 °C). Thus coordination to the transition metal atom led to a significant stabilisation of the unstable free radical. The nature and mode of metal–ligand bonding determine to a significant extent the stability of organometallic free radicals.

The observed sequence of the influences

$$\sigma > \pi \gg n, \sigma \rangle\rangle n$$

characterises the ability of the metal atom in complexes of the above type to influence the degree of delocalisation of the unpaired electron in the molecule. In σ-phenyl compounds the unpaired electron is in essence delocalised over the entire molecule (the phenoxy-radical, the metal atom, and the phosphine ligands), which is the reason for the exceptionally high stability of the radicals formed.

Derivatives of sterically hindered phenols can function as π-ligands:

However, in this case the complexes are constructed differently and are diamagnetic derivatives of the phenoxide anion[201].

* * *

The data considered in the present review permit the conclusion that the presence of the unpaired electron in transition metal complexes permits the derivation of information about the detailed characteristics of the structures of complex and organometallic compounds as a result of the application of the EPR method in combination with other physicochemical procedures. The nature of the delocalisation of the unpaired electron in the paramagnetic coordination and organic compounds of transition metals makes it possible to infer the nature of the metal–ligand bonding and the distribution of electron density via the metal–ligand–other ligands bond system. The greatest amount of information can be deduced in the case of complexes with paramagnetic ligands under the conditions of the maximum delocalisation of the spin density of the unpaired electron over the entire molecule. Intramolecular electron transfer then takes place and the systems formed can serve as convenient models for the study of the mechanisms of the oxidation-reduction processes occurring in a living organism.

Investigation of Paramagnetic Metallocenes and Diarene Complexes of Transition Metals by Magnetic Resonance Methods

S.P.Solodovnikov

EPR and NMR data for paramagnetic metallocenes and diarene complexes of transition metals are presented. The analysis of the *g*-factors and the hyperfine and spin-spin interaction constants for the EPR spectra as well as the paramagnetic shifts in the NMR spectra have been used to determine the electronic configurations of the complexes. The manifestation of the Jahn-Teller effect in the EPR spectra of sandwich compounds is described. The scheme of the *d*-electronic levels in metallocenes and the mechanism of the spin delocalisation are discussed.
The bibliography includes 67 references.

I. INTRODUCTION

The nature of the bond in metallocenes and diarene complexes of metals has continuously attracted the attention of both experimenters and theoreticians. Since 1951, the time of the first synthesis of ferrocene, numerous theoretical studies, which explained the stability and aromaticity of ferrocene, have been carried out. Quantitative comparison of the theoretical results with spectroscopic data serves as an objective test of the reliability of the continuingly improving computational methods.

This review is devoted to the results of the study of paramagnetic sandwich complexes of transition metals. Examination of paramagnetic complexes alone simplifies somewhat the analysis of the electronic structure, since the EPR and NMR parameters are in this case determined by the distribution of one or several unpaired electrons and not all the electrons of the molecule.

Jaffé[1] was the first to point out the unusual nature of the chemical bond in metallocenes, consisting in the fact that this many-electron bond is formed by the molecular π orbitals of the cyclopentadienyl rings and the orbitals of the central metal ion. A quantitative theory of the chemical bond in sandwich compounds was subsequently developed by a group of workers[2-6]. A survey of the early theories can be found in a monograph[7]. These theories are based on the consideration of the symmetry of the molecular orbitals of the ligand and the orbitals of the metal. The molecular orbitals of each cyclopentadienyl ring are formed by five atomic $2p_z$ orbitals, which can be divided into three groups differing in their symmetry relative to rotation about an axis perpendicular to the plane of the five-membered ring and passing through its centre. In order of increasing energy, the above orbitals are designated by a_1, e_1, and e_2, the symbols being related to the symmetry properties. The single a_1 orbital has no nodal planes perpendicular to the plane of the ring, while e_1 and e_2 are degenerate orbitals which do have nodal planes—one in e_1 and two in e_2. Linear combinations of these localised molecular orbitals give rise to the set of molecular orbitals a_{1g}, a_{2u}, e_{1g}, e_{1u}, e_{2g}, and e_{2u} embracing both cyclopentadienyl rings. The orbitals belong to the symmetry point group D_{5d} to which ferrocene and other metallocenes having the structure of a pentagonal antiprism belong. As before, the symbols *e* and *a* refer to the degenerate and non-degenerate states. The subscripts 1 and 2 define the number of nodal planes in the *e*-type orbitals. The additional subscripts *g* and *u* indicate the symmetry properties of the new orbitals as regards inversion relative to the centre of the molecule, i.e. relative to the metal atom. Such transformation either leaves the sign of the orbital unchanged (*g*) or alters it (*u*).

The metal orbitals 3d, 4s, and 4p can also be classified as belonging to the symmetry point group D_{5d} with the aid of the representations $a_{1g}(3d_{z^2})$, $a_{1g}(4s)$, $a_{2u}(4p_z)$, $e_{1g}(3d_{xz}, 3d_{yz})$, $e_{2g}(3d_{xy}, 3d_{x^2y^2})$, and $e_{1u}(4p_x, 4p_y)$.

The classification of the ring and metal orbitals in terms of their symmetries makes it possible to determine the combinations which contribute to the bonding states. Only those ring and metal orbitals which belong to the same representation can contribute to the overall overlap and only these combinations will lead to the formation of a metal–ring bond.

All the remaining combinations are orthogonal. The following orbitals of the cyclopentadienyl (Cp) rings and metal (M) orbitals have the appropriate symmetries: $a_{1g}(Cp) - 4s(M)$; $a_{1g}(Cp) - 3d_{z^2}(M)$; $e_{1g}(Cp) - 3d_{xy, yz}(M)$; $e_{2g}(Cp) - 3d_{xy, x^2-y^2}(M)$: $e_{1u}(Cp - 4p_x(M)$; $a_{2u}(Cp) - 4p_z(M)$. The electronic configuration of the complex can be represented as follows: $[a_{1g}(Cp)]^2$, $[a_{2u}(Cp)]^2$, $[e_{1u}(Cp)]^4$, $[3d_{z^2}(M)]^2$, $[3d_{xy}(M)]^2$, $[3d_{x^2-y^2}(M)]^2$, $[e_{1g}(Cp) - 3d_{xz}(M)]^2$, and $[e_{1g}(Cp) - 3d_{yz}(M)]^2$. (We may note that the energy levels of the electrons in the cyclopentadienyl rings are below the energy levels of the metal electrons.) Since several such combinations are allowed by the symmetry, the determination of the relative contribution of each combination to the metal–ring bond energy requires the calculation of the

overlap integrals and the determination of the relative energies of the combining states.

The principal results of the theoretical calculation are the disposition of the energy levels and the distribution of electron density. In the paramagnetic complexes the outer orbital is half-filled. The magnetic properties of the complex depend on whether the unpaired electron occupies the d_{xy}, $d_{x^2-y^2}$ orbitals (the projection of the orbital moment $M_z = \pm 2$), the d_{xz}, d_{yz} orbitals ($M_z = \pm 1$), or the d_{z^2} orbital ($M_z = 0$). The degeneracy of the d_{xy}, $d_{x^2-y^2}$ and d_{xz}, d_{yz} orbitals should be manifested in the corresponding deviations of the g-factor of the complex from its spin-only value. When the nucleus of the transition metal atom or the nuclei of the ligand atoms have magnetic moments, the hyperfine splittings in the EPR spectra or the magnetic shifts in the NMR spectra can serve as a measure of the unpaired electron density at the corresponding atoms. Fig. 1 illustrates schematically the formation of molecular orbitals by means of a linear combination of the 3d orbitals of the metal and the $2p_z$ orbitals of the carbon atoms of the cyclopentadienyl rings. Fig. 2 presents a diagram of the upper levels of the cyclopentadienyl complexes of Mn, Fe^+, Co, and Ni^+.

II. MAGNETIC PROPERTIES AND THE CHARACTERISATION OF THE EPR AND NMR SPECTRA OF PARAMAGNETIC SANDWICH COMPOUNDS

The study of magnetic susceptibility makes it possible to measure the effective magnetic moment of the molecule, to obtain information about the number of unpaired electrons, and to draw inferences about the properties of the ground state and about the fraction of the orbital component in the measured magnetic susceptibility from the deviation of the effective magnetic moment from the spin-only value. Table 1 presents the magnetic moments of metallocenes and Table 2 those of the diarene complexes.

A change in the oxidation state of the metal atom leads to the transformation of the diamagnetic complexes into paramagnetic complexes and hence permits the application of the EPR method to the study of the electronic structures of sandwich compounds.

A general discussion of the magnetic and magnetic resonance properties of sandwich compounds can be found in the paper of Robertson and McConnell[8]. The characteristics of these compounds are wholly determined by the nature of the central metal atom. In the case of orbital degeneracy (the unpaired electron occupies an e-type orbital), the effective magnetic moment and the g-factor are determined by spin–orbital coupling, by a low-symmetry distortion of the system, and by static and dynamic Jahn–Teller effects. Naturally the contribution of each of the above interactions to the splitting of the degenerate levels is different and depends on the nature of the metal.

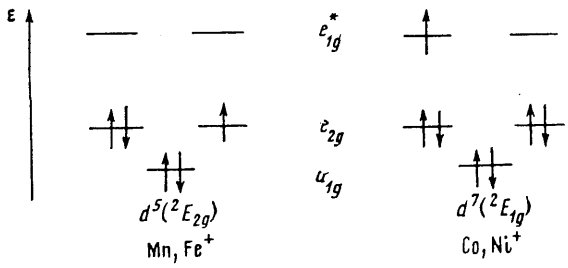

Figure 2. The energy levels of the d electrons in metallocenes.

Table 1. Experimental (μ_{eff}) and spin-only (μ) magnetic moments of metallocenes[8].

Metallocene	μ_{eff}, μ_B	S	μ, μ_B
Vanadocene	3.84	3/2	3.87
Chromocene	3.20	1	2.83
Ferrocenium cation	2.61	1/2	1.73
Manganocene	5.71	5/2	5.91
Cobaltocene	1.76	1/2	1.73
Nickelocene	2.86	1	2.83

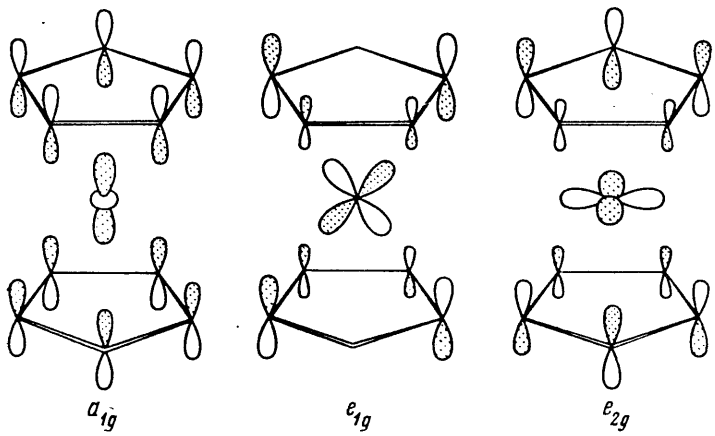

Figure 1. Schematic representation in terms of symmetry characteristics of the valence 3d orbitals of the metal and the molecular orbitals of cyclopentadienyl involved in a linear combination.

For complexes in which the unpaired electrons are distributed among the degenerate orbitals, larger deviations of the g-factor from the value for the free electron are observed. A small splitting of the degenerate levels leads to the appearance of short spin–lattice relaxation times; low temperatures (4–20 K) are required for the observation of EPR in such complexes.

Table 2. Magnetic moments of the diarene complexes of metals[24].

Complex	μ^{*}_{eff}, μ_B	S
Dibenzenevanadium	1.68	1/2
Dimesitylvanadium cation	2.80	1
Dibenzenechromium cation	1.77	1/2
Bishexamethylbenzeneiron cation	1.89	1/2
Bishexamethylbenzeneiron	3.08	1
Bishexamethylbenzenecobalt dication	1.73	1/2
Bishexamethylbenzenecobalt cation	2.95	1
Bishexamethylbenzenecobalt	1.86	1/2
Bishexamethylbenzenenickel dication	3.00	1

*The spin-only moments μ are 1.73 and 2.83 for $S = 1/2$ and $S = 1$ respectively.

The presence of more than one unpaired electron in the molecule leads to the splitting of the levels in a zero external magnetic field as a consequence of the interaction between the unpaired electrons. Such splitting sometimes constitutes an additional difficulty in the observation of EPR. Since zero field splitting can greatly exceed the attainable energy microwave quanta, EPR cannot be observed. In such cases, the observation of EPR is impossible and the application of NMR, which is not subject to the above limitations is particularly valuable. In the NMR spectra of complexes with short electron spin–lattice relaxation times, lines which are relatively narrow for paramagnetic specimens are observed. In the case of systems with a large zero field splitting, NMR is the only feasible microwave spectroscopic research technique.

The hyperfine structure (HFS) of the EPR spectra, the zero field splitting of the signal, and the paramagnetic shift of the NMR lines are important sources of information about the distribution of the unpaired electron density. In the EPR spectra of metallocenes and diarene complexes, a hyperfine structure, which depends on the nature of the metal and is due to the interaction of the unpaired electron with the magnetic moment of the metal nuclei and the ligand protons, is observed. Analysis of the HFS in the solid phase (in single crystals or in vitrified solutions) makes it possible to determine values of the hyperfine interaction (HFI) tensor as well as the isotropic HFI constant which enters into the so-called contact paramagnetic shift of the NMR line.

Under the conditions of rapid electron spin–lattice relaxation, the contact shift $\Delta\nu$(Hz) of the NMR line is described by the equation

$$\Delta\nu/\nu_0 = -Ag_{av}\beta_e S(S+1)/g_N\beta_N(3kT),$$

where A is the constant of the isotropic hyperfine interaction of the unpaired electron with the corresponding nucleus, $g_{av} = 1/3(g_\parallel + 2g_\perp)$, β_e and β_N are the electronic and nuclear magnetons, g_N is the nuclear spectroscopic splitting factor, S the spin of the paramagnetic complex, k the Boltzmann constant, and T the temperature on the Kelvin scale. The above formula shows that the temperature variation of the contact shift is consistent with the Curie law[9]. Hence it follows that only when this law holds is it possible to calculate A from the slope of the plot of $\Delta\nu$ against $1/T$.

The expression for the constant A is

$$A = \frac{8\pi}{6S} g_e\beta_e g_N\beta_N |\psi(0)|^2 ,$$

where $|\psi(0)|$ is the molecular wave function of the unpaired electron at the nucleus. Thus the contact shift carries potentially the same information about the distribution of the unpaired electron density in the paramagnetic complex as the isotropic HFI constant obtained from the EPR spectra. The study of the contact shifts of the NMR lines is of particular value in view of the fact that, apart from the determination of the constant A, it also yields its sign. This permits in its turn the determination of the sign of the spin density at the corresponding atom. The determination of the magnitudes and signs of the spin density permits conclusions concerning the mechanism of the delocalisation of the unpaired electron in the complexes.

When the anisotropy of the g-factor is considerable, the pseudocontact shift[9], arising as a result of the dipole–dipole interaction of the magnetic moment of the unpaired electron with the magnetic moment of the corresponding nucleus at a distance r, makes a contribution, apart from the contact shift, to the experimental paramagnetic shift. The form of the expressions describing the contribution of the pseudocontact shift depends on the ratio of the correlation times of the rotational mobility τ_2 (τ_2 is the time of the rotation of the complex by one radian), the characteristic time determined by the anisotropy of the g-factor, and the electron spin–lattice relaxation time T_1.[10] Two cases are distinguished:

(a) $1/\tau_2 \ll |g_\parallel - g_\perp|\beta H/\hbar$, $T_1 \ll \tau_2$, $\Delta\nu/\nu_0 = \Gamma(g_\parallel^2 - g_\perp^2)/3$;

(b) $1/\tau_2 \gg |g_\parallel - g_\perp|\beta H/\hbar$, $T_1 \ll \tau_2$, $\Delta\nu/\nu_0 = \Gamma(3g_\parallel + 4g_\perp)(g_\parallel - g_\perp)/15$,

where Γ is the so-called geometrical factor taking into account the relative positions of the unpaired electron and the nucleus:

$$\Gamma = -\frac{\beta^2 S(S+1)}{3kT}\left\langle\frac{3\cos^2\varphi - 1}{r^3}\right\rangle .$$

Proton magnetic resonance spectroscopy has been supplemented in recent years by the ^{13}C magnetic resonance spectroscopy. The application of ^{13}C NMR greatly extended the scope of the study of paramagnetic complexes and made it possible to construct a map of the spin density distribution incorporating all the atoms of the complex. Analysis of the spin density distribution makes it possible to estimate the relative involvement of the metal and ligand atoms in the molecular orbital of the unpaired electron, which is important for understanding the nature of the bond in sandwich metal complexes.

1. EPR and NMR Spectra of Sandwich Compounds of Iron

The first EPR spectra of the ferrocenium cation were not obtained until 1969[11], much later than the EPR spectra of the sandwich compounds of other metals. The difficulties in the study of the EPR spectra of ferrocenium and its derivatives are associated with the short spin–lattice relaxation time T_1, which hinders measurements at temperatures above 77 K. The EPR spectra of the ferrocenium cation and its derivatives have been recorded at 20 K in dimethylformamide. Fig. 3 presents the EPR spectra of $Fe(C_5H_5)_2I_3$, $CH_3C_5H_4Fe.C_5H_5I_3$, and $(CH_3C_5H_4)_2FeI_3$. Table 3 presents the values of $g_\parallel$, $g_\perp$, the line widths $\Delta H_\parallel$ and $\Delta H_\perp$, as well as certain

parameters characterising the electronic state of the ferrocenium cation[12]. The line width $\Delta H_\perp$ was measured between the peaks and $\Delta H_\parallel$ was measured at the level of half the height of the signal corresponding to $g_\parallel$. It follows from the data in Table 3 that the introduction of substituents lowers $\Delta H_\perp$ by a factor greater than ten.

Table 3. EPR parameters* of the ferrocenium cation and its derivatives[15].

Substituent	$g_\parallel$	$g_\perp$	$\Delta H_\parallel$, G	$\Delta H_\perp$, G	K	X	δ, cm^{-1}

*Notation: K is the fraction of the unpaired electron density on the iron atom; $X = \xi/\delta$, where ξ is the spin–orbit coupling constant: δ = energy of the splitting of the e_{2g} level in a low-symmetry field.

Ligand field theory predicts the sequence of the levels of the five degenerate orbitals of the transition metal ion[8], illustrated schematically in Fig. 2. This sequence arises as a result of the influence of the field of the cyclopentadienyl rings on the metal ion orbitals. As a consequence of symmetry properties, the orbital $e_{1g}(3d_{\pm1})$ and $e_{2g}(3d_{\pm2})$ remain degenerate. Since ferrocene is diamagnetic, it has the low-spin configuration $^1A_{1g}(e_{2g})^4(a_{1g})^2$. The distance between the e_{1g} and a_{1g}, e_{2g} orbitals is fairly large and exceeds the exchange interaction energy stabilising the high-spin configuration of the d^6 level.

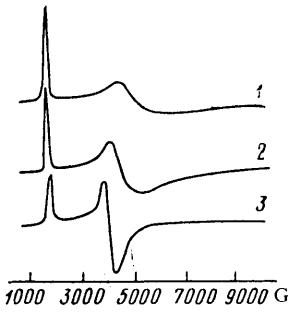

Figure 3. EPR spectra of ferrocenium cations in dimethylformamide at 20 K: 1) $Fe(C_5H_5)_2I_3$; 2) $Fe(C_5H_5)(C_5H_4CH_3)I_3$; 3) $Fe(C_5H_4CH_3)_2I_3$.[15]

Measurement of the magnetic susceptibility of the $FeCp_2^+$ cation showed that it has the low-spin d^5 configuration and that its magnetic moment deviates appreciably from the spin-only value[8]. The orbitally degenerate state $^2E_{2g}(a_{1g})^2(e_{2d})^3$ has been proposed as the ground state of $Fe_2Cp_2^+$.[13,14]

A system of five d electrons has been examined theoretically[15] by replacing it by a single electron "hole" having the electronic configuration $^2E_{2g}(e_{2g})$. In an axial ligand field H_0, this configuration is quadruply degenerate—doubly degenerate for the spin functions α and β and doubly degenerate for the orbital functions e_{+2} and e_{-2}. In view of the axial symmetry of the system, the eigenfunctions of the projection operator of the orbital moment L_z, where the main molecular axis perpendicular to the plane of the ligand rings was selected as the z axis, were chosen as a basis set of wave functions. The spin–orbit interaction $\hat{H}_{SO}$ splits the quadruply degenerate level into two doubly degenerate levels: $\{e_{+2}\alpha, e_{-2}\beta\}$ with $|M_j| = 5/2$ and $\{e_2\alpha, e_{+2}\beta\}$ with $|M_j| = 3/2$. The energies of these states differ by 2ξ, where ξ is the spin–orbit coupling parameter. For the electron "hole", ξ is negative and the doublet with $|M_j| = 5/2$ refers to the ground state of the unpaired electron. This doublet is located several hundreds of cm^{-1} below the doublet with $|M_j| = 3/2$.

$$g_\parallel = 2\langle e_{+2}\alpha|l_z + 2S_z|e_{+2}\alpha\rangle = 2 + 4K\,,$$
$$g_\perp = 2\langle e_{+2}\alpha|l_x + 2S_x|e_{-2}\beta\rangle = 0\,,$$
$$K = \tfrac{1}{2}\langle e_{+2}|l_z|e_{+2}\rangle\,.$$

The result $g_\perp = 0$ implies that, to a first approximation, the levels to which the ground state doublet corresponds are not split by a magnetic field parallel to the x and y axes. On the other hand, the probability of the EPR transitions in the case where the magnetic field is parallel to the z axis is $\langle e_{+2}\alpha|S_x|e_{-2}\beta\rangle = 0$. Hence it follows that the EPR spectrum of the ferrocenium cation should not be observed. On the basis of the results obtained, the author[15] concludes that the symmetry of the cation $FeCp^+$ is lower than the axial symmetry and this explains the presence of the EPR signal.

The decrease of the symmetry of the cation $FeCp_2^+$ may be induced by the solvent molecules, the anion, or the distortion due to the Jahn–Teller effect; in substituted $FeCp_2^+$ the symmetry can also be reduced by the influence of the substituent.

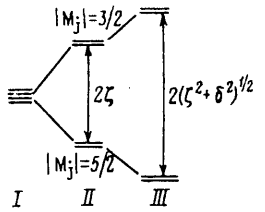

Figure 4. Diagram of the $^2E_{2g}$ levels of the ground state of $Fe(C_5H_5)_2^+$: I) in the axial field of the ligand; II) in the axial field of the ligands with superposition of the spin–orbit coupling (2ξ); III) in the axial field with superposition of spin–orbit coupling and a low-symmetry field (δ).

The overall Hamiltonian $\hat{H}$, describing the behaviour of the unpaired electron, can be represented by the sum of the effective one-electron Hamiltonian $\hat{H}_0$, corresponding to the axial symmetry of the complex, and the terms $\hat{H}_{SO}$ and $\hat{H}_1$ associated respectively with the spin–orbit coupling and the interaction with a low-symmetry field. The latter interaction removes the degeneracy and splits the e_{2g} level into two components, $e_{x^2-y^2}$ and e_{xy}, separated by a distance $\sim 2\delta$. It may be expected that $\hat{H}_1$ and $\hat{H}_{SO}$ are of the same order of

magnitude and that the determination of the splitting requires the solution of the secular equation. The solution of the secular determinant yields two doubly degenerate levels whose location is illustrated in Fig.4.

$$\Psi_1 = (\cos\varphi \cdot e_{x^2-y^2} + i \sin\varphi \cdot e_{xy})\alpha \ ,$$
$$\Psi_2 = (\cos\varphi \cdot e_{x^2-y^2} - i \sin\varphi \cdot e_{xy})\beta \ ,$$

where $\tan\phi = (1 + 1/X^2)^{1/2} - 1/X$ and $X = -\xi/\delta$. The energy of the lower doublet level corresponding to these functions is $-(\xi^2 + \delta^2)^{1/2}$ and the energy of the upper doublet is $+(\xi^2 + \delta^2)^{1/2}$. New values of the g-factors were calculated using these wave functions[15]:

$$g_z = 2\langle\Psi_1|l_z + 2S_z|\Psi_1\rangle = 2 + \frac{4KX}{(1+X^2)^{1/2}} \ ,$$
$$g_x = g_y = 2\langle\Psi_1|l_x + 2S_x|\Psi_2\rangle = \frac{2}{(1+X^2)^{1/2}} \ .$$

The parameters K and X can be determined from the two equations for g_z and $g_x = g_y$.

The orbital $|e_{+2}\rangle$ is a linear combination of the 3d orbital of the iron atom and the ligand π orbital L_π, which is a linear combination of the $2p_z$ orbitals of the carbon atoms in the cyclopentadienyl rings:

$$|e_{+2}\rangle = C_1|3d_{+2}\rangle + C_2|L_\pi\rangle \ .$$

Substitution in the equation for K yields the following expression:

$$K = \frac{1}{2}\langle e_{+2}|l_z|e_{+2}\rangle =$$
$$= C_1^2 + C_1C_2\langle 3d_{+2}|l_z|L_\pi\rangle + \frac{1}{2}C_2^2\langle L_\pi|l_z|L_\pi\rangle \ .$$

As the initial approximation it was assumed that the orbital moment associated with the ligand electrons is to a large extent extinguished[15] and for this reason the last two integrals were assumed to be zero. Hence it follows that $K = C_1^2$. It is seen from the data in Table 3 that the average $K = 0.82$ and $C_1 = 0.91$, which shows that the 3d orbital of the iron atom makes the main contribution to the e_{2g} orbital of the complex and that the unpaired electron is localised mainly at the iron atom. Calculations of the molecular orbitals carried out for ferrocene predict the same results. Values in the range 0.85–0.91 were found for C_1.[2-4]

The splittings of the energy levels in a low-symmetry field $\hat{H}_1$ can be determined from the parameter X. Since $\delta = -\xi/X$ and $\xi = C_1^2\xi_0$, where $\xi_0 = 400$ cm^{-1}, the spin–orbit coupling constant for the Fe^{3+} cation is $C_1 = 0.82$. The results obtained show that the axial symmetry is infringed even in the unsubstituted ferrocenium cation. The high value $\delta = 270$ cm^{-1} leads to the conclusion that the infringement of the symmetry is associated with external factors[15].

The similarity of the energies of the states with $|M_j| = 3/2$ and $|M_j| = 5/2$ explains the short spin–lattice relaxation time of the ground state. The energy difference $\Delta E = 2(\xi^2 + \delta^2)^{1/2}$ of the states with $|M_j| = 5/2$ and 3/2 is 860 cm^{-1} in $FeCp_2^+$, 1200 cm^{-1} in $(CH_3C_5H_4)_2Fe^+$, and 1390 cm^{-1} in $(CH_3COC_5H_4)_2Fe^+$. The order of magnitude of these quantities explains why the EPR signal of $FeCp_2^+$ is too broad to be observed at 77 K, while the EPR spectra of complexes with a higher ΔE can be observed at this temperature.

The magnetic moment of the cation $FeCp_2^+$ has been determined[15] by measuring the magnetic susceptibility ($\mu = 2.61$ μ_B in crystalline powders of ferrocenium salts and by the NMR method from the paramagnetic shift of the solvent protons ($\mu = 2.30$ μ_B). The magnetic moment obtained by NMR is in good agreement with the value calculated from EPR data:

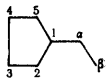
$$\mu = \left\{\frac{1}{3}(g_\parallel^2 + 2g_\perp^2)\,S\,(S+1)\right\}^{1/2}\mu_B = 2.35\mu_B \ .$$

The apparent conflict between the results of the theoretical analysis of the distortion of the axial symmetry of $FeCp_2^+$ and the equality of g_x and g_y obtained from the EPR spectrum is due to the fact that the difference $g_x - g_y$ is proportional to $\xi/\Delta E_i$, where $\Delta E_i = E(e_1g) - E(e_2g) \cong 30000$ cm^{-1} is unduly small compared with the line width in the EPR spectrum.

Simultaneously with Prins' communication[15], the study of Horsfield and Wassermann[16], dealing with the same problem, was published. They investigated the EPR spectra of $FeCp_2^+$ trichloroacetate, picrate, and chloride at 77 K. The g-factors obtained differ appreciably ($g_\parallel \cong 3.20$; $g_\perp \cong 1.80$) from Prins' data[15]. In the subsequent discussion, attention was drawn to the instability of the ferrocenium cation[17,18] and the possible formation of paramagnetic impurities. The additional studies which followed the discussion[18] established that the signals recorded by Horsfield and Wassermann are observed in freshly prepared specimens at 77 K, but, on reducing the temperature to 20 K, the more intense signals with the values of $g_\perp$ and $g_\parallel$ obtained by Prins are recorded[15].

Theoretical calculations and experimental EPR spectra of the ferrocenium cation have shown that the main contribution to the orbital of the unpaired electron of the cation comes from the 3d orbital of the metal atom. The shift of the unpaired electron to the ligands might be indicated by the hyperfine structure of the spectrum due to the interaction with the protons of the cyclopentadienyl rings. Since A_H is much smaller than the width of the EPR line, this information cannot be obtained from the EPR spectrum. It was obtained with the aid of NMR.

Fritz et al.[19] were the first to investigate the NMR of the ferrocenium cation and its alkyl derivatives. They measured the paramagnetic shifts of the signals due to the protons in the cyclopentadienyl ring and the protons of the α-CH_2, β-CH_2, and γ-CH_3 groups in the substituted ferrocenium cation. The paramagnetic shifts $\Delta\nu$ (p.p.m.) measured at a frequency of 100 MHz proved to be small:



Cp ring	α-CH_2	β-CH_2	γ-CH_3
$-(30-16)$	15 — 18	7	0

The results obtained indicate quantitatively a low unpaired electron density in the ligand orbitals. However, the constants for the isotropic HFI between the unpaired electron and the protons cannot be calculated directly from the paramagnetic shifts because of the contributions to $\Delta\nu$ by the pseudocontact shift. Attempts have been made in a number of studies to separate the contact and pseudocontact contributions[15,19,20]. The inaccuracy of the first attempts was due to the insufficiency of the EPR data and data concerning the structure of the ferrocenium cation[15,19].

It has been found[20] that the dipole contribution to the observed paramagnetic shifts of the signal due to the methyl protons of the cation $Fe(C_5H_4CH_3)_2^+$ is ~55% and the contribution to the paramagnetic shift of the protons of the cyclopentadienyl rings is 25%. The calculated isotropic HFI constants are $A_H = 0.168$ G for $Fe(C_5H_5)_2^+$ and $A_H = 0.161$ G and $A_{CH_3} = 0.095$ G for $Fe(C_5H_4CH_3)_2^+$.

A more thorough analysis of the temperature variation of the paramagnetic shift[21] showed that this variation is different for the protons of the cyclopentadienyl rings of $FeCp_2^+$ and $(RC_5H_5)_2Fe^+$. Whereas in the case of $FeCp_2^+$ the Curie law hold rigorously, deviations are observed for the protons of the $(RC_5H_4)_2Fe^+$ rings. Köhler[21] concluded that the protons in substituted cyclopentadienyl rings are non-equivalent, which leads to the observed deviations in the temperature variation. This hypothesis has been confirmed. The application of ^{13}C NMR showed that the carbon atoms in the cyclopentadienyl rings of $(RC_5H_4)_2Fe^+$ are non-equivalent[22].

Table 4 presents the paramagnetic shifts of the ^{13}C NMR of the ferrocenium cation and some of its alkyl derivatives.

In conformity with the signs of the paramagnetic shifts of the NMR lines of the ^{13}C and ^{1}H nuclei, the signs of the spin density on the corresponding atoms can be obtained. The spin densities on the carbon and hydrogen atoms of the cyclopentadienyl rings have the positive sign. The positive sign of the shift of the proton signal of the CH_3 group in $Fe(C_5H_4CH_3)_2^+$ is due to the fact that the positive pseudocontact shift is greater in absolute magnitude than the negative contact shift[20]. Thus, although the spin densities on the carbon nuclei are in fact positive, the ^{1}H NMR line of the CH_3 group is displaced upfield.

Table 4. Shifts of the ^{13}C NMR lines (p.p.m.) in the spectrum of ferrocenium hexaphosphate in acetone at 28 °C.[22]

Ferrocenium cation	C(1)	C(2, 5), C(3, 4)	C^{α}	C^{β}
$(C_5H_5)_2Fe^+$	—	−314.5	—	—
$(CH_3C_5H_4)_2Fe^+$	−415	−263.0	+10	—
$(C_2H_5C_5H_4)_2Fe^+$	−402.5	−259.8	+0.5	+9.2
$(C_4H_9C_5H_4)_2Fe^+$	−414.0	−233.6 −250.6	−16.3	+3.9

The bis(hexamethylbenzene)iron cation is an example of a 19-electron system (d^7). Three signals, corresponding to three values of the g-factor, are observed in the EPR spectrum: $g_x = 1.865$, $g_y = 1.996$, and $g_z = 2.086$.[23] It is of interest that there is no axial symmetry in such a highly symmetrical molecule. The absorption signal is observed in the range from 25 to 80 K, disappearing at 90 K owing to the considerable broadening of the line. It has been suggested[23] that the unpaired electron occupies the non-bonding ligand orbital e_{2u}. Subsequent study of the NMR spectra of this compound showed that the unpaired electron density on the ligands is low[24]. This result is inconsistent with the hypothesis that the unpaired electron is located in the e_{2u} orbital. It is most likely that the electron occupies the e_{1g}^* orbital of the iron atom.

The electrically neutral arenecyclopentadienyliron complexes also belong to d^7 systems. The reduction of the salts $[AreneFeC_5H_5]^+BF_4^-$ in 1,2-dimethyoxyethane at −70 °C on a sodium mirror leads to the transformation of the d^6 system, isoelectronic with ferrocene, into the d^7 system $a_{1g}^2e_{2g}^4(e_{1g}^*)^1$.[25]

The doubly degenerate e_{1g}^* level is split as a consequence of the low-symmetry interaction with the arene ligand. On the assumption that the unpaired electron occupies mainly one of the two orbitals d_{xz} or d_{yz}, expressions were obtained for $g_{\parallel}$ and $g_{\perp}$:

$$g_z = g_{\parallel} = 2\left(1 - \frac{\lambda_0}{\Delta E}\right);\ g_x = g_y = g_{\perp} = 2,$$

where

$$\Delta E(e_{1g}^*) = E_{d_{xz}} - E_{d_{yz}}, \quad \text{and} \quad \lambda_0(Fe^+) = -350\ cm^{-1}.$$

Table 5 presents the values of $g_{\parallel}$ for electrically neutral arenecyclopentadienyliron complexes (the values of $g_{\perp}$ for all the compounds are close to 2). The table shows that $g_{\parallel}$ decreases in the sequence of ligands benzene, naphthalene, phenanthrene. The values of $\Delta E(e_{1g}^*)$ for benzene, naphthalene, and phenanthrene are respectively 2700, 7700, and 10000 cm^{-1}. The increase of $\Delta E(e_{1g}^*)$ can be attributed to the increase of the electron-donating capacity of the ligands in this sequence, leading to the enhancement of the interaction of the ligands with the iron atom on which there is a positive charge.

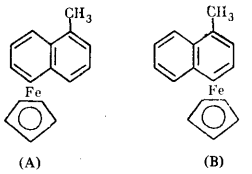
Table 5. The values of $g_{\parallel}$ for electrically neutral arenecyclopentadienyliron complexes[25].

Arene	$g_{\parallel}$	Arene	$g_{\parallel}$	Arene	$g_{\parallel}$
Benzene	2.26	Tetralin	2.21	Fluorene*	2.10
Toluene	2.25	Dihydroanthracene	2.22	Naphthalene	2.09
Diphenylmethane	2.24	Mesitylene	2.24	Phenanthrene	2.07
p-Xylene	2.25	Durene	2.21		

*Breakdown of axial symmetry: $g_x = 2.00$; $g_y = 1.99$.

The study of the EPR spectra of the dications $[AreneFeC_5H_5]^{2+}$,[26] obtained by oxidising the initial salts $SbCl_5$ in CH_2Cl_2 at −70 °C, can yield data about the d^5 system which is isoelectronic with the ferrocenium cation[15]. Table 6 presents the values of $g_{\parallel}$, $g_{\perp}$, and $\Delta E(e_{2g}) = E_{d_{x^2-y^2}} - E_{d_{xy}}$:

$$g_z = g_{\parallel} = 2\left(1 - \frac{2\lambda_0}{\Delta E(e_{2g})}\right);\ g_x = g_y = 2;\ \lambda_0 = -400\ cm^{-1}.$$



Evidently, the splittings $\Delta E(e_{1g}^*)$ are much greater than $\Delta E(e_{2g})$. This result reflects the greater "π character of the d_{xz} and d_{yz} orbitals and their more effective overlap with the molecular π orbitals of the ligands compared with the $d_{x^2-y^2}$ and d_{xy} orbitals. Comparison of the data in Table 6 with the parameters of the EPR spectra of ferrocenium cations (Table 3) shows that the low-symmetry splitting in the dications $[AreneFeC_5H_5]^{2+}$ is much greater than in ferrocenium cations.

Table 6. The values of $g_{\parallel}$, $g_{\perp}$, and $\Delta E(e_{2g})$ for the EPR spectra of arenecyclopentadienyliron dications[26].

Arene	$g_{\parallel}$	$g_{\perp}$	$\Delta E(e_{2g})$, cm^{-1}
$CH_3OC_6H_5$	3.14	1.940	1400
$C_6H_5OC_6H_5$	3.14	1.920	1400
p-$FC_6H_4C_6H_5$	3.16	1.898	1380
$C_6H_5C_6H_5$	3.04	1.930	1540
$C_{10}H_8$	2.80	1.976	2000
β-$FC_{10}H_7$	2.83	1.976	1930
α-$CH_3C_{10}H_7$ (A)	2.81	1.977	1970
α-$CH_3C_{10}H_7$ (B)	2.71	1.988	2260
$C_{14}H_{10}$	2.86	1.964	1860

It is of interest to compare the data for $[C_{10}H_8FeC_5H_5]^{2+}$, $[\alpha\text{-}CH_3C_{10}H_7FeC_5H_5]^{2+}$, and $[\beta\text{-}FC_{10}H_7FeC_5H_5]^{2+}$. Table 6 shows that the signal corresponding to $g_{\parallel}$ in the $[\alpha\text{-}CH_3C_{10}H_7.FeC_5H_5]^{2+}$ spectrum is split into two components. A smaller splitting is observed also in the signal corresponding to $g_{\perp}$.

We attributed this feature of the $[\alpha\text{-}CH_3C_{10}H_7FeC_5H_5]^{2+}$ spectrum to the existence of two different isomers[26]:

(A) (B)

This hypothesis is confirmed by the NMR data for the cations $[\beta\text{-}CH_3C_{10}H_7FeC_5H_5]^+$ and $[\alpha\text{-}FC_{10}H_7FeC_5H_5]^+$.[27] The ratio of isomers (A) and (B) for the former cation is 55:45 while for the latter cation only isomer (A) is observed.

2. The EPR and NMR Spectra of Sandwich Compounds of Vanadium

The EPR spectrum of VCp_2 has been investigated[28] for a single crystal of diamagnetic $FeCp_2$ and the splitting parameter in a zero magnetic field $D = 0.83$ cm^{-1} was determined for the quartet ground spin state. On the other hand, the EPR spectrum obtained previously[29] in benzene solution at room temperature and consisting of eight well resolved lines ($A_V = 25.6 \times 10^{-4}$ cm^{-1}) with $g = 2.00$ was also attributed to vanadocene. These data are in conflict, since a much greater width of the spectral line recorded in solution is to be expected for such a high value of D.

The EPR spectrum of VCp_2 in vitrified solution in 2-methyltetrahydrofuran has been investigated[30] at 77 K and it has been shown that the signal observed in solution at room temperature is due to an impurity. The VCp_2 signal observed at 77 K is characterised by the parameters $g_\parallel = 2.002$, $g_\perp = 1.99$, $|D| = 2.3$ cm^{-1}, $|A| = 3.7 \times 10^{-4}$ cm^{-1}, and $|B| = 21 \times 10^{-4}$ cm^{-1}.[30] The difference between the given value of $|D|$ and that obtained in another study[29] was attributed[30] to the differences between the matrices in which the EPR spectra of VCp_2 were recorded. The similarity of the measured g-factor to the value for the free electron is consistent with measurements of the magnetic susceptibility and shows that the ground state for vanadium is an orbital singlet $^4A_{1g}$ and corresponds to the configuration $a_{1g}^1 e_{2g}^2$.

On the assumption that a_{1g} is a non-bonding metal orbital, the parameters of the hyperfine interaction tensor can be expressed by the formulae

$$A = A_{iso} - \frac{4}{21}P(2\alpha^2 - 1);\ B = A_{iso} + \frac{2}{21}P(2\alpha^2 - 1),$$

where α is the contribution of the e_{2g} orbital of the metal to the molecular orbital and $P = 2\gamma_e\beta_e\beta_N\langle r^{-3}\rangle$. For $P = 110 \times 10^{-4}$ cm^{-1}, it was found that $\alpha = 0.86$.[30]

Rettig and Drago[9] investigated the NMR spectrum of VCp_2 in toluene at a frequency of 60 MHz and found that the paramagnetic shift of the ring proton signal is −18500 Hz relative to the protons of the diamagnetic dimethylferrocene, i.e. ~300 p.p.m. An estimate of the contribution of the pseudocontact shift showed that it is an insignificant proportion of the overall shift observed experimentally. The temperature variation of the shift obeys the Curie law. The isotropic HFS constant is 0.832 G.

The contact shifts in 1,1-dimethylvanadocene are −20190 G for the protons of the cyclopentadienyl rings and 7195 G for the protons of the methyl group. The constant for the hyperfine interaction with the protons of the methyl group, determined from the NMR data, is 0.323 G.[9]

Comparison of the values and signs of the contact shifts of the ring and methyl group protons has been used[9] to determine the mechanism of the displacement of the unpaired electron density from the metal atom to the ligand. The mechanism of the delocalisation of the unpaired electron in paramagnetic metallocenes proposed previously[13] presupposes the involvement of the 3d orbitals of the metal atoms and the π orbitals of the ligand as well as the spin polarisation of the CH bonds in the ring. The main contradiction between this theory and the experimental data obtained from the NMR spectra of VCp_2 is that the mechanism of the spin polarisation developed by Levy and Orgel[13] in relation to the π-electron free radicals presupposes different signs of the HFI constant for the protons of the CH bond and of the CH_3 group, while their absolute magnitudes are approximately equal. However, in the case of vanadocene the signs of the experimental HFI constants for the ring and methyl group protons are the same, while their absolute values differ greatly—the HFI constant for the ring protons exceeds in absolute magnitude the HFI constant for the methyl group protons by a factor greater than two. The markedly lower HFI constants for the protons of the alkyl substituent compared with the HFI constant for the ring protons had already been noted earlier in a study of the EPR spectra of the cations of alkyl derivatives of dibenzenechromium[31].

Rettig and Drago[9] suggested that the principal mechanism for the transfer of spin density from the central metal atom in individual metallocenes to the ligand protons involves transfer via σ and not π bonds. A characteristic feature of this mechanism is a marked decrease of spin density along the chain of σ bonds and the identical signs of the constants of the hyperfine interaction with the protons of the CH bonds and the CH_3 groups.

^{13}C NMR data for vanadocene and 1,1-dimethylvanadocene have shown that the delocalisation pattern is much more complex[32]. Table 7 presents the contact shifts of the ^{13}C and ^1H NMR signals for vanadocene and its alkyl derivatives. The positive shift of the signal from the ^{13}C atom in the ring implies that the unpaired electron spin density on the ring carbon atoms has a negative sign. The negative sign of the contact shift of the ring protons supports the spin polarisation mechanism and is an argument against the mechanism involving delocalisation via σ bonds.

Table 7. Paramagnetic shifts (p.p.m.) of the ^{13}C and ^1H NMR lines of vanadocene, chromocene, and their alkyl derivatives[32].

Compound	C(1)	C(2,5)	C(3,4)	C^α	C^β	H(2,5)	H(3,4)	H^β	H^γ
$(C_5H_5)_2V$	+588	+588	—	—	—	−315	−315	—	—
$(CH_3C_5H_4)_2V$	+482	+750	+533	−915	—	−326	−326	−116	—
$(C_2H_5C_5H_4)_2V$	+480	+743	+562	−792	−420	−340	−340	−90	−5.4
$(C_4H_9C_5H_4)_2V$	+503	+730	+533	−557	−220	—	—	—	—
$(C_5H_5)_2Cr$	+325	+325	+325	—	—	−324	−324	—	—

The EPR spectra of the diarene sandwich complexes of zerovalent vanadium (with benzene, toluene, mesitylene, and naphthalene as ligands) have been investigated[33]. Hyperfine interaction with the magnetic moment of the vanadium nucleus is observed in the spectra of all these compounds, which leads to the appearance of eight HFS lines ($I_V = 7/2$) with a splitting $A_V = 63$ G. Each of the eight lines in the spectrum of the dibenzenevanadium(O) complex is additionally split into 13 lines with a binomial distribution of relative intensities as a result of the interaction with the protons of

the benzene rings: A_H = 4 G and g = 1.987.[33] The introduction of substituents into the ligands (toluene and mesitylene) does not alter the HFI constants, but merely diminishes the number of lines in the spectrum; hyperfine interaction with the protons of the CH_3 groups is not observed[34].

Analysis of the HFS spectrum of the dinaphthalenevanadium(0) complex showed that only one benzene ring of naphthalene is involved in a bond with the vanadium atom. The spectral parameters (A_V = 63 G, A_H = 4 G, g = 1.987) do not differ from those quoted above for the dibenzenevanadium(0) complex. The electronic configuration $...(e_{1u})^4 (e_{2g})^4 (a_{1g})^1$ with an unpaired electron in the $a_{1g}(3d_{z^2})$ orbital is characteristic of zerovalent vanadium complexes[35].

The results show that the delocalisation of the unpaired electron over the π bonds does not play a significant role in the diarenevanadium(0) compounds.

The paramagnetic shifts of the proton signals of the CH bonds and the CH_3 groups in the ^{1}H NMR spectra of $V(C_6H_6)_2^+$, $V(C_6H_5CH_3)^+$, and $V[C_6H_3(CH_3)_3]_2^+$ [24] (ν_0 = 60 MHz) have been measured:

Compound	$V(C_6H_6)_2^+$	$V(C_6H_5CH_3)_2^+$	$V(C_6H_3(CH_3)_3)_2^+$
A_H, G	1.13	1.34	1.23
δ_H, G	−13 990	−16 740	−16 410
A_{CH}, G	—	0.824	0.306
δ_{CH_3}, Hz	—	−8 400	−3 860

The electronic configuration $(e_{2g})^3 (a_{1g})^1$, corresponding to the degenerate $^3E_{2g}$ ground state, has been proposed on the basis of molecular orbital calculations[36].

3. EPR and NMR Spectra of Sandwich Compounds of Chromium

Nüssbaum and Voitländer[37,38] were unable to observe the EPR signals of the complex $CrCp_2$ either in the 3-cm or 8-mm wavelength range at temperatures from room temperature to 4 K; the reasons for this failure were recognised to be the large zero field splitting and the short relaxation time. The magnetic moment of chromocene greatly exceeds the value of the spin-only magnetic moment, which indicates a degenerate electronic state of the complex. According to theoretical calculations, the ground state of chromocene is $(e_{2g})^3 (a_{1g})^1$ [39] and the a_{1g} level is higher by 0.4 eV than the e_{2g} level.

The paramagnetic shift of the proton signals of chromocene in the NMR spectrum relative to the signals of the dimethylferrocene protons is −18850 Hz (ν_0 = 60 MHz), which corresponds to an HFI constant of 1.23 G.[9] In the spectrum of dimethylchromocene the lines due to the protons of the cyclopentadienyl ring are split into two components, which indicates some redistribution of the unpaired electron density in the cyclopentadienyl rings under the influence of the methyl groups. The shifts of the proton signals of the cyclopentadienyl rings are −18630 and −21896 Hz, while that of the methyl group protons is −2160 Hz. The chemical shifts correspond to the HFI constants A_H = 1.22 and 1.43 G and A_{CH_3} = 0.41 G.

Table 7 lists the contact shifts in the ^{13}C and ^{1}H NMR spectra of chromocene and its alkyl derivatives[32]. As in the case of vanadocene, the contact shift of the lines due to the carbon nuclei of chromocene has a positive sign, which indicates a negative unpaired electron spin density in the cyclopentadienyl ring. In conformity with the CH bond spin polarisation model, the spin density on the hydrogen atoms has a positive sign.

Numerous studies have been devoted to the EPR and NMR spectra of the dibenzenechromium cation and its derivatives. The EPR of dibenzenechromium was observed in 1954.[40] Subsequent investigation[31] showed that the EPR spectrum of the dibenzenechromium cation exhibits a splitting of the lines due to the interaction with both the central atom (the ^{53}Cr isotope) and with the protons of the benzene rings (Fig. 5): $A_{^{53}Cr}$ = 19 G and A_H = 3.6 G. The substitution of hydrogen atoms by methyl groups does not entail splitting by the CH_3 protons. In the case of the isopropyl and cyclohexyl substituents, a splitting of ~1 G by the α-proton is observed[31]. In the spectrum of the cation $[C_6H_2(CH_3)_4]_2Cr$ the splitting by the ring protons increases to 4.34 G.[41]

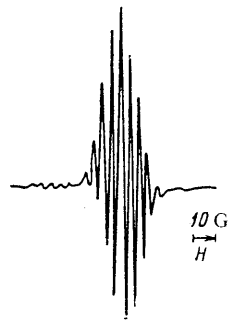

Figure 5. EPR spectrum of the cation $Cr(C_6H_6)_2^+$ in a 1:1 dimethylformamide–chloroform mixture at 200 K.[42]

Analysis of the unpaired electron spin density distribution in the dibenzenechromium cation, assuming delocalisation of the unpaired electron over the π bonds of the ligands, leads to paradoxical results. The employment of the McConnell relation between the splitting A_H and the spin density in the $2p_z$ orbital of the carbon atom ρ_C ($A_H = Q\rho_C$, where Q = −27 G) leads to the conclusion that the overall spin density in the π-electron system of the two benzene rings is approximately equal to two unpaired electrons. On the other hand, the splitting due to the interaction with the ^{53}Cr nucleus in the EPR spectra of inorganic chromium compounds is approximately the same as in the spectrum of the dibenzenechromium cation. This result may be evidence that the unpaired electron in the dibenzenechromium cation is mainly localised at the chromium atom. According to calculations[42], the coefficients α_1, characterising the contribution of the $3d_z$ orbital of the chromium atom to the molecular orbital of the unpaired electron in the dibenzenechromium cation, is close to unity.

Thus the quantitative relations derived on the basis of the study of the π-electron radicals to not hold for the dibenzenechromium cation.

The study of the paramagnetic shifts of the proton signals of the benzene rings and the protons of the methyl groups in the NMR spectra of the dimethyl derivatives of dibenzenechromium cation established the signs of the HFI constants[24,43]. The constant for the splitting by the protons of the benzene ring in the cation $Cr(C_6H_5CH_3)_2^+$ is +3.46 G and that for the splitting by the protons of the methyl groups is −0.46 G.

It has been suggested that the proton HFS is due to the direct interaction of the unpaired electron in the $3d_{z^2}$ orbital with the protons of the benzene ring. Estimates of the contribution of this HFI mechanism showed that it is negligibly small[31,44]. An attempt has been made[24] to explain the observed results by the competition between two mechanisms of the delocalisation of the spin density via π and σ bonds.

As for dinaphthalenevanadium(0), only one naphthalene ring in the dinaphthalenechromium cation is involved in the formation of a bond with the metal. This conclusion is based on the analysis of the proton HFS of the EPR spectrum[35]. The splitting hardly differs from the splittings observed in the spectrum of the dibenzenechromium cation.

4. The EPR and NMR Spectra of Sandwich Compounds of Cobalt

The EPR spectrum of $CoCp_2$ has been investigated at 4 K in a ferrocene single crystal obtained by the joint sublimation of these two compounds[38]. For certain orientations of the crystal, a spectrum with an eight-line HFS, corresponding to the interaction of the unpaired electron with the cobalt nucleus, was recorded. Owing to the uncertainty in the orientation of the crystal, the EPR parameters were not determined accurately: $g_1 = 1.67$, $g_2 = 1.74$, $A = 274$ or 469 MHz, and $B = 274$ or 384 MHz.

More accurate measurements of the EPR parameters of the complex $CoCp_2$ were carried out at 4.2 K in a ruthenocene single crystal: $g_x = 1.140$, $g_y = 1.219$, $g_z = 1.584$, $A_x = +25.5 \times 10^{-4}$ cm^{-1}, $A_y = -120.6 \times 10^{-4}$ cm^{-1}, and $A_z = -103.4 \times 10^{-4}$ cm^{-1}.[42]

Two states have been proposed in accordance with calculations for cobaltocene:

$$(a_{1g}^1)^2(e_{2g})^4(a_{1g}^*)^1 \text{ (Ref.36)}$$

and

$$(a_{1g}^1)^2(e_{2g})^4(e_{2u})^1 \text{ (Ref.3)}$$

The a_{1g}^* orbital is the virtually pure 4*s* orbital of the metal. In this case the constant for the hyperfine interaction with the cobalt nucleus should be ~4800 MHz,[9] whereas the experimental value is ~300 MHz. The hypothesis that the unpaired electron is located in the non-bonding e_{2u} orbital of the ligand, which does not interact with the cobalt orbital by virtue of symmetry considerations, should lead to a vanishingly weak hyperfine interaction with the cobalt nucleus. The ground state $(e_{2g})^4(a_{1g}^1)^2(e_{1g}^*)^1$ is consistent with the EPR data[38]. It has been shown that spin–orbit coupling, orthorhombic distortion, and the dynamic Jahn–Teller effect influence the EPR parameters of the orbitally degenerate $^2E_{1g}$ ground state of cobaltocene. The e_{1g}^* orbital of the unpaired electron is determined to the extent of 58% by the 3*d* orbital of the metal and 42% by the π orbital of the ligand.

The contact shift in the ^{1}H NMR spectrum of $CoCp_2$ is +3230 Hz ($\nu_0 = 60$ MHz) and $A_H = -1.01$ G. The ring protons in $Co(C_5H_4CH_3)_2$ are non-equivalent and two lines with shifts of +2917 and 4305 Hz and $A_H = -0.904$ and -1.34 G are observed. The shift of the line of the CH_3 protons is -687 Hz with $A_{CH_3} = 0.214$ G.[9]

The data in Table 8, which presents the contact shifts of the ^{13}C and ^{1}H NMR lines of cobaltocene and its alkyl derivatives, make it possible to follow the characteristics of the spreading of the spin density from the metal atom to the ligand atoms. The signs of the shifts show that the spin density is positive on the carbon atom and negative on the hydrogen atoms of the rings[32].

A large upfield shift of +3535 Hz is observed in the NMR spectrum of the cation $Co(C_6H_6)_2^+$. The substitution by the methyl group in $Co(C_6H_5CH_3)_2^+$ leads to a shift of the line due to the methyl protons by -2650 Hz.[24] The directions and magnitudes of the ring and methyl proton line shifts indicate the predominance of the mechanism involving the delocalisation of the unpaired electron density via the π bonds. The lines of the CH_3 protons in the $Co[C_6(CH_3)_6]_2^+$ spectrum are displaced downfield by 3695 Hz with $A_H = 0.308$ G.

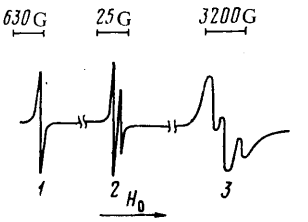

Figure 6. ^{1}H NMR spectrum of the ditoluenecobalt cation in toluene at 298 K: 1) line of the methyl protons of the cation; 2) line of the protons in the solvent molecules; 3) line of the protons in the benzene ring of the cation[24].

When a methyl group is introduced, the lines due to the protons of the benzene rings in the $Co(C_6H_5CH_3)_2^+$ spectrum are split into three signals. Fig.6 shows that the relative intensities of these signals are 2:2:1. These lines have been attributed[24] to the *ortho*- and *meta*-protons (overall intensity 4) and to the proton in the *para*-position (intensity 1). The nature of the splitting of the ring proton lines has been compared with the HFS and the distribution of the unpaired electron density in the toluene radial-anion[46]. Together with the similarity of the spectroscopic data for $Co(C_6H_5CH_3)_2^+$ and $C_6H_5CH_3^-$ (approximate equivalence of the *ortho*- and *meta*-protons and their difference from the *para*-proton), there is also a significant difference, which consists in the fact that the constant for the hyperfine interaction with the proton in the *para*-position in the toluene radical-anion is approximately nine times smaller than the constant for the hyperfine interaction with the protons in the *ortho*- and *meta*-positions. On the other hand, the ratio of these constants in the ^{1}H NMR spectrum of the cation $Co(C_6H_5CH_3)_2^+$ is close to unity. The HFI constant for the protons of the methyl group in the toluene radical-anion is approximately ten times smaller than the HFI constants for the *ortho*- and *meta*-protons. The corresponding quantities for $Co(C_6H_5.CH_3)_2^+$ are of the same order of magnitude and have the same signs, which implies that there is no significant redistribution of the unpaired electron density in the π-electron system of the benzene rings in $Co(C_6H_5CH_3)_2^+$ compared with $Co(C_6H_6)_2^+$.

III. NMR SPECTRA OF NICKELOCENE

McConnell and Holm[47] were the first to observe the proton magnetic resonance of solid nickelocene. The large shift of the NMR proton line which they noted was the first example of the observation of what is nowadays well known as a contact shift.

The EPR spectrum of nickelocene has not been observed in the wavelength range 3.0–0.8 cm and at temperatures from 77 to 4 K.[37] Measurements of the magnetic susceptibility showed that $g_\parallel = 2.0023$, $g_\perp = 2.06$, and the zero-field splitting constant $D = 25.6$ cm^{-1}.[48] Consequently, the magnetic fields and bond lengths used by Nüssbaum and Voitländer[37] were insufficient for the observation of the EPR of nickelocene.

In the ground state of nickelocene $(a_{1g}^1)^2(e_{2g})^4(e_{2u})^2$, proposed on the basis of theoretical calculations, two unpaired electrons are located in the ligand orbital e_{2u}.[3] However,

the large splitting of the signals in a zero field shows that both unpaired electrons are located at the metal atom. It is known that the zero-field splittings or organic triplet molecules are much smaller[49].

The states

$$(a_{1g}^1)^2(e_{2g})^4(e_{1u}^*)$$

and

$$(a_{1g}^1)^2(e_{2g})^4(e_{1g}^*)^2$$

have been proposed for nickelocene on the basis of a study of the magnetic susceptibility[48]. The first state includes the metal $4p_x$ and $4p_y$ orbitals as carriers of the unpaired electron, while in the second the unpaired electron is in the d_{xz} and d_{yz} orbitals. NMR data are consistent with the second state.

Table 8. Paramagnetic shifts (p.p.m.) of the ^{13}C and ^1H NMR lines of cobaltocene, nickelocene, and their alkyl derivatives[32].

Compound	C(1)	C(2, 5)	C(3, 4)	C^α	C^β	H(2, 5)	H(3, 4)	H^β	H^γ
$(C_5H_5)_2Co$	−577	−577	−577	—	—	+56.2	+56.2	—	—
$(CH_3C_5H_4)_2Co$	−358	−437	−755	+112	—	+49.0	+73.6	−12.2	—
$(C_2H_5C_5H_4)_2Co$	−337	−433	−705	+112	−56	—	—	−13.6	−2.4
$(C_4H_9C_5H_4)_2Co$	−458	−458	−633	+94	−123	+50.2	+64.0	—	−2.7
$(C_5H_5)_2Ni$	−1436	−1436	−1436	—	—	+263	+263	—	—
$(CH_3C_5H_4)_2Ni$	−1285	−1475	—	+640	—	+263	+263	−210	—
$(C_2H_5C_5H_4)_2Ni$	—	—	—	+603	−475	+257	+257	−203	−4.5

The study of the ^1H NMR spectra of $NiCp_2$ and $Ni(C_5H_4CH_3)_2$ in solution in toluene at a frequency of 60 MHz and 298 K showed that the ring proton line is displaced by +15300 Hz in the $NiCp_2$ spectrum and by +15190 Hz in the $Ni(C_5H_4CH_3)_2$ spectrum, while the CH_3 proton line is displaced by 11900 Hz. The calculated HFI constants are $A_H = -1.24$ and -1.23 G and $A_{CH_3} = 0.96$ G.[9] Table 8 lists the ^{13}C and ^1H NMR data for nickelocene and its alkyl derivatives. The spin density at the ring carbon atom has the positive sign and that at the ring hydrogen atoms has the negative signs. Comparison of the signs and magnitudes of the contact shifts for the ring and methyl protons shows that the mechanism involving delocalisation via π bonds is most clearly manifested in nickelocene.

IV. EPR SPECTRA OF MANGANOCENE

Depending on the axial splitting (i.e. on the ligand field strength) and on the splitting in a zero magnetic field, the complex $MnCp_2$ can exist in two states: in the high-spin state $(a_{1g}^1 e_{2g}^2 e_{1g}^2)\,^6A_{1g}$ and in the low-spin state $(a_{1g}^2 e_{2g}^3 g)\,^2E_{2g}$ or $(a_{1g}^1 e_{2g}^4 g)\,^2A_{1g}$. Pure $MnCp_2$ gives rise to a broad EPR signal with $g = 2$, which completely disappears on cooling to 4.2 K.[50]

The environment of $MnCp_2$, which arises on its joint crystallisation with various diamagnetic molecules, has a considerable influence on the form of its EPR spectrum[51]. Manganocene in the $MgCp_2$ lattice exhibits at 4.2 K and a frequency of 9.5 GHz a spectrum characteristic of a high-spin d^5 system with $g \cong 2$, the splitting due to the hyperfine interaction with the ^{55}Mn nucleus being characterised by the constant $A = 65$ G and the order of magnitude of the splitting in a zero magnetic field being equal to the order of magnitude of the applied quantum ($0.3\ cm^{-1}$).

In other isostructural lattices ($FeCp_2$ and $RuCp_2$) manganocene exhibits completely different EPR spectra, which characterises it as a low-spin system. The low-spin $MnCp_2$ state $^2E_{2g}$ is isoelectronic with the state of the ferrocenium cation. As for the ferrocenium cation, a strong anisotropy of the g-factor is observed ($g_\parallel = 3.519$, $g_\perp = 1.222$, $A_\parallel = 52.3 \times 10^{-4}\ cm^{-1}$, and $A_\perp = 26 \times 10^{-4}\ cm^{-1}$ for the $FeCp_2$ lattice)[51]. As in the case of the ferrocenium cation, the introduction of substituents into the cyclopentadienyl ring decreases the anisotropy of the g-factor.

In the $Fe(C_5H_4CH_3)_2$ crystal, the g-factor for the complex $Mn(C_5M_4CH_3)_2$ has the following values: $g_\parallel = 3.06$ and $g_\perp = 1.850$ ($A_\parallel = 11.4 \times 10^{-4}\ cm^{-1}$ and $A_\perp = 24.5 \times 10^{-4}\ cm^{-1}$).[51]

None of the low-spin $MnCp_2$ states gave rise to EPR signals on heating above 77 K. The low-symmetry splitting is $\delta = 200\ cm^{-1}$ for $MnCp_2$ and $\delta = 630\ cm^{-1}$ for $Mn(C_5H_4CH_3)_2$. The spin–orbit coupling parameter is $\xi = 260\ cm^{-1}$.[51]

The results obtained show that the energies of the low- and high-spin states of manganocene differ by a small amount and weak intermolecular forces are sufficient to alter the ground electronic configurations. The lattices which promote the formation of longer metal–ring bonds favour the appearance of the high-spin system and conversely those promoting the formation of shorter bonds favour the appearance of the low-spin system. The "distance" between these two states is ~0.5 kcal mol^{-1}.[51]

V. THE JAHN–TELLER EFFECT IN SANDWICH COMPOUNDS

In those cases where the orbital state of the ion is degenerate because of symmetry factors, the ligands are acted upon by forces which distort the distribution of the nuclei until the ion assumes a configuration having both a lower symmetry and a lower energy; the existing degeneracy is thereby eliminated (the Jahn–Teller effect). The theory of the Jahn–Teller effect and its manifestation in the EPR spectra of coordination compounds have been described in monographs[52,53].

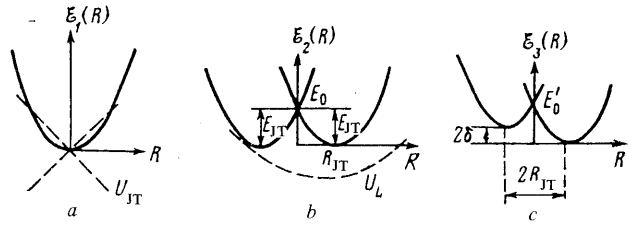

Figure 7. Schematic representation of sections through potential surfaces: *a*) for an orbitally non-degenerate complex; *b*) and *c*) section along the active Jahn–Teller coordinate of a doubly orbitally degenerate complex.

The electronic rearrangements arising as a result of the Jahn–Teller effect can be accounted for qualitatively by considering the potential energy surfaces (Fig. 7). In contrast to the orbitally non-degenerate complexes [$\mathscr{E}_1(R)$, Fig. 7*a*], in an orbitally degenerate complex there are several equivalent potential energy minima stabilised by the energy associated with the Jahn–Teller effect (E_{JT}) and displaced by an amount R_{JT} relative to the nuclear configuration corresponding to the maximum symmetry of the complex [$\mathscr{E}_2(R)$, Fig. 7*b*]. The curves in Fig. 7*b* have been obtained from the plot illustrated in Fig. 7*a* by adding to the $\mathscr{E}_1(R)$ potential energy curve the linear potential U_{JT} with the opposite slope.

The superposition of the weak asymmetric perturbing potential U_L (for example, the field of the surrounding molecules) onto the symmetrical potential $\mathscr{E}_2(R)$ leads to the appearance of an asymmetric potential $\mathscr{E}_3(R)$ (Fig.7c).

Potential surfaces known as the "sombrero" or "Mexican hat" surfaces correspond to octahedral complexes whose symmetry has been distorted by the Jahn–Teller effect. The shape of the surface is determined by the interaction of the doubly degenerate electronic E level with the doubly degenerate e vibration. Such a surface is obtained by rotating the potential energy curve illustrated in Fig.7b about the ordinate axis. The geometrical locus of the points orresponding to the energy minimum is a circumference with the radius R_{JT}.[53] Allowance for the quadratic terms in the Jahn–Teller potential leads to an increase in the complexity of the form of the potential surface and to the appearance of three minima on the above circumference, corresponding to distortions of the octahedra along three different axes. Fig.8 illustrates an expanded section through the lower surface for the E level of the octahedral complex; both the energy of the vibrational quantum $\hbar\omega$ and the tunnel splitting Δ, determining the probability of the transition between the minima, are shown. The manifestation of the Jahn–Teller effect in the EPR spectra depends on the ratios of E_{JT}, $\hbar\omega$, and Δ.

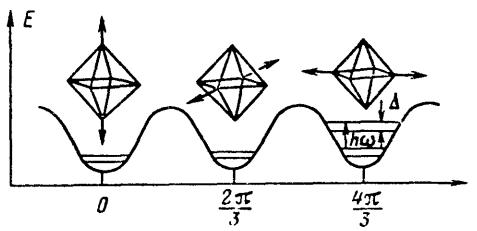

Figure 8. Potential surface corresponding to the distortions of an octahedral complex along three axes: $\hbar\omega$ = energy of vibrational quantum; Δ = tunnel splitting.

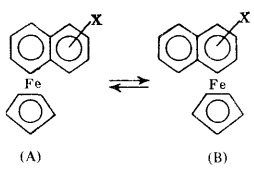
Numerous data on the manifestation of the Jahn–Teller effect in the EPR spectra have been obtained for crystals containing the Cu^{2+} ion. The characteristic features of this manifestation are as follows. At high temperatures the spectrum is characterised by an isotropic g-factor of ~2.2. As the temperature is reduced, the form of the spectrum changes reversibly with temperature in a certain transition region. The temperature range in which this occurs is different for different salts and is usually below 60 K, most frequently in the range from 40 to 4 K. At temperatures below the transition region three different spectra with anisotropic g-factors ($g_\parallel \cong 2.4$, $g_\perp \cong 2.1$) are observed; these spectra have axial symmetry relative to each of three mutually perpendicular fourfold axes of the complex CuY_6. A characteristic feature of the behaviour of the spectrum in the transition region is the simultaneous existence of anisotropic and isotropic spectra. With increase of temperature, the intensity of the lines of the first spectrum falls and that of the second increases.

Within the framework of the qualitative description of the Jahn–Teller effect presented above, the temperature-induced changes in the spectra of CuY_6 are described as follows. If $E_{JT} > \hbar\omega$ and the temperature is below the transition region, then the distortion of the octahedron is stable. The system is in one of the minima. Since an increase in the length of one of the three axes of the octahedron takes place at random, the observation of three anisotropic spectra corresponds to their random orientation relative to the direction of the magnetic field. An increase of temperature leads to the population of the excited vibrational states. Whereas the tunnel splitting is small in the zeroth vibrational level, in the excited states it increases sharply, as a result of which the distortion of the complex ceases to be stable and begins to move along its axes. If the quantity $\gamma_e(g_\parallel - g_\perp)\mu_\sigma H$ (γ_e is the gyromagnetic ratio of the electron) is smaller than $1/\tau$ (the rate of transition between equivalent distortions), then one line corresponding to $\bar{g} = 1/3(g_\parallel + 2g_\perp)$ will be recorded in the spectrum. On the other hand, if $E_{JT} < \hbar\omega$, the distortion is unstable within the limits of a single minimum however low the temperature. The Jahn–Teller effect influences not only the form of the EPR spectrum but also the g-factors and the HFI constants.

The influence of the Jahn–Teller effect on the low-spin d^5 and d^7 states of metallocenes has been investigated in studies[54,55] dealing with cobaltocene, manganocene, ferrocenium cations, and nickelocenium cations. Paramagnetic complexes have been investigated in a large number of different diamagnetic crystal lattices in order to estimate the influence of the asymmetric environment on the parameters of the spin-Hamiltonian. For all the orbitally degenerate d^5 and d^7 complexes, an appreciable dependence of the g-tensor on the structure of the crystal lattice has been observed. On the other hand, the absence of the sensitivity by the magnetic parameters to the molecular environment is characteristic of orbitally non-degenerate complexes [vanadocene, $d^3(^4A_{1g})$].

When the Jahn–Teller effect is taken into account, the g-factor is found to depend on the selected orbital moment quenching factor V in addition to its dependence on the low-symmetry distortion δ. The formula quoted above assumes the following form for g_z of the ferrocenium cation with allowance for V: $g_z = 2 + 4KXV/(1 + X^2)^{1/2}$. In the absence of the Jahn–Teller effect, $V = 1$, tending to zero in the case of a strong linear Jahn–Teller effect. For the separate determination of KV and $X = -\zeta/\delta$, Ammeter and coworkers[54,55] used terms of the spin-Hamiltonian other than g_z. The determination of the factor V as a function of the parameter δ in various crystal lattices showed that the dynamic Jahn–Teller motion of a free molecule is suppressed by the increasing asymmetric fields of the matrix. Systematic variation of the lattice structure and the introduction of substituents into the cyclopentadienyl ring made it possible to observe a gradual transition from the purely dynamic Jahn–Teller effect to the limiting case of a static distortion of the complexes. Extrapolation to the case of a free molecule ($\delta = 0$) shows that, for all the orbitally degenerate systems investigated, the distortion of the C_5H_5 rings remains fully dynamic, i.e. the Jahn–Teller stabilisation energy E_{JT} does not exceed the energy of the quantum $\hbar\omega$ corresponding to the active vibration. Ammeter and coworkers[54,55] considered different types of vibrations and indicated those which are active as regards the formation of a linkage between the electronic and vibrational motions.



There are indications of the possibility of the existence also of the static Jahn–Teller effect in metallocenes. X-Ray diffraction analysis of decamethylferrocene $[d^6(^1A_{1g})]$ and decamethylmanganocene $[d^5(^2E_{2g})]$ revealed a distortion of the symmetry for the orbitally degenerate manganocene complex[56].

A pattern analogous to that observed in the case of Cu^{2+} ions has been observed in the study of the EPR spectra of naphthalenecyclopentadienyliron[57]. The anisotropic signal at 77 K ($g_\parallel = 2.09$, $g_\perp = 2.006$) is converted into an isotropic signal at 150 K with $\bar{g} = 1/3(g_\parallel + 2g_\perp)$. Averaging of the anisotropy of the g-factor with increase of temperature has

also been observed for other arenecyclopentadienyliron complexes near the melting point of 1,2-dimethoxyethane (−70 °C), in which these complexes have been obtained by reducing the corresponding cations with sodium[25].

The possibility of the manifestation of the Jahn–Teller effect in arenecyclopentadienyliron complexes is determined by the quasi-degenerate nature of the iron states $d^7(^2E_{1g})$, split owing to the low-symmetry interaction with the arene ligand. A characteristic feature of the chemical bond in the given compounds compared with the dicyclopentadienyl compounds consists in the fact that the symmetries of the molecular wave functions of the arene and cyclopentadienyl ligands are different. For this reason, the common molecular orbitals leading to the formation of a chemical bond are formed only from the fully symmetrical molecular orbitals of the ligands. Other (higher) occupied orbitals consist only of combinations of the atomic orbitals of the iron atom with the molecular orbitals of the cyclopentadienyl ring[58]. In the fully symmetric molecular wave function of naphthalene, the maximum electron density corresponds to the 9- and 10-positions and one can assume that an energy minimum in the neutral complex corresponds to the symmetrical position of the iron atom when no account is taken of the Jahn–Teller effect. The distortion of this symmetrical structure associated with the shift of the iron atom towards the centre of one of the benzene rings of naphthalene can lead to the appearance of two potential energy minima located symmetrically relative to the bond between the carbon atoms in the 9- and 10-positions. The tunnelling of the iron atom between these two minima in combination with the rotation of the naphthalene ligand about the bond between naphthalene and the iron atom should lead to the averaging of the anisotropy of the g-factor.

In order to confirm the above model of motion, the EPR spectra of α-$CH_3C_{10}H_7FeC_5H_5$ and β-$FC_{10}H_7FeC_5H_5$ were obtained[57]. At 77 K their spectra do not differ from that of $C_{10}H_8FeC_5H_5$. With increase of temperature, the $g_\parallel$ signals in the spectra of α-$CH_3C_{10}H_7FeC_5H_5$ and β-$FC_{10}H_7FeC_5H_5$ are split into two components. The appearance of two $g_\parallel$ signals was attributed to the existence of two isomers (A) and (B):

At 77 K only the single isomer (A) exists, being the most stable, while with increase of temperature the isomer (B) also arises as a result of the migration of the iron atom. The quantity $g_\parallel^A - g_\parallel^B$ corresponds to the energy difference $\Delta E_{AB} \cong 200$ cm^{-1}. The energy of the vibrational quantum (300 cm^{-1}) and the tunnel splitting (1 – 3 cm^{-1}) were determined from the temperature variation of the EPR spectrum of $C_{10}H_8FeC_5H_5$.[57]

VI. THE ELECTRONIC STRUCTURE OF METALLOCENES AND THE MECHANISM OF SPIN DELOCALISATION

In combination with electronic absorption spectroscopic, photoelectron spectroscopic, and γ-spectroscopic data as well as the results of quantum-chemical calculations, the magnetic resonance data presented make it possible to describe fairly completely the entire scheme of the energy levels of metallocenes and fit qualitatively quite well within the general sequence of the energy levels of metallocenes: $a_{1g} \leqslant e_{2g} \ll e_{1g}^*$. A quantitative description of the above scheme based on experimental data is impossible in the absence of theoretical analysis.

The d–d transition bands in the electronic absorption spectra of the d^6 metallocenes $Fe(C_5H_5)_2$, $Ru(C_5H_5)_2$, and $Co(C_5H_5)_2^+$ were analysed within the framework of the ligand field theory[59]. The following one-electron parameters characterising the energy level scheme were obtained: $\Delta_1 = \varepsilon(e_{2g}) - \varepsilon(a_{1g}) = 7000$ cm^{-1} and $\Delta_2 = \varepsilon(e_{1g}^*) - \varepsilon(a_{1g}) \cong 22000 - 30000$ cm^{-1}. The result $e_{2g} < a_{1g}$ conflicts with the EPR data for ferrocenium, the ground state of which is $^2E_{2g}$. According to non-empirical calculations for ferrocene, $e_{2g} > a_{1g}$.[60] Within the framework of non-empirical calculations for ferrocene, considerable differences (10000 cm^{-1}) arise on comparing the energies of the d–d transition bands with the differences between the total energies of the ground and excited states and the difference between the energies of the "frozen" molecular orbitals. Although the first method is more rigorous, it is difficult to give preference to it from the standpoint of agreement with experiment[60]. In the theoretical analysis of the ionisation potentials, the above differences reach approximately 6 eV, which makes it necessary to treat with caution the estimate of the distance between different orbitals from the difference between the ionisation potentials (the Koopmans theorem). The principal source of the large differences is the contribution of the electronic relaxation and of the energy of the rearrangement of the electron cloud on ionisation of the complex[61].

Analysis of the charge-transfer bands makes it possible to estimate the distance from the energy levels of the metal to the levels of the ligand[59,60]. The bands of the d–d transitions between the a_{1g}, e_{2g}, and e_{1g}^* orbitals and the charge-transfer bands are in the visible and ultraviolet regions. According to the available data, the possible transitions between the a_{1g} and e_{2g} orbitals occur in the red and infrared regions. One of the infrared bands (200 cm^{-1}) in the ferrocenium spectrum has been assigned to the electronic transition between the $^2E_2$ and $^2A_1$ states[62].

Thus the fundamental energy level scheme for sandwich compounds has now been firmly established and is quite fully characterised in quantitative terms. A compilation of the electronic states of certain complexes, based on the analysis of theoretical and experimental data, has been published[24] (Table 9).

Table 9. The electronic configurations of various metallocenes and diarene complexes.

Complex	No. of d electrons	Electronic configuration	Ground state
$V(Cp)_2$	3	$(e_{2g})^2(a_{1g})^1$	$^4A_{1g}$
$Cr(Cp)_2$	4	$(e_{2g})^3(a_{1g})^1$	$^3E_{2g}$
$V(C_6H_6)_2^+$	4	$(e_{2g})^3(a_{1g})^1$	$^3E_{2g}$
$Cr(C_6H_6)_2^+$	5	$(e_{2g})^4(a_{1g})^1$	$^2A_{1g}$
$Fe(Cp)_2^+$	5	$(a_{1g})^2(2_{2g})^3$	$^2E_{2g}$
$V(C_6H_6)_2$	5	$(e_{2g})^4(a_{1g})^1$	$^2A_{1g}$
$Cr(C_6H_6)_2$	6	$(e_{2g})^4(a_{1g})^2$	$^1A_{1g}$
$Fe(Cp)_2$	6	$(e_{2g})^4(a_{1g})^2$	$^1A_{1g}$
$Fe(C_6(CH_3)_6)_2^+$	6	$(e_{2g})^4(a_{1g})^2$	$^1A_{1g}$
$Co(Cp)_2$	7	$(e_{2g})^4(a_{1g})^2(e_{1g})^1$	$^2E_{1g}$
$Fe(C_6(CH_3)_6)_2^+$	7	$(e_{2g})^4(a_{1g})^2(e_{1g})^1$	$^2E_{1g}$
$Ni(Cp)_2$	8	$(e_{2g})^4(a_{1g})^2(e_{1g})^2$	$^3A_{1g}$
$Co(C_6(CH_3)_6)_2^+$	8	$(e_{2g})^4(a_{1g})^2(e_{1g})^2$	$^3A_{1g}$
$Ni(C_6(CH_3)_6)_2^+$	8	$(e_{2g})^4(a_{1g})^2(e_{1g})^2$	$^3A_{1g}$

The most complex problem in the description of the electronic structure of the compounds considered here is the mechanism of the delocalisation of spin density. The attempts undertaken hitherto at the calculation of the distribution of spin density cannot be regarded as satisfactory,

because they were based solely on the idea of the competition between processes involving delocalisation via the π and σ bonds[63]. ^{13}C NMR data for metallocenes showed that the delocalisation pattern is more complex. It is seen from a comparison of the ^{13}C NMR spectra of various metallocenes that, depending on the nature of the metal, not only the magnitude but also the sign of the paramagnetic shift changes. Whereas the shift is negative for nickelocene and cobaltocene, it is positive for vanadocene and chromocene, which corresponds to a negative spin density of the unpaired electron on the carbon atom. Although the signs of the shifts of the proton signals of metallocenes are correlated with the signs of the shifts of the ^{13}C nuclei in accordance with the McConnell equation, a quantitative correspondence is not observed.

In order to account for the magnitude of the ^{13}C shifts, it was suggested that one assumes that they are determined by the sum of three contributions[64]:

$$\sigma^{c}_{obsd} = \sigma^{\pi}_{con} + \sigma^{\sigma}_{con} + \sigma_{dip} ,$$

where the σ^{π}_{con} contribution is of a complex type. It can include directly the unpaired electron density due to the exchange interaction between the 3*d* orbitals of the metal and the $2p_z$ orbitals of the ligands. This situation apparently arises in nickelocene and cobaltocene. However, the spin density can be displaced onto the carbon atoms also via a different pathway resulting from an indirect polarisation mechanism. The polarisation mechanism operates in those cases where the degree of direct conjugation is slight or zero. According to the theory[65], the interaction of the unpaired electron with the electrons in the occupied orbitals results in the motion of electrons with α- and β-spins in somewhat different orbitals. The summation of the spin densities over all the occupied orbitals results in the possibility of the appearance of a spin density at an individual atom with both positive and negative signs. It is believed[64] that the polarisation of the atomic orbitals of the metal and their interaction with the π orbitals of the ligands leads to the appearance of a negative spin density on the carbon atoms in vanadocene and chromocene.

Although the exchange polarisation does predominate in the transfer of spin density to the carbon atoms of vanadocene and chromocene, the available data show that there is a simultaneous direct delocalisation of the positive spin density via the σ orbitals, which leads to a negative contribution to the shift of the ^{13}C NMR lines. This effect is manifested by a smaller ratio of the shifts of the ^{13}C and ^{1}H lines, which is −2 for vanadium compared with −4.5 for nickel[64].

Direct exchange between the 3*d* electrons of the metal and the σ orbitals located in the plane of the cyclopentadienyl rings should lead to higher HFI constants as a consequence of the significant *s* character of these orbitals. The pseudo-contact contribution is apparently small for vanadocene and chromocene, since they are in the *A* states and the degree of anisotropy of their *g*-factors is small. However, this contribution can be appreciable for chromocene and cobaltocene.

The separation of the contributions determining the HFI constants and the contact shifts of the ^{13}C and ^{1}H lines is important for the understanding of the nature of the aromaticity and the properties of the π-electron system of the complexes investigated, particularly in the case of substituted metallocenes and diarene complexes. The results exhibit significant differences between the properties of the free ligands and the ligands in the complexes.

Measurements were made of the paramagnetic shifts in the ^{13}C and ^{1}H NMR spectra of symmetrical polymethyl-substituted ferrocenium cations. The isolation of the contact (Fermi) and pseudo-contact (dipole–dipole) terms showed that the signs of the contact shifts for the carbon atoms of the cyclopentadienyl rings vary in a complex manner as a function of the number and positions of the methyl groups[66,67]. When one methyl group is introduced, the sign of the contact shift changes from negative to positive only at the carbon atom linked to the CH_3 group. When four methyl groups are introduced, the contact shifts at all the carbon atoms, with the exception of the unsubstituted atom, acquire positive signs. If the number of methyl groups in the cyclopentadienyl ring is 0, 2, 3, and 5, then a negative contact shift is characteristic of all the carbon atoms in the ring. In order to explain the complex distribution of spin density, it proved necessary to take into account, apart from the competition between different delocalisation mechanisms mentioned above, the thermal population of the close vacant *d* orbitals by the unpaired electron and the influence of the splitting of the degenerate levels of the molecular π orbitals of cyclopentadienyl under the influence of substituents.

---o0o---

The analysis of the experimental and theoretical studies on sandwich compounds indicates a considerable progress in the understanding of the nature of the complex organometallic chemical bond. The many-electron nature of this bond determines the existence of a large number of interesting effects, vigorous investigation of which is being continued.

A Hydrodynamic Invariant of Polymeric Molecules

V.N.Tsvetkov, P.N.Lavrenko, and S.V.Bushin

Theories of the hydrodynamic properties of macromolecules in solution are examined, from which the invariant relation $A_0 = k\eta_0(M[\eta]/100)^{1/3}f$ can be obtained between the intrinsic viscosity $[\eta]$, the molecular mass M, and the coefficient of sliding friction of the molecule f. Analysis of the experimental results will indicate the most probable values of the invariant A_0 for various classes of polymers. A list of 314 references is included.

I. INTRODUCTION

Determination of the molecular mass of a polymer is one of the most important problems in research on macromolecular compounds. Two "absolute" methods—light scattering and sedimentation–diffusion analysis of the polymer in solution—can usually be successfully applied[1]. However, neither method is effective with many polymers commonly used at the present time, which dissolve only in highly specific solvents[2]. The molecular masses of such polymers must therefore be found from certain hydrodynamic characteristics of their molecules, which can be determined experimentally with adequate reliability. Such characteristics are primarily the intrinsic viscosity $[\eta]$ and the coefficient of sliding friction of the molecule f, the latter determined from diffusion in solution.

II. CONCEPT OF THE HYDRODYNAMIC INVARIANT

Both intrinsic viscosity $[\eta]$ and coefficient of friction f are related to the molecular mass M or the contour length of the molecular chain $L = \lambda M/M_0$ (where λ is the projection of a monomer unit in the direction of the chain) by the well known formulae[1,3]

$$[\eta] = \Phi(LA)^{3/2}/M \qquad (1)$$

$$f = kT/D = P\eta_0(LA)^{1/2} \qquad (2)$$

in which D is the coefficient of translational diffusion of the polymer at infinite dilution, η_0 the viscosity of the solvent, A the Kuhn segment length representing the equilibrium rigidity of the polymer chain, M_0 the molecular mass of a monomer unit, k Boltzmann's constant, T is the temperature, and Φ and P are hydrodynamic coefficients depending on L, A, and certain other parameters such as intramolecular hydrodynamic interaction and effects of the excluded volume in non-ideal (non-θ) solvents. Calculation of the functions Φ and P is the main object of theories of the hydrodynamic properties of macromolecules in solution[3]. If the coefficient of friction f is determined experimentally not from diffusion but from sedimentation measurements, formula (2) is replaced by the equivalent expression

$$f = (M/sN_A)(1-\bar{v}\rho) = P\eta_0(LA)^{1/2} \qquad (3)$$

in which s is the sedimentation coefficient at infinite dilution, N_A Avogadro's number, $\bar{v}$ the specific partial volume of the polymer in solution, and ρ the density of the solvent.

Each of the relations (1)–(3) contains, in addition to one quantity that can be measured experimentally ($[\eta]$, D, or s), two molecular characteristics A and L (or $M = LM_0/\lambda$), which determine the equilibrium rigidity and the molecular mass respectively of the polymer chain. In order that the molecular mass can be found from experimental values of intrinsic viscosity or coefficient of friction, it is therefore necessary that both A and the form of function $\Phi(L, A)$ or $P(L, A)$ should be known for the given polymer. Since such data are usually absent for a newly investigated polymer, neither viscometry, measurement of diffusion coefficient, nor rapid sedimentation can usually serve in isolation as an independent method (not involving preliminary calibration) for determining the molecular mass of the polymer. However, use of two independently determined experimental quantities in Eqns.(1)–(3), with simultaneous solution of the appropriate pair of these equations, may yield an expression that does not contain the product LA in explicit form. Thus the two formulae (2) and (3) will give Svedberg's equation, from which are absent not only LA but also the parameters Φ and P and which serves as the chief absolute method for determining molecular mass from combined sedimentation and diffusion data.

Elimination of LA from formulae (1) and (2) yields the relation

$$kP^{-1}(\Phi/100)^{1/3} = \eta_0 D(M[\eta]/100)^{1/3}T \equiv A_0 \qquad (4)$$

while the use of Eqns.(1) and (3) for this purpose gives

$$kP^{-1}(\Phi/100)^{1/3} = R\eta_0(1-\bar{v}\rho)^{-1}M^{-2/3}([\eta]/100)^{1/3}s \equiv A_0 . \qquad (5)$$

The expression on the right-hand side of (4) was first discussed by Vallet[4,5], who measured diffusion coefficients and intrinsic viscosities for polystyrene fractions differing in molecular mass, and showed that the product $(M[\eta])^{1/3}D\eta_0$ was invariant in a series of these fractions. He explained this rule by regarding the polymer molecule as a solid sphere and applying to it the Stokes and Einstein laws to describe the diffusion and viscosity phenomena of polymer solutions. A little later Mandelkern and Flory[6] based the invariance of (5) on a chain molecule regarded as a hydrodynamically impermeable sphere of radius proportional to the mean square distance between the ends of the chain $\langle h^2\rangle^{1/2}$, with both P and Φ considered to be universal constants for all polymers.

At the same time Tsvetkov and Klenin[7], using the Debye–Bueche model of a partly permeable sphere[8], showed that the parameter A_0 (Eqn.4) can in principle be invariant over a

wide range of molecular masses even with appreciable permeability of the molecular coil, i.e. under conditions such that P and Φ do not individually remain constant with variation in molecular mass. They illustrated the invariance of A_0 by measuring D and $[\eta]$ of polystyrene fractions in dichloroethane over the molecular-weight range $(250-1320) \times 10^3$ g mole^{-1} and determining the corresponding value $A_0 = (3.42 \pm 0.06) \times 10^{-10}$ erg deg^{-1} mole$^{-1/3}$. From this they concluded[7] that it was possible and advisable to determine the molecular masses of polymers from viscosimetric data and the measured diffusion coefficient of their solutions by means of formula (4) and the above value of A_0.

In order to demonstrate the possibility of using this method it is necessary to analyse in greater detail the properties of the polymer–solvent system that ensure invariance of the hydrodynamic parameter A_0.

III. THEORY OF THE HYDRODYNAMIC PROPERTIES OF MACROMOLECULES

1. Chain Length and Hydrodynamic Interaction

If a solution is present under θ-conditions and the conformation of a molecular chain can be regarded as a Gaussian coil (i.e. $\langle h^2 \rangle = LA$), expressing P and Φ in formula (4) in terms of the theory of sliding friction and Kirkwood–Riseman viscosity[9] respectively yields for A_0 the expression

$$A_0 = \frac{k}{6\pi}(N_A/100)^{1/3} F(\sigma) \tag{6}$$

$$F(\sigma) = \frac{1+(8/3)\sigma}{\sigma}\left[\frac{\sigma}{1+(2/3)\sigma}\right]^{1/2} \tag{7}$$

in which

$$\sigma = \frac{3}{\sqrt{6\pi}} \cdot \frac{d}{\lambda}\left(\frac{L}{A}\right)^{1/2} \tag{8}$$

is a parameter representing the intramolecular hydrodynamic interaction. It follows from (6)–(8) that A_0 is a function of the relative chain length L/A, the length of a monomer unit λ in the direction of the chain, and its hydrodynamic diameter d (i.e. the diameter of a sphere representing a monomer unit for sliding friction).

For a polymeric homologous series (d/λ constant) the dependence of A_0 on chain length L can be readily ascertained by analysing the expressions (6)–(8). With increase in L/A and hence in the parameter σ the function $F(\sigma)$ tends to the limit $F(\sigma)_\infty = (8/3)(3/2)^{1/3} = 3.053$, while A_0 tends to $A_\infty = 4.1 \times 10^{-10}$ erg deg^{-1} mole$^{-1/3}$ (or 4.1×10^{-17} J deg^{-1} mole$^{-1/3}$). With very small L/A values and hence $\sigma \ll 3/8$, on the other hand, it follows from (7) that $F(\sigma) \approx \sigma^{-2/3}$ and $A_0 \to \infty$ as $L/A \to 0$, as noted previously[1]. Thus, according to theory[9], at sufficiently low values of L/A the parameter A_0 is by no means invariant but increases with decrease in chain length. Since, however, $d/\lambda \approx 1$, it is readily seen that this increase becomes appreciable only when $L/A < 1$: for example, with $L/A = 0.5$ the value of A_0 exceeds A_∞ by only 10%; throughout the remaining range of values $1 < L/A < \infty$, it follows from (6)–(8) that A_0 is indeed invariant, differing from A_∞ at most by tenths percent.

It must be borne in mind, however, that the hydrodynamic properties of polymer chains in the range $L/A \leq 1$ cannot be discussed in terms of a theory[9] that regards a polymer molecule as a Gaussian chain, which assumes that $L/A \gg 1$.

Hence theories of the hydrodynamic properties of vermiform chains must be used to discuss the dependence of A_0 on chain length throughout the range of possible values of L/A. The best hydrodynamic model of a chain molecule in a θ-solvent may be a vermiform cylinder of contour length L and diameter d, the ends of which are bounded by hemispheres[10,11].

With this model expressions have been obtained for the parameters P and Φ as functions of the relative length L/A and the relative diameter d/A of the chain molecule[10–13]. They can be written as the ratios P_∞/P and Φ/Φ_∞, where $P_\infty = 9/4(\pi/6)^{1/2}\pi = 5.11$ and $\Phi_\infty = 2.87 \times 10^{23}$ mole^{-1} are the asymptotic values of P and Φ as $L/A \to \infty$. In the range $L/A \geq 2.28$ we have[12]

$$\frac{P_\infty}{P} = 1 + \frac{B_2}{B_1}\left(\frac{L}{A}\right)^{-1/2} + \frac{B_3}{B_1}\left(\frac{L}{A}\right)^{-1} + \frac{B_4}{B_1}\left(\frac{L}{A}\right)^{-3/2} + \frac{B_5}{B_1}\left(\frac{L}{A}\right)^{-2} \tag{9}$$

where

$$B_1 = \frac{4}{3}\left(\frac{6}{\pi}\right)^{1/2} = 1.843;$$

$$B_2 = \left[-1-0.01412\left(\frac{d}{A}\right)^2 + 0.00592\left(\frac{d}{A}\right)^4\right]\ln\frac{d}{A} - 1.0561 - 0.1667\frac{d}{A} - 0.19\left(\frac{d}{A}\right)^2 - 0.0224\left(\frac{d}{A}\right)^3 + 0.019\left(\frac{d}{A}\right)^4;$$

$$B_3 = 0.1382 + 0.691\left(\frac{d}{A}\right)^2;$$

$$B_4 = -\left[0.04167\left(\frac{d}{A}\right)^2 + 0.00567\left(\frac{d}{A}\right)^4\right]\ln\frac{d}{A} - 0.3201 + 0.5\frac{d}{A} - 0.585\left(\frac{d}{A}\right)^2 - 0.0094\left(\frac{d}{A}\right)^3 - 0.0421\left(\frac{d}{A}\right)^4;$$

$$B_5 = -0.03 + 0.1209\left(\frac{d}{A}\right)^2 + 0.0259\left(\frac{d}{A}\right)^4.$$

The corresponding expression over the range $L/A \leq 2.28$ is[10]

$$\frac{P_\infty}{P} = \left(\frac{A}{L}\right)^{1/2} B_1^{-1}\left[C_1 \ln\frac{L}{d} + C_2 + C_3\frac{L}{A} + C_4\left(\frac{L}{A}\right)^2 + C_5\left(\frac{L}{A}\right)^3 + C_6\left(\frac{L}{A}\right)^4 + C_7\left(\frac{L}{A}\right)^5 + \ldots\right] \tag{10}$$

in which

$$C_1 = 1 - 0.125\frac{L}{d}\cdot\frac{d}{A} + 0.1406\frac{d}{L}\left(\frac{d}{A}\right)^3;$$

$$C_2 = 0.386 + 0.6863\left(\frac{d}{L}\right) - 0.0625\left(\frac{d}{L}\right)^2 - 0.01042\left(\frac{d}{L}\right)^3 - 0.000651\left(\frac{d}{L}\right)^4 + 0.0005859\left(\frac{d}{L}\right)^5;$$

$$C_3 = 0.1667 - 0.06838\left(\frac{d}{L}\right)^2 + 0.02083\left(\frac{d}{L}\right)^3 - 0.01693\left(\frac{d}{L}\right)^4 - 0.00859\left(\frac{d}{L}\right)^5;$$

$$C_4 = 0.01111 + 0.07917\left(\frac{d}{L}\right)^2 - 0.1799\left(\frac{d}{L}\right)^3 + 0.1055\left(\frac{d}{L}\right)^4 + 0.02461\left(\frac{d}{L}\right)^5;$$

$$C_5 = 0.001058 - 0.00496\left(\frac{d}{L}\right)^2 + 0.001653\left(\frac{d}{L}\right)^3 - 0.07348\left(\frac{d}{L}\right)^4 - 0.03281\left(\frac{d}{L}\right)^5;$$

$$C_6 = 0.0001587 - 0.0007275\left(\frac{d}{L}\right)^2 + 0.0003638\left(\frac{d}{L}\right)^3 - 0.0863\left(\frac{d}{L}\right)^4 + 0.4\left(\frac{d}{L}\right)^5;$$

$$C_7 = 0.00003748 - 0.0001714\left(\frac{d}{L}\right)^2 + 0.0001142\left(\frac{d}{L}\right)^3 + 0.006183\left(\frac{d}{L}\right)^4 - 0.002897\left(\frac{d}{L}\right)^5.$$

The function Φ/Φ_∞ with $LA \leq 2.28$ can be calculated[11] by means of the formula

$$\frac{\Phi}{\Phi_\infty} = \frac{\pi N_A}{24\Phi_\infty}\left(\frac{L}{A}\right)^{3/2} F(p)\cdot f\left(\frac{L}{A}\right) \tag{11}$$

in which $p = L/d$, $\Phi_\infty = 2.87 \times 10^{23}$ mole^{-1}, and

$$F(p) \equiv F\left(\frac{L}{A}, \frac{A}{d}\right) = \frac{16}{15}\left\{\ln p + 2\ln 2 - \right.$$
$$- \frac{25}{12} + \frac{\ln 2}{\ln(p+1)}\left[\frac{8}{75} - 2\ln 2 + \frac{25}{12} - 4.970572\right] + \frac{3.60517}{p^{1/4}} - \frac{15.35634}{p^{1/2}} +$$
$$\left. + \frac{28.0617}{p^{3/4}} - \frac{14.8934}{p} + \frac{3.553442}{p^{5/4}}\right\};$$

$$f(L/A) = 1 - 0.321593\frac{L}{A} - 0.0466384\left(\frac{L}{A}\right)^2 + 0.106466\left(\frac{L}{A}\right)^3 -$$
$$- 0.0379817\left(\frac{L}{A}\right)^4 + 0.00399576\left(\frac{L}{A}\right)^5 .$$

Values of Φ in Table 1 of Ref. 13 can be used to calculate Φ/Φ_∞ over the range $L/A \geq 2.28$.

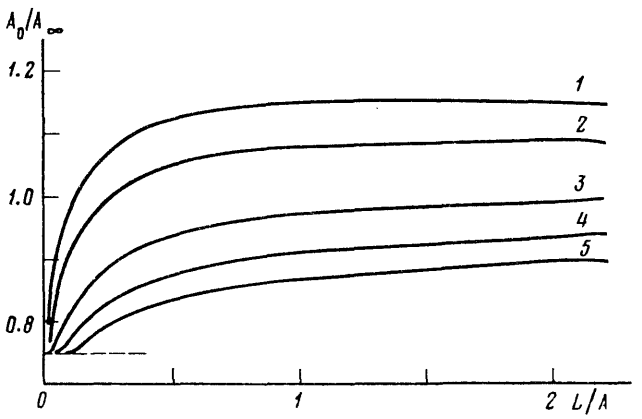

Figure 1. Dependence of A_0/A_∞ on relative length L/A of a vermiform chain in the range of low values $L/A = 0-2$ for different relative chain diameters d/A: *1*) 0.005; *2*) 0.01; *3*) 0.03; *4*) 0.06; *5*) 0.1.

Calculations based on Eqns. (9)–(11) enable the parameter $A_0 = kP^{-1}(\Phi/100)^{1/3}$ to be determined throughout the range of possible values of L/A and A/d. The results thus obtained for $A_0/A_\infty = (P_\infty/P)(\Phi/\Phi_\infty)^{1/3}$ are listed in Table 1 and illustrated by the curves in Figs. 1 and 2. The upper limit to A_0 predicted by theory[12,13] is $A_\infty = kP^{-1}(\Phi_\infty/100)^{1/3} = 3.84 \times 10^{-10}$ erg deg^{-1} mole$^{-1/3}$. A finite limiting value of A_0 at low L/A is also predicted by theory[10,11], and is obtained from formulae (10) and (11) by putting $L/A = d/A \to 0$. We then find that $\lim_{L/A \to 0}(A_0/A_\infty)$ and $\lim_{L/A \to 0} A_0$ are respectively 0.75 and 2.88×10^{-10} erg deg^{-1} mole$^{-1/3}$.

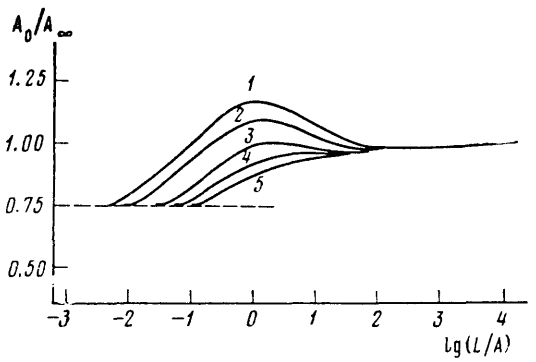

Figure 2. Dependence of A_0/A_∞ on L/A over a wide range for a vermiform chain having the same relative diameters d/A as in Fig. 1.

Table 1 together with Figs. 1 and 2 shows that according to theory[10,11] the parameter A_0 is invariant and close to A_∞ for all polymers in the range $L/A > 20$, where the molecule has a coiled conformation. With flexible-chain polymers ($d/A > 0.1$) in the range $L/A < 20$ a monotonic decrease in A_0 to its lower limit (i.e. by 25%) must be expected with decrease in chain length. In the case of polymers having moderately rigid chains ($0.1 \geq d/A \geq 0.03$) this decrease begins at lower values of L/A and is most developed in the range $L/A \leq 1$. Finally, the theory predicts for polymers of high equilibrium chain rigidity ($d/A \leq 0.01$) a non-monotonic dependence of A_0 on L/A in the region of short chains: A_0 increases with decrease in L in the range $L/A < 10$, reaches a maximum in the region of $L/A \approx 1$, and then drops abruptly to a lower limit. Thus in the region of short chains ($L/A \leq 10$), where A_0 can be expected to change with L/A, theory[10,11] indicates that a more rigid polymer has a rather higher value of A_0. This last conclusion is consistent with calculations[13] of A_0 for the range $L/A \geq 10$.

2. Excluded-volume Effects

If the conditions of a polymer solution are non-θ, osmotic swelling of the molecular coil may in principle influence not only P and Φ but also A_0, since change in molecular conformation in a thermodynamically "good" solvent is associated with change in intramolecular hydrodynamic interaction.

In the original form of Flory's theory of volume effects it was assumed that, on extension of a molecular coil in a "good" solvent and with increase in its linear dimensions (i.e. $\langle h^2 \rangle^{1/2}$) by a factor α, the coefficient of sliding

friction f also increases by this factor, while the intrinsic viscosity increases by a factor α^3. Hence P and Φ in formulae (1) and (2)—and thus also A_0 in (4)—were regarded as universal constants, remaining unchanged when a θ-solvent was replaced by a "good" solvent.

Later, however, it proved necessary to assume, in order to explain experimental results obtained for solutions of flexible-chain polymers, that linear extension of a molecular coil by a factor α was accompanied by change in f by a factor α_f, and in $[\eta]$ by a factor α_η^3, with both α_f and α_η smaller than α. Therefore the values of P and Φ in a "good" solvent should be less than their limiting values P_∞ and Φ_∞ in a θ-solvent, in conformity with the equations

$$P/P_\infty = \alpha_f/\alpha \; ; \; \Phi/\Phi_\infty = (\alpha_\eta/\alpha)^3 \; . \qquad (12)$$

Theories of volume effects in solutions of flexible-chain polymers and their influence on P and Φ were developed in a series of papers[3]. Although the results of different theories in several cases are by no means in quantitative agreement, they all lead to analogous qualitative conclusions: (i) both P and Φ diminish under the influence of volume effects; and (ii) increase in α produces a greater change in Φ than in P. For example, in an approximate calculation Kurata and Yamakawa obtained[3]

$$\Phi/\Phi_\infty = 1-0.46\,z+\ldots, \quad P/P_\infty = 1-0.22\,z \qquad (13)$$

where z is the excluded-volume parameter. Equation (13) yields the relation

$$A_0/A_\infty = (1-0{,}46\,z)^{3/2}/(1-0{,}22\,z) = 1+0.07\,z \qquad (14)$$

between A_0 in a "good" solvent and A_∞ in a θ-solvent. According to Ref.14 volume effects produce a slight increase in A_0. On the other hand, if results obtained by Fixman[15] ($\Phi/\Phi_\infty = 1-0.2z$) and by Stockmayer and Albrecht[16] ($P/P_\infty = 1-0.03z$) are used, the ratio $A_0/A_\infty = 1-0.04z$ is found, which predicts a slight decrease in A_0 under the influence of volume effects. In view of the above it is evident that, even if volume effects in solutions of flexible-chain polymers do lead to changes in A_0, such changes are so insignificant that they cannot be reliably predicted by existing theories.

Table 2. Theoretical values of Φ_∞ and corresponding values of A_∞ ($P_\infty = 5.11$).

$10^{-23}\Phi_\infty$, mole^{-1}	$10^{10}A_\infty$, erg deg^{-1} mole$^{1/3}$	Ref.	$10^{-23}\Phi_\infty$, mole^{-1}	$10^{10}A_\infty$, erg deg^{-1} mole$^{1/3}$	Ref.
3.62	4.1	[9]	2.68	3.75	[23]
3.37	4.0	[20]	2.76	3.79	[24]
2.87	3.83	[21]	2.19	3.51	[25]
2.84	3.82	[22]	2.51	3.43*	[26]

*$P_\infty = 5.99$.

It has been shown experimentally[17] and confirmed theoretically[18] that the influence of volume effects on molecular conformation is considerably weaker with polymers having molecular chains of enhanced rigidity than with flexible-chain polymers. In practice this means that even in "good" solvents the coefficient α in formula (12) is close to unity, and still more that α_η and α_f are close to α. It can thus be expected that for rigid-chain polymers the parameters P, Φ, and A_0 will be extremely insensitive to volume effects, although Hearst's theory[14] predicts some increase in A_0 with increase in the excluded volume.

3. Numerical Values of the Constants P_∞, Φ_∞, and A_∞

It follows from Eqn.(4) that the value of A_∞ predicted by theory depends on the theoretical values of P_∞ and Φ_∞. Both the latter were first calculated, in terms of the theories of sliding friction and Kirkwood–Riseman viscosity[9], by "pre-averaging" the Oseen hydrodynamic interaction tensor T_{ik} (i.e. by averaging T_{ik} over all chain conformations before using it to calculate f or $[\eta]$). To this approximation the value $P_\infty = 5.11$ was obtained, later refined to 5.2,[19] practically identical with the former value, which is usually employed in modern work.

Calculation of Φ_∞ involves several model concepts and mathematical approximations, depending on the character of which different authors have obtained different results (Table 2, first column). The calculated values show a chronological tendency to decrease, in some measure because in the later calculations the authors attempted to avoid pre-averaging T_{ik}, which always leads to rather lower values of Φ_∞. The lowest value $\Phi_\infty = 2.19 \times 10^{23}$ mole^{-1} was obtained by Hearst and Tagami[25], who differed from all tne other investigators in using as molecular model a vermiform instead of a Gaussian chain.

Values of A_∞ in the second column of Table 2 have been calculated by means of Eqn.(4) from the corresponding value of Φ_∞ and $P_\infty = 5.11$ (apart from the last line, in which it is assumed that $P_\infty = 5.99$).

Values in the last line in Table 2 were obtained by Zimm[26], who made a thorough review of the effect of pre-averaging the hydrodynamic interaction in chain molecules on the calculation of coefficient of friction and intrinsic viscosity. Using the Monte Carlo method and generating in a computer experiment a set of random configurations of the polymer chain, he solved the problem of hydrodynamic interactions in sedimentation and viscosity phenomena for each configuration, and only then averaged the results. The values of Φ_∞, P_∞, and A_∞ thus obtained, extrapolated to a chain having an infinite number of segments, are included in Table 2. The values of Φ_∞ and A_∞ proved to be smaller, but those of P_∞ were larger, than the values usually employed. The value $P_\infty = 5.99$ appears most unusual, but it is noteworthy that at one time Kuhn et al.[27] obtained the still higher value $P_\infty = 7.3$ from experiments with wire models.

The above values of P_∞, Φ_∞, and A_∞ apply to a polymer that is homogeneous with respect to molecular mass. The presence of molecular-mass polydispersity in a specimen may be expected to lead to a decrease in Φ.[28] The parameter A_∞ also depends on polydispersity, and may be either diminished or increased depending on the way in which the experimental quantities D, s, $[\eta]$, and M in Eqns.(4) and (5) have been averaged[29,30]. However, the variations in A_∞ to be expected in moderately polydisperse specimens are small[29], and in many cases can apparently be disregarded.

IV. EXPERIMENTAL RESULTS

1. Values of Φ and P

It follows from Eqns.(1)–(3) that experimental determination of the coefficient Φ or P separately requires the measurement of two or three molecular characteristics. One of these must necessarily be the radius of inertia of the chain molecule, which for a polymer of sufficiently high molecular mass in a θ-solvent is $\langle R\rangle = (LA/6)^{1/2}$. Measurement of this radius, which is based on the asymmetry of light scattering, is a most difficult experimental procedure, always entailing the possibility of considerable errors and

inaccuracies. Incidentally, the method of light scattering permits determination of a second quantity—the molecular mass M—occurring in Eqns.(1) and (3). Finally, the third quantity which must be measured experimentally is either the intrinsic viscosity (for the determination of Φ by means of Eqn.1) or the sedimentation coefficient s (if P is determined from formula 3). When the latter is determined by means of (2), it is necessary to measure the diffusion coefficient D in addition to the radius of inertia, but the molecular mass is not required in this case.

**In cyclohexene ("good" solvent) at 25 °C.

Since viscometry is a considerably more accessible procedure than measurement of sedimentation or diffusion coefficients, the majority of the experimental work has involved the determination of Φ by means of formula (1). In most cases polystyrene having a narrow molecular-mass distribution was used in a θ-solvent. Table 3 gives several typical results of such measurements. The experimental values show a considerable scatter. However, they do indicate that, despite the quite high molecular masses of the test specimens, the values obtained for Φ were usually considerably lower than the theoretically predicted Φ_∞ values (Table 2). An unambiguous dependence of Φ on the nature of the solvent cannot be discerned from existing results[34].

Poly-α-methylstyrene	cyclohexane	34.5	5.5	43, 44

*Thermodynamically "good" solvent.

Published information on the experimental determination of P is extremely meagre, practically limited to the examples in Table 4. Four of the five experimental values of P exceed the 5.11 predicted by theory, and only one is lower. The difference between values of P for polystyrene in a "good" solvent and in a θ-solvent could be attributed[34] equally to an excluded-volume effect and to scatter due to experimental error. Thus the problem of reliable experimental values of Φ and P remains open, and requires further careful investigation.

Comparison of the experimental results in Tables 3 and 4 with the theoretical values in Table 2 indicates that Zimm's method[26], using the technique of a computer experiment and avoiding pre-averaging of the Ozeen tensor, gives better agreement between theoretical and experimental values of Φ and P than that obtained by other workers. In view of the great scatter and unreliability of available experimental results and also the difficulties of theoretical calculations, however, it seems premature to adopt Zimm's values as the most reliable and the preferred for use.

2. Values of A_0

Discrepancies in the experimental values of Φ and P obtained by different authors are due not only to polydispersity of the specimens (to which reference has often been made) but primarily and in no less degree to errors in the measurements of molecular dimensions $\langle h^2 \rangle$ or $\langle R^2 \rangle$ from the asymmetry of light scattering in solutions of the polymer. As already mentioned, calculation of A_0 from experimental results requires values of molecular mass, intrinsic viscosity, and coefficient of friction, while the procedure involved in determining $\langle R^2 \rangle$ is excluded. Therefore the accuracy and the reliability of the experimental determination of A_0 in principle exceeds considerably those of the determination of Φ and P.

If molecular mass is determined from the scattering of light (in which method asymmetry indicatrixes, though used, play a considerably less important part than in the measurements of $\langle R^2 \rangle$), the calculation of A_0 requires the determination of coefficient of friction in addition to the measurement of intrinsic viscosity. Such determination can be made by rapid sedimentation and A_0 calculated by means of formula (5); or diffusion measurements can be used for this purpose, and A_0 calculated by means of (4). In the latter method the accuracy with which the diffusion coefficient is measured becomes important, since in Eqn.(4) it is raised to a power thrice that of molecular mass and intrinsic viscosity.

If molecular weight is determined by a combination of the diffusion and rapid sedimentation methods, replacing M by M_{sD} in formula (4) or (5) with use of the Svedberg equation yields

$$A_0 = \eta_0 \left(\frac{D}{T}\right)^{2/3} \left(\frac{[\eta] sR}{100(1-\bar{v}\rho)}\right)^{1/3}. \qquad (15)$$

Thus in this case the determination of A_0 involves in effect sedimentation–diffusion and viscosimetric measurements, in which as before the accuracy with which diffusion coefficient is determined is important, since in (15) the power to which this factor is raised is double that of the sedimentation coefficient and the intrinsic viscosity.

A comparative assessment of the suitability of the different methods for determining A_0 must first take into account the experimental difficulties associated with the use of light scattering, which requires that the test solutions be highly purified. This applies especially to those cases in which sparingly soluble polymers are investigated in binary solvents, polyelectrolyte buffer solutions, and other such systems that are difficult to purify.

The sedimentation and diffusion methods do not require such careful purification of the solution, which is a substantial advantage in comparison with the light-scattering method. When aqueous and buffer solvents are

used, however, a complication arises from charge effects when diffusion and sedimentation coefficients are measured in polyelectrolyte systems. Although these effects may be diminished by increasing the ionic strength of the solution and reliably extrapolating to zero polymer concentration[45] using a sensitive interferometric technique[1], their complete elimination is difficult to guarantee. Furthermore, a significant error in the sedimentation method is associated with measurement of the partial specific volume $\bar{v}$, which governs the buoyancy factor $1-\bar{v}\rho$ in Eqns.(5) and (15). This disadvantage is absent in the diffusion method, which does not require measurement of the partial specific volume and enables the coefficient of friction f to be determined most directly.

Table 5. Values of A_0 (erg deg^{-1} mole$^{-1/3}$) for fractions of flexible-chain polymers in thermodynamically "good" solvents.

*Values of A_0 in parentheses in Tables 5—10 disregarded in calculation of mean experimental values of A_0.

**These fractions investigated both in a thermodynamically "good" solvent (in this Table) and in a θ-solvent (Table 6).

***Here and subsequently n_W is the number of branchings per molecule.

From the above considerations it may be expected that the combination of light-scattering and sedimentation methods using formula (5) will lead to the greatest errors in the determination of A_0. On the other hand, the combination of diffusion and sedimentation methods involves formula (15), in which the buoyancy factor occurs as the cube root, which diminishes errors in the determination of partial specific volume, while the diffusion coefficient, occurring to the two-thirds power in (15), is measured quite reliably (by an interferometric technique[1]). Therefore the sedimentation–diffusion method for determining A_0 must be the most strongly preferred, at least when organic solvents are used.

Tables 5—10 list experimental values of A_0 for various polymer–solvent systems obtained by different methods in various laboratories. The methods used are indicated in the appropriate column by the abbreviations D for diffusion, S sedimentation, SE sedimentation equilibrium, LS light scattering, and OS osmometry. The type of averaging of molecular mass (M_W, M_n, M_{SD}) used in the calculation of A_0 is also indicated. In all cases viscometry was used in addition to the methods listed.

Table 5 lists numerous results obtained for flexible-chain (mainly vinyl) polymers in good (non-θ) solvents. All measurements were made on fractions of molecular-mass range indicated in the first column. Examination of original sources (from literature references) does not usually reveal any systematic variation in A_0 for individual fractions with their molecular weight. Table 5 gives values of A_0 averaged over all fractions of a given polymer in each paper, while the error indicated is a mean of the deviations from this value for different fractions. On comparing values of A_0 for the 172 different polymer–solvent systems (including ~800 fractions) represented in Table 5, it is impossible to detect any systematic dependence of A_0 on the method used.

The average of all values of A_0 in Table 5 is $(3.2 \pm 0.2) \times 10^{-10}$ erg deg^{-1} mole$^{-1/3}$. This mean scatter of values obtained by different authors in different polymer–solvent systems has the same order of magnitude as the scatter of A_0 values between different fractions of a polymer investigated in the same work, which gives grounds for supposing that differences in the values for different polymers lie within the limits of experimental error.

Table 6. Values of A_0 (erg deg^{-1} mole$^{-1/3}$) for flexible-chain polymers in θ-solvents.

*, **As for Table 5.

Table 6 contains results for fractions of flexible-chain polymers analogous to those in Table 5 but obtained for solutions in θ-solvents. The average value over all 26 systems (total number of fractions 137) is $A_0 = (3.2 \pm 0.2) \times 10^{-10}$ erg deg^{-1} mole$^{-1/3}$, the same as that obtained in "good" solvents (Table 5).

Values obtained both in thermodynamically "good" solvents and in θ-solvents are given in Tables 5 and 6 for several of the polymers (denoted by a pair of asterisks **). Comparison shows that for the same fractions the experimental value of A_0 under θ-conditions may be either slightly greater or slightly smaller than A_0 in a "good" solvent. However, these differences are no greater than those in A_0 in different θ-solvents or in different "good" solvents, and lie within the limits of experimental error.

Thus it can be concluded from Tables 5 and 6 that excluded-volume effects have no appreciable influence on the value of A_0.

Experimental information on the influence of molecular-mass polydispersity on A_0 is rather meagre. Several results are given in Table 7, which compares values of A_0 for the initial unfractionated specimens and those obtained from their fractions. The number of polymers is 14, and the total number of fractions 203. Table 7 reveals no unambiguous independence of A_0 on polydispersity, since in about half the cases A_0 is greater for the unfractionated specimen than for the corresponding fractions, whereas for the other half the opposite relation is found. The observed differences lie within the limits of experimental error, and therefore may in general be disregarded. These results are consistent with the theoretical conclusions[29] mentioned above: for moderately polydisperse polymers ($M_w/M_n < 2$) only a slight dependence of A_0 on the width of the molecular-mass distribution can be expected.

Table 8 lists experimental values of A_0 obtained for fractions of polymers whose molecules have a ladder or semi-ladder structure. They cover 31 different polymer–solvent systems with a total of 351 fractions. The mean is

$A_0 = (3.14 \pm 0.13) \times 10^{-10}$ erg deg^{-1} mole$^{-1/3}$, which coincides within the limits of experimental error with the corresponding experimental value for flexible-chain polymers (Tables 5–7), although ladder polymers are characterised by increased equilibrium rigidity of the molecular chains, which may exceed several times the rigidity of flexible-chain polymers[17]. This difference in rigidity is apparently insufficient, while the molecular masses of polymers in Table 8 are too large, for experiments to be able (in conformity with the predictions of theory, Figs.1 and 2) to detect a difference in the values of A_0 for more rigid polymers (Table 8) and for more flexible polymers (Tables 5–7).

Table 9 contains experimental values of A_0 for derivatives of cellulose and other polysaccharides, obtained for 62 polymer–solvent systems with a total of 428 fractions. They can conveniently be divided into two groups, applying respectively to solutions in organic solvents and to aqueous and buffer systems. If values in organic solvents are averaged, obtained by light-scattering and sedimentation methods, the result is $A_0 = (3.30 \pm 0.23) \times 10^{-10}$ erg deg^{-1} mole$^{-1/3}$, whereas averaging in the first group of values, obtained by sedimentation and diffusion methods, yields $A_0 = (3.32 \pm 0.32) \times 10^{-10}$ erg deg^{-1} mole$^{-1/3}$. These two values are almost identical, and agree within the limits of

**Polyimide based on diaminodiphenylmethylphenylmethane and oxydiphenyl-3,3',4,4'-tetracarboxylic acid.

error with the value for flexible-chain polymers. This is not unexpected, since the rigidity of the molecular chains of cellulose derivatives, though greater than for flexible-chain polymers, is close to that of the ladder polymers considered above.

A rather different situation is found for the second group of values, obtained in aqueous and buffer solutions of polysaccharides. The mean obtained by light-scattering and sedimentation is $A_0 = (4.02 \pm 0.38) \times 10^{-10}$, but the use of sedimentation and diffusion gives a mean of $A_0 = (3.50 \pm 0.80) \times 10^{-10}$ erg deg^{-1} mole$^{-1/3}$. Both values exceed that obtained in organic solvents, and are characterised by a greater experimental error. This illustrates the difficulties of working with aqueous and buffer solutions, especially when the sedimentation–diffusion method is used together with Eqn.(15).

In Table 10 data have been assembled on rigid-chain polymers, which are divided into three classes. The first comprises rigid-chain aromatic polyamides, polyamides having heterocycles in the chain, and poly(alkyl isocyanates), whose molecules have high equilibrium rigidity characterised by a Kuhn segment length 500–600 Å.[228] Polymer molecules in the second class are no less rigid than those in the first class, but the rigidity is due to the presence of a secondary structure leading to a helical chain conformation[1]. Finally, the third class comprises compounds, mainly also aromatic, arbitrarily termed "semi-rigid". Although the Kuhn segment length for their chains is smaller than for molecules of the first two classes[228], it is sufficient to ensure considerable permeability of the molecular coil in solution, which should increase the parameter A_0. This is confirmed on comparing values in Table 10 for the three classes of polymers.

The total number of polymer–solvent systems covered in Table 10 is 61, and the total number of fractions investigated 412. The mean over all polymers and fractions is $A_0 = (3.7 \pm 0.4) \times 10^{-10}$ erg deg^{-1} mole$^{-1/3}$. The averaging excluded values for specimens No.7 and 8, solutions of which are not molecularly disperse. As with cellulose derivatives, the error in determination of A_0 is appreciably greater for rigid-chain than for flexible-chain polymers, as a consequence of specific experimental difficulties in working with solutions of the polymers in Table 10. Yet the average value of A_0 exceeds considerably that for flexible-chain polymers, and this difference is real, since it lies outside the experimental error. For all specimens in Table 10 (other than No.9) the parameter A_0 was invariant in the series of fractions investigated. For fractions of poly(butyl isocyanate) (No.9), investigated over a wide range of molecular weights, A_0 increased with decrease in chain length L. This can be regarded as confirmation of the theoretical predictions (Fig.1) for a polymer in which d/A is lower than for other polymers.

V. CONCLUSION

The experimental results surveyed in the previous Sections can be summarised in the statement that, for every polymer–solvent system throughout the range of molecular masses accessible to experiment, the parameter A_0 determined from formulae (4), (5), and (15) is indeed invariant, independent of chain length, solvent, and, for moderately polydisperse specimens, their degree of polydispersity.

For all flexible-chain polymers and synthetic polymers having moderately enhanced chain rigidity the most reliable experimental value is

$$(A_0)_{flex} = (3.2 \pm 0.2) \cdot 10^{-10} \text{ erg deg}^{-1} \text{ mole}^{-1/3} = (3.2 \pm 0.2) \cdot 10^{-17} \text{ J deg}^{-1} \text{ kmole}^{-1/3} \quad (16)$$

from which we obtain

$$\beta \equiv P^{-1}(\Phi/100)^{1/3} = 2.3 \cdot 10^6 .$$

These experimental values are considerably lower than those predicted by analytical theories—$A_\infty = 3.8 \times 10^{-10}$ erg deg^{-1} mole$^{-1/3}$ and $\beta = 2.71 \times 10^6$—and agree well with those obtained by Zimm's computer experiment[26]—$A_\infty = 3.13 \times 10^{-10}$ erg deg^{-1} mole$^{-1/3}$ and $\beta = 2.33 \times 10^6$ (Table 2).

For polymers of high chain rigidity the mean experimental value

$$(A_0)_{rig} = (3.7 \pm 0.4) \cdot 10^{-10} \text{ erg deg}^{-1} \text{ mole}^{-1/3} \quad (17)$$

is identical with that of A_∞ predicted by the analytical theories. However, this experimental value cannot be regarded as A_∞, since it has been obtained for short polymer chains, in several cases with $L/A < 10$. It is more logical to adopt as experimental value of A_∞ the quantity $(A_0)_{flex}$ determined by means of Eqn.(16), since it has been obtained with the maximum chain lengths accessible to experiment. In conformity with this the difference between $(A_0)_{rig}$ and $(A_0)_{flex}$—respectively from Eqns.(17) and (16)—must be regarded as a result of increase in the ratio A_0/A_∞ for a rigid-chain polymer ($d/A \ll 1$) in the region of low values of L/A in conformity with the theory of vermiform chains (Table 1 and Figs.1 and 2).

Thus in the practical utilisation of the present results to determine the molecular mass of a polymer from experimental values of $[\eta]$ and f by means of formulae (4) and (5) the value of A_0 determined by means of formula (16) can be recommended for flexible-chain and moderately rigid-chain polymers, and that obtained from (17) for polymers of high chain rigidity. For derivatives of cellulose and other polysaccharides of adequate purity and molecular dispersity of non-electrolyte solutions Table 9 indicates use of the value $A_0 = (3.30 \pm 0.30) \times 10^{-10}$ erg deg^{-1} mole$^{-1/3}$, obtaining which, however, has involved considerable error.

As mentioned at the beginning of this Review, use of the invariant A_0 in determining molecular masses M is especially important for polymers of high chain rigidity, which have low molecular mass and also are soluble only in such specific solvents as concentrated sulphuric acid. The combination of all these properties in effect excludes the possibility of using sedimentation and makes light scattering a relatively ineffective method[2]. The most useful combination under these conditions is that of viscometric and diffusion measurements with the use of formula (4) and the above experimental values of A_0. This method is widely used at the present time.

The fact that the experimental A_∞ corresponds to $\beta = 2.3 \times 10^6$ instead of the 2.7×10^6 predicted by theories of sliding friction and viscosity of macromolecules means that the theoretical values $P_\infty = 5.11$ and $\Phi_\infty = 2.8 \times 10^{23}$ mole^{-1} are incompatible. Thus interpretation of experimental data on diffusion (or sedimentation) and on solution viscosity for the same polymer in terms of a single theory of these

Table 10 (cont'd.).

***Polyimide based on oxydiphenyl-3,3′,4,4′-tetracarboxylic dianhydride and 9,9-di-*p*-aminophenylfluorene.
****Polysulphonamide based on di-*p*-aminophenyl sulphone and terephthalic acid.

processes[12,13] cannot yield identical values of chain rigidity (Kuhn segment length). Theories of transport processes in polymer solutions require elaboration, which in turn should eliminate the above inherent contradiction and provide a theoretical value of A_∞ corresponding to experimental results. By means of Zimm's computer experiment[26] it has proved possible to do this by some decrease in the theoretical value of Φ_∞ and a considerable increase in the theoretical value of P_∞. Whether this is the only possible method should appear from further research.

Phase Structure of Epoxide-Rubber Systems

V.P.Volkov, G.F.Roginskaya, A.E.Chalykh, and B.A.Rozenberg

Formation of the phase structure during three-dimensional polycondensation in heterophase epoxide-rubber systems is discussed. Aspects of the phase equilibrium and the interdiffusion of the components in the initial systems and during the chemical reaction are examined. A two-stage mechanism of structure formation is suggested. A relation is demonstrated between the thermodynamic affinity of the components and the final phase structure. Possible methods for obtaining systems having specified parameters are considered. A list of 102 references is included.

I. INTRODUCTION

Current research on the manufacture and application of polymeric materials is commonly aimed at utilising known polymers by combining or modifying them[1,2]. An urgent task is to improve the physicomechanical properties of vitreous solid polymers (to diminish brittleness, increase resilience, enhance resistance to cracking and creep under the influence of the surrounding medium, and lower thermal shrinkage). A most effective way for solving this problem is to produce heterophase compositions by introducing a modifier as particles of a disperse phase into a vitreous polymer matrix[2-6]. The physicochemical properties of the modified polymers depend significantly[2,4-6] on the proportion by volume and the particle size of the disperse phase and on other parameters of the phase structure. However, research in this field does not yet have a general theoretical basis.

The problem of controlling the properties of heterophase compositions cannot be solved without establishing a quantitative relation between the parameters of the phase structure and the physicochemical properties of the composition, nor without knowledge of the mechanism of formation of the phase structure of modified polymers.

The present Review summaries the results of research on phase-structure formation in epoxide—rubber systems. Problems connected with phase equilibrium and interdiffusion of components during three-dimensional polycondensation of the epoxide oligomer are considered separately.

II. PHASE EQUILIBRIUM IN INITIAL SYSTEMS

When a system includes a region of phase separation the compositions of the phases can be calculated from the equality of the chemical potentials of each component in the coexisting phases, with the condition for phase equilibrium that the Gibbs free energy should be a minimum. For a binary system we have[7]

$$\Delta\mu_1' = \Delta\mu_1'', \quad \Delta\mu_2' = \Delta\mu_2''$$

where the primes are used to denote different phases.

Consideration of the thermodynamics of polymer solutions can conveniently start from the Flory—Huggins lattice theory[8-11], in which statistical concepts were used to produce the first quantitative explanation of the thermodynamic properties of the solutions. According to this theory the change in free energy on mixing is given by the expression

$$\Delta G_{mix} = RT[\varphi_1 \ln\varphi_1 + \varphi_2 m^{-1} \ln\varphi_2 + \chi\varphi_1\varphi_2] \quad (1)$$

in which ϕ_1 and ϕ_2 are the volume fractions of solvent and polymer respectively, $m = v_2/v_1$ is the ratio of the molar volumes of polymer and solvent, and χ is a parameter representing the excess free energy of interaction required to transfer one mole of solvent from the pure solvent to the pure polymer phase. The formulae for the changes in chemical potential of solvent and polymer are respectively

$$\begin{aligned} \Delta\mu_1 &= RT[\ln(1-\varphi_2) + (1-1/m)\varphi_2 + \chi\varphi_2^2], \\ \Delta\mu_2 &= RT[\ln(1-\varphi_1) + (1-m)\varphi_1 + m\chi\varphi_1^2]. \end{aligned} \quad (2)$$

Differentiating $\Delta\mu_1$ with respect to ϕ_2 yields the spinodal equation

$$1-(1-m^{-1}+2\chi\varphi_2)(1-\varphi_2) = 0. \quad (3)$$

At the critical point at which the difference between the coexisting phases disappears $(\partial\mu_1/\partial\phi_2)_{p,T}$ and $(\partial^2\mu_1/\partial\phi_2^2)_{p,T}$ vanish. Hence the critical point is characterised by the relations

$$(\varphi_2)_{cr} = 1/(1+m^{1/2}), \quad (4)$$

$$\chi_{cr} = 1/2 + 1/m^{1/2} + 1/2m. \quad (5)$$

From these it follows that the phase diagrams of the solutions are unsymmetrical, and also that $\chi_{cr} \to \frac{1}{2}$ as $m \to \infty$. Flory termed the critical point at which $m = \infty$ the *θ-point*.

Later research established a quantitative relation between critical temperature and degree of polymerisation[12]. The interaction parameter comprises enthalpy and entropy components[9,12-14]:

$$\chi = \chi_H + \chi_S = -\frac{\Delta H_1}{RT\varphi_2^2} - \frac{\Delta S_1}{R\varphi_2^2}. \quad (6)$$

As $m \to \infty$ we have

$$T_{cr} = \theta \text{ and } \frac{\Delta H_1}{R\theta\varphi_2^2} = \frac{1}{2} + \frac{\Delta S_1}{R\varphi_2^2} \equiv \Psi. \quad (7)$$

Simultaneous solution of Eqns.(4)-(7) yields

$$\frac{1}{T_{cr}} = \frac{1}{\theta}\left[1 + \frac{1}{\Psi}\left(\frac{1}{m^{1/2}} + \frac{1}{2m}\right)\right]. \quad (8)$$

The Flory-Huggins theory proved extremely useful for analysing a large number of experimental results. Despite all its undoubted merits, however, this theory has several defects. The most significant consists in ignoring the concentration dependence of the parameter χ, and also the changes in volume of the components accompanying mixing. The limited character of the lattice theory was noted repeatedly by Flory, who later suggested an improved theory of polymer solutions[15-17].

A vast amount of information has now been accumulated experimentally on the miscibility of components of binary systems. The majority of this research has been done on systems comprising liquids of low molecular weight and also on solutions of polymers. Polymer–oligomer and oligomer–oligomer systems have been studied least[18-29]. Noteworthy among such work has been the use of thermochemical measurements to calculate[18,19] the concentration dependence of the main thermodynamic functions of mixing for a system comprising an epoxide oligomer and a polymeric butadiene-nitrile rubber. The free energy of mixing proved to be negative throughout the composition range, but the concentration dependence was complicated, showing over a certain range a convex curve characteristic of a metastable state. It was concluded that the systems investigated comprised components of limited miscibility.

Phase equilibrium in systems comprising an oligomeric ester-acrylate and an elastomer has been studied[21,22] by an interference method[23]. Examination of the compatibility of polyisoprene with various ether-acrylate oligomers has established the presence of an upper consolute temperature, with the range of compatibility depending on the number of functional groups in the molecule and also on the chemical nature and length of the oligomeric block. Application of the Flory–Huggins theory gave an analytical dependence enabling such lengths to be calculated at which the acrylate end-groups have no effect on the compatibility of the components.

Table 1. Thermodynamic parameters* of ED-20–rubber systems[29].

Rubber	χ^{298}	χ_S	χ_H^{298}	δ_2, cal$^{1/2}$ cm$^{3/2}$	
				expt.	calc.
PB (M_w = 25 000)	2.22	−0.96	3.18	7.5	7.6
OB-KGG(M_n = 2 200) **	1.48	−0.56	2.04	7.9	7.8
OB-KGG(M_n = 3 100)	1.46	−0.50	1.96	8.0	7.7
OB-KGG(M_n = 4 240)	1.49	−0.42	1.91	8.0	7.7
OB-KG (M_n = 3 100)	1.82	−2.35	4.17	7.1	8.1
PDI-1 (M_n = 3 500)	1.86	−0.64	2.50	7.8	7.9
PDI-3A (M_n = 3500)	1.52	−0.52	2.04	8.0	8.3
SKN-8KKG (M_n = 3 100)	0.75	−0.10	0.85	8.6	8.4

* Relative error in determination of the parameters does not exceed 10%.

** M_n = number-average molecular mass.

Hydroxylated oligomeric systems have been studied[24] on mixtures of oligo(propylene glycol) with oligo(ethylene adipate), poly(ethylene glycol), and oligobutadiene, of molecular mass M respectively 1050, 2000, 15 000, and 2360. Reverse gas chromatography was used to measure the retention volume of the sorbate at various temperatures, and then the thermodynamic parameters of mixing were calculated. Results for the compatibility of the components were compared with those predicted by the classic Flory-Huggins theory and the new Flory theory of liquid mixtures. It was found[24] that the thermodynamics of mixing of the oligomers was qualitatively more correctly described by the new theory. However, the concentration dependence of the thermodynamic functions of mixing proved to be extremely complicated, and quantitative agreement between experimental results and theoretical calculations was not observed, which was attributed to the influence of intermolecular interactions (hydrogen bonding) on structure formation.

Oligosiloxanes and oligoisobutenes showed no significant change in component volumes on mixing[26]. The observed heat of mixing was slightly dependent on temperature, which permitted application of the classic Flory-Huggins theory to this system. A non-monotonic dependence of χ on mixture composition was obtained on the assumption that this parameter was enthalpic in nature. The most important result[26] was the need to take into account a non-combinatorial entropy contribution to χ. The oligobutadiene-oligostyrene system showed[27] qualitative confirmation of the main principles of Scott's theory[28], a development of the classic Flory-Huggins theory to apply to polymer mixtures.

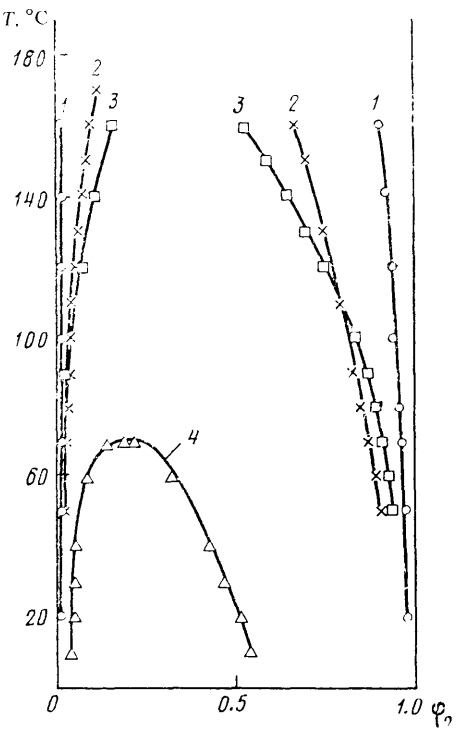

Figure 1. Phase equilibrium diagrams[29] for systems comprising ED-20 with different brands* of rubber: *1*) PB; *2*) OB-KGG with terminal hydroxy-groups; *3*) OB-KKG with terminal carboxy-groups; *4*) SKN-8KKG.

The first investigation of phase equilibrium in systems comprising an epoxide oligomer and an oligomeric rubber established[29] that the introduction of polar groups improves the compatibility of an oligobutadiene (OB) with an epoxide component (Fig. 1). Use of the binodal equation[2]

$$\chi = \frac{\ln(\varphi_1'/\varphi_1'') + (1 - v_1/v_2)(\varphi_2' - \varphi_2'')}{m_1[(\varphi_2'')^2 - (\varphi_2')^2]} \qquad (9)$$

(in which ϕ_1 and ϕ_2 are the respective fractions by volume of ED-20 and an oligomeric rubber, v_1 and v_2 are their molar volumes, $m_1 = v_1/v_0$ with v_0 the molar volume of a segment, and the single and double primes denote symbols corresponding to the two phases in equilibrium) to calculate thermodynamic interaction parameters χ (Table 1) showed a linear dependence on the reciprocal of the absolute temperature. From this relationship χ_H and χ_S were calculated. The equation[30,31]

$$\chi_H = \frac{v_1}{RT}(\delta_1 - \delta_2)^2 \qquad (10)$$

where $\delta_1 = 9.9$ cal$^{1/2}$ cm$^{-3/2}$ is the solubility parameter of ED-20, has been used to calculate values of the corresponding parameter δ_2 for the rubber. Table 1 shows satisfactory agreement with values determined from the theory of group contributions[32]. The carboxylated oligobutadiene (OB-KG) is an exception, apparently owing to marked initial association of the rubber molecules. Such an explanation is supported by the large negative absolute value of χ_S and also by inversion of the binodals of the hydroxylated and carboxylated oligobutadienes at ~100 °C (Fig. 1).

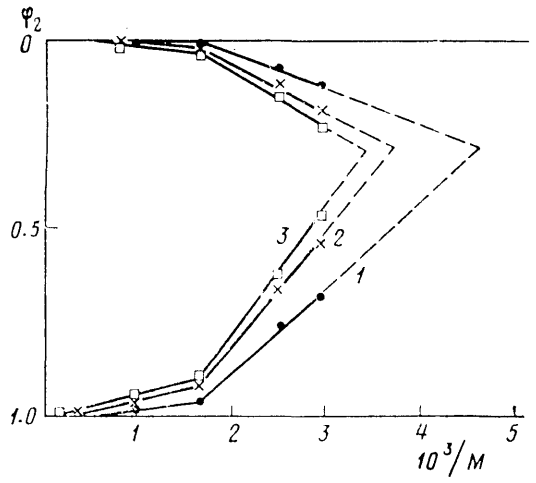

Figure 2. Dependence[6] of solubility of components on molecular mass of epoxide oligomer in ED-20–OB-KGG ($M_n = 2200$) at different temperatures (°C): *1*) 120; *2*) 160; *3*) 180.

Miscibility diminishes with increase in molecular mass of a component, while the upper consolute temperature rises. The influence of molecular mass on phase equilibrium is especially clearly evident in graphs of the dependence of solubility on molecular mass at constant temperature (Fig. 2). On such a diagram two-phase regions are located within the solubility curves, and solutions outside them. With rise in temperature (Fig. 2) and increase in polarity of the oligomeric rubber the region of phase separation becomes smaller. A noteworthy feature of Fig. 2 is the presence of breaks on the graphs. The apparent explanation is that the role of specific intermolecular interactions becomes more important with increase in molecular mass of the epoxide oligomer (EO), which is accompanied by increase in the number of hydroxy-groups in its molecule. The simultaneous improvement in miscibility due to formation of hydrogen complexes partly balances its diminution due to increase in molecular mass of the epoxide. Thus in the presence of specific interactions between the components constancy of δ_{EO} is not a sufficient condition to determine the dependence of the miscibility limits of the components on its molecular mass. The influence of these interactions on the thermodynamics of mixing becomes weaker on passing to lower epoxide oligomers.

III. INTERDIFFUSION IN INITIAL SYSTEMS

If the rate of attainment of phase equilibrium is determined by diffusion, mass transfer by such processes is described by the well known Fick's law[33]

$$I = -D\frac{dc}{dx} \qquad (11)$$

in which I (g cm^{-2} s^{-1}) is the material flux, D (cm^2 s^{-1}) the diffusion coefficient, and dc/dx (g cm^{-4}) the concentration gradient. For binary systems the main process is interdiffusion, which is governed by the coefficient D_v. Analysis based on the thermodynamics of irreversible processes shows that the rate of mass transfer in a multicomponent system depends on the chemical potential gradient of each component[34,35]. The relation between the interdiffusion coefficient and the thermodynamic properties of the system is given by the equation

$$D_v = D_i^* \frac{d\ln a_i}{d\ln \varphi_i} = D_i^* \frac{\varphi_i}{RT}\frac{d\mu_i}{d\varphi_i} \qquad (12)$$

where D_i^* is the self-diffusion coefficient of the ith component a_i its activity, and ϕ_i its volume fraction. The self-diffusion coefficient characterises the thermal mobility of the component molecules and is independent of the chemical potential gradient. The specific form of the composition dependence of the interdiffusion coefficient can be obtained by substituting in (12) expressions for the chemical potentials of solvent and polymer in the solution[36]:

$$D_v = D_1^*[1-(1-1/m)\varphi_1 - 2\chi\varphi_1\varphi_2] \qquad (13)$$

$$D_v = D_2^*[1-(1-m)\varphi_2 - 2m\chi\varphi_1\varphi_2]\,. \qquad (14)$$

To the approximation $m \to \infty$ Eqn. (13) becomes

$$D_v/\varphi_2 = D_1 = D_1^*(1-2\chi\varphi_1) \qquad (15)$$

where D_1 is the relative diffusion coefficient. By means of this formula the dependence of χ on mixture composition is calculated from the concentration dependence of D_1 and D_1^*.

Interdiffusion coefficients are usually determined by an optical-wedge method[37]. Analysis of the component concentration distribution curves with respect to distance by the Matano–Boltzmann method gives a solution of the Fick equation describing a non-stationary diffusion process:

$$\frac{\partial c}{\partial t} = \frac{\partial}{\partial x}\left(D_v\frac{\partial c}{\partial x}\right)\,. \qquad (16)$$

Self-diffusion coefficients are calculated by means of the modified Fujita equation[36]

$$\lg\frac{D_{1,\varphi}^*}{D_{1,0}^*} = \lg\frac{D_{1,1}^*}{D_{1,0}^*} - \frac{\beta f_1\varphi_1}{f_2+\beta\varphi_1} \qquad (17)$$

in which $D_{1,\phi}^*$, $D_{1,0}^*$, and $D_{1,1}^*$ are respectively the self-diffusion coefficient at various ϕ values, the extrapolated value of $D_{1,\phi}$ as $\phi_1 \to 0$, and the self-diffusion coefficient of the solvent, $\beta = f_1 - f_2$, and f_1 and f_2 are the fractional free volumes of solvent and polymer respectively. The last two quantities can be found from the temperature dependence of viscosity by means of Doolittle's equation[38]; $D_{1,1}^*$ is usually

determined independently by means of the Einstein-Stokes equation or by the spin-echo method[39,40].

This approach has been used in calculating thermodynamic functions of mixing of the components for an epoxide oligomer-oligomeric rubber system[41]. The observed composition dependence of interdiffusion coefficients for binary epoxide–rubber systems show (Fig.3) that the absolute value of the coefficient increases with the thermodynamic affinity between the components. At temperatures remote from the critical, as in the Ed-20-SKN-14KKG and ED-20-SKN-40KKG systems, the dependence of D_ν on mixture composition is monotonic.

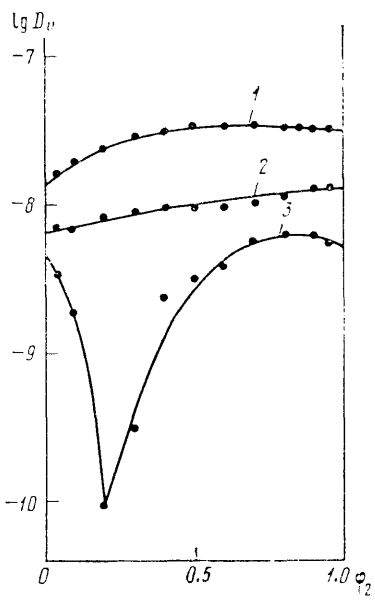

Figure 3. Concentration dependence[41] of interdiffusion coefficient of components at 70 °C in systems comprising ED-20 with different rubbers: *1*) SKN-40KKG; *2*) SKN-14KKG; *3*) SKN-8KGG.

For the ED-20-SKN-8KKG system, which separates into layers at 70 °C (Fig.1), the concentration dependence is characterised by a sharp minimum (Fig.3) in the region of critical compositions. The appearance of such minima is usually attributed to a contribution to the interdiffusion coefficient by a thermodynamic factor (Eqn.12), which tends to zero in the vicinity of the binodal[42]. The coefficient is indeed larger and greater the difference in concentration between the coexisting phases, but such difference is absent at the consolute point[7]. The depth of the extremum diminishes with rise in temperature, and at 130 °C the concentration dependence of χ becomes monotonic.

The plots in Fig.4 show a quite definite concentration dependence of χ calculated by means of Eqn.(16) for epoxide–rubber systems. It is most marked for the ED-20-SKN-8KKG system, which is characterised by the least thermodynamic affinity between the components. A similar effect of the thermodynamic nature of the components on such dependence was found experimentally for solutions of polymers[10,16,17]. With increased content of oligomeric rubber in a binary system with an epoxide the value of χ increases monotonically. An exception is the above ED-20–SKN-8KKG system, curves for which show a clear minimum ($\phi_2 = 0.2$–0.4). The quantity $\partial^2 G_{mix}/\partial\phi_2^2 > 0$ at all mixture compositions in the region of unrestricted miscibility and vanishes at the consolute point[7], and its extremal variation can be assumed to extend over a certain temperature range close to this point. The observed concentration dependence of χ is probably due to this circumstance. In general, one reason for the composition dependence of χ is the formation of association complexes of the solvent in the polymer phase[43,44].

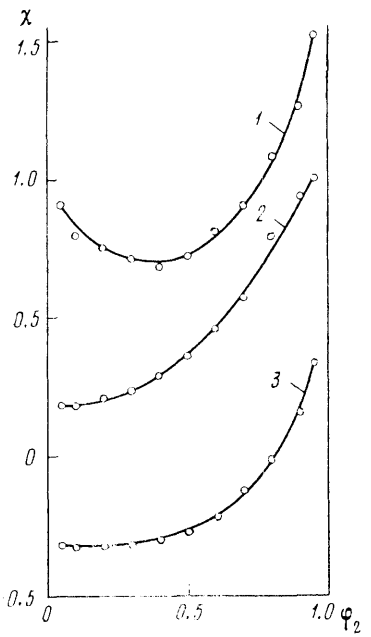

Figure 4. Concentration dependence[41] at 100 °C of χ in binary systems of ED-20 with different rubbers: *1*) SKN-8KKG; *2*) SKN-14KKG; *3*) SKN-40KKG.

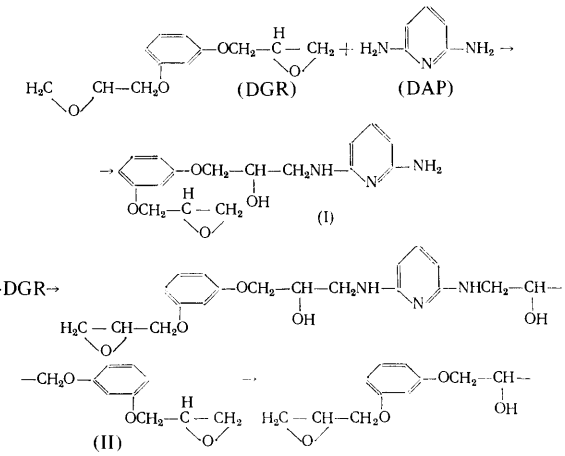
Calculation disregarding the concentration dependence(9) for the ED-20-SKN-8KKG system with $(\phi_2)_{cons} = 0.24$ at $T_{cons} = 70$ °C gave $\chi_{cons} = 0.82$. Use of Eqn.(16) for the same conditions gives 0.88, which can be regarded as a more reliable value, since it is almost identical with that (0.87) predicted on the basis of the Flory-Huggins theory (Eqn.5). Calculation by means of a binodal equation apparently gives information on the mean interaction parameter of the components. This method can be usefully applied to estimate χ for systems with similar thermodynamic affinities of the components and in calculations of a spinodal.

We have used isoconcentration curves of the temperature dependence of χ to calculate thermodynamic parameters of mixing for the epoxide–rubber systems investigated[41]. The dependence on the reciprocal of the temperature is linear for all compositions, and the temperature coefficient usually increases with the volume fraction of the rubber. From the results molar thermodynamic functions of mixing were calculated for the epoxide–rubber systems by means of Eqn.(2). Results for the systems formed by ED-20 with SKN-8KKG and SKN-40KKG at 100 °C show that the function ΔG_{mix} is negative throughout the composition range (Fig.5). However, the curves differ in character: for the latter system the ΔG_{mix}–ϕ_2 curve (Fig.5*b*, curve 4) is concave

$(\partial^2 G_{mix}/\partial\phi_2^2 > 0)$, which means that the system is thermodynamically stable with respect to phase separation; from the corresponding dependence it can be concluded that the former system is considerably less stable thermodynamically. Indeed, with fall in temperature the ΔG_{mix} curves exhibit a tendency to form a convex segment, which is characteristic of systems having limited mutual solubility. Similar results have been obtained[18,19] for the ED-20–SKN-10 and ED-20–SKN-18 systems, which were regarded as having restricted compatibility. The positive enthalpies ΔH_{mix} (Fig.5) indicate that mixing is endothermic, and dissolution is due to the positive values of $T\Delta S_{mix}$ exceeding those of ΔH_{mix}. As complied above, the entropy of mixing comprises combinatorial and non-combinatorial components. Estimates showed these quantities to be comparable for the systems investigated (maximum difference between them not exceeding 50%), for which reason it is completely unjustified to ignore the non-combinatorial contribution to the entropy ΔS_{mix}.



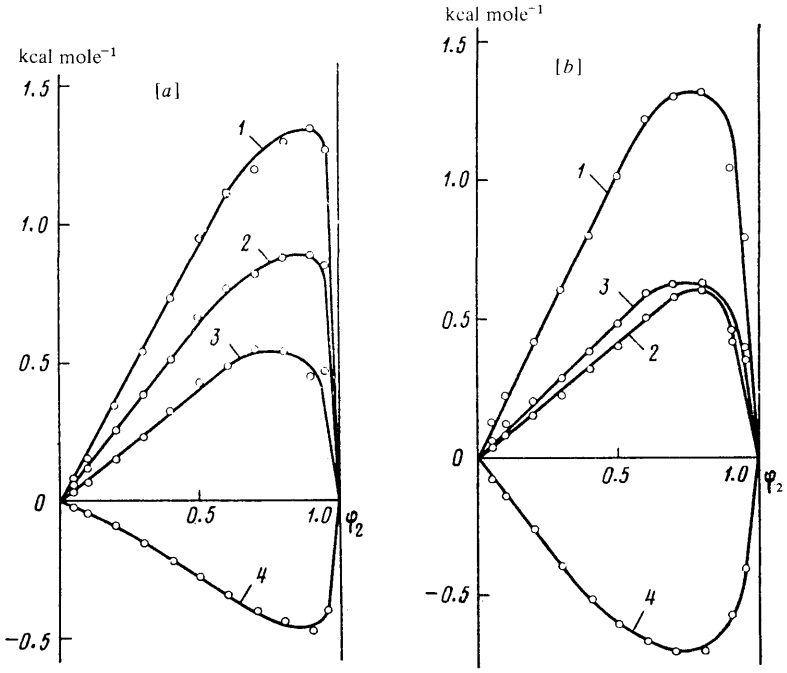
Analysis of the results obtained for all the systems investigated indicates that increase in the thermodynamic affinity between the components due to growth in polarity of the oligomeric rubber increases the absolute values of the free energy ΔG_{mix}, mainly as a consequence of decrease in the enthalpy ΔH_{mix} (Fig.5). For the system with the greatest solubility of the components (ED-20–SKN-40KKG) the enthalpy $\Delta H_{mix} = T\Delta S_{noncomb}$. Mixing under these conditions is due to the combinatorial component $T\Delta S_{comb}$: i.e. the system can be regarded as quasi-ideal.

Thus certain general conclusions can be drawn from the examination of phase equilibria and interdiffusion in the initial epoxide–rubber systems. The Flory–Huggins theory taking into account the non-combinatorial entropy component χ provides an explanation of the dependence of solubility on the thermodynamic affinity between the components.

The thermodynamic stability of the initial systems can be assessed from the quantitative relations between their kinetic and thermodynamic properties.

IV. PHASE EQUILIBRIUM AND INTERDIFFUSION DURING SETTING

The phase state established when the components are mixed undergoes significant changes during the chemical reaction. The reason is a continuous change in the chemical nature of the epoxide component, evident in variation in its thermodynamic properties and increase in the molecular mass:



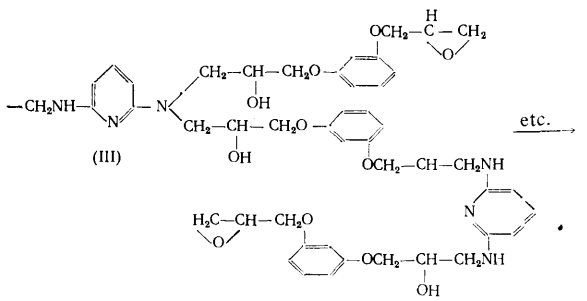


Figure 5. Concentration dependence[41] at 100 °C in binary systems of ED-20 with: *a*) SKN-8KKG; *b*) SKN-40KKG for thermodynamic functions of mixing: *1*) $T\Delta S_{mix}$; *2*) ΔH_{mix}; *3*) $T\Delta S_{mix,non\text{-}comb}$; *4*) ΔG_{mix}.

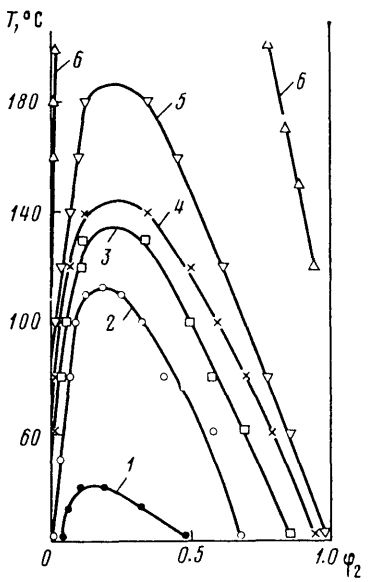
Phase equilibrium and diffusion during the three-dimensional polycondensation of an epoxide have been investigated on epoxide–rubber systems based on the diglycidyl ether of resorcinol (DGR) and oligomeric rubbers varying in chemical nature[45]. The hardener used was 2,6-diaminopyridine (DAP).

Additive calculation of the solubility parameters of the chemical conversion products of an epoxide oligomer showed[45] that they remain almost unchanged up to high degrees of converson. However, increase in the number of hydroxy-groups in the epoxide component during the reaction favours specific interactions in the setting system. The presence of such interactions and the increase in molecular mass of the epoxide are probably responsible for the change in phase state during the reaction. The character of the phase equilibrium and the rate of its attainment at different stages in the hardening of the epoxide can be assumed to be the main factors determining the mechanism of structure formation.



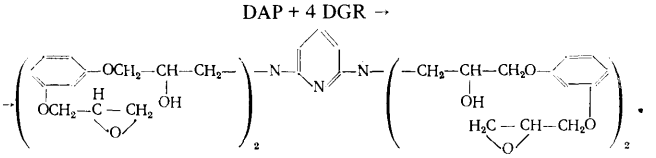


Figure 6. Phase equilibrium diagrams[45] of (DGR-DAP)–PEF-3A system for different degrees of conversion (%): *1*) 31; *2*) 37; *3*) 40; *4*) 42; *5*) 44; *6*) 53.

Analysis of the position of the binodals in the epoxide–rubber system at the stage of mixing of the components shows that increase in the thermodynamic affinity of the rubber for the epoxide in the sequence SKN-8KKG < SKN-14KKG < PEF-3A leads to expansion of the region of homogeneous mixing, in agreement with earlier results. Change in phase equilibrium during chemical reaction was studied on model systems representing products of the hardening of diglycidyloxybenzene by various quantities of pyridinediamine that are completely consumed:

The model systems adopted—DGR + (IV)—are not adequate, of course, to describe the actual products of hardening (I–III) and can be regarded merely as qualitative analogues of the real systems, employed for the phenomenological description of the change in phase state under the influence of chemical reaction.

Polycondensation of the epoxide oligomer is accompanied by expansion of the region of phase separation (Fig. 6); the solubility curves shift to higher temperatures, and the solubility of the components becomes infinitesimal when a certain degree of chemical conversion of the epoxide is reached. Analysis of the results revealed a relation between the initial compatibility (i.e. before the start of reaction) and the rate of change of miscibility during reaction. Breakdown of the stability of the epoxide solution in the setting system takes place at different stages of chemical conversion of the epoxide depending on the initial compatibility. As a consequence, change in the phase state of the system occurs at different rates of conversion of the epoxide (Fig. 7).

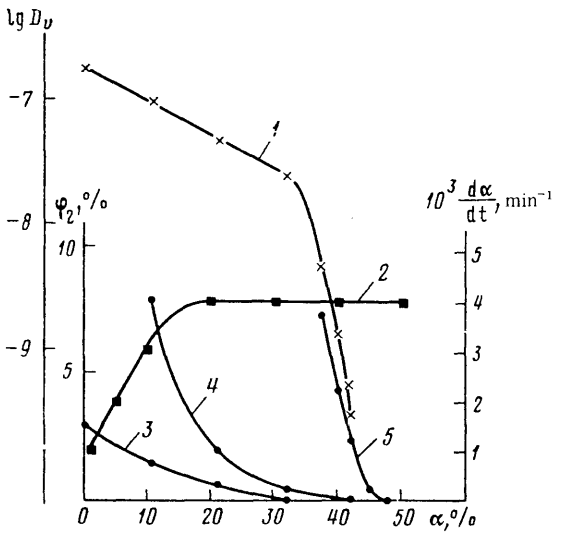

Figure 7. Variation[45] of parameters during hardening at 90 °C in binary systems of DGR–DAP with different rubbers: *1*) interdiffusion coefficient, PEF-3A; *2*) rate of reaction, PEF-3A; 3) solubility of SKN-8KKG; 4) solubility of SKN-14KKG; 5) solubility of PEF-3A.

Fig. 8 illustrates the temperature dependence of the interaction parameter calculated from the binodal equation for the (DGR-DAP)–PEF-3A system. A significant difference in the type of dependence is evident for systems at the stages of

mixing of the components and of chemical conversion of the epoxide. The dependence of the enthalpy of mixing (the temperature coefficient of χ) over a wide temperature range evident in the latter case cannot be explained by ignoring the concentration dependence of χ, since averaging χ with respect to composition leads to its linear dependence on the reciprocal of the temperature, as shown earlier on binary systems. The reason for the anomalous behaviour of setting systems must most probably be sought in their tendency to develop specific interactions. The increase in the enthalpy of mixing as the temperature is lowered suggests that the predominant form of specific interaction is association of oligomeric epoxide molecules, which ultimately impedes mutual dissolution.

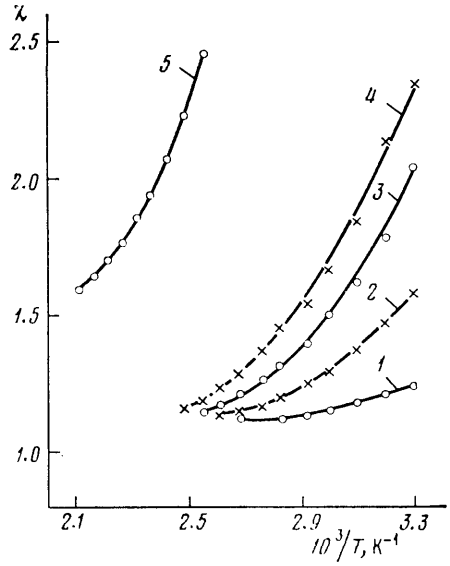

Figure 8. Temperature dependence[46] of χ in (DGR-DAP)–PEF-3A system at different degrees of conversion (%): *1*) 37; *2*) 40; *4*) 44; *5*) 53.

The diffusion method described previously[36] has been used to determine thermodynamic functions of mixing in a hardening epoxide–rubber system of type (DGR-DAP)–PEF-3A. The character of the concentration dependence of the interdiffusion coefficient is found experimentally to change during the course of polycondensation of the epoxide oligomer, from a monotonically increasing to a non-monotonic function of composition with a break in the region of two-phase mixtures[46]. Analogous results have been obtained in a study of diffusion in systems formed by an epoxide oligomer with a hardener and with a plasticiser[47]. The appearance of minima and breaks on the concentration curves during the chemical conversion of the epoxide is due to diminution in the mutual solubility of the components and separation of the hardening system into layers.

The concentration dependence of the interaction parameter calculated by means of Eqn.(16) for such systems with different degrees of hardening of the epoxide oligomer is qualitatively the same as the corresponding dependence at the mixing stage. It is more marked for a system containing the epoxide oligomer at a higher degree of conversion, which is consistent with the hypothetical formation of molecular association complexes of the solvent in the polymer phase[43,44].

The dependence of the interaction parameter on the reciprocal of the temperature is linear over the range 90–130 °C whatever the proportions of the hardening epoxide oligomer and the rubber[46]. As with the initial systems, the temperature coefficient increases with the proportion of the rubber. Its absolute value at a constant volume fraction of the rubber is almost independent of the degree of conversion of the epoxide oligomer. Molar thermodynamic functions have been calculated for mixing the rubber PEF-3A with epoxide oligomers of different degrees of chemical conversion. The changes in chemical potential of both components decrease in absolute magnitude during the chemical reaction: i.e. the thermodynamic affinity of the components diminishes. A consequence is a decrease in the absolute magnitude of the molar free energy of mixing (Fig. 9).

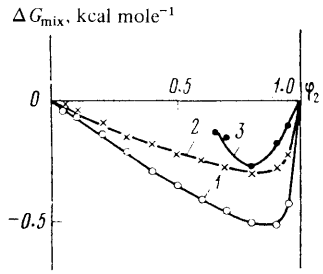

Figure 9. Concentration dependence[46] of ΔG_{mix} in (DGR-DAP)–PEF-3A system at 90 °C for different degrees of conversion (%): *1*) 0; *2*) 21; *3*) 42.

Analysis of the results[46] has shown that the solubility remains endothermic in character during hardening of the epoxide oligomer, with the enthalpy of mixing little changed. This means that the change in free energy of mixing during the reaction is due mainly to the entropy factor. For the initial systems the change in free energy has been determined predominantly by the enthalpy component. The entropy of mixing in turn changes during hardening of the system mainly because of the non-combinatorial term. From this it can be concluded that over the temperature range investigated the hardening system exhibits a tendency to form a solution having a more ordered arrangement of the molecules.

Thus study of phase equilibrium and interdiffusion during hardening of an epoxide–rubber system has shown that the Flory–Huggins theory describes satisfactorily the thermodynamics of the process only over a narrow temperature range. The thermodynamic stability of a solution of an oligomeric rubber in a hardening epoxide oligomer is determined mainly by the entropy factor. The role of specific interactions becomes greater with hardening of the epoxide.

V. MECHANISM OF FORMATION OF PHASE STRUCTURE

The mechanism of phase separation is determined by the relative rates of transition of the system into a non-equilibrium state w_{neq} and for structural relaxation w_{sr}.[48] When $w_{neq} < w_{sr}$, heterophase fluctuations increase with time while remaining unchanged with respect to composition: i.e. the system comprises two phases from the very start. Such a mechanism of phase separation is termed *nucleation*. When $w_{neq} > w_{sr}$, the system stratifies by a spinodal mechanism without formation of heterophase nuclei. For a long time,

right until phase separation, the structure comprises a single phase with fluctuations of composition, which increase with time. A characteristic feature of structures formed by spinodal stratification is the spatial coherence of each phase and the absence of isolated inclusions. Such a mechanism of phase separation is observed comparatively rarely and has been little studied hitherto. Separation by a nucleation mechanism has been studied in greater detail[10,49-98]. Generation of particles of a new phase (nucleation) can take place homogeneously (within a single phase), heterogeneously (e.g. on the surface of the vessel or trace impurities[53-55]), and also by "self-nucleation"[56-59].

The first theories of the homogeneous formation of nuclei[60-63] were based on the postulate that the factor governing nucleation is the relative supersaturation $\Pi = c_{sup}/c_{sat}$, the ratio of the concentrations of supersaturated and saturated solutions. The rate of nucleation is related to the supersaturation by the formula

$$w_{nu} = K_1 \exp[-K_2/(\ln\Pi)^2] \qquad (18)$$

in which K_1 and K_2 are constants. In view of the strong dependence of the rate on the supersaturation it was suggested[62,63] that a critical supersaturation Π_{cr} existed, below which the rate of formation of nuclei was so small that it could be neglected, i.e. $w_{nu} = 0$. Supersaturation is necessary to accumulate the energy required to surmount the barrier ΔG_{nu} associated with formation of nuclei (creation of an interface). The maximum free energy ΔG_{nu} corresponds to the critical size below which a nucleus cannot grow.

Theories of homogeneous nucleation were subsequently improved[64-67]. The rate of generation of a new phase in a condensed system was shown to depend not only on the degree of supersaturation but also on the rate of diffusion of material through the interface. For example, the rate of generation of crystals is described by the equation[67]

$$w_{nu} = (NkT/h)\exp[-(\Delta G_{nu} + \Delta G_D)/kT] \qquad (19)$$

in which N is the number of molecules in 1 cm^3 of liquid, k Boltzmann's constant, h Planck's constant, and ΔG_D the activation free energy of diffusion. The principles underlying the theories of homogeneous nucleation were used to develop theories of heterogeneous nucleation and "self-nucleation" of a new phase. The kinetics and the mechanism of growth of the nuclei have been investigated in greatest detail for crystallisation[64,68-73]. The development of isothermal crystallisation can be expressed[71-73] by the formula

$$a_t = 1 - \exp(-Kt^n) \qquad (20)$$

where a_t is the fraction of the material that has crystallised by time t, and K and n are constants. The rate of growth of a phase structure in a viscous condensed system is proportional to the diffusion coefficient D and the concentration gradient dc/dx resulting from supersaturation[74]:

$$w_{gr} \sim D\frac{dc}{dx} . \qquad (21)$$

The total rate of formation of the new phase is determined by the rate of nucleation and the rate of particle growth[74]:

$$w_{ph} = w_{nu} w_{gr}^n . \qquad (22)$$

Such are the general laws of formation of a new phase in various heterophase systems.

In real heterophase polymer systems, which are of the greatest interest, chemical reaction and phase separation often take place in some measure simultaneously, and exert a strong mutual influence. We shall examine some examples of such processes. Heterophase polymerisation processes of dispersion[75], suspension[76], emulsion[10,77-79], and precipitation[80-87] types have been investigated in some detail.

The main conclusion from the diffusion theory of dispersion polymerisation[75] has been the relation

$$w_{nu} = w_{init}[1 - \pi r^2 N (2P_{cr}D/K_p[M])^{1/2}] \qquad (23)$$

where w_{init} is the rate of initiation, r the particle radius, N the number of particles in unit volume, P_{cr} the critical degree of polymerisation necessary for nucleation of the growing macroradical, D the mean diffusion coefficient for the growing radical, k_p the polymerisation rate constant, and [M] the monomer concentration. The equation for the critical degree of polymerisation relates the final number of particles formed to the solubility of the polymer, dissolving power of the medium, and the critical relative supersaturation:

$$P_{cr} = -\ln\varphi_p \Big/ \left(\chi - 1 - \frac{v_0}{v_m}\ln\Pi_{cr}\right) \qquad (24)$$

with ϕ_p the fraction by volume of the polymer, v_0 the molar volume of a monomer unit, and v_m the molar volume of the solution. Other theoretical approaches have been made to the description of dispersion polymerisation, but none gives more than a qualitative explanation of the observed relations between particle size, polymer solubility, dissolving power of the medium, and quantity of stabiliser.

The simple relation

$$w_p = K_p(N/2)[M] \qquad (25)$$

was established[78] for the dependence of rate of emulsion polymerisation on number of particles. It was subsequently found that this equation provides a satisfactory description of the polymerisation only of those monomers that dissolve their own polymers, e.g. styrene, butadiene, isoprene. The emulsion polymerisation of vinyl chloride and acrylonitrile, which do not dissolve their own polymers, takes place on the surface of particles, not within them. These processes are described in terms of the theory of Medvedev and Sheinker[79], according to which the rate of polymerisation is proportional to the total particle surface. Furthermore, neither theory[78,79] has proved applicable to the emulsion polymerisation of ethylene and vinyl acetate.

Precipitation polymerisation may be accompanied by crystallisation of the polymer[64,88]. The resulting crystals then have a special morphology (fibrillar and acicular), and their macromolecules have extended conformations. Crystallisation in turn influences polymerisation, changing its rate and mechanism.

The copolymerisation of styrene with rubber in bulk or in the block-suspension modification merits separate consideration[84]. The resulting copolymers have a peculiar phase structure: rubber particles surrounded by a thin film of grafted butadiene–styrene copolymer are dispersed in a polystyrene matrix; the particles are inhomogeneous, containing a large quantity of occluded polystyrene as still finer inclusions. The polystyrene particles are occluded by the rubber phase at the moment of phase inversion (occlusion of the first kind) and also during further copolymerisation by separation from the rubber phase of the polystyrene formed (occlusion of the second kind).

A special case of phase separation is observed in the formation of a network structure by polymers[89]. This phenomenon, which has been studied in detail by Dusek[90-93], has been termed *microsyneresis*. It is evident in the separation of liquid (solvent, monomer, oligomers) from swollen cross-linked macromolecules as a consequence of diminution in their swellability due to intramolecular cross-linking of the macromolecules in the course of three-dimensional polymerisation. To describe the thermodynamics of microsyneresis Dusek started from the equation

$$\mu_i - \mu_i^0 = (\Delta\mu_i)_{mix} + RTv_i\left[\varphi_p^{1/3}\frac{\langle r^2\rangle_d}{\langle r^2\rangle_{sw}} - \frac{1}{2}\varphi_p\right] \qquad (26)$$

in which μ_i and μ_i^0 are the chemical potentials of swollen and unswollen polymers respectively, $(\Delta\mu_i)_{mix}$ is the change in chemical potential of the polymer on mixing, ν is the concentration of elastically active chains, v_i is the molar volume of the solvent, ϕ_p is the fraction by volume of the polymer, and $\langle r^2\rangle_d$ and $\langle r^2\rangle_{sw}$ are the mean square distances between the ends of the network in dry and swollen polymers respectively. Dusek took into account also the variation in entropy of mixing and in chain distribution with degree of swelling. Substitution in Eqn.(26) for $(\Delta\mu_i)_{mix}$ from the Flory-Huggins theory (2) yields a condition of phase separation depending on χ and ν. Hence there should exist critical values of χ and ν on attaining which (in the course of three-dimensional polymerisation) the system begins to stratify. In spite of the availability of experimental results consistent with the theoretical calculations, the legitimacy of the postulates made by Dusek in the calculations is open to doubt[89]. This arises from disagreements concerning the form of the elastic potential[94,95], and also to the absence under real conditions of the proportionality between the dimensions of the network during swelling and the volume of solvent absorbed that is assumed in the calculations.

Thus formation of a new phase complicated by chemical reaction is difficult to describe quantitatively. Existing theories of these processes have not yet reached a stage of development at which a clear physicochemical model could be used to predict the number, size, and shape of the particles formed under any specified conditions.

Table 2. Degrees of conversion α_{sep} at which phase separation begins in (DGR-DAP)-rubber systems[98].

Rubber (%)	PEF-3A (0,2)	PEF-3A (0,5)	PEF-3A (1,0)	PEF-3A (3,0)	PEF-3A (5,0)	SKN-8KKG (0,1)	SKN-8KKG (0,2)	SKN-14KKG (0,2)
α_{sep}*	0.46	0.45	0.44	0.42	0.39	0.30	0.30	0.39

* Determined from phase equilibrium diagrams.
** Determined from light-scattering data.

Investigation of the formation of a phase structure in epoxide–rubber systems began quite recently[45,98]. Views on the mechanism for a heterophase polymer system were based on results for the phase equilibrium, interdiffusion of components, and kinetics of particle growth of the disperse phase. The scattering of light[99] and the turbidity spectrum[100] were used to examine the kinetics. The phase structure of a hardened system has been studied by electron microscopy[101]. The start of phase separation in the hardening system was established from the kinetic curves of light-scattering intensity. Comparison of these results with Fig.7 revealed that phase breakdown takes place at a later stage than would follow from the phase equilibrium diagram (Table 2). The difference may be due to inadequacy of the model for the real system, but also may have thermodynamic causes. Chemical conversion of the epoxide oligomer disturbs the condition of thermodynamic stability of the solution, corresponding on the phase equilibrium diagram to passage of the binodal through a point determined by the concentration adopted and the hardening temperature. However, separation of heterophase particles begins not at the solution composition corresponding to the limiting solubility of the components but on the attainment of some critical degree of supersaturation.

The variation in mean particle size of the disperse rubber phase during hardening, indicated by the turbidity spectrum, is extremal (Fig.10). The observed course of the kinetic curves can be attributed to the appearance at a certain instant of a fraction of smaller particles.

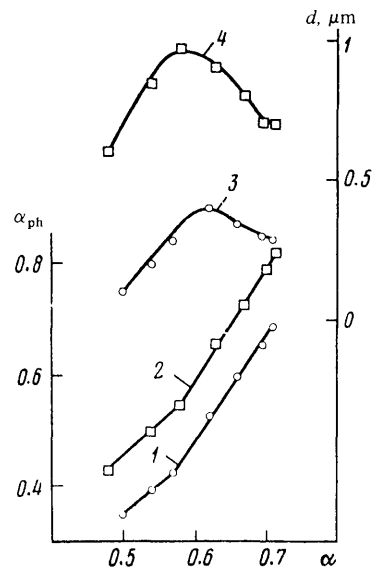

Figure 10. Dependence at 90 °C [98] of degree of phase conversion and mean particle size of disperse phase on extent of chemical reaction for the (DGR-DAP)–PEF-3A system containing different initial rubber contents (%): *1*) conversion (0.5); *2*) conversion (1.0); *3*) particle size (0.5); *4*) particle size (1.0).

Comparison of the particle-size distribution curves for the disperse rubber phase in the hardened systems with the phase diagrams at the mixing stage (Fig.11) indicates that the structure of the hardened composition is related to the compatibility of the initial components. Indeed, the rubber SKN-8KKG, which is poorly compatible with the epoxide oligomer, has the widest particle-size distribution. The use of systems that are most remote from the consolute temperatures, e.g. EO–PEF-3A, narrows the distribution significantly. All the compositions investigated have a bimodal particle-size distribution of the disperse phase. The bimodal character is retained with increase in the volume fraction of the oligomeric rubber. The ratio between coarse and fine particles changes: the mean particle size increases.

The peculiarities of the phase structure of a hardened modified composition—the presence of discrete, spatially unconnected rubber particles dispersed in an epoxide matrix—indicate a nucleation mechanism of heterophase formation. The passage of the particle-size distribution curve of the rubber phase through two maxima apparently indicates a two-stage formation of the phase structure.

Analysis of the results suggests a mechanism of formation of a two-phase structure in a hardening epoxide–rubber system with two stages—nucleation of a new phase and its subsequent growth—involved in transition to a non-equilibrium

state. The rate of growth of nuclei is determined by a parameter equal to the product of the interdiffusion coefficient and the concentration gradient. This gradient is in turn related to the degree of supersaturation of the solution, which is proportional to the rate of chemical reaction of the epoxide oligomer. Fig.7 illustrates the experimental variation in rate of chemical conversion and in interdiffusion coefficient of the components with the degree of conversion of the epoxide. Since this coefficient and the concentration gradient vary in opposite senses, the rate of growth of nuclei is an extremal function of duration of hardening. At the start of the process particle growth is limited by the rate of chemical reaction.

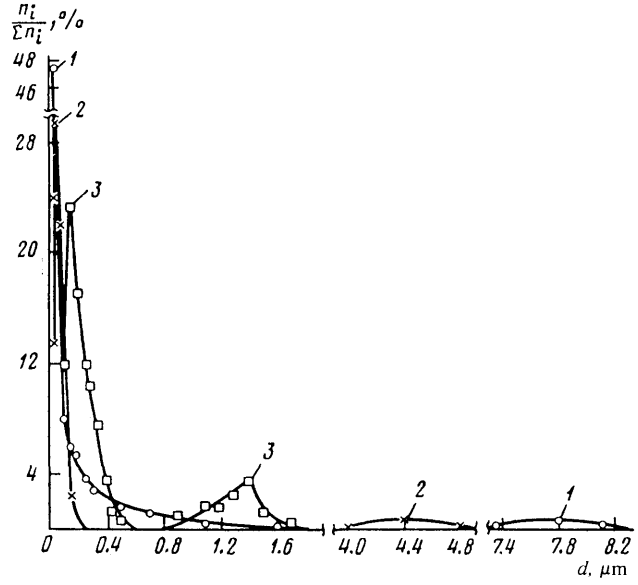

Figure 11. Particle-size distribution curves[45] of disperse phase in hardened systems comprising DGR-DAP with different rubbers: *1*) SKN-8KKG; *2*) SKN-14KKG; *3*) PEF-3A.

The compatibility of the components of an epoxide—rubber system determines the time at which nucleation of a new phase begins (Fig.7). If primary nucleation takes place at a stage limited by the concentration gradient dc/dx, the increase in supersaturation of the solution during polycondensation of the epoxide oligomer is balanced by diffusion in the direction of the centre of growth. A feature of this stage is the coarsening of heterophase particles by "diffusion consumption" of finer particles. Compensation of supersaturation breaks down at a stage determined by the interdiffusion coefficient: as the latter decreases, the radius of the diffusion sphere around the growth centre diminishes. A consequence is the appearance and growth at the periphery of this sphere of regions of localised supersaturation, in which formation of new growth centres—secondary nucleation—results from further chemical change. A mechanism of two-stage nucleation is confirmed by the kinetics of particle growth of the disperse rubber phase. Decrease in the mean heterophase particle diameter is apparently also due to secondary nucleation (Fig.10).

Two-stage formation of the phase structure is evident also in the variation in number of heterophase particles during hardening. The first stage involves a sharp drop in the number as a consequence of intense "diffusion consumption" of extremely fine particles. Increase in the number of particles of the disperse phase at the second stage is due to secondary nucleation. This may be due to diminution in the ability of the cross-linked macromolecules to swell during three-dimensional polycondensation, by analogy with microsyneresis[97]. This hypothesis is supported[98] by the experimental dependence of degree of phase conversion on extent of chemical reaction in the system (Fig.10). Breaks in the curves occur in the region of a critical extent of chemical conversion ($\alpha_{cr} \approx 0.58$):[102] i.e. secondary nucleation begins in the region of gel formation.

The suggested mechanism of structure formation enables us to elucidate the type of relation between the thermodynamic compatibility of the components and the phase structure of the hardened modified compositions. The particle size of the disperse phase is determined by the rate and the duration of growth. The free energy of mixing of the initial epoxide—rubber system determines the "reserve" of thermodynamic stability of the solution towards separation into layers. The greater the affinity between the components the longer the life of the hardening solution and the later does the first nucleation take place: i.e. increase in the compatibility of the components leads to a shortening of growth time and hence a decrease in particle size at the first stage. The size of the particles separating after the first nucleation (second peak in the particle-size distribution curves of the heterophase—Fig.11) does indeed diminish with increase in compatibility. Furthermore, a high degree of supersaturation in systems of well miscible components leads to earlier onset of diffusion control. As a result, both the rate and the time of growth of particles of the disperse phase that separate after the second nucleation (first peak on the distribution curves) increase. Hence the particle-size distribution of the disperse phase becomes narrower with increase in thermodynamic affinity between the components.

Thus the remoteness of the system from the consolute temperature affects the evolution of phase transitions and ultimately determines the character of the phase structure.

VI. CONCLUSION

The laws of structure formation established in this Review enable certain conclusions to be drawn on possible ways of controlling the phase structure. Among factors determining the latter are the thermodynamic properties of the components and the conditions of hardening of epoxide-rubber systems.

Increasing the thermodynamic affinity between the components may effect a narrower particle-size distribution of the disperse phase. In the limit, with systems having components of high miscibility, the solution may remain stable up to the point of gelation. Two-stage formation of the phase structure will then become a single-stage process, with a consequent unimodal particle-size distribution of the heterophase. In this case the particle size diminishes when the components are more compatible[6]. By combining components differing in chemical nature and also varying their molecular masses it is possible to regulate between wide limits the mean particle size and polydispersity of the rubber in the hardened systems. It is noteworthy that the mean size and the polydispersity of the heterophase particles are related in such a way that increase in one of them leads to an increase in the other, and conversely.

Varying the temperature conditions of hardening has a more complicated influence on the mechanism of structure formation. Raising the reaction temperature both increases the rate and shortens the time of particle growth. The particle size of phase inclusions is determined by the influence of temperature on each of these factors, so that the temperature dependence of the particle size of the rubber should be extremal.

With rise in reaction temperature the primary nucleation takes place at a higher degree of conversion. The time at which secondary nucleation begins depends on the ratio of the activation energies of chemical reaction and diffusion. Thus with rise in temperature the two successive nucleations must be expected to approach each other in degree of conversion, as a result of which the polydispersity of the particles should diminish. If it is assumed that secondary nucleation is associated with gel formation, change in the reaction temperature should not displace the start of diffusion control. The polydispersity will then be less dependent on temperature.

Change in the functionality of the initial oligomers has a significant influence on the critical extent of conversion, which constitutes yet another factor affecting polydispersity. Increasing the rubber concentration leads to an increase in the mean particle size of the disperse phase without significant change in polydispersity. Thus the most effective method for regulating the particle size and polydispersity of the rubber during hardening of an epoxide–rubber system is to vary the chemical nature of the components.

Research on heterophase polymer compositions should be aimed at establishing a quantitative theory of formation of the phase structure, which will contribute to a deeper insight into the relation between the chemical nature of the initial components and the phase structure of the polymer compositions. On the basis of the quantitative relations between these factors it will become possible to control the physicomechanical properties of the multicomponent materials, which will lead to further progress in this promising field of polymer science.

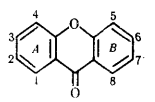
Natural Xanthones

O.A.Denisova-Dyatlova and V.I.Glyzin



The available information on the abundance of natural xanthones in nature and the methods for the determination of their structure, biogenesis, and pharmacological properties is surveyed and described systematically.
The bibliography includes 151 references.

CONTENTS

VII. Pharmacology of xanthones 1016

I. INTRODUCTION

The term "xanthone" denotes a chemical compound with the dibenzo-γ-pyrone structure:

The unsubstituted xanthone has not been discovered in nature but its numerous derivatives have been isolated from representatives of higher plants, lichens, and lower fungi.

The first review on natural xanthones, published in 1961,[1] describes only 17 compounds of which 11 have been detected in various parts of flowering plants, 5 are metabolic products of lower fungi, and one has been isolated from lichen species.

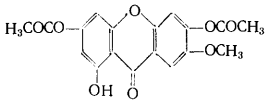
Eight years later Carpenter et al.[2] examined the chemotaxonomic aspect of more than 70 natural xanthones and surveyed the available information about the possible ways of their biogenesis in plants. Chemotaxonomic problems were subsequently considered in greater depth in connection with xanthones from tropical plants[3].

In 1977 Hostettmann and Wagner[4] described one of the extensive groups of natural xanthones—xanthone glycosides.

The sharp growth of interest in natural xanthones in recent years can be readily accounted for by the fact that the first studies in the field of the pharmacological properties of xanthone derivatives already indicated that compounds of this class show promise.

The enormous amount of information accumulated during the last 20 years requires a clear-cut systematic treatment as regards questions concerning primarily the qualitative composition and physicochemical and pharmacological properties of natural xanthones. The employment of synthetic chemical methods for the preparation of highly efficient medicinal agents based on natural xanthones is also of considerable interest. However, the reviews published in recent years deal mainly with problems associated with the chemotaxonomy and biogenesis of xanthones. The aim of the present review is therefore to give a systematic account of the data on the qualitative composition, the methods for the determination of structure, and the pharmacological properties of natural xanthones.

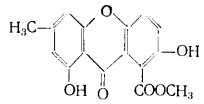
II. CLASSIFICATION OF NATURAL XANTHONES



The qualitative composition of natural xanthones is extremely varied. The earlier classification of xanthones was based on the principle adopted in the classification of coumarins and chromones (derivatives of 5,6-benzo-α-pyrone and 5,6-benzo-γ-pyrone respectively).[5] However, in recent years compounds which do not fit within the framework of the proposed classification have been discovered. We believe that all the natural xanthones known at the present time should be divided into the following three groups:

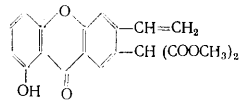
1. Xanthones proper substituted by alkoxy-, alkyl, and alkenyl groups, *C*- and *O*-glycosidic residues, and chlorine atoms in positions *1—8*.
2. Pyrano- and dihydropyrano-xanthones.
3. Furano- and dihydrofurano-xanthones.

1. Xanthones Proper



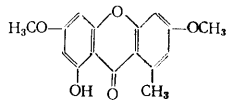
The majority of the xanthones discovered in nature are hydroxy- or methoxy-derivatives of xanthone. Tri- and tetra-substituted xanthones are most abundant. A characteristic feature of the tetrasubstituted xanthones is the presence, as a rule, of substituents in the 1- and 3-positions in the xanthone nucleus and in the main these are xanthones with substituents in the 1,3,5,8-, 1,3,7,8-, and 1,3,6,7-positions[2,4]. Pentasubstituted xanthones are encountered quite frequently. These are as a rule partly or fully methoxylated compounds containing in most instances between three and four methoxy-groups. Xanthones with one or two substituents are encountered somewhat more rarely and among the disubstituted xanthones those having substituents in the 1,5- and 1,7-positions are most abundant[3,5], Several hexasubstituted xanthones have been described. These are mainly either fully methoxylated compounds or compounds containing five methoxy-groups[5,6].

Xanthones with a greater number of substituents have not been detected in nature. Acetoxy-derivatives of xanthones are encountered in nature extremely rarely, especially among higher plants. A compound of this type [compound (I)] has been isolated from *Lawsonia inermis* (Lythraceae):[7]

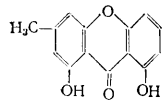


(I)

Several methoxycarbonyl derivatives of xanthone have been described. Among higher plants, *Cassia occidentalis* (Fabaceae), for example, contains methoxycarbonylxanthones (II).[8] Methoxycarbonylxanthones (III) have also been found in certain lower fungi—in the mycelium of *Mycosphaerella rosigena*:[9]

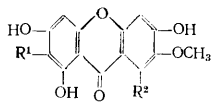


(II)



(III)

Methylated xanthones are encountered mainly in lichens, in the mycelia of certain fungi [compounds (IV)], and extremely rarely in certain higher plants [compounds (V)].[10]

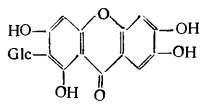


(IV)

(V)

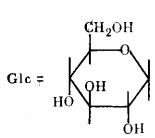
Xanthones containing the isopropenyl group constitute a fairly extensive set of compounds distributed mainly among plants of the family Guttiferae [structures of type (VI, a and b)].[2,3,5] Substituents with a longer aliphatic chain are not characteristic of xanthones, but a xanthone containing the diene substituent geranyl has been isolated from the stems of *Garcinia cowa* (Guttiferae) [compound (VIc)]:[11]

(VI)



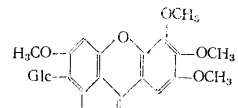
(a) R^1=H, R^2=$CH_2CH{=}C(CH_3)_2$; (b) R^1=R^2=$CH_2CH{=}C(CH_3)_2$; (c) R^1=H, R^2=geranyl.

Chloroxanthones constitute a special group among xanthones proper, since they are the products of the vital activity of lichens and have not been detected in higher plants.



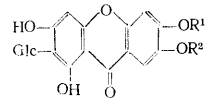
Xanthones containing in their molecule a carbohydrate substituent—xanthone glycosides—merit special attention. They can be divided into two groups: *C*-glycosides and *O*-glycosides. In contrast to the *O*-glycosides, the *C*-glycosides are resistant to acid and enzymatic hydrolysis, since the sugar component is attached to the aglycone by a C–C bond. The xanthone *C*-glycosides are encountered in nature comparatively rarely and have as a rule isotypical structures.

The aglycones of xanthone *C*-glycosides are hydroxy-derivatives of xanthone with substituents in the 1,3,6,7- or 1,3,5,6-positions in the xanthone nucleus. The carbohydrate component of the *C*-glycosides consist of glucose or glucobiose residues.



Mangiferin (VII),[12–16] which has the structure of 2-*C*-β-D-glucopyranosyl-1,3,6,7-tetrahydroxyxanthone, is the most abundant representative of the *C*-glycosides:

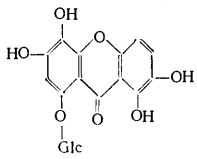
(VII)

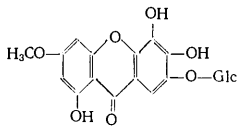


In plants mangiferin is as a rule accompanied by its isomer isomangeriferin, which has the structure of 4-*C*-β-D-glucopyranosyl-1,3,6,7-tetrahydroxyxanthone[17]. Among the derivatives of 1,3,6,7-tetrahydroxyxanthone, the 3-methyl ether of mangeriferin[18], glucomangiferin (2-*C*-β-D-glucobiosyl-1,3,6,7-tetrahydroxyxanthone), and glucoisomangiferin (4-*C*-β-D-glucobiosyl-1,3,6,7-tetrahydroxyxanthone) have also been discovered in nature[19]. The xanthone *C*-glycosides with substituents in the 1,3,5,6-positions in the aglycones are encountered more rarely. 2-*C*-β-D-glycosyl-1,3,5,6-tetrahydroxyxanthone[20], its 5-methyl ether, called iris-xanthone, since it was first isolated from the roots of *Iris florentina* L.,[21] and its 3,5,6-trimethyl ether, obtained from *Hoppea dichotoma*,[22] have now been described. The only *C*-glycoside of a penta-substituted xanthone [compound (VIII)] known at the present time has also been isolated from *Hoppea dichotoma*:[22]

(VIII)

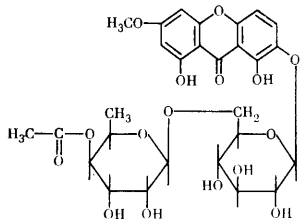
The discovery in nature of compounds having two carbohydrate substituents, one of which is linked to the aglycone by a C–C bond and the other by a C–O bond, made an important contribution to the study of xanthone glycosides. Thus acid hydrolysis of these compounds can yield the corresponding sugar and the *C*-glycoside. An example is provided by the *O*-glycosides of mangiferin isolated from *Gentiana asclepiadea* L. [compounds (IX) and (X)].[23]





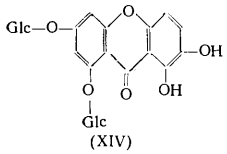
(IX) R^1=H, R^2=β-D-glucosyl;
(X) R^1-β-D-glucosyl, R^2=H.

Xanthone *O*-glycosides are encountered in plants much more frequently than the *C*-glycosides and have a more varied qualitative composition. Both *O*-monosides and *O*-biosides have been described. The monosaccharide *O*-glycosides of xanthones contain only β-D-glucose as the carbohydrate substituent[3]. Disaccharides are formed as a rule by primeverose (β-D-xylopyranosyl-β-D-glucopyranose) and rutinose (α-L-rhamnopyranosyl-β-D-glucopyranose).



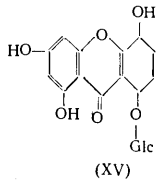
The aglycones of xanthone *O*-glycosides are tri-, tetra-, and penta-hydroxy-xanthones. The glycosides of tetra-substituted xanthones with oxygen-containing substituents in the 1,3,7,8-positions are most widely distributed. The glycosides of trihydroxyxanthones are encountered more rarely. Hitherto only two such compounds have been described in the literature: 1-hydroxy-7-methoxy-3-*O*-primeverosylxanthone, detected in the roots of the various *Gentiana* species[24], and 5-hydroxy-1-methoxy-3-*O*-rutinosylxanthone, isolated from *Canscora decussata* Schult[25]. Of the pentahydroxyxanthone glycosides, 1-*O*-β-D-glucopyranosyl-3,8-dihydroxy-4,5-dimethoxy-xanthone, detected in the leaves of *Gentiana campestris* L.,[26] 1-*O*-glucosyl-3,4,7,8-tetrahydroxyxanthone from the aerial part of *Swertia angustifolia* Buch.-Ham. [compound (XI)],[27] and 7-*O*-glycosyl-1,5,6-trihydroxy-3-methoxyxanthone from *Hoppea dichotoma* [compound (XII)] [22] have now been

described.



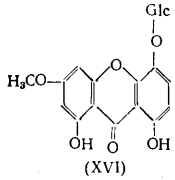
(XI)

(XII)



The only xanthone acyl-*O*-glycoside known hitherto, which was discovered in the leaves of *Gentiana bavarica* L.,[28] has the structure of 7-*O*-acetylrutinosyl-1,8-dihydroxy-3-methoxyxanthone (XIII).[29]

(XIII)



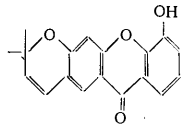
The xanthone diglucoside having the structure of 1,3-di-*O*-glucosyl-7,8-dihydroxyxanthone (XIV) was isolated in 1977 from *Swertia perennis* L.[30].

(XIV)

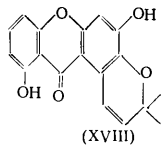
A novel xanthone *O*-glycoside, whose *B* ring is partly hydrogenated [compound (XV)] has been isolated from the aerial part of *Gentiana campestris* L.[31].

(XV)

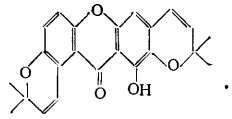
The carbohydrate substituent in xanthone *O*-glycosides usually occupies the 1-position, glycosides with substituents in the 3-, 7- and 8-positions being encountered somewhat more rarely. The first and hitherto only xanthone *O*-glycoside having the carbohydrate substituent in the 5-position was isolated by the present authors from the aerial part of *Swertia iberica* Fish et May[32] and subsequently also from *Swertia connata* Schrenk[33]. The compound called bellidifoloside has the structure of 5-*O*-β-D-glucopyranosyl-1,8-dihydroxy-3-methoxyxanthone (XVI).



(XVI)

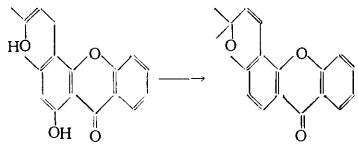


It is of interest to note that, whereas the presence of the carbohydrate substituent in the 2- and 4-positions is characteristic of the xanthone *C*-glucosides, not a single *O*-glycoside with substituents in these positions has been described hitherto. Furthermore, all the xanthone glycosides discovered in nature contain only hydroxy- and methoxyxanthones as aglycones and not a single glycoside has been found whose aglycone contains alkyl substituents and pyran or furan rings.



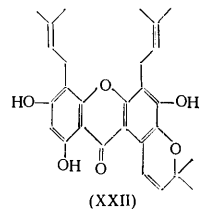
Pyrano- and Furano-Derivatives of Xanthone

Xanthones containing pyran or furan substituents in the molecule have a limited distribution in nature. They have been detected in plants of the families Guttiferae and Polygalacae and also in certain lower fungi.[3,5]



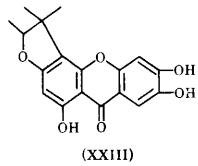
Compounds with one or two pyran rings having the linear and angular structures (XVII)–(XIX) have been described:

(XVII)

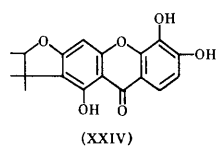


(XVIII)

(XIX)

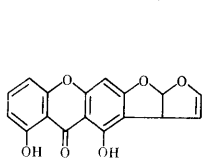


The pyranoxanthones in plants are always accompanied by xanthones with isoprenyl substituents, which are their biogenetic precursors [compounds (XX) and (XXI)]:[34]



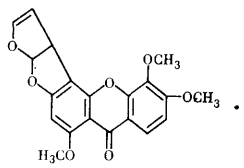
(XX) (XXI)

Partial cyclisation of the isoprenyl chain can lead to the formation of compounds containing simultaneously both the pyran ring and an alkenyl substituent [compound (XII)]:[35]



(XXII)

Furanoxanthones have been discovered in nature at the beginning of the 1970's. They have a very limited distribution and have been isolated from certain plants of the family Guttiferae and also from the mycelia of lower fungi. Mainly dihydrofuranoxanthones with a single furan ring [compounds (XXIII) and (XXIV)] are encountered in plants of the family Guttiferae[36,37]:



(XXIII)

(XXIV)

The mycelia of lower fungi (certain *Aspergillus* species) contain condensed furanoxanthones [compounds (XXV) and (XXVI)]:[38,39]

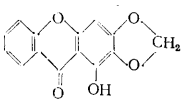
(XXV)

(XXVI)

This class of natural xanthones is at present only just beginning to be investigated.

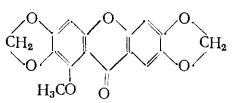
III. CHEMOTAXONOMY OF NATURAL XANTHONES

The distribution and quantitative compositions of natural xanthones have chemotaxonomic importance. A correlation has been found for higher plants between the nature of the substituents in the xanthone ring, their relative positions, and the assignment of the plants to specific families[3,40,41].



The distribution of xanthones in the family Gentianacae has been studied in greatest detail from this standpoint. Thus the presence of xanthones is characteristic of plants of the genera *Enicostemma, Hoppea, Canscora, Gentiana, Swertia, Halenia, Eustoma, and Frasera.*[42–45].

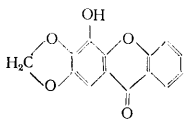
The importance of polyhydroxyxanthones as a chemotaxonomic marker is mainly limited to the genera *Swertia* and *Gentiana*, where xanthones are encountered most frequently. Thus the distribution of xanthone glycosides has been investigated in very great detail within the limits of individual sub-families of the genus *Gentiana*. Studies have shown that the plants belonging to different sub-families have as a rule a specific set of xanthones and in addition individual plant species within the limits of one sub-family can contain a xanthone glycoside specific only to the given species. For example, the presence of 7,8-dihydroxy-3-methoxy-1-*O*-primeverosylxanthone, 7-hydroxy-3,8-dimethoxy-1-*O*-primeverosylxanthone, and 3,7,8-trimethoxy-1-*O*-primeverosylxanthone is characteristic of the majority of plants in the *Cyclostigma* section. At the same time gentiabavarutinoside (7-*O*-acetylrutinosyl-1,8-dihydroxy-3-methoxyxanthone), discovered in *Gentiana bavarica* L., is absent from the other species of the *Cyclostigma* section investigated. At the same time *Gentiana verna* L. contains 8-*O*-glucosyl-1,7-dihydroxy-3-methoxyxanthone, the only glycoside with the carbohydrate substituent in the 8-position within the limits of the sub-family[3,30,46]. The mode of substitution in the xanthone ring is specific to each sub-family. Thus xanthones with substituents in the 1,3,7,8-positions predominate in the *Cyclostigma* sub-family, whereas 1,3,5,8- and 1,3,4,5,8-substituted xanthones predominate, for example, in plants of the *Amarella* sub-family[47]. The presence of 1-hydroxy-7-methoxy-3-*O*-primeverosylxanthone is characteristic of plants of the sub-family *Coelanthe*[48].



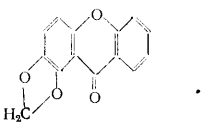
An extremely important chemotaxonomic feature of plants in the family Guttiferae is the presence of pyranoxanthones and xanthones with isoprenyl substituents.

The quantitative compositions of xanthones in plants of the genera *Garcinia*[49], *Calophyllum*, and *Kielmeyera*[50,51] have been studied in greatest detail.

Xanthones containing the methylenedioxy-group are encountered in nature comparatively rarely and their presence in plants is an extremely interesting chemotaxonomic feature. Xanthones with the methylenedioxy-group have been discovered in plants of the families Polygalaceae and Guttiferae. In plants, xanthones with this structure are accompanied as a rule by polyhydroxyxanthones which are partially or completely methylated. In the family Polygalaceae, mono- and bis-methylenedioxy-derivatives of xanthone have been discovered in plants of the genus *Polygala* [compounds (XXVII) and (XXVIII)]:[52–55]



(XXVII)

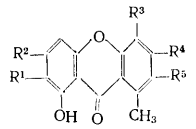


(XXVIII)

In the family Guttiferae xanthones with this structure are encountered in representatives of the genera *Caraipa*[56,57] and Kilelmeyera,[58–61] xanthones with the methylenedioxy-group in the *A* ring predominating in plants of the genus *Kilelmeyera* [compounds (XXIX) and (XXX)]:

(XXIX)

(XXX)



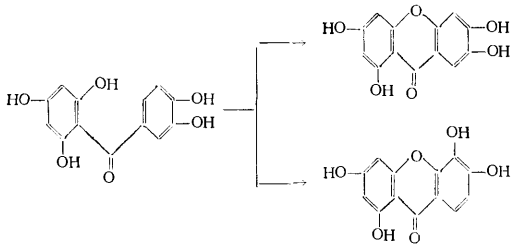
Among all the xanthone glycosides known at the present time, mangiferin is most widely distributed in nature. It has been discovered in plants of almost 20 families[1,v,62,63]. Plants of the families Gentianaceae, Fabaceae, and Iridaceae have the highest content of mangiferin. However, the attempts to establish a regularity in the distribution of mangiferin in plants within the limits of the sub-families of the genus *Gentiana* have not been successful, since mangiferin has been discovered in plants of almost all the sub-families.

Among plants of the family Iridaceae, mangiferin has been sought in various Iris species[64,65]. Although specimens with a very high mangiferin content (1–2.7%) are encountered among the plants of the Iris species investigated, its presence in plants of individual sections shows no particular regularity[64]. The studies on plants of the genus *Hedysarum* (the family Fabaceae) were more successful. Investigations were made of 26 different species belonging to five sub-families of the genus *Hedysarum* (representatives of the sub-family *Spinosissima* were not investigated, since they are virtually not encountered on the territory of the USSR). Mangiferin was detected in 12 plant species belonging to the sub-family *Obscura* and in one plant species belonging to the sub-family *Subacaulia*[62]. Among plants of this sub-family, mangiferin was also detected in *Hedysarum denticulatus* Rgl.[66]. Thus, among plants of the genus *Hedysarum*, a relation is observed between the content of mangiferin and the assignment of the plant to a particular sub-family.

It is also of particular interest to note that, among all the plants of the family Guttiferae investigated at the present time, mangiferin is present mainly in plants of the genus *Hypericum*[63,67]. The systematic study of the mangiferin content in plants of this species is only just beginning.

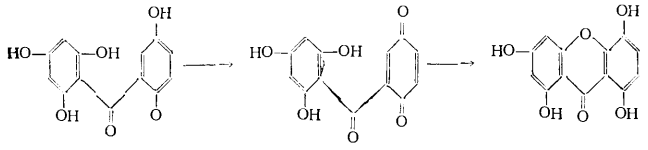
The structural features of lichen xanthones exhibit a definite regularity: the substituents in the xanthone ring are in the 1-, 3-, 6-, and 8-positions, the 8-position is occupied by the methyl group, the 1-position is occupied by the hydroxy-group, and the 3- and 6-positions are occupied by methoxy-groups [compound (XXXIa)]. In the study of lower plants, lichens were found to possess a novel property consisting in their ability to biosynthesise chloro-xanthones. Chlorine atoms occupy the 2-, 4-, 5-, and 7-positions in the xanthone ring. Di- and tri-chloro-xanthones are encountered most frequently, the tetra- and mono-chloro-derivatives being rarer [compounds (XXXI, b

and c)]:[68-71]



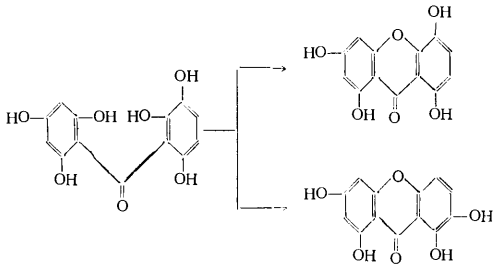
(XXXI)

(a) $R^1=R^3=R^5=H$, $R^2=OCH_3$, $R^4=OH$;
(b) $R^1=R^5=Cl$, $R^3=H$, $R^2=R^4=OCH_3$;
(c) $R^1=R^3=R^5=Cl$, $R^2=OCH_3$, $R^4=OH$.



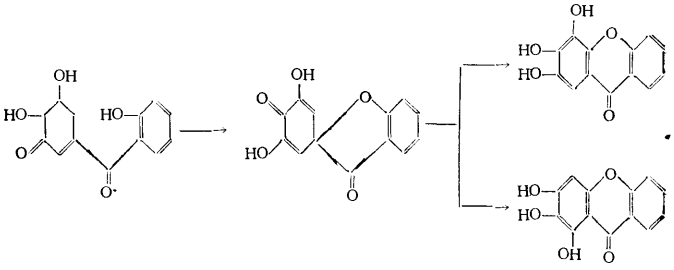
IV. BIOGENESIS OF XANTHONES

At the present time numerous studies on the biogenesis of xanthones have been described in the literature[2,3,72-74]. In higher plants the xanthone compounds with oxygen-containing substituents are biosynthesised by a mixed shikimate–acetate pathway, i.e. intermediates based on shikimic and acetic acid are condensed with formation of polyhydroxybenzophenones, the intramolecular transformations of which lead to the formation of xanthones. The possible mechanisms of such intramolecular transformations are presented in Schemes 1–4.

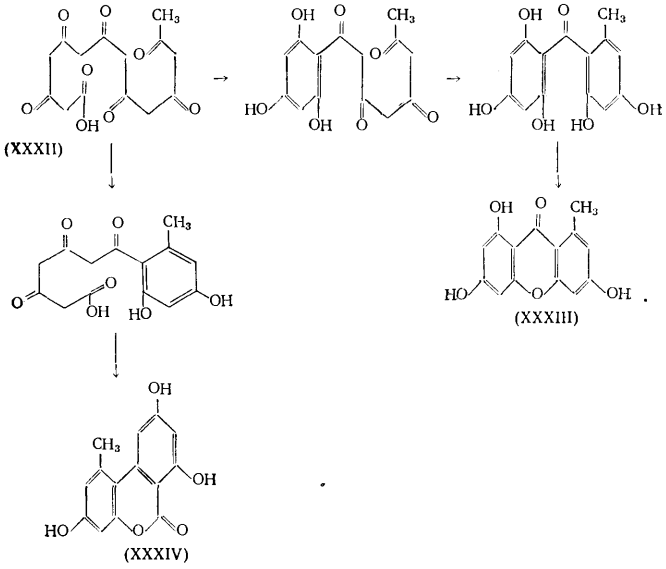


Scheme 1

Scheme 2



Scheme 3

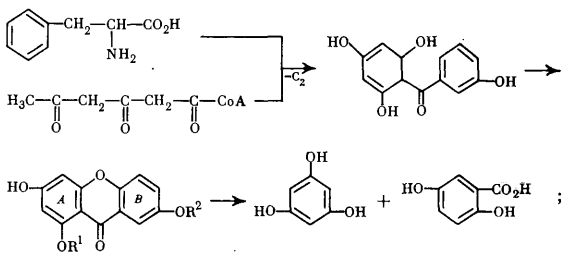


Thus the xanthone structures can be obtained from benzophenones via direct phenolic oxidative addition (Scheme 1), via a quinone stage (Scheme 2), by the dehydration reaction between the OH groups of the ring formed by the acetate mechanism and the ring formed by the shikimate mechanism (Scheme 3), and finally via a spirodiene structure with its subsequent transformation into the xanthone (Scheme 4).

Scheme 4

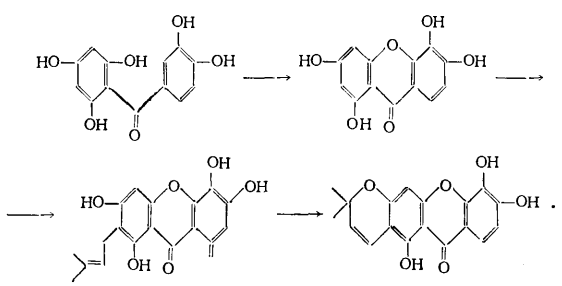
There exist data showing that direct phenolic oxidation of hydroxybenzophenones predominates in higher plants. The formation of xanthones from compounds having the spirodiene structure is more characteristic of certain micro-organisms, which is confirmed by the joint presence of spirans and xanthones in the latter[50]. In higher plants xanthones have not been isolated together with spirans[2].

The same workers pointed out previously[2] the possible involvement of compounds of the polyketone type in the mechanism of the formation of hydroxybenzophenones. In the study of the biogenesis of lichen xanthones by the chemical synthetic method, the involvement of the poly-β-ketone structure (XXXII) in the formation of norliche-xanthone (XXXIII) was demonstrated[75]:



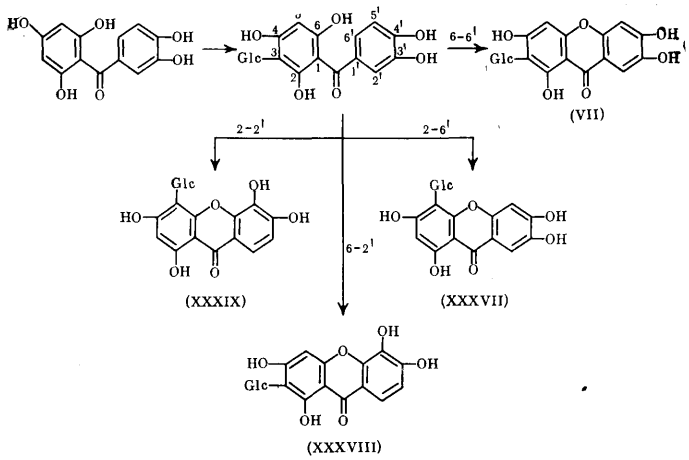
(XXXII) (XXXIII) (XXXIV)

The above scheme shows that there exist two possible reaction pathways for compound (XXXII): as a result of one of these there is a possibility of the formation of the pyranocoumarin (XXXIV), while the other leads to norliche-xanthone (XXXIII). However, in the lichens investigated a pyranocoumarin having the above structure was not detected and the intramolecular transformations of compound (XXXII) in lichens therefore lead to the formation of the xanthone structure.



In order to demonstrate the validity of the hypothesis that hydroxybenzophenones are biosynthesised from shikimic acid derivatives and polyhydroxyphenols formed via the acetate pathway, [^{14}C]phenylalanine was injected into *Gentiana lutea* L.[72]. The xanthone derivatives gentisin (XXXV) and isogentisin (XXXVI), containing, as shown by

the analysis of the pyrolysis products, the radioactive label in the *B* ring, were then isolated from the plant:



CoA = coenzyme A, $R^1 = CH_3$, $R^2 = H$; $R^1 = H$, $R^2 = CH_3$.

In the study of the biogenesis of pyranoxanthones and xanthones containing isoprenyl derivatives, it was established that the isoprenyl substituent is introduced in the *ortho*- or *para*-position relative to the OH group after the formation of the xanthone structure, this being followed by the closure of the isoprenyl chain at the neighbouring hydroxy-group, which leads to the formation of a pyran ring:

The validity of the assumptions made is confirmed by the simultaneous presence in plants of benzophenone precursors and the corresponding "daughter" xanthones with isoprenyl substituents and pyran rings[34,51,76].

The possible pathways in the biosynthesis of xanthone glycosides have been investigated by introducing labelled precursors of the intermediate benzophenones into *Anemarrhena asphodeloides* Bunge[73]. It was found that glycosylation precedes the formation of the xanthone structure; there is then a possibility of four versions of the closure of the γ-pyrone ring (see below). The proposed mechanism has been confirmed by the isolation of mangeriferin and isomangeriferin (XXXVII) from *Anemarrhena asphodeloides* Bunge[17] and of 2-*C*-β-D-glucopyranosyl-1,3,5,6-tetrahydroxyxanthone (XXXVIII);[20] only 4-*C*-glucosyl-1,3-5,6-tetrahydroxyxanthone (XXXIX) has not so far been detected in nature.

(XXXIX) (XXXVII)

(XXXVIII)

V. METHODS FOR THE DETERMINATION OF THE STRUCTURES OF XANTHONES

For the isolation of xanthones, the plant starting material is ground and extracted by the usual methods using, as a rule, solvents with increasing polarity: petroleum ether, chloroform, and methanol[77-79], hexane and acetone[80], ether, acetone, and ethanol[81], etc. Xanthones are extracted usually from lichens using acetone as the solvent, this being followed by treatment of the evaporated extracts with alkali[82-84].

When the starting material is treated with non-polar solvents, mainly the aglycones are extracted. Glycosides are usually extracted with polar solvents after the separation of the total aglycones. The compounds are purified by recrystallisation and also by column and thin-layer chromatography[3]. Apart from thin-layer and column chromatography, gas–liquid chromatography of the TMS-derivatives of xanthones[89] as well as high-pressure liquid chromatography[90,91] have been used successfully for the qualitative and quantitative analysis. The separation by liquid chromatography has been investigated in relation to the compounds obtained from plants of the genus *Gentiana*. A satisfactory separation of the positional isomers has been achieved.

The structures of xanthones are nowadays determined using extensively physicochemical methods such as ultraviolet and infrared spectroscopy, ^1H NMR, mass spectrometry, and X-ray diffraction analysis[39,92].

1. Ultraviolet Spectroscopy

This method is used mainly to determine the positions of the OH groups in the xanthone nucleus. It has been established that the ultraviolet spectra of all natural xanthones are characterised by four intense bands regardless of structural differences: $\lambda_{max}(E)$ = 230–260 nm (20000 – 50000), 260–350 nm (6000 – 28000), 285–300 nm (3000 – 10000), and 325–395 nm (3000 – 12000) [4] (Fig.1).

Sometimes the number of bands increases to five or diminishes to three, but the characteristic spectrum with a specific ratio of the intensities of the short-wavelength and long-wavelength maxima is in general retained. Thus, a given substance can be assigned to the class of xanthones

on the basis of the nature of the absorption in the ultraviolet. In order to determine the location of the OH groups, ionising and complex-forming additives are employed. The ionising additives are usually sodium acetate, methoxide, or ethoxide or caustic alkalis. Thus, in the presence of a free OH group in the 3- or 6-position, the ultraviolet spectrum of the compound in the presence of sodium acetate exhibits a bathochromic shift of the long-wavelength maximum in the range 300–330 nm.

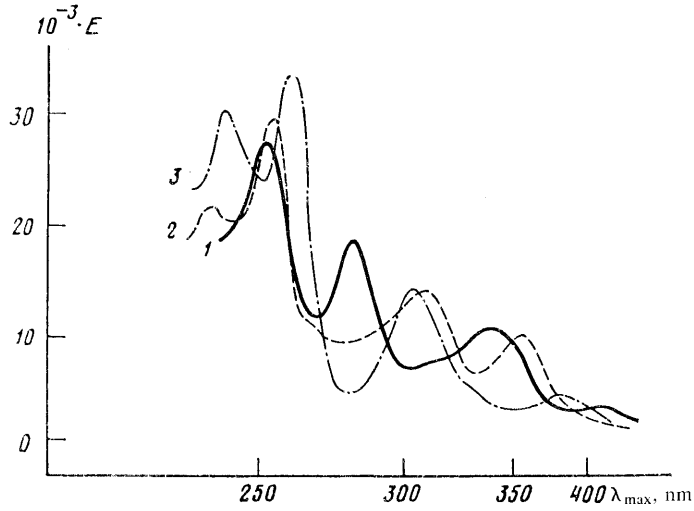

Figure 1. Ultraviolet spectra of xanthones with different modes of substitution in the nucleus (solvent–methanol): *1*) 1,5,8-trihydroxy-3-methoxyxanthone; *2*) 1,3,6,7-tetrahydroxyxanthone; *3*) 1-hydroxy-3,7,8-trimethoxyxanthone.

The OH groups in the 1- and 8-positions can be detected and the presence of the *ortho*-dioxy-group in the molecule can be demonstrated with the aid of complex-forming additives. $AlCl_3$ and boric acid in the presence of sodium acetate are most widely employed for such purposes. The presence of OH groups in the 1- and 8-positions is indicated by the bathochromic shift of the short-wavelength maximum in the range 260–335 nm by approximately 20 nm in the presence of $AlCl_3$. Despite the fact that in the presence of $AlCl_3$ the bathochromic shift of the long-wavelength maximum is about 60 nm, the more intense short-wavelength maximum is used in the test for the presence of the OH groups in the 1- and 8-positions[93,94]. The *ortho*-dioxy-groups also form a compound with $AlCl_3$, but such a complex decomposes in the presence of hydrochloric acid. Boric acid in the presence of sodium acetate, which causes a bathochromic shift of the long-wavelength maximum, is used in the test for the *ortho*-dioxy-groups.

The addition of sodium methoxide to an analytical solution of xanthones can be used to detect vicinal OH groups. This constitutes the optical version of the Bargellini reaction and is manifested by the absence from the ultraviolet spectrum of the four absorption maxima characteristic of the xanthone structure[95,96] (Fig. 2).

2. ^{1}H NMR

^{1}H NMR is a method which yields most information for the determination of the structures of xanthones as regards the nature and relative positions of the substituents. There have been a number of studies in which the proton spectra of hydroxy- and methoxy-xanthones, recorded in different solvents, were analysed[97–99].

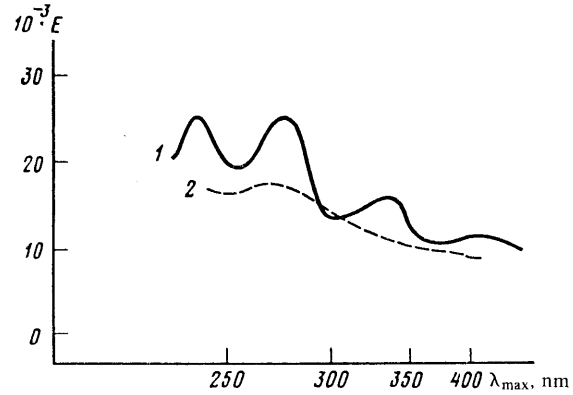

Figure 2. Changes in the ultraviolet spectrum of swertiaperennin (1,2,3-trihydroxy-7,8-dimethoxyxanthone) in the presence of $NaOCH_3$ (solvent–methanol): *1*) swertiaperennin; *2*) ditto plus $NaOCH_3$.

The aromatic protons of xanthones are manifested in the range 6.00–8.05 p.p.m. If the compound is a glycoside, then also the aliphatic protons of the carbohydrate substituents are observed in the range 3.00–5.60 p.p.m.[79] The protons of the aromatic methoxy-groups give rise to signals in the range 3.80–4.10 p.p.m. The ^{1}H NMR spectrum of a hydroxyxanthone recorded in dimethyl sulphoxide exhibits in the range 12–14 p.p.m. the signal of the protons of the OH groups in the 1- and 8-positions, while the proton signals of the OH groups in the other positions of the xanthone nucleus are displaced upfield to 9–11 p.p.m. The ^{1}H NMR of acetylxanthones has been used successfully recently for the determination of the structures of xanthones[79,100]. Thus signals in the range 2.40–2.50 p.p.m. (solvent–chloroform) indicate the presence of the acetyl substituent in the 1- and 8-positions, while the acetyl substituents in the other positions of the aromatic nucleus are manifested in the range 2.30–2.35 p.p.m. The signals of the protons of the aliphatic acetyl groups are displaced to a still stronger field—1.90–2.20 p.p.m. (Fig. 3).

The protons of the aromatic ring containing the chelate hydroxyl (OH groups in the 1- or 8-position) give rise to signals in a stronger field than the corresponding protons of the ring without a chelate hydroxyl. This can be accounted for by the higher electron density in the ring owing to chelation. In the case of glycosides this effect is observed most effectively in solution in deuteriated DMSO.[4]

The signals of the protons of the methyl groups of the isopropenyl substituent in the xanthone molecules are usually manifested as three-proton singlets in the range 1.1 to

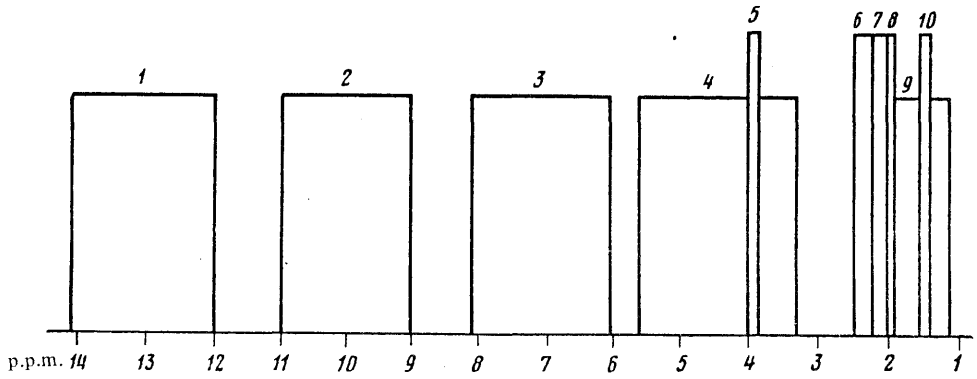

Figure 3. The proton chemical shifts in the ^{1}H NMR spectra of xanthone derivatives: *1*) OH groups in the 1- and 8-positions; *2*) OH groups in the 2–7-positions; *3*) aromatic protons; *4*) aliphatic protons; *5*) protons of aromatic CH_3O groups; *6*) protons of the CH_3OCO group in the 1- and 8-positions; *7*) protons of the CH_3OCO group in the 2–7-positions; *8*) protons of the carbohydrate component; *9*) protons of the $(CH_3)_2C=$ group; *10*) protons of the $(CH_3)_2C$ group.

1.8 p.p.m.[5]. The signals of the protons in the angular methyl groups in the molecule of a pyranoxanthone are observed in the range 1.4–1.5 p.p.m. (Fig.4).

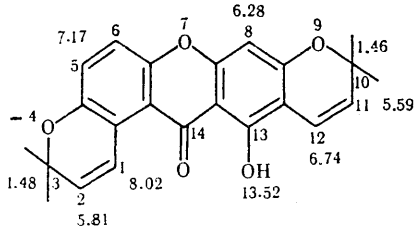

Figure 4. Distribution of the proton chemical shifts (p.p.m.) in pyranoxanthone[101].

Fig.4 shows that the chemical shifts of the protons in the 2- and 11-positions of the pyran ring are displaced upfield relative to the signals of the protons in the 1- and 12-positions, which can be accounted for by the electron-donating influence of the protons of the angular methyl groups at the C(3) and C(10) atoms.

The problem of the site where the carbohydrate component is attached frequently arises in the determination of the structures of xanthone glycosides. The exhaustive methylation method with subsequent hydrolysis of the glycosides proved to be extremely effective for the solution of this problem. Furthermore, direct comparison of the spectra of the glycosides and their aglycones yields information about the site of addition of the carbohydrate component to the xanthone nucleus. The spin–spin interaction constant for the signal of the anomeric protons of the glycosidic centre yields information about the nature of the glycosidic linkage.

The Overhauser effect has also been used to elucidate the positions of the substituents in the xanthone nucleus[102].

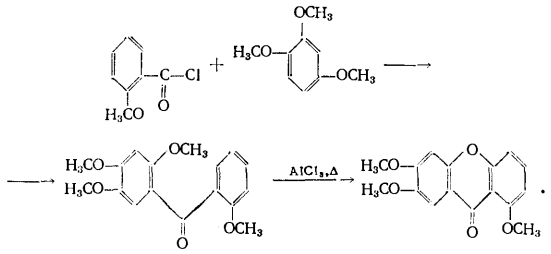
^{13}C NMR has been used successfully in recent years for the determination of the structures of xanthones[103–105]. The ^{13}C NMR spectra of polyhydroxyxanthones (aglycones, *O*- and *C*-glycosides) have been investigated. ^{13}C NMR spectroscopy is of special diagnostic importance for the determination of the nature of the relative positions of the monosaccharides in diglycosidic substituents[4].

3. Infrared Spectroscopy

The assignments in the infrared spectra of xanthones are complicated by the strong interaction of the vibration of the carbonyl group and the C=C bonds of the γ-pyrone ring. According to some data[106], the highest-frequency 1660 to 1670 cm^{-1} band in the range 1500–1700 cm^{-1} has been assigned to the vibrations of the carbonyl group. However, further investigations showed that this band is due to the vibrations of the C=C bonds of the γ-pyrone ring, while the vibrations of the C=O group give rise to a band in the range 1620–1640 cm^{-1}.[4,107]

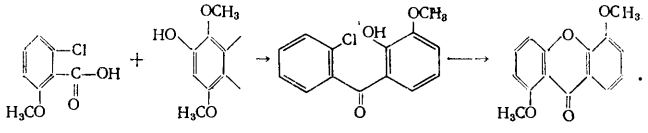
Santesson[108] investigated the infrared spectra of lichen polyhydroxyxanthones in the range 1500–1700 cm^{-1}.[108] It was found that the frequency of the band corresponding to the C=O group is reduced by 15–25 cm^{-1} after the introduction of an OH group in the 1-position. This effect is evidently due to chelation, since alkylation or esterification of the OH group returns the frequency of the C=O group to its previous value.

Klimenko et al.[109] carried out a theoretical calculation of the vibrations of the xanthone molecule; the symmetry of certain vibrations was determined from the dichroism of the infrared bands.



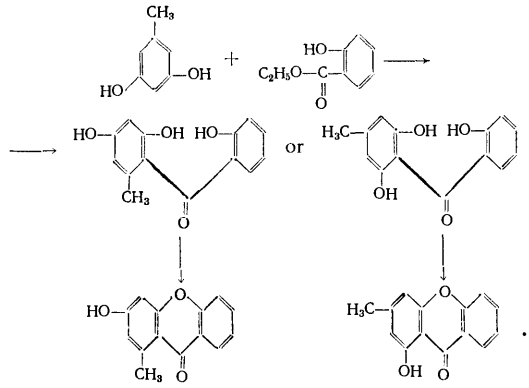
The band in the range 3200–3500 cm^{-1} in the infrared spectra of hydroxyxanthones is due to the vibrations of the chelate hydroxyls, while the bands in the range 1500 to 1600 cm^{-1} are assigned to the vibrations of the aromatic C=C bonds. The region below 1500 cm^{-1} is specific to each compound and can be used successfully for the identification of xanthones.

Mass spectrometry has been used widely in recent years for the determination of the structures of xanthones. Aritomi et al.[110] used this method in the study of the fully acetylated derivatives of mangiferin and isomangiferin. The mass spectra of xanthone *O*-glycosides do not contain the characteristic molecular peak, but the molecular peak of the aglycone (M^+) and the nature of its fragmentation yield information about the structure of the substance. Thus the mass spectra of hydroxyxanthones usually exhibit signals due to the fragments (M^+-OH), (M^+-CO), and (M^+-CHO). When one or several methoxy-groups are introduced into the xanthone, its mass spectrum shows signals due to the fragments (M^+-CH_3), (M^+-CH_2O), and (M^+-CH_3CO).[111,112] The presence of a weak molecular peak has been noted in the fully methylated derivatives of xanthone *O*-glycosides[4].

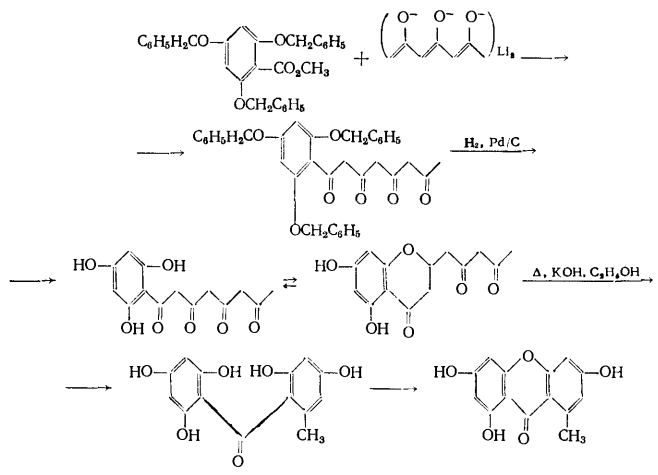


VI. SYNTHETIC CHEMICAL METHODS IN THE STUDY OF NATURAL XANTHONES

The preparation of synthetic xanthone derivatives was used previously only to confirm the structures of natural xanthones[1]. At the present time the applications of synthesis in the study of natural xanthones have expanded and make it possible to solve certain biogenetic problems. Furthermore, chemical synthesis is used to prepare biologically active natural xanthones.



One of the common reactions used to synthesise xanthones is the Friedel–Crafts reaction between aromatic carboxylic acid chlorides and polyhydroxyphenols[113–116]. The corresponding benzophenone is an intermediate. The benzophenone cyclises to the xanthone on heating the reaction mixture to 200–220 °C.[117] If polymethoxyphenols are involved in the reaction, then the benzophenone formed as an intermediate undergoes partial demethylation in the *o*-position relative to the carbonyl group. Aluminium chloride is usually employed as the dimethylating agent[113,118]:



If *o*-chlorobenzoic acids are used in the reaction, then the cyclisation of benzophenone to the xanthone takes place under milder conditions[117]:

Xanthones can be obtained by the cyclocondensation of phenols with methyl or ethyl *o*-hydroxyarenecarboxylates in diphenyl ether[119]:

In the modelling of processes occurring in the biogenesis of xanthones in lichens, an aldol-type cyclisation of 1-(2,4,6-trihydroxyphenyl)octane-1,3,5,7-tetraone was used to prepare natural xanthones. The corresponding benzophenone is formed as an intermediate, undergoing subsequent dehydration[75]:

(XXIX)

The acid-catalysed cyclocondensation of hydroxy-derivatives of diphenyl ether and phosgene[120] and also the intramolecular cyclisation of 2-carboxy-derivatives of diphenyl ether[121] can be used to synthesise polyhydroxy-xanthones.

A reaction involving the synthesis of xanthones from ω-acetoxy-2-acylcyclohexanones has been described[122].

The most convenient method of synthesising pyrano-xanthones has been developed by Locksley and coworkers[123–126]. It is based on the synthesis of 2-alkyl-1-hydroxyxanthones from 1-allyloxyxanthones by the Claisen rearrangement with subsequent modification of its side chain. The derivatives of 1-hydroxy(3-methylbut-2-enyl)xanthones obtained in this way are treated with hydrobromic or hydriodic acid. Depending on the reaction conditions, angular or linear pyranoxanthones are obtained.

The syntheses of xanthone glycosides have been investigated. The addition of the glycosidic residue to the aglycone takes place via a reaction involving the condensation of the aglycone with acetyl-α-D-glycosyl bromide, the formation of both *C*- and *O*-glycosides being possible depending on the reaction conditions. Thus, when the

reaction is carried out in methanol in the presence of sodium methoxide, the hydrocarbon substituent adds to the aglycone via a C–C bond[118]. *O*-Glycosides are formed when the reaction is carried out in pyridine in the presence of silver carbonate[127,128].

VII. PHARMACOLOGY OF XANTHONES

Plants containing xanthones have been used for a long time in Soviet medicine[129,130]. Current research has shown that xanthones exhibit an extremely wide variety of pharmacological activities. Antidepressant, antimicrobial, cardiotonic, diuretic, and antiviral activities of xanthones have been noted.

The stimulating activity on the central nervous system (CNS) and the antitubercular activity of certain natural and synthetic derivatives of xanthones have been investigated in greatest detail.

The search for natural compounds with antidepressant activity has been prosecuted mainly among plants of the family Gentianaceae[131]. Xanthones differing in the number and relative positions of hydroxy- and methoxy-groups have been the object of study. It was noted that the aglycones[130] and also the xanthone *C*-glycoside mangiferin[132] have the most marked antidepressant activity. The fact that the xanthone *O*-glycosides have in fact a depressant activity on the CNS and an anticonvulsant activity proved to be of very great interest[133]. However, natural xanthones do not exhibit a clear-cut relation between the nature of the antidepressant activity and structure. In order to investigate in greater detail the dependence of the nature and strength of the antidepressant effect on the structure, a series of semisynthetic methoxy-amino- and chloro-xanthones substituted in the 2-, 3-, 4-, and 6-positions were screened[134,135]. The introduction of the hydroxy-group in the 3-position increased the activity of the xanthone compound and substitution of the 6-position by a chlorine atom greatly altered the nature of the antidepressant activity and increased the toxicity of the compound.

The studies on the antitubercular activity of natural xanthones proved to be extremely fruitful[136,137]. Thus, in the investigation of xanthones from the ethanol extract of *Canscora decussata* Achult, it was observed that the sum of the aglycones has a more marked tuberculostatic activity than the xanthones and the glycoside mangiferin[138]. In order to investigate in greater detail this behaviour, a study was made of fourteen natural and semisynthetic xanthones differing in the positions of the hydroxy- and methoxy-groups and in the presence or absence of a carbohydrate substituent[139]. Experimental results revealed a definite relation between the type of substitution in the xanthone nucleus and the tuberculostatic activity: the activity of xanthones is manifested in the presence of hydroxy- or methoxy-groups in the 1,3,5,6- or 1,3,8-positions in the xanthone nucleus. With increase of the number of hydroxy-groups in the above positions, the activity rises. Thus 1,3,5,6,7- and 1,3,6,7,8-pentahydroxyxanthones proved to be the most active. When a carbohydrate substituent is introduced into the molecule, the activity falls.

3,6,8-Trihydroxy-1-methylxanthone, with appreciable antibacterial activity, has been isolated from the metabolic products of *Penicillium patulum*.[140]

Studies on the antitumour activity of natural xanthones have been started in recent years. Thus 1,6-dihydroxy-xanthones and 1,3-dihydroxyxanthones among the 18 natural xanthones isolated from *Mammeae americana* were found to have an appreciable inhibiting activity in relation to sarcoma 180.[141]

1,8-Dihydroxy-3-methylxanthone, which exhibits an antifungal activity, was obtained from the defatted seeds of *Cassia tora*. The compound manifested an activity in relation to certain *Trichophyton*, *Microsporum*, and *Geatrichum* species in the presence of 100 mg ml^{-1} of L-ascorbic acid as the antioxidant[10]. An antifungal activity in relation to certain *Fusarium* species has also been noted in mangiferin[142,143].

Mangiferin is the most thoroughly investigated xanthone derivative from both physicochemical and pharmacological points of view. Apart from its stimulating effect on the CNS,[132] it exhibits cardiotonic and diuretic effects[144], influences the water metabolism[145], and has some antitubercular activity[138,142,143]. Medicinal forms of this substance have been developed: tablets, suppositories, and solutions for injection[144].

The results of a pharmacological study of mangostin [3,6,8-trihydroxy-2-methoxy-1,7-di(3-methylbut-2-enyl)-xanthone] and its derivatives were published in 1979.[146] Almost all the compounds have a depressant effect on the CNS and in addition the 3,6-di-*O*-glucoside of mangostin has a stimulating effect on heart muscle and increases blood pressure. Mangostin, 1-isomangostin, and mangostin triacetate have an appreciable anti-inflammatory activity, manifested even in the case of bilateral adrenalectomy in rats; mangostin has also been found to have an antiulcer activity.

Together with the study of natural xanthones, investigations have been made in recent years of the pharmacological properties of synthetic xanthone derivatives in order to carry out specific syntheses of compounds with a specified spectrum of pharmacological activity.

The synthesis of various alkylaminoxanthones constitutes the most interesting trend. Thus Fleming and coworkers[147] synthesised a series of di(aminoacetyl)xanthones which act against certain viruses affecting warm-blooded animals, including the viruses of encephalomyocarditis, the viruses of the herpes group, etc.

Baum[148] investigated the antiarrhythmic activity of bis(dialkylamino)ethoxyxanthones in experiments on dogs. The highest activity was noted in 1,6-bis-2-di-(isopropenylamino)ethoxyxanthone.

Studies on the pharmacological activity of various derivatives of xanthone-2-carboxylic acid, which proved to be active in asthmatic conditions, have been of very great interest[149]

* * *

The studies carried out hitherto on natural xanthones undoubtedly demonstrate their enormous value as regards the creation of new medicinal preparations. The continually growing interest in this type of compound is indicated by the fact that in recent years studies have begun on the mechanism of the pharmacological activity of xanthones at the biochemical level. Thus, in connection with the investigation of the stimulating effect of natural xanthones on the CNS, detailed studies have been made of the mechanism of the inhibition of monoamino-oxidase by isogentisin and its 3-*O*-glucoside.[150] The relation between the structures of xanthones and their ability to inhibit AMP phosphodiesterase has been investigated[151].

There is no doubt that further more profound studies on these lines will extend the pharmacological applications of natural xanthones.

Russian Chemical Reviews

November 1982

Translated from *Uspekhi Khimii*, 51 1777-1817 (1982)

U.D.C. 541000–547000

In the Vanguard of Chemical Progress (Jubilee of *Uspekhi Khimii*)

V.A.Nikanorov

UK/11.1777

In 1982 fifty years have elapsed since appearance of the first issue of the periodical *Uspekhi Khimii*.

This journal was founded at the beginning of the 1930s by a decision of the USSR State Education Committee to publish the most important reviews in the field of theoretical and experimental chemistry and chemical technology, as indicated in the first editorial statement[1]. This had serious methodological or generalising value and resulted from constructive critical thought combining the most recent scientific advances into a single elegant whole. It has now become the leading publication of the USSR Academy of Sciences having comprehensive chemical interest, on whose pages are fully reflected all aspects of the development of chemical science in our country and abroad.

For a long period of time now, coinciding with exceptionally vigorous development of chemical science, *Uspekhi Khimii* has performed successfully two important and worthy functions. Firstly, the journal is the most authoritative vehicle for the most recent theoretical and practical achievements of Soviet chemists, regularly acquainting the international chemical community with them. The reviews carry great weight and authority, since they have usually been presented as serious scientific and analytical summaries of the results of many years' experimental or theoretical investigations by whole teams of scientists, which had already been approved either as ordinary papers or at congresses and conferences, and in several cases have been incorporated into current practice. The second function of the journal is to acquaint the Soviet specialist reader with the most important achievements of world chemistry and cognate disciplines, with the best reviews, and with current trends. Since chemical science in our country, while retaining, of course, all its national, organisational, and historic features and traditions, also constitutes an extremely authoritative part of the world chemical community, making its own original contribution to the general development of this science, these two scientific information functions have long been the principal characteristics of the activity of the journal: *Uspekhi Khimii* is now one of the most authoritative vehicles of the international policy of world scientific collaboration, contributing by its work to the comprehensive development of current scientific and technical progress.

Analysing the various aspects of the many sided scientific informational, educational, and also organisational activity of the journal, reflecting the growth in its international authority, it is of interest to recall the creative history of *Uspekhi Khimii*, in order to assess through the prism of its most important scientific papers the contribution that academic chemists have made to the development of Soviet chemical science and industry, to the establishment and elaboration of new branches and trends, also to the organisation and growth of the chemical press and chemical education, and to the training of scientific and technical personnel in our country.

Five main periods of activity of the journal can now be distinguished—an initial stage (from the founding to the beginning of the 1940s), its work during the years of the Great Patriotic War (1941–1945), then the first postwar decade, the 1950s and 1960s, and the present stage—each period characterised by definite scientific and organisational experience, reflecting the efforts by members of its

editorial boards and all its authors and collaborators, which has now served the scientific training of several generations of research chemists.

The initial stage, associated with the names of the founders of the journal (N.P.Gorbunov, A.N.Bakh, A.M. and B.M.Berkengeim, E.V.Britske, S.I.Vol'fkovich, V.V.Potemkin, N.D.Zelinskii, N.S.Kurnakov, and A.N.Frumkin), was distinguished by exceptional fruitfulness. In view of the long absence of a chemical review journal of our own together with a large accumulated scientific potential, due both to many years of work by older generations of chemists and to the influx of fresh scientific and technical personnel, the main value of the journal during those years lay chiefly in its informational and organisational functions both in fundamental science and in the practical application of chemical advances to the national economy.

Founded in the circumstances of the industrial upsurge of the early five-year plans, *Uspekhi Khimii* responded promptly during those years to the most urgent problems of the chemical industry then being established in the USSR. The first issue already containing the full text of the directive by the USSR State Planning Committee and the Committee on Chemicalisation of the National Economy to draw up a plan for scientific research on chemistry and chemical technology[2], in which growth of the chemical industry depended on solving problems of fuel and power (the efficient industrial utilisation of petroleum, coal, lignite, bituminous shales, and peat, and also the liquefaction of solid fuel), working out the most effective technical chemical processes in ferrous, non-ferrous, and electrical metallurgy (development of flotation methods, formulation of novel metal alloys, in particular acid-resistant, heat-resistant, and high-speed steels, protection of metals from corrosion, use of oxygen in metallurgical processes, extraction of light metals—lithium, sodium, beryllium, magnesium, aluminium), chemicalising agriculture and forestry (the search for combined and concentrated organic and inorganic fertilisers, use of new insecticides, development of agricultural chemistry and biochemistry), and finally developing further mineral and organic technology with the aim of obtaining inorganic and organic substances, products, and materials†.

The pages of the journal reflect during those years the problems of combining power–chemical, metallurgical–chemical, and purely chemical processes in single industrial units, aspects of the study of rare and radioactive elements with procedures for their isolation and separation, technological features of the production of ammonia, chlorine, bromine, and iodine, improvements to the cracking of petroleum, the manufacture of synthetic rubber, dyes, artificial fibres, and plastics, medicinals, surface-active agents and perfumes, lubricating oils, and many other products of industrial importance.

The journal paid close attention also to raw-materials problems. The first issue already contained a paper# by A.E.Fersman on "New Problems in the Study of Mineral Resources", devoted to aspects of the utilisation of air, clay, sand, quartzites, and nephelines in large-scale combined production. Together with problems of the technology of natural resources (metals, sodium carbonate, cement, silicates) several papers examined aspects of the widespread industrial use also of agricultural resources (manufacture of alcohol, acetone, acetaldehyde, furaldehyde, acetic acid), the development of biochemical methods for increasing the content of valuable substances in plants (fibres, oils, fats, ethers, esters, starch, glycerol, proteins, vitamins, alkaloids, and tanning agents), and also the production of important organic compounds (hydrocarbons, ethylene, acetylene, butadiene, fatty acids). Effective use of solar energy was regarded as having promise for the future.

Papers in the journal during those years responded also to problems involved in establishing and developing new provincial industrial complexes. Thus aspects of the investigation of natural salt equilibria in terms of physicochemical analysis, developed in N.S.Kurnakov's school, were examined in the paper "The Kara-Bogaz-Gol Problem"; a special paper was also concerned with prospects for industrial organic synthesis associated with construction of the Kuibyshev hydroelectric station and the Second Baku.

Industrial growth in chemical fields of the national economy should be based on an intensification of fundamental scientific research, directed primarily at study of the structure of matter by the latest physical methods, development of the theory of catalysis and chemical kinetics, study of surface phenomena (including adsorption), application of new physicochemical methods to solve problems of organic chemistry, development of new production processes based on novel catalytic reactions, application of the methods of colloid chemistry, and study of solid-phase and photochemical reactions, as well as the chemistry of ultrapure substances.

Among the chief administrative measures taken to secure such investigations were development of a network of general and specialised research institutes and up-to-date works laboratories, and also expansion of the research activity of higher educational institutions with intensified training of personnel for scientific research (in 1939 the journal published the slogan of the Mendeleev All-Union Chemical Society "Youth for Science!").

Thus the historical circumstances of these years themselves promoted in every possible way conversion of the first native academic review journal into a unique and most authoritative forum of science, information and organisation to bring together the combined efforts of all investigators developing new lines of chemical research in the country.

Analysis of the activity of the journal shows that it coped with the task entrusted to it, many of its papers on fundamental science paving the way for current chemical trends. From a methodological point of view, perhaps the most considerable achievement of *Uspekhi Khimii* during the initial period was to develop its own original scientific personality, with an independence and systematic strategy for interpreting current chemical advances. The strategy consisted in particular in orienting the journal towards quantitative features of various aspects of chemistry and elucidating the physical nature of the principles underlying chemical changes.

Although the journal has on the whole preserved its chemical character from its founding till the present time, its editorial board realised even during the initial stage that future progress in all chemical sciences would be determined in considerable measure by advances in contemporary theoretical and experimental physics, including quantum mechanics. In the opinion of I.Langmuir, a paper by whom was published in the journal§, theoretical scientific research is of

†One detail indicating the active organising work of the editorial board of *Uspekhi Khimii* was a special note asking readers to send in their additions to this plan, for consideration by the Chemicalisation Committee in the subsequent planning of scientific research topics.

#Precise references to all the papers discussed subsequently in the survey can be found from keywords in review titles or from the reviewers' names in the appropriate subject and author indexes[3].

§The work of foreign investigators was published in *Uspekhi Khimii* during those years either as Russian translations of contributions to international periodicals or as specially commissioned papers and reviews by leading specialists.

immense value to mankind. However, although theoretical physics underwent an exceptional flowering precisely during those years, the validity of a so-to-say "physical" orientation for a chemical publication was nevertheless far from obvious at that time, and it is only now that, while giving credit to the scientific intuition of the journal, we are able to assess the correctness of the path chosen.

Among purely physical contributions of those years ("Physics of the Nucleus" by P.Debye, "Atomic Structure and Chemistry" by B.F.Ormont, "New Elementary Particles" by E.V.Shpol'skii and later D.D.Ivanenko, "Nuclear Reactions" by S.Z.Roginskii, and "Isomeric States of Atomic Nuclei" by A.A.Grinberg) work on natural and artificial radioactivity and the production of new elements (protactinium, neptunium, technetium, francium) attracted especial attention from the journal. As always, preference was given to original sources, i.e. contributions by the most authoritative workers in these fields (F.Joliot and I.Joliot-Curie's "On the Artificial Production of Radioactive Elements", O.Hahn's "Application of Radioactive Methods to Chemistry" and "Chemical Elements and Natural Forms of Atoms", L.Meitner's "On Artificial Radioactivity" and I. and W.Noddacks' "Current State of Theories of Radioactive Disintegration").

The reader was kept regularly informed of advances in research on nuclear fission (papers by F.Joliot and N.Bohr on "New Work on the Splitting of Uranium and Thorium Nuclei" and "Spontaneous Fission of Uranium"), and briefly acquainted annually with the current literature on nuclear physics, with sessions of the Physics Group of the USSR Academy of Sciences, and also with foreign and All-Union scientific conferences (we may note I.V.Kurchatov's report on the 1940 All-Union Meeting on the Physics of the Atomic Nucleus). As a consequence of such effective operations by the journal every chemistry specialist who regularly examined its contents could be kept informed on the most recent scientific advances in these fields during all those years.

The achievements of nuclear physics and the discovery of new elements aroused great interest at the time in the structure of Mendeleev's Periodic System of the Elements and in the nature of the Periodic Law. The journal satisfied readers' interest in these problems extremely fully, with articles by such authorities as E.Rutherford ("The Periodic Law and its Interpretation"), L.Meitner ("Atomic Weight in Present-day Science"), and V.G.Khlopin ("Transmutation of Elements and the Periodic Law"); that by B.M.Kedrov refined the very concept of "chemical element".

Progress in all these scientific fields would have been inconceivable without the creation of a universal theoretical apparatus to describe microphenomena—quantum mechanics—the current state of which was presented in E.Schrödinger's paper. Among its contents, the journal revealed also the contemporary quantum-chemical treatments of such concepts as "chemical bond" and "valency", by linking analytical papers on this important topic with instructive surveys in the 1940 Section "Aid to the Chemistry Instructor in Higher Education", in which Ya.K.Syrkin, M.E.Dyatkina, and A.A.Zhukhovitskii were active.

Another important feature of the quantum mechanics of those years reflected in the papers of *Uspekhi Khimii*, besides its contribution to pure physics and the study of molecular structure, was its incipient penetration even into chemistry. The development of quantum mechanics at that time acted as a powerful stimulus to that of several classical fields of physical chemistry (e.g. the quantum-mechanical adsorption theory of D.Blokhintsev and S.Shekhter), and to the establishment of a basis for a new and independent branch of science—chemical physics, whose object was to investigate the fundamental physical principles of chemical reactions.

Since many of the fundamental successes of chemical physics in understanding the physical essence of chemical processes occurred precisely in prewar decades, it is remarkable that establishment of the journal *Uspekhi Khimii* (1932) almost coincided in time with foundation of the USSR Academy of Sciences' Institute of Chemical Physics (1931), the first in the world, whose chief scientific interests and achievements (a physical basis for the concepts of valency and chemical affinity, investigation of chemical kinetics and construction of a theory of primary chemical processes in gas and condensed phases, study of the mechanism of energy exchange and transfer in chemical reactions, development of new physical research methods), and also the production of novel substances and materials (e.g. artificial diamonds—O.I.Leipunskii) are reflected in the pages of the journal from the very early years right until the present time.

N.N.Semenov's paper "Chemical Forces and the Theoretical Foundations of Chemical Kinetics" in the first issue already drew attention to the inability of classical physical chemistry—based on thermodynamics, which is concerned with equilibrium states (and therefore, in the author's opinion, would have been more correctly termed *thermostatics*)—to provide a true understanding of the dynamic process of chemical change, i.e. to solve the main problem of chemical physics, which is to calculate absolute rates and activation energies of chemical reactions. This paper suggested that the theoretical principles of chemical kinetics should be based on atomic structural data treated by quantum mechanics; methods for estimating forces of chemical affinity from the analysis of continuous and line spectra and use of these results in chemical dynamics were given for several thermal and photochemical reactions, including various types of dissociation and association stages and energy-exchange processes.

Prewar decades, which coincided with the years during which the scientific activity of the journal was initiated and developed, were characterised by exceptional progress in chemical physics, especially in those branches concerned with formulating a theory of primary chemical processes. *Uspekhi Khimii* showed great efficiency in publicising all these achievements, so that several basic researches in this field, undertaken both in the USSR and abroad, and of fundamental importance for the subsequent development of chemical science, as is now evident, appeared in the journal amost without delay.

Such work included the theory of thermal ignition (N.N.Semenov) and a mathematical formulation for describing thermal flame propagation(D.A.Frank-Kamenetskii), the theory of branched chain reactions, which explains the nature of the lower and upper (pressure) limits of ignition in the oxidation of hydrogen and other elements (N.N.Semenov, C.N.Hinshelwood), and finally direct spectroscopic proof of intermediate formation of the free radical HO· and the determination of its concentration during the oxidation of hydrogen (V.N.Kondrat'ev).

Exceptional progress was made during those years also in formulating theoretical principles of chemical kinetics, with the introduction of such basic concepts as the potential-energy surface and the barrier to reaction. The reader could become acquainted with them from original sources—through review papers by the founders of the theory of rate processes and the transition-state method—H.Eyring, M.Polanyi, E.Wigner, and their successors. Later a special issue appeared in memory of N.A.Shilov, who had elaborated the theory of concerted chemical reactions and made a considerable contribution to the development of several branches of physical chemistry.

Progress in quantum theory, as well as in chemical physics and the kinetics of primary chemical processes, served during those years as a powerful stimulus to elucidation of

the fundamental physical principles underlying chemical changes involving complicated organic compounds. The most significant contributions on this theme were theoretical papers by E.Hückel and by L.Pauling, in which discussion of the structure and the properties of several aromatic and unsaturated organic molecules involved use of molecular orbitals and resonance theory, and also C.K.Ingold's papers ("Principles of the Electronic Theory of Organic Reactions" and "Structure of Benzene"), in which the concept of mesomerism (B.Eistert) was used in posing the same problems. Together with L.Hammett, who published in *Uspekhi Khimii* his review "Some Relations between Reaction Velocities and Equilibrium Constants", which initiated the subsequent widespread use of correlation equations in chemical kinetics (principle of the linear variation of free energy), and in the 1960s introduced the concept of the acidity function H_0 of solutions of strong acids. All the above authors are regarded as founders of the new scientific discipline that was subsequently termed *physical organic chemistry*.

Together with all these trends, research on physical chemistry was also actively pursued during prewar years, and was also exceptionally fully represented on the pages of the journal. This involved physicochemical analysis of salt and colloidal systems, and also of metallic equilibria, the theory of intermolecular forces (G.Briegleb), the theory of melts and solutions (numerous articles on their viscosity and electrical conductivity were provided by V.K.Semenchenko, a collaborator of the journal for many years), the theory of aerosols, adsorption, condensation, evaporation, and vapour pressure. During these and subsequent years the journal reflected in detail the physicochemical interpretation of the photographic process—the theory of the photolysis of silver bromide and formation of the latent image in the emulsion (K.V.Chibisov), optical sensitisation (Kh.S.Bagdasar'yan) and desensitisation, aspects of the mechanism of development, including that of multilayer colour film.

An important direction in which *Uspekhi Khimii* was active in the initial period, which later became traditional, was detailed coverage of the theory and practice of physicochemical methods of investigation and analysis. The journal always appreciated the importance of such contributions, for their conclusions and recommendations were generally promptly used by chemists of the most diverse specialities and have very many practical applications. During the 1930–1940s reviews and papers were published on X-ray structural analysis (W.Bragg), on crystal-optical methods of investigation, dipole moments (N.Sidgwick), the parachor, X-ray diffraction by liquids (H.Stuart), thermotensimetry and calorimetry, ultrasonic methods.

Since many of these methods were at that time relatively novel and not always known to a wide circle of readers, it was important to acquaint specialists with their theoretical basis and practical applications, by publishing papers by their direct originators. This applies to the ultracentrifuge (T.Svedberg), and also to the then recently discovered Raman effect (L.I.Mandel'shtam, G.S.Landsberg), which during those years was used especially widely to establish the structures of organic, inorganic, and polymeric molecules, and also to analyse the hydrocarbons present in liquid fuels. *Uspekhi Khimii* printed also work on molecular spectroscopy (as applied to problems of molecular structure or thermodynamics—Ya.I.Gerasimov), on polarography and chromatography, which subsequently became among the most popular research methods in chemistry and have occupied a prominent place in later issues.

The range of scientific activity of *Uspekhi Khimii* was extremely diverse during those years. The pages reflected organic chemistry (reviews by N.Ya.Dem'yanov and M.Tiffeneau on the novel molecular rearrangements of cyclic hydrocarbon systems with ring expansion and contraction that they discovered), the coordination chemistry of complex compounds (I.I.Chernyaev and A.A.Grinberg's papers), geochemistry (A.P.Vinogradov's papers), the chemistry of hetero-organic compounds—of lithium (G.Wittig), boron and thallium (N.N.Mel'nikov), mercury (A.N.Nesmeyanov), germanium, tin, and lead (K.A.Kocheshkov), and phosphorus (V.M.Plets)—and the chemistry of macromolecular compounds (contributions by H.Staudinger and W.Carothers, its founders), which was especially evident on the pages of the journal during the following decades.

Much of the work published in *Uspekhi Khimii* received high international recognition. Thus physical fields of chemical research or the establishment of novel chemical disciplines were reviewed by winners of the Nobel Prize for chemistry—F.Aston, G.Wittig, O.Hahn, P.Debye, I. and F.Joliot-Curie, W.Lipscomb, I.Langmuir, G.Natta, L.Pauling, W.Prelog, T.Svedberg, N.N.Semenov, G.Seaborg, J.Wilkinson, O.Fischer, G.Hevesy, C.Hinshelwood, H.Staudinger, H.Urey—during various years. Another leading research subject during the 1920–1930s was the chemistry of natural compounds. It is sufficient to state that around ten Nobel Prizes were awarded for work in this field during fifteen prewar years. Most of the winners—A.Windaus (sterols), P.Karrer (carotenoids and flavins, vitamins A and B_2), R.Kuhn (carotenoids and B-group vitamins), A.Butenandt (hormones), L.Ruzicka (polymethylenes and higher terpenes), G.Wieland (cholic acids and oxidative dehydrogenation reactions in Nature)—reviewed their achievements on the pages of this journal. A contributor in 1947 was R.Robinson (research on plant anthocyanins), and later contributors included R.B.Woodward (vitamin B_{12} and development of the chemistry of natural products), A.Todd (nucleotides and coenzymes), D.Crowfoot-Hodgkin (X-ray structural analysis of protein crystals), and quite recently J.Cornforth (biosynthesis of sterols).

The increasing international and All-Union authority of the journal led to the appearance on its pages of papers devoted to several important theoretical studies by major science schools—those of A.N.Frumkin (physicochemical basis of flotation theory and nature of the electrical double layer in electrochemistry), V.M.Goldschmidt (foundations of quantitative geochemistry and principles of the distribution of chemical elements in minerals and rocks), L.Michaelis (semiquinones—intermediate stages in reversible oxidation–reduction involving quinones and hydroquinones), A.Szént-Györgyi (concept of biological oxidation), O.Meyerhof (bioenergetics of muscular contraction), A.N.Bakh (theory of slow oxidation and activation of oxygen in biological systems), and D.Brønsted's theory of acid–base equilibrium.

The great and fruitful editorial experience that had accumulated by the end of the first decade enabled the journal during its subsequent growth to evolve that combination of breadth of coverage of all contemporary chemical literature with depth of insight into physical essence that even in future years will determine the character of much of its contents.

Sometimes the appearance of particular reviews was dictated by contemporary circumstances (e.g. a series of reviews on chemical warfare agents—mustard gas, chloroarsines, lachrymators—and problems of chemical protection), in other cases by the interest taken by the journal in extreme states of matter (chemistry at high temperatures and at high and ultrahigh pressures) and in novel types of action on matter (electric discharge, electric or magnetic fields (E.Müller), ultrasound), or finally simply by day-to-day practical demands, such as reviews on analytical chemistry (radioactive and adsorption indicators (I.M.Kolthoff), organic reagents in inorganic microanalysis (F.Feigl), and

microanalytical advances in studying the composition of minerals and technical products—I.P.Alimarin). During all those years, however, the journal not only followed faithfully the chemical traditions of that time but in several cases was ahead of them or even initiated new ones. By embracing comprehensively almost all the traditional branches of chemistry, many of which, enriched by a physical or physicochemical approach, often evolved into new and independent sciences, the journal served always as a unique methodological clasp permitting the particular scientific interests of chemists of various specialties to be combined into a single whole and conferring on its work a general chemical importance, which it has consistently maintained throughout its half-century history.

Besides its main scientific work *Uspekhi Khimii* paid great attention during all those years to chemical bibliography and the current literature, published many different kinds of information notices and reports (in particular on the activities of science laboratories and institutes of the USSR Academy of Sciences—Institute of General and Inorganic Chemistry, Institute of Organic Chemistry, Bakh Institute of Biochemistry, High-pressure Laboratory—and also on sessions and meetings of the Academy, international scientific congresses, and Mendeleev congresses on general and applied chemistry), and inserted topical notes on various competitions and awards of prizes: i.e. it undertook the great task of informing its readers of the most important events in contemporary chemical science.

Historical and biographical matter also occupied a special place. The journal regularly printed papers and notes on the pioneers of chemical science (M.V.Lomonosov, D.I.Mendeleev, A.P.Borodin, A.B.Bidgeim, M.Berthelot, J.J.Berzelius, J.J.Becher, J.H.van't Hoff, F.Wöhler, J.W.Gibbs, S.Sörensen, H.L.le Châtelier, J.Priestley, J.Thomson, M.Faraday, M.E.Chevreul) and also on eminent contemporary Soviet and foreign academic chemists (A.N.Bakh, A.M.Berkengeim, M.A.Blokh, N.A.Vorontsov, K.K.Gedroits, D.K.Dobroserdov, A.P.Karpinskii, N.S.Kurnakov, A.N.Lebedev, V.V.Longinov, B.N.Menshutkin, V.K.Pershka, N.P.Peskov, L.V.Pisarzhevskii, D.N.Pryanishnikov, A.N.Reformatskii, V.E.Tishchenko, A.E.Favorskii, N.I.Chervyakov, P.P.Shorygin, A.Pictet, J.Ray, M.Sklodowska-Curie, J.Urbain).

The journal published several interesting memoirs (e.g. by P.L.Kapitsa on E.Rutherford, by N.S.Kablukov on the development of chemistry in Moscow University since the 1870s), the historical study by S.S.Nametkin, "Chemistry in Moscow University for 185 Years", and also an analysis of the work of the celebrated International Congress of Chemists at Karlsruhe (1860).

The proportion of articles and reviews of historical and biographical character grew somewhat during the war years, when difficulties in the exchange of world scientific and technical information resulted in a diminished volume of strictly scientific matter, although the journal continued to appear regularly. The editorial board during those years comprised B.M.Berkengeim and V.G.Khlopin (editors-in-chief), A.F.Plate and V.V.Serpinskii (secretaries-in-chief), G.V.Akimov, A.I.Brodskii, A.P.Vinogradov, A.D.Gel'man, B.A.Kazanskii, A.F.Kapustinskii, and A.E.Porai-Koshits. The historical and biographical matter published during the 1940s and 1950s was distinguished by great variety and completeness. Together with biographical information and articles on memorable dates in the history of science, associated with the names of V.F.Alekseev (discovery of the law of the rectilinear diameter), N.N.Beketov, A.P.Borodin, A.M.Butlerov, E.E.Vagner, A.A.Voskresenskii (unknown letter of J.Liebig about him), A.N.Vyshnegradskii and G.G.Gustavson (centenaries of birth), P.D.Dankov, I.A.Dvigubskii (first Russian professor of chemical technology), N.N.Efremov, P.A.Il'enkov (centenary of appearance of *Kurs Khimicheskoi Tekhnologii*), A.A.Colley, D.P.Konovalov, M.G.Kucherov, V.V.Lermantov (author of an early theory of the photographic process), A.A.Letnii (75th anniversary of discovery of the pyrolysis of petroleum), T.E.Lovits, M.V.Lomonosov (bicentenary of his *Slova o Pol'ze Khimii*—"Some Words on Behalf of Chemistry"), V.V.Markovnikov, D.I.Mendeleev, N.A.Menshutkin, N.A.Morozov (scientific forecasts of the well known Schlüsselburger), E.I.Orlov, I.M.Sechenov (chemical work of the Russian physiologist), N.N.Sokolov, L.A.Chugaev, A.El'tekov, and A.A.Yakovskin, as well as A.Werner, B.Clapeyron, A.L.Lavoisier, J.Liebig, the journal continued to print diverse matter also on contemporary scientists (A.E.Arbuzov, G.I.Arbuzov, A.A.Baikov, A.A.Balandin, A.P.Belopol'skii, A.M.Bochvar, E.V.Britske, S.I.Vavilov, V.I.Vernadskii, V.N.Verkhovskii, S.I.Vol'fkovich, N.N.Vorozhtsov, E.N.Gapon, N.Ya.Dem'yanov, A.V.Dumanskii, I.I.Zhukov, Yu.S.Zal'kind, N.D.Zelinskii, S.I.Kanevskaya, V.L.Komarov, V.N.Kondrat'ev, D.P.Konovalov, P.P.Lebedev, S.V.Lebedev, A.I.Loginova, P.G.Melikishvili, Ya.I.Mikhailenko, I.N.Nazarov, S.S.Nametkin, V.A.Nemilov, A.N.Nesmeyanov, B.A.Nititin, B.A.Pavlov, N.P.Peskov, V.M.Petriashvili, L.V.Pisarzhevskii, S.A.Pletenev, A.E.Polesitskii-Yakhnin, A.M.Polyak, A.E.Porai-Koshits, A.V.Rakovskii, P.A.Rebinder, S.Z.Roginskii, V.M.Rodionov, N.N.Semenov, V.K.Semenchenko, M.I.Ushakov, S.N.Ushakov, A.E.Fersman, A.V.Frost, V.G.Khlopin, and I.I.Chernyaev). Furthermore, the journal printed during those years the correspondence of N.N.Zinin, V.V.Markovnikov, A.M.Butlerov, and D.I.Mendeleev (in particular with "supporters" of the Periodic Law—Lecoq de Boisbaudran, Winkler, Nilson, and Brauner), articles on important dates in the history of the discovery of individual chemical elements (argon, ruthenium), on the founder of the nitrogen industry in Russia (I.I.Andreev), and also on the influence of the Kazan chemical school on development of the world chemical industry.

A special issue in 1943 was devoted to the centenary of the discovery of aniline by N.N.Zinin; it included three papers by the eminent Russian chemist and comprehensive biographical material on his life and work. *Uspekhi Khimii* printed other interesting historical studies (e.g. "Some Facts on Chemistry in Armenia from Early Manuscripts"), played an active part in preparations for celebrating the bicentenary of the USSR Academy of Sciences, and, finally, published jubilee reviews on the development in the USSR during the previous 25 years of organic chemistry (A.N.Nesmeyanov), the chemistry of organic dyes and intermediates (A.E.Porai-Koshits), general and inorganic chemistry (A.A.Grinberg), and biochemistry (A.N.Bakh).

Among scientific matter in the journal during the war years were reviews on the chemistry of chlorophyll (by B.N.Stepanenko, who during subsequent years wrote on carbohydrate chemistry in the journal) and on the mechanisms of organic addition, elimination, and substitution (L.M.Smorgonskii), and a fundamental paper on the series rule in analytical chemistry (N.A.Tananaev). During those years the journal followed attentively the achievements of the contemporary X-ray diffractometry and radioscopy of metals, metallic compounds, alloys, and melts; and work on the thermodynamics of solutions at high temperatures, on the application of its achievements to theoretical metallurgy, and on electrokinetic phenomena applied to electrolysis. Other reviews published at that time covered the molecular-spectroscopic analysis of organic compounds, the geochemistry of rare and trace elements in sea-water and the primary migration of radioactive elements in Nature (I.E.Starik),

and also results of and prospects for the coordination theory of A.Werner. Stereochemical matter was not confined to complex compounds (the journal had previously published P.Debye's "Stereochemistry and Physics", H.Hillemann's theory of molecular asymmetry, and M.V.Vol'kenshtein's theory of natural optical activity): interest was extended to internal rotation and rotational isomerism (M.V.Vol'kenshtein). Reviews were published during the war also on the stability of colloidal systems, molecular monolayers on a solid surface, and the role of intermolecular forces of attraction and repulsion in the formation of tactoids, thixotropic gels, and coacervates (I.Langmuir).

The steady interest in such a new subject (at that time) as the chemistry of isotopes requires special mention. As early as the prewar years *Uspekhi Khimii* published a paper by the discoverer of deuterium H.Urey, a fundamental review by F.Aston, who had made several discoveries in this field and had first detected 213 of the 276 then known stable isotopes of chemical elements, and a review by one of the founders of modern radiochemistry G.Hevesy, who had described the first application of radioactive indicators (labelled atoms) to biology. In the 1940s this method had already become one of the main tools of fine chemical research, and the journal helped in all possible ways to disseminate it, having at once published six important reviews, on the use of isotopes of nitrogen, carbon (V.L.Tal'roze, M.B.Neiman), iron (V.I.Gol'danskii, M.B.Neiman), and also deuterium (G.P.Miklukhin) and tritium in chemistry (in the investigation of reaction mechanisms) and in biology. Later, at the end of the 1950s and the beginning of the 1960s, authors providing contributions on radiochemistry were A.N.Murin (thermal diffusion methods for separating isotopes, chemical effects of nuclear reactions in solids), An.N.Nesmeyanov (chemical state of atoms formed in nuclear reactions, hot syntheses of compounds labelled with radiocarbon and tritium, vapour pressure measurements), and V.D.Nefedov (chemical changes in β-disintegration processes, radiochemical methods of obtaining hetero-organic compounds). A major experimental achievement in this field was also the design and accomplishment of a process for isolating more than 100 g of protactinium-231 from residues from the purification of uranium (D.A.Collins et al.).

The stimulation of chemical research, both fundamental and applied, determined the character of the journal in the immediate post-war decade. The extensive series of investigations begun at that time gave rise later to the reviews by A.I.Shatenshtein ("New Work on the Theory of Generalised Lewis Acids and Bases", "Acids and Bases in Liquid Ammonia"), G.A.Razuvaev ("Free-radical Reactions in Tetrachloromethane"), S.I.Vol'kovich ("Progress in Fertiliser Research"), Kh.M.Minachev ("Catalysis in the Hydrogenation of Fuels"), and F.F.Vol'kenshtein ("Electronic Theory of Catalysis on Semiconductors"), all this work being distinguished by the novelty of the theoretical approaches and the up-to-dateness of the experimental methods. The chemistry of natural products was widely represented in the journal at that time in contributions from L.D.Berel'son (steroid hormones, stereochemistry of steroids, chemistry of cortisone), V.M.Berezovskii (vitamins of the B_6 group, pteridines, flavins), N.S.Vul'fson (chemistry of pterins and, later, natural colouring matters), Z.A.Shabarova (structure and synthesis of nucleosides), I.Ya.Postovskii (antibiotics, natural guanidine compounds, antitubercular preparations), and M.M.Shemyakin (vitamins and their inactivators). Other active contributors were A.I.Kiprianov ("Influence of Solvent on Colour of Dyes (Solvatochromism)", "Effect of Steric Hindrance on Properties of Aromatic Amines and Nitro-compounds", "Colour of Dyes and Steric Interference in their Molecules") and A.N.Terenin ("Molecular Compounds and the Intermolecular Electron-transfer Spectrum"), both of whose researches were largely instrumental in converting photonics into an independent branch of science.

A characteristic feature of the work of *Uspekhi Khimii* at that time was unflagging attention to problems of catalysis. Even in its early contents, among which we may note in the first issue an encyclopaedic review by W.Frankenburg and F.Dürr (containing 860 references), it fully appreciated the outstanding value of this branch of science for development of the most diverse fields of chemistry—both its theoretical aspects (physical basis of catalytic reaction mechanisms and theoretical principles underlying the choice of catalysts) and its applied aspects (for the development of up-to-date large-scale catalytic manufactures).

During prewar and postwar years the journal published several important reviews whose authors had shown that the theoretical foundations of the science of catalysis were deeply rooted in the chemical physics and the physical chemistry of heterogeneous and homogeneous reactions (H.S.Taylor's concept of active centres on the surface of a heterogeneous catalyst, K.Weiss's scheme of redox catalysis on transition-metal ions, A.V.Frost's theory of the thermal conversion of hydrocarbons, M.V.Polyakov's idea of hetero-homogeneous reactions, and N.I.Kobozev's theory of active ensembles) and had shed light on the structure and properties of the most important heterogeneous catalysts, problems of the catalytic synthesis of ammonia, and the mechanism of hydrogenation reactions.

Special mention must be made here of the fundamentally important contribution to the work of the journal made by A.A.Balandin, who published in it all his main work—"Catalysis and Change in Form of Molecules", "Catalysis and the Periodic System"—and also a paper on the foundations of his multiplet theory of heterogeneous catalysis on metals, which was most completely formulated in a 1960s two-part paper ("Structural Factors in Catalysis" and "Energetic Factors in Catalysis"). In another contribution to the journal Balandin had raised as early as the 1940s the question of deducing theoretically the complete set of chemical reactions possible for any specified molecular system, and had proposed a special mathematics ("structural algebra") for its solution. This work was one of the first examples of the application, to the analysis of chemical problems, of the logical-heuristic approaches and methods of investigation that are now widely used in organic chemistry, hetero-organic chemistry, and stereochemistry under the general name of *molecular design methods*.

During the 1930s and 1940s contributions in which problems of catalysis were intimately related to those of organic chemistry became especially significant. The general prospects for this approach were outlined in a review by N.D.Zelinskii, A.A.Balandin, and A.M.Rubinshtein, in which catalytic interconversions of saturated, unsaturated, and aromatic hydrocarbons of open-chain and cyclic structure were acknowledged as the main line of investigation.

Hydrocarbon chemistry was very important during those years in connection with the need to solve the problem of obtaining natural and artificial liquid fuel. In *Uspekhi Khimii* these aspects were most widely exposed in a series of reviews by Ya.T.Eidus, who was concerned for a long time with theoretical and applied research on the synthesis of hydrocarbons by the catalytic hydrogenation of carbon monoxide (the Fischer–Tropsch reaction). The journal covered also aspects of the catalytic and contact desulphurisation of petroleum products, regularly acquainted readers with contemporary physicochemical methods of analysis of

hydrocarbon mixtures, and informed them of the most important advances in the processing of petroleum and the production of aviation fuel abroad.

Together with articles summarising the theory and practice of catalytic processes either for particular classes of typical chemical reactions—aromatisation (A.F.Plate), hydrogenation and dehydrogenation (R.Ya.Levina), ring-opening in cyclic hydrocarbons (B.A.Kazanskii)—or for certain types of catalysts (e.g. Raney), the journal regularly included reviews on the chemistry of individual key compounds of enhanced applied value. In the early stages the number of such publications was in general small (e.g. reviews on the use of aluminium chloride in organic chemistry, and also on methanol, pyridine, liquid ammonia, formaldehyde solution, phosphorus, and phosphoric acid). However, such reviews had already become traditional for the journal from the 1940s and 1950s, and covered an increasing variety of compounds.

Articles appeared also on the chemistry of several common large-scale products (gaseous alkanes and alkenes, actylene, butadiene, cyclopentadiene, lower aliphatic alcohols from alkenes, organosilicon monomers, cyanamide, hydrazine, activated carbon) and on new or non-traditional substances and reagents (selenium dioxide, diazomethane, lithium tetrahydroaluminate, new polymerisation initiators, and also boron trifluoride, whose great possibilities as an electrophilic catalyst for alkylation and isomerisation were exhaustively covered in reviews by A.V.Topchiev, Ya.M.Paushkin, and S.V.Zavgorodnii).

We must emphasise also the detailed exposure, typical of the work of the journal at the end of the 1940s and beginning of the 1950s, of progress in the study of several most important organic intermediates and starting materials for fine and special organic syntheses, investigated by the schools of I.N.Nazarov, A.A.Petrov, A.D.Petrov, M.F.Shostakovskii, and V.I.Isagulyants. These were usually unsaturated or difunctional compounds—1,3-dienes and diene esters (and also their halogeno-derivatives), divinyl ketones, pent-1-en-4-yn-3-ols, dienynes, vinyl ethers and sulphides, butadiyne, keten (A.Ya.Yakubovich), 1,3-dichlorobut-1-ene-β-amino-acids (V.M.Rodionov). Several industrially important organic reactions were also given detailed coverage—Kucherov hydration of alkenes (V.N.Belov), formation of oxirans, chlorination of alkenes (studied by N.I.Shuikin's school), alkylation of the aromatic ring (I.P.Tsukervanik), and sulphochlorination of alkanes (A.Ya.Yakubovich), in addition to the nitration of hydrocarbons, the mechanism of which was examined in detail in physicochemical terms by A.I.Titov.

During the postwar period the journal has paid unflagging attention not only to organic synthesis but also to aspects of inorganic and mineral technology. Discussion has covered a wide range of problems in the physical chemistry and technology of glasses, silicates, and spinellides, beginning with contemporary views on their nature (taking into account the contribution to this problem by the I.V.Grebenshchikov school) before examining the kinetics and the mechanism of reactions in solid mixtures (P.P.Budnikov) and specific aspects of glass-making. The journal has paid attention also to problems of thermal reduction methods in metallurgy and of physical phenomena in extrusion and sintering processes in powder metallurgy, and published reviews on the separation of rare-earth elements. Articles by S.I.Vol'fkovich were concerned with the broad task of obtaining compound mineral fertilisers by decomposing phosphates with nitric acid, and also with bringing the teaching of chemical technology up to date.

It must be noted that broadly all reviews on a then important applied subject were characterised by fundamental and diverse coverage of both theoretical and experimental matter, and played an important role in the participation of our chemists in the postwar rehabilitation and development of the chemical industry and the national economy in our land.

The fourth, transitional period in the work of *Uspekhi Khimii* (1950–1960s)¶, which involved preparations for increasing its size (1965), is of great importance for understanding how the present character of the journal has been moulded. It saw further activation of the work of the editorial board, which comprised V.V.Korshak (chief editor), B.M.Berkengeim, S.I.Vol'fkovich, M.M.Dubinin, B.A.Kazanskii, V.V.Mikhailov, B.V.Nekrasov, V.K.Semenchenko, A.M.Sladov (secretary-in-chief), R.P.Lastovskii, Kh.S.Bagdasar'yan, M.I.Kabachnik, and N.M.Emanuel'.

This period was distinguished by considerably intensified development of all chemical sciences. In fundamental research the elaboration and improvement of methods of calculation and computing techniques resulted in great progress in understanding the structure of complicated molecules; such advances as the formulation of theories of perturbations and boundary orbitals, with later discovery of the principle of the conservation of orbital symmetry, paved the way to a deeper insight into the relationship between structure and reactivity. Those years saw the introduction by the experimental chemist of the routine use of such important physical methods of investigation and analysis as nuclear magnetic resonance, mass spectrometry, and also new types of chromatography. The quality of instrumentation also rose considerably during that time. As a consequence of all these factors the traditional sharp division of chemistry into a series of separate classic branches gradually gave way to different, more complicated and significant forms of interrelationship and division between sciences. The major scientific advances and discoveries of those years paved the way for a final shaping of several borderline scientific fields into independent scientific disciplines, among which molecular biology, hetero-organic chemistry, and macromolecular chemistry underwent especially marked development. At the same time stronger demands were made for relevance in scientific research and for a closer relationship with applied, industrial, and technical chemical subjects.

These trends found their organisational expression in the creation of new science research institutes and higher educational institutions, in the founding of new major science centres in several towns. New science schools and lines of chemical research were actively established in those years.

At that time considerable changes were occurring also in the field of chemical information. The total flow of information underwent remarkably strong growth, owing to the inauguration of several new journals and a sharp increase in volume of most chemical publications throughout the world, to an intensification of the issue of monographs, special periodical editions and collections, and to greater activity in the holding of scientific congresses and conferences. In several cases publications exhibited a tendency to narrow specialisation, which might make it difficult to acquaint wide circles of the chemical community with the main trends in contemporary science and prospects for their development.

The profound organisational and structural changes that occurred universally in Soviet and world science during that period posed for the journal the acute problem of working out, under the new conditions, a strategy that would correspond to the greatly increased requirements of specialised chemists for expert and authoritative provision of information. In this situation it was of fundamental importance that the journal should not choose a path of narrow specialisation but,

¶ The silver jubilee of the journal was reported elsewhere[4].

on the contrary, should broaden its interests, by paying attention essentially to the then most promising borderline and contiguous fields of chemical science. As a consequence it is now evident not only that *Uspekhi Khimii* contained the origins of many new sciences initiated in those years but also that its work actively supported their establishment and development.

The most characteristic feature of that time to which the journal responded was the development of hetero-organic chemistry. Just after the war *Uspekhi Khimii* published a paper by A.N.Nesmeyanov on "Hetero-organic Compounds and the Periodic System", which showed results of and the immediate prospects for research on various organic derivatives of metals and non-metals, as well as the important position occupied by this work in the general development of chemical sciences and their interrelationship with various practical requirements and problems. The extremely important role of hetero-organic chemistry in contemporary science was recognised by the creation in 1954 of the Institute of Hetero-organic Compounds of the USSR Academy of Sciences, the first in the world, the work of many of whose personnel on hetero-organic and polymer chemistry, as well as on artificial food, has since been intimately connected with the history of the journal and has appeared in its pages.

These advances were analysed in a 1959 paper by R.Kh.Freidlina, M.I.Kabachnik, and V.V.Korshak included in a special issue celebrating the jubilee of A.N.Nesmeyanov.

The initial growth of this branch of science was due primarily to the development of new methods for obtaining organic derivatives of fluorine, phosphorus, and silicon and was governed by the importance and variety of their fields of practical application. In this connection we may note papers in the journal on methods for introducing fluorine into organic compounds (I.L.Knunyants, O.V.Kil'disheva), on the polymerisation of fluoroalkenes and the addition to them of hydrogen sulphide and thiols, yielding perfluorinated organosulphur compounds (I.L.Knunyants, A.V.Fokin), and also on electrophilic addition to fluoroalkenes (B.L.Dyatkin, I.L.Knunyants), on organofluorine compounds containing functional groups, and on fluorocarbon oils and greases. The chemistry of organic derivatives of silicon was covered by numerous papers by K.A.Andrianov, A.D.Petrov, A.A.Zhdanov, V.F.Mironov, E.A.Chernyshev, and later V.A.Ponomarenko (organofluorosilicon compounds) and also A.B.Topchiev and N.S.Nametkin (organopolysiloxane liquids). The chemistry of organic derivatives of phosphorus appeared during those years in papers by A.E.Arbuzov (organic derivatives of phosphorus acids) and by M.I.Kabachnik (addition of halogen derivatives of phosphorus to organic compounds), and great attention was paid to their biological and insecticidal action (N.N.Mel'nikov).

The journal followed closely the development of the chemistry of organic boron derivatives (U.Lipskii [?W.N.Lipscombe]), regularly publishing for several years reviews on hydroborons (B.V.Nekrasov, Ya.M.Paushkin), diborane, intermediate boranes, borazole (B.M.Mikhailov). It paid attention also the chemistry of new classes of organic derivatives of beryllium, calcium, strontium, barium, and covalent bihetero-organic compounds (N.S.Vyazankin, O.A.Kruglaya), as well as to those of non-metals—the chemistry of cyanuryl chloride, nitrogen-ylides, and phosphorus-ylenes (G.Wittig), cyanohydrocarbons, and compounds containing a nitrogen–fluorine bond (A.V.Fokin).

The vigorous development of the chemistry of σ-bonded organic derivatives of non-metals and non-transition metals (K.Ziegler) was accompanied during those years by great development of a fundamentally new branch—the hetero-organic chemistry of π-complexes of transition metals—which followed on the 1950s discovery of ferrocene and dibenzene-chromium. Its successes were covered in the journal by the reviews of F.Cotton and G.Wilkinson (cyclopentadienyl and arene complexes of metals), G.Wilke (cyclo-oligomerisation of butadiene and π-complexes of transition metals), E.Abel (metal carbonyls), G.A.Razuvaev, V.N.Latyaeva (covalent organometallic compounds of transition metals), and M.I.Rybinskaya, L.V.Rybin (reactivity of a double bond coordinated with a metal atom in nucleophilic reactions). All these early investigations on organometallic π- and σ-complexes paved the way for the subsequent development of metal-complex catalysis in organic and polymer chemistry, which was subsequently reflected on the pages of *Uspekhi Khimii*.

The intense development of synthetic and applied aspects of hetero-organic chemistry in the two postwar decades posed acutely the question of the need to organise systematic quantitative research on the structure and reactivity of hetero-organic compounds and their reaction mechanisms.

During those years the journal responded actively to theoretical questions of hetero-organic chemistry. It was found that organic derivatives of metals and non-metals could serve as new models helping to reveal the physical nature of many chemical phenomena. Thus for several functionally substituted organic derivatives of phosphorus it was possible to elucidate the quantitative laws of tautomeric processes, trace their connection with the principles of acid–base catalysis, and discover on this basis new reactions and rearrangements (M.I.Kabachnik). Articles by O.A.Reutov published in *Uspekhi Khimii* at that time showed that many reactions involving σ-bonded organometallic compounds, in which homolytic transformations are observed with formation of free and latent radicals, may be convenient models for the investigation of radical and chain processes in the condensed phase, and can also be used in hetero-organic synthesis. Finally, detailed examination of the kinetics, stereochemistry, and mechanism of many typical electrophilic reactions (proto- and halogeno-demetallation, alkyl exchange, etc.), precisely on organometallic model compounds (including optically active compounds and those labelled with radioactive mercury-203), enabled quantitative laws to be formulated for electrophilic substitution at saturated and unsaturated carbon atoms (O.A.Reutov) and the broad question to be posed whether the principles of stereochemical dynamics (stereochemistry of substitution in the organometallic series) and statics (the asymmetric non-carbon atom—O.A.Reutov, V.I.Sokolov) could be extended to hetero-organic derivatives of metals and non-metals.

It is significant that, just as in the 1930s the journal had reacted keenly to the development of chemical physics and physical organic chemistry, its contents in the 1950s–1960s directed attention to the physical trend then emerging even in hetero-organic chemistry.

The contents of the journal reflected also segregation of coordination chemistry as a separate field of science at the junction between the organic and the inorganic chemistry of complex compounds. An important role in its development was played by research on the kinetics, stereochemistry, and mechanism of various inner- and outer-sphere reactions of coordination compounds in aqueous and non-aqueous media, and also by R.Nyholm's important generalisation (now known as the Gillespie–Nyholm rule) establishing a direct relation between the electronic configuration and the three-dimensional structure of metal complexes.

Together with the evolution of theoretical ideas on reaction mechanisms involving inorganic and organometallic compounds, great importance was attached at that time to research on the mechanism of purely organic reactions. As reflected in

papers in the journal this involved mainly establishing by correlation analysis quantitative relations between the structure and the reactivity of organic compounds (V.A.Palm) and identifying various intermediate species, the most important of which were carbocations and free radicals (in particular in the nitration of hydrocarbons investigated by A.I.Titov). Later the journal paid great attention also to radical-ion states of molecules (both cation- and anion-radicals), and examined in detail the urgent problem of formation of the antecedent intermediate donor–acceptor complexes and of charge-transfer complexes, which play an important part in the mechanism of such reactions as the addition of halogens to alkenes. Three important reviews were devoted to concerted reactions (Ya.K.Syrkin, J.Mathieu), which involve cyclic electron transfer in closed transition states.

Among the reaction mechanisms investigated in the greatest detail were various acid–base processes (A.I.Shatenshtein), kinetic isotope effects (Ya.M.Varshavskii), including the kinetics and thermodynamics of the isotope exchange of hydrogen, reactions of peroxides, diene synthesis, esterification, hydrolysis of esters (Ya.K.Syrkin, I.I.Moiseev), catalytic redistribution of hydrogen in unsaturated cyclic systems (V.M.Gryaznov), various reactions of isocyanates with compounds containing mobile hydrogen (S.G.Entelis), halogenation of alkenes, and Beckmann rearrangement of oximes (I.L.Knunyants). A series of papers was devoted also to the current problem of the dual reactivity of ambidentate systems (V.I.Erashko, S.A.Shevelov, A.A.Fainzil'berg).

To this day many contributions to the journal on several theoretical aspects of physical organic chemistry have not lost their value, among them reviews by R.Pearson, R.Hudson, A.Parker, J.Edwards, K.U.Ingold, and R.Dessy, in which consideration was given to several contemporary approaches (perturbation theory, principle of hard and soft acids and bases) to the theory of reactivity, and the concepts of basicity and nucleophilicity and the influence of solvation (in particular by bipolar aprotic solvents) on rate, equilibrium, and composition of products in homogeneous reactions were discussed. Several articles appeared also on quantum chemistry, covering the nature of σ- and π-bonds in molecules, the theory of electron shells in molecules (N.D.Sokolov), and principles governing the calculation of conjugated unsaturated systems (M.Dewar).

As before, the most prominent position in the journal was occupied by reviews on chemical physics, in conformity with its great scientific importance. During the period that had elapsed since the beginning of the 1930s many problems had been solved, and the results of all this work had found their place on the pages of *Uspekhi Khimii*. This applies especially to research on the mechanism of gas-phase chain reactions, studied in detail by N.N.Semenov, V.V.Voevodskii, and V.N.Kondrat'ev, the theory of ignition and spontaneous combustion, burning and detonation, and also aspects of the energetics of chemical bonds.

Besides this, establishment of the physical characteristics of primary reactions in the condensed phase became during the 1950–1960s an important problem, investigated for the chain decomposition of halogenated alkanes (N.N.Semenov) and in especial detail for liquid-phase oxidation (N.M.Emanuel'). Additions of inhibitors enabled critical phenomena to be studied, and the possibility of catalysis by salts of metals of variable valency was established (N.M.Emanuel', E.T.Denisov). Elucidation of the mechanism of the action of several inhibitors permitted during those and subsequent years the organisation of a scientific search for and the industrial production of new stabilisers for polymers and various antioxidants, which have great practical value.

As the journal showed, several novel opportunities were offered to chemical physics by the use of new and up-to-date experimental methods, e.g.flash spectroscopy for studying fast photoreactions, chemiluminescence for studying kinetics, vibrational spectroscopy for the structure of polyatomic molecules, and also the method of molecular beams (V.B.Leonas) for elementary chemical reactions. In other cases important results were obtained by developing the theory of chemical kinetics (additive calculation of activation energies, derivation of kinetic equations for homolytic reactions and the temperature dependence of their rates, in some complicated cases taking into account topochemistry and chemisorption processes at the interface). It is evident from the journal that advances in chemical physics contributed much to develop a theoretical basis for contemporary chemical technology, especially in the construction of mathematical models and the search for optimum conditions taking into account the peculiarities of heat and mass transfer in complicated heterophase processes (V.V.Kafarov).

A special number of *Uspekhi Khimii*, issued to celebrate the jubilee of N.N.Semenov, was entirely devoted to the latest advances in chemical physics. Topics covered were investigation of the kinetics and mechanism of branded chain reactions in the gas phase (A.B.Nalbandyan), critical phenomena in degenerate branched chain reactions in the liquid phase (N.M.Emanuel'), current state of the theory of thermal explosion (A.G.Merzhanov, F.I.Dubovitskii), free radicals and chemiluminescence (V.Ya.Shlyapintokh), formation of radicals in reactions of valency-saturated molecules (A.E.Shilov, F.E.D'yachkovskii), chain-transfer reactions with rupture in polymerisation and copolymerisation (N.S.Enikolopov), and chemical reactions at around 77 K (G.B.Sergeev).

Work on high-energy chemistry is near in scientific significance to the above topics, and also has been subject to the constant attention of the journal—ionic and electronic processes in the condensed phase under the influence of radiation (E.L.Frankevich), development of a theory of the primary step in "hot" reactions, various theoretical and applied aspects of the radiation chemistry of aqueous (including frozen) and non-aqueous solutions of organic and inorganic compounds (I.V.Vereshchinskii, A.K.Pikaev, A.J.Swallow).

Thus the work of the journal during the 1950s and 1960s showed that the fundamentally physical direction of chemical research, the results and achievements of which were summarised in the papers "Forty Years of Development of Chemical Physics in the USSR" (V.N.Kondrat'ev) and "Fifty Years of Soviet Physical Chemistry" (N.M.Emanuel'), had succeeded and made it possible to solve the most complicated theoretical and experimental problems by investigating the basic principles of structure and reactivity in chemical compounds.

The third largest sphere of activity of the journal in the 1960s, in addition to hetero-organic chemistry and chemical physics, was the chemistry of macromolecular compounds, whose development was largely governed by the needs of industry and the national economy. A set of reviews on polymer topics was selected by the journal with great care, while the scientific range of the problems covered was extremely varied.

For five to seven years in all the journal dealt creatively with almost every conceivable aspect of this science of great world-wide actuality, beginning with synthesis of the most diverse types of macromolecular compounds—heterochain polyamides (V.V.Korshak, T.M.Frunze), polyarylates, polyacetylenes (A.M.Sladov), polyethyleneimines, polymeric carbonyl compounds, fluorinated organic polymers—discussing the polymerisation possibilities of the most diverse classes of monomers—non-conjugated dienes (G.S.Kolesnikov), iso-butene, polyfluorinated linear compounds, difunctional monomers,

α-oxides—and finishing with the use of physical methods to study various physicomechanical and operating characteristics of macromolecular compounds (gel formation and structure in polymer solutions, electrode properties of ion-exchange membranes, self-diffusion and interdiffusion phenomena (S.S.Voyutskii), as well as the plasticisation of polymer systems, molecular relaxation in polymeric dielectrics, and the chemical action of ultrasonic waves on macromolecules). Special reviews were devoted to the most diverse groups of polymeric substances and materials having great practical value (macromolecular dielectrics and semiconductors (B.I.Sazhin), redox and optically active polymers (I.N.Topchieva), ion-exchange and electron-exchange resins, structural plastics (B.A.Kiselev), and also various kinds of telomers and oligomers). Among other problems discussed were ways of enhancing the frost-resistance and the thermal stability of artificial polymeric materials (M.M.Koton) (including the introduction of cyclic fragments into the polymer chain).

Great attention was paid also to extending the ideas of polymer chemistry to macromolecular systems of natural origin, from organic biopolymers to inorganic systems such as cement and silicates. A series of reviews discussed the chemical modification of macromolecular compounds (e.g. of rubber by vulcanisation or of cellulose by phosphorylation) and indicated the technical prospects of cellulosic ion-exchangers, capable in particular of serving as effective supports in the chromatographic separation of proteins (A.Ya.Nikolaev).

Interesting articles during those years were devoted to the interaction of colorants with macromolecular substances, which was of great importance for development of a textile industry of synthetic fibres, and also to the production of new slow-release medicinal preparations by mixing with macromolecular fillers or by grafting to polymer chains.

In several cases the journal has even arranged series of reviews on related topics, if the problem involved deserves that the gap should be urgently filled with consequent stimulation of its development. For inclusion in such series only those reviews are selected, of course, that give independent and expert views without duplicating general information on the subject. An example is the publication over only a few years of about ten reviews covering the most diverse aspects of the main subject "Macromolecular Hetero-organic Compounds", then especially timely. By surveying both purely inorganic systems as a whole (H.J.Emeléus) and also polymers having inorganic main chains (K.A.Andrianov, A.A.Zhdanov), with a discussion of hetero-organic systems, as well as coordination polymers and polymeric chelates, the journal gave within a short period a very complete picture of the state of this branch of science throughout the world in the 1960s.

Examination of the work of the journal on electrochemistry reveals firstly a steady growth in the total number of contributions on this important discipline and secondly an unusual list of review topics in past and present years, reflecting the chief changes in the theoretical and applied content of this extremely broad and diverse branch of science.

Electrochemical matter in *Uspekhi Khimii* during its first two decades was primarily associated with the name of A.N.Frumkin, who as early as 1935 contributed his well known review on the nature of the electrical double layer in electrochemistry (a general analysis of his publications will be found in a 1941 paper by N.A.Bakh). The former followed with his reviews on surface adsorption phenomena in electrochemical oxidation and reduction, on the electrochemistry of protective films (together with G.V.Akimov), and also on electrochemical kinetics, aspects of which were discussed also in contributions by S.Glasstone and by N.I.Zhukov (as applied to electrodialysis).

During subsequent years these questions were further developed on the pages of the journal by the work of Frumkin's students and followers (a special number of *Uspekhi Khimii* was dedicated to him in 1975). This comprised primarily a detailed account of a wide range of topics in the theory of the electrical double layer (B.B.Damaskin) at the boundary between an electrolyte and various electrodes (including those based on bismuth, tin, cadmium, and lead (U.V.Palm, V.E.Past), for all of which the influence of the crystallographic structure of the solid surface was examined, and also that of specific interaction of the surface with the solvent, on the properties of the double layer, the adsorption of ions, and the kinetics of hydrogen evolution in acid and alkaline media). Most of the reviews on this subject gave the most detailed consideration to mercury and platinum electrodes, study of which, in particular, made use of a radioactive tracer method that had been employed also to examine solid electrolytes (S.V.Karpachev, Yu.Ya.Gurevich) and non-aqueous media. The great interest taken by the journal in electrochemical processes in non-aqueous solvents (a special article on this topic as early as 1948 was devoted to the work of L.V.Pisarzhevskii's school) was due to the frequent possibility of controlling in them the progress of the proton-transfer processes accompanying electron transfer, which produces favourable conditions for electrometric analysis—electrochemistry of chelates in non-aqueous media (G.K.Budnikov), polarography in organic solvents (S.I.Zhdanov).

Surface adsorption phenomena, whose study is important both from the general physicochemical viewpoint and for an understanding of the mechanism of ensuing electrode processes and the laws of electrochemical kinetics, were covered in detail by the reviews of B.B.Damaskin (laws of the adsorption of organic compounds) and of O.A.Petrii (adsorption of electrodes of platinum-group metals), which gave a thermodynamic theory of the platinum electrode. Great attention was paid by the journal also to the kinetics and mechanism of electrochemical reactions, as well as the nature of unstable intermediate species. Apart from papers on electrometry and electrosynthesis, which will be named below, this range of problems was considered in relation to the most diverse systems—from metal ions in unusual and unstable states of oxidation (B.G.Ershov) and metal complexes in aqueous electrolyte solutions (V.I.Kravtsov) to molecular oxygen (L.I.Nekrasov) and semiconductors—kinetics of chemical etching, formation of new phases (V.A.Myamlin, Yu.V.Pleskov). Of great value for an understanding of several pressing problems of theoretical electrochemistry were the papers of B.V.Ershler (problem of absolute potential), G.A.Tedoradze and A.B.Ershler (effect of large coverages), and also R.R.Dogonadze, A.M.Kuznetsov, and L.I.Krishtalik, on theories of electronic processes in liquids, barrierless electrode processes, and also the nature of the primary step in electrode reactions.

The journal has always associated theoretical aspects of electrochemistry closely with practical applications, among which the greatest attention is now paid to three vast fields—the development of classic and new methods for the electrometric analysis of inorganic and organic compounds, preparative electrolysis and electrosynthesis of organic and mineral substances, and also problems of the corrosion of metals and alloys.

Uspekhi Khimii has at different times published papers both on equilibrium and on non-equilibrium methods of electrometric analysis (with application of a potential or passage of

a current), the interrelationship between which has been considered in greatest detail in I.M.Kolthoff's well known review "Relation between Potentiometric and Amperometric Titration and Voltammetry". During recent years the journal has given space to especially detailed consideration of the possibilities of the polarographic method of investigation and analysis, both of inorganic systems (e.g. ions of bivalent iron, cobalt, nickel—V.N.Pavlov, V.V.Bondar') and their chemical reactions (e.g. study of equilibrium complex formation—S.I.Zhdanov), with redoximetry for interactions in solutions (V.V.Pal'chevskii), and of various hetero-organic (S.G.Mairanovskii) and organic compounds—cathodic reduction of benzenoid aromatic hydrocarbons (S.I.Zhdanov), coumarins (Yu.E.Orlov), and aminoalkyl esters of αβ-unsaturated acids, and also study of the reactions of carbonyl compounds with ammonia, including their use in polarographic analysis (Ya.I.Tur'yan). The journal has also covered such methods as oscillopolarography and extraction polarography (G.K.Budnikov), inversion amalgam chronopotentiometry (V.I.Bakonov, M.S.Zakharov), and also thin-layer electrochemistry (S.I.Zhdanov). Electrochemical processes produced by alternating currents have also been discussed (impedance method—B.M.Grafov, E.A.Ukshe). Among new electrochemical achievements reported during recent years have been ion-selective electrodes (A.A.Belyustin), opening up several opportunities for investigating complicated enzyme systems involving choline esterases, and also the photoemission of electrons from metals in electrolyte solutions (Yu.V.Pleskov, Z.A.Rotenberg).

Electrochemical methods of investigation, based on a common treatment of acid–base and redox processes under homogeneous and heterogeneous conditions, are now widely used in solving a wide range of problems of physical chemistry and related disciplines. This important trend, whose earlier development was evident in the contributions by V.A.Pleskov (electrode potentials and ionic solvation energies) and by S.S.Voyutskii (electrokinetic potential as measure of aggregate stability of disperse particles), is now represented by the papers of A.Ya.Gokhshtein (elastic method for the study of various surface phenomena), and of R.Sh.Nigmatullin et al. (electrochemical investigation of mass and momentum transfer in solid–liquid systems, electrochemical modelling of heat and mass exchange, and also several hydrodynamic characteristics).

Important practical applications of electrochemical research results are associated in the journal with preparative electrolysis and electrosynthesis. The electrodeposition and electrocrystallisation of metals, surveyed in the 1950s by V.V.Mikhailov and by L.I.Antropov, were subsequently developed in papers on electrolysis at a mercury cathode as a method of isolation of uranium and separation of rare-earth elements (G.M.Kolesov). Several general problems of the electrolysis of molten media (surveyed by A.I.Belov in connection with the 150th anniversary of this method) have been examined in detail for oxide (A.M.Samarin) and hydroxide (O.G.Zarubitskii) melts. Together with inorganic systems (electrochemistry of iodine, selenium, tellurium, as well as metals and their complexes) the journal has always taken great interest in the electrosynthesis of organic compounds, first discussed by N.N.Mel'nikov as early as the 1930s and then by M.Ya.Fioshin in the 1950s. Recent reviews (M.Ya.Fioshin, A.P.Tomilov, L.A.Mirkind, I.N.Rozhkov) show that modern trends in development involve primarily expansion of the range of cathodic and anodic reactions initiated by electrochemical methods. Thus detailed studies are now being made of the oxidation of organic compounds at transition-metal oxide anodes, electrochemical alkoxylation and anodic dimerisation, addition, and substitution, and also cathodic coupling and electrolytic reduction of multiple bonds. A series of papers covered the mechanism of electrosynthetic processes involving organic compounds, the role of free radicals in electrolysis, reactions of these species with the electrode material, and also the cation–radical mechanism of anodic fluorination.

In addition to electrometric analysis, electrolysis, and electrosynthesis an independent and very important field of practical application of electrochemical knowledge is the mechanism and prevention of corrosion. The corrosion of metals as a special problem of colloid electrochemistry was first raised in the journal by V.A.Kistyakovskii as early as 1933 (later, outlines of the achievements of his scientific school were published in *Uspekhi Khimii* in 1945 and 1951). The bulk of the contributions on this theme belong to the 1950–1960s, when the journal published within a short period a whole series on the chemical nature of the corrosion and protection of metals from most diverse external attacks (atmospheric, subterranean, and pitting corrosion, as well as by sea-water at the water-line, or under conditions of limited access of electrolyte). A characteristic feature of this work is the discussion of ways for improving the corrosion resistance of metals and alloys in terms of the electrochemical theory of corrosion (N.D.Tomashov), including the theory of multielectrode systems (G.V.Akimov). The wide and up-to-date coverage of the whole set of most complicated questions associated with corrosion, in whose investigation radioisotope methods were used earlier, and also the influence of anions on the kinetics of dissolution of metals (Ya.M.Kolotyrkin), shows the great value attached by the journal to this important problem of applied science.

While attaching great importance to applied aspects of macromolecular chemistry, all that time the journal never lost sight of fundamental problems of general scientific and theoretical character in this field. Several reviews in those years were devoted to such questions as kinetic features of primary stages in polymerisation and further chemical reactions of the macromolecular compounds, mechanisms of interfacial polycondensation and ionic telomerisation, as well as free-radical, ionic [cationic (L.S.Bresler) or anionic], radiochemical, and cyclic polymerisation and copolymerisation of the most diverse classes of monomers under various experimental conditions, in several cases drawing special attention to novel, unusual, or anomalous types of reactions.

The journal has also extensively published many reviews and papers on general aspects of polymer chemistry—on progress in studying the chief types of processes in polymer formation (e.g. non-equilibrium and equilibrium polycondensation (V.V.Korshak), polymerisation of chemically activated monomers—V.A.Kabanov), on the main lines of research on polymer structure (e.g. the role of structural phenomena in shaping their properties—V.A.Kargin) and study of their reactivity (A.A.Berlin)—indicated future prospects for development in this field of science (reviews by M.Szwarc on "Progress in Polymers" and by H.W.Melville on "Future of Polymer Science"), and acquainted the reader—from original sources, as always—with the story of the major scientific discoveries ("Advances in Stereospecific Polymerisation" by G.Natta). This group can be completed by two articles—"Nomenclature of Linear Polymers based on their Structure" and "Nomenclature of Stereoregular Polymers" (H.Mark)—which have proved extremely useful in bringing the fairly intricate systematisation of complicated three-dimensional polymer structures into harmony with international requirements.

Uspekhi Khimii always reacted so keenly and originally to the conception and establishment of new scientific disciplines, to their differentiation, specialisation, and integration, that its reviews could form the basis of an objective and accurate view both of the origin of most of the most recent branches

of chemistry and of the current trends in their development. It is instructive in this connection to consider e.g. the dynamics of qualitative and quantitative changes in character of reviews in such an important field of applied science as adsorption (M.M.Dubinin), colloid chemistry (B.V.Deryagin), and chromatographic analysis.

With regard to the review activity of the journal on chromatographic analysis, there was a time when practice in this field clearly lagged behind theory. Although in the 1930s great progress was made in understanding the nature of adsorption bonding, heats of adsorption, and the work of adsorption forces (A.V.Kiselev), chromatographic methods of separation and analysis had not yet been properly developed.

At the beginning of the 1940s, however, major scientific developments—A.Martin and R.Synge's improvement of M.S.Tswett's adsorption chromatography and the elaboration of convenient methods of partition chromatography—and also the discovery in the 1950s of methods of column and capillary gas–liquid chromatography led to an immediate intensification of research in this field. The number of reviews on this subject in the journal increased by a factor of several tens, and they themselves came to acquire a differentiated character. Separation of the subject-matter of scientific and applied investigations took place in several directions. Thus paper chromatography (V.V.Rachinskii) became an individual subject, while partition chromatography was so greatly perfected that its application to analytical (N.N.Fuks), inorganic (E.N. and T.B.Gapon), organic, and biological (V.S.Asatiani) chemistry acquired independent significance according to the character of the substances to be separated and analysed.

Subsequently (in the 1960s) a tendency to still more far-reaching and detailed specialisation of individual types of scientific and practical chromatography began to appear, further subdivision of which began at once on three or four planes depending both on the chromatographic method and on the nature of the mixtures of gaseous (A.A.Zhukhovitskii and N.M.Turkel'taub), inorganic, organic, or natural substances to be separated or analysed. Special reviews were now required both on individual types of sorbents (e.g. ion-exchange celluloses, separation of biopolymers on calcium phosphate gels, or asymmetric adsorption as a method of resolving racemates on dissymmetric sorbents—S.V.Rogozhin, B.A.Davankov) and on the types of substrates to be separated (e.g. in the case of organic compounds comprehensive data were accumulated on the chromatographic separation of liquid petroleum hydrocarbons and individually on compounds of the benzene series, and matter on biologically active polymers came to be subdivided into separate reviews on the separation of mixtures of amino-acids (V.M.Belikov), lipids, carbohydrates, nucleic acids and their components, and decomposition products of proteins). Chromatographic methods became increasingly valuable for analysis and separation [?omission, Ed. of Translation] (including as volatile complexes), and also of Groups I–IV organometallic compounds (K.I.Sakodynskii).

In the current stage the coverage of chromatography by *Uspekhi Khimii* is governed by three principal stimuli—firstly further improvements in instrumental chromatographic technique, secondly introduction of several fundamentally novel forms of chromatographic analysis, and thirdly significant expansion of areas of practical use of these methods in the most diverse scientific and applied fields—so that only during recent years has the journal published reviews on the theory of the chromatographic microreactor, the use of packed capillary columns, chromatographic analysis with temperature programming, pulsed and high-temperature chromatography, chromatography in a stream of water vapour, gas chromatography with organic eluants, and also high-pressure gas and liquid chromatography (M.S.Vigdergauz). Newly introduced methods of chromatographic separation and analysis, whose establishment is attentively followed by the journal (peak paper chromatography, ion-exchange, precipitation, reverse, affinity, electrolytic, and gel chromatography), are subject in several cases to a tendency to undergo further differentiation. Thus within the scope of the promising method of reaction chromatography several variants have appeared, e.g. chemispecific covalent chromatography (S.V.Rogozhin) or adsorption–complexing chromatography, in particular involving the formation of charge-transfer complexes.

At the same time a vigorous world-wide search is now being made for new carriers, mobile and stationary phases (in particular surface-film sorbents), and in recent years the journal has drawn attention to the use for this purpose of liquid-crystal systems (gas–liquid-crystal chromatography, and also adsorption–absorption chromatography on Silochromes having films of liquid crystals). Another trend that can be observed in recent issues is the contrary tendency to integrate separate scientific disciplines at new and higher levels, which is evident e.g. in the active penetration of chromatographic methods into adjacent scientific fields for the solution of such problems as the determination of thermodynamic interpretation of the concepts of the polarity and the selectivity of sorbents, for the study of problems in catalysis and polymer chemistry, for investigation of the kinetics of liquid-phase reactions and the state of the multivalent ions in solution, and for the functional analysis of organic compounds (V.G.Berezkin et al.) and of unstable inorganic and heteroorganic species, quite apart from the analysis of trace impurities, atmospheric pollution, etc.

Since reviews on the development of a general-purpose chromatographic method are, very likely, of the greatest interest literally to all experimental specialists in chemistry and chemical technology, the above examples confirm how closely and effectively the journal has followed the most advanced attainments of scientific and technical ideas, and has responded to the continual interchange between the enrichment of various fields of chemical science and practice.

With regard to the modern period in the work of *Uspekhi Khimii* it must be remarked that the present stage in the development of chemical science is indeed characterised by an avalanche of primary information with simultaneous increase in its complexity and saturation. Monographs and textbooks are often unable to react promptly to such developments in various areas, and therefore delay considerably the dissemination of information to chemists in comparison with the periodical literature. This makes the work of chemical review journals especially valuable.

Furthermore, a modern review journal cannot allow itself simply to inform the reader on new scientific achievements: it should serve as a reliable guide in the flux of scientific trends and, by actively directing this process, form a fine structure of contemporary scientific knowledge. By making good the informational deficiency on the most important and urgent scientific questions, while actively moulding the reader's taste and providing a system of contemporary chemical values and priorities, *Uspekhi Khimii* by its practice of strict selection and commission of primary reviews exerts a necessary controlling and organising influence on the very course of the informational process, often foreseeing important tendencies in current and future chemical progress.

The methodological basis of the journal remains as before, as also fifty years ago, to publish contributions on chemical physics, whose importance in modern science is continually increasing. The main prospects for development in

experimental chemical physics, in the opinion of N.N.Semonov expressed in his recent address to an International Symposium on Chemical Physics (Moscow and Erevan, 1981)[5], are governed by a combination of possibilities of the modern theory of primary chemical processes with the use of new experimental physicochemical methods of investigation, among which special value attaches to those that allow appropriate reagents and products to be specified in definite quantum states (electronic, rotational, spin) and thereby the microscopic rate constants of primary reactions and energy-exchange processes to be found.

It is precisely these aspects of chemical physics (both theoretical and experimental) that the journal has been covering during the modern stage. Concerning the theory of primary chemical processes and chemical kinetics (an important part in the establishment of these domains was played by V.N.Kondrat'ev and V.V.Voevodskii, in whose memory special issues were published) the journal has contained during recent years reviews on the current state of the theory of bimolecular reactions, the mechanism of non-adiabatic bimolecular reactions and non-adiabatic energy transfer in gases (E.E.Nikitin), and the nature of the pre-exponential factor in the rate equations of unimolecular gas reactions and hydrogen-abstraction reactions. In addition, the kinetics of molecular reactions, the theory of complicated unimolecular reactions, molecular and kinetic aspects of the chemical physics of the condensed state and reactions in solid polymers (P.Yu.Butyagin), and dynamic primary processes in liquids have been discussed, quantitative appraisals of the mechanism of several reactions of hydrocarbons given, and finally the kinetics of homogeneous reactions in a vessel with ideal mixing (open systems) described (N.M.Emanuel').

Several articles have been devoted to the use of correlation equations in the kinetics of free-radical reactions, and also to questions of the separation of polar, steric, and resonance effects in organic reactions on the principle of the linearity of free energy changes (this same principle has been used also to analyse and summarise extraction data).

Reviews of experimental work continue to pay attention mainly to the kinetics and the mechanism of homolytic processes, having discussed the formation of radicals in the devitrification of matrices, the mutual interaction of atoms and radicals in the liquid phase and their redox reactions with ions in solution, the reactivity of radicals and molecules in various radical reactions (including ternary recombination processes, and also in the solid phase—in connection with the mechanism of the oxidation of carbon-chain polymers), and finally reversible recombination and redox reactions of radicals (I.V.Khudyakov, V.A.Kuz'min).

A number of articles have shown that research on radicals and their reactions now makes use of the great variety of physical methods—electron spin resonance, nuclear magnetic resonance and chemical polarisation of electrons and nuclei (A.L.Buchachenko), chemical lasers (to determine rate constants of reactions of atoms with molecules and the relaxation of vibrationally excited molecules), flash photoexcitation (A.K.Chibisov—to investigate triplet states of organic substances), and finally isotope and mass-spectrometric methods in solution, as well as the method of spin traps (*inter alia* to study radical species containing chlorine or sulphur).

A major achievement here was the discovery of the influence of a magnetic field on radical reactions in solution (R.Z.Sagdeev, K.M.Salikhov, Yu.N.Molin, A.L.Buchachenko).

During the past decades *Uspekhi Khimii* has paid especially close attention to the chemistry of excited states of substances. This subject has been covered by reviews on mechanisms of excitation of chemiluminescence, mechanisms of reactions of electronically excited radicals and quenching of excited states of radicals, primary photoionisation processes and ion–molecule reactions of organic substances (including those induced by β-disintegration of hydrogen-3 in tritiated compounds), photoreactions of free radicals in the solid phase (the nature of the primary photochemical step was examined by K.M.Dyumaev), and proton-transfer reactions in electronically excited aromatic molecules (M.G.Kuz'min).

Research workers have now become very interested in catalytic and photoinduced electron transfer (and also the tunnel transfer of an electron to great distances), photoinitiated reactions of quinones and the photoreduction of aromatic nitro-compounds, radiation-induced electronic processes in solid organic systems, and the investigation in such systems of primary chemical reactions due to the formation of radical-pairs. Understanding of the mechanism of formation of free radicals in the liquid-phase halogenation of alkenes has been facilitated by the concept of intermediate formation in them of corresponding donor–acceptor molecular complexes.

Several papers in the journal have been concerned with fundamental aspects of high-energy chemistry—problem of the solvated electron in polar organic and non-polar molecular liquids (A.V.Vannikov), influence of impurities on radiation-chemical processes in inorganic salt crystals (V.V.Gromov), action of radiation on dissolution, and also the kinetics of chemical reactions initiated by hot atoms and the chemistry of hot (1–3 eV) hydrogen atoms.

The current interest of chemical physics in radical processes is due in particular to their use in the hydroxylation of aromatic compounds and the direct epoxidation of alkenes in the liquid phase (D.I.Metelitsa), as well as in subsequent chemical reactions of epoxy-compounds. However, the main value of such reactions lies in the oxidation of the most diverse classes of organic compounds—benzene (E.T.Denisov, D.I.Metelitsa), alkylaromatic hydrocarbons, alkenes, cycloalkenes, and aldehydes, for which the kinetics and reaction mechanisms have been studied, in particular the role of steric factors and spatial strain of the double bond.

Parallel development is occurring in study of the chemical and chemicophysical properties of oxidants—molecular oxygen and its radical-anion O_2^- oxygen activated by transition-metal complexes, singlet oxygen (its formation, quenching, chemical properties, and value in biological systems), and also the reactivity of the oxygen-containing radicals $HO^\cdot$, $O^\cdot$, $HO_2^\cdot$, and atomic oxygen (V.Ya.Shlapintokh, I.B.Afanas'ev, V.B.Aleskovskii) (results of and prospects for study of $HO_2^\cdot$ have been covered in the greatest detail in view of the contributions by V.V.Voevodskii).

Theoretical work of the preceding years (much of which also has been published in *Uspekhi Khimii*) has shown that a fundamentally important stage in the mechanism of many liquid-phase oxidations is degenerate chain branching, in which molecular products of the primary chain reaction (in the autoxidation of hydrocarbons these are hydroperoxides) can in turn act as initiators of further chain reactions. Subsequent development of this branch of chemical physics has involved detailed investigation of individual stages in liquid-phase oxidations, mostly by modelling them in specially selected reaction systems (E.T.Denisov, D.B.Pobedimskii). Thus intensive research has been undertaken on the primary reactions of oxidation inhibitors, whose role is either chain termination by reaction with alkyl radicals (nitroxyl and quinone inhibitors) or peroxy-radicals (amine and phenolic inhibitors) or non-radical decomposition of the accumulating hydroperoxides (I.V.Khudyakov, V.A.Kuz'min). Reviews in the journal have shown that these two types of reactions are modelled e.g. by the interaction of known hydroperoxides (as well as $PO^\cdot$, $PS^\cdot$, $PO_2^\cdot$ radicals) with sulphides, phosphines, and aromatic amines (D.G.Pobedimskii) and by the oxidation of sterically hindered phenols and amines. The kinetics

and the mechanism of the breakdown of hydroperoxides in the presence of transition-metal compounds and the metal-catalysed oxidation of organic compounds by hydroperoxides are also being investigated (G.A.Tolstikov, V.P.Yur'ev, U.M.Dzhemilov). Association in alcohols and phenols has been studied by nuclear magnetic resonance (V.D.Pokhodenko). All these current lines of research, represented in detail in the journal, are important for an understanding of the main features of the mechanism of inhibited oxidation, for a scientifically based search for new inhibitors and antioxidants, and for the study of synergism in their action in composite materials. An important part has been played by posing in the journal the question whether selectivity in chemical reactions is not a kinetic problem (N.M.Emanuel').

All work on the chemical physics of oxidation, among which an important position is occupied by investigations of the aging and the stabilisation of polymers, and also the kinetics of their degradation (*inter alia* in aggressive liquid media), is directly related to the most important practical problem of the protection from oxidation of several artificial and natural materials—fuels, lubricants, oils and fats [the problem of studying physicochemical mechanisms of damage to DNA is raised in the work—by means of various types of synthetic oxidation inhibitors and bioantioxidants (which include chemical geroprotectors)]. The great interest taken by the journal in such questions is indicated by its gathering together in one issue reviews on allied topics, in which the task of predicting changes in the properties of polymer materials on prolonged storage and service (including polyalkenes on photo-oxidation), and also measuring their durability and service life, was treated as a general physicochemical problem, whose solution could be facilitated by the construction of appropriate kinetic models. By using such interrelated series of publications to direct the attention of the reader to matters of great scientific and applied importance, *Uspekhi Khimii* is in some measure following the practice of another of our review publications—*Zhurnal Vsesoyuznogo Khimicheskogo Obshchestva im. D.I.Mendeleeva* [Journal of the Mendeleev All-Union Chemical Society] (published since 1956), every number of which is devoted to the subject-matter of a single major problem.

During recent years *Uspekhi Khimii* has published, besides reviews on the above scientific trends, several contributions on the chemistry of the positron, the muon, and mesoatoms (V.I.Gol'danskii, V.G.Firsov), the physics and chemistry involved being studied even in complicated polymer systems. The positron method enables the effective charge on anions in ionic media to be determined, and also new results on the structure of materials to be interpreted in the light of the Periodic Law (V.I.Gol'danskii). Several studies have appeared on novel physical actions on matter—processes occurring in solids under the influence of shock waves (A.N.Dremin), changes in condensed substances on shock-wave compression under controlled thermodynamic conditions (V.I.Gol'danskii), and epitaxial production of diamond in the metastable region (B.V.Deryagin, D.V.Fedoseev). Consideration has been given also to the formation of organic surface films by an electron beam, ultraviolet radiation, and a glow discharge, as well as the production of high-temperature materials by direct high-frequency melting in a cold container.

The classic problems of chemical physics—the theory of ignition, combustion, and explosion—first covered by the journal as early as 1930s, are now undergoing development. The present interests of research workers lie in using mass spectrometry to study flame structure and burning processes, in studying the thermal decomposition of aliphatic *C*- and *N*-nitro-compounds, and in the possibilities of practical application of the results to chemical technology and metallurgy (F.I.Dubovitskii, A.G.Merzhanov). The completeness of coverage of modern scientific trends in study of the physical foundations of chemical science is shown also by articles on the chemistry of low and extremely low temperatures associated with the phenomenon of a low-temperature quantum limit to the rate of chemical reactions (V.I.Gol'danskii), on solid-state chemistry (V.V.Boldyrev, P.Yu.Butyagin) (kinetics and nature of mechanochemical reactions, mechanism and kinetics of the dehydration of crystal hydrates), and on the classic thermodynamics of isotope exchange (N.M.Zhavoronkov).

The activity in publicising the fundamental physical foundations of chemical processes is especially important at the present stage in the work of the journal also because it is knowledge of the physical principles underlying the structure and the reactivity of various classes of compounds that is of the greatest interest to the majority of readers. Despite the organisation and publication during recent years of a multitude of sectional and interdepartmental review symposia, and also the active participation of many specialised chemical journals in review work, *Uspekhi Khimii* continues to play its part of general chemical review publication, reflecting not only the specialisation and differentiation occurring in chemical sciences but also the considerably more complicated contrary processes of mutual integration with the formation of new major fields of science.

Especially significant in this respect is the great attention paid to enzyme chemistry, a fundamentally new and important trend in the activity of the journal during the past decade. On this subject *Uspekhi Khimii* by no means publishes work on the structure of individual enzymes (which is the concern of specialist journals) but focuses its attention on reviews of general character, of interest to wide circles of specialists. At the present time it appears from the contents (I.V.Berezin, K.Martinek) that the main interest lies in the problem of enzymatic catalysis, for whose solution the methods of chemical kinetics and thermodynamics are widely used (in particular in study of the nature of intermediate compounds). Apart from its theoretical significance this type of catalysis has recently acquired immense applied importance, and now the chief problem is to stabilise enzymes, a key factor in the introduction of biocatalysis both into industrial practice and into organic synthesis. This many-sided research is directed mainly at immobilising enzymes, especially by the use of polymeric carriers. In sum, all this work draws attention to a new and independent branch of science, development of which will stimulate growth in all related theoretical and applied disciplines and promises major advances in the near future.

At present the most promising direction in the search for new catalysts—chemical bionics—involves chemical modelling of the action of enzymes (primarily lysozyme, which effects biocatalytic hydrolysis (V.I.Maksimov), as well as cytochromes, oxygenases and nitrogenases, responsible respectively for the anobolism of atmospheric oxygen and nitrogen *in vivo*). A convincing advance in this field is the discovery of new nitrogen-fixing systems based on vanadium in a low state of oxidation, which operate in aqueous solutions at ordinary temperatures and pressures (A.E.Shilov). Another modern line of research (bioinorganic chemistry), at the boundary between biochemistry and the coordination chemistry of physiologically active oxygen-, nitrogen-, and sulphur-centred ligands, is also represented in reviews, on chlorophyll, its synthetic analogues, metal porphyrins, and also the interaction of metals with nucleic acids (E.E.Kriss, K.B.Yatsimirskii) and proteins (V.A.Sergeev, M.G.Bezrukov). Yet another direction of advance (bioheteroorganic

chemistry) is apparent in papers on establishing the nature of hydrophobic sites on the active surface of choline esterases and of the mechanism of their inhibition by organophosphorus compounds (M.I.Kabachnik, N.N.Godovikov, M.Ya.Mikhel'son, A.P.Brestkin, Vi.I.Rozengart, et al.).

The journal has always paid great attention to the three-dimensional structure of complicated molecular systems, both by publishing special reviews on stereochemistry and conformational analysis (anomeric effect, stereospecific synthesis and catalysis, asymmetric synthesis of α-amino-acids, planar chirality of metallocenes, stereochemistry of hydroxymercuration, transannular effects in macrorings and *p*-cyclophanes) and by discussing various types of steric and spatial effects in a considerable number of the most diverse studies. As early as the 1960s the journal opportunely discerned the permeation of classic stereochemistry by several novel and fertile trends ("Algebraic Aspect of Chirality" by E.Ruh, "Problems of Chemical Topology" by W.Prelog, "Topological Ideas in Stereochemistry" by V.I.Sokolov) promoting an understanding of spatial relations in the molecular world. During recent years a close interest has been taken in framework and polyhedral structures—adamantanes and their hetero-analogues, the problem of tetrahedrane (N.S.Zefirov), carboranes and their rearrangements (L.I.Zakharkin, V.N.Kalinin, V.I.Stanko, V.I.Bregadze)—and a clearly structural approach characterises matter on the theory of cyclisation–recyclisation processes and also on structural aspects of several solid-phase reactions and rearrangements (right up to polymerisation processes).

Modern in both content and form is a recent review by V.I.Minkin and R.A.Minyaev on "Polyhedral Organic Molecules and Ions—Structural Analogues of Organometallic Clusters", which uses current orbital ideas and R.Hoffman's principle of isolobality to show the possibility of a single approach to understanding the fundamental interrelations between organic and hetero-organic compounds. A feature of this work is a general and fruitful analogy revealing interrelations between different branches of chemistry, unexpected at first glance but capable of serving as a guide to further experimental and theoretical investigations.

New stereochemical ideas are finding application also in practical chemistry. For example, several reviews in the journal explain catalysis on zeolites by the enclosure of reactant molecules in cavities bounded by the aluminosilicate framework (Kh.M.Minachev), and the molecules of inorganic heteropoly-acids have a different but also very complicated three-dimensional structure (V.I.Spitsyn); catalysis by cyclodextrins is attributed also to the presence in their spiralled molecules of a special kind of cylindrical cavity surrounded by polysaccharide chains. In the molecules of macrocyclic crown polyethers, which now play a very important part in the most diverse branches of chemistry (K.D.Pedersen), the appearance of coordination vacancies for particles of suitable size (e.g. metal ions) is also due to a peculiarity of the spatial structure of the cyclic multidentate ligand. Complexes formed by them find application as polymerisation catalysts (V.A.Kargin, S.L.Davydova).

Uspekhi Khimii exhibits two main approaches to publishing matter on catalysis—firstly towards a deeper insight into the mechanism of several traditional catalytic processes, and secondly to acquaint the reader with new types of catalysis arising during recent years in borderline and related sciences.

Together with the classic problems of acid–base catalysis (a special form of which is difunctional catalysis—L.M.Litvinenko) the journal gives detailed consideration to all aspects of traditional heterogeneous catalysis (kinetics, thermodynamics, problems of adsorption and chemisorption). The current scientific trend in this field is to use quantum-chemical calculations and physical methods of investigation—electron spectroscopy (V.B.Kazanskii), Mössbauer spectroscopy (V.I.Gol'danskii), ferromagnetic resonance (A.A.Slinkin), internal reflectance spectroscopy, paramagnetic probes, and isotope methods (G.K.Boreskov)—to study the surfaces of catalysts and to determine the nature of the intermediate surface compounds formed. The interest long taken by the journal in the catalytic hydrogenation of carbon monoxide to the hydrocarbons of synthetic liquid fuel (the Fischer–Tropsch reaction) has also been freshly stimulated by progress in understanding that this process involves intermediate formation of carbonyl and carbonyl–hydride complexes of transition metals.

During recent years the discovery of fundamentally new types of compounds to serve as heterogeneous catalysts (e.g. lamellar compounds of graphite—M.E.Vol'pin, Yu.N.Novikov) has been accompanied by the development of homogeneous metal-complex catalysis, which plays an important part in exploiting new opportunities for the industrial organic synthesis of several most important products—monomers for polymerisation and polycondensation, alcohols, aldehydes, ketones, carboxylic acids and esters, amines, alkyl halides—from a comparatively accessible unsaturated starting material (alkenes and alkynes). Reviews in the journal suggest that homogeneous catalysis is now a borderline discipline, whose theoretical basis comprises recent advances in organometallic, organic, coordination, and quantum chemistry and which has applications to chemical industry and technology. Theoretical research in this field is currently directed at establishing the nature of the catalytically active centres in stereospecific coordination and coordination–ionic polymerisation (B.A.Dolgoplosk) and studying the detailed mechanism of the catalytic reactions of organic compounds. In some approaches (M.L.Khidekel') coordination of reactive unsaturated ligands with coordinatively unsaturated metal atoms may be a factor removing orbital prohibitions on subsequent chemical reactions by concerted mechanisms.

The journal covers also new types of catalysis—hetero-homogeneous combining the ideas of heterogeneous and homogeneous catalysis, micellar due to special factors at the interface between colloidal micelles and the external medium, and finally phase-transfer catalysis in which the transport of active reactant species to the interface is effected by additions of special surface-active agents (M.Mankosha).

In organometallic chemistry, which now plays a key role in the development of related sciences, the journal publishes matter surveying the results of many years of systematic research and opens up new prospects for organometallic synthesis and the investigation of reaction mechanisms. It comprises reviews on the discovery of carbene complexes of transition metals (E.O.Fisher), the preparation of new types of organometallic compounds, analogues of alkenes and ketones having a multiple bond linking a carbon atom with a Group IV metal (L.E.Gusel'nikov, V.M.Vdovin, N.S.Nametkin), a review by the authors of the Taylor–McKillop reaction, which has enabled thallium(I) compounds to be introduced into the everyday practice of organic synthesis, and finally papers on the preparation and properties of silatranes (M.G.Voronkov) and polymetallic chains (M.G.Bochkarev). Consideration has been given also to organometallic peroxy-compounds (G.A.Razuvaev) and their rearrangements, dinuclear complexes of transition metals containing nitrogen bridging ligands (M.I.Rybinskaya, L.V.Rybin), oxidation of organometallic compounds by transition-metal salts (I.P.Beletskaya, A.N.Kashin), possibilities of using carbonyl chloride in the chemistry of functionally substituted silicon

derivatives (V.F.Mironov, V.D.Sheludyakov), preparation and properties of ethynyl derivatives of Group IV elements, and the chemistry and practical applications of silver and copper acetylides (A.M.Sladkov).

Recent advances in the chemistry of organophosphorus compounds are illustrated by new derivatives of quinquevalent phosphorus (G.Wittig), compounds containing phosphorus–phosphorus (I.F.Lutsenko, M.V.Proskurnina) and phosphorus–hydrogen (E.E.Nifant'ev) bonds, and optically active thiophosphates. Ever new physical phenomena are now being discovered for organophosphorus compounds—e.g. diastereoisomeric intermolecular interactions, studied in detail by nuclear magnetic resonance (M.I.Kabachnik et al.), synthetic possibilities such as the capacity for involvement in 1,3-cycloaddition (A.N.Pudovik), and also new practical applications as insecticides (N.N.Mel'nikov) and, in the case of alkylenediphosphine dioxides, as complexones (M.I.Kabachnik).

Uspekhi Khimii has widely illumined during recent years the introduction into modern hetero-organic chemistry of physical methods of investigation—thermochemistry, nuclear magnetic and quadrupole resonance, infrared spectroscopy (N.A.Chumaevskii), the vibrational spectroscopy of hydrogen-bonded and charge-transfer complexes, and polarography (S.P.Gubin, L.I.Denisovich)—which in several cases have provided new structural information on organometallic compounds and have broadened current views on their reactivity. Among theoretical concepts that have evolved in hetero-organic chemistry during the 1960–1970s are the important role of solvation and intramolecular coordination (O.Yu.Oxlobystin, A.K.Prokof'ev), the organometallic α-effect (M.G.Voronkov, V.P.Feshin), the nature of the siloxane bond (M.G.Voronkov, Yu.A.Yuzhelevskii), the role of non-bonding electron-pairs of the phosphorus atom in organophosphorus chemistry (M.I.Kabachnik, E.N.Tsvetkov), and the use of $\alpha\pi$- and $d_\pi p_\pi$-conjugation effects to explain the properties of carbon–metal and heteroelement–metal bonds. On the fairly controversial topic of the role of *d*-orbitals in hetero-organic chemistry (H.Jaffé published his review in 1957) the journal has even published several articles in which it has provided a forum for both supporters (A.N.Egorochkin) and critics (N.P.Gambaryan, L.M.Epshtein, D.A.Bochvar) of this concept.

A new interest of the journal during recent years has been work on hetero-organic medicinals—biological activity of silicon compounds (M.G.Voronkov, E.Ya.Lukevits), antitumour action of certain platinum complexes—and also on industrially convenient methods of obtaining organometallic compounds from atomic metals in the gas phase (G.A.Domrachev) and their practical application to the production of films, coatings (G.A.Domrachev, O.N.Suvorova) and ultrapure substances (B.G.Gribov).

In 1967 *Uspekhi Khimii* published an article by N.S.Zefirov on "Soviet Organic Chemistry after Fifty Years" (containing more than 600 references). Since that period elapsed many new and interesting advances have been made in this field, several evident on the pages of the journal. Although contributions on this subject have generally been exhaustive in character, with a considerable breadth of coverage of both experimental and theoretical work, a few overlapping fields have been treated in depth, and in the review activity of the journal on organic chemistry five main trends can now be distinguished, giving in total a very complete view of the current state of this scientific discipline.

Firstly, systematic publication is continuing of reviews on general aspects of the chemistry of a number of important classes or organic compounds, including thi-irans (A.V.Fokin, A.F.Kolomiets), carbon suboxide, small carbon rings (E.Vogel), tropylium and cyclopropenylium cations, organic peroxides (V.Karnozhitskii), triptycenes (V.R.Skvarchenko), sterically hindered phenols and cyclohexadienones (V.V.Ershov, G.A.Nikiforov, A.A.Volod'kin), and cyclododeca-1,5,9-triene (L.I.Zakharkin). The chemistry of saturated and unsaturated functionally substituted open-chain and cyclic systems containing oxygen, sulphur, and especially nitrogen atoms in various states of oxidation is also undergoing development. Such systems exhibit considerable chemical activity and offer various structural opportunities for organic synthesis, as the journal has shown for pernitriles (N.S.Zefirov, D.I.Makhon'kov), tetracyanoquinodimethane (B.P.Bespalov, V.V.Titov), chloro-derivatives of nitriles (E.M.Movsum-zade), hydrazones (Yu.P.Kitaev, B.I.Buzykin), nitro- and diazo-derivatives, nitramines and nitrosamines (S.S.Novikov, A.L.Fridman, S.L.Ioffe, V.A.Tartakovskii), as well as systems containing a nitrogen–nitrogen bond (B.V.Gidaspov) and *N*-fluoroimines (A.V.Fokin).

A definite tradition of the journal has been to pay special attention to the chemistry of heterocycles, which has always been represented very broadly, with detailed examination of three–seven-membered systems containing one or more heteroatoms, including aromatic derivatives and their benzoanalogues. Together with oxygen heterocycles—2-pyrones, enolic δ-lactones (R.Ya.Levina, N.P.Shusherina, E.A.Luk'yanets), 1,3-dioxans, $\Delta^{\alpha\beta}$-butenolides, pyrylium salts—and the still fairly exotic derivatives of selenium (2,1,3-thia- and selena-diazoles—V.G.Lesin), tellurium (tellurans—V.I.Minkin), and phosphorus (1,3,2-dihetero-phospholans and -phosphorinans—R.A.Cherkasov, M.A.Pudovik, A.N.Pudovik; E.E.Nifant'ev—and oxaphosphorinans—B.A.Arbuzov), the bulk of the material relates to nitrogen heterocycles—benzoisoquinolines, azafluorenes, indolizines, γ-piperidones (N.S.Prostakov), azaindoles, quinuclidines (L.N.Yakhontov), perimidines (A.F.Pozharskii), indoles and indolines (M.N.Preobrazhenskaya), aziridines (A.P.Sineokov, V.S.Etlis), 1,4-benzodiazepines (A.V.Bogatskii), quinolizidines, indolizidines, pyrrolizidines (I.M.Skvortsov), purines, oxapurines (E.S.Golovchinskaya), pyridine bases (M.Ya.Karpeiskii), sydnones (V.G.Yashunskii), quinolinium salts (B.M.Gutsulyak), *N*-acylated pyridines (A.K.Sheinkman, S.I.Suminov, A.N.Kost)—and many other compounds. In all these papers detailed consideration is given to methods of preparation of the systems, their structure (an important part in whose determination is played by various physical methods) and reactivity, and also many practical applications (in particular as analytical reagents—V.M.Ivanov). Reviews by R.A.Khmel'nitskii, P.B.Terent'ev, and N.S.Vul'fson, V.G.Zankin (coumarins, quinolizidine alkaloids) have discussed the mass-spectral behaviour of heterocycles. The journal pays close attention also to the theoretical problems of heterocyclic chemistry—prototropic tautomerism (A.R.Katritzky), application of the principle of hard and soft acids and bases to the coordination chemistry of azoles (V.N.Sheinker, A.D.Garnovskii, O.A.Osipov), mechanisms of recyclisation (O.P.Shvaika, V.N.Artemov), of condensation with elimination of ammonia (B.A.Geller), and of electrophilic substitution in 3-hydroxypyridines (K.M.Dyumaev, L.D.Smirnov) and other heterocycles and arenes (L.D.Smirnov) and other heterocycles and arenes (L.I.Belen'kii), and also the Fischer reaction and its analogues (I.I.Grandberg).

The special value of many classes of organic compounds (including some containing heterocyclic structural fragments) is largely due to their natural origin or their role in metabolic processes (including genetic aspects). The steady attention paid by the journal to structural and synthetic aspects of the chemistry of natural products and bio-organic chemistry is now responsible for a major independent line

in its work. Thus during recent years it has covered questions of the structure, biosynthesis, and properties of several important biopolymers of animal origin—chitin (E.A.Plisko, S.N.Danilov)—and vegetable origin—e.g. cellulose, its biologically active derivatives, and dextrans (A.D.Virnik), lignin (O.P.Grushnikov)—and also progress in and problems of solid-phase peptide synthesis (Yu.P.Shvachkin), the chemistry of glycero- and inosito-phosphatides and myoinositol (V.I.Shvets, B.A.Klyashitskii), phosphamides, laws of the three-dimensional structure of nucleosides, nucleotides, and oligonucleotides (N.N.Preobrazhenskaya, Z.A.Shabarova), and chemical methods of synthesis of their amino-acid and peptide derivatives (B.P.Gottikh). The journal continues actively to inform readers also on current directions in the search for natural and synthetic medicinals, which in several cases is able to reveal quantitative relations between chemical structure and biological activity (S.V.Nizhnii, N.E.Epshtein). Thus special reviews have been devoted to aminoglycosidic antibiotics, antimycotics, and glycosamidines, analogues of vitamin D_3, derivatives of γ-aminobutyric acid, as well as heterocyclic analogues of prostaglandins and steroids (A.A.Akhrem, Yu.A.Titov and G.N.Dorofeenko, G.I.Zhungietu), barbiturates (E.A.Cherkasova), anaesthetics (S.V.Bogatkov), chemical searchlight radar (V.G.Yashunskii), and bis-2-chloroethyl derivatives of amino-acids and peptides possessing antitumour activity (L.P.Rasteikene, M.I.Dagene, I.L.Knunyants).

The third trend in the output of the journal on organic chemistry is the provision of information on recent research on reactions involving organic compounds. Reactions or rearrangements having the most general significance are selected for review, many of which have become during recent years independent synthetic methods. Such are ionic hydrogenation and catalytic ionic hydrogenation (D.N.Kursanov, Z.N.Parnes), 1,5-sigmatropic migration in dienyl systems (V.A.Mironov, A.A.Akhrem), degenerate rearrangements of *O*-metallated *o*-semiquinolate radicals (M.I.Kabachnik, A.I.Prokof'ev), heterocyclisations involving acetylene (B.A.Trofimov), acyl migrations in unsaturated compounds (V.I.Minkin, L.P.Olekhnovich, Yu.A.Zhdanov), and also β-ketovinylation (M.I.Rybinskaya, A.N.Nesmeyanov, N.K.Kochetkov), aromatic nucleophilic substitution (O.N.Chupakhin), dimerisation of alkenes (V.Sh.Fel'dblyum), the Wurtz reaction, oxidative decarboxylation of carboxylic acids, and oxidation of alkylaromatic compounds (I.P.Beletskaya, D.I.Makhon'kov, Yu.A.Serguchev).

The fourth, vast area of reviews on organic chemistry, concerned with the mechanism of organic reactions, is represented by matter on the kinetics and the stereochemistry of such important processes as cleavage of the epoxide ring, hydroxymercuration, substitution, elimination, and incorporation. As before, *Uspekhi Khimii* is paying close and systematic attention to all the advances in research on the various kinds of unstable intermediate species that can be found in organic reactions. The number of such species has increased considerably in comparison with earlier periods of the journal. For example, perfluorinated carbanions and arenonium ions, dehydroarenes (arynes) arising from *o*-halogenated organometallic aryl systems (O.M.Nefedov, A.I.D'yachenko, A.K.Prokof'ev), and carbenes, in particular, which may be formed by α-elimination (G.Köbrich), have become very important. Long ago the journal forecast, as it were, the blossoming of this field of chemistry, publishing in 1934 its first review on the carbene theme (containing, incidentally, only eight references to the literature).

Apart from the classic carbocations (carbonium and carbenium ions) appearing in electrophilic reactions (G.Olah) and the free radicals generated in various homolytic processes, importance is now attached to radical-ion species (O.Yu.Okhlobystin, A.S.Morkovnik), of interest with respect to stereochemical features (Z.V.Todres). Material in the journal shows that cationic and anionic radical species can be formed in chemical reactions both in consequence of one-electron transfer as the primary step in the chemical process (K.A.Bilevich, O.Yu.Okhlobystin) and in a special type of hetero-homolytic mechanism such as radical–nucleophilic substitution (I.P.Beletskaya, V.N.Drozd). It is fundamentally significant that many of these modern radical-ion processes often take place by chain mechanisms, the importance of which in chemistry was realised in the very first years of *Uspekhi Khimii* and which it has covered in detail at all later stages. The chemistry of homolytic species is in general the longest established theme in the journal. Since the times of A.E.Arbuzov, who published his review on the chemistry of organic free radicals as early as the first volume, the structural variety and the range of thermodynamic and kinetic stability of these species have greatly expanded—from stable radicals (including nitroxyl, phenoxyl, and organometallic) to extremely unstable reactive intermediates capable of taking part in new molecular rearrangements (R.Kh.Freidlina, A.B.Terent'ev, G.I.Nikitin, A.D.Stepukhovich).

Ion-pairs constitute another type of intermediate to which the journal has paid close attention, especially during recent years. They have an important role, firstly in practice, since their formation enables the true mechanism of several reactions to be understood and the latter to be controlled (e.g. the anodic polymerisation of alkenes—M.Szwarc); and secondly in general theoretical terms, for it has emerged that taking into account the intermediate formation of ion-pair species is important for a fuller understanding of the state both of classic carbocations and of carbanions in solution. According to modern theoretical ideas discussed in the journal, ion-pairs play an important part in the mechanism of electrophilic and nucleophilic substitution at a saturated carbon atom (I.P.Beletskaya, A.A.Solov'yanov).

Finally, the fifth direction in which the journal covers organic chemistry is the development of modern theoretical principles and concepts of physical organic chemistry, on which are now based both planned organic synthesis and the study of mechanisms of chemical processes involving organic compounds. Such coverage includes theoretical aspects of the equilibrium acidity of carbon–hydrogen bonds (O.A.Reutov, I.P.Beletskaya, K.P.Butin), progress concerning the nature of the dual reactivity of ambident ions (O.A.Reutov, A.L.Kurts), the nature of differences in the acidity of organic and hetero-organic compounds on passing from condensed to gas phases (M.I.Kabachnik), role of hydrogen bonding in nucleophilic substitution, prototropy of triad nitrogen-containing systems, metallotropy, and transmission and nature of substituent effects in organic and hetero-organic molecules (D.N.Krasvtsov). Modern theoretical organic chemistry appears in the journal as such a varied scientific field that it finds room even for fertile qualitative concepts of intuitive character, such as e.g. the well known ideas on strained double bonds (L.I.Belen'kii, V.I.Sokolov, N.S.Zefirov), used successfully to explain peculiarities in the oxidation of strained cycloalkenes (V.V.Voronenkov) and for strictly quantitative approaches based on an orbital (L.Salem) or a kinetic–thermodynamic analysis of the theory of chemical reactivity (R.Zahradnik) and, as already mentioned, the principles of selectivity in chemical processes (N.M.Emanuel'). Further development of this area of investigation may arise also from advances in quantum-chemical calculations on complicated molecules, covered in reviews by C.Coulson, V.G.Dashevskii (conformational energies of organic compounds), A.A.Ovchinnikov, I.A.Misurkin (conjugated π-electron systems).

As before, *Uspekhi Khimii* has actively covered during recent years new physical methods for the investigation of organic and inorganic compounds, striving to keep the reader informed about the latest advances—infrared photochemistry (Yu.A.Molin), resonance Raman effect (P.P.Shorygin), mass spectrometry with chemical ionisation (O.S.Chizhov), dynamic nuclear magnetic resonance (N.M.Sergeev), and X-ray structural analysis—the last of which has created a revolutionary situation in crystallography (W.C.Hamilton). The n.m.r. method now permits the study of heterophase solvation (G.S.Bystrov), and the electron spin resonance method for investigating complicated molecular systems containing special spin labels has found several important applications in chemistry and biology. Useful tabular and reference data with exhaustive analyses have been given in reviews on the thermochemistry of organometallic compounds (I.B.Rabinovich) and the search for molecules possessing enhanced electron affinity (L.N.Sidorov). Among physicochemical matter special mention must be made of several contributions especially useful with respect to experimental method—reviews by E.N.Gur'yanova on "Mathematical Treatment of Results of Physicochemical Research on Complex Compounds" and by A.N.Korol' on "Reproducibility of Retention and Identification Data in Gas–Liquid Chromatography", as well as a few early journal papers that are still of interest—International System of Retention Factors in Gas Chromatography (for results obtained by this method see review by R.V.Golovnya), "Nomographic Methods in Physical Chemistry", and "Errors in and Accuracy of Measurements" (1947).

In concluding this survey we shall examine the character of the most recent material on the chemistry of macromolecular compounds, which at the present time, perhaps, is absorbing in the highest measure all the latest advances both in related fundamental scientific disciplines and in the instrumental technique of modern scientific research. The journal reflects all the chief lines of development, among which a few main trends in scientific research can be noted.

Firstly, new systems are constantly used in the formation of polymers, the main tendency being that, apart from purely organic monomers—acetylenes and diynes, dialkenylaromatic (B.A.Krentsel') and alkyl systems, adamantane derivatives, and mono- and bis-α-diketones (E.S.Krongauz)—enhanced importance is being attached to macromolecular derivatives of the most diverse elements—nitrogen (polyimides based on nitrogen heterocycles, polycyclotrimerisation of aromatic nitriles and acetylenes (V.A.Sergeev, V.K.Shitikov, V.A.Pankratov), polyisocyanates (S.G.Entelis), polytriazines, polyazaporphyrins (A.A.Berlin) and polyquinoxamines, and also thermostable polymers from tetramines and aromatic tetracarboxylic dianhydrides), fluorine (fluorination of polyethers and polythioethers, polyfluorovinyl), sulphur (polymers based on alkene sulphides and αβ-unsaturated sulphur-containing compounds—E.N.Prilezbaeva), phosphorus (and also polyphosphazens and oligomers of organo-oxaphosphazens—E.F.Chernyshev), and silicon (including organosiloxazans and oligodialkylsiloxanes—V.V.Korshak, A.A.Zhdanov). Broad investigations have been made also on polymers based on carboranes (V.V.Korshak) and ferrocene, various inorganic and metal-containing macromolecules (V.A.Kargin), and also coordination polymers.

Secondly, an intense search is being made for ever new promoters, initiators, and catalysts of the formation of macromolecular compounds, and detailed investigation of their mechanism is being based on the latest advances in physical organic, organometallic, coordination, and quantum chemistry. Methods are being elaborated for the polymerisation of chemically activated monomers, and redox reactions are acquiring great value in polymerisation processes—e.g. initiation by one-electron oxidation or reduction (including electrochemical) with formation of active intermediate radical-ions (N.G.Gaylord) or oxidative polymerisation of vinyl monomers and reductive polyheterocyclisation—a new method of synthesis of polyheteroarylenes. In several cases initiating systems based on readily oxidisable organic derivatives of non-transition metals (E.B.Milovskaya) cause radical polymerisation of polar monomers; derivatives of magnesium (B.L.Erusalimskii) and alkaline-earth metals (A.A.Arest-Yakubovich) initiate anionic polymerisation. The main laws governing the capacity of lactams for anionic polymerisation as a function of their structure are being established, and new activators for this process investigated (T.M.Frunze, V.V.Kurashev). Study continues of the mechanism of, and the nature of active centres for, stereospecific polymerisation of alkenes under conditions of metal-complex catalysis by transition metals (B.A.Dolgoplosk), while linking the ideas of anionic and coordination forms of catalysis has led to the discovery of anionic–coordination polymerisation (S.S.Medvedev). Finally, detailed research on the mechanism of polymerisation continues by the application of quantum-chemical and spectroscopic methods: the kinetics (and in the case of emulsion polymerisation also the topochemistry) of individual stages and the influence of the solvent are being studied, rates of growth and termination measured, and quantitative theories formulated to explain polycondensation processes and also (with the application of topological principles—S.Ya.Frenkel') random and heterophase copolymerisation.

Advances in the synthetic chemistry of macromolecular compounds (the title of a recent review by V.V.Korshak) involve at the present time the formation of many classes of polymeric molecules, which is apparently the third major line of development. Only in recent years have syntheses been accomplished of block copolymers of polycondensation type (P.M.Valetskii), semi-rigid chain molecules, ladder polyheteroarylenes (A.L.Rusanov), skeleton and network polymers (Ya.S.Vygodskii, S.V.Vinogradova—interpenetrating networks), polymers having a stellar or comb-like structure, ion-exchange membranes (B.N.Laskorin), oligo- and polyphenylenes with functional groups, and finally poly(arylene sulphides) (V.A.Sergeev, V.K.Shitikov, Ya.N.Nedel'kin).

The most diverse synthetic methods, several using novel types of catalysts (including stereospecific for optically active polymers—E.L.Klabunovskii), are now employed to obtain the bulk of such varied classes of compounds. Since many of these methods often acquire independent scientific and practical value, their exploitation represents a fourth line of research in polymer chemistry during recent years. This has been closely followed in the journal by the inclusion of reviews on polycondensation methods, of value for the synthesis of thermostable polymers, which have been covered also by special reviews (V.V.Korshak, S.V.Vinogradova, A.A.Berlin), on copolymerisation of cyclic compounds (T.M.Frunze, V.V.Kurashev), and on hydro-dehydropolymerisation and isomerisation polymerisation of unsaturated hydrocarbons (B.A.Krentsel'). Detailed discussions have appeared also on non-equilibrium copolycondensation in homogeneous systems, solid-phase polymerisation(V.E.Shklover, Yu.T.Struchkov), and heterophase radical polymerisation, as well as on polycyclisation, polycyclotrimerisation, trimerisation polycondensation (M.M.Teplyakov), and acceptor–catalytic polyesterification (V.A.Vasnev).

Many of the macromolecular compounds obtained during these years possess most interesting properties of practical value, such as the ability to catalyse chemical reactions and stabilise polymers (N.A.Plate) and to form macromolecular

charge-transfer complexes. Several of these polymers show great technical promise—e.g. electrical, photoelectric, and photochromic—as well as photoconduction and electrophotographic phenomena in linear polymers containing saturated and conjugated bonds. Semiconducting pyropolymers, conjugated inorganic polymers based on carbon (M.I.Cherkashin), and vitreous carbon (M.Ya.Fioshin) have also been obtained. Progress in the structural study of polymeric carbon has been surveyed by A.M.Sladkov.

Many of these properties are also of great theoretical interest (thus a quantum-chemical interpretation of the electronic structure and properties of polymers containing conjugated bonds has been given in a paper by A.A.Ovchinnikov, I.A.Misurkin), while others are of interest in biochemistry (use of polymers as matrices for peptide synthesis, formation of biologically active cellulose derivatives, use of polyethylene glycol in biochemistry, the grafting of biologically active compounds to the surface of optical materials, and the preparation of polymeric biological chemotherapeutic agents having carcinolytic activity), as well as for other purposes (e.g. use of ion-exchange resins in photometry, development of thermostable antifriction plastics (I.A.Gribova, S.V.Vinogradova), and formation of coatings by anodic electrodeposition of water-thinned paint systems based on water-soluble oligomers).

In view of the extraordinary value of polymeric substances for the most varied branches of practical science and technology, all this work probably indicates yet another, fifth line of research in modern polymer chemistry—the synthesis of macromolecular substances and materials having specified properties—for which those properties that are directly related to the service characteristics of macromolecular compounds are, naturally, of especial interest. In this connection the journal has continually published during recent years matter on the mechanism of stabilisation and the thermal stability of polymers and its dependence on their chemical structure (V.V.Korshak, S.V.Vinogradova), including cation- and anion-exchange resins, frost-resistance of polymers, their plasticisation, improving the water resistance of fibreglass plastics by additions of water-repellent adhesives, and finally problems of the photodegradation (M.B.Neiman), photostabilisation, and photostability of polymers (including coloured materials).

Finally, the sixth trend in macromolecular chemistry now evident in the journal is the physical chemistry and the physicochemical mechanics of polymer substances and materials, whose development also is regarded as very important. General contributions on this subject cover a wide range of problems—molecular-mass distribution in the production of homopolymers (N.S.Enikolopov), chemical defects in heterounit polymer molecules (V.V.Korshak), composition inhomogeneity of polymers (S.Ya.Frenkel'), and finally the nature of supermolecular structures in rubbers (V.A.Kargin). Great attention has been paid to the structure and properties of heat-resistant polymers (A.A.Askadskii, G.L.Slonimskii), block polymers and their solutions (L.Z.Rogovina, G.L.Slonimskii), and amorphous polymers, as well as to mechanisms of the diffusion of electrolytes (G.E.Zaikov) and the sorption of certain polymers in relation to their porous structure.

The most diverse physical methods are now used in solving physicochemical problems of macromolecular chemistry—sedimentation of polydisperse polymers, n.m.r. study of systems comprising a polymer with a substance of low molecular mass, electrochromism (for the study of slow movements in macromolecules), and also study of surface electrical characteristics of polymer-containing disperse systems—low-temperature methods being covered in a special review by A.G.Merzhanov). In combination with progress in developing new approaches to a theoretical interpretation of the experimental results this work has yielded in recent years very important quantitative data for several individual polymers, their mixtures, and solutions. Examples are studies of ion exchange and the swelling of exchangers, of structural features of homo- and co-polyurethanes and of networks based on heat-resistant polymers, of dilatancy of colloid structures and polymer solutions, of conformational and thermodynamic properties of macromolecules in ternary polymer systems, and of the polymeric structure of selenium also photoelectric phenomena. Furthermore, the influence of hydrogen bonding and ionic interactions has been established on several carboxyl-containing copolymers and ionomers based on them, and also that of a solid surface on relaxation and structure formation in polymer boundary layers (a theory of the "isofree" volume and the glass transition was constructed for amorphous polymers).

The value of such research is that the results can be used in the exploitation of macromolecular substances and materials. This applies in particular to investigations on the nature of gel formation, the structure and properties of polymer gels, also changes in rheological properties accompanying the formation and transformation of polymers, and those of thermosetting resins. Furthermore, the importance of modern research on the physics of polymers, to which the journal has recently paid such close attention, lies in the theoretical possibility of using the resulting quantitative characteristics to predict important practical properties of new synthetic macromolecular compounds. A recent review was devoted to methods for calculating physical parameters of high polymers (A.A.Askadskii, G.L.Slonimskii).

A survey of the contents of *Uspekhi Khimii* in the modern period must take note of two additional tendencies. The first is a definite increase in the number of contributions in which purely scientific interest in a research field is combined with great applied significance. Examples are a detailed examination of the ozonolysis of alkenes (an important method for obtaining dibasic carboxylic acids and other carbonyl compounds—G.A.Tolstikov), a long-term comprehensive study of radical reactions of 1,3-dioxans—an important class of saturated heterocycles—which are extremely promising compounds in organic synthesis (D.L.Rakhmankulov, S.S.Zlotskii, R.A.Karakhanov, U.B.Imashev, V.V.Zorin), and finally an analysis of current prospects for the use of organosulphur compounds present in crude petroleum and the determination of trace elements (Yu.A.Zolotov).

A second clear trend is for the journal to establish new headings. Examples are provided by new interrelations found between chemical and biological kinetics (N.M.Emanuel'), enabling the quantitative laws of many most complicated biological processes to be investigated and the effectiveness of several medicinal (including antitumour) preparations to be assessed and optimum régimes determined, the regular appearance of matter on synthetic food products—"Ways of using Amino-acids in Industry", "Plasteins in Nutrition", and "Chemistry of Odour and Flavour" (V.M.Belikov, S.V.Rogozhin, B.V.Tolstoguzov, R.V.Golovnya)—the discovery of new chemical possibilities in recording and storing information (A.V.Vannikov), including the use of photosensitive enzyme systems (I.V.Berezin, K.Martinek), papers on problems of silverfree photography, high-temperature exciton conduction, and photocatalytic conversion of solar energy (K.I.Zamaraev), and papers on enzyme electrodes. The contents have covered also aspects of the prebiological evolution of organic substances, and quite recently ecological questions, at present causing great interest throughout the world in connection with global problems of the protection of the environment. The great work of the journal is now actively crystallising the views of wide circles of its readers and

guiding them in the saturation flow of world chemical information has required that it should make its own appraisals of the relevance of reviews in various fields of chemical science.

Activity in scientific information during recent years was summarised at a 1977 All-Union conference on "Problems in the Improvement of Review Information on Chemistry", at which the chief editor of *Uspekhi Khimii*, Academician N.M.Emanuel', gave a lecture on "Criteria of the Quality of Reviews in the Field of Chemistry"†. He showed that, since it is chemical science that now produces the greatest amount of experimental material (especially on organic chemistry), while being actively involved in forming new fields of science and creating interdisciplinary networks, chemical literature has constituted during recent years an especially weighty portion of the total flow of world scientific and technical information#. Since for ordinary chemical journals (not only original but also abstracts) it is now difficult to ensure effective identification of scientific papers and facilitate their retrieval, the most efficient route for disseminating information, incorporating it, and bringing it to the attention of chemists is the review literature, with its inherent ability to condense primary scientific information, as well as its critical analysis and skilled generalisation.

The journal now considers that an immediate task, as was mentioned later, is to examine the possibility of condensing primary information by publishing analytical surveys. Numerical data in several leading science and science-assessing papers have shown that such analytical review activity enhances considerably the efficiency of scientific work and in several cases may lead to economies in the material resources consumed in scientific research.

To assess the quality of review literature the lecture proposed the use of a special "condensation factor", equal to the ratio of the volume of the primary information to that of the scientific review and representing the saving in the time of the specialist reader. A yearly analysis in the lecture showed that for *Uspekhi Khimii* the factor has more than doubled (its value at ten-year intervals from 1936 to 1976 was 20, 26, 36, 50, and 50), and has now apparently reached an optimum value (in the opinion of specialists further increase would heighten the risk of distorting the primary scientific information).

Later in the lecture it was stated that the most objective quantitative criterion of the scientific value of review papers may be their citation index, which depends exponentially on two factors—topicality, i.e. timeliness of a particular item, and timeless scientific importance—and as a rule (although these are exceptions) diminishes with the time that has elapsed since publication. According to statistics given in the lecture the number of highly quoted papers (>4–5 references in 3 years) in *Uspekhi Khimii* for the period 1961–1969 was ~7% of the total number of publications, more than double the index for ordinary (non-review) academic scientific journals on chemistry.

In the concluding part of the lecture it was shown that reviews published in *Uspekhi Khimii* are usually cited regularly by all the major journals published in various countries. For all years the maximum numbers of citations are found in the *Journal of the American Chemical Society* (1240 references), *Journal of Organic Chemistry* (360), and *Journal of Chemical Physics* (310). Each of the other major science journals examined contains on the average 240 citations, which over all the journals amounts to >12000 references to items in *Uspekhi Khimii* (of which >1000 in 1972)[7]§.

All these statistics confirm that our leading review journal fulfills successfully its scientific information function, and is up to the standard of modern demands on world analytical review literature.

The journal has also played an important scientific educational role in the training of science personnel. Throughout its many years *Uspekhi Khimii*, whose editorial board has contained at various times many most eminent representatives of chemical science, has educated its active expert staff and writers. Matter published in it has enabled many scientific workers to improve thei qualifications and prepare to solve complicated scientific problems, and workers in applied fields of chemistry, engineers, and works laboratory technicians to find on its pages valuable practical tips for everyday work. Reviews in the journal have always been widely used to raise the level of instruction in chemistry and chemical technology in higher education, and its contents have always been useful to students for their undergraduate and degree work. It is now difficult to imagine modern candidate or doctoral theses, monographs, handbooks, or textbooks without references to *Uspekhi Khimii*.

The geographical range of the journal's activity is constantly expanding. Among its authors have been chemists in Moscow and Leningrad, Riga, Vilnius and Tallinn, Kiev and Minsk, Kharkov, Donetsk, Rostov-on-Don, Ufa and Kazan, Gorky and Sverdlovsk, Irkutsk and Novosibirsk, Erevan, Baku, Tashkent and Dushanbe—i.e. all those towns in which new science and information centres have grown and developed, and important and interesting results have been obtained in various modern fields of chemistry. The journal regularly contains also contributions from leading research workers in the USA, Japan, the Federal Republic of Germany, France, England, Czechoslovakia, Poland, Bulgaria, Italy, Switzerland, and many other countries.

Results obtained from a questionnaire on improving review information in the country recently issued to our chemical community¶ are objective and significant for a general appraisal of the work of the journal. Many of the specialists questioned (10000 questionnaires were distributed among workers in academic and specialised scientific organisations, as well as higher educational institutions) named *Uspekhi Khimii* as their principal source of general chemical information, and expressed satisfaction with its work.

We can be confident that *Uspekhi Khimii* will continue to fulfill its important function of review journal, shedding light on prospects of development for current chemical trends.

---

†The conference was held in Moscow on the initiative of the Moscow administration of the Mendeleev All-Union Chemical Society, the editorial board of the society's journal, the local organisation of the Nesmeyanov Institute of Heteroorganic Compounds of the USSR Academy of Sciences, and the Chemistry Section of the Moscow Scientists Club. A précis of the lecture was published[6].

#Estimates by several experts indicate that its proportion increased between 1968 and 1976 from 18.7% to 23% of the total number of published items.

§The citation index of *Uspekhi Khimii* rose sharply in the 1960s, from the first issue of a complete ("cover-to-cover") English translation (published under the title Russian Chemical Reviews from January 1960 by the Royal Society of Chemistry, Burlington House, London, in collaboration with the British Library).

¶The enquiry was conducted in 1981 by the Section on Review Information on Chemistry and Chemical Technology of the Central Administration of the Mendeleev All-Union Chemical Society together with the Chemistry Division of the All-Union Institute of Scientific and Technical Information of the USSR Academy of Sciences.

All readers heartily congratulate their journal on its fine jubilee and wish it further achievements in its efficient contribution to the progress of world chemical science.

Activation of Oxygen by Cytochrome P-450 and Other Haemoproteins

D.I.Metelitsa

Data on the activation of molecular oxygen by the full microsomal hydroxylating system containing cytochrome P-450 as the terminal oxygenase are examined*. The nature of the hydroxylating agent, which is the oxenoid $Fe^{3+}O$, is analysed. The autoxidation reactions of cytochrome P-450 from various sources, haemoglobin, myoglobin, and peroxidases are compared and the role of the axial ligands of the haem iron and the structure of the active centres of the haemoproteins in this process is demonstrated. The possible mechanisms of the oxidation of organic compounds by peroxides with participation of cytochrome P-450, cytochrome *c*, haemoglobin, and catalase are examined critically. Haemoproteins have been divided into three groups in terms of the type of peroxide oxidation reactions. The relative contributions of the radical and two-electron reactions in the oxidation of compounds by peroxides with participation of different haemoproteins are analysed.
The bibliography includes 184 references.

I. INTRODUCTION

Hydroxylating enzyme systems which employ molecular oxygen as the oxidant and require pyridine nucleotides (NADH or NADPH) for their functioning are widely distributed in the living world. The large number of reactions catalysed by such systems are characterised by the following stoichiometry:

$$AH + NADPH(NADH) + H^+ + O_2 \rightarrow AOH + NADP^+(NAD^+) + H_2O.$$

The enzymes which insert one oxygen atom in the substrate and reduce another oxygen atom to water are called monoxygenases or mixed-function oxidases[1-18]. The most numerous group of monoxygenases consists of involved multienzyme complexes containing unique haemoproteins as the terminal oxidase—cytochromes P-450. Hydroxylating systems of this type are present in human and animal liver microsomes and adrenal cortex mitochondria and form part of the composition of the cells of many bacteria, yeasts, and fungi, are constituents of the liver cells of cold-blooded animals, and are present in certain higher plants.

The liver microsomal hydroxylating system has attracted particular attention in connection with the great importance of its functions. This system oxidises endogenic substrates (steroids and cholesterol) and numerous xenobiotics entering the organism, including drugs, poisons, carcinogens, industrial chemicals from the environment, etc. The liver microsomal hydroxylating system consists of three components, each of which has been fully characterised[7,11,17,18]: NADPH–cytochrome P-450 reductase (EC 1.6.2.4), cytochromes P-450 (EC 1.14.14.1), the existence of many forms of which has been convincingly demonstrated[11], and phospholipids[9]. The steroid hydroxylating system from adrenal cortex mitochondria also consists of three components: adrenodoxin reductase (EC 1.6.7.1), ferredoxin (adrenodoxin), and two forms of cytochrome P-450, one of which is responsible for the reactions involving the scission of the cholesterol side chain ($P\text{-}450_{scc}$) and the other is responsible for the 11-β-hydroxylation reaction of steroids ($P\text{-}450_{11\beta}$).[18] The camphor-hydroxylation bacterial system also includes three components: putidaredoxin reductase, ferredoxin (putidaredoxin), and cytochrome $P\text{-}450_{cam}$.[18,19] As a result of the efforts of investigators from many countries, the most significant aspects of the structure, functions, and mechanism of the action of enzymatic hydroxylating complexes have been extensively investigated and surveyed in a series of monographs, reviews, and collections[1-19]. However, two most important problems have not been finally solved, namely the mechanism of the activation of molecular oxygen by cytochrome P-450 and the organisation of multienzyme complexes in the membranes of the endoplasmic reticulum, the adrenal cortex mitochondria, and bacterial cells.

The aim of the present review is a critical consideration and survey of the experimental data on the activation of molecular oxygen by cytochrome P-450 obtained very recently for the microsomal hydroxylating system of the liver. The ability of cytochrome P-450 to oxidise many substrates of different chemical types in combination with organic peroxides and other oxidants is extremely significant for the understanding of the mechanism of the activation of oxygen by cytochrome P-450. In this connection much attention has been devoted to reactions involving the oxidation of a substrate by hydroperoxides and other oxidants with participation of cytochrome P-450. The mechanism of the action of cytochrome P-450 differs from that of the other haemoproteins capable of catalysing many oxidative processes. One of the aims of this review is the consideration and analysis of the causes of this difference between cytochrome P-450 and other haemoproteins in oxidation-reduction processes. In order to solve the latter problem, the author has confined himself to the range of haemoproteins listed in Table 1, in view of the availability of data permitting a comparison of the reactions involving these haemoproteins and also the possibility of analysing the role of axial ligands and the structure of apoproteins in the activation of oxygen. Much attention has been devoted to the nature of the hydroxylating agents and

† The following abbreviations are used in the review: $P\text{-}450\text{-}LM_2$ = cytochrome from liver microsomes of rabbits administered phenobarbital-sodium; $P\text{-}450\text{-}LM_4$ = cytochrome from liver microsomes of rabbits administered 3-methylcholanthrene or β-naphthoflavone; $P\text{-}450_{cam}$ = cytochrome P-450 from camphor-hydroxylating bacteria; $P\text{-}450_{scc}$ = cytochrome from adrenal cortex mitochondria catalysing the scission of the cholesterol side chain; CHP = cumenyl hydroperoxide: TBHP = t-butyl hydroperoxide; DMA = *N*,*N*-dimethylaniline; ROOH = organic hydroperoxides and peracids; AH = substrate; AOH = reaction product.

the relative contributions of the homolytic and heterolytic stages in oxidation processes with participation of the haemoproteins enumerated.

II. ACTIVATION OF MOLECULAR OXYGEN BY THE FULL MICROSOMAL HYDROXYLATING SYSTEM

We shall employ the concept of the full microsomal hydroxlating system to designate the reconstructed systems containing NADPH-cytochrome P-450 reductase, cytochrome P-450, NADPH, oxygen, and the substrate, and also in the description of the oxidation by liver microsomes with participation of NADPH and oxygen in contrast to the oxidation of substrates by hydroperoxides with participation of microsomes or individual forms of cytochrome P-450.

The process involving oxidation by microsomes and reconstructed systems is complex and consists of at least eight stages (Fig.1). In the first stage the substrate forms a complex with the oxidised form of cytochrome P-450, which is accompanied by a change in the oxidation-reduction potential and the spin state of the haemoprotein: the majority of substrates convert the low-spin form of cytochrome P-450 into the high-spin form, while certain amines induce the reverse transition. It has been suggested that the high-spin form of cytochrome P-450 loses the axial ligand in the sixth position but retains the cysteinyl group as the fifth ligand[20]. The rates of formation of the enzyme–substrate complexes are high and are characterised by constants in the range 10^2–10^6 litre mol^{-1} s^{-1} depending on the nature of the substrate[21]. The binding of substrates to cytochrome P-450 facilitates the reduction of the enzyme–substrate complex by the first electron arriving from the NADPH-specific electron transport chain[18,22]. The chain incorporates NADPH-cytochrome P-450 reductase (FP_1) and possibly cytochrome b_5. NADPH-cytochrome P-450 reductase is a flavoprotein (FP_1) with a molecular weight of approximately 79 000 and containing one FAD group and one FMN group in the molecule[23,24]. FMN reductases receive two electrons from NADPH, while FAD is involved in the transfer of these electrons to cytochrome P-450.[24] The mechanism of the action of the reductase has not been ultimately elucidated, since the relative positions of the two flavin fragments in the enzyme molecule are unknown. The second stage of the process in microsomes and in reconstructed systems consists of two phases[12]. A possible cause of the two phases in the reduction of the enzyme–substrate complex by the first electron in microsomes may be the heterogeneity of cytochrome P-450 [12,17] and, what is more likely, the different rates of reduction of different spin forms of cytochrome P-450,[32] since high-spin haemoproteins are reduced faster than the low-spin haemoproteins[20].

In the third stage the enzyme substrate complex reduced by the first electron combines rapidly with molecular oxygen: the rate constants for the addition of O_2 to different complexes vary in the range 10^4–10^6 litre mol^{-1} s^{-1}.[21] The oxygenated form of reduced cytochrome P-450 from liver microsomes was first detected spectrophotometrically in 1971 by Estabrook et al.[22] At the same time Gunsalus et al.[33] and Ishimura et al.[34] demonstrated spectroscopically the formation of a complex of oxygen with the reduced camphor-hydroxylating cytochrome P-450$_{cam}$. The camphor–P-450$_{cam}$–O_2 and P-450$_{cam}$–O_2 complexes were isolated for the first time in 1976 [35,36] by chromatography at temperatures below 0 °C in mixed aqueous organic solvents. These complexes have been characterised spectroscopically and kinetically. The camphor–P-450$_{cam}$–O_2 ternary complex undergoes autoxidation: the activation energy for this process is 18 kcal mol^{-1} in water and 19 kcal mol^{-1} in an aqueous organic medium[35].

The oxygenated complex of cytochrome P-450 was isolated for the first time in 1979 from rabbit liver microsomes at −30 °C in aqueous glycerol solution[37]. The complex is characterised by absorption maxima at 420 and 557 nm and the activation energy for [its] autoxidation is ~10 kcal mol^{-1}.[37] The ternary complex of cytochrome P-450$_{scc}$ from bovine adrenal cortex mitochrondria with cholesterol and oxygen was purified quite recently in the same medium: the complex has an absorption maximum at 414 nm and an extinction coefficient of 84 ± 2 litre mmol^{-1} cm^{-1},[38]

The complex formation reaction of highly purified cytochrome P-450 from rabbit liver microsomes (P-450-LM) has been investigated spectrophotometrically using stopped flow methods[39]. The reaction was carried out in two stages in the presence of the substrate (benzphetamine) and was found to consist of two stages: the short-lived oxygenated Complex A, having absorption maxima in the difference spectrum at 430 and 450 nm, is formed initially and is then converted into

Complex B with an absorption maximum at 440 nm. The complex formation reaction between oxygen and the reduced cytochrome is described by the scheme

$$P\text{-}450^{r}_{LM} + O_2 \xrightarrow{k_1} A \xrightarrow{k_2} B \xrightarrow{k_3} P\text{-}450^{o}_{LM}\ .$$

The rate constants are $k_1 > 6.0 \times 10^4$ min^{-1}, $k_2 = 270$ min^{-1}, and $k_3 = 3.0$ min^{-1}.[39] Complex B has spectroscopic characteristics close to those of Complex I in the reactions of peroxidases with hydrogen peroxide[28] and is probably analogous to it. The reaction components have the following Soret bands: P-450r—424 nm, P-450o—418 nm, A—432 nm, and B—421 nm. The oxidation of cytochrome P-450 in the ternary complex is the rate-limiting stage of the process and leads to the hydroxylation of the substrate.

The structure of the oxygenated haemoprotein is of primary importance for the mechanism of the activation of oxygen by cytochrome P-450. The state of oxygen in the substrate—P-450—O_2 complex and its configuration are still unknown. By analogy with oxyhaemoglobin, it has been suggested that oxygen receives an electron from the haem iron and its state is best reproduced by the structure proposed for oxyhaemoglobin by Weiss[40]: $Fe^{3+}O_2^-$ (Fig.1). By analogy with oxyhaemoglobin, one can postulate that the oxygen in the oxygenated cytochrome P-450 has the configuration Fe—O=O, in which the Fe—O=O angle is close to 120°. Attempts have been made to calculate the most favourable configuration for the oxygenated cytochrome P-450 by quantum-mechanical methods[41,42]. The calculations showed that the unusual spectroscopic properties of the oxygen and carbonyl complexes of cytochrome P-450 are fully associated with the thiol ligand in the fifth axial position and depend very strongly on the distance between the haem iron atom and the sulphur atom of the thiol ligand. An increase of this distance by 0.2 Å and more is quite sufficient to convert cytochrome P-450 into the inactive form P-420, which differs from the former by the maximum of the Soret band of the carbonyl complex of the cytochrome in the reduced state[42]. It would be premature and risky to reach definite conclusions about the configuration of oxygen in the oxygenated cytochrome P-450 on the basis of quantum-mechanical calculations, since theoretical calculations for the Fe—O_2 bond in oxyhaemoglobin proved unconvincing. Such calculations, carried out by the molecular orbital method[43], give preference to Pauling's structure[44], whereas it follows from calculations by the MO-LCAO method carried out by other workers[45] that only the closed Griffith structure[46] ensures the existence of the stable low-spin complex of oxyhaemoglobin. An X-ray diffraction study of oxygenated myoglobin confirmed Pauling's model, i.e. the axis of the O_2 molecule forms an angle close to 120° with the plane of the porphyrin ring[47].

The substrate—P-450—O_2 ternary complex in microsomal hydroxylating system is unstable and undergoes autoxidation. The reduction of this complex by yet another electron, which occurs in the fourth stage of the process (Fig.1), is necessary for the hydroxylation of the substrate. It has been suggested that the second electron comes from the NADH-specific microsomal chain containing NADH-cytochrome b_5 reductase and cytochrome b_5. Hitherto this stage of the process has not been resolved into individual steps and its rates have not been measured for microsomal systems. The important role of cytochrome b_5 in the transport of the second electron has been confirmed in the study of oxidation by microsomes[48–53] and in the oxidation of a series of substrates in reconstructed systems[54–65]. It is believed that cytochrome b_5, reduced in the NADH-specific electron transport chain, can transmit the second electron directly to cytochrome P-450.[48] The participation of cytochrome b_5 in the transport of the second electron to the ternary complex is indicated by a whole series of experimental data, which have been discussed[66].

Firstly, in the microsomal oxidation of substrates of the first type (hydrocarbons, tertiary amines, and alicyclic compounds) with participation of two pyridine-nucleotides (NADH and NADPH), a synergistic effect is observed, reflecting the important role of the two electron transport chains in the oxidation process[48,50]. The synergistic effect is not observed for substrates of the second type (aniline and other amines)[17]. It is important to note that only endogenic cytochrome b_5 participates in the synergistic effect, while the exogenic cytochrome b_5 (incorporated in the microsomal membranes) does not always stimulate microsomal oxidation and actually retards the reactions of aminopyrine and DMA.[49,66] Evidently the cytochrome b_5 incorporated in the membrane differs from the native cytochrome b_5 by the fact that it cannot enter a cluster containing cytochrome P-450 and reductase and cannot participate in the reduction of cytochrome P-450. The inhibiting effect of the cytochrome b_5 incorporated in microsomes can be explained by its ability to receive electrons from NADPH-cytochrome P-450 reductase and to consume the latter non-productively from the standpoint of the hydroxylation process. The reduction of cytochrome b_5 by NADPH-cytochrome P-450 reductase was initially merely postulated[48,50] but now it has been confirmed experimentally[17,56,59]. The different effects of the endogenic and exogenic cytochrome b_5 on the microsomal oxidation can be explained by the different oxidation-reduction potentials of the native haemoprotein and the haemoprotein incorporated in the membrane.

Secondly, in the oxidation by microsomes or reconstructed systems cytochrome b_5 frequently accelerates the oxidation of some substrates, but is indifferent in the reactions of others; the oxidation of benzo[*a*]pyrene,[53,57] acetanilide[57], 4-ipomeanol[52], benzphetamine[54], 7-ethoxycoumarin[53,55,61], and *p*-nitroanisole[59–61] is accelerated by cytochrome b_5, while the oxidation of aminopyrine[49] and aniline[66] is inhibited by this haemoprotein. It may be that the substrates of the first group form complexes with cytochrome P-450 whose oxidation-reduction potentials favour the reduction of the substrate—P-450—O_2 complexes by cytochrome b_5; on the other hand, aniline and aminopyrine form complexes with oxidation-reduction characteristics which prevent their reduction by cytochrome b_5.[49,66]

Thirdly, the influence of cytochrome b_5 on oxidation in the reconstructed systems is determined to a large extent by the nature of the cytochrome P-450 itself. Cytochrome P-450 with an increased affinity for cytochrome b_5 has been isolated recently[60] and it has been shown that the oxidation demethylation of *p*-nitroanisoles is in this case effectively accelerated by cytochrome b_5.[56,59] Cytochrome b_5 accelerates the oxidation of the same substrate, namely benzo[*a*]pyrene with different efficiencies under identical conditions in the presence of two different forms of cytochrome from rabbit liver (P-450-LM and P-450-LM_4), i.e. the nature of cytochrome P-450 determines to a significant extent the stimulating possibilities of cytochrome b_5.[62] Direct evidence has been obtained recently for the reduction of oxygenated cytochrome P-450 from liver microsomes by cytochrome b_5:[65] it was shown that the autoxidation of the oxygenated cytochrome P-450 is accelerated in the presence of reduced cytochrome b_5.

Thus the influence of cytochrome b_5 on the oxidation reactions of various substrates in microsomes and in reconstructed systems is determined by several factors: the nature of cytochrome b_5 (exogenic or endogenic) and its oxidation-reduction potential, the nature of the substrate oxidised and its influence on the oxidation-reduction characteristics

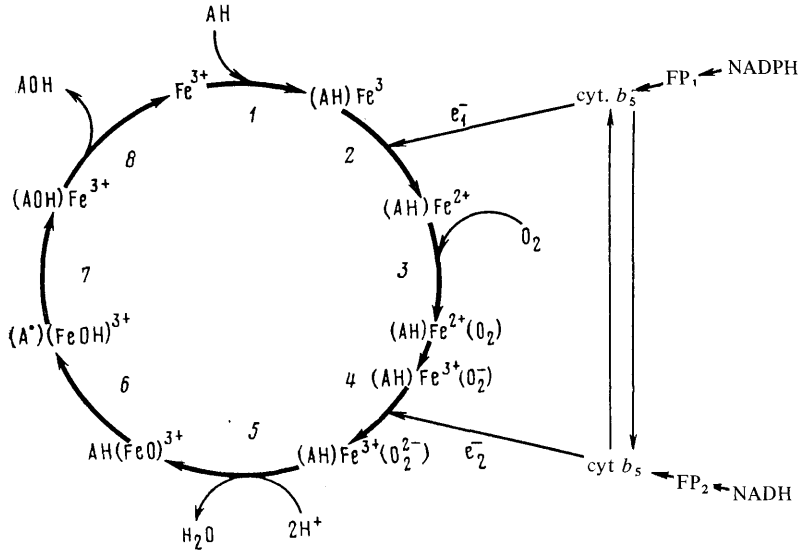

Figure 1.

of the ternary substrate–P-450–O_2 complex, and finally the nature of cytochrome P-450 itself and its affinity for cytochrome b_5. We may also note the influence of the methods used to reconstruct the enzyme systems, the content of admixtures of detergents which have not been removed, and the reaction conditions. For a favourable ratio of the oxidation-reduction parameters of cytochrome b_5 and the ternary complex, the haemoprotein stimulates the oxidation of substrates, while under the conditions of an unfavourable ratio of the above parameters, cytochrome b_5 can receive electrons from NADPH-cytochrome P-450 reductase but is incapable of transmitting them to cytochrome P-450, which retards the oxidation process.

The fourth stage of the microsomal oxidation is a complex process in which several macromolecular biocomponents of the microsomal system can participate. The rates of this stage have not so far been measured. We may note that the stage in which the ternary camphor–P-450_{cam}–O_2 complex is reduced by the second electron in the camphor-hydroxylating system has been studied in detail and characterised by its rate constants. This process proceeds with participation of an effector—putidaredoxin, and is the rate-limiting stage in the oxidation of camphor in a bacterial system[19,67].

After the reduction of the ternary complex by the second electron, the fourth stage of the process involves the hydroxylation of the substrate, the liberation of the molecules of water and the reaction product, and the regeneration of the initial catalyst in the oxidised form (Fig.1). It must be emphasised that at the present time none of these processes has been investigated separately and furthermore it is not known in what sequence the processes occur. One cannot rule out the possibility that the number of stages after the fourth may be greater or less than the four stages indicated in Fig.1. It is possible that after the fourth stage the hydroxylation step is followed by the simultaneous liberation of the molecules of the reaction product and water from the ternary complex, i.e. the complex hydroxylation step constitutes a cooperative process, which is frequently encountered in enzymatic reactions. Another possibility has been considered by White and Coon[12]: the fourth stage is followed by the cleavage of the O–O bond in the ternary complex with formation of water, the hydroxylating agent ruptures the C–H bond in the substrate, and this is followed by the formation of the reaction product, which is released in the last stage of the process. The oxidising agent has not been identified directly in any of the hydroxylating enzyme systems. Its nature and properties must be inferred from indirect data concerning the stereoselectivity and specificity of the microsomal oxidation, the presence or absence of isotope effects in the oxidation of labelled substrates and, what is very important, the similarities and differences in the oxidation of the same substrates in the complete system and with participation of hydroperoxides in combination with cytochrome P-450. The inhibition of the reactions by antioxidants, which retard the radical oxidation processes, plays an important role in the consideration of the relative contributions of the homolytic and heterolytic stages in the microsomal oxidation process[68,69]. Stages *5–8* of the process (Fig.1) will be henceforth discussed taking into account all the data concerning different aspects of the microsomal oxidation of substrates.

It is believed[12] that the fourth stage of the process is followed by the cleavage of the O–O bond in the ternary complex with formation of a hydroxylating species containing only one oxygen atom. This claim is supported by the high oxidising capacity of iodosobenzene $C_6H_5I{=}O$ and its derivatives in combination with the oxidised cytochrome P-450, first observed by Ullrich and coworkers[70]. Indeed iodosobenzene can transmit to the oxidising agent only one oxygen atom, since it has no other. Two groups of investigators were able to obtain with the aid of iodosobenzene relatively stable compounds simulating the hydroxylating agent of cytochrome P-450, which contains only one oxygen atom[71,72]: the oxidation of hydrocarbons by iodosobenzene is catalysed by chlorodimethylferriprotoporphyrin IX,[71] while in the presence of octaethylporphyrinatoiron(III) chloride in $CHCl_3$ or CH_2Cl_2 2-iodoso-*m*-xylene gives rise to a species whose magnetic susceptibility corresponds to the high-spin state of iron(IV).[72] It is believed[72] that the structure of the compound obtained is analogous to that of Complex I of

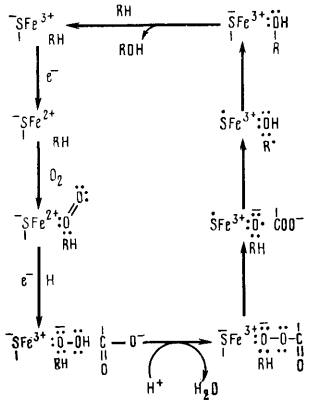
peroxidases, catalases, and chloroperoxidase and is characterised by the following formulae:

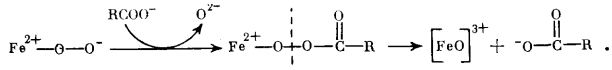
$$P^{+}Fe^{IV}O^{2-} \longleftrightarrow PFe^{IV}O^{-} \longleftrightarrow PFe^{III}O \ ,$$

where P is the porphyrin. The high degree of oxidation of iron in these model complexes is stabilised, according to the authors, by the porphyrin ring, which gives up one electron to the iron or oxygen atom. In many instances evidence has been obtained for the existence of porphyrin cations[73,74]. The species whose structure is illustrated above is called oxene[18,75], since its oxygen atom contains six electrons in the outer shell and is distinguished by a high reactivity, by analogy with carbenes and nitrenes[76,77]. As a result of the cleavage of the O–O bond in the ternary complex, such a species is in fact formed in the scheme proposed by White and Coon[12]. The O–O bond dissociation process takes place with participation of the carboxy-group of one of the aminoacids of the active centre of cytochrome P-450 (Fig.2). The authors believe that the structure of the peracid formed on interaction of the carboxy-group of the oxygen complex of cytochrome P-450 is favourable for the subsequent cleavage of the O–O bond and the formation of the hydroxylating species. This consideration is confirmed by the high hydroxylating capacity of peracids in relation to aromatic and aliphatic hydrocarbons, which increases when the peracids are coordinated to metal complexes. It is not fortuitous that peracids are convenient models of monoxygenases simulating the step in which oxygen is inserted in the substrates of the microsomol system[4,75,78]. It is believed[12] that the oxenoid formed in stage 5 (Fig.1) is stabilised by the thiol ligand of cytochrome P-450, which constitutes an unusual reservoir of electrons in the formation of the hydroxylating species and its reactions:

$$S^{-}Fe^{V}O^{2-} \longleftrightarrow S^{-}Fe^{IV}O^{-} \longleftrightarrow S^{-}Fe^{III}O \leftrightarrow S^{\cdot}Fe^{III}O^{-} \ .$$

The possibility of the involvement of the carboxy-group of one of the aminoacids of the active centre of cytochrome P-450 in the formation of the hydroxylating agent has been confirmed experimentally[79] in relation to cytochrome P-450$_{cam}$.





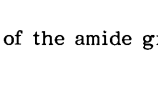


Figure 2.

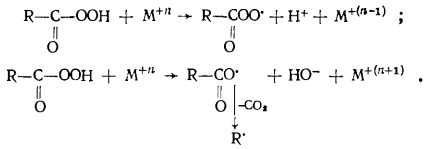
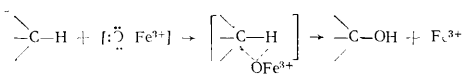


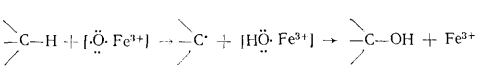
Using labelled oxygen ($^{18}O_2$), it has been shown[79] that dihydrolipoic acid acylates the distal oxygen atom in the oxygenated complex P-450$_{cam}$ $^{18}O_2$, forming an intermediate peroxy-compound, the dissociation of the O–O bond of which is greatly facilitated, which results in the insertion of one ^{18}O atom in camphor and of the other in the carboxylate group of dihydrolipoic acid:

The heterolytic decomposition of an acyl peroxide results in the formation of the oxenoid $[Fe^{18}O]^{3+}$ and lipoic acid labelled in the carboxy-group:

As an alternative to the heterolytic decomposition of the acyl peroxide formed as a result of the covalent binding of the carboxy-group of the aminoacid to the oxygenated cytochrome P-450, the possibility of the homolytic decomposition of the intemediate peroxy-compound, formed with participation of the amide group  , has been considered[12]. In this case one must postulate that the C–H bond in the substrate is attacked by the amidyl radical  . We believe that this reaction pathway is unlikely, because the amidyl radical is relatively stable and at temperatures close to physiological temperatures cannot rupture the stable C–H bond in the majority of substrates of cytochrome P-450. The homolytic dissociation of the O–O bond in the intermediate acyl peroxide must also be ruled out, because the homolysis of this bond with participation of metal complexes and ions is accompanied by the decarboxylation of the acylperoxy-radical formed[80]:



As a result of the last reaction, the acid of the apoenzyme participating in the covalent fixation of oxygen in the oxygenated cytochrome P-450 would be irreversibly consumed and the catalyst would rapidly break down.



Thus the most probable pathway leading to the formation of the oxenoid in the complete microsomal system is heterolytic decomposition of the acyl peroxide formed on interaction of the carboxy-group of one of the aminoacids of the active centre with the activated oxygen of the ternary substrate–P-450–O_2 complex reduced by the second electron. It is important to note that the oxygen coordinated to cytochrome P-450 is not only fixed to the matrix of the enzyme, as suggested for oxyhaemoglobin[44,81], but is covalently bound to one of the acids of the apoenzyme with formation of an intermediate peroxy-compound.

In the sixth stage of the process (Fig.1) a C–H bond in the substrate molecule is ruptured. It is believed[12] that this stage proceeds via a radical mechanism. This claim is supported by experimental data, which we shall consider in detail below. The electronic structure and reactivity of the oxenoid $[Fe^{3+}O \leftrightarrow Fe^{4+}O^{-}]$ are completely unknown. Presumably one of two mechanisms of attack on the substrate

obtains[16,18]: the first (oxenoid) or two-electron mechanism:

and the second (cryptoradical) or one-electron mechanism:

It would be incorrect to claim that one of the reaction pathways is universal. If the oxygen in the oxenoid is in the singlet state, the first mechanism operates, in which the oxygen atom is inserted in the C–H bond without its dissociation, as happens in the reactions of carbenes, nitrenes, and atomic oxygen with aromatic and aliphatic hydrocarbons[76,77,78]. This reaction pathway is most likely in oxidation reactions of aromatic compounds and is the only one possible in the microsomal oxidation of cyclohexene and other unsaturated compounds and it is difficult to imagine the formation of epoxy-derivatives of cyclohexene and olefins via a radical mechanism. If the oxenoid is in the triplet state, then the direct insertion of the oyxgen atom in the substrate is impossible—such a reaction is spin-prohibited. In this case the one-electron, cryptoradical mechanism operates, which is reflected in the scheme (Figs.1 and 2). The radical mechanism of the oxidation reaction in the complete microsomal system has been supported by a number of pieces of important evidence.

Table 2. The primary isotope effects (k_H/k_D) in the microsomal oxidation of various substrates.

Substrate	k_H/k_D	References
[CD_3]Morphine	1.4	83
[α-D_2]Ethylbenzene	1.8	84
[D_{12}]Cyclohexane	1.0	85
[11-D_2]Lauric acid	3.0	86
[9-D_2]Caproic acid	3.0	86
Saturated compounds	1.4	87
[16α-D]Pregnenolone	3.0	88
[7α-^{3}H]Taurodeoxycholic acid	3.8	89
[α-D_2]Isopropylamphetamine	1.6	90
[CD_3]-*o*-Nitroanisole	2.0	91
[Cd_3]Methoxyanisole	10.0	92
Aromatic compounds	1.3-1.75	93
[1,1-D_2]-1,3-Diphenylpropane	11.0	94
Biphenyl	1.4	95
N,N'-Dimethylphentermine	1.4	96
Norbornane	11.5	97
7-Ethoxycoumarin	13.5	98

Firstly, a mixture of methylcyclohexanols with the isomer ratios 1° : 2° : 3° = 0.072 : 1 : 1.25 has been obtained in the hydroxylation of methylcyclohexene with participation of cytochrome P-450-LM_2.[82] Such proportions of the reaction products are consistent with a radical process mechanism.

Secondly, the dissociation of the C–H bond in the microsomal oxidation process is supported by the primary isotope effects, which have been observed in a number of instances (Table 2). It is remarkable that, in the oxidation of aromatic compounds of the benzene series and biphenyl, the isotope effects are small: k_H/k_D = 1.3–1.8. Small isotope effects have also been obtained for the oxidative dealkylation reactions of [CD_3] morphine[83], *N,N'*-dimethylphentermine[96], [CD_3]-*o*-anisole, and [α-D_2]isopropylamphetamine[90,91]. This means that the oxidation of aromatic compounds and oxidative dealkylation of certain substances either do not involve the dissociation of the C–H bonds or this process is not rate-limiting. In a number of instances measurements have been made of the intramolecular isotope effect which occurs when the molecule contains hydrogen and deuterium in the same position. The microsomal oxidation of *exo, exo, exo, exo*-tetradeuteronorborane yielded a mixture of *endo*- and *exo*-2-norborneols[97]. The ratio of the *exo*- and *endo*-alcohols was 3.4 : 1 for norbornane, decreasing to 0.76 : 1 for the deuterated substrate. The isotope effect was 11.5 in this instance[97]. It was shown in the same study that the oxidation of norbornane is not accompanied by the complete retention of configuration on formation of the alcohol, which confirms the intermediate formation of the carbon-containing radical. Measurements have been made recently of the isotope effect in the *O*-de-ethylation of 7-ethoxycoumarin[98] in the oxidation by two cytochromes from rat liver microsomes—P-450 and P-448. The ratios k_H/k_D were 11.8 and 13.5 for P-450 and P-448 respectively. The large isotope effects in a number of instances confirm that the rate-limiting stage of the microsomal oxidation process involves the dissociation of the C–H bonds in the substrates.

Thirdly, systematic kinetic studies of the influence of 1-naphthol and mannitol on the oxidation of aniline and DMA by microsomes with participation of NADPH and O_2 and by reconstructed systems with participation of the same cofactors demonstrated an effective retarding effect of 1-naphthol[69]. The 1-naphthol concentrations were significantly lower than those of both substrates and the mixed type of inhibition in the oxidation of the two substrates cannot therefore be accounted for solely by their competition with the inhibitor for binding to cytochrome P-450. Under the experimental conditions, 1-naphthol serves as an effective trap for active radicals participating in the oxidation reaction, whereas mannitol does not retard the oxidation process. The results led to the conclusion that radicals may participate in the oxidation of aniline and DMA in the complete microsomal system[69].

Thus the proportions of the reaction products in the oxidation of hydrocarbons, the large primary isotope effects in the oxidation of a series of substrates, the inhibiting effect of antioxidants on the oxidation of aniline and DMA, and the partial retention of configuration in the oxidation of norbornane confirm the possibility of radical stages in oxidation by the complete microsomal system.

The last stage of the microsomal oxidation reaction (Fig.1) is associated with the liberation of the reaction product from the ternary complex and the regeneration of cytochrome P-450 in the initial stage. This stage is rapid, since the more polar reaction products are less strongly bound to cytochrome P-450 than the less polar substrates and are easily displaced by the substrate molecules from the active centre of the enzyme.

The problem of the determination of the rate-limiting stage of the microsomal oxidation reaction is fairly complex. We may note immediately that the rate-limiting stages in the oxidation of the same substrate in microsomes and reconstructed systems may differ.

Extensive kinetic data concerning the oxidation of various substances by microsomes and the rates of invdividual stages of the process were considered previously[16,18]. Here the reader should merely be reminded that some of the stages of the microsomal oxidation reactions are known beforehand to

be incapable of being rate-limiting. The interaction of many substrates with oxidised cytochrome P-450 takes place at high rates[18,21] and the reduction of the enzyme–substrate complex by NADPH-cytochrome P-450 reductase is also rapid and it has been shown[21,99] that it cannot limit the rate of the entire oxidation process. The third reaction stage, namely the binding of molecular oxygen to the reduced enzyme–substrate complex, has high rate constants in the range 10^3–10^6 litre $mol^{-1}s^{-1}$.[21] It has so far been impossible to estimate the rate of reduction of the ternary complex by the second electron in the fourth stage of the microsomal oxidation process. It is sometimes suggested that this stage can in fact limit the rate of the process as a whole[12,17]. An analogy is frequently drawn between the microsomal system and the bacterial camphor-oxidising hydroxylating system in which the stage involving the reduction of the ternary camphor–P-450_{cam}–O_2 complex by the second electron is the rate-limiting stage for the process as a whole[19,67]. However, this analogy may be erroneous, because the reduction of the ternary complex by the second electron in the bacterial system involves yet another protein—putidaredoxin. On the other hand, the turnover number in the microsomal system is less than one-tenth of that in the hydroxylation of camphor with participation of P-450_{cam}.[12]

The most correct solution of the problem of the nature of the rate-limiting stage in the microsomal oxidation process involves the measurement of the rates of all the stages of the complex process and their comparison. Such a study has been carried out in Sato's laboratory in connection with the oxidation of benzphetamine in a reconstructed system[99]. Table 3 presents the kinetic characteristics of the individual stages of the process.

Table 3. The kinetic parameters k and ν of the N-demethylation of benzphetamine in the reconstructed systems of liver microsomes[99].

Stage of the process	Kinetic characteristics
Binding of benzphetamine to cytochrome P-450	$k_1 = 50\ s^{-1}$
Reduction of enzyme-substrate complex by first electron	$k_2 = 4\text{–}12\ s^{-1}$
Binding of oxygen to enzyme-substrate complex	$k_3 = (1.0\text{–}1.3) \times 10^3\ s^{-1}$
Decomposition of ternary complex with formation of reaction products	$\nu \geqslant 2.3$
Oxidation of NADPH	$\nu = 0.8\text{–}1.2$
Accumulation of formaldehyde	$\nu = 0.5\text{–}0.7$

Note. The rates of the processes are given in nmol s^{-1} per nmol of cytochrome P-450.

Analysis of the rates of the individual stages of the oxidation of benzphetamine led the authors[99] to the conclusion that the rate-limiting stage may be either the reduction of the ternary complex by the second electron or any process after this step, since the reaction product accumulates at rates less than the rate of decomposition of the ternary complex.

Some years ago we suggested that the rate-limiting stage of the microsomal oxidation process is the attack on the substrate in the ternary complex by the hydroxylating agent accompanied by the dissociation of the attacked C–H bond[100,101]. This hypothesis is supported by several experimental facts. Firstly, as already mentioned, large primary isotope effects are observed in the microsomal oxidation in most cases (Table 2), which implies the dissociation of the C–H bonds in the substrate molecule in the rate-limiting stage of the reaction. If such dissociation occurred before or after the rate-limiting stage, it would be impossible to obtain isotope effects of 11–13.

Secondly, there exist the so-called uncoupling compounds which are bound effectively to cytochrome P-450 but are not oxidised by microsomes. They include fully fluorinated hydrocarbons[102–105]; in this case the C–F bonds are very stable and cannot be ruptured by the oxidising agent in the rate-limiting stage.

Thirdly, we have shown that, in the complete microsomal system and with participation of hydroperoxides, the kinetic and energetic characteristics of the oxidation of the same substrates are in both cases very close or do not differ at all. This may reflect the attack on the substrate by the same oxidising agent in both systems. However, in the hydroperoxide oxidation there is no necessity for the transport of two electrons to the oxidising agent, since the oxygen of the hydroperoxide is already activated by two electrons. Consequently both systems may have the same rate-limiting stage, involving the transformation of the ternary complex containing the substrate, cytochrome P-450, and oxygen in the first case and the substrate, cytochrome P-450 and the hydroperoxide in the second. This is apparently entirely valid for the majority of substrates, although one cannot ignore certain differences between the oxidation by microsomes in the complete system and the oxidation with participation of hydroperoxides. The differences between the two systems will be discussed below.

In conclusion of this section, it must be emphasised that the rate-limiting stage of the microsomal oxidation reaction can vary as a function of the reaction conditions. A change in the process temperature is extremely significant from this point of view. The microsomal phospholipids undergo phase transformations at temperatures in the range 17–20 °C, which affect the energetic characteristics of the oxidation of the same substrates: the activation energies for the oxidation of substrates of the first type above the phase transition temperatures vary in the range 9–14 kcal mol^{-1}; at temperatures below the phase transition temperature, the activation energies increase to 17–25 kcal mol^{-1}.[106] The break in the relations between the oxidation rate constants and temperature and the points corresponding to the phase transitions of the microsomal phospholipids can denote a change in the rate-limiting stage of the process: above the break point under the conditions of enhanced mobility of cytochrome P-450 and the reductase, their interaction is facilitated and does not limit the rate of oxidation; below the phase transition point, the liquid-crystal state of the membrane lipids hinders contact between the two enzymes and the stage involving the reduction of cytochrome P-450 by the reductase may limit the rate of the entire process. The activation energies below the break point may therefore refer to the stage in which cytochrome P-450 is reduced by the reductase, while the activation energies above the break point may refer to another stage, for example, the decomposition of the ternary complex with formation of the reaction product or to the dissociation of a C–H bond by the hydroxylating agent in the ternary complex.

III. AUTOXIDATION OF HAEMOPROTEINS

Comparative analysis of the autoxidation of haemoproteins is useful from two points of view: firstly, the autoxidation of myoglobin and haemoglobin constitutes the only method of

activation of molecular oxygen by these proteins and, secondly, comparison of the rates of autoxidation of haemoproteins makes it possible to estimate the role of the axial ligands and the structure of the apoenzyme in the activation of oxygen by haemoproteins. Table 4 presents certain characteristics of the oxygenated complexes of haemoproteins. It shows that the oxygenated complexes of five haemoproteins are characterised by similar absorption spectra. All the proteins enumerated undergo autoxidation. It has been shown that the oxidation of cytochromes P-450$_{cam}$ and P-450-LM$_2$ results in the formation of the superoxide radical-anions $O_2^{\cdot-}$.[108-111] Somewhat unexpectedly, the $O_2^{\cdot-}$ radical-anions could not be detected by direct methods in the autoxidation of cytochrome P-450-LM$_4$ from the liver microsomes of rabbits given β-naphthoflavone[112]. Some authors erroneously attributed to the $O_2^{\cdot-}$ radical-anion the role of the hydroxylating species in the microsomal oxidation on the grounds that the oxidation processes are inhibited by superoxide dismutase and copper complexes which can model this enzyme[113]. A detailed study of the inhibition of the oxidation of DMA by copper(II) ions and the copper(II) complexes of tyrosine and lysine showed that the role of the copper compounds reduces to the interaction with the $O_2^{\cdot-}$ radical-anion and to displacing the equilibrium to the right[114]:

$$[Fe^{2+}O_2 \equiv Fe^{3+}O_2^{\cdot-}] \rightleftarrows Fe^{3+} + O_2^{\cdot-} .$$

This process leads to the non-productive consumption of the oxygenated cytochrome P-450 and competes with the reduction of the latter by the second electron, i.e. lowers the concentration of the hydroxylating species in the system and thereby retards the oxidation. Copper compounds also enter into other reactions which, together with that discussed above, are responsible for the complex mixed type of inhibition in the oxidation of DMA by rabbit liver microsomes[114].

Table 4. Characteristics of oxygenated complexes of haemoproteins.

System	λ_{max}, nm	E^*, kcal mol^{-1}	References
S-P-450$_{cam}$-O_2	418, 552	17.0; 18.0	19, 35, 36
P-450$_{cam}$-O_2	—	24.0; 14.5	19, 35, 36
S-P-450$_{scc}$-O_2	414	—	38
P-450-LM$_2$-O_2	420, 557	9.6	37
Haemoglobin-O_2	412, 542, 577	17.7	29, 107
Myoglobin-O_2	417, 544, 582	—	29

*E = activation energy for the oxidation reaction.

Myoglobin and haemoglobin are autoxidised very slowly, which is not surprising, since their main function is to transfer molecular oxygen and not to activate it. Nevertheless it has been shown repeatedly that the oxidation of myoglobin and haemoglobin results in the formation of the radical-anions $O_2^{\cdot-}$.[81] The autoxidation of oxygen-transferring proteins has attracted the attention of investigators for a long time[115]. At the present time it is entirely possible to consider the main pathways leading to the autoxidation of myglobin and haemoglobin. There are three mechanisms of the oxidation of these proteins:

$$Fe^{2+}O_2 + H_2O \rightleftarrows Fe^{3+}OH_2 + O_2^{\cdot-} , \quad (1)$$

$$Fe^{2+}O_2 + Fe^{2+} \rightleftarrows Fe^{2+}O_2Fe^{2+} \rightarrow 2Fe^{3+} + O_2^{2-} , \quad (2)$$

$$Fe^{2+}O_2 + H \text{ (or } e^-) \rightarrow Fe^{3+}O_2H \rightarrow \text{products.} \quad (3)$$

Reaction (1) is an important stage of the autoxidation of iron-porphyrins, but the formation of $O_2^{\cdot-}$ or $HO_2^{\cdot}$ is hindered by the hydrophobic environment within the protein. Comparison of the corresponding oxidation-reduction potentials shows that the reactions of simple ions are endothermic and for this reason can hardly constitute the main pathway in the autoxidation of myoglobin and haemoglobin at pH 7:

$$Fe^{2+} + O_2 \rightarrow Fe^{3+}OH_2 + O_2^{\cdot-} ,$$
$$Fe^{2+}O_2 \rightarrow Fe^{3+}OH_2 + O_2^{\cdot-} ,$$

Reaction (1) may become the principal stage in the autoxidation of haemoglobin if the oxidation-reduction potential of the Fe^{2+}/Fe^{3+} pair is significantly reduced. Such reduction of the potential is possible when histidine in the fifth axial position is replaced by another ligand, for example, tyrosine or cysteine, which is observed in certain mutant haemoglobins. However, the axial ligand is not the only species which can decrease the oxidation-reduction potential of the haemoprotein; this can be done by the protein itself. Indeed, myoglobin, haemoglobin, and peroxidase have the same fifth axial ligand (histidine), but they have different oxidation-reduction potentials and as a consequence their oxygenated complexes have different capacities for autoxidation (Table 5). Table 5 shows that the capacity for autoxidation of oxygenated haemoproteins increases with decrease of the oxidation-reduction potential, which decreases markedly on replacement of the fifth ligand (histidine in myoglobin, haemoglobin, and peroxidases) by cysteine (in cytochromes P-450).

Table 5. The oxidation-reduction potential (E_0') of haemoproteins and qualitative comparison of the stabilities of their oxygenated complexes $Fe^{2+} + O_2$ (K).

Haemoprotein	E_0' (pH 7), V	K	References
Haemoglobin	+0.2	very stable	115
Myoglobin	+0.1	very stable	115
Turnip peroxidase, P$_7$	-0.12	stable for 20 min	115
Horseradish peroxidase	-0.25	oxidises rapidly, not detected	115
S-P-450$_{cam}$	-0.17	oxidises very rapidly	19, 35, 36
P-450$_{cam}$	-0.27	stable only at -30 °C	19, 35, 36

Reaction (2) is unlikely for protein iron-porphyrins, since the protein hinders the dimerisation of the oxygenated form by reaction with another porphyrin molecule, but such dimerisation has been observed for non-protein iron-porphyrins. It is noteworthy that the dismutation of two Fe^{2+}–P-450$_{cam}$–O_2 complex species has been demonstrated for the bacterial hydroxylating system[19]:

$$2[Fe^{3+}\text{—P-450}_{cam}\text{—}O_2^{\cdot-}] \rightarrow Fe^{3+}\text{—P-450}_{cam} + O_2^{2-} + Fe^{3+}\text{—P-450}_{cam} + O_2 .$$

This is possible only in the case of the association of two molecules of cytochrome P-450$_{cam}$, which cannot be ruled out.

The oxidation of the oxygenated myoglobin and haemoglobin usually takes place with participation of a donor of a hydrogen atom or an electron [reaction (3)]. Such donors can be nitrite[116], phenol[116], 1-naphthol[107], aniline[30], phenylhydrazine[117], and other organic and inorganic reductants. It has been shown that oxyhaemoglobin oxidises these reductants via a radical mechanism[107,118]. The activation energy for the oxidation of 1-naphthol by oxyhaemoglobin is 17.7 kcal mol^{-1}.[107]

In the absence of electron donors, oxyhaemoglobin is fairly stable and different techniques, for example, flash photolysis (λ = 300 nm), must be used to generate the O_2^- radical-anion[119].

Thus oxyhaemoglobin and oxymyoglobin are distinguished under normal conditions by a greater stability compared with other oxygenated haemoproteins. It has been suggested that this stability is ensured by the structure of the oxygen-transferring proteins and, in particular, by the important role of the distal histidine moiety, which stabilises oxygen by forming hydrogen bonds with it.[44] However, slow oxidation of myoglobin and haemoglobin nevertheless occurs and in oxygenated blood there is usually a steady-state concentration of methaemoglobin $Fe_3^{3+}OH_2$, amounting to 1–2%. In the presence of H^+ ions or electron donors, the oxidation of haemoglobin is accelerated: for example, the aniline hydroxylase activity of erythrocytes has been convincingly demonstrated. Haemoglobin, which is not usually regarded as an enzyme, catalyses the oxidation of aniline to *p*-aminophenol[120]:

$$\text{aniline} + Fe^{2+}O_2 \rightarrow \text{aniline}\cdot Fe^{2+}O_2 \xrightarrow{e^-,2H^+} p\text{-aminophenol} + Fe^{3+} + H_2O .$$

It is important to note that the oxygenated cytochromes P-450$_{cam}$ and P-450-LM$_4$ are incapable of oxidising their substrates[18,19]. In the former case the oxidation requires reduced putidaredoxin—the effector of the oxidation of camphor and in the latter case oxidation takes place in the presence of reduced cytochrome b_5.[121] This parallelism suggests that in the microsomal system cytochrome b_5 can play the role of an effector analogous to that of the Fe- and S-containing putidaredoxin in the bacterial camphor-oxidising system. In the literature there is only one indication of the oxidising capacity of oxygenated cytochrome P-450-LM$_2$ in the absence of electron donors[122]. However, we believe that these data have been obtained using a doubtful analysis of the reaction product and require additional confirmation.

In conclusion of this section, we emphasise yet again that the autoxidation of haemoproteins takes place with formation of the O_2^- radical-anion, which is not itself a hydroxylating species but on recombination can give rise to hydrogen peroxide, which is a source of the active oxidant radical-anions $HO^{\cdot}$. The rates of oxidation of haemoproteins are determined by the oxidation-reduction potentials of the Fe^{2+}/Fe^{3+} pair and increase sharply when histidine in the fifth axial position (myoglobin, haemoglobin, and peroxidases) is replaced by cysteine (cytochromes P-450). The oxidation-reduction potential of iron-porphyrins is determined not only by the nature of the fifth axial ligand but also by the structure of the protein itself. The distal histidine in the myoglobin and haemoglobin molecules probably significantly stabilises the oxy-complexes of these oxygen-transferring haemoproteins, protecting them from autoxidation with liberation of the toxic radical-anion O_2^-. The activation of oxygen in the coordination sphere of cytochrome P-450 is ensured by its anomalously low oxidation-reduction potential.

IV. THE MECHANISMS OF THE CATALYSIS OF PEROXIDE OXIDATION BY HAEMOPROTEINS

It has already been mentioned that oxidised cytochrome P-450 combined with organic hydroperoxide catalyses the oxidation of many substrates of the microsomal system. After the first study by Kadlubar et al.[123], in which the ability of liver microsomes to catalyse reactions involving the oxidative dealkylation of amines by hydroperoxides was demonstrated, numerous investigations, surveyed and discussed in a series of reviews[12,16,124], were carried out. It is known that cytochromes P-450-LM$_2$, P-450$_{cam}$, and certain others are catalytically active in peroxide oxidation[16,125]. On the other hand, it has not been possible to detect a catalytic activity of cytochrome P-450-LM$_4$ in peroxide oxidation[126,127]. The range of oxidants employed is extremely wide and includes, apart from organic hydroperoxides (CHP and TBHP), also peracids, hydrogen peroxide[128], sodium periodate[129], sodium chlorite[130], iodosobenzene[70], iodosobenzene diacetate[131], and pyridine *N*-oxide[132]. The number of reactions catalysed by cytochrome P-450 when peroxy- and non-peroxy-oxidants are used is also large: oxidation of aromatic compounds[106,133–140], oxidative *O*- and *N*-dealkylation of aromatic compounds[106,133–140], oxidative *O*- and *N*-dealkylation of ethers and tertiary amines[123,130,141–148], epoxidation of cyclohexene[100], oxidation of saturated and alicyclic compounds[149–151], and oxidation of aliphatic alcohols[152]. Thus all reactions catalysed by microsomal cytochrome P-450 in the complete system can take place in the presence of peroxides[16,18]. The peroxide oxidation of the lipids in the microsomal membranes, in which radical initiation reactions may play a significant role on interaction of lipid peroxides with membrane haemoproteins, occupies an important place. The formation of lipid peroxides has been investigated in detail[5]. Two systems for the peroxide oxidation of unsaturated aliphatic acids exist in the microsomal fraction: a non-enzymatic system in which iron is reduced by ascorbic acid and an enzymatic system in which the reductant is NADPH. The endogenic haem iron atoms serve as the inducing centres. The consideration of the important class of lipid peroxide oxidation reactions is outside the framework of this review, since it is of independent interest. We shall merely mention that the reactions of lipid peroxides with cytochrome P-450 may become an important source for the generation of the active radicals $RO^{\cdot}$ and $RO_2^{\cdot}$ via mechanisms which will be discussed in detail below. In the first stages of their investigations, several groups of workers postulated that the oxidising agent in peroxide oxidation is Complex I (Fig.3), analogous to the well known intermediate complex in the reactions of peroxidases, catalases, and chloroperoxidase[100,133–143]. The formation of Complex I in the hydroperoxide system and its comparison with the formation of the same agent in the complete microsomal system are presented in Fig.3. This analysis is supported by several important experimental data. Firstly, different spectra, identical with the spectra of Complex I for certain peroxidases (for example, cytochrome *c* peroxidases), have been recorded in the interaction of hydroperoxides with microsomes or with the highly purified cytochrome P-450-LM$_2$.[153] Table 6 presents the characteristics of the difference spectra of the complexes of hydroperoxides with cytochrome P-450 and other haemoproteins. Secondly, when microsomes were mixed with CHP, the EPR spectrum of a product having a *g*-factor of 2.0 was recorded, i.e. a radical species analogous to Complex I is formed[154]. Thirdly, the oxidation of [4-^{3}H]acetanilidine in the hydroperoxide system yielded the same NIH shifts as in the complete microsomal system, i.e. the mechanism of the insertion of an oxygen atom in acetanilide is the same in both cases[155]. Fourthly, as already mentioned, the oxidation of many substrates in the complete and hydroperoxide systems yielded similar or identical kinetic and energetic parameters for the oxidation of the same substrate in the two systems[18,100,101]. All the facts enumerated above confirm the hypothesis put forward by several workers that the mechanisms of the oxidation reactions in the complete and hydroperoxide systems are similar[16,100,146] and make it possible to postulate the existence of the same hydroxylating agent in both systems—the oxenoid [$Fe^{3+}O \leftrightarrow Fe^{4+}O^-$], analogous to Complex I of per-

oxidases and catalases. However, a series of results have been obtained recently indicating a more complex mechanism of the hydroperoxide oxidation and possible differences between the hydroxylating agent and Complex I.

Table 6. Spectroscopic characteristics of the complexes of haemoproteins with hydroperoxides.

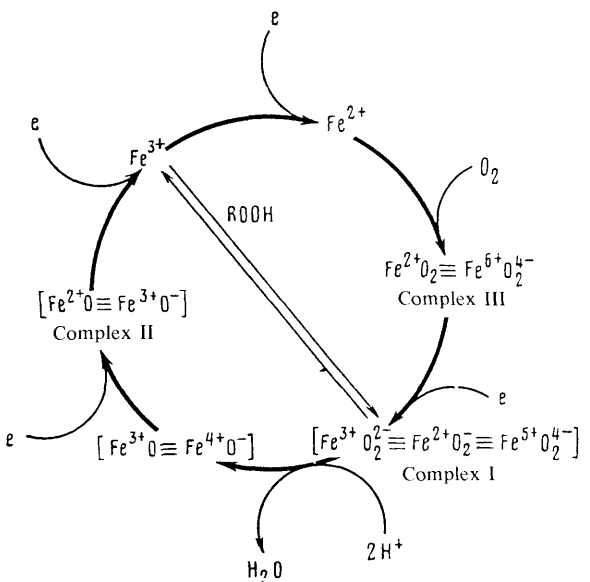
*Substituted perbenzoic acids, substituted CHP, and substituted benzyl hydroperoxides were used here; K_S = dissociation constant of complex.



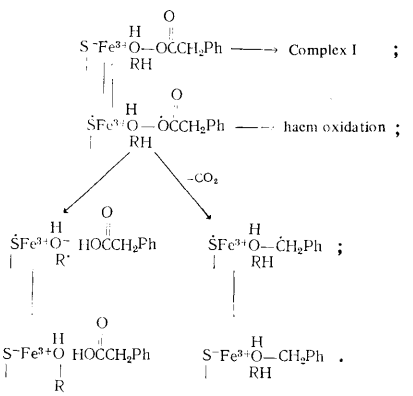


Figure 3.

The application of spectrophotometry and stopped flow techniques permitted a detailed investigation of the interaction of a large number of substituted perbenzoic acids, CHP derivatives, and benzyl hydroperoxide derivatives with cytochrome P-450-LM_2 and to reconstruct the absolute absorption spectra of the intermediate compounds formed[128]. Spectra differing appreciably for different peroxides were obtained as a result. The absolute absorption spectrum of a mixture of *m*-chloroperbenzoic acid with cytochrome P-450-LM_2 is characterised, in particular, by maxima at 375, 425, and 540 nm. This spectrum differs significantly from the known spectra of Complexes I: Complexes I of peroxidase and catalase have an absorption maximum at 400 nm, while Complex I of chloroperoxidase has a maximum at 395 nm.[74,156,157] The complex detected for cytochrome P-450 is analogous to Complex I of cytochrome *c* peroxidase (λ_{max} = 419 nm) [153] and Complex II of horseradish peroxidase (λ_{max} = 420 nm).[156] The second significant difference between the complexes of cytochrome P-450 with hydroperoxides and Complex I of peroxidases and catalyses consists in the kinetics and stoichiometry of their formation[128]. Peroxidases and catalases react with H_2O_2 or hydroperoxides (ROOH) in accordance with 1 : 1 stoichiometry and their reaction is believed to be irreversible. Admittedly very recently it has been shown that the formation of Complex I and Complex II by peroxidases can be a reversible process; Complex I can be reduced to ferri-peroxidase in two stages with the intermediate formation of Complex II when K_2IrCl_6 is used as the reductant[158]. Blake and Coon[128] showed that the interaction of hydroperoxides with cytochrome P-450 is complex and consists of at least two reversible stages:

$$\text{P-450} + \text{ROOH} \underset{k_2}{\overset{k_1}{\rightleftharpoons}} \text{C} \underset{k_4}{\overset{k_3}{\rightleftharpoons}} \text{D},$$

where C is the enzyme–substrate complex and D an unstable compound which can be detected spectroscopically according to the authors. The rate constant ratio k_1/k_2 depends greatly on the type of hydroperoxides and is correlated with their hydrophobic properties[128]. It has also been shown that the rate constants k_3 and k_4 are determined by the structure of the peroxides and the spectra of compound D differ for different peroxides, i.e. the nature of the peroxide has a marked influence on the interaction with cytochrome P-450 and on the characteristics of the intermediate compounds. This led White and Coon[12] to the conclusion that the intermediate complex of cytochrome P-450 with ROOH differs from Complex I of peroxidases and catalases. They therefore proposed[12] a new mechanism of the peroxide oxidation differing by the fact that the O–OR bond in the ternary substrate–P-450–ROOH complex undergoes homolytic dissociation and the oxidising agent is the alkoxy-radical RO$^{\cdot}$ derived from the hydroperoxide (Fig.4). The homolytic pathway in the dissociation of the O–OR bond was confirmed in a study of the interaction of cytochrome P-450-LM_2 and R-450$_{cam}$ with phenylperacetic acid[125]. The homolysis of the O–OR bond is supported by the decarboxylation of phenylperacetic acid catalysed by cytochrome P-450:

In the peroxide oxidation mechamism[128] (Fig.4) an important role is attributed to the thiol ligand of cytochrome P-450. The possible involvement of this ligand in the homolytic

decomposition of hydroperoxides was suggested previously by the present authors[139]:

$$ROOH + Fe^{3+}—SH \rightarrow RO^{\cdot} + H_2O + Fe^{3+}—S^{\cdot} .$$

Thermochemical calculation shows that, under favourable solvation conditions, this reaction is entirely feasible close to physiological temperatures[159]. The thiol ligand is in fact an electron donor facilitating the homolytic dissociation of the O–OR bond. The complex formed after the homolysis of the O–OR bond may be equivalent to Complex II of peroxidases and catalases:

$$S^{\cdot}Fe^{2+}OH^{\cdot} \leftrightarrow S^{\cdot}Fe^{3+}OH^{-} \leftrightarrow S^{-}Fe^{3+}OH^{\cdot} \leftrightarrow S^{-}Fe^{4+}OH^{-} .$$

It may be that the intermediate compound detected spectroscopically after mixing ROOH and cytochrome P-450 is in fact Complex II: it is not fortuitous that the absorption maxima of Complex II of peroxidases and of the mixture of cytochrome P-450 with ROOH coincide (at 420 nm).[156]

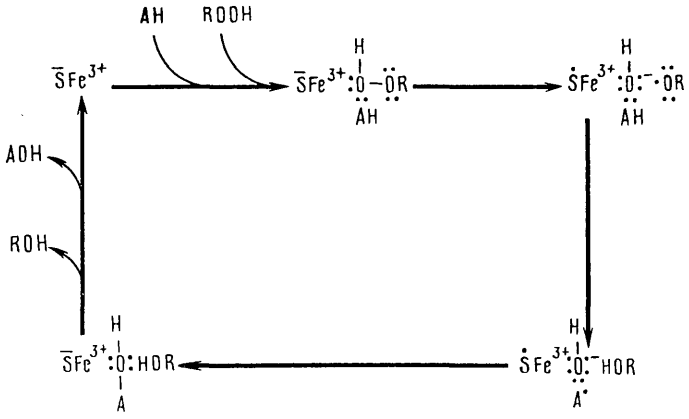

Figure 4.

Without denying the possibility of homolytic decomposition reactions of organic hydroperoxides in the presence of cytochrome P-450, which has been demonstrated in a number of studies[125,139,159], we shall nevertheless make a number of significant comments concerning the interpretation of data obtained by Coon and coworkers[12,128]. Firstly the absorption spectra of Complexes I for peroxidases and cytochrome P-450 need not necessarily be identical and, furthermore, they should in fact differ, since the hydroperoxides become ligands of the haemoprotein, occupying the sixth coordination site, while the fifth axial position contains histidine in peroxidases and cysteine in cytochrome P-450. The differences between the ligands are quite sufficient to account for the difference between the spectra of Complexes I for different haemoproteins. It follows from Table 6 that the nature of the fifth ligand is responsible for the difference between differential absorption spectra of the complexes of ROOH with cytochrome *c* and haemoglobin, on the one hand, and cytochrome P-450, on the other. Secondly, the formation of Complexes I of peroxidases as well as the interaction of ROOH with cytochrome P-450 can be reversible[158]. Thirdly, the oxidation of cyclohexene in the microsomes–TBHP system leads to the formation of epoxycyclohexane, which is inconsistent with the radical process mechanism[100]. Fourthly, the oxidation of labelled acetanilide yielded identical NIH shifts in the complete and hydroperoxide systems, which confirms the similarity of the mechanisms in the two cases. Bearing in mind all the data available at present, one may claim that the hydroperoxide systems involve, apart from the reactions via the oxenoid pathway similar to the reactions in the complete system, also radical processes which are responsible in many instances for the oxidation of certain substrates and the degradation of cytochrome P-450. The processes where the radical stages may predominate include the *N*-dealkylation of tertiary amines, which is effectively retarded by radical process inhibitors (1-naphthol, etc.[69]) and the oxidation of alcohols[14,155]. On the other hand, the oxidation of aromatic compounds and the epoxidation of olefins proceed via the oxenoid pathway, considered in the second section of this review. It is noteworthy that some of the most reactive aromatic compounds can be oxidised simultaneously via two pathways—oxenoid and radical. Benzo[*a*]pyrene is probably oxidised in this way in hydroperoxide systems[165]; the oxenoid reaction pathway leads to the formation of epoxides, while radical processes result in the accumulation of phenols and quinones. The claim[165] that there is a fundamental difference between the mechanisms of the oxidation of benzo[*a*]pyrene in the complete system and with participation of CHP, based on the difference between the reaction products in the two systems, is unduly categorical: we simply have the situation that in the hydroperoxide system yet another reaction pathway (the radical pathway) occurs in addition to the oxenoid pathway.

Other haemoproteins can also catalyse the peroxide oxidation reactions of certain substrates (Table 7), although not all the reactions characteristic of cytochrome P-450 are accelerated by other iron-porphyrins: peroxidase cannot oxidise saturated compounds and alcohols and cytochrome P-450 cannot participate in any of the reactions quoted in Table 7. The question arises how to explain the different reactivities and the differences between the mechanisms of the peroxide oxidation reactions involving different haemoproteins. The first stage of the process is the same for all haemoproteins—the formation of complexes with the peroxides (Table 6). Table 6 does not include data for the known reactions of peroxidases and catalases with hydroperoxides. Complexes of ROOH with different haemoproteins differ in the parameters of the difference absorption spectra—the difference between the axial ligands in the fifth position has an effect. Apart from the axial ligands, the aminoacid residues in the active centres can play an important role in complex formation between ROOH and haemoproteins. It has been suggested that the hydrogen bonds formed between the carboxy-groups of the aminoacids and the distal histidine play a very significant role in the complexes of ROOH with haemoproteins[16] (Fig.5). An important role in the heterolytic cleavage of the O–OR bond in cytochrome *c* by peroxidase has been attributed to the distal histidine-52, arginine-48, and tryptophan-51 [166] (Fig.6). Fig.6 shows that the distal histidine-52 is a kind of acid–base catalyst, the arginine-48 residue stabilises the charge, while the proximal histidine-174 stabilises the haem iron in a high oxidation state, i.e. the active centre of peroxidase is directly involved in the formation of Complex I. It is also known that aspartate-43 of horseradish peroxidase is incorporated via its carboxy-group in the formation of a complex with H_2O_2.[174] In the myoglobin molecule the glycine E8 occupies the same site as aspartate-43 in the horseradish peroxidase molecule and for this reason myoglobin does not form Complex I, in contrast to peroxidase[174]. Thus, despite

the fact that all haemoproteins form complexes with ROOH, not all of them are capable of generating Complex I owing to the differences between the structures of the active centre.

Table 7. Catalytic properties of haemoproteins in the oxidation of organic compounds by peroxides and certain non-peroxide oxidants[16].

*The oxidants employed are indicated in brackets.

The coordination of hydroperoxides at the sixth site in haemoproteins is well known[16,175,176]. The fate of the complexes of hydroperoxides with haemoproteins can be various; peroxidases and catalases form Complex I, while myoglobin does not give rise to such a complex. The formation of radicals in the interaction of certain haemoproteins with hydroperoxides has been demonstrated. The detection of a low-intensity chemiluminescence as a result of the recombination of the peroxy-radicals ROO$^{\cdot}$ showed that such radicals are formed on interaction of hydroperoxides with cytochrome *c*, myoglobin, methaemoglobin, and horseradish peroxidase[177], i.e. in the cases enumerated there is a possibility of radical stages in the oxidation of the substrate introduced into the system. It is at present possible to compare the efficiencies of various haemoproteins in the oxidative dealkylation reactions of *N*-alkylamines and to discuss the differences between the mechanisms of their action (Table 8). Horseradish peroxidase is most effective in the oxidation of amines by hydrogen peroxide[167], while catalase is most effective in the oxidation of DMA by cumenyl hydroperoxide[168]. The radical-cations of the substrate have been detected by EPR in the H_2O_2–peroxidase system on oxidation of aminopyrene[167]. The oxidation of aminopyrene in the CHP–cytochrome P-450 and CHP–myoglobin systems takes place with the same efficiencies and is accompanied by the formation of substrate radicals[178]. Griffin and Ting[179] believe that all the oxidative dealkylation reactions of amines listed in Table 8 proceed via a radical mechanism. Griffin proposed the following mechanism for the oxidative dealkylation of *N*-alkylamines[179]:

$$R_2N{-}CH_3 \xrightarrow[-e^-]{} R_2\dot{N}{-}CH_3 \xrightarrow[-H^+]{} R_2\dot{N}{=}CH_2 \rightarrow \xrightarrow{H_2O} R_2\dot{N}H_2 + H_2C{=}O.$$

A distinctive feature of this mechanism is the radical nature of the process and the incorporation in formaldehyde of an oxygen atom from water and not from an O_2 molecule. We confirmed the radical stages of the reactions in the oxidation of DMA by cumenyl hydroperoxide with participation of microsomes, cytochrome P-450-LM_2,[69] and haemoglobin[168] using 1-naphthol as the radical process inhibitor. The complex nature of the inhibition of the oxidation of DMA by 1-naphthol is consistent with the possible role of radical reactions in the peroxide oxidation with participation of CHP and haemoglobin, catalase, or cytochrome P-450.

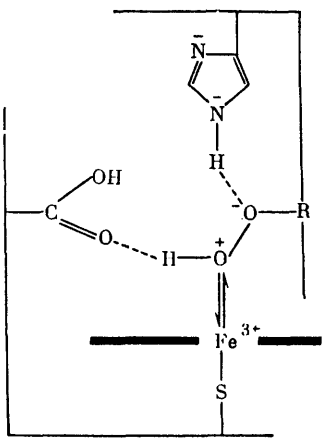

Figure 5.

Thus radical stages are observed in reactions involving the oxidative dealkylation of *N*-alkylamines by hydroperoxides with participation of horseradish peroxidase, myoglobin, haemoglobin, catalase, protohaemin, and cytochrome P-450. In the oxidation of aminopyrine radicals were detected by EPR,[182] while in the oxidation of DMA effective process inhibition by an antioxidant (1-naphthol) was noted[69,168].

We carried out a systematic comparative kinetic study of the oxidation of aniline by cumenyl hydroperoxide with participation of cytochrome P-450,[69,106,136] haemoglobin[169], and cytochrome c.[163] Aniline forms complexes with the three haemoproteins (Table 9). The most stable complexes are formed between cytochrome P-450 and aniline. The difference spectra of the complexes of cytochrome P-450 and cytochrome *c* differ owing to the different nature of the axial ligands in the fifth position (Table 1). An allosteric effect was observed in the interaction of aniline with haemoglobin and the complexes were characterised in this case by three

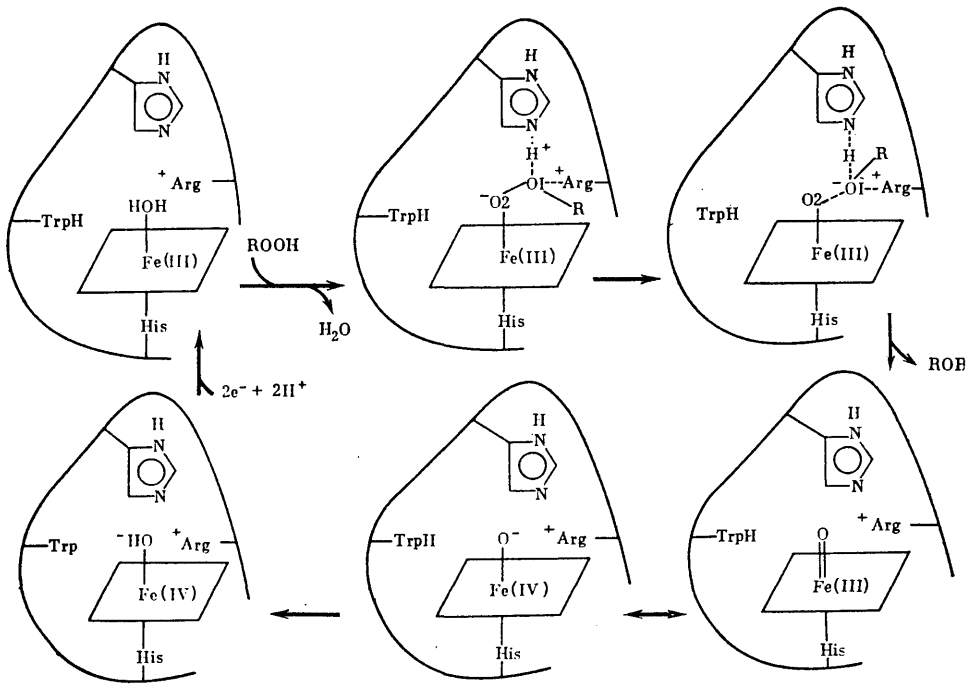

Figure 6.

dissociation constants—K_R, K_T, and K_S. All three haemoproteins catalyse effectively the oxidation of aniline to p-aminophenol. 1-Naphthol inhibits all three reactions, but does not arrest them completely. The reactions involving cytochrome *c* and haemoglobin have a radical mechanism, whereas in our view the reactions catalysed by cytochrome P-450 may involve not only radical stages but also the oxenoid pathway[69].

The hydroperoxide oxidation reaction of DMA is inhibited by a $CuCl_2$ and the copper complexes of lysine and tyrosine[144]. The inhibition of the oxidation of DMA by $CuCl_2$ in the reaction involving CHP and cytochrome P-450-LM^2 is non-competitive, while the copper complexes of lysine and tyrosine inhibit this process via a mechanism of the mixed type. The inhibiting effect of copper compounds on the oxidation of

DMA by cumenyl hydroperoxide can be explained by the decomposition of the hydroperoxide via the Haber–Weiss reaction with formation of the radicals $RO^{\cdot}$ and $RO_2^{\cdot}$, which causes the degradation of cytochrome P-450. Copper chloride at concentrations of ~0.001 M and above denatures cytochrome P-450 in the absence of CHP.[144]

The similarities and differences between the hydroperoxide oxidation reactions with participation of cytochrome P-450 and other haemoproteins can be discussed on the basis of the data presented in this section[16,18]. These processes are characterised by the following sequence of reactions:

$$Fe^{3+} + ROOH \rightleftarrows Fe^{3+}(H)-O-OR \quad ; \qquad (4)$$

$$Fe^{3+}(H)-O-OR \rightarrow [Fe^{3+}O] + ROH \quad ; \qquad (5)$$

Complex I

$$Fe^{3+}(H)-O-OR \rightarrow Fe^{2+} + H^+ + RO_2^{\cdot} \quad ; \qquad (6)$$

$$Fe^{3+}(H)-O-OR \rightarrow [FeOH]^{3+} + RO^{\cdot} \quad ; \qquad (7)$$

$$[Fe^{3+}O] + AH \rightarrow Fe^{3+} + AOH \qquad (8)$$

$$[Fe^{3+}O] + AH \rightarrow [Fe^{2+}O] + A^{\cdot} + H^+ \quad ;$$

Complex II

$$[Fe^{2+}O] + AH \xrightarrow{H^+} Fe^{3+} + A^{\cdot} + H_2O \quad . \qquad (10)$$

As already mentioned, all haemoproteins (with the exception of cytochrome P-450-LM_4) form complexes with ROOH [reaction (4)]. Peroxidases, catalases, and cytochrome P-450 subsequently form Complex I [reaction (5)]. Myoglobin, haemoglobin, and cytochrome *c* apparently do not form Complex I owing to the differences between the structure of the active centre and the structures of peroxidases, catalases, and cytochrome P-450. The formation of Complex I (where this occurs) is accompanied by the simultaneous reactions involving the decomposition of the complexes of haemoproteins with ROOH into radicals [reactions (6) and (7)]. All haemoproteins without exception can generate the radicals $RO^{\cdot}$ and $RO_2^{\cdot}$, which are capable of oxidising the majority of substrates of monoxygenases and can decompose the porphyrin ring in haemoproteins[16,159]. Reaction (5), on the one hand, and reactions (6) and (7), on the other, depend on the type of haemoprotein. Reactions (6) and (7) predominate for myoglobin, haemoglobin, and cytochrome *c*, while reaction (5) is the main one for cytochrome P-450, peroxidases, and catalyases, i.e. one group of haemoproteins (myoglobin, haemoglobin, and cytochrome *c*) decompose hydroperoxides via the homolytic mechanism, while the other group (cytochrome P-450, peroxidases, and catalases) cleave the O–OR bond mainly via the heterolytic mechanism with formation of Complex I. The presence of the substrates of cytochrome P-450 (aniline, DMA, and naphthalene) and radical reaction inhibitors (1-naphthol and substituted phenols) suppresses reactions (6) and (7) and promote the specific enhancement of reaction (5).[16,139]

The mechanism of the oxidation of Complexes I is determined, in the first place, by the nature of the haemoprotein and, in the second place, by the nature of the substrate. Complex I of peroxidases and catalases is characterised by the presence of an iron ion in a high oxidation state (Fe^{4+}) and is distinguished by its ability to undergo one-electron oxidation processes, since it is a radical [reaction (9)]. Reaction (9) results in the formation of Complex II, which oxidises in its turn yet another molecule of the substrate AH. The activity of Complexes I of peroxidases and catalases is fairly high and these complexes readily oxidise a multiplicity of substrates—phenols, amines, etc.[27,28], but cannot rupture the strong C–H bonds of saturated hydrocarbons, which are not substrates of peroxidases and catalases.

Complex I of cytochromes P-450 is capable of undergoing simultaneously two-electron oxidation reactions (with the oxenoid or hydroxylase mechanism) and one-electron oxidation reactions (with the radical or peroxidase mechanism). Presumably the reactivity of Complex I of cytochromes P-450 is higher than the reactivity of the same complex of peroxidases and catalases, i.e. the iron ion in Complexes I of cytochrome P-450 can exist in a higher oxidation state than the iron ion in Complexes I of peroxidases and catalases. The highest oxidation state of iron in Complex I of cytochrome P-450 is stabilised not only by the porphyrin ring, as in peroxidases[73,74], but also by the thiol ligand in the fifth coordination site. The main difference between cytochrome P-450 and other haemoproteins, responsible for its unique properties, consists in the possibility of the stabilisation of Complex I via two pathways—with participation of the porphyrin ring and the thiol ligand. The relative contributions of the radical and heterolytic stages in oxidation by Complex I of cytochrome P-450 are determined by the nature of the substrate: *N*-alkylamines, saturated hydrocarbons, ethers, and alcohols are oxidised by the radical mechanism, while aromatic compounds and olefins are oxidised mainly via the oxenoid heterolytic pathway, i.e. with the transfer of two electrons from the substrate to Complex I simultaneously. Naturally, in many instances there is a possibility of the simultaneous occurrence of the one- and two-electron oxidation reactions. This probably happens in the oxidation of benzo[*a*]pyrene and cyclohexene by hydroperoxides: the epoxyarene derivatives of benzo[*a*]pyrene and epoxycyclohexane are formed via the oxenoid mechanism, while the phenols derived from benzo[*a*]pyrene and 2-cyclohexanol are formed via the radical mechanism. Tertiary amines readily give up an electron to many oxidants and are therefore oxidised mainly via the radical mechanism, which has been proposed and proved by Griffin[179], with the intermediate formation of the relatively stable iminium cation $R_2\overset{+}{N}=CH_2$, which is converted into a secondary amine and formaldehyde in an aqueous medium.

Table 10 summarises the available information about the nature of the oxidation of different substrates by peroxides with participation of various haemoproteins. We have divided haemoproteins into three groups: the reactions of myoglobin, methaemoglobin, and cytochrome *c* *proceed only via the radical pathway* with participation of the radicals $RO^{\cdot}$ and $RO_2^{\cdot}$, the second group of haemoproteins—peroxidases and catalases—catalyse reactions via the radical mechanism with formation of Complexes I of these proteins, and finally the third group consists of cytochromes P-450, which, depending on the nature of the substrates, can convert them via the heterolytic pathway with participation of Complexes I {cyclohexene, naphthalene, aniline, and benzo[*a*]pyrene} or via the radical pathway with participation of the same Complex I and the radicals $RO^{\cdot}$ and $RO_2^{\cdot}$ (DMA, aminopyrine, cyclohexane, cumene, ethylbenzene, alcohols, and camphor).

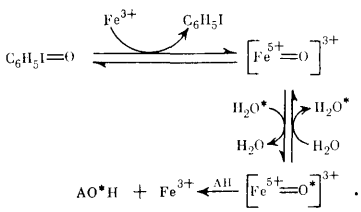

Table 10 shows that there are substrates with "amphoteric" properties, capable of being oxidised simultaneously via two pathways—the homolytic and heterolytic pathways {benzo[*a*]pyrene and possibly other aromatic hydocarbons}. It follows from the data presented here that there is no universal mechanism of the catalysis of the peroxide oxidation by haemoproteins. The mechanism of the peroxide reactions of haemoproteins is determined by several factors:

1. The nature of the haemoprotein, the structure of its active centre, and the fifth axial ligand.
2. The nature of the substrate oxidised, its ability to undergo one- or two-electron redox reactions, and the strength of the C–H bonds dissociated in hydrocarbons or the oxidation-reduction potential of *N*-alkylamines.
3. The nature of the oxidant employed.

Table 10. Reactions in ROOH–haemoprotein systems.

Cytochrome $P\text{-}450_{cam}$ + phenylperacetic acid	$[Fe^{3+}O]$, $RO^{\cdot}$, $RO^{2\cdot}$	alcohols [152] camphor [125]	—

The last postulate has been confirmed by the different behaviour in oxidation reactions with participation of cytochrome P-450 of oxidants such as hydrogen peroxide, organic hydroperoxides[12,128], and iodosobenzene[184]. It has been shown recently that, in the oxidation of camphor by iodosobenzene with participation of cytochrome $P\text{-}450_{cam}$ using $H_2{}^{18}O$, the oxygen incorporated in the oxidation product originates from water and not from the oxidant[184]. The authors[184] suggest that in the presence of $P\text{-}450_{cam}$ iodosobenzene forms a unique oxenoid capable of exchanging its oxygen rapidly with that of water:

In the absence of cytochrome $P\text{-}450_{cam}$, there is no isotope exchange between iodosobenzene and water. In our view, there is a possibility of another mechanism which explains the results of the above study: cytochrome P-450 catalyses the decomposition of iodosobenzene with formation of an oxygen atom, whose high reactivity explains its rapid isotope exchange with $H_2{}^{18}O$. The hydroxylating agent may be the ^{18}O atom, which exhibits a high hydroxylating capacity[18].

---o0o---

In conclusion one should note that the final determination of the mechanisms of the catalytic action of haemoproteins in oxidation reactions requires further studies of several different kinds: comparative investigation of the oxidation of a wide range of substrates with participation of different haemoproteins under comparable conditions and the search for new approaches to the study of the intermediate stages in processes with participation of cytochrome P-450 in order to elucidate the nature and structure of the hydroxylating agent. The determination of the nature of the active species in microsomal oxidation will lead to new possibilities for a specific search for simple catalytic chemical systems capable of replacing a unique haemoprotein, namely cytochrome P-450, and for devising oxidation processes which will not be inferior in their efficiency and selectivity to enzymatic processes.

Kinetics of Gas-phase Ion-Molecule Exchange Reactions

G.V.Karachevtsev, A.Z.Marutkin, and V.V.Savkin

The kinetics of ion-molecule exchange reactions (IMR), which are important in high-energy and analytical chemistry, are discussed, and their special features and the factors influencing the reaction rate are analysed. Special attention is paid to slow IMR with rate constants substantially smaller than the gas-kinetic ion-molecule collision rate.

I. INTRODUCTION

The foundations of the kinetics of gas-phase ion-molecule reactions (IMR), a new branch of chemical kinetics, were laid by Tal'roze[1,2]. Since then, interest in IMR has grown very considerably as a result of new developments in radiation chemistry, the physics and chemistry of plasmas and of gas discharges, the chemistry of planetary ionospheres and of interstellar clouds, and other systems in which the molecular composition of an ionised medium is determined mainly by IMR[3-6].

Ion–molecule reactions play an important role in analytical techniques, especially in mass spectroscopy, because they yield simple line spectra which facilitate the analysis of complex organic compounds and their mixtures and from which information on the structure and the energy state of the ions can be obtained[7-10].

Methods based on the study of IMR offer important information on the acid-base properties of molecules in the gas phase: their proton and electron affinity[11,12], the mechanism by which the ions become solvated in a liquid, and the mechanism of the gas-liquid phase transition.

Ion-molecule reactions are a convenient way of experimentally identifying and studying the special features of the elementary chemical acts, and the fundamental nature of the reactivity of the system.

The reacting ions can be obtained relatively simply with different energy distributions (controlled by varying the energy of the ionising radiation) in IMR. An electric field can be used to vary the kinetic energy of the reacting ions and to analyse the resulting ions in terms of their energy. Both the reacting and the resulting ions can be separated and monitored very effectively by mass-spectrometric methods. IMR can be studied without difficulty at flow rates of the order of one ion per second by existing experimental techniques. The sensitivity and selectivity of the method are sufficient to justify detailed studies of IMR under non-equilibrium conditions (which are far less easily undertaken in the case of neutral reacting species). These features of the method explain the important contribution of IMR data to recent developments in the theory of elementary processes.

Experimental methods used in quantitative studies of IMR are fully reviewed in a recent monograph[17], and we shall only discuss a few special aspects of the technique in this review. In the internal ionisation methods[20] both the primary ion and the secondary (product) ion are obtained within the ionisation chamber of the ion source of a mass spectrometer. The most detailed information on the initial vibrational energy distribution of the primary ions is obtained by using photon impact ionisation[21-25]. The pulse method[26], in conjunction with ion trapping[27-30] and ion cyclotron resonance (ICR)[31-34] techniques, allows the reactions of thermal ions to be studied at low pressures. At relatively high pressures other methods are used (plasma decomposition in a flow[35] and ion drift in an electric field[37]).

In the external ionisation methods the primary ions are introduced into the ionisation chamber from outside[20,38-40], thus allowing the kinetic energy of the ion to be determined. These methods include the crossed beam method[41-44], which is particularly convenient for measurements of the angular distribution of the products. Information on the internal energy and structure of the primary ions is obtained by analysing the radiation[45,46], by impact spectroscopy methods[47,48], and by analysing the radiolysis products of gases and of condensed phases.

Several monographs dealing specifically with various aspects of IMR have appeared in recent years[13-19]: the aim of the present review is to examine some of the factors affecting the rate of bimolecular IMR and the kinetics of the elementary processes in these reactions.

II. METHODS OF CALCULATING THE KINETIC PARAMETERS

Mutual polarisation plays an important role in the collision between an ion and a molecule. The Langevin formula can be used to allow for this effect in the expressions for the rate constant and the cross section of ion-molecule collisions[50]:

$$k = 2\pi e(\alpha/\mu)^{1/2} \quad (1)$$

$$\sigma = \pi e(2\alpha/E)^{1/2} \quad (2)$$

where α is the polarisability of the molecule, e is the charge on the electron, μ is the reduced mass, and E is the kinetic energy of the relative motion of the ion and the molecule. When an ion interacts with a molecule which has a constant dipole moment an upper limit for the collision rate can be obtained by the formula[51,52]

$$k = 2\pi e\mu^{-1/2}[\alpha^{1/2} + \mu_D(2/\pi k_B T)^{1/2}] \quad (3)$$

where μ_D is the dipole moment, k_B is Boltzmann's constant,

and T is the absolute temperature. Methods of calculating the rate constants of collisions between ions and atoms (or molecules) with allowance for electronic polarisation, dipole orientation, ion–quadrupole forces, and interactions between induced dipoles are reviewed in a recent monograph[51]. It is often found that the rates of exothermic or thermoneutral exchange IMR are close to the corresponding ion–molecule collision rates[53].

The efficiency of the exchange reaction depends on the shape of the multidimensional potential energy surfaces for the system of colliding particles and on the probability of transitions between these surfaces. Exact calculations of the potential surfaces and of the cross-sections of IMR have been attempted only for very simple systems[54,55].

We shall confine our discussion to the factors directly related to the parameters of the reactants and able to influence the effectiveness of the reactions. The first calculation of the rate constant of an IMR was reported by Eyring and coworkers[56], who applied to the reaction

$$H_2^+ + H_2 = H_3^+ + H \qquad (4)$$

a variant of the transition state method in which only long-range attractive forces are considered, and the effective activation energy is assumed to be determined by the competing effects of the centrifugal force and the attractive force between reactants due to the polarisation of the neutral species. In this model of the interaction, the distance between the reacting species in the activated complex is large, and the rotation of the two reacting particles can be treated as the rotation of uncoupled partners. The vibrational degrees of freedom are assumed to be the same as for the isolated reactants (the molecule and the ion). Therefore the vibrational and the rotational partition functions of the reactants and of the activated complex are simplified in the expression for the rate constant of the reaction, and the rate constant of an exothermic reaction is defined by Eqn.(1) and is equal to the rate constant of the ion–molecule collision process.

We should stress that the first strict calculation[57] of the rate constants of IMR with zero activation energy by the transition state theory appeared in 1978, i.e. many years after Eyring's original paper[56].

Most of the specific calculations of cross sections and rate constants for IMR have relied on the statistical theory, which is particularly convenient for non-activated reactions. This theory assumes strong interactions between all the degrees of freedom in the intermediate complex, making the decomposition of the intermediate complex in any direction allowed by the conservation laws equally probable. The first step in the reaction is the formation of the intermediate complex, within which the energy and momentum of the reactants become statistically distributed over all degrees of freedom up to the instant of decomposition; the second step consists in the decomposition, which depends only on the total energy and momentum, and is independent of the other initial conditions under which the complex was formed.

The statistical theory was first applied to IMR by Tal'roze and Firsov[58,59] in a simplified form which did not allow for conservation of the total momentum, but it was subsequently further developed and expanded[60,61]. In all the calculations the exothermic and thermoneutral IMR were assumed to have zero activation energy, and the rate constant for the formation of the intermediate complex was identified with the rate of ion-molecule collisions. A valuable feature of this variant of the statistical theory is the small number of parameters (relating only to the reactants and products, and not to the collision complex) needed to calculate the full set of characteristics of the elementary act of the IMR.

The statistical theory has been used to calculate the dependence of the rate constants and cross-sections of IMR on the translational and internal energy of the reactants[62,63] and the energy distribution of the products of the IMR.[63,64]

The application of the statistical theory to IMR has been discussed by several reviewers[63,65,66], and the agreement between calculation and experiment has been shown to be good. For example, the steeper fall in the cross-section of exothermic IMR with increase in the kinetic energy of the ions [as compared with the effect predicted by formula(2)] can be explained in terms of the statistical theory by the competing effect of the backward decomposition of the intermediate complex into the initial reactants[58]. The reaction cross-section falls more steeply when the secondary ion can dissociate[67]. The subsequent decomposition reactions can also be described by the statistical theory.

In some systems serious discrepancies are observed between experiment and calculations by the statistical theory. For example, collisions of the type of

$$CH_3CDO^+ + CD_3CDO \rightarrow H_3C{-}C\begin{matrix}O\cdots D\\ +\\ D\cdots O\end{matrix}C{-}CD_3$$

produce a symmetrical complex which should (according to the statistical theory) yield CD_3CDOD^+ and CH_3CDOD^+ as products with equal probabilities. Experimentally[68] we find that CD_3CDOD^+ is formed preferentially, suggesting that the charge in the complex has not been fully delocalised.

Reported differences between calculation and experiment may be due to the following factors:

1) the probability of formation of the intermediate ion–molecule complex is not unity (as is assumed in the theory),

2) the exchange of energy between the different degrees of freedom in the complex is hindered,

3) the potential surface of the IMR includes an energy barrier.

To allow for these factors we need to formulate the theory of IMR in greater detail, and to introduce additional parameters. For exothermic IMR taking place without activation through a "soft" polarisation complex the statistical theory and the activated complex theory give identical results.

In the case of endothermic IMR the statistical theory is applicable only when the collision complex has a stable configuration. For example, the reaction

$$C^+ + H_2 \rightarrow CH_2^+ \rightarrow CH^+ + H \qquad (5)$$

can form the strongly bound complex CH_2^+, whereas the H_4O^+ complex formed in

$$H_2O^+ + H_2 \rightarrow H_3^+ + OH \qquad (6)$$

is unstable. The statistical theory satisfactorily describes the dependence of the cross-section on the kinetic energy near the threshold for reaction (5), but for reaction (6) the same calculation gives unacceptable results[69,70].

Reaction (6) can be described by the activated complex theory on the assumption that the energy threshold is shifted towards the reactants[70]. In general, the activated complex theory is most successfully applied to reactions with a threshold energy when these are "direct" processes, i.e. reactions in which the interaction time of the reactants is small compared to the characteristic time of the redistribution of energy over the degrees of freedom of the system.

The validity of the activated complex theory or of the statistical theory when applied to a specific reaction is determined by the ratio of the height of the energy barrier corresponding to the transition state to the depth of the potential well corresponding to the intermediate complex. A recently developed unified statistical model yields a generalised expression for the rate constant of the reaction which can be

used for direct reactions as well as for reactions taking place through a long-lived complex[71]. This model has not yet been used in the calculations for IMR.

III. STERIC FACTORS AND TEMPERATURE EFFECTS

The low rate constants of some exothermic IMR (as compared to the values predicted by the statistical theory) have been ascribed[72] to the need for a particular mutual orientation of the colliding particles to allow chemical rearrangement in the ion–molecule complex. The following expression is obtained for the differential collision cross-section of the ion and the molecule with an orbital quantum number L:

$$\sigma(L, E) = (2L+1)\pi\hbar^2/2\mu E \ .$$

Noting that only one of the $(2L+1)$ possible projections of the vector for the momentum of the relative motion of the reactants leads to reaction, and that the maximum value L^* is determined by the Langevin capture cross-section according to the formula

$$L^*(L^*+1) = 8\mu^2\alpha e^2 E)^{1/2}\hbar^2$$

for the full cross-section of the reaction produced by the collision of the reactants, we arrive at

$$\sigma(E) = \pi\hbar(\alpha e^2/2\mu^2 E^3)^{1/4} \qquad (7)$$

so that the rate constant is

$$k(E) = \pi\hbar(2\alpha e^2/E)^{1/2}/\mu \ . \qquad (8)$$

In the case of a Maxwellian distribution of the velocities of the reacting particles at temperature T the expression for the rate constant becomes

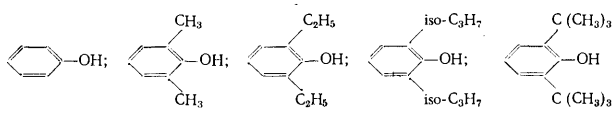
$$k(T) = 3.2(2\alpha e^2/k_B T)^{1/2} \ . \qquad (9)$$

In the case of IMR involving symmetrical reactants the right-hand sides of Eqns.(7)–(9) should be multiplied by the degeneracy factor g, Thus, for the reaction

$$CF^+ + C_3F_8 = CF_2 + C_3F_7^+ . \qquad (10)$$

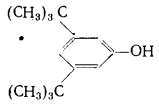
we have $g = 8$, since any one of the eight fluorine atoms in the C_3F_8 molecule can act as a reaction centre. The calculated[72] rate constant of reaction (10) is 5.2×10^{-11} cm^3 s^{-1}, and the Langevin collision rate constant of the reactants is 1.08×10^{-9} cm^3 s^{-1}. The experimental value[73] of the rate constant for this reaction is 3.7×10^{-11} cm^3 s^{-1}, in good agreement with the calculated value[72]. In IMR in binary mixtures of ethylene and fluorinated ethylenes the rate of the condensation reactions giving $C_3(H,F)_5^+$ and $C(H,F)_3^+$ as products has been shown[74] to be very sensitive to the replacement of H atoms by F atoms. In the $C_2H_4^+ + C_2H_4$ system every collision leads to interaction, whereas in the $CF_2CH_2^+ + CF_2CH_2$ system the rate constant of the corresponding reaction is less than 10^{-12} cm^3 s^{-1}. The presence of the fluorine atoms does not make the reaction thermodynamically forbidden, but it increases the height of the barriers opposing the migration of atoms (H, or F) in the intermediate complex. The high rate constants of reactions similar to (10) but involving hydrocarbons have been explained[72] in terms of the relatively high mobility of H, H^+, and H^- in the intermediate complex (as compared to the mobility of the fluorine atom).

Fast IMR involving the transfer of a fluorine atom have been recently discovered experimentally[75]:



$$CH_3^+ + CH_2F_2 \rightarrow CH_3F^+ + CH_3F$$
$$CH_3^+ + CHF_3 \rightarrow CH_3F + CHF_2^+$$
$$CH_3^+ + CF_4 \rightarrow CF_3^+ + CH_3F \ .$$

The rate constants of these reactions calculated by formula (8) are much lower than the experimental values. Evidently, the validity of formulae (7)–(9) in calculations of the kinetic parameters of IMR must be limited by a number of factors (not merely the mass of the migrating atom). Thus in the collision between an ion and a molecule some of the energy of the relative motion may be converted into vibrational or rotational energy of the reactants, giving a complex in which the reactants can experience many intramolecular collisions. For example, according to the activated complex theory[57] the ion-atomic and a diatomic particle at 300 K and with a potential well of 2 eV gives a complex with a life time equivalent to 100 vibrations (vibration period 3×10^{-13} s). The complex formed by two diatomic species for the same parameters is even longer-lived (3×10^3 vibrations), thus increasing the probability of acheiving a mutual orientation of the reactants favourable to the reaction. However, we should stress that the number of intra-complex conditions is greater in the $CH_3^+ \ldots CH_2F_2$ than in the $CF^+ \ldots C_3F_8$ system. At present formulae (7)–(9) have been shown to be consistent with experiment only for IMR between neutral and charged unsubstituted fluorocarbons.



Orientation effects are even more important when the collision has to be followed by the transfer of a large group of atoms (as opposed to the transfer of a single atom). An example is the transfer of the acetyl ion[76], in which the reacting ion is formed by the reaction

$$CH_3COCOCH_3^+ + CH_3COCOCH_3 \rightarrow (CH_3CO)_3^+ + CH_3CO \ .$$

Bursey and coworkers have shown[76] that in the phenol series

the acetylation reaction takes place only with the first three members: the last two compounds do not react because the approach of the $C_6H_9O_3^+$ ion and the transfer of the acetyl ion are sterically hindered. The role of the steric effect is confirmed by the observation that the phenol

(in which the methyl groups are remote from the reaction centre) is readily acetylated[77]. Thus even in the ion–molecule collision of complex multi-atomic particles, which can be expected to produce a long-lived collision complex, the exothermic IMR may be found to be slow as a result of steric effects opposing the formation of an intermediate reactive complex with strong interactions between the degrees of freedom responsible for the chemical regrouping of the atoms.

These (and other similar) experimental results have led to the realisation that ion–molecule complexes must be classified into two distinct types. The collision between an ion and a molecule can give rise to a "soft" complex, in which the reactants are bound by relatively weak polarisation forces and remain relatively far apart, so that energy and mass exchange in the complex are hindered. Such a complex can either dissociate back into its initial reactants or be converted into a "hard" complex, characterised by a strong chemical bond between the reactants. The "hard" complex can be treated in terms of the statistical theory to calculate the relative probabilities of alternative decomposition paths.

The need to distinguish between two types of complex is evident also from the temperature dependence of the rate constants of IMR. Thus, a study[78,79] of the transfer of the

hydride ion from isobutane to s-$C_3H_7^+$ has revealed the existence of two temperature regions, with different temperature dependences of the rate constant. At high temperatures the rate constant has a negative temperature coefficient, and at low temperatures it becomes independent of temperature and equal to the Langevin limiting value. This temperature dependence can be explained by postulating the following scheme:

$$R_1^+ + R_2H \underset{k_b}{\overset{k_c}{\rightleftarrows}} [R_1^+ \ \ldots \ R_2H]_{soft} \xrightarrow{k_T} [R_1 \ldots R_2H]^+_{hard} \rightarrow \text{products} .$$

It is assumed[78,79] that the rate constants for the formation (k_C) and for the back dissociation (k_b) of the soft intermediate complex are independent of temperature whereas the rate constant of the transition from the soft to the hard complex (k_T) is a function of temperature. This dependence was calculated by the activated complex theory for bimolecular reactions, assuming that the activation energy is zero and that only the pre-exponential factor is temperature-dependent:

$$A(T) = \gamma T^{-(2+r/2)} \qquad (11)$$

where γ is temperature-independent and r is the number of internal rotators in the reacting molecules which are converted into oscillators in the activated complex (performing torsional vibrations). For example, from the temperature dependence of the rate constant of the reaction

$$t\text{-}C_4H^+_9 + iso\text{-}C_5H_{12} \rightarrow C_5H^+_{11} + C_4H_{10} \qquad (12)$$

we obtain (experimentally) $r = 2$. This means that the formation of the activated complex of reaction (12) is accompanied by the disappearance of two internal rotators (probably methyl groups, since the rotation of these groups can be strongly hindered in an activated complex). According to the structural formulae of the reactants the maximum number of rotators which may become hindered is six. Thus the model (in conjunction with experimental data on the temperature dependence of the rate constant) offers valuable information on the properties of the activated complex for IMR.

In some reactions the experimental temperature coefficient is even smaller than the value expected from the number of hindered rotators according to the above model. The temperature dependence of the rate constant for the reaction

$$CH_4D^+ + CH_4 \rightarrow CH_5^+ + CH_3D$$

has been explained[80] by postulating a model which assumes the existence of a soft and a hard complex but allows the rate constant of the backward decomposition of the soft complex into the initial reactants to be temperature-dependent. This model is free from the stringent limitations imposed on the temperature coefficient by the number of hindered rotators, but it includes some parameters which cannot easily be calculated theoretically (for example, the life time of the soft complex). The results of experiments under non-equilibrium conditions have also been explained by this qualitative model. For example, in IMR of s-$C_3H_7^+$ with iso-butane, normal butane, pentane, and hexane the rate constant for the exchange of a hydride ion is much lower in the pure vapours than in mixtures (which are diluted with molecules not involved in the interaction with the reactant ion[81]). This difference has been ascribed[81] to decrease in internal energy of the reactant ion resulting from the increased number of collisions with molecules of the buffer gas prior to the reaction. The characteristic time of the backward decomposition decreases as the excitation energy of the soft complex increases, and therefore the probability of the exchange reaction decreases: it is assumed that the rate constant for the conversion of the soft complex into a hard complex is weakly dependent on the excitation energy.

The rate constant for the formation of the soft complex is not always equal to the Langevin limit. According to measurements of the rate constant of associative IMR the high-pressure limit[82] for the formation of the soft complex can be much lower than the rate constant of the ion-molecule collisions. Collision may be followed by reflection or rapid back-dissociation of the complex into the reactants during a single vibration if the relative kinetic energy of the reactants cannot be accommodated in internal degrees of freedom of the ion-molecule complex during the collision. No theoretical calculations of the efficiency for the formation of soft complexes during ion-molecule collisions have yet been reported.

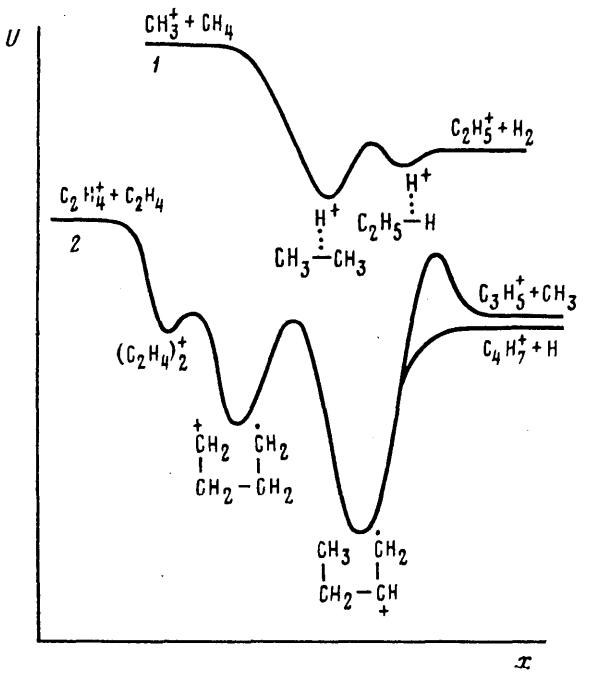


Figure 1. Profiles of the reaction paths $CH_3^+ + CH_4 \rightarrow C_2H_5 + H_2$ [85] (*1*) and $C_2H_4^+ + C_2H_4 \rightarrow C_3H_5^+ + CH_3$ [86] (*2*); U is the potential energy, x is the reaction co-ordinate.

The potential curve for the formation of ion-molecule complexes of two types in processes such as

$$A^+ + B \rightleftarrows AB^+ \rightleftarrows CD^+ \rightarrow C + D^+ \qquad (13)$$

has two minima, separated by a small barrier. In the state AB^+ the system has enough energy to be converted into the state CD^+, or to decompose into the initial reactants. The potential barrier opposing the reverse dissociation into A^+ and B is high, but under these conditions the pre-exponential factor in the expression for the rate constant is also large, and the decomposition of the soft complex (AB^+) takes place through a soft transition state. On the other hand the potential barrier to the transition of AB^+ into the hard complex CD^+ is relatively small, but the transition takes

place through a hard transition state and therefore the pre-exponential factor is small[83]. This model accounts for the low efficiency and negative temperature coefficient of the rate constants of isotope exchange reactions of the type of

$$CD_3\overset{O}{\overset{\|}{C}}CD_2^- + CH_3\overset{O}{\overset{\|}{C}}CH_3 \rightarrow CH_3\overset{O}{\overset{\|}{C}}CH_2^- + CD_3\overset{O}{\overset{\|}{C}}CD_2H$$

$$^{37}Cl^- + CH_3{}^{35}Cl \rightarrow {}^{35}Cl^- + CH_3{}^{37}Cl$$

and allows us to calculate the height of the barrier separating the soft from the hard complex. The concept of a soft and a hard complex can also be used to explain the effect of temperature and pressure on the kinetics of IMR.[84]

Some ion-molecule systems can include several types of hard complex, or they may not have a complex of either type. Information on the form of the potential surface along the reaction co-ordinate can be obtained from data on ion-molecule equilibria[85] and from experiments on the photo-ionisation of the van der Waals molecular complexes[86]. Typical potential energy profiles are shown in Fig.1.

IV. PATH PROFILES AND KINETIC FEATURES OF IMR

Statistical methods of calculation assume a quasi-equilibrium distribution of the reaction products in excitation energy, but substantial departures from equilibrium are often observed in experiments. If the shape of the potential energy surface is known, both the reaction cross-section and the distribution functions of the products in excitation energy can be obtained from calculations by the dynamic method[87]. This method is usually applied to a linear reaction of the type of

$$A + BC \rightarrow AB + C$$

whose potential energy surfaces do not include deep potential wells. In this case the reaction takes place without the formation of a long-lived intermediate complex. The largest non-equilibrium effects can be expected in these direct reactions. The probability of the reaction can be calculated (for each trajectory) by the classical equations of motion. The energy distribution over the degrees of freedom of the products is very sensitive to the mass ratios of the atoms A, B, and C, and to the shape of the potential energy surface. For example, if the evolution of energy in an exothermic reaction takes place during the ejection of the products the energy of the reaction appears as kinetic energy of the products, but if the evolution of energy takes place during the approach of the reactants a higher proportion of the energy of the reaction will appear as vibrational energy of the product molecule AB.

Calculations by the dynamic method for the potential energy surfaces of exothermic reactions with a potential barrier show that the barrier can be surmounted by the kinetic energy of the reactants if it is located in the region of the reactants. On the other hand if the barrier is displaced towards the reaction products it is surmounted by the vibrational energy of the reactant.

Non-empirical calculations of the potential energy surface are extremely laborious even for the simplest systems, and they require a large number of approximations which can seriously degrade the precision of the result[55,87]. For this reason the most successful methods so far have been semi-empirical[55,87].

The simple and effective "bond order–bond energy" method[88,89] is now widely used for reactions between neutral species because it allows the profiles of reaction paths to be calculated precisely. It is based on empirical relationships between the order and the length of a bond, and between the bond energy D and the bond order n:

$$D = D_S n^p$$

where D_S is the energy of the simple bond and p is an empirical parameter termed the bond index.

The method can be applied to IMR without fundamental changes[90,91], though the bond index for an ion has to be calculated in a different way. In the case of neutral species this index is calculated from the parameters of diatomic complexes of the inert gases, whereas in the case of ions the parameters of "inert gas atom–alkali metal positive ion" complexes have to be used. This method makes some allowance for the specific properties of the bond between an ion and a neutral particle.

The method has been applied to about 20 proton or hydrogen atom transfer reactions of the type of

$$HeH^+ + He \rightarrow He + HeH^+$$
$$H_2^+ + He \rightarrow HeH^+ + H$$
$$NH_3^+ + H_2 \rightarrow NH_4^+ + H \quad .$$

Examples of complex exchange IMR involving the transfer of atoms from the second period of the Periodic Table will be given in the last section of the present review: the path profiles for these reactions were calculated by a modified "bond order–bond energy" method.

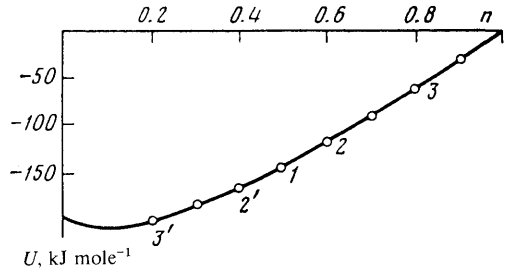

Figure 2. Profile of the reaction path $HeH^+ + Ar \rightarrow He + ArH^+$; U is the potential energy, n is the order of the He–H^+ bond. The distance R between the He and Ar atoms in the linear reactive complex He...H...Ar is 2.52 Å at point *1*, 2.54 Å at points *2* and *2'*, and 2.65 Å at points *3* and *3'*.[128]

The path profile of the reaction

$$HeH^+ + Ar \rightarrow He + ArH^+$$

is shown in Fig.2. Decreasing n from 1 to 1/2 causes a decrease in R due to the closer approach of the reactants, but if n is decreased still further the repulsion of the products causes R to increase. The energy of reaction is released mainly during the approach of the reactants. According to the Eyring–Polanyi rule in this case most of the reacton energy is localised in the vibrational degrees of freedom of the product (ArH^+). When $R \cong 2.8$ Å we find a small minimum in the potential energy, indicating the possibility of stable existence of the $[ArHHe]^+$ ion, with a dissociation energy of ~1.0 kcal $mole^{-1}$. There is no potential barrier in the reaction profile. These results (absence of activation energy and preferential evolution of the reaction energy in a vibrational form) are typical of all the proton transfer reactions so far examined.

In the case of the hydrogen atom transfer reaction

$$NH_3^+ + H_2 \rightarrow NH_4^+ + H \qquad (14)$$

the bond index was calculated by making the potential barrier in the path profile of the reaction equal to the experimentally measured activation energy. The barrier for this reaction was found to be displaced towards the reactants, showing that in this case the barrier is most effectively surmounted by the translational energy of the reactants.

The dependence of the cross-section of the reaction

$$NH_3^+ + D_2 \rightarrow NH_3D^+ + D \qquad (15)$$

on the translational energy of the ion and on the energy of its vibrational excitation has been studied experimentally[92], using a double mass spectrometer with coaxial primary and secondary ion beams[93]. The influence of vibrational excitation on the cross-section of the IMR (15) has been studied experimentally on a photo-ionisation mass spectrometer[22].

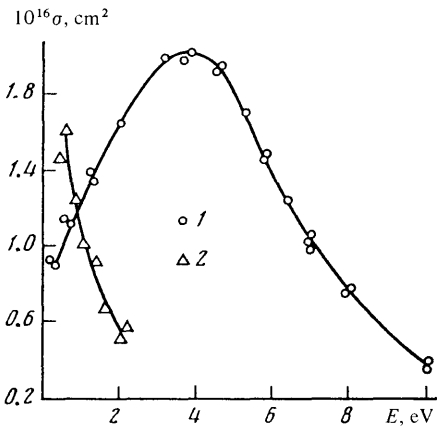

Figure 3. Cross-sections of the reactions $NH_3^+ + D_2 \rightarrow NH_3D^+ + D$ [92] (*1*) and $D_2^+ + H_2 \rightarrow D_2H^+ + H$ [94] (*2*) as a function of the relative kinetic energy of the reactants (the scale of curve *2* is a factor of 10 smaller).

The dependence of the reaction cross-section σ on the kinetic energy E_k of the NH_3^+ ions (assumed to be localised at the centre of gravity of the ion) is shown in Fig.3. When the energy is increased to ~4 eV the cross-section increases to 2×10^{-16} cm^2, but it begins to decrease if E_k is increased still further. This shows that the translational energy of the relative motion of the reacting species is effective in activating the reaction, in keeping with the theoretical calculation of the profile of the reaction path[91]. For comparison Fig.3 also shows the dependence[94] of σ upon E_k for the reaction

$$D_2^+ + H_2 \rightarrow D_2H^+ + H$$

which is typical of an exothermic reaction without activation energy.

The dependence of the cross-section of reaction (15) and of the reaction

$$NH_3^+ + NH_3 \rightarrow NH_4^+ + NH_2 \qquad (16)$$

on the ionising photon energy (Fig.4) shows the effect of the vibrational excitation of the electronic ground state of the primary ions formed by electron removal from a non-bonding nitrogen orbital on the yield of secondary ions. An increase in photon energy raises the vibrational excitation energy of the NH_3^+ ions to ~1 eV. Under these conditions the cross-section of reaction (16) decreases slightly, according to Potapov[21], as expected for a fast exothermic reaction. The increase in the cross-section of reaction (15) with the vibrational excitation energy of the NH_3^+ ions shows that the vibrational energy of the ion plays an important part in surmounting the activation barrier of the IMR: in other words, it is incorrect to consider the kinematics of the reactants in reaction (15) merely in terms of a simpler linear model with a two-dimensional potential energy surface[91].

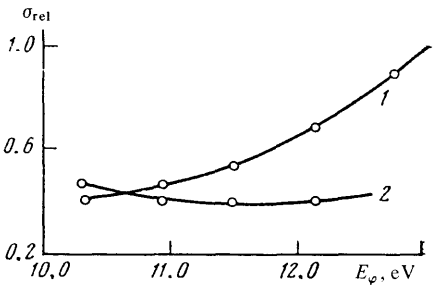

Figure 4. Dependence of the relative cross-sections of the reactions $NH_3^+ + D_2 \rightarrow NH_3D^+ + D$ (*1*) and $NH_3^+ + NH_3 \rightarrow NH_4^+ + NH_2$ (*2*) on the photo-ionisation energy E_ϕ. [92]

The dependence of the IMR cross-section on the excitation energy of the ion has been studied in detail by the photoelectron–photo-ion coincidence method[25], but so far only for reaction (4). The results (Fig.5) for different kinetic energies of the relative motion of the reactants give a $\sigma(E)$ relationship consistent with the prediction from statistical theory: the cross-sections decrease as the excitation energy of the reactants increases, and the effect is most marked at the lower translational energies[62]. The application of the statistical theory is not entirely justified in this case, because molecular beam experiments have shown that even at low translational energies the life-time of the intermediate complex is less than the rotation period of the complex, i.e. the reaction takes place by a direct mechanism. The absence of a long-lived complex in reaction (4) has been confirmed by calculations[96] of the potential energy surface for H_4^+.

In addition to reaction (15), the following exothermic reactions have been shown[97] to be slow:

$$CH_3OH^+ + D_2 \rightarrow CH_3OHD^+ + D \ , \qquad (17)$$

$$C_2H_5OH^+ + D_2 \rightarrow C_2H_5OHD^+ + D \ , \qquad (18)$$

$$C_2H_5OH^+ + CD_4 \rightarrow C_2H_5OHD^+ + CD_3 \ , \qquad (19)$$

$$CH_3NH_2^+ + D_2 \rightarrow CH_3NH_2D + D \ , \qquad (20)$$

$$CH_3NH_2^+ + CD_4 \rightarrow CH_3NH_2D^+ + CD_3 \ . \qquad (21)$$

A possible explanation of the anomalous behaviour of the IMR (17)–(21) is suggested in Ref. 97. In all these reactions the recombination energy of the reactant ions is very different from the ionisation potential of the reactant molecules: the recombination energies of the NH_3^+, CH_3OH^+, $C_2H_5OH^+$, and $CH_3NH_2^+$ ions are 10.1, 10.8, 10.5, and 9 eV respectively, whereas the ionisation potential of H_2 is 15 eV. The molecular orbital diagram for the participants in these reactions is shown in Fig. 6*a*. The upper, half-filled orbital of the reacting ion A^+ lies at a large distance from both the occupied and the unoccupied orbital of D_2.

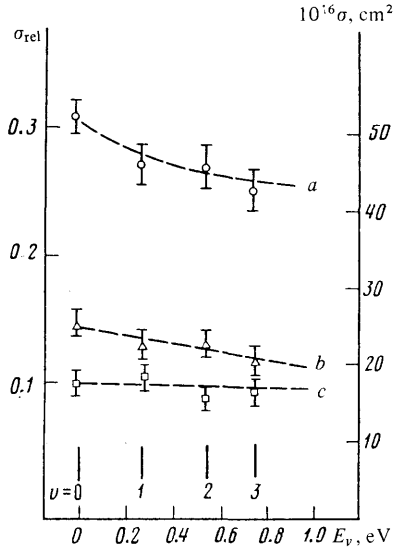

Figure 5. Cross-section of the reaction $H_2^+ + H_2 \rightarrow H_3^+ + H$ as a function of the vibrational excitation energy of the H_2^+ ion for different energies of the relative motion of the reactants [25]: *a*) 0.11, *b*) 0.46, *c*) 0.93 eV; σ_{rel} [defined as $I_{H_3^+}/(I_{H_3^+} + I_{H_2^+})$] is the ratio of the H_3^+ and H_2^+ ion currents, E_v is the vibrational excitation energy, v is the vibrational quantum number.

According to perturbation theory[98–100] the attractive energy between particles at distances consistent with chemical re-grouping is inversely proportional to the difference in energy between the interacting orbitals. For example, in the simplest two-electron system the interaction between He^+ and H (which have very different orbital energies) leads to a net repulsion both in the $^3\Sigma$ and in the $^1\Sigma$ state[100]. In addition to the interaction of the lower unoccupied orbital of D_2 with the upper half-filled orbital of the A^+ ion, which can only cause weak attraction, we must also consider the interaction of the occupied D_2 orbital with the occupied A^+ orbital, which have similar energies. This interaction between occupied orbitals can lead to repulsion (similar to the repulsion between atoms with full electron shells). The overall effect of the interaction between these pairs of orbitals could be to create an energy barrier opposing the reaction. Reaction (16), like reaction (15), has a high rate constant[17] (10^{-9} cm^3 s^{-1}), typical of an exothermic IMR. This can be explained by the similarity of the energies for the upper molecular orbitals of the reactants NH_3^+ and NH_3, which leads to a net attraction, similar to the attraction observed in simpler systems with equal molecular orbital energies (H^+...H, H...H, He^+...He).

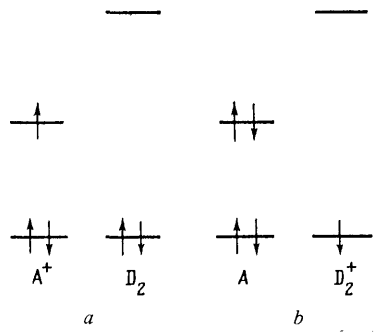

Figure 6. Molecular energy level diagram for the $A^+ + D_2$ (*a*) and $A + D_2^+$ systems (*b*).[97]

We shall now examine the reaction

$$NH_3^+ + CD_4 \rightarrow NH_3D^+ + CD_3 \cdot \qquad (22)$$

The upper energy level diagram for the reactants is qualitatively similar to the diagram of Fig. 6*a*, but the ionisation potential of CD_4 is 2.7 eV lower than the ionisation potential of H_2, and therefore the distance between the occupied upper orbitals of NH_3^+ and CD_4 is less than the corresponding distance for NH_3^+ and H_2. This is a case intermediate between reactions (15) and (16), and the attraction between the reactants NH_3^+ and CD_4 should be greater than the attraction between NH_3^+ and D_2. The methanol ion CH_3OH^+ also reacts more rapidly with CD_4 than with D_2. The rate constants of the reaction of the ethanol ion $C_2H_5OH^+$ with CD_4 and with D_2 are both small. Since the ionisation potential of alcohols decreases as the length of their hydrocarbon chain increases, the above considerations suggest that the molecular ions of all the $C_nH_{2n+1}OH^+$ alcohols with $n > 1$ should react very slowly with molecular hydrogen and deuterium.

Let us now consider the reaction

$$H_2^+ + NH_3 \rightarrow NH_4^+ + H \qquad (23)$$

analogous to (15) but with the opposite localisation of charge on the reactants. The configuration and occupancy of the energy levels of the reactants are similar to those shown in Fig. 6*b*. In this case the interaction between the half-filled orbital of H_2^+ and the inner filled orbital of A, which has a very similar energy, produces an attractive force between the particles at small distances. The rate constant of reaction (23) and that of the corresponding reaction involving D are high (10^{-9}–10^{-10} cm^3 s^{-1}),[17] as expected from the attraction between the reactants. We note that reaction (23) (like the analogous reaction with D_2^+) is strongly exothermic, and therefore the secondary ion can dissociate, with formation of NH_3^+ and NH_2^+ (or NH_2D^+ and NHD^+). Furthermore, the interaction between an ion with a high recombination energy and a complex molecule with a relatively low ionisation energy is usually accompanied by charge transfer[102], because of the ease with which resonance transitions can take

place in the closed-spaced system of energy levels of the complex molecule. Charge transfer by resonance process can take place at much greater distances than the transfer of heavy particles. This makes the rate constant of a reaction involving the transfer of a heavy particle lower than in the absence of competing charge transfer processes[103]. The competition between the charge transfer reaction

$$Ar^+ + CH_4 \rightarrow Ar + CH_3^+ + H$$

and the hydrogen atom transfer reaction

$$Ar^+ + CH_4 \rightarrow ArH^+ + CH_3 \qquad (24)$$

can account for the presence of an energy threshold[104] in the exothermic reaction (24). At low kinetic energies the charge transfer and the subsequent fast dissociation of the excited ion

$$(CH_4^+)^* \rightarrow CH_3^+ + H$$

take place while the reacting particles are relatively far apart, and the closer approach of Ar and CH_3^+ cannot lead to a re-grouping of the heavy particles because this process would be endothermic. As the kinetic energy of the reactants increases, the time during which they are in contact after the redistribution of charge becomes comparable to the dissociation time of the excited molecular ion, and the effectiveness of reaction (24) (with a re-grouping of heavy particles) increases.

A similar explanation can be suggested for the appearance of a potential barrier[105] in the reaction

$$N_2^+ + CH_4 \rightarrow N_2H^+ + CH_3 .$$

Other reactions between ions with a high recombination energy and complex molecules with a relatively low recombination coefficient can be expected to be slow, for the same reason: for example

$$Ar^+(N_2^+, H_2^+) + C_nH_{2n+2} \rightarrow ArH^+(N_2H^+, H_3^+) + C_2H_{2n+1} .$$

Exothermic reactions between an ion with a high recombination energy and simple molecules with a relatively low ionisation potential and a low density of energy levels may have low rate constants both for the charge rearrangement and for the transfer of heavy particles. A good example is the low efficiency of the reactions between ions with a high recombination energy (He^+ and Ne^+) and the simplest molecule (H_2).[106]

It has been assumed[107,108] that in collisions between particles with a low kinetic energy the electron, ion, and atom transfer processes are fully analogous and controlled by the "random resonance" condition $\tau_t \cong \tau_c$, where $\tau_t = h/|\Delta E|$ is the time of the transition between the electronic-vibrational-rotational energy levels of the reactants and the products separated by a distance ΔE (the energy defect), and $\tau_c = a/v$ is the collision time (a being the effective width of the collision region and v the relative velocity of the translational motion of the reactants). The reaction cross-sections were calculated by the semi-empirical formula

$$\sigma = \begin{cases} \sigma_m \exp\left[k'\left(1 - \frac{a|\Delta E|}{hv}\right)\right] & \text{for } v < \frac{a|\Delta E|}{h} \\ \sigma_m & \text{for } v \geqslant \frac{a|\Delta E|}{h} \end{cases} .$$

Here σ_m is the cross-section of the resonance process for $v = a|\Delta E|/h$, and k' is a parameter whose optimum value is 2. The optimum value of a for IMR is 100 Å. A large value of a corresponds to a spiral trajectory for the motion of the reactants at low kinetic energies. At thermal energies the rate constants were calculated by the formula

$$k = \sigma v .$$

The six lowest possible exothermic energy defects were determined, a cross-section was calculated for each of them, and the results were combined. The calculation included averaging over the rotational states and summing over the accessible electronic levels of the products.

The rate constants of approximately 20 charge transfer and exchange reactions during collisions between mono-atomic and diatomic particles have been calculated. For example, for the reaction

$$N^+(^3P_{0,2,1}) + O_2 \rightarrow NO^+(X^1\Sigma^+, a^3\Sigma^+) + O(^3P_2, {}^1D_2, {}^1S_0)$$

the calculated rate constant is $\sim 3 \times 10^{-10}$ cm^3 s^{-1}, and the experimental value is $\sim 4 \times 10^{-10}$ cm^3 s^{-1}. For the reaction

$$O^+(^4S_{3/2}) + N_2(^1\Sigma_g^+) \rightarrow NO^+(X^1\Sigma^+) + N(^4S_{3/2}) \qquad (25)$$

the calculated rate constant is $\sim 10^{-12}$ cm^3 s^{-1}, and the experimental values lie in the range $(1-3) \times 10^{-14}$ cm^3 s^{-1}. The agreement between calculation and experiment is always good, in spite of the fact that the energy defects are calculated for the isolated reactants and no allowance is made for the effect of Franck–Condon factors in the transition probabilities.

Though the calculations are simple (in principle), they require a knowledge of the energy levels, and therefore they rely on accurate spectroscopic data, which are not always available. We should also note that calculations by this method predict a positive temperature effect for slow IMR, whereas reactions such as (25) show a negative temperature effect at low kinetic energies.

V. LAW OF CORRELATION OF THE SYMMETRY OF STATES

A qualitative method of estimating the rates of chemical reactions is implicit in the law of conservation of state symmetry in reactions. Reactions are considered to be allowed if the symmetries of the wave functions and the total spin of the electronic ground state are the same for reactants and products. In reactions between an atom and a diatomic molecule or between two diatomic molecules under conditions leading to the formation of linear product molecules the symmetry type of the reactants and products is determined by the quantum number of the orbital angular momentum. In this case conservation of symmetry reduces to conservation of the resulting angular momentum of reactants and products.

Reactions which are forbidden in this sense can take place only if the reactants or the products are electronically excited.

The law of conservation of state symmetry has been used to explain[109] the anomalously low rate constant of the ion-molecule reaction (25), which is important in the chemistry of the Earth's ionosphere. It was pointed out[110] that under laboratory conditions and for a kinetic energy of the O^+ ion of a fraction of an electron-volt the rate constant of this reaction is $\sim 10^{-11}$ cm^3 s^{-1}, which is much lower than the Langevin limit. Reaction (25) was later studied in detail by different methods and over a wide range of kinetic energies of the ions (Fig.7). Measurements in a drift tube at kinetic energies of 0.04–2 eV detected an initial decrease in the reaction cross-section, with a minimum of ~ 0.01 Å^2 at an energy of 0.3 eV, followed by an increase in cross-section with ion energy. In the high energy region the measurements were made with a double mass spectrometer. The highest cross-section (~ 5 Å^2) is reached for a kinetic energy of 8 eV, and beyond this point the cross-section falls off very steeply.

The ground states of the reactants are $^1\Sigma_g^+$ for N_2 and ^4S_u for O^+. The linear approach of N_2 and O^+ gives N_2O^+ in the $^4\Sigma^-$ excited state. Without allowance for the polarisation energy the potential energy curve for this state has no

minimum, and the energy increases monotonically as the particles move closer together. The potential curve for the reaction products $NO^+(^1\Sigma^+)$ and $N(^4S_u)$ has a similar shape. The potential surface calculated for $N_2O^+(^4\Sigma)$ has a potential barrier between the reactants and products of this exothermic IMR ~8 eV high, and the depth of the potential well due to the polarisation attraction between the reactants[111] is ~0.38 eV. Since the two branches of the energy curve for the $^4\Sigma^-$ state intersect the potential curve of the ion in the ground state $[N_2O^+(^2\Pi)]$ the reaction can follow a different path which avoids the high potential barrier. The low probability of reaction (25) at low kinetic energies can be ascribed to the low probability of non-adiabatic transitions from the $^4\Sigma^-$ curve (corresponding to the approach of the O^+ ion towards the N_2 molecule) to the curve for the ground state of $N_2O^+(^2\Pi)$, and of the backward transitions from the $N_2O^+(^2\Pi)$ curve to the $^4\Sigma^-$ curve, corresponding to the separation of the NO^+ and N products, since these transitions are forbidden for orbital angular momentum and for spin.

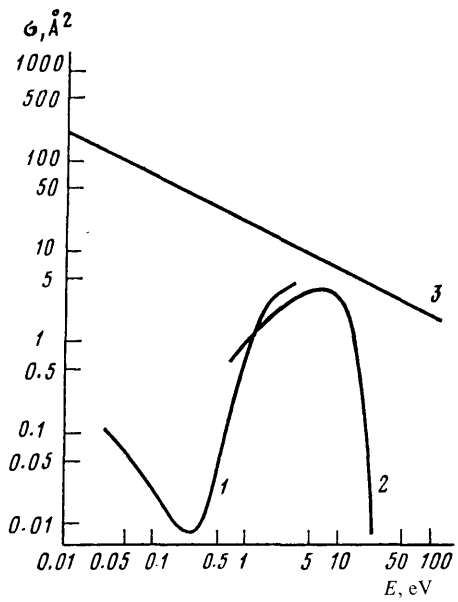

Figure 7. Cross-section of the reaction $O^+ + N_2 \rightarrow NO^+ + N$ against the kinetic energy of the O^+ ion. Cross-sections measured: *1*) by the drift tube method[18] and *2*) by using a double mass spectrometer[118]. Curve *3* denotes the cross-section of the ion–molecule collisions, calculated by formula (2).

The increase in reaction cross-section with kinetic energy of the ions arises from the increased probability of non adiabatic transitions, whereas the decrease in cross-section in the low-energy region can be explained by the decrease in life-time of the soft polarisation complex[112]. We note that the activated complex theory as used to explain the negative temperature dependence of the IMR rate in the case of the transfer of a hydride ion can also explain the change in sign of the effect of ion energy on the rate constant (because of the increased contribution from the vibrational partition functions when the complex has a high energy[113]).

The decreasing cross-section of reaction (25) at high ion energies has been explained[114] by the direct reaction mechanism (removal of a nitrogen atom followed by capture of the incident O^+ ion with formation of the molecular ion NO^+). The theory of these reactions[115] assumes that the system of particles remains on a fixed energy surface throughout the reaction, that the interaction potential V is of the pair type, and that the interaction between the ion and the bound nitrogen atom can be treated in the impulse approximation, i.e. that we can write

$$\omega a/v \ll 1$$

where ω is the vibrational frequency of the molecule. The calculated dependence of the cross-section on the ion energy correctly reflects the most striking feature of the experimental curve: a steep fall of σ with increasing energy of the colliding particles for $E > 12$ eV. The position and height of the maxima in the theoretical and the experimental curve are almost the same, and the position of the maximum in the theoretical curve corresponds to the largest phase volume defined by the capture conditions. Thus the complex energy dependence of the cross-section of reaction (25) is adequately explained by existing qualitative models.

The law of conservation of orbital momentum can also explain the difference between the rate constants of the isotope exchange reactions

$$^{15}N^+ + {}^{14}N_2 \rightarrow {}^{14}N^+ + {}^{14}N^{15}N \quad , \qquad (26)$$

$$^{18}O^+ + {}^{16}O_2 \rightarrow {}^{16}O^+ + {}^{16}O^{18}O \quad . \qquad (27)$$

The rate constant of reaction (26) is more than two orders of magnitude greater than that of reaction (27): this has been ascribed[116] to the symmetry- and spin-forbidden formation of a triatomic linear complex in the electronic ground state in the case of reaction (27) but not of reaction (26). It has been shown[117] that exothermic IMR with proton transfer of the type of

$$C^-(^4S) + XH \rightarrow X^- + CH(^2\Pi)$$

(where X is a radical of various types) are usually slow, but they become fast when the energy evolved by the reaction is sufficient to give $CH(^4\Sigma)$ as a product.

Some reactions involving relatively simple molecules are incompatible with the above law. For example, though the reaction

$$N^+(^3P) + O_2(^3\Sigma) \rightarrow NO_2^+(^1\Sigma) \rightarrow NO^+(^1\Sigma) + O(^3P) \qquad (28)$$

is forbidden for orbital angular momentum conservation, and the reaction

$$O^+(^4S) + CO_2(^1\Sigma) \rightarrow O_2^+(^2\Pi) + CO(^1\Sigma) \qquad (29)$$

is also spin-forbidden, their rate constants are close to the Langevin limit (5×10^{-10} and 11×10^{-10} $cm^3\ s^{-1}$ respectively[118]).

The removal of the restrictions on reaction (28) is due to the strong coupling between the rotational and the orbital momentum of the electron[119], and in the case of reaction (29) it is due to the strong coupling between the orbital and the spin momentum. The spin-orbital coupling in the intermediate complex of reaction (29) has been shown[119] to be due to the strong resonance interaction of the reactants, arising from the very similar values of the ionisation potential in O and CO_2.

Cases of symmetry-allowed yet slow reactions have also been reported. For example, the exothermic exchange reaction

$$CO^+(^2\Sigma^+) + O_2(^3\Sigma_g^-) = CO_2^+(^2\Pi_g) + O(^3P) \qquad (30)$$

is slow, whereas the competing (forbidden) exothermic charge transfer reaction

$$CO^+(^2\Sigma^+) + O_2(^3\Sigma_g^-) \rightarrow CO(^1\Sigma^+) + O_2^+(^2\Pi) \quad (31)$$

is fast[120].

We note that a theoretical explanation of the high rate of reactions (28) and (29) can be put forward. In the case of IMR of the type of

$$A^{\pm} + BC \rightarrow AB^{\pm} + C \quad (32)$$

(where A, B, and C can be carbon, oxygen, and nitrogen atoms) a simple method of calculating the rate constant can be based[121] on the assumption that the reaction will be fast if it does not involve a substantial redistribution of the charge density. This hypothesis leads to the rule that reaction (32) will have a large cross-section if atom A is less electronegative than atom B (in the case of IMR involving positive ions), since the positive charge in the reaction product AB^+ can then remain on the atom A.

In the case of reactions involving negative ions we can expect a large cross-section if the electronegativity of the A atom is greater than that of the B atom. If the electronegativities of A and B are similar, the reactions in which the redistribution of electron density in the product molecule C as compared with the reactant BC is least marked will be the fastest. This will be the case when the C molecule has the same dipole moment and the same geometry as the BC molecule. It has also been pointed out that the rate constants of slow IMR involving a rearrangement of the electron density increase with the internal energy of the reactants, whereas in fast IMR (with an unchanged electron density) the rate constants decrease as the internal energy increases.

Let us examine the application of the electronegativity rule to reaction (25). The oxygen is more electronegative than the nitrogen atom: we can therefore expect reaction (25) to have a low efficiency. In reaction (29) the CO_2 molecule has no net dipole moment, though the electron density is sharply divided between the oxygen atoms and the carbon: as a result, the oxygen atoms carry a negative charge and the carbon atom a positive charge. In the CO molecule the negative charge is also shifted towards the oxygen, i.e. reaction (29) can take place without a major redistribution in the electron density. According to the rule formulated above we can expect this reaction to be fast.

The rule was later extended[123] to IMR of the type of

$$AH_k^+ + BCH_l \rightarrow ABH_m^+ + CH_n$$
$$AH_k^+ + BH_l \rightarrow ABH_m^+ + p\,H_2 + q\,H$$
$$AH_k^+ + BCH_l \rightarrow ABCH_m^+ + p\,H_2 + q\,H$$

where A, B, and C are large central atoms, and k, l, m, n, p, and q are integers. To a first approximation the hydrogen atoms can be ignored, so that only the electronegativity of the large central atoms needs to be considered. A large number of IMR has been examined[121], and the validity of the rule has been demonstrated. For example, symmetrical exchange reactions with transfer of the electronegative O^+ ion are found to be slow[122,124,125]:

$$^{12}CO_2^+ + {}^{13}CO \rightarrow {}^{12}CO + {}^{13}CO_2^+ , \quad (33)$$

$$^{14}N_2O^+ + {}^{15}N_2 \rightarrow {}^{15}N_2O^+ + {}^{14}N_2 . \quad (34)$$

The slowness of these reactions can also be explained by the need for excitation of the reactants in the intermediate decomposition step of the primary ion, since the ground states of the linear CO_2^+ and N_2O^+ ions do not correlate with the ground states of the decomposition products $CO + O^+$ and $N_2 + O^+$.[124]

The fast IMR

$$C^+ + O_2 \rightarrow O^+ + CO \quad (35)$$

in which charge is transferred from the less electronegative C atom to the more electronegative O^+, is incompatible with the electronegativity rule[126]. The reaction

$$C^+ + O_2 \rightarrow CO^+ + O \quad (36)$$

in which the positive charge remains on the C atom, is slower[126] than reaction (35). In this case the contradiction can be explained by postulating a two-step elementary act: initially the intermediate complex has the structure $[O...CO^+]$, corresponding to the products of reaction (36), but in a time comparable to the dissociation time this complex undergoes an internal charge redistribution and is converted into the more stable $[O^+...CO]$ structure, corresponding to the products of reaction (35).

The following exothermic reactions were found to be slow:

$$N^+(^3P) + CO(^1\Sigma) \rightarrow NO^+(^1\Sigma) + C(^3P) \quad (37)$$

$$N^+(^3P) + CO_2(^1\Sigma_g) \rightarrow NO^+(^1\Sigma) + CO(^1\Sigma) \quad (38)$$

though the positive charge in the NO^+ ion is concentrated on the N atom[127–129]. Reaction (37) is symmetry allowed. It is interesting to note that the reactants in reactions (37) and (38) can undergo the fast non-dissociative charge transfer reactions:

$$N^+ + CO \rightarrow CO^+ + N . \quad (39)$$

$$N^+ + CO_2 \rightarrow CO_2^+ + N . \quad (40)$$

The dependence of the cross-sections of reactions (37) and (39) on the kinetic energy of the ions (E_i) is illustrated in the Table.

Cross-sections of reactions (37) and (39) as a function of the kinetic energy of the ions[128].

E, eV	0.2	0.5	1.0	2.5	5.5	10.0	20.0
σ_{37}, Å^2	2.6	1.3	0.6	0.4	1.0	0.9	0.17
σ_{39}, Å^2	28	10	4.8	2.4	2.0	2.6	3.3

When the kinetic energy is increased from 0.2 to 20 eV the cross-section of the IMR (37) initially decreases from 2.6 to 0.4 Å^2 (at 2.5 eV), then increases to ~1 Å^2 (at 5.5 eV), and finally falls off sharply, reaching 0.17 Å^2 at 20 eV. The cross-section of the charge transfer process (39) initially decreases from 28 to 2 Å^2 (at 5.5 eV), and then increases to 3.3 Å^2 at 20 eV. Thus the allowed reaction (37) has a low cross-section, whose dependence on the kinetic energy of the ion is similar to that of the forbidden reaction (25). The cross-section of reaction (38) at a kinetic energy of 2 eV is only 6% of the cross-section of the charge transfer reaction (40).[129]

The statistical theory, which allows for the formation of only one type of intermediate complex, predicts the opposite ratio of cross-sections for heavy particle transfer and charge transfer reactions, since in the examples considered the enthalpy of the heavy particle transfer reactions is greater than the enthalpy of charge transfer. The observed relative

cross-sections can be explained only if the initially formed soft complex has a short life-time (as a result of a fast exothermic charge rearrangement, which can take place at relatively long distances in a soft complex). This effect inhibits the formation of the hard complex, which must precede the regrouping of the chemical bonds. Thus the non-dissociative charge transfer processes (like the dissociative processes discussed above) can lower the cross-section of IMR involving the regrouping of heavy particles.

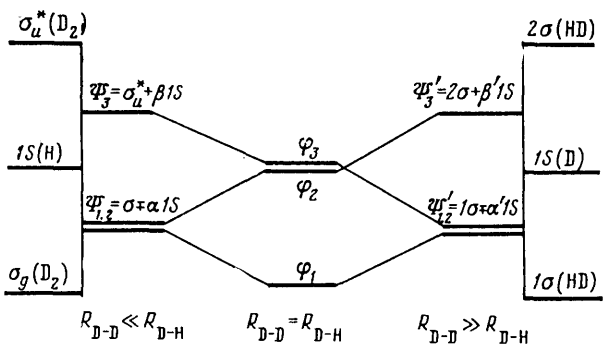

Figure 8. Correlation diagram of the molecular orbitals of the D...D...H system[130].

VI. LAW OF CONSERVATION OF ORBITAL SYMMETRY

The rate constants of IMR can be discussed qualitatively by drawing the correlation diagrams for the molecular orbitals, based on the law of conservation of the symmetry of molecular orbitals during a reaction. For the linear HD_2 system the correlation diagram of the molecular orbitals[130] is shown in Fig.8. The diagram explains the difference in probability of the reactions

$$H^+ + D_2 \rightarrow HD + D^+ \qquad (41)$$

$$H + D_2 \rightarrow HD + D \qquad (42)$$

$$H^- + D_2 \rightarrow HD^- + D \qquad (43)$$

in which the occupancy of the $1S(H)$ orbital is 0, 1, and 2 respectively. It is clear from the diagrams that the $\sigma_g(D_2)$ orbital correlates with the lowest orbital (ϕ_1) of the complex. In the course of the reaction two electrons are transferred from the $\sigma_g(D_2)$ orbital through the ϕ_1 orbital of the intermediate complex to the $1\sigma(HD)$ orbital of the product. For reaction (41), in which only two electrons take part, the close approach of the reactants lowers the potential energy, and should lead to a fast reaction. The electrons located on the $1S(H)$ orbital are transferred to the ϕ_2 orbital of the intermediate complex, which has a node, and therefore the potential energy increases as the reactants move closer together. The greater the number of electrons in the orbital, the stronger the repulsion. Therefore reaction (41) should be fast, and reaction (43) should be the slowest, though attractive polarisation forces between the ion and the molecule are present in both cases. This conclusion has been confirmed experimentally[131,132]. The recently discovered[132] activation energy for the exothermic proton transfer IMR

$$NH_2^- + H_2 \rightarrow H^- + NH_3$$

$$CH_2{=}CH{-}CH_2^- + C_6H_5CH_3 \rightarrow C_6H_5CH_2^- + CH_2{=}CH{-}CH_3$$

probably has a similar origin. Here, as in reaction (43), a negative ion interacts with a molecule which has no partially filled orbitals.

The correlation diagram shown in Fig.8 also explains the low efficiency of IMR of the type of

$$D_2^+ + H \rightarrow DH^+ + D$$

since in this case only one electron is found on the bonding orbital (ϕ_1) of the complex, whereas the second electron is transferred to the antibonding ϕ_2 orbital. Under these conditions the resulting interaction is repulsive, because the increase in energy of the antibonding orbitals caused by bringing the particles closer together is usually much greater than the corresponding decrease in energy of the bonding orbitals. Vibrational excitation of the D_2^+ ion raises the $\sigma_g(D_2)$ level, bringing it closer to the $1S(H)$ level, and thus facilitates electron transfer from the $1S(H)$ to the $\sigma_g(D_2)$ level. This opens a path for charge transfer and new paths for non-adiabatic exchange reactions involving the ground state and the first electronically excited state of the D_2H^+ complex. The calculation of the dependence of the cross-section of non-adiabatic IMR on the kinetic and internal energies of the ions requires a detailed knowledge of the potential energy surfaces of the ground and the excited state of the D_2H^+ system, and of the probabilities of transitions between these states[54,133].

The correlation diagram[106] for the reactions

$$He^+ + H_2 \rightarrow HeH^+ + H \qquad (44)$$

$$H_2^+ + He \rightarrow HeH^+ + H \qquad (45)$$

is similar to the diagram shown in Fig.8, differing from it only in the absence of resonance between the energy levels of reactants and products. In reaction (44) one electron is found on the $1S(He)$ orbital and two on the $\sigma_g(H_2)$ orbital. During the reaction the electron in the $1S(He)$ orbital is adiabatically transferred to the $1\sigma(HeH)$ orbital. The two electrons from the $\sigma_g(H_2)$ orbital are transferred to the antibonding orbital of the complex, from which they pass into the antibonding $2\sigma^*(HeH)$ orbital, giving the highly excited HeH* particle and a proton. Alternatively, the two electrons can be transferred to the $1S(H)$ level in the region of contracting orbital energies, giving HeH^{2+} and H^-. These two reaction channels are allowed for orbital symmetry, but they are strongly endothermic and therefore inaccessible at low kinetic energies. The exothermic channel giving $HeH^+ + H$ from the reactants He^+ and H_2 is forbidden, because it requires the transfer of an electron between potential surfaces of very different energy which nowhere approach each other sufficiently closely. A similar set of arguments shows that all reactions of the type of

$$He^+(Ne^+) + XH \rightarrow HeH^+(NeH^+) + X$$

must be slow (X is a radical with an ionisation potential a few eV lower than the ionisation potential of Ne).

In reaction (45) the $1S(He)$ orbital is occupied by two electrons, and the $\sigma_g(H_2)$ orbital by one electron. In this case the molecular orbitals of the ground states of reactants and products are correlated, and reaction (45) can be expected to be fast (as is found experimentally[106]). A reaction is facile when the orbitals of the reactants in their ground state

are correlated to those of the products in their ground state. If on the other hand the ground state orbitals are correlated to those of an excited state we can expect the reaction to be very ineffective (at low kinetic energies and low internal excitation energies) towards endothermic processes with formation of excited products.

The correlation diagrams for a large number of IMR involving complex atoms are given in Ref.106. Forbidden reactions include double decompositions by a planar four-centre cyclic transition state[134], such as

$$H_2 + D_2 \rightarrow 2HD \ . \qquad (46)$$

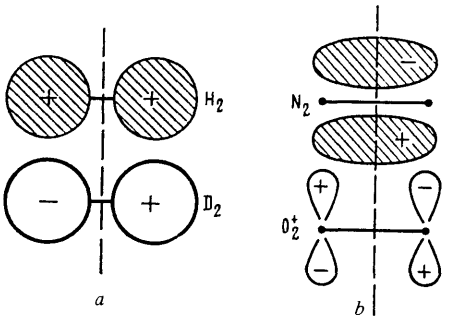

Figure 9. Molecular orbitals involved in the reactions $H_2 + D_2 \rightarrow 2HD$ (*a*) and $O_2^+ + N_2 \rightarrow NO^+ + NO$ (*b*).

In the case of the reaction

$$AB + CD \rightarrow AD + BC \qquad (47)$$

and assuming that the orbital energies are equal to the corresponding bond energies of the molecules, the correlation diagrams give the following expression for the activation energy[135]:

$$E_a = \frac{D(CD)\,[D(CD) + D(AB) + D(AD) - D(BC)]}{D(CD) + D(AD)} \qquad (48)$$

where D(AB) and D(CD) are the dissociation energies of the stronger and the weaker bond in the reactants, and D(AD) and D(BC) are the dissociation energies of the weaker and the stronger bond in the products. For example, for reaction (46) the activation energy calculated by this formula is 420 kJ mole^{-1}. In the case of molecules consisting of atoms with many electrons the orbital correlation diagrams become extremely complex, and in order to classify a reaction as forbidden or allowed we must use Pearson's method[136,137], in which only the highest occupied and the lowest unoccupied orbitals of the reactants are considered. Whereas in the Woodward and Hoffman method[134] the correlation between the molecular orbitals of reactants and products in their ground states is used as a criterion of whether the reaction is allowed or forbidden, in the Pearson approach the criterion is the positive overlapping of the highest occupied molecular orbital (HOMO) of the donor and the lowest unoccupied molecular orbital (LUMO) of the acceptor. For the chemical reaction to have a low activation energy we require the HOMO of the donor to have the same symmetry as the LUMO of the acceptor, and the transfer of an electron from the donor to the acceptor must weaken the bonds being broken and strengthen those being created. In reactions involving positive ions the donor is always the reactant molecule, and in reactions with negative ions the molecule is always the acceptor.

The shape of the molecular orbitals taking part in reaction (46) is shown in Fig.9*a*. The occupied bonding orbital of H_2 is cross-hatched, and the unoccupied D_2 antibonding orbital is left blank. These orbitals have different symmetries, and the approach of the reactants leads to repulsion (and hence to a high activation energy for the reaction).

In the isotope exchange reactions

$$^{15}N_2^+ + {}^{14}N_2 \rightarrow {}^{15}N^{14}N^+ + {}^{15}N^{14}N$$
$$^{18}O_2^- + {}^{16}O_2 \rightarrow {}^{18}O^{16}O^- + {}^{18}O^{16}O$$

electrons are transferred from an N_2 bonding orbital to an N_2^+ bonding orbital, and from an O_2^- antibonding orbital to an O_2 antibonding orbital. The overlap of the orbitals is positive in both cases (the overlapping orbitals have the same sign), but the electron transfer weakens one of the existing bonds and strengthens the other. Therefore these reactions also are forbidden.

Another example of the application of Pearson's rule to IMR is the double decomposition reaction

$$N_2^+ + O_2 \rightarrow NO^+ + NO \qquad (49)$$

which has a very small cross-section[138]. In this case the acceptor is the N_2^+ ion, whose lowest unoccupied orbital is the $\sigma_g(2p_x)$ bonding orbital. The highest occupied orbital of O_2 is the antibonding π_g^x orbital. Again, the orbitals of the reactants have different symmetries with respect to the plane normal to the axis of the molecule, and this accounts for the slowness of the reaction.

A reaction analogous to (49) but with the opposite charge distribution on the reactants

$$O_2^+ + N_2 \rightarrow NO^+ + NO \qquad (50)$$

is also forbidden, since in this case the electron has to be transferred from a bonding N_2 orbital to an antibonding O_2^+ orbital (Fig.9*b*).

An experimental study[139] of ion-molecule reactions caused by collisions between O_2^+ and N_2 has shown that if the kinetic energy of the O_2^+ ions is less than 15 eV the rate constant of the formation of NO^+ is less than 3×10^{-13} cm^3 s^{-1}. Under these conditions NO^+ can be formed by the reaction

$$O_2^+ + N_2 \rightarrow NO^+ + N + O \qquad (51)$$

as well as by reaction (50). It has also been reported[138] that the weakly endothermic reactions [analogous to (51)]

$$NF^+ + O_2 \rightarrow NO^+ + F + O \qquad (52)$$

$$N_2^+ + O_2 \rightarrow NO^+ + N + O \qquad (53)$$

have very small cross-sections (less than 10^{-17} cm^2 for ions with kinetic energies between 2 and 50 eV), whereas the cross-sections of the strongly endothermic dissociations

$$NF^+ + O_2 \rightarrow N^+ + F + O_2$$
$$N_2^+ + O_2 \rightarrow N^+ + N + O_2$$

are much higher.

The most likely reason for the lack of dependence of the rate of exchange reactions on the kinetic energy of the reactants is a displacement of the potential barrier towards the products for reactions (51)–(53) or towards the high-curvature region of the path for reactions (49) and (50). The profiles of the reaction paths for some symmetry-forbidden double decomposition reactions of the type of (50) and of exchange reactions with dissociation of the type of (51) have recently been calculated by a modified "bond order–bond energy" method[140,141].

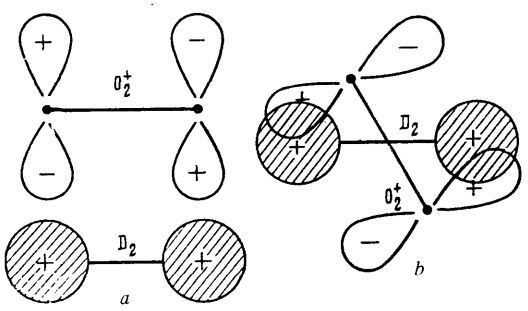

Figure 10. Molecular orbitals participating in the reaction $O_2^+ + D_2 \rightarrow OD^+ + OD$: *a*) is the planar complex, *b*) is a complex formed by the approach of the reactants in a non-parallel mutual configuration.

The approach of the reactants with formation of a non-planar complex can convert a reaction which is forbidden for a planar complex into an allowed reaction. For the reaction

$$O_2^+ + D_2 \rightarrow OD^+ + OD \cdot \qquad (54)$$

the planar complex is shown in Fig.10*a* and the complex formed when the reactants approach each other along an axis perpendicular to the plane of the paper (with the molecular axes in a non-parallel configuration) is shown in Fig.10*b*. In the latter case reaction (58) is allowed, because the overlap of the orbitals is positive and the bond in the reactants is weakened by the electron transfer. The analogous reaction

$$D_2^+ + O_2 \rightarrow OD^+ + OD$$

is forbidden, because the bond in the reactants is strengthened by the electron transfer. These conclusions are consistent with experimental results[138]: the cross-section for the formation of OD^+ is higher for collisions between O_2^+ and D_2 than for collisions between D_2^+ and O_2.

---oOo---

The examples discussed in this review show the importance of wide-ranging and detailed studies of the elementary reaction act in IMR in establishing the origin of the chemical reactivity and the mechanism of the elementary reaction acts in the chemical regrouping of particles, and in characterising the elementary acts of the energy redistribution processes.

Heteropolyacids in Catalysis

I.V.Kozhevnikov and K.I.Matveev

The application of heteropolyacids (HPA) as catalysts of oxidation and acid-type reactions as well as certain physicochemical properties of the HPA important for the understanding of the mechanism of their catalytic action are examined. The mechanisms of catalytic reactions in the presence of HPA are discussed.
The bibliography includes 182 references.

V. Applications of heteropolyacids in heterogeneous catalysis 1083

I. INTRODUCTION

The application of heteropolyacids (HPA) as catalysts may be regarded as a new field in catalysis. Systematic study of this field began approximately 10 years ago, although isolated (and frequently successful) attempts to employ HPA in homogeneous and heterogeneous catalytic reactions were made even earlier. Extensive investigation of homogeneous systems based on HPA began after the discovery of the ability of molybdovanadophosphoric acids having the composition $H_{3+n}PMo^{VI}_{12-n}V_nO_{40}$ (HPA-n, where $n = 2-8$) and their salts to undergo reversible oxidation-reduction reactions in aqueous solution[1,2]:

$$\text{HPA-}n + \text{Red} + i\,\text{H}^+ \rightarrow \text{H}_i\text{HPA-}n + \text{Ox}, \quad (1)$$

$$\text{H}_i\text{HPA-}n + (i/4)\text{O}_2 \rightarrow \text{HPA-}n + (i/2)\text{H}_2\text{O}, \quad (2)$$

where Red and Ox are the i-electron reductant (the substrate or the reduced form of the cocatalyst) and its oxidised form respectively and $H_iHPA\text{-}n = H_i[H_{3+n}PMo^{VI}_{12-n}V^{V}_{n-i}V^{IV}_{i}O_{40}]$ is the heteropolyblue—the reduced form of HPA-n ($i \leq n$). The reversibility of the oxidation-reduction properties made it possible to carry out numerous oxidation reactions using HPA-n solutions as catalysts and O_2 as the oxidant[2].

Heteropolyacids have a unique set of valuable catalytic properties. They consist of polynuclear molybdenum(VI), tungsten(VI), and vanadium(V) complexes, which may also include many other elements as central atoms or ligands. HPA are many-electron oxidants and at the same time are strong Brønsted acids. The oxidation-reduction and acid properties of HPA can be varied within fairly wide limits by altering their composition. Many HPA are fairly soluble and stable in water and oxygen-containing organic solvents. At the same time they exhibit a high thermal stability in the solid state. This makes it possible to use HPA as homogeneous and heterogeneous catalysts of oxidation and acid-type reactions and also as bifunctional catalysts.

Among different HPA, the acids and their salts belonging to the saturated 12-series are of greatest importance for catalysis. They include the heteropolyanions (HPA) $X^{x}M^{VI}_{12}O^{x-8}_{40}$ or $X^{x}M^{VI}_{12-n}V^{V}_{n}O^{x-8-n}_{40}$, where X is the central atom (Si^{IV}, Ge^{IV}, P^{V}, As^{V}, etc.), x the degree of oxidation, and M the metal ion (Mo^{VI} and W^{VI}). The representatives of the 12-series are distinguished by a high stability and their properties have been investigated in detail. In this review the HPA are understood as derivatives of the 12-series unless otherwise stated. In the formulae of the HPA the H and O atoms may be omitted for brevity.

Until recently the number of studies devoted directly to the catalytic properties of HPA was less than 1% of the total number of studies on such compounds[3]. In recent years the relative contribution of these investigations increased greatly both in the USSR[2,4] and abroad[5]. This occurred as a result of the synthesis of a large number of new HPA and the accumulation of extensive information about their properties. The main contribution to the development of the chemistry of HPA was made by the schools of Spitsyn and Alimarin in the USSR, Souchay in France, and Pope in the USA.

This review deals with the results of studies on homogeneous and heterogeneous catalytic systems based on HPA carried out mainly during the last 10 years. The physicochemical properties of HPA (mainly in solutions), necessary for the understanding of the mechanism of their catalytic action, are also considered. Several short reviews devoted to the catalytic properties of HPA in homogeneous[1,2,6] and heterogeneous[7] reactions† were published previously. The synthesis, properties, and other applications of HPA of different series were examined in earlier reviews[8-14] and monographs[15,16] and the application of HPA in chemical analysis has been dealt with in two communications[17,18]. One should note that the catalytic properties of HPA are employed in a series of kinetic analytical methods (analyses for phosphorus[19] and arsenic[20]).

II. CERTAIN PHYSICOCHEMICAL PROPERTIES OF HETEROPOLYACIDS

1. The Molecular Structure of HPA of the 12-Series

Molecules of the 12-series HPA of the type $H_{8-x}X^{x}M^{VI}_{12}O_{40}$ and $H_{8-x+n}X^{x}M^{VI}_{12-n}V^{V}_{n}O_{40}$ have the Keggin structure with T_d symmetry (Fig.1), which has been established reliably as a result of numerous X-ray diffraction investigations of HPA hydrates[8-10,21-23]. This structure includes a central XO_4 tetrahedron surrounded by 12 MO_6 octahedra having common edges and vertices (O atoms). It has been frequently suggested that the MO_6 octahedra constitute a single polydentate ligand[9], but the equilibria in the degradative dissociation of HPA in solutions (see below) show that this review is not entirely justified. The radius of the HPA molecule is ~6 Å.[9] Since the ionic radius of O^{2-} greatly exceeds the radii of M^{VI} and X^{x}, the state of the O atoms in HPA is nearly close-packed[10]. The following types of chemical bonds are present in the HPA molecule: 12 quasi-linear bonds, 12 M—O—M angular bonds, 4 X—O—M bonds with bridging O atoms, and 12 M=O bonds with terminal O atoms.

†See also the review by M.Otake, J.Synth.Org.Chem. Japan, 1981, **39**, 385.

In these bonds the coordination numbers of the oxygen atom are 2,2,4 and 1 respectively. Thus the HPA contain the fundamental elements of the structures of the molybdenum, tungsten, and vanadium oxides. The HPA crystallise in the form of hydrates containing variable numbers of molecules of water of crystallisation (up to 30 and more).

2. The State of HPA in Solution. Kinetics and Mechanism of Ligand Substitution

The Keggin structure is preserved in concentrated HPA solutions but in dilute solutions ($<10^{-2}$ M) account must be taken of the degradative dissociation with ligand elimination. The retention of the Keggin structure in concentrated solutions has been demonstrated by X-ray diffraction[24-26] and by the identity of the infrared and Raman spectra of the crystals and aqueous and non-aqueous solutions of the HPA[27-31]. This is also indicated by ^{17}O NMR spectra[32-34] and the results of studies by other physical methods[35].

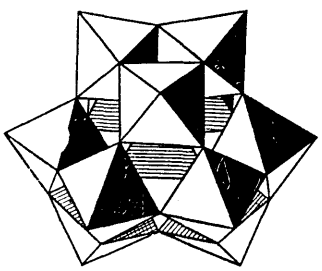

Figure 1. The Keggin structure of the 12-series HPA.[9]

By virtue of the symmetry of the anion and its large size combined with a low surface density of the negative charge, HPA and many of their salts are frequently fully dissociated in solution and the heteropolyanions are weakly solvated and behave as weak complex-forming ligands. The latter does not apply to defective heteropolyanions (HPAn), for example $SiW_{11}O_{39}^{8-}$, in which the vacancy in the Keggin structure has a high coordinating capacity[9,36,37]. The above property of the defective HPA is widely used to obtain HPA with different metal ions in the coordination sphere, for example compounds with polyanions having the general formula $XZW_{11}O_{39}^{m-}$, where X = Si^{IV}, Ge^{IV}, or P^{V} and Z = Co^{II}, Co^{III}, Ni^{II}, etc.[10].

The state of the HPA in solution is determined by the set of little investigated dissociation, disproportionation, etc. equilibria and depends on the acidity of the medium, the composition and concentration of the HPA, and the nature of the solvent. The region corresponding to their existence has been determined for a comparatively small number of HPA. The equilibration times in HPA solutions vary from a fraction of a second to several months[38].

The stability of the heteropolyanions as regards hydrolysis in aqueous solutions decreases in the sequence $W^{VI} > Mo^{VI} > V^{V}$.[10] The stability of the HPAn-Mo^{VI} decreases in the following sequence as a function of X: $Si^{IV} > Ti^{IV}$, $Zr^{IV} > Ge^{IV} > P^{V} > As^{V}$.[10] 12-Molybdophosphates exist in an acid aqueous solution at pH ≤ 1.5;[16] with increase of pH, they undergo alkaline hydrolysis, which proceeds via the following mechanism in dilute solutions ($\leq 10^{-3}$ M):[10,16]

$$PMo_{12}O_{40}^{3-} \overset{OH^-}{\rightleftarrows} PMo_{11}O_{39}^{7-} + MoO_4^{2-} \overset{OH^-}{\rightleftarrows} HP_2Mo_5O_{23}^{5-} + MoO_4^{2-} \overset{OH^-}{\rightleftarrows} HPO_4^{2-} + MoO_4^{2-}.$$

In concentrated solutions ($\sim 10^{-1}$ M) the hydrolysis proceeds via the formation of a dimeric 9-molybdophosphate $P_2Mo_{18}O_{62}^{6-}$ as an intermediate[10,16]. The polyanions with P : Mo ratios of 1 : 9, 2 : 18, and 2 : 5 predominate in the H^+–MoO_4^{2-}–HPO_4^{2-} system at pH 1.5–6.0; their stability constants have been determined[39]. In highly acidic media (pH < 1.5) the heteropolyanions undergo acid hydrolysis with formation of defective polyanions and oxomolybdenum(VI) cations[10].

The stability of HPA increases in organic media[10,12]. It has been established by the conductimetric method that acids such as PMo_{12}, PW_{12}, $SiMo_{12}$, SiW_{12}, $PMo_{11}V$, and $PW_{11}V$ are resistant to solvolysis in ethanol, acetone, and acetic acid up to concentrations in the range 10^{-6}–10^{-5} M.[40,41]. The introduction of vanadium(V) into molybdenum HPA increases their resistance to hydrolysis[42,43]. The stability of $H_{3+n}PMo_{12-n}V_nO_{40}$ (HPA-n) in aqueous solutions decreases with increasing n in the sequence HPA-1 > HPA-2 > HPA-3.[42] Although HPA-n with $n > 3$ have not been isolated as individual compounds[23,44], their salts are known[38,45,46]. The most stable HPA-1 begins to hydrolyse only in 0.8 M HCl.[38] The acids HPA-n with $n > 1$ are converted into HPA-n with a smaller value of n on increase of $[H^+]$;[43] for example, the following reaction takes place for $n = 3$:

$$10H_6PMo_9V_3O_{40} + 12H^+ \rightleftarrows 9H_5PMo_{10}V_2O_{40} + 12VO_2^+ + H_3PO_4 \quad (3)$$

The first stage of the reaction of HPA-n is probably degradative dissociation:

$$H_{3+n}PMo_{12-n}V_nO_{40} + H_3O^+ \rightleftarrows VO_2^+ + H_{6+n}PMo_{12-n-1}V_{n-1}O_{39} \quad (4)$$

At pH 1–3 the acids HPA-n disproportionate[43,47]

$$2PMo_{11}V \rightleftarrows PMo_{12} + PMo_{10}V_2 \cdot \quad (5)$$

The equilibrium constant of reaction (5) is 5.5×10^{-2} at pH 2.[43] The disproportionation reaction of $PW_{11}V$ is of second order with respect to $PW_{11}V$; the rate of reaction increases with pH and ionic strength I (the rate constants are 0.69 and 22.4 litre mol^{-1} s^{-1} at 25 °C, $I = 3$, and pH 3.9 and 4.9 respectively).[48] The heteropolyblues also disproportionate[49,50] in accordance with the mechanism

$$2PW_{11}^{VI}W^{V} \rightleftarrows PW_{12}^{VI} + PW_{10}^{VI}W_2^{V}.$$

Such reactions take place very readily and probably involve electron transfer.

The 12-series polyanions PMo_6V_6 and PMo_2V_{10} are stable in moderately acid solutions (pH 2.5–5.5).[38] Using the isotopes ^{99}Mo, ^{185}W,[51,52] and ^{17}O,[34] it was shown that the ligands in the HPA exchange with the solution. The ^{99}Mo exchange between PMo_{12} (0.01 M) and $Na_2^{99}MoO_4$ (0.1 M) in aqueous solution at 20 °C and pH 1.2 takes place to the extent of 100% in 15 min.[51] The central atom does not exchange. According to ^{17}O NMR data, the oxygen atom in the M=O, M–O–M, and X–O–M bond in HPA have markedly different chemical shifts, rates of exchange with the solvent, and degrees of protonation[32-34]. The rate of ^{17}O exchange in the HPA-n ($n = 0, 1, 2$) decreases by an order of magnitude following the introduction of each successive V^{V} atom into the HPA molecule. It has been suggested that the oxygen exchange proceeds via a dissociation reaction of type (4) and via ligand exchange with the solvent.

The kinetics and mechanism of the ligand substitution in heteropolyanions have been studied[53-56]. The reaction

$$VO^{2+} + SiW_{12} \rightarrow SiW_{11}V + W^{VI}$$

in aqueous solution proceeds in accordance with the kinetic equation $w = k[SiW_{12}][OH^-]$, where $k = 2.8 \times 10^6$ litre mol^{-1} s^{-1} at 25 °C. The process proceeds via a dissociative mechanism with the rate-limiting stage

$$SiW_{12}O_{40}^{4-} + OH^- \rightarrow SiW_{11}O_{39}^{8-} + W^{VI}.$$

Next vanadium(IV) is rapidly inserted in the vacancy formed[53,54]. $SiW_{11}O_{39}^{8-}$ reacts analogously with Co^{2+}, forming $SiW_{11}O_{39}Co^{6-}$.[55] In the reaction of VO^{2+} with $PW_{12}O_{40}^{3-}$ the dissociative pathway competes with the associative pathway, which includes the formation of the complex $[(HPA).VO^{2+}]$.[54]

The rate of reaction of HPA-n (n = 0–6) with VO^{2+}, i.e.

$$PMo_{12-n}V_n^V + VO^{2+} \rightleftarrows PMo_{12-n}V_{n-1}^V V^{IV} + V^V \text{ (or } Mo^{VI}), \quad (6)$$

at pH 2.2–3.0 is described by the kinetic equation $w = k[\text{HPA-}n][VO^{2+}]/[H^+]^a$, where $1 < a < 2$.[56] The formation of the intermediate complex $[(\text{HPA-}n).VO^{2+}]$ has been noted. The reactivity of HPA-n in reaction (6) varies in the sequence HPA-0 > HPA-1 > HPA-2 > HPA-3 > HPA-4 > HPA-5 > HPA-6. The mechanism of reaction (6) depends on the composition of HPA-n. The process involving HPA-0 probably proceeds via the migration of V^{IV} to the existing vacancy in the coordination sphere of the polyanion. The reaction of HPA-1 apparently involves substitution of Mo^{VI} by V^{IV}, while the inner-sphere electron transfer from V^{IV} to HPA-n is more probable in the case of HPA-n ($n > 1$).[56] The equilibrium constants of the reaction of HPA-n with VO^{2+},

$$PMo_{12-n}V_{n-i}^V V_i^{IV} + VO^{2+} + H_2O \rightleftarrows PMo_{12-n}V_{n-i-1}^V V_{i+1}^{IV} + VO_2^+ + 2H^+ \quad (7)$$

(where $0 \leq i \leq n$, $n = 3.6$) at pH 2.0–2.7 are almost independent of n and are approximately 10^{-6} mol^2 litre^{-2},[57] i.e. HPA-n are most resistant to hydrolysis than the corresponding blues.

The kinetics and mechanism of the formation and decomposition of heteropolyanions have been investigated[58–61]. The formation of the PMo_{12} and $PMO_{10}V_2$ anions from phosphate, Mo^{VI}, and V^V in an acid aqueous solution is very rapid[59,60]. The kinetics of these reactions are complex and their mechanism is insufficiently clear.

3. Oxidation-Reduction Properties of HPA

Many HPA are fairly strong oxidants. They are reduced by various reductants both electrochemically[10] and photochemically[62,63]. Pope[64] found an empirical rule for isopolyanions and heteropolyanions of different structures, according to which the anion is reduced without decomposition when it contains M atoms linked to one terminal O atom. Such anions include those having the Keggin ($XM_{12}^{VI}O_{40}^{x-8}$) and Dawson ($X_2M_{18}^{VI}O_{62}^{2x-16}$) structures in which each M atom has one oxo-group M=O (Pope's structural type I). The heteropolyanions decompose on reduction if each M atom has a *cis*-dioxo-group O=M=O (structural type II; $XMo_6O_{24}^{x-12}$, $Mo_7O_{24}^{6-}$, etc.). Anions containing both types of M atoms (type III; $H_2W_{12}O_{42}^{10-}$) are reduced in the same way as the heteropolyanions of structural type I. This rule makes it possible to predict the structure of the polyanion on the basis of its reducing properties.

On reduction, the HPA are converted into heteropolyblues—"mixed valence" complexes which are coloured an intense blue as a result of intervalence electronic transitions. The optical density of the blues is frequently proportional to the degree of their reduction[10,50,57,65]. Correlations have been established between the changes in the energies of the spectral bands of the blues and the half-wave potentials of the reduction of the heteropolyanions and also the charge of the heteropolyanion[28,66]. Many blues have been isolated in the form of the acids or salts.

The molecular structure of the blues has not been established rigorously. Nevertheless it is generally accepted that, for a low degree of reduction, it is the same as the structure of the initial heteropolyanions[8,9,64]. This is indicated by the identity of the X : M ratios in the blues and in the initial heteropolyanions[10,67,68], the similarity of the ultraviolet absorption spectra of the blues and the heteropolyanions[67,69], electron diffraction data[69], and also the reversibility of the polarographic reduction of many Mo^{VI}, W^{VI}, and V^V heteropolyanions[10,48–50,65,70]. The exceptional ease of the heteropolyanion reduction and oxidation reactions is apparently also a consequence of the constancy of the structure of the polyanion in oxidation-reduction reactions.

Heteropolyanions are many-electron oxidants. The limiting number of electrons accepted by the HPA molecule without decomposition depends on its composiiton and the reduction conditions: it can reach six and more electrons[49,50,65,70–72]. The addition of electrons increases the basicity of the polyanion and may be accompanied by its protonation[49,50,65,70]. The oxidative properties of HPA are closely related to their acid properties. The degree of protonation of the heteropolyanion increases with increasing basicity of the initial heteropolyanion and the degree of reduction and with decrease of the pH of the medium. These data have been obtained in the study of the dependence of the half-wave potential of the polarographic reduction of the heteropolyanions on the pH.[49,50,65,70]. The reduction of the Mo^{VI} or W^{VI} heteropolyanions can be represented by the equation

$$XM_{12}^{VI}O_{40}^{x-8} + p\,e^- + q\,H^+ \rightarrow H_qXM_{12-p}^{VI}M_p^VO_{40}^{x+q-p-8}, \quad (8)$$

where $q \leq p$. On reduction in an acid aqueous solution (pH ≤ 1), the HPAn-W^{VI} of the 12-series can have a charge up to −6 without the addition of a proton, while in a neutral medium the charge can be up to −9. The corresponding values for the more stable $X_2W_{18}O_{62}^{2x-16}$ heteropolyanions are −8 and −12.[49] The heteropolyanions are protonated preferentially on reduction at the bridging O atoms probably in the angular M–O–M linkages[73,74]. As a rule, the molybdenum and tungsten blues are more resistant to hydrolysis than the initial heteropolyanions[49].

Many studies have been devoted to the location of the added electrons in the blues[50,65,66,73–80]. According to the results obtained by spectroscopic and magnetic methods, the electrons are located in the blues at the metal ions (without the formation of a many-centre molecular orbital). There is then thermal oscillation of the electrons between all the equivalent states at frequencies $\geq 10^8$ s^{-1}; the oscillation decays at a temperature close to that of liquid helium[75,76,80]. Such oscillation probably occurs via tunnel electron transitions between the metal ions in different oxidation states.

The oxidative properties of HPA depend on the nature of both the ligands and the central atom. The standard oxidation potentials of HPA are unknown because the equilibria in their solutions have not been investigated. Instead one uses the formal potentials ϕ^0 which depend on the pH and [HPA].[11,81] The potentials ϕ^0 are considered below relative to the normal hydrogen electrode.

The oxidation potential of the HPA is lower than the potential of the ligands in the polyanion; the HPA and ligand potentials then vary in parallel. The oxidising capacity decreases in the sequences[69,82,83]

$$\text{HPA-}V^V > \text{HPA-}Mo^{VI} > \text{HPA-}W^{VI};$$
$$VO_3^- > MoO_4^{2-} > WO_4^{2-}.$$

The central constant-valence ion influences the HPA potential via a change in the charge of the polyanion[83]. The oxidation potential of the heteropolyanion decreases with increasing ionic charge in the sequence

$$PW_{12}O_{40}^{3-}(0.15) > SiW_{12}O_{40}^{4-}(-0.05) \simeq GeW_{12}O_{40}^{4-}(-0.02) > BW_{12}O_{40}^{5-}(-0.36);$$

the reduction potentials (V) of the heteropolyanions at a graphite cathode in 1 M H_2SO_4 are given in brackets[76]. The oxidation potential of the HPA increases if X is a strong oxidant. Thus the reduction of $Co^{III}W_{12}O_{40}^{5-}$ to $Co^{II}W_{12}O_{40}^{6-}$ is characterised by $\phi^0 \cong 1$ V.[48,84]. The electrochemical reduction of $Fe^{III}W_{12}O_{40}^{5-}$ gives rise to a blue with Fe^{III} and not Fe^{II}.[50]

The oxidative properties of HPA-*n*, widely used as catalysts of liquid-phase oxidation, are of great interest. The introduction of vanadium(V) into HPA-Mo increases the oxidation potential of the HPA.[82,83,85]. It has been established by EPR that, on reduction of HPA-*n*, the electrons are located at the vanadium atoms[78]. The blues HPA-*n* dissociate in solution with elimination of VO^{2+}; the degree of degradative dissociation falls with decrease of *n* and with increase of pH.[86]

Fig. 2 illustrates the dependence of the HPA-*n* potential on the degree of reduction[81,87]. The reduction of HPA-*n* with $n = 1-4$ at pH 1 is characterised by a single jump of the potential $\phi^0 = 0.68-0.71$ V, which corresponds to the conversion of the entire vanadium(V) into vanadium(IV) in the heteropolyanion. The reduction process consists of a sequence of one-electron stages occurring at a single potential. The absence of individual one-electron stages can be explained by the protonation of the heteropolyanion in accordance with Eqn.(8), as a consequence of which the charge of the polyanion remains unaltered on its reduction[11]. The reduction of $PW_{12-n}V_nO_{40}^{(3+n)-}$ takes place analogously[48]. The oxidising capacity of HPA-*n* is somewhat inferior to that of the VO_2^+ ion, for which $\phi^0 = 0.87$ V at pH 1.[88] However, in contrast to the one-electron oxidant VO_2^+, the HPA-*n* is a complementary partner for one-, two-, and many-electron reductants. This makes it possible to employ the HPA-*n* as catalysts of a wide variety of oxidation reactions.

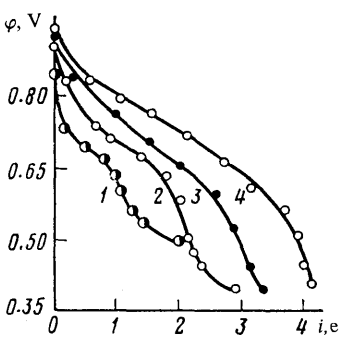

Figure 2. Dependence of the oxidation potential of HPA-*n* on the degree of reduction *i* (relative to the normal hydrogen electrode, pH 1.1, reductant—hydrazine):[81,87] *1*) $n = 1$; *2*) $n = 2$; *3*) $n = 3$; *4*) $n = 4$.

4. HPA as Oxidants Acting Reversibly

The application of HPA in homogeneous oxidative catalysis is based in many instances on their capacity for being reversibly oxidised [Eqns.(1) and (2)].[1,2] The thermodynamic condition for the occurrence of reactions (1) and (2) is

$$\varphi^0_{Red} < \varphi^0_{HPA} < \varphi^0_{O_2} = 1.23\text{V}.$$

The "mixed-ligand" HPA of structural type (I), such as HPA–Mo–V, HPA–W–V,[1,2] and HPA–Mo–W,[89] are reversibly oxidisable in the range of potentials ϕ^0 of interest for homogeneous catalysis. The HPA-*n* ($PMo_{12-n}V_n$, $n = 2-6$) have been studied in greatest detail. HPA-*n* containing at least two V atoms are reversible-action oxidants. The Mo and V heteropolyacids incorporating ligands of the same type do not have this property because their blues are hardly oxidised by the oxygen in solution. The W blues are readily oxidised by oxygen in solution[90] and are oxidised even by water (with liberation of H_2).[91] However, the HPA-W have a potential which is too low for their employment in oxidative catalysis. It is noteworthy that crystalline monometallic HPA, for example PMo_{12}, becomes reversible oxidants under more severe conditions at 200–300 °C (see Section IV).

The central atom does not exert a significant influence on the reversible oxidisability of the HPA. Furthermore, its presence is sometimes not required for the occurrence of reactions (1) and (2). For example, the mixed Mo–V isopolycompounds are reversible-action oxidants[92]. Among all the HPA having this property, the HPA-*n* are of greatest interest because of the ease of their preparation, their stability in solution, and their high reactivity.

We shall now consider the mechanism of reactions (1) and (2). It has been suggested that the true oxidants in reaction (1) are one-electron oxidants, namely the VO_2^+ ions formed as a result of the reversible dissociation reaction (4).[93] However, this mechanism is not general. The electrochemical reduction of the HPA can proceed either via successive one-electron transfers or via the simultaneous transfer of several electrons[48,49,65,70]. The oxidation of the test reagent Ph(t-Bu)CHOH by HPA-6 in aqueous solution proceeds preferentially (to the extent of 67%) via a heterolytic mechanism involving oxidation by polyanions and partly (to the extent of 33%) via a homolytic mechanism involving oxidation by VO_2^+ ions[94].

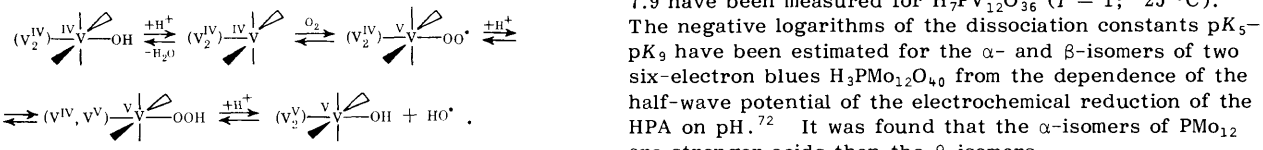
The free VO^{2+} ion is oxidised by oxygen only at pH $\geq$ 2.5. The degrees of conversion of $VOSO_4$ (0.01 M) at 14 °C after 1 week at pH 2.5 and 3.5 are 1.5 and 21% respectively[95]. In more acid media vanadium(IV) can be oxidised via reaction (2) only when it is part of the composition of the heteropolyanion. It follows from the potentials for the HPA-*n* ($\phi^0 \geq 0.68$ V) and ϕ^0 ($O_2/HO_2^\cdot$) = −0.32 V [96] that the one-electron oxidation of the blues H_i(HPA-*n*) with formation of the free radical $HO_2^\cdot$ is thermodynamically unfavourable[97–100]. The mechanism of reaction (2) depends on *i*—the degree of reduction of the blue. The blues H_i(HPA-*n*) with i, $n \geq 4$ are oxidised via the transfer of four electrons in the complex of H_i(HPA-*n*) with O_2 without the release of the free radicals into space[97–99]. For $i < 4$, free radicals are formed in reaction (2), which is indicated by the detection of acetone when reaction (2) is carried out in the presence of isopropyl alcohol[97].

The mechanism of reaction (2) was specified in detail in the study of the kinetics of the oxidation of weakly reduced blues with $i < 1$.[100] Such values of *i* are in fact usually observed in catalytic processes involving HPA-*n*. The solution of the blue then contains the anions H_1(HPAn-*n*) and HPAn-*n*. The mechanism of reaction (2) is examined below in relation to the oxidation of H_i(HPA-3).

For $i < 1$, the oxidation of H_i(HPA-3) proceeds in accordance with the kinetic equation

$$w = k[V^{IV}]^3[O_2]/[HPAn\text{-}3]^2 \qquad (9)$$

which corresponds to the mechanism



$$2PMo_9V_2^VV^{IV} \rightleftarrows PMo_9V_3^V + PMo_9V^VV_2^{IV}; \qquad (10)$$

$$PMo_9V^VV_2^{IV} + PMo_9V_2^VV^{IV} \rightleftarrows PMo_9V_3^V + PMo_9V_3^{IV}; \qquad (11)$$

$$PMo_9V_3^{IV} + O_2 + 3H^+ \xrightarrow{\text{slow}} PMo_9V_3^V + H_2O + HO^\cdot \quad (12)$$

$$PMo_9V_2^VV^{IV} + HO^\cdot + H^+ \rightarrow PMo_9V_3^V + H_2O,$$

where $PMo_9V_3^V$ = HPAn-3. Stages (10) and (11) are rapid disproportionation reactions which apparently proceed via electron transfer. The rate-limiting stage (12) includes the formation of a vacancy in the coordination sphere of H_3(HPA-n). Next a complex of H_3(HPA-n) with O_2, in which successive transfer of three electrons accompanied by the addition of H^+ takes place, is formed:

The complex of the heteropolyanion with O_2 apparently has a linear or angular structure.

The rate of oxidation of H_i(HPA-n) with $n > 3$ decreases in the sequence H_i(HPA-3) > H_i(HPA-4) > H_i(HPA-6), which can be explained by the increase of ϕ^0 for HPA-n in the same sequence (Fig.2).[100] The oxidation of H_i(HPA-2) proceeds similarly to the reaction with H_i(HPA-3) and is described by the kinetic equation (9). The process probably involves the disproportionation reaction

$$2PMO_{10}V_2 \rightleftarrows PMo_9V_3 + PMo_{11}V,$$

which is indicated by the fact that the three-electron mechanism is more favourable than the two-electron mechanism[10]. The latter has also been confirmed by the thermodynamic data for the reduction of HPA-n (Fig.2) and O_2.[101] The two-electron mechanism apparently operates in the oxidation of $SiW_{10}^{VI}W_2^V$ by water with evolution of hydrogen[91].

5. The Acid Properties of HPA

Heteropolyacids are strong Brønsted acids[8-10,15]. Their strength is much greater than that of simple acids formed by the corresponding heteroatoms[102]. The basicity of the HPA, which follows from the Keggin structure $H_{8-x}X^xM_{12}^{VI}O_{40}$, has been demonstrated by numerous direct measurements[10,23,85,102-104]. When Mo^{VI} or W^{VI} is substituted by V^V and on reduction of the HPA, the basicity increases by unity for each V^V ion and for each electron added. An increase of basicity is accompanied by a decrease of the acid strength of the HPA.[8-10,102,103].

Information about the proton structure of the HPA hydrates has been obtained mainly by broad-line ^1H NMR.[73,74,105-107]. Two types of protons have been found in the HPA molecules: the non-localised hydrated and localised unhydrated H^+. The former are linked to the polyanion as a whole and rapidly exchange with the protons of the water molecules in the hydration shell of the HPA. The protons of the second type appear on reduction of the HPA and on substitution of Mo^{VI} or W^{VI} by V^V. These protons are more strongly bound to the HPA and are located at the O atoms of the angular M–O–M bonds. Analogous conclusions have been reached on the basis of ^{17}O NMR data for HPA solutions[33,34].

The available acid dissociation constants of the HPA are limited as a consequence of the instability of many polyanions in solution. In aqueous solution the stepwise nature of the first three dissociations of the HPA is usually undetectable as a consequence of the levelling influence of the solvent[15,108,109]. Non-aqueous solvents have a differentiating effect on the dissociation of the HPA.[103]

According to conductimetric data, the acids $H_4PMo_{11}VO_{40}$ and $H_5PMo_{10}V_2O_{40}$ in aqueous solution are strong 1–4 and 1–5 electrolytes respectively[104]. The average $pK_{1-4} = 0.75$ was found for $H_4PMo_{11}VO_{40}$.[42] In $H_5PMo_{10}V_2O_{40}$, $H_6PMo_9V_3O_{40}$, and $H_7PV_{12}O_{36}$ the first three protons are split off completely, while the remaining are split off in steps (as the pH is increased). $pK_4 = 1.16$ and $pK_5 = 2.14$ have been found for $H_5PMo_{10}V_2O_{40}$ and $pK_4 = 1.25$, $pK_5 = 1.62$, and $pK_6 = 2.00$ have been found for $H_6PMo_9V_3O_{40}$ ($I = 0$; 25 °C).[109] $pK_4 = 3.4$, $pK_5 = 4.9$, $pK_6 = 6.4$, and $pK_7 \cong 7.9$ have been measured for $H_7PV_{12}O_{36}$ ($I = 1$; 25 °C).[108] The negative logarithms of the dissociation constants pK_5–pK_9 have been estimated for the α- and β-isomers of two six-electron blues $H_3PMo_{12}O_{40}$ from the dependence of the half-wave potential of the electrochemical reduction of the HPA on pH.[72] It was found that the α-isomers of PMo_{12} are stronger acids than the β-isomers.

Table 1. The acid dissociation constants of HPA in non-aqueous media at 25 °C and $I = 0$ (the pK_i were estimated from the Bjerrum equation).[40,41]

Acid	Acetone			Ethanol			Acetic acid	Acid	Acetic acid
	pK_1	pK_2	pK_3	pK_1	pK_2	pK_3	pK_1		pK_1
H_3PW_{12}	(1.6)	(3.0)	3.98	(1.6)	(3.0)	4.10	4.77; 4.75 [103]	H_4GeW_{12}	4.25 [103]
$H_4PW_{11}V$	(1.8)	(3.2)	4.37	—	—	—	4.74	$H_5GeW_{11}V$	4.65 [103]
$H_5PW_{10}V_2$	—	—	—	—	—	—	4.78	$H_6GeW_{10}V_2$	4.60 [103]
H_4SiW_{12}	(2.0)	3.61	(5.3)	(2.0)	3.96	(6.3)	4.97; 4.75 [103]	$HClO_4$	4.87 [113]
								HBr	5.6 [113]
H_3PMo_{12}	(2.0)	3.62	(5.3)	(1.8)	3.41	(5.1)	4.70	H_2SO_4	7.0 [113]
$H_4PMo_{11}^{VI}Mo^V$	(2.1)	3.69	(5.5)	(1.9)	3.77	(5.9)	—	HCl	8.4 [113]
$H_4PMo_{11}V$	(2.1)	3.73	(5.6)	(1.9)	3.74	(5.8)	4.68	HNO_3	10.1 [113]
H_4SiMo_{12}	(2.1)	3.90	(5.9)	—	—	—	4.78		

Note. The dissociation constant of PW_{12} in ethanol were measured conductrimetrically as in the study of Kulikov and Kozhevnikov[41]. $pK_1 = 4.0$ for HCl in acetone[88] and $pK_1 = 3.57$ for HNO_3 in ethanol[88].
The numbers in square brackets here and in Table 2 denote references (Ed.of Translation).

The acidity of the HPA has been studied more widely in non-aqueous media[40,41,103,110]. In such media the heteropolyanions are much more resistant to solvolysis[10,12]. Table 1 lists the thermodynamic dissociation constants of the HPA in ethanol, acetone, and acetic acid, measured conductrimetrically[40,41] and potentiometrically[103]. In acetone and ethanol, which are solvents of moderate polarity, the first proton of all the HPA and also the second proton in $H_3PW_{12}O_{40}$ and $H_4PW_{11}VO_{40}$ are fully dissociated at concentrations in the range 10^{-6}–10^{-3} M. The subsequent protons are only partly dissociated. In the weakly polar acetic acid the HPA behave as monobasic acids whose strength is similar to that of $HClO_4$.[40,41]

The weak dependence of the acid strength of the HPA on their composition is striking. This is due to the large size of the heteropolyanion and the unusual proton structure of the HPA.[40,41,105,109]. In aqueous and non-aqueous solutions the HPA consist of solvate-separated ion pairs $H^+(H_2O)_m \| HPAn^-$, in which the protons are hydrated and linked to the anion as a whole and not to a specific centre in the heteropolyanion[40,41]. The structure of the HPA is satisfactorily consistent with the model consisting of a

charged sphere with a large radius on the surface of which the acid protons are accommodated (with a minimal electrostatic repulsion energy) in the form of point charges[40,41].

The acidity of HPA-W is greater than that of HPA-Mo,[41,107,111] which agrees with the higher negative charge on the O atoms in HPA-Mo compared with HPA-W.[111] According to X-ray electronic spectroscopic data, the effective charges in the PMo_{12} heteropolyanion are distributed as follows: $[P^{2.5+}Mo_{12}^{1.1+}O_{40}^{0.43-}]^{3-}$.[111] The HPA are much stronger than the usual inorganic acids, which is true of both dilute and concentrated HPA solutions. The acidity of concentrated aqueous and non-aqueous $H_3PW_{12}O_{40}$ solutions (≤50 wt.%) is higher than that of $HClO_4$ and H_2SO_4 solutions by 1–1.5 units of the Hammett acidity function H_0.[112]

III. HETEROPOLYACIDS AS LIQUID-PHASE OXIDATION CATALYSTS

The liquid-phase oxidation reaction takes place in solutions in the presence of HPA-*n* or their soluble salts and more rarely other mixed HPA capable of being reversibly oxidised. The stages of the catalytic process—reactions (1) and (2)—can be carried out simultaneously in a single reactor or separately. In the latter case contact between the organic substrates and O_2 is eliminated. The catalysts may be the HPA-*n* themselves (one-component systems) or in combination with other compounds (two-component systems). Among the latter, the HPA-*n* + Pd^{II} system is of greatest importance. Homogeneous catalysts based on HPA consist as a rule of complex equilibrium mixtures of polyanions of different compositions with products of the degradative dissociation of the heteropolyanion. A common deficiency of homogeneous catalysts is the difficulty of separating the reaction products from the catalyst when high-boiling products are formed. The reactions in which the HPA-*n* are used as one- and two-component catalysts are considered below and the mechanism of their catalytic action is discussed.

1. One-Component Systems

(*a*) *Oxidation of sulphur compounds.* The oxidation of H_2S, SO_2, and mercaptans catalysed by HPA-*n* is promising for the elimination of sulphur compounds from industrial and natural gases, while the oxidation of alkyl and aryl sulphides is promising for the industrial synthesis of sulphoxides and sulphones[114–118]:

$$H_2S + 1/2O_2 \xrightarrow[H_2O,20^\circ C]{\text{HPA-}n} S + H_2O\ ; \qquad (13)$$

$$SO_2 + 1/2O_2 + H_2O \xrightarrow[H_2O,20^\circ C]{\text{HPA-}n} H_2SO_4\ ; \qquad (14)$$

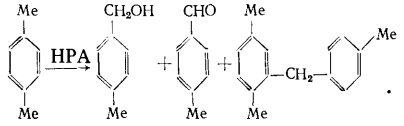
$$2RSH + 1/2O_2 \xrightarrow[80^\circ C]{\text{HPA-}n} RSSR + H_2O\ ; \qquad (15)$$

$$R_2S + 1/2O_2 \xrightarrow[Me_2CO,120^\circ C]{\text{HPA-}n} R_2SO\ ; \qquad (16)$$

$$R_2SO + 1/2O_2 \xrightarrow[Me_2CO,120^\circ C]{\text{HPA-}n} R_2SO_2\ . \qquad (17)$$

In reaction (13) HPA-6 has a selectivity of ~97%; ~3% of H_2S is oxidised to H_2SO_4.[116] Reactions (16) and (17) are highly selective—up to 100% with respect to the sum of R_2SO and R_2SO_2 for a 100% degree of conversion of the sulphide[115]; on this basis, a non-radical mechanism has been proposed for these processes[115]. However, subsequent studies established that the oxidation of diethyl sulphide with $^{18}O_2$ leads to the formation of a sulphoxide enriched in the ^{18}O isotope to the extent of 44–54%. It has also been shown that, in the absence of oxygen, HPA-*n* does not oxidise Et_2S and Et_2SO to the sulphone. These data indicate a radical mechanism of reactions (16) and (17).[119]

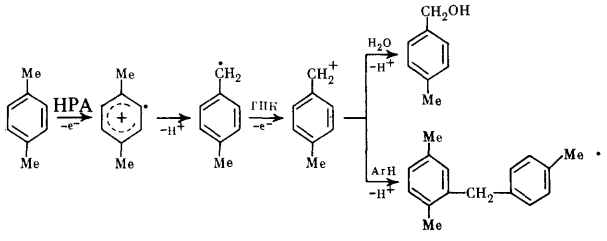
(*b*) *Bromination of aromatic compounds.* It has been recently established[120] that HPA-*n* catalyse the oxidative bromination of arenes in the ring with participation of HBr as the brominating agent and O_2 as the oxidant. In the case of arenes, namely benzene, its derivatives, naphthalene, thiophen, etc., the process takes place in the HOAc–H_2O–H_2SO_4 solution at 50–100 °C and includes the following stages:



$$2HBr + HPA\text{-}n + 2H^+ \rightarrow Br_2 + H_2(HPA\text{-}n); \qquad (18)$$

$$\begin{gathered} ArH + Br_2 \rightarrow ArBr + HBr \\ H_2(HPA\text{-}n) + 1/2O_2 \rightarrow H_2O + HPA\text{-}n. \end{gathered} \qquad (19)$$

Reaction (18) takes place readily in the absence of ArH. The presence of stage (19) has been confirmed by the similarity of the isomeric compositions of the products and of the relative rates of oxidative bromination and the bromination of ArH by molecular bromine. The oxidative bromination has the advantage that one can use Br^- ions instead of Br_2 in the reaction, but it suffers from the disadvantage that the alkyl substituents in ArH are oxidised in a side reaction.



The halogenation of arenes by HCl and HI does not take place under analogous conditions, because the oxidation potential of HPA-*n* is insufficiently high for the oxidation of HCl to Cl_2; the I^- ion is readily oxidised by HPA-*n* to I_2 but I_2 is too weak as an iodinating agent.

(*c*) *Oxidation of hydrocarbons.* Heteropolyacids with a sufficiently high oxidation potential oxidise alkyl substituents in the aromatic ring[121–123]. Thus $K_5Co^{III}W_{12}O_{40}$ oxidises methylbenzenes under heterogeneous conditions in a non-catalytic process to a mixture of aldehydes, alcohols, and diarylmethanes[121]:

This reaction has been carried out catalytically using HPA-*n*.[120] In acetic acid in the presence of $K_5CoW_{12}O_{40}$ and potassium acetate, methylbenzenes undergo ring acetoxylation[123].

The proposed mechanism involves electron transfer from ArH to HPA with formation of an aromatic radical-cation whose reactions give rise to benzyl alcohol and diarylmethane[120,121]:

The alcohol undergoes further oxidation with formation of the aldehyde. When H is replaced by D in the methyl group, a large isotope effect is observed ($k_H/k_D = 6$), showing that the proton is removed from the radical-cation in the rate-limiting stage.

Heteropolyacids of different compositions have been used as catalysts of the liquid-phase oxidation of tetralin[124] and olefins[125].

(*d*) *Epoxidation of olefins by aromatic hydroperoxides.* The salts of HPA-Mo are effective catalysts of the industrially important reaction in which olefins are epoxidised by organic hydroperoxides[126–128]:

$$RCH=CH_2 + R'OOH \xrightarrow[80\sim110^\circ C]{HPA} RCH-CH_2 + R'OH \quad (20)$$

The application of the HPA themselves is undesirable because they catalyse the acid decomposition of organic hydroperoxides[129]. The mechanism of the epoxidation of olefins has been examined[128,130,131]. Molybdenum compounds are in many instances the most active catalysts. The true catalysts are probably the glycol complexes of molybdenum(VI) formed in the reaction mixture regardless of the initial ligand environment and the degree of oxidation of the metal[130,132].

The epoxidation of hex-1-ene by cumenyl hydroperoxide in isopropyl alcohol in the presence of $Na_3PMo_{12}O_{40}$ takes place without an inductive period and with a selectivity close to 100%.[133] A mechanism including rapid degradative dissociation of $PMo_{12}O_{40}^{3-}$ with formation of monomeric molybdenum(VI) and a defective heteropolyanion has been proposed on the basis of kinetic data and the study of the composition of the spent catalyst:

$$PMo_{12}O_{40}^{3-} \rightleftarrows HPAn' + nMo^{VI}.$$

The molybdenum(VI) monomers are active in reaction (20), although one cannot fully rule out also catalysis by HPAn' species. The catalytic activity of HPAn-Mo decreases slightly in the sequence $PMo_{12} > SiMo_{12} \cong PMo_{11}V$, in which the resistance of the heteropolyanion to hydrolysis increases; HPAn-Mo is much more reactive than HPAn-W.[133]

2. Two-Component Catalysts

(a) The HPA-n + Pd^{II} system. The HPAn-*n* + Pd^{II} system belongs to the class of the most important catalysts of liquid-phase oxidation based on HPA-*n*. It is highly selective in many reactions involving the oxidation of organic substances by palladium(II) salts:

$$S + Pd^{II} \rightarrow P + Pd^0, \quad (21)$$

where S and P are the substrate and reaction products. All the catalytic processes presented in Table 2 are based on a combination of reactions (21), (1), and (2) in which Red = Pd^0 and Ox = Pd^{II}. Among these, the oxidation and acetoxylation of olefins, the oxidation of alcohols, the oxidative coupling of organic compounds etc. are reactions of practical importance[1,2]. The applications and the mechanism of the action of the HPA-*n* + Pd^{II} system have been examined in a number of reviews[1,2,6,134,135].

Analogous catalytic systems based on other oxidants acting reversibly, such as Cu^{II}, Fe^{III}, NO_3^-, etc. are known[136–138]. Among them, $CuCl_2$ is of greatest importance:

$$Pd^0 + 2CuCl_2 \rightarrow PdCl_2 + 2CuCl;$$
$$2CuCl + 1/2O_2 + 2HCl \rightarrow 2CuCl_2 + H_2O.$$

A deficiency of the $CuCl_2$ + Pd^{II} redox system is its secondary chlorinating activity, the pronounced corrosion of the apparatus, and also the low catalytic activity of palladium(II). Like stronger oxidants, the HPA-*n* are capable of oxidising palladium(0) to palladium(II) in the absence of Cl^- ions. The HPA-*n* + Pd^{II} system is therefore free from the above deficiencies[1,2,6].

It has been established that many reactions catalysed by the HPA-*n* + Pd^{II} system proceed mainly via a multistage heterolytic mechanism with stages (21), (1), and (2).[2] Thus the oxidation of isopropyl alcohol in aqueous solution proceeds preferentially via the following stages[139,140]:

$$Me_2CHOH + Pd^{II} \rightarrow Me_2CO + Pd^0 + 2H^+;$$
$$Pd^0 + HPA\text{-}n + 2H^+ \rightarrow Pd^{II} + H_2(HPA\text{-}n);$$
$$H_2(HPA\text{-}n) + 1/2O_2 \rightarrow HPA\text{-}n + H_2O.$$

However, the radical pathway in the oxidation of the substrate, due to the intermediate formation of the HO$^\cdot$ free radicals in reaction (2), may also make an appreciable contribution under certain conditions[97,139,140], for example:

$$Me_2CHOH + HO^\cdot \rightarrow Me_2\dot{C}OH + H_2O;$$
$$Me_2\dot{C}OH + O_2 \rightarrow MeCOO^\cdot;$$
$$\mid OH$$
$$Me_2COO^\cdot + H_i(HPA\text{-}n) \rightarrow Me_2CO + H_2O_2 + H_{i-1}(HPA\text{-}n).$$
$$\mid OH$$

Table 2. The liquid-phase oxidation reactions catalysed by the HPA + Pd^{II} system [Pd^{II} in the form of $PdSO_4$, $Pd(OAc)_2$, or $PdCl_2$].

Reaction	Substrate	HPA
$RCH=CH_2 + {}^1/_2O_2 \xrightarrow[H_2O]{20\sim110^\circ C} RCCH_3$ (O)	C_2-C_8 α-olefins	HPA-*n* (*n*=2–6) [141–14]; $H_3PW_6Mo_6O_{40}$ [89]
$RCH=CH_2 + HOAc + {}^1/_2O_2 \xrightarrow[HOAc]{90\sim125^\circ C} R(AcO)C=CH_2 + H_2O$	R=H, *Me*	HPA-6 [146]
$C_2H_4 + HOAc + {}^1/_2O_2 \xrightarrow[HOAc]{20\sim40^\circ C} AcOCH_2-CH_2OH$	ethylene	HPA-6 [147]
$R_1R_2CHOH + {}^1/_2O_2 \xrightarrow[H_2O]{90\sim125^\circ C} R_1R_2C=O + H_2O$	R_1=H, R_2=Me, Pr; R_1=Me, R_2=Et; R_1, R_2=Me	HPA-*n* (*n*=2–6) [140, 148]
$ArH + HOAc + {}^1/_2O_2 \xrightarrow[HOAc]{90^\circ C} ArOAc + H_2O$	ArH = benzene, toluene	HPA-*n* (*n*=2–6) [149]
$2ArH + {}^1/_2O_2 \xrightarrow[HOAc]{50\sim90^\circ C} Ar-Ar + H_2O$	ArH = PhR (R=H, Me, Et, iso-Pr, *n*-Pr, OMe, OPh, NMe_2, Cl, COOH, CF_3), *o*-, *m*-, *p*-xylene, mesitylene, durene, thiophen, furan, sylvan	HPA-2, $H_6SiW_{10}V_2O_{40}$ [150–152]
$ArH + C_2H_4 + {}^1/_2O_2 \xrightarrow[DMF]{90^\circ C} ArCH=CH_2 + H_2O$	ArH = benzene, thiophen, furan	HPA-2, HPA-3 [153]
$R_1R_2CHCHR_3COR_4 + {}^1/_2O_2 \xrightarrow[H_2O]{60\sim70^\circ C} R_1R_2C=CR_3COR_4 + H_2O$	R_1-R_4 = H, alkyl, aryl, etc.	HPA-2 [154]

In acid solutions the oxidants for palladium(0) in reaction (1) are apparently heteropolyanions (complementary oxidation) and the VO_2^+ ions formed on dissociation of the heteropolyanion in accordance with Eqn.(4) (non-complementary oxidation).[135] The relative contributions of the heteropolyanions and VO_2^+ to reaction (1) are unknown, because the equilibrium constants of reaction (4) are not available and there are no data concerning the state of VO_2^+ in HPA-*n* solutions. The VO_2^+ ions probably form complexes with HPAn-*n*, which may influence the reactivity of VO_2^+. The question of the value of $\phi^0(Pd^{II}/Pd^0)$ has been discussed[1,6] in connection with the choice of HPA as an oxidant acting reversibly.

Apart from the HPA-*n*, other vanadium-containing HPA-Mo and HPA-W with central Si^{IV}, As^V, etc. atoms can also be used in combination with Pd^{II}.[2] It has been found recently that HPA having the composition $H_3PMo_{12-n}W_nO_{40}$ can be used as reversible-action oxidants in the oxidation of but-1-ene to ethyl methyl ketone. The catalyst incorporating $PdSO_4$ + $H_3PMo_6W_6O_{40}$ is the most active[89]. In principle there is also a possibility of employing HPA analogously in processes involving $PtCl_4^{2-}/Pt^0$ or $PtCl_6^{2-}/PtCl_4^{2-}$, but so far no examples of such reactions are known.

(b) The HPA-n + Tl^{III} system. The non-catalytic oxidation of unsaturated hydrocarbons by thallium(III) salts is used widely in preparative organic chemistry[155]. The

reactions cannot be catalysed because of the difficulty of oxidising thallium(I) to thallium(III) with oxygen. The possibility of oxidising thallium(I) to thallium(III) with oxygen in the presence of copper(II) and iron(III) halides has been noted in a number of patents[156,157].

It has been found that HPA-*n* (n = 2–8) easily oxidise thallium(I) to thallium(III) in aqueous acid or aqueous acetic acid solutions in the presence of Br^- ions[158]. The role of the Br^- ions reduces to diminishing $\phi^0(Tl^{III}/Tl^I)$ as a result of the formation of the thallium(III) bromide complex:

$$TlBr + HPA\text{-}n + 2HBr \rightarrow TlBr_3 + H_2(HPA\text{-}n). \quad (22)$$

Since H_2(HPA-*n*) is rapidly oxidised by oxygen, the HPA-*n* + $TlBr_3$ system can serve as a catalyst of the oxidation of organic substances by oxygen. An example of such a reaction is provided by the bromination of C_6–C_8 olefins with formation of dibromoalkanes and bromohydrins[158]. Further studies of the HPA-*n* + Tl^{III} redox system with other ligands, ensuring the formation of oxygen derivatives of the substrate being oxidised, are desirable.

(*c*) *The HPA-n + Ru^{IV} and HPA-n + Ir^{IV} systems.* Alkanes are oxidised by HPA-6 in aqueous solution in the presence of ruthenium(IV) and iridium(IV) chloride complexes (pH 1; 100–120 °C).[159] The oxidation of propane yielded acetone. The rate of oxidation of the t-C–H bond is higher than that of the s-C–H bond. The reaction mechanism has not been investigated, but it is probably analogous to the mechanism of the oxidation of alkanes by the Cr^{VI} + Ru^{IV} system[159].

(*d*) *The HPA-n + I_2 system.* The ability of I_2 to add rapidly and reversibly to the double bond of an olefin and the ease of the oxidation of I^- to I_2 by HPA-*n* constitute the basis of the application of the HPA-*n* + I_2 system in the oxidation of olefins to glycol ethers[160]:

$$CH_3CH{=}CH_2 + HOAc + 1/2O_2 \xrightarrow[HOAc]{HPA\text{-}6+I_2} \underset{\underset{OAc}{|}}{\overset{\overset{OH}{|}}{CH_3CH{-}CH_2}} .$$

The catalytic process can be represented by the following stages:

$$CH_3CH{=}CH_2 + I_2 + H_2O \rightleftarrows \underset{\underset{I}{|}}{\overset{\overset{OH}{|}}{CH_3CH{-}CH_2}} + HI; \quad (23)$$

$$\underset{\underset{I}{|}}{\overset{\overset{OH}{|}}{CH_3CH{-}CH_2}} + HOAc \rightarrow \underset{\underset{OAc}{|}}{\overset{\overset{OH}{|}}{CH_3CH{-}CH_2}} + HI; \quad (24)$$

$$2HI + HPA\text{-}6 \rightarrow H_2(HPA\text{-}6) + I_2; \quad (25)$$

$$H_2(HPA\text{-}6) + 1/2O_2 \rightarrow HPA\text{-}6 + H_2O. \quad (26)$$

Stage (24) is apparently rate-limiting[160]. Instead of HPA-*n*, it is possible to use also other oxidants acting reversibly. The most active catalyst is $CuCl_2$ + I_2; here copper(II) acts as an electrophile in collaborating in the elimination of the halogen from the carbon atom in stage (24).[160] The catalysis by metal complexes in halide ion elimination reactions has been examined[161].

IV. HETEROPOLYACIDS AS CATALYSTS OF HOMOGENEOUS REACTIONS OF THE ACID TYPE

The likely usefulness of the HPA as acid catalysts is determined by their high Brønsted acidity. In aqueous solutions which level off the acidities of strong acids, the HPA have no significant advantages over the usual inorganic acids. However, in non-aqueous media which differentiate acidities, the HPA proved to be much more effective than inorganic acid, because under such conditions their acidities are higher. In reactions of the acid type oxidising properties are usually harmful, since the acidity of the HPA is lowered when they are reduced. The HPA-W are therefore preferable to the HPA-Mo, because the former compounds are stronger acids and weaker oxidants than the latter.

1. Hydration and Esterification of Olefins

The hydration of olefins constitutes an industrial method of synthesising alcohols (particularly ethanol and isopropyl alcohol):

$$RCH{=}CH_2 + H_2O \overset{H^+}{\rightleftarrows} \underset{\underset{OH}{|}}{RCHCH_3} . \quad (27)$$

The reaction is carried out at an elevated pressure ensuring the displacement of equilibrium (27) to the right. The application of the HPA-W on solid carriers as heterogeneous catalysts of the hydration of olefins has been known for a long time[162,163]. Thus $H_4SiW_{12}O_{40}$ and $NaH_3SiW_{12}O_{40}$ (10^{-5}–10^{-3} M) catalyse the hydration of C_2–C_4 olefins in aqueous solution at temperatures in the range 170–350 °C and pressures in the range (1–5) × 10^4 kPa.[164] The reaction is carried out in the presence of silicic acid at a concentration of 0.5–4.5 g litre^{-1}, which increases the stability and activity of the catalyst. The process selectivity reaches 95–99% and the alcohol content in the reaction mixture is 8–12%.

The analogous reaction of C_3–C_{20} olefins in solution in carboxylic acids in the presence of 10^{-4}–10^{-2} M HPA-Mo or HPA-W at 20–140 °C leads to the formation of esters[165,166]:

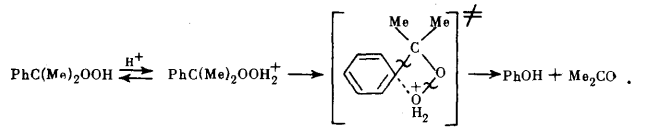
$$RCH{=}CH_2 + HOAc \xrightarrow{HPA} \underset{\underset{OAc}{|}}{RCHCH_3} . \quad (28)$$

The selectivity of reaction (28) reaches 100% for a 90% conversion of the olefin.

The formation of 2-hexyl acetate from hex-1-ene solution in acetic acid proceeds in accordance with the kinetic equation:

$$w = k_1[HPA][C_6H_{12}] - k_{-1}[HPA][ester],$$

where k_1 = 0.23 litre mol^{-1} s^{-1} and k_1/k_{-1} = 6.2 for $H_3PW_{12}O_{40}$ at 110 °C.[167] Since the HPA are weak acids in solution in acetic acid ($pK_1 \cong 5$),[41] the first order term in HPA shows that the reaction proceeds via general acid catalysis by undissociated HPA molecules. The catalytic activity of the HPA is almost independent of their composition and is ~100 times higher than the activity of H_2SO_4, which agrees well with the dissociation constants of the acids in acetic acid (Table 1). In the course of reaction (28), the HPA-Mo are appreciably reduced and for this reason their values of k_1 are lower than for the HPA-W.



2. The Composition of Alkylphenyl Hydroperoxides

This important reaction constitutes the basis of the industrial method of the joint synthesis of phenol and acetone. It is catalysed by many HPA-Mo and HPA-W:[129,168,169]

$$PhC(Me)_2OOH \xrightarrow[40\rightarrow90\,^\circ C]{HPA} PhOH + Me_2CO . \quad (29)$$

Reaction (29) proceeds with a quantitative yield in solution in acetone or in an equimolar mixture of phenol and acetone for [HPA] = 0.01–0.08 wt.%. The selectivity of the HPA is so high that the phenol obtained does not require purification before its subsequent hydrogenation to cyclohexanol in the presence of the palladium catalyst[168].

The acid decomposition of alkylphenyl hydroperoxides proceeds via the protonation of the peroxy-group and subsequent synchronous rearrangement in the cyclic transition state (see Kozhevnikov and Kulikov[128] and the references quoted therein):

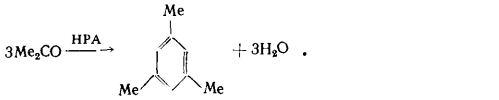
Reaction (29) in acetone in the presence of $H_3PMo_{12}O_{40}$ proceeds via the mechanism of general acid catalysis:

$$w = (k_H[H^+] + k_A[H_3PMo_{12}O_{40}^-])[ROOH] .$$

$k_H = 4.5$ litre mol^{-1} s^{-1} and $k_A = 14$ litre mol^{-1} s^{-1} were obtained at 25 °C.[129] Under the conditions indicated, the acid $H_2PMo_{12}O_{40}$ has a fully dissociated first proton and partly the second proton[40]. The main contribution comes from the $k_H[H^+]$ specific acid catalytic pathway. The catalytic activity of the HPA in acetone varies in parallel with their dissociation constants and is higher by a factor of 10^3 than the activity of H_2SO_4. HPA on γ-Al_2O_3 also catalyse reaction (29), but the activity of the heterogeneous catalyst is much lower than that of the homogeneous catalyst[129].

3. Other Reactions of the Acid Type

The acids PW_{12}, PMo_{12}, and SiW_{12} are effective homogeneous catalysts of the alcoholysis of epoxides with formation of hydroxyethers:



where R_{1-3} = H, alkyl, or aryl[170]. In the presence of an excess of the alcohol the polymerisation of epoxides does not take place. On interaction with allyl alcohol, epichlorohydrin gives rise to 1-allyloxy-3-chloro-2-propanol in 95–97% yield:

The reaction is of first order with respect to epichlorohydrin and the HPA. The strongest acid PW_{12} is also the most active catalyst among the HPA investigated; H_2SO_4 and $HClO_4$ are less effective than the HPA.

The acids $H_{8-x}X^xM_{12}O_{40}$ (X = Si^{VI} or P^V; M = Mo^{VI} or W^{VI}) on a solid carrier or in solution catalyse the condensation of alkyl ketones to aromatic compounds[171,172]. In the presence of a heterogeneous catalyst, the reaction requires severe conditions (200–450 °C, 7×10^3 kPa).[171] The homogeneous condensation proceeds under milder conditions. Thus in a solution of 40 wt.% HPA in acetone at 25 °C, aromatic hydrocarbons (mesitylene and other alkylbenzenes) are obtained at 25 °C in the course of 1–10 days in 40–55% yield relative to the reacted ketone in a mixture with water, methyl acetate and mesityl oxide[172]:

The degree of conversion of acetone is 25–45% and the catalyst can be used repeatedly.

In the presence of the HPA as homogeneous or heterogeneous acid catalysts, other reactions of practical importance also take place, such as the alkylation of aromatic compounds by olefins[173], the carbonylation of alcohols, the synthesis of formic acid from CO and water[174], the oligomerisation of olefins[175], etc.

V. APPLICATIONS OF HETEROPOLYACIDS IN HETEROGENEOUS CATALYSIS

Heteropolyacids and their salts have been used for a long time as heterogeneous catalysts in various oxidative and acid processes of practical importance. The studies up to 1975 have been briefly considered in a number of reviews[7,10,15]. It has recently become clear that heteropolycompounds are also of great interest for fundamental research into heterogeneous catalysis[2,176]. By altering the composition of the HPA, it is possible to vary independently and within wide limits their oxidising and acidic properties and also to achieve bifunctional catalysis. The constancy of the structure and the similarity of many physicochemical properties of the HPA in crystals and in solution (see below) permit the employment of the ideas concerning the mechanism of homogeneous catalytic reactions of the HPA for the analogous heterogeneous catalytic reactions.

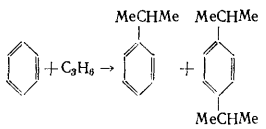
HPA hydrates in the form of massive specimens are usually employed in heterogeneous catalysis. They are frequently deposited (10–15 wt.%) on solid carriers (SiO_2, Al_2O_3, etc.). Many HPA exhibit a fairly high thermal stability. For example, the acids PW_{12}, SiW_{12}, PMo_{12}, and $SiMo_{12}$ have average decomposition temperatures of 465°, 445°, 375°, and 350 °C respectively[107]. It is significant that the thermal stability of the HPA greatly increases in the presence of water vapour[177], but there are few quantitative data concerning this question.

The HPA hydrates behave in many respects similarly to solutions, which enables one to expect an analogy between the mechanisms of the action of the homogeneous and heterogeneous HPA-based catalysts. The behaviour of the HPA as a "pseudoliquid phase" [176] is manifested primarily in the mobility of structural elements. In the HPA hydrates, the polyanions are not linked to one another; the regularity of the packing is achieved as a result of the formation of hydrogen bonds with the molecules of the water of crystallisation[9,10]. According to ^{31}P NMR data, in the PW_{12} and PMo_{12} acid hydrates with a high water content the heteropolyanions rotate fairly readily at a frequency $\geq 10^3$ Hz [178] and their acid protons exchange rapidly with the protons of the water of crystallisation[73,74,105,106]. Even in anhydrous HPA the structural elements migrate freely at temperatures in excess of 150 °C. The activation energy for the self diffusion of H^+ decreases with increasing acid strength and amounts to 78.5, 54.6, 44.1, and 29.4 kJ mol^{-1} for PW_{12}, SiW_{12}, PMo_{12}, and $SiMo_{12}$ respectively. Small amounts of added water vapour accelerate the self diffusion of H^+.[107] The oxygen atoms in the M=O and M–O–M bonds in crystalline HPA exchange with water, as in solutions[176]. The rate of exchange of oxygen in the HPA is appreciably higher than in metal oxides. Thus 80% of the oxygen in PMo_{12} is exchanged in the course of 1 h at 250 °C, while only 0.4% is exchanged in MoO_3 in the course of 1.5 h at 440 °C.[176]

The adsorption of pyridine on massive specimens of the HPA PMo_{12}, PW_{12}, and $SiMo_{12}$ has been studied[176,177]. It has been established that the entire adsorbed pyridine exists in the form of the ion $C_5H_5NH^+$, i.e. the acidity of the HPA is of the Brønsted type. The amount of pyridine per HPA molecule is equal to the basicity of the HPA and is independent of the fact that part of the heteropolyanion is inaccessible to pyridine vapour. Thus not only surface

protons but also protons belonging to the heteropolyanion and located within the bulk of the specimen react with pyridine, similarly to reactions in solution[176]. The acidity of the crystalline HPA has been little investigated; according to the available data[107,176], the acidities of the HPA in the solid state and in solutions vary equally with their composition.

At 200–250 °C, $H_3PMo_{12}O_{40}$ is reduced by hydrogen. On subsequent treatment with molecular oxygen, the reduced form is reoxidised to the initial state. Such oxidation-reduction transformations of PMo_{12} are fully reversible for the addition (in the reduction process) of two electrons by an HPA molecule, but become irreversible when the degree of reduction corresponds to the addition of five electrons[176]. The analogy between the oxidation-reduction properties of solid HPA and the properties of the HPA-*n* in solutions can be seen in this example (see Section III).



There have been several new studies of the application of the HPA in heterogeneous acid and oxidative catalysis and of the mechanism of their catalytic action. Like zeolites, the HPA-W catalyse the conversion of methanol into hydrocarbons[179]. Such reactions are of great interest in connection with the problem of the synthesis of an artificial liquid fuel from CO and H_2. In the presence of PW_{12} in a flow-type reactor at 245–357 °C and at atmospheric pressure, a mixture of olefins and alkanes ranging from C_1 to C_7 as well as traces of CO and CO_2 are formed. At 245 °C the mixture contains 43% of the butane–butene and 27% of the pentane–pentene fractions. The selectivity with respect to these products decreases with increase of temperature. A mechanism analogous to that of the corresponding reactions in the presence of superacids in solution has been proposed:

$$MeOH + H^+ \rightarrow Me^+ + H_2O\ ,$$

$$Me^+ + MeOH \rightarrow \left[\begin{matrix} H \\ Me^+ \end{matrix}\right\rangle\!\cdots CH_2OH \rightarrow MeCH_2OH + H^+\ ;$$

$$MeCH_2OH \rightarrow C_2H_4 + H_2O\ .$$

The very active catalyst of the alkylation of benzene by propene (the first stage of the cumene process of the synthesis of phenol and acetone) is 40% $H_4SiW_{12}O_{40}/SiO_2$:[173]

(30)

The reaction proceeds at 150 °C, 15×10^2 kPa, and $[C_6H_6]/.[C_3H_6] = 4$ with a selectivity of 72.5% with respect to isopropylbenzene for a propene conversion of 97.5%. The lifetime of the catalyst is 500 h. Di-isopropylbenzene is returned to the system to be transalkylated. The SiW_{12} HPA has virtually the same parameters as the aluminosilicate catalyst—one of the best heterogeneous catalysts of reaction (30). However, the latter operates under more severe conditions (300 °C and 3×10^3 kPa). In the alkylation process the catalysts are gradually saturated with coke and require regeneration; the coke is burnt off in a stream of air. After regeneration, the aluminosilicate catalyst has the previous activity and stability, but the HPA does not withstand severe regeneration conditions—it is dehydrated and loses activity irreversibly. This example demonstrates the urgent need for the development of new methods of regenerating HPA-based catalysts which do not reduce their activity.

The kinetics of the dehydration of isopropyl alcohol in the presence of HPA have been studied by a flow method[176]. The steady-state rate of reaction at 100 °C, referred to the catalyst surface, decreases in the following sequence of HPA: $PW_{12} > SiW_{12} > PW_{10}V_2 > PMo_{12} > PMo_{10}V_2 \cong SiMo_{12}$, and in the following sequence of their salts: $H_3PW_{12}O_{40} > Na_2.HPW_{12}O_{40} > Na_3PW_{12}O_{40}$. The catalytic activity of the HPA is satisfactorily correlated with their dissociation constants in acetone (Table 1).

The mechanism of the oxidation of methacrolein (RCHO) to methacrylic acid has been investigated in the presence of water vapour ($p_{H_2O} \cong 40$ kPa) at 280–300 °C.[176] The catalysts were massive HPA and their salts. The HPA-Mo (PMo_{12}, $SiMo_{12}$) and their copper(II) and caesium salts proved to be the most active and selective. The tungsten(VI) compounds have a lower activity and selectivity. In a flow reactor at 300 °C in the presence of PMo_{12} the reaction proceeds with a selectivity of 74.4% and a conversion of the substrate of 16.6%. Acetic acid (2.3%), Co (11.9%), and CO_2 (11.4%) are also formed. Water plays an important role in this reaction: in the absence of water, the selectivity and conversion are much lower. The process proceeds in accordance with the kinetic equation

$$-d[RCHO]/d\tau = kp_{RCHO}^{(0.8-1.0)}p_{O_2}^{(0.6-0.2)}p_{H_2O}^{0}\ . \qquad (31)$$

The process selectivity hardly changes after the cessation of the supply of O_2 under the conditions of the steady-state activity of the catalyst, which shows that the reaction proceeds in accordance with the oxidation-reduction mechanism via the following stages:

$$RCHO + HPA + H_2O \rightarrow RCOOH + H_2(HPA); \qquad (32)$$

$$H_2(HPA) + \tfrac{1}{2}O_2 \rightarrow HPA + H_2O\ . \qquad (33)$$

It follows from the kinetic equation(31) that stage (32) is rate-limiting. The mechanism described by reactions (32) and (33) is also supported by the rapid exchange of ^{18}O between acroleine and PMo_{12} at 300 °C.[176]

In principle, using HPA it is possible to achieve bifunctional oxidative and acid catalysis, but this interesting application of the HPA has so far been only slightly investigated. It has been established that, together with the oxidative properties of the HPA, their acidity plays a significant role in the oxidation of methacroleine, which has been confirmed by the poisoning of the catalyst by added pyridine[176]. The bifunctional catalysis by the HPA probably occurs in the oxidative hydration of propene to acetone[180].

Among new and promising but hitherto little investigated applications of HPA in heterogeneous catalysts, one should mention their employment for the synthesis of catalysts having a specified composition. All or some of the components of the catalyst can then be incorporated in the heteropolycomplex as ligands, central atoms, or outer-sphere cations. The complex is then deposited on a carrier and is subjected to a chemical or thermal treatment in order to obtain the final catalyst. This method has significant advantages over the successive deposition of the components. It reduces the number of stages in the preparation of the catalyst and ensures a very intimate mixing of the components (up to mixtures at the molecular level) starting from the heteropolycomplex, which is much more difficult and sometimes impossible to achieve by other methods. Studies[181,182] in which the formation of HPA on the surface of a solid carrier during the synthesis of heterogeneous catalysts by traditional methods was observed are of interest in this connection. Thus the silica–molybdenum oxide catalyst for the oxidation of propene, obtained by the spray drying of an aerosil suspension in an ammonium paramolybdate solution, contains molybdosilicic acid which determines the activity of the catalyst in the oxidation of propene. The HPA obtained in stable up to 500–600 °C as a result of stabilisation by the SiO_2 surface.

Polycyclic Azulenoid Systems

Yu.N.Porshnev, V.B.Mochalin, and M.I.Cherkashin

The principal methods of synthesis of polycyclic azulene hydrocarbons and their derivatives are described and certain aspects of the practical applications of polycyclic azulenes are considered.
The bibliography includes 122 references.

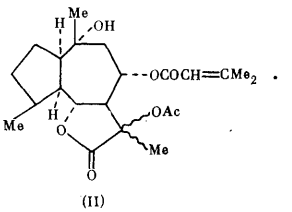
IV. Physiological properties of polycyclic azulenes 1106

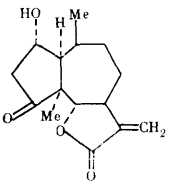
I. INTRODUCTION



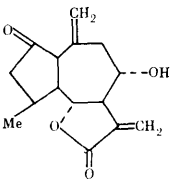
Azulene derivatives containing more than two condensed rings in the molecule have come to be called polycyclic azulenes. At the present time several tens of polycyclic azulenoid systems containing from three to seven condensed rings are known, many derivatives incorporating nitrogen-, sulphur-, and oxygen-containing heterocycles. To facilitate the description and nomenclature of polycyclic azulenes, we divided them into two subgroups: (1) carbocyclic azulenoid systems; (2) azulenes condensed with nitrogen-, sulphur-, and oxygen-containing heterocycles. The true heterocyclic analogues of azulenes as well as their π-electronic analogues—the so-called pseudoazulenes containing heteroatoms directly in one or both rings of the pseudoazulene nucleus—are not considered in this review because their number is very large and they might constitute the subject of a special review (see, for example, Timpe and Elcov[1]).

It is noteworthy that fully conjugated, i.e. dehydrogenated, polycyclic azulene hydrocarbons are not encountered in nature.

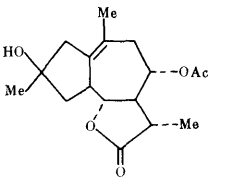
Only sesquiterpene precursors of polycyclic azulenes, usually incorporating saturated oxygen-containing heterocycles of the lactone type, are known. For example, the sesquiterpene derivatives (I) and (II) have been isolated from the extract of the roots of *Laserpitium silver*:



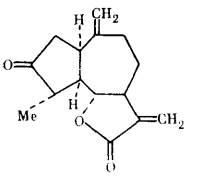
(I)



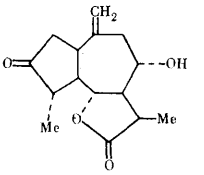
(II)



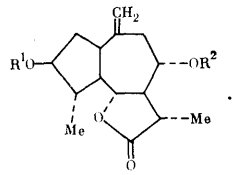
The structure of ivoxanthin (III)—a sesquiterpene lactone isolated from *Cyclachaena xanthifolia*[3], grossheimin (IV), isolated from *Grossheimia macrocephala*[4], and certain other sesquiterpenes [(V)–(VIII)] [5,6] which are in the main genetic precursors of guaiazulene and vetivazulene, have been established:



(III)

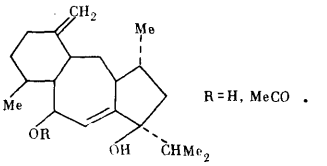


(IV)



(V)

(VI)



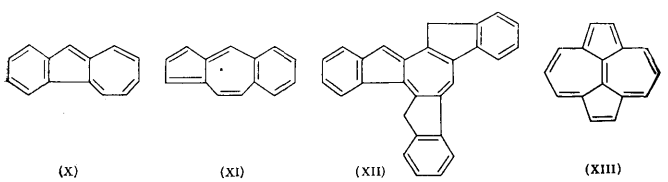
(VII)

(VIII)

The diterpene dolatriol (IX), which has the hydrocarbon skeleton of a hydrogenated precursor of 5,6-benzazulene, has been recently isolated from the tissues of molluscs[7]. Its structure was established by X-ray diffraction:

(IX)

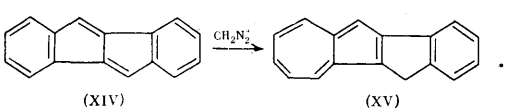
The majority of carbocyclic azulenes have been considered[8] in connection with the discussion of a new approach to the concept of the aromaticity of conjugated cyclic hydrocarbons. The author bases his views on the concept of conjugated circuits recognised at the present time as significant structural elements characterising conjugated systems. The structures of conjugated hydrocarbons were investigated and circuits with an alternation of double and single C–C bonds were enumerated. Systems having only conjugated circuits of the $(4n + 2)$ type are defined as aromatic. Systems with conjugation contours only of the $(4n)$ type are regarded as antiaromatic, i.e. destabilised as a result of the delocalisation of the π electrons. Finally systems having circuits of both



types simultaneously are classified as intermediate, manifesting only a partial aromatic character. This approach constitutes a logical extension to polycyclic systems of the famous Hückel (4*n* + 2) rule, which is rigorously applicable only to monocyclic systems. Furthermore, in the above study a brief comparison was made with several alternative schemes and their limitations were demonstrated[8].

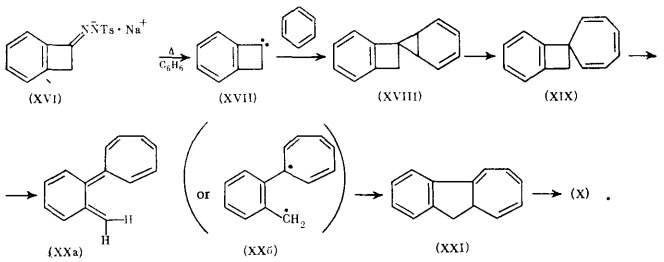
Almost all polycyclic azulenes (particularly fully conjugated compounds) are high-melting readily crystallisable aromatic compounds. They are deeply coloured and frequently absorb light at longer wavelengths than the usual azulenes and their homologues and sometimes even in the near infrared. Isolated information concerning the synthesis of polycyclic azulenes is given in a number of reviews[9–11], but they do not provide a complete view of the state of affairs in this field, since they are devoted mainly to individual questions of synthesis or reactivity.

CARBOCYCLIC AZULENE DERIVATIVES



1. Expansion of the Benzene Ring of Azulene Precursors by Carbenes

The simplest tricyclic derivatives, namely the benzazulenes (X) and (XI), which are formed by the expansion of the benzene ring of fluorene and the corresponding indan derivative on treatment with an alkoxycarbonylcarbene, produced in its turn on thermal or catalytic decomposition of diazoacetic ester (the Buchner synthesis) with subsequent dehydrogenation and removal of the alkoxycarbonyl group, were obtained before other representatives of carbocyclic condensed systems[12–14].

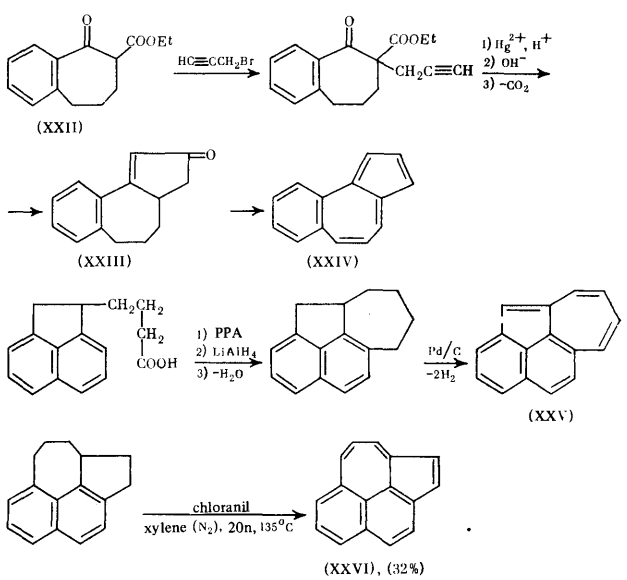


(X) (XI) (XII) (XIII)

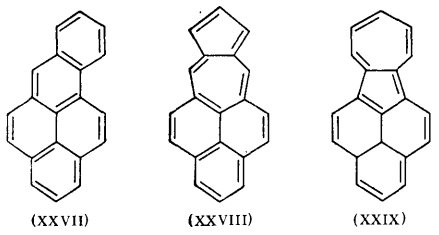
Substituted 1,2-benzazulenes[15–18] as well as the heptacyclic azulene (XII)[19] and azupyrene (XIII),[20] which consists of a system of two condensed azulene nuclei, have been obtained analogously. The expansion of one of the benzene rings in 1,2 : 4,5-dibenzopentalene (XIV) leads to indeno[2,1-*a*]-azulene (XV):[21]

(XIV) (XV)

It has been shown recently that the thermolysis of the sodium salt of the tosylhydrazone of benzocyclobutenone (XVI) (a familiar method of synthesising carbenes[22]) in benzene gives rise to 9a,10-dihydrobenzo[*a*]azulene (XXI) in 30% yield. The synthesis of compound (XXI) can be represented as a result of the addition of benzocyclobutenylidene (XVII) to benzene with formation of spiro-norcaradiene (XVIII), which isomerises to spiro-cycloheptatriene (XIX). The ring opening of the benzocyclobutene part of compound (XIX) can lead to the *o*-quinodimethane derivatives (XXa) or to the equivalent biradical (XXb), which cyclises to compound (XIX). The dehydrogenation of compound (XXI) leads to benzo[*a*]azulene (X):[23]

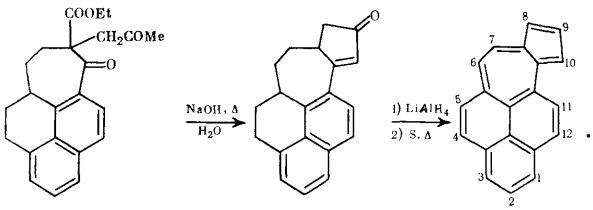


The methods described above are of great theoretical interest from the standpoint of the synthesis and study of new condensed azulenoid systems, but their preparative values is restricted by the low availability of the initial compounds and also by the low yields in the stages involving the expansion of the benzene ring and the dehydrogenation of the resulting precursors of azulene hydrocarbons. These methods have been significantly supplemented by syntheses which are based on the employment of non-azulenoid compounds as the starting materials, i.e. by another variety of the total synthesis.



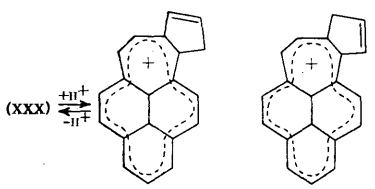
2. Total Synthesis of Carbocylic Derivatives of Azulene from Non-azulenoid Compounds

The total synthesis of polycyclic azulenes presupposes either the addition of a new five-membered ring to the complete seven-membered ring or conversely, at least one of the initial compounds must be condensed with at least one polymethylene, benzene, naphthalene, or another ring. The concluding stage is usually dehydrogenation.

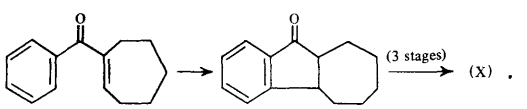


This method of synthesis of complex tri- and tetra-cyclic systems can be illustrated by the synthesis of 4,5-benzazulene (XXIV),[24] naphth[2,1,9,8-*ija*]azulene (XXV),[25] naphth[2,1,9,8-*cde*]azulene (XXVI),[26] and certain other derivatives:

In order to investigate the biological properties of polycyclic arenes and to compare them with the carcinogenic benzo[*a*]pyrene (XXVII), its non-alternant isomers were obtained: azuleno[5,6,7-*cd*]phenalene (XXVIII),[27] which exhibits a powerful carcinogenic activity, the weakly carcinogenic azulene[1,2,3-*cd*]phenalene (XXIX),[28] and azuleno-[4,5,6-*cd*]phenalene (XXX),[29] which, judging from the topology of its π-electron system [similarity to compound (XXVIII)] and its molecular structure [similarity to compound (XXVII)], should exhibit an appreciable biological activity:

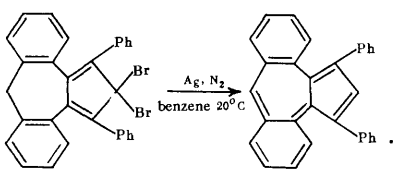


(XXVII) (XXVIII) (XXIX)



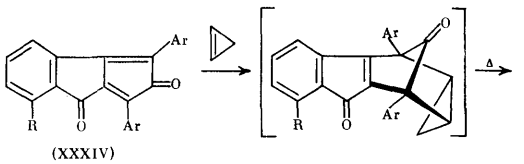
(XXX)

Compound (XXX) is distinctly basic and undergoes reversible protonation by trifluoroacetic acid, giving rise to a mixture of the cations (XXXIa) and (XXXIb) in proportions of 4 : 1:

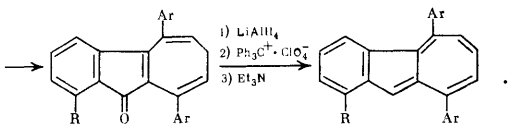


(XXXIa) (XXXIb)

An example of another method of closure of the five-membered ring is provided by the synthesis of 1,2-benzazulene [30–32]:

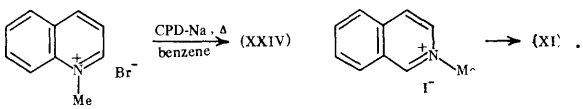


The synthesis of 1,3-diphenyldibenz[*eh*]azulene (XXXIII) by the dehydrobromination of the dibromo-derivative (XXXII) with silver dust in a nitrogen atmosphere was reported in 1974.[33] Compound (XXXIII) is stable only at temperatures not exceeding −18 °C (in a N_2 atmosphere).

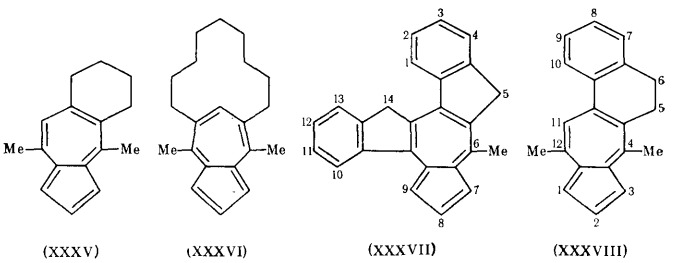


(XXXII) (XXXIII)

The synthesis of substituted 1,2-benzazulenes from the "indanocyclone" (XXXIV) was included among those which involve the rearrangement of the five-membered ring to a seven-membered ring with subsequent reduction and dehydrogenation of the intermediates[34]:



(XXXIV)



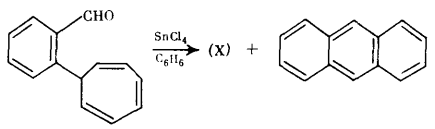
The methods examined have the advantage over those involving the expansion of the benzene ring in that they lead to final products with higher overall yields. However, they too are fairly cumbersome which reduces their preparative value compared with methods based on the cleavage of certain heterocyclic systems.

3. Quinolinium, Isoquinolinium, and Pyrylium Salts in the Synthesis of Polycyclic Azulenes

In contrast to pyridinium salts, quaternary quinolinium[35] and isoquinolinium[36] salts give rise to the corresponding benzazulenes (XXIV) and (XI) only in low yields on high-temperature condensation with cyclopentadienylsodium (CPD-Na):

There are at present almost no publications about the successful synthesis of polycyclic azulenes from benzopyrylium, isobenzopyrylium, and other condensed pyrylium derivatives. It is only known that tetrahydrobenz[*f*]azulene (XXXV) has been obtained from a tetrahydrobenzopyrylium salt and cyclopentadienylsodium is 3.3% yield[36] and that 4,8-dimethyl-5,7-nonamethyleneazulene (XXXVI) has been synthesised from the corresponding salt in 0.3% yield[37].

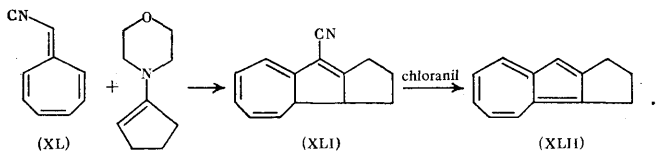
(XXXV) (XXXVI) (XXXVII) (XXXVIII)



The deficiencies of the above syntheses are extremely low yields and the low availability of the initial salts, for example, in the second case. However, despite the fact that the methods have been as yet hardly elaborated, their possibilities are probably very considerable. It has been established recently that 2-methyldi-indeno[2,3;2',3'-*c*;*e*]pyrylium perchlorate, obtained by the method of Zhdanov et al.[38], reacts

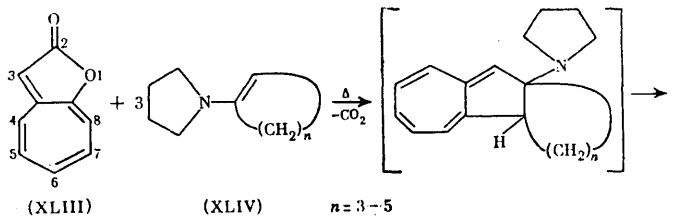
with cyclopentadienylsodium to form 6-methyldi-indeno[3,2;;3',2'-*e*;*g*]azulene (XXXVIII) in 16% yield[39]. Under similar conditions, 2,10-dimethyl-3,4-dihydronaphtho[2,1-*c*]pyrylium perchlorate[40] gives rise to 4,12-dimethyl-5,6-dihydronaphth-[2,1-*f*]azulene (XXXVIII) in 22% yield[39]. The attempt to dehydrogenate compound (XXXVIII) by chloranil led merely to the product of "*ene*-synthesis", as in the reaction of *p*-benzoquinone with azulene[41].

When the initial substance contains a complete unsaturated seven-membered ring, the possibilities of the synthesis are greatly expanded. Such initial compounds may be, for example, derivatives of the cycloheptatriene and cycloheptafulvene series.



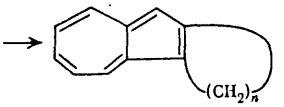
4. Syntheses based on Cycloheptatriene and Cycloheptafulvene Derivatives

Japanese investigators developed several methods for the synthesis of the five-membered ring of the azulene system from derivatives of the cycloheptatriene series, which lead to the formation of tri- and tetra-cyclic hydrocarbons. Thus, the catalytic intramolecular cyclisation of *o*-cycloheptatrienylbenzaldehyde (XXXIX) on treatment with $SnCl_4$ in benzene, leading to the formation of 1,2-benzazulene and anthracene, has been reported[42]:



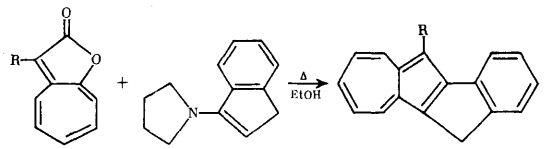
(XXXIX)

The condensation of 8-cyanocycloheptafulvene (XL) with morpholinocyclopentene leads to the formation of the dihydroazulene derivative (XLI), whose dehydrogenation yields 1-cyano-2,3-trimethyleneazulene (XLII):[43]

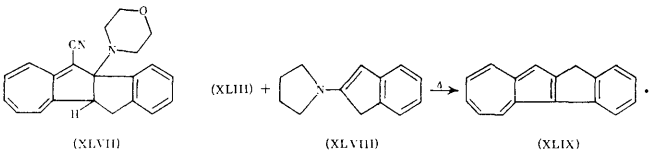


(XL) (XLI) (XLII)

It has been established[44] that 2*H*-cyclohepta[*b*]furan-2-one (XLIII), formed on condensation of equimolar amounts of 2-chlorotropone with sodiomalonic ester, also undergoes the cycloaddition reaction with enamines of type (XLIV) accompanied by the elimination of CO_2 and the amine, which leads to the formation of azulene derivatives (XLV):

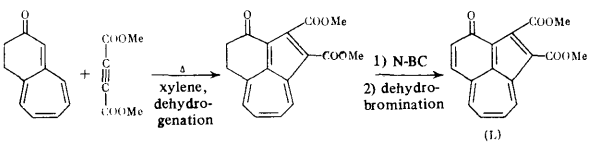


(XLIII) (XLIV) $n = 3-5$



(XLV)

Heating of compound (XLIII), or its 3-cyano-derivative with 1-*N*-pyrrolidinoindene gives rise to indeno[2,1-*e*]azulene (XLVIa) or cyanoazulene (XLVIb) (yields 93 or 19% respectively):[45]

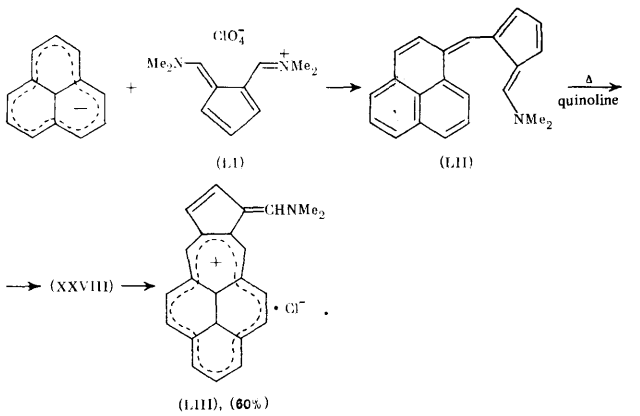


R = H (a), CN (b) (XLVI, a and b)

1-*N*-Morpholinoindene reacts with 3-cyano-2*H*-cyclohepta-[*b*]furan-2-one, forming 20% of compound (XLVIb) and 57% of the adduct (XLVII), which is converted quantitatively into compound (XLVIb) during chromatography on silica gel (eluent—benzene). The furanone (XLIII) reacts with 2-*N*-pyrrolidinoindene (XLVIII) much more slowly (140 h, 78 °C, alcohol), giving a 30% yield of indeno[1,2-*a*]azulene (XLIX), but compound (XLVIII) does not react with 3-cyanofuranone:

(XLVII) (XLVIII) (XLIX)

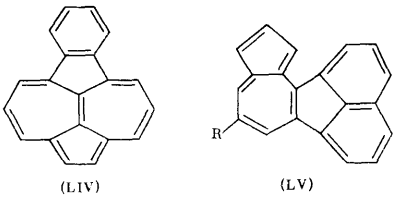
It was found that cycloheptafulvene derivatives can undergo the cycloaddition reaction with strong dienophiles, which led to the formation of the new tricyclic fully conjugated 3-*H*-benzo[*cd*]azulenone (L) system[46]:



(L)

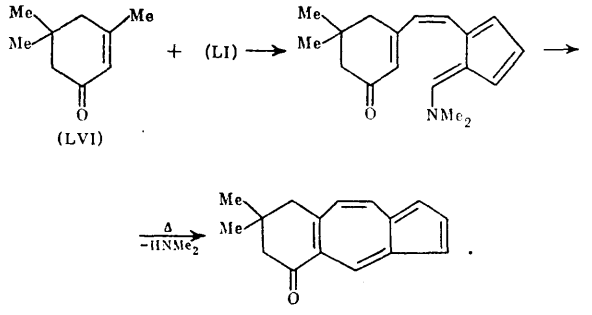
Presumably the scope for development of the above methods of synthesis may be inherent in the properties of the benzotropone and benzocycloheptafulvene derivatives (or other condensed systems of this type), but at the present time such data are not available.

5. Cyclisation of Polymethinium Salts and Fulvenes

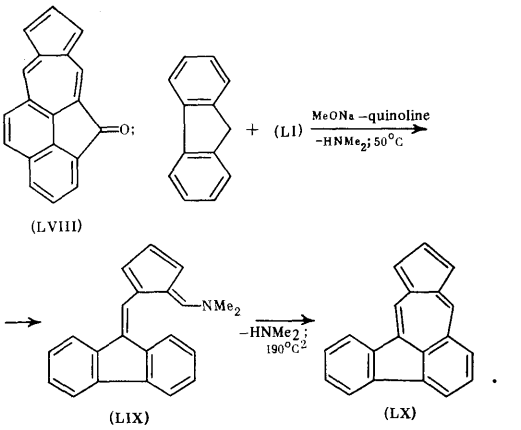


The cyclisation of fulvenes, developed by Ziegler and Hafner, is at present perhaps the most effective method of synthesis of azulenes[47,48]. This method proved to be effective also for the synthesis of polycyclic azulenes which are dfficult to obtain, such as, for example, azuleno[5,6,7-*cd*]-phenalene. The phenalene anion condenses with 6-dimethylamino-2-dimethylimmoniamethylfulvene perchlorate (LI) to form the enamine (LII), which can be converted into azuleno-[5,6,7-*cd*]phenalene by thermal cyclisation with elimination of dimethylamine[27]. Compound (XXVIII) is more basic than azulene and is extracted reversibly from benzene by 60%

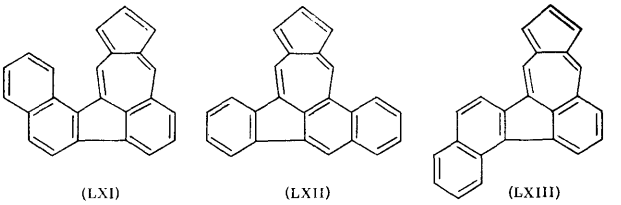
H_3PO_4. When compound (XXVIII) is treated with the Vilsmeier reagent, the highly fluorescent salt (LIII) is formed:



The carcinogenic azulene[5,6,7-*cd*]cyclopenta[*gh*]phenalene has been obtained similarly from the acephenalene anion[49].



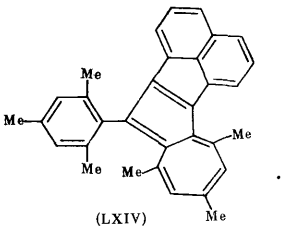
The cyclisation of fulvenes yielded azuleno[1,2,3-*cd*]-phenalene (XXIX) [28] and pyraceheptylene (XIII),[50] mentioned above, as well as benzopyraceheptylene (LIV) [50] and azuleno-[4,5-*a*]acenaphthylene (LV),[51] the mechanisms of the syntheses of which have been fully considered in a review[11].



As in the synthesis of the azulene [5,6,7-*cd*]phenalene (XXVIII) system, the deprotonation of isophorone (LVI), in which the methyl group conjugated with the carbonyl group via the C=C bond reacts instead of the sterically hindered α-methylene group, leads to the formation of a stabilised allyl anion, which condenses with the heptamethinium salt (LI) to 7,7-dimethyl-5,6,7,8-tetrahydro[*f*]azulen-5-one (LVII) (yield 15%).[51]

Under similar conditions, 1-acenaphthenone condenses with compound (LI) to form a fulvenoid enaminoketone, which cyclises to azuleno[5,6,7-*cd*]acenaphthylen-6-one (LVIII) at 180 °C:[51]

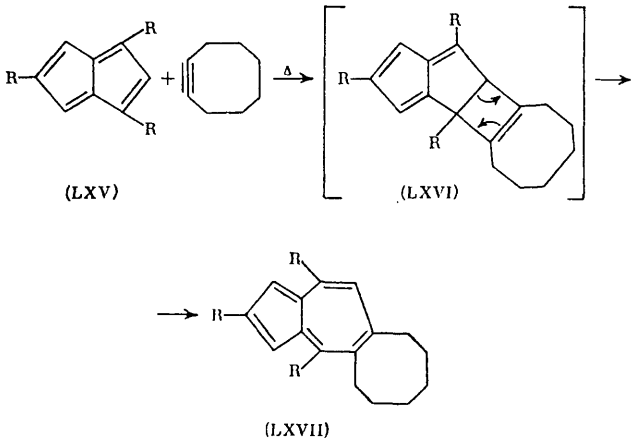
The heptamethinium salt (LI) reacts similarly with fluorene to form the enamine (LIX), which undergoes ring closure at 190 °C to azuleno[5,6,7-*jk*]fluorene (LX) with elimination of dimethylamine. Benzofluorenes also condense with the salt (LXI), forming deeply coloured benzo-derivatives of the enamine (LIX), which can cyclise to the hexacyclic azulenes (LXI)–(LXIII). It has been established that only azulene-[5,6,7-*jk*]benzo[*a*]fluorene (LXI) is formed from benzo[*a*]-fluorene. However, the enamines formed from benzo[*b*]fluorene and benzo[*c*]fluorene can formally undergo ring closure via two different pathways, namely they can undergo annelation to the naphthalene or benzene nucleus of the benzofluorene system[51].



The azuleno[5,6,7-*jk*]benzo[*h*]fluorene (LXII) and azuleno-[5,6,7-*jk*]benzo[*c*]fluorene (LXIII) structures proposed by the authors[51] follow from the localisation energies L_r for the cyclisation reaction estimated by the Hückel method. In each case traces of the second isomer were detected. It is noteworthy that the theoretical evidence cannot replace, accordinto to the authors themselves, a rigorous chemical demonstration of structures (LXII) and (LXIII).

The cyclisation of polymethinium salts and fulvenes is one of the universal methods of synthesis of an extremely wide variety of highly condensed azulene hydrocarbons despite certain difficulties in the preparation of the initial and intermediate compounds. The scope of this method has been by no means fully exhausted, since, as will be shown below, other azulene derivatives readily enter into such reactions instead of fulvenes, cyclopentadienes, and other hydrocarbons.

6. Syntheses based on Acetylenic Compounds and Other Methods

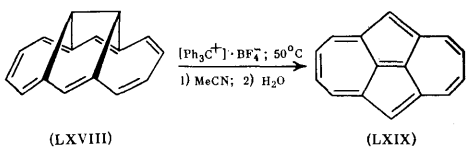


Among polycyclic fully conjugated azulenoid systems obtained from acetylene derivatives, only substituted acenaphthylenoazulene (LXIV), formed on irradiation of

diphenylperibisethynylnaphthalene, is known[52]:

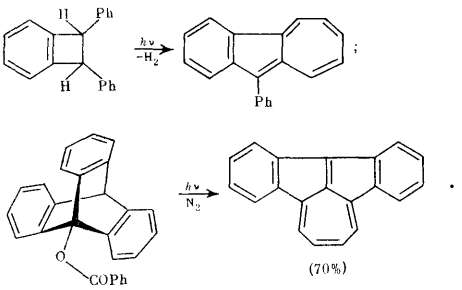
(LXIV)

It has been observed[53] that the pentalene derivative (LXV) reacts at 270 °C with the highly strained triple bond of cyclo-octyne and it is tentatively suggested that this involves the intermediate formation of the cyclobutene derivative (LXVI), yielding 2,4,12-tri-t-butyl-5,6,7,8,9,10-hexahydrocyclo-octa[*f*]azulene (LXVII):



(LXV) (LXVI) (LXVII)

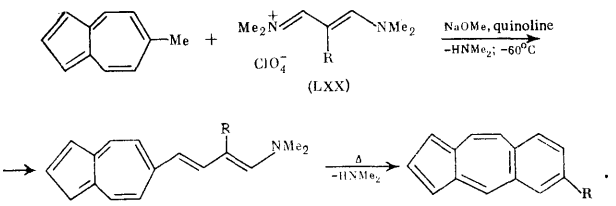
R = t-Bu .



The exclusive formation of compound (LXVII) in 70% yield at such a high temperature indicates (in contrast to pentalene and methylpentalene) only a slight tendency of the 2,4,6-trisubstituted pentalene (LXV) to dimerise, i.e. the steric influence of bulky substituents.

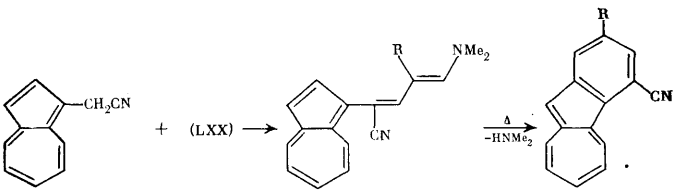
An interesting reaction involves dehydrogenation of the non-polar 1,6,8,13-ethanediylidene[14]annulene (LXVIII) to dicyclohepta[*cd,gh*]pentalene (LXIX), which takes place under the influence of triphenylcarbonium tetrafluoroborate in 70% yield, has been discovered[54]. Compound (LXIX) is a new non-benzenoid isomer of pyrene:

(LXVIII) (LXIX)



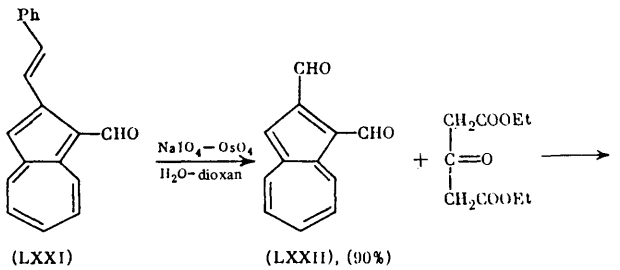
The photochemical isomerisation of 3,4-diphenyl-1,2-benzocyclobutene to 1-phenyl-2,3-benzazulene[55] and of benzoyloxytriptycene to benz[*a*]indeno[1,2,3-*cd*]azulene [56] has been described:

The fact that in the methods of synthesis described the azulene system is formed from the most "unexpected" precursors confirms its fairly high thermodynamic stability.



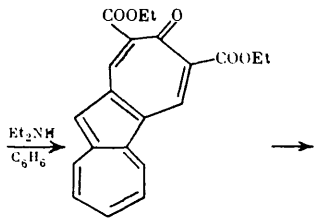
7. Derivatives of Azulenes as Starting Materials for the Synthesis of Polycyclic Systems

Many new and extremely varied polycyclic azulenoid systems have been obtained from comparatively simple azulene derivatives containing functional groups in the five-membered ring, seven-membered ring, or both rings simultaneously. The formation of the benzo-ring on the azulene system may be illustrated by the synthesis of 5,6-benzazulene and its derivatives[57]:

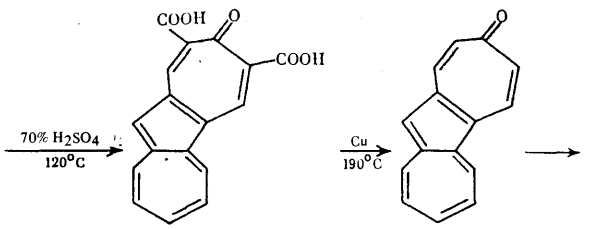


(LXX)

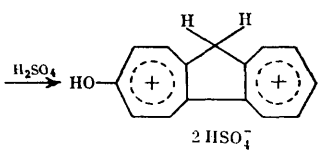
Here R = H, Et, Ph, $PhCH_2$, or OMe. The successful condensation of their trimethinium salt (LXXX) with the methyl group of 6-methylazulene is evidently due to the electron-accepting influence of the seven-membered ring of the azulene system, which leads to an increase of the mobility of the methyl protons. The authors[57] used the mobility of the methylene protons in 1-azulenylacetonitrile to achieve the formation of a similar 1,2-benzo-ring:



The corresponding functional derivatives of azulene, for example, 1,2-diformylazulene (LXXII), obtained[58] from 2-styrylazulene-1-aldehyde (LXXI) by the Lemieux–Johnson oxidation, are very convenient for the formation of new rings condensed with the 1- and 2-positions of the azulene nucleus. Subsequent condensation of the dialdehyde (LXXII) with acetonedicarboxylic ester, hydrolysis, and decarboxylation

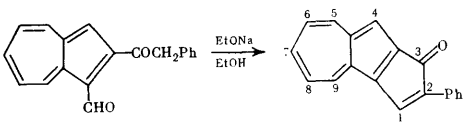


lead to azuleno[1,2-*d*]tropone (LXXIII):[58]



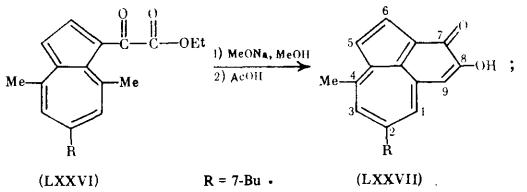
(LXXI) (LXXII), (90%)

(58%)



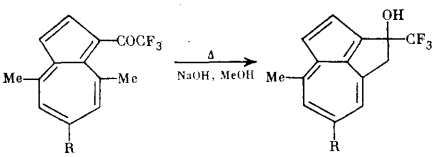
(LXXIII), (31%)

(LXXIV)



Azulenotropone (LXXIII) dissolves in H_2SO_4 with formation of the doubly charged cation (LXXIV).

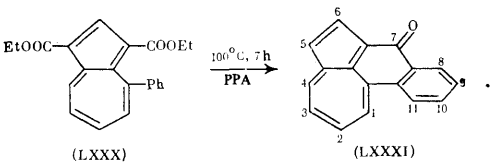
Another example of the utilisation of a 1,2-dicarbonyl derivative of azulene is the synthesis of 2-phenylazuleno-[1,2-d]cyclopentadien-3-one (LXXV):[59]



(LXXV).

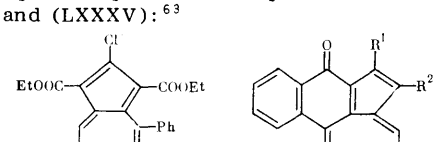
In those compounds where the functional groups or substituents reacting with one another are located in different rings of the azulene system, for example, in the 1- and 8-positions, intramolecular condensation leads to a closer condensation of the newly formed ring with the azulene nucleus. Thus ethyl 6-t-butyl-4,8-dimethyl-1-azulenyl glyoxylate (LXXVI) cyclises to 2-t-butyl-8-hydroxy-4-methyl-7*H*-benz[*cd*]azulen-7-one (LXXVII) on treatment with sodium methoxide[60]:

(LXXVI) R = 7-Bu . (LXXVII)



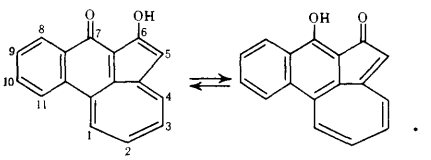
The analogous treatment of 1-trifluoroacetyl derivatives of 4,6,8-trimethylazulene (LXXVIIIa)[61] or 4,8-dimethyl-6-styrylazulene (LXXVIIIb)[39] results in the formation of the corresponding stable tertiary alcohols—derivatives of dihydroaceazulene (LXXIX, a and b):

(LXXVIII, a and b) (LXXIX, a and b)



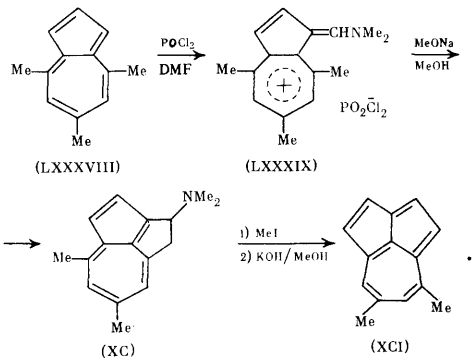
R = Me (a), —CH=CH—Ph (b) .

The intramolecular cyclisation of diethyl 4-phenylazulene-1,3-dicarboxylate (LXXX) has been achieved[62] in polyphosphoric acid (PPA) with formation of a new heterocyclic system—7*H*-naph[3,2,1-cd]azulen-7-one (LXXXI), which is the azulene analogue of benzanthrone:



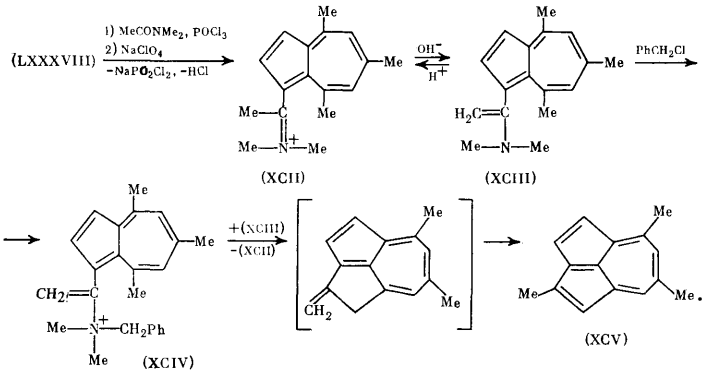
(LXXX) (LXXXI)

The cyclisation of the 2-chloro-derivative (LXXXII) at 100 °C for 3 h in polyphosphoric acid results in the formation of all three possible products—compounds (LXXXIII), (LXXIV), and (LXXXV):[63]



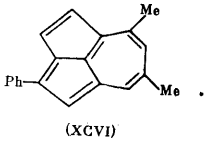
(LXXXII) (LXXXIII): R^1 = Cl, R^2 = H;
(LXXXIV): R^1 = Cl, R^2 = COOEt;
(LXXXV): R^1 = H, R^2 = COOEt .

The ethoxycarbonyl group can be eliminated from compound (LXXXIV) and the latter can exchange its chlorine for the methoxy-group: the demethylation of the intermediate methoxy-derivative yields 6-hydroxy-7*H*-naphth[3,2,1-*cd*]azulen-7-one (LXXXVI), which exists in tautomeric equilibrium with compound [LXXXVII]:



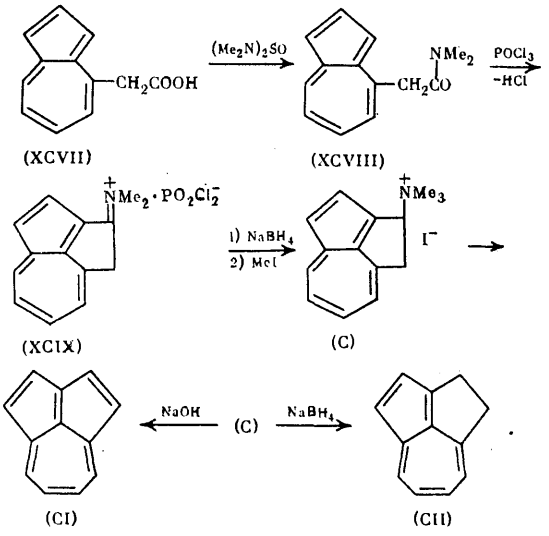
(LXXXVI) (LXXXVII)

The mobility of the hydrogen atoms in the methyl groups of 4,6,8-trimethylazulene enabled Hafner and Schneider[64] to achieve the closure of the five-membered ring condensed along the *cd* faces of the azulene nucleus, which ultimately led to the formation of a new tricyclic conjugated system—aceazulene (XCI):

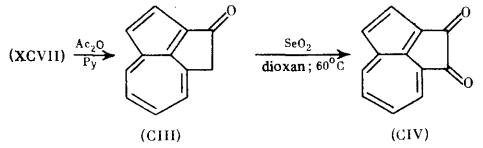


Like acenaphthylene, compound (XCI) is not aromatic; it is stable only at temperatures below 77 °C.

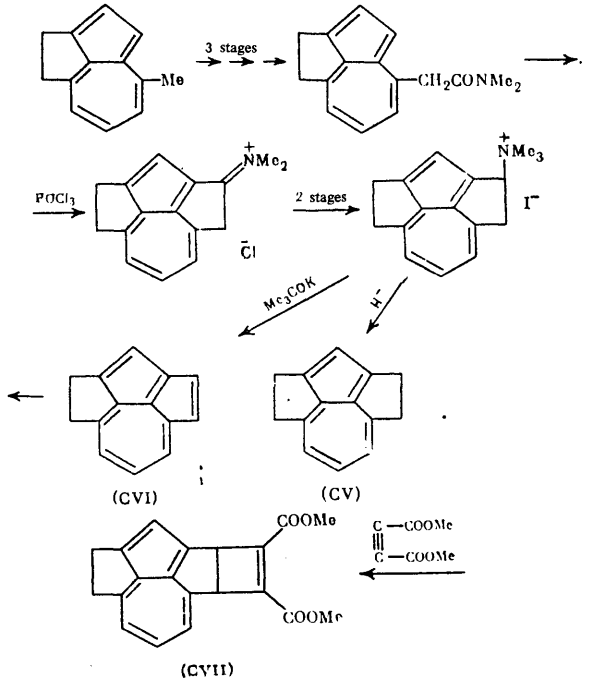
In the Vilsmeier acetylation of compound (LXXXVIII), the immonium salt (XCII) formed initially does not hydrolyse immediately to an acetyl derivative when rendered alkaline but gives rise to the enamine (XCIII). Treatment of the latter with benzyl chloride results in the intermediate formation of a quaternary ammonium salt (XCIV), which undergoes the Hofmann cleavage on treatment with an excess of the enamine (XCIII), accompanied by the closure of a new five-membered ring with formation of the aceazulene derivative (XCV):[65]



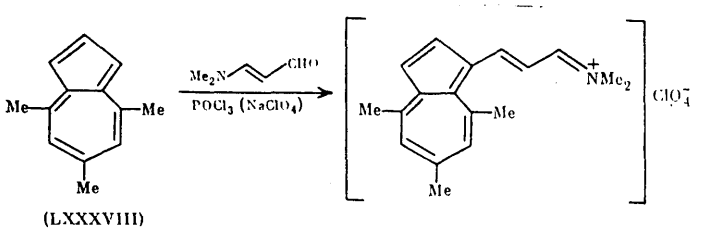
The Vilsmeier benzoylation of compound (LXXXVIII) also results in the formation of the corresponding aceazulene derivative (XCVI) in addition to the main reaction product (the 1-benzoyl derivative):



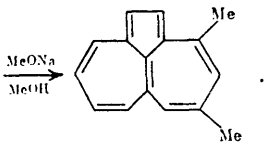
(XCVI)



The unsubstituted cyclopent[*cd*]azulene (CI) was obtained from azulene-4-acetic acid (XCVII) as a result of a series of successive transformations[66]:

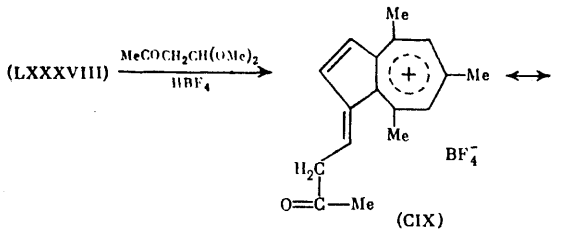


Direct cyclisation of compound (XCVII) in acetic anhydride in the presence of pyridine leads to the formation of the 2-oxo-derivative (CIII), whose oxidation with selenium dioxide in dioxan (60 °C, 3 h) yielded cyclopent[*cd*]azulene-1,2-dione (CIV)—a non-benzenoid isomer of acenaphthenequinone[66]:

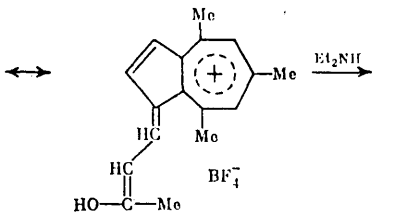


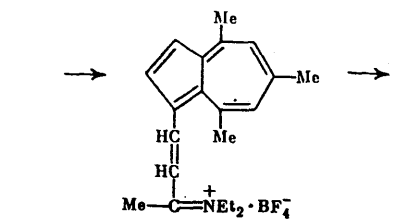
Using the scheme indicated below, Hafner et al.[66] obtained 1,2,6,7-tetrahydrodicyclopent[*cd;ij*]azulene (CV) and 1,2-dihydrodicyclopent[*cd;ij*]azulene (CVI); the latter is capable of undergoing the cycloaddition reaction with dimethyl acetylenedicarboxylate via one of the double bonds of the cyclopentane ring, forming the adduct (CVII):

Hafner and Schneider[64] obtained for the first time from 4,6,8-trimethylazulene (TMA) a new stable aromatic system—3,5-dimethylaceheptylene (CVIII):

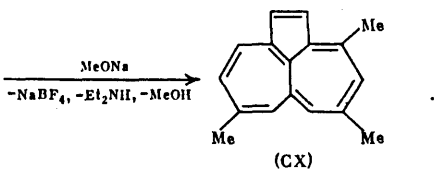


(LXXXVIII)



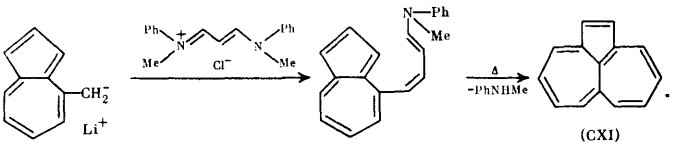


(CVIII)

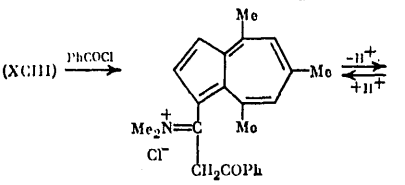


If formylacetone acetal in a strongly acid medium is used instead of β-dimethylaminoacroleine, then the intermediate azulenylium salt (CIX) is cleaved after treatment with diethylamine and subsequent heating with sodium ethoxide to form 3,5,8-trimethylaceheptylene (CX):[67]

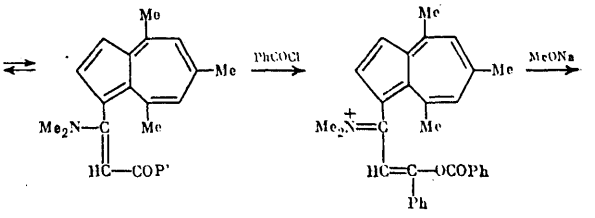
(CIX)

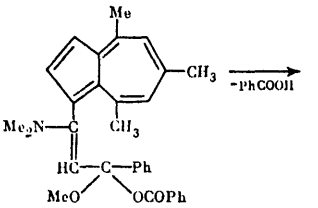


(CX)

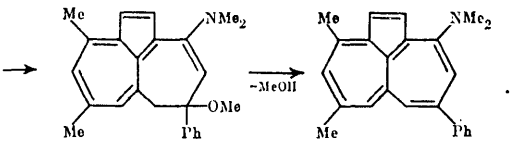


The unsubstituted aceheptylene (CXI) has been obtained by the intramolecular cyclisation of 1-(4-azulenyl)-4-methylphenylaminobutadiene[68]:



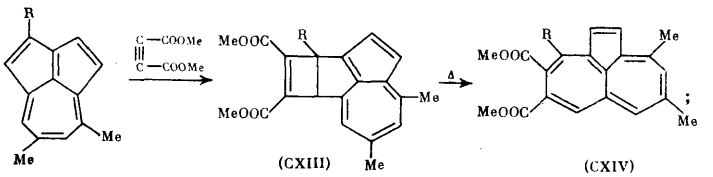


(CXI)



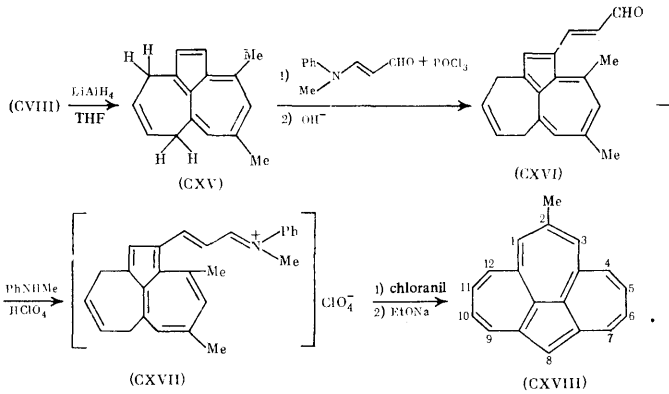
This method has been extended[57] to guaiazulene, from which a series of substitued aceheptylenes were obtained. Similar substituted derivatives have also been synthesised by the same workers from 4-methylazulene.

3,5-Dimethyl-10-dimethylamino-8-phenylaceheptylene (CXII) has been obtained by the benzoylation of the enamine (XCIII) in a series of successive stages[65]:



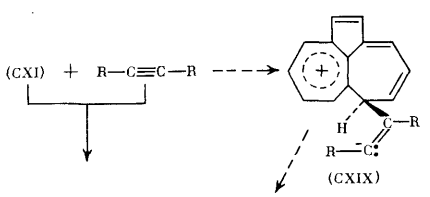
(CXII)

Derivatives of aceheptylene can be obtained also by the cycloaddition reaction of cyclopent[*cd*]azulenes with acetylenedicarboxylic esters followed by thermal isomerisation of the adduct (CXIV):[69]

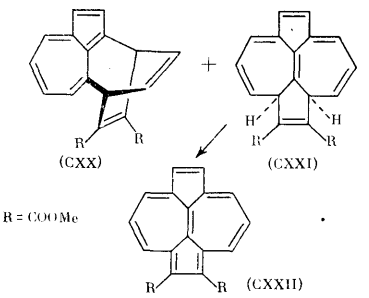


(CXIII) (CXIV)

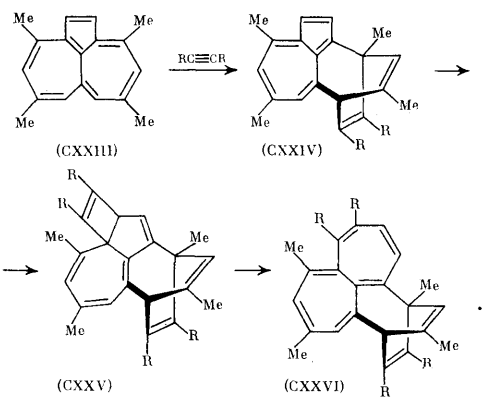
R = H, Me, Ph .



It has been established[70] that the aceheptylene derivative (CVIII) is reduced to the dihydro-derivative (CXV) on treatment with lithium tetrahydroaluminate. The involvement of

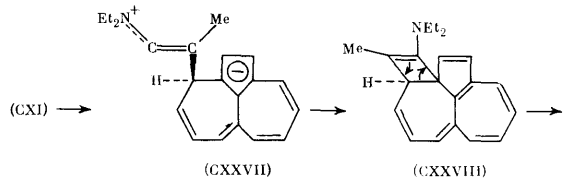


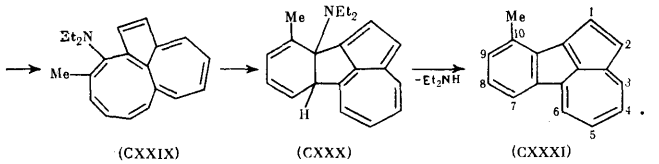
compound (CXV) in the Vilsmeier reaction ($POCl_3$ + β-methylphenylaminoacroleine) leads to the aldehyde (CXVI), which reacts with *N*-methylaniline in the presence of $HClO_4$ to form the immonium salt (CXVII). Dehydrogenation of the salt obtained with chloranil and subsequent cyclisation in the presence of bases lead to a new tetracyclic conjugated azulenoid system—2-methylazuleno[8,8a,1,2-*def*]heptalene (CXVIII):[70]



Pentalene[53], azulene, cyclopent[*cd*]azulene[71], and the readily available aceheptylene (CXI) [72] undergo cycloaddition reactions with activated alkynes unusually readily with formation of new polycyclic systems[73]. When compound (CXI) is heated for 1 h with dimethyl acetylenecarboxylate in 1 : 1 molar proportions in boiling tetralin, it is possible to obtain, together with the Diels–Alder adduct (CXX) (in 1% yield), also a 25% yield of 1,2-dicyclopenta[*ef*,*kl*]heptalenedicarboxylic ester (CXXII). The latter is probably formed from the primary adduct (CXXI), which can be obtained, like compound (CXX), from the intermediate dipolar compound (CXIX), arising either from the attack of the electron-accepting alkyne on the position with the highest electron density in the molecule of compound (CXI) or by virtue of a synchronous cycloaddition.

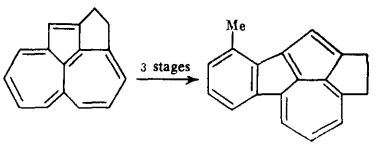
3,5-Dimethylaceheptylene and 3,5,8,10-tetramethylaceheptylene (CXXIII) react with acetylenic esters like compound (CXI).[70] However, in these cases the formation of a Diels–Alder adduct of type (CXX) predominates. The tetracyclic system on which compound (CXXII) is based had been obtained earlier only by a multistage procedure with an extremely low overall yield[74]. Within the limits of the possible comparison, the spectroscopic properties of compound (CXXII) are consistent with those of the unsubstituted tetracyclic hydrocarbon:



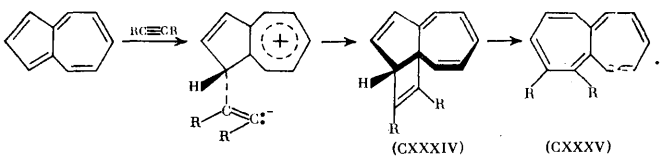


Like azulene, Diels–Alder adducts of type (CXX) undergo a dipolar cycloaddition reaction with acetylenedicarboxylic ester at 200 °C in the 1,8a-positions of the azulenoid component of compound (CXX). Thus, 3,5,8,10-tetramethylaceheptylene, which is more enriched in electrons compared with compound (CXI), reacts with acetylenedicarboxylic ester in molar proportions of 1 : 2 to form the 3,5,8,10-tetramethyl derivative (CXXV) (3%), the Diels–Alder adduct (CXXIV) (26%), and the thermally stable diene adduct of cyclohepta[*ef*]heptalene (CXXVI) (12%):

The primary formation of the 1 : 1 adduct (CXXIV) is followed by a secondary cycloaddition with formation of the adduct (CXXV), whose valence isomerisation, accompanied by the opening of the cyclobutene ring, leads to the formation of compound (CXXVI).

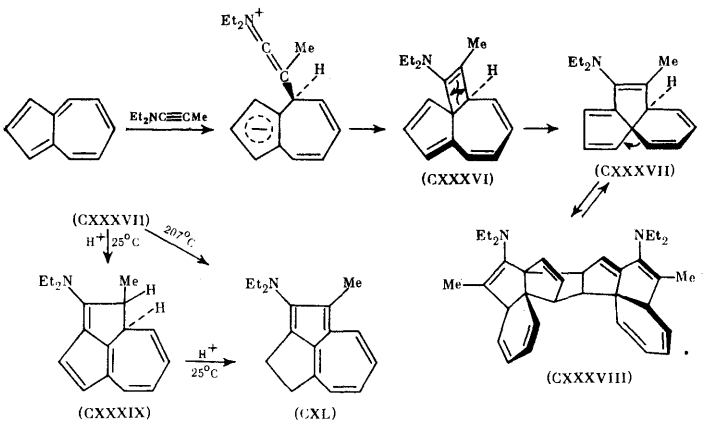


Aceheptylene (CXI) and its derivatives also undergo the cycloaddition reaction (involving very high yields) with ynamines, but the alkyne, which has an enhanced electron density, initially attacks the position most depleted in electrons. The reaction of (CXI) with *N*,*N*-diethyl-1-propynylamine probably proceeds via the formation of the intermediate (CXXVII) and the cyclic adduct (CXXVIII). The reaction involving the expansion of the cyclobutene ring leads to the thermally unstable cyclonon[*cd*]azulene derivative (CXXIX), whose valence isomerisation to compound (CXXX) and subsequent elimination of diethylamine give a 75% yield of 10-methylbenzo[*a*]cyclopent[*cd*]azulene (CXXXI)—a non-benzenoid analogue of fluoranthene, which cannot be obtained by other methods:



(CXXIX) (CXXX) (CXXXI)

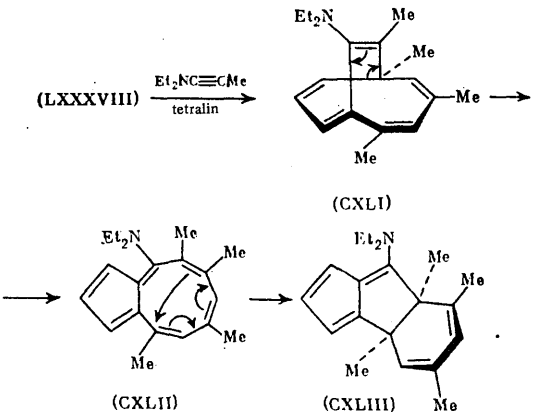
3,5-Dimethyl- and 3,5,8,10-tetramethyl-aceheptylenes react with *N*,*N*-diethyl-1-propynylamine to form 3,5-dimethyl- and 3,5,7,9-tetramethyl-derivatives of the hydrocarbon (CXXXI) in yields of 68 and 92% respectively. A tetracyclic hydrocarbon (CXXXII), for example, can be converted by an analogous procedure into 4,9-dimethyl-1,2-dihydrobenzo-[1,2]dicyclopent[*cd*,*ij*]azulene (CXXXIII) in 21% yield[73]:



(CXXXII) (CXXXIII)

It is known that azulene can not only undergo substitutional addition reactions with electron-deficient alkynes (for example with dimethyl acetylenedicarboxylate)[75] but also, like electron-enriched alkenes, the thermally induced dipolar cycloaddition via the five-membered ring of the azulene nucleus, the valence isomerisation of the primary adduct (CXXXIV) yielding the heptalene derivative (CXXXV), which is the nearest higher homologue of azulene[53]:

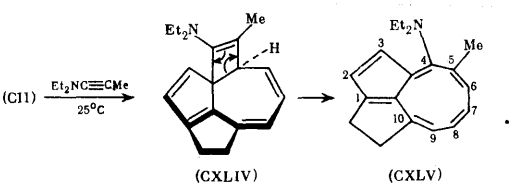
(CXXXIV) (CXXXV)



An attempt to make azulene react with *N*,*N*-diethyl-1-propynylamine led to the rapid formation of a 1 : 1 adduct (CXXXVII) in 83% yield[76]. In its crystalline form the bridged spiro-[4,5]decatetraene (CXXXVII) exists in the form of the dimer (CXXXVIII) by virtue of the [4 + 2]cycloaddition of its cyclopentadiene components, while in solution (in benzene and CCl_4 as solvents) the retrodiene synthesis takes place rapidly. Compound (CXXXVII) can be formed via the primary adduct (CXXXVI), which contains the structural element of spiro-[3,4]octa-1,5,7-triene, which readily undergoes[77] 1,5-sigmatropic ring expansion with formation of the dihydropentalene derivative (CXXXIX). The latter is converted into the more stable form (CXL) in 80% yield after 3 h under the conditions of the formation reaction of compound (CXXXIX):

(CXXXVI) (CXXXVII) (CXXXVIII) (CXXXIX) (CXL)

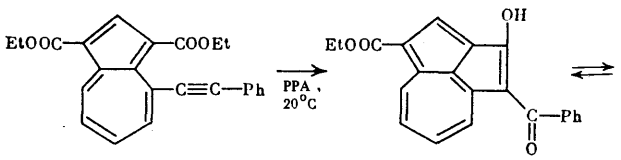
The reaction of azulene with *N*,*N*-diethyl-1-propynylamine in boilbing tetralin gives rise immediately to compound (CXL) in 17% yield, probably also via compound (CXXXVII) as an intermediate stage.



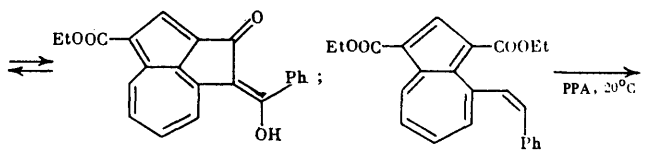
Compound (LXXXVIII) reacts with propynylamine only in boiling tetralin, the cycloaddition being hindered by the alkyl groups in the 4- and 8-positions:

(CXLI) (CXLII) (CXLIII)

The main product proved to be the dihydrocyclopentindene (CXLIII) obtained in 15% yield and containing the resonance-stabilised aminofulvene component. The intermediate state (CXLI), which is incapable of the 1,5-sigmatropic ring expansion owing to the steric hindrance due to the methyl groups but undergoes valence isomerisation to the unstable cyclononatetraene derivative (CXLII), is postulated in this thermally induced reaction. Valence isomerisation is characteristic of cyclononatetraene derivatives[78] and leads to the thermally stable system (CXLIII).

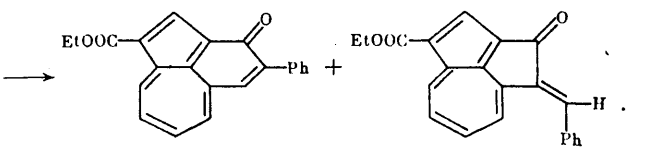


The bridged azulene (CII) reacts with propynylamine even at room temperature with formation of the red-brown crystalline derivative 4-diethynylamino-5-methylcyclopentacyclononatetraene (CXLV) in 47% yield[79]:



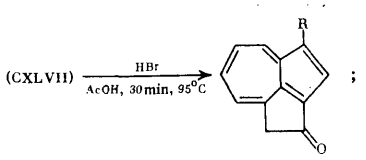
(CXLIV) (CXLV)

The conformation of the nine-membered ring in compound (CXLV) is close to the boat conformation in cyclo-octatetraene.



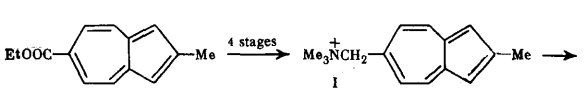
It has been shown recently[80] that diethyl 4-phenylethynylazulene-1,3-dicarboxylate (CXLVI) undergoes intramolecular cyclisation under the conditions of a reaction of the Friedel–Crafts type (treatment with polyphosphoric acid) with formation of the cyclopent[*cd*]azulene derivative (CXLVII).[81] Similarly diethyl-4-styrylazulene-1,3-dicarboxylate (CXLVIII) forms derivatives of benz[*cd*]azulene (CXLIX) and cyclopent-[*cd*]azulene (CL):

(CXLVI) (CXLVII)

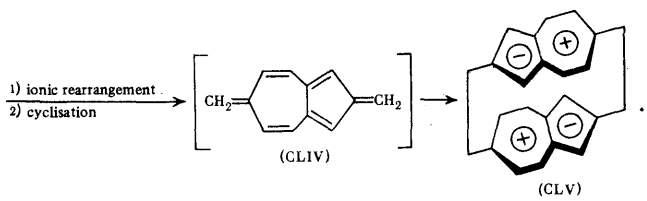


(CXLVIII)

(CXLIX) (CL)



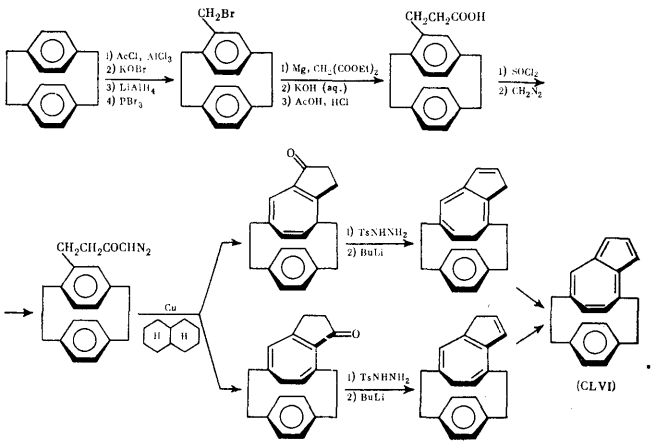
Treatment of compound (CXLVII) with 48% hydrobromic acid in acetic acid leads to the formation of the products of the elimination of the benzoyl and partly the ethoxycarbonyl groups [compounds (CLI, a and b)]:



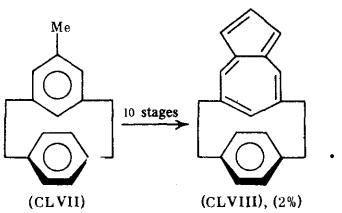
(CLI, a and b)

R = H (a), COOEt (b) .

The multiplicity of the polycyclic azulenoid systems obtained from simple azulenes with functional groups is not exhausted merely by planar conjugated molecules. In 1976 American workers[82] obtained the first azulene-containing macrocyclic system of *anti*-[2.2](2,6)azulenophane (CLV) from 6-ethoxycarbonyl-2-methylazulene synthesised in 8 stages from propiophenone:



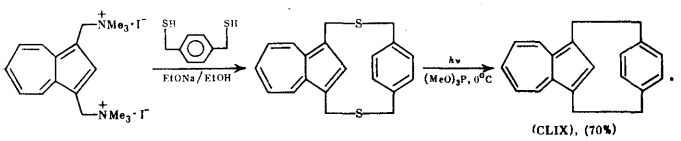
(CLII) (CLIII)



(CLIV) (CLV)

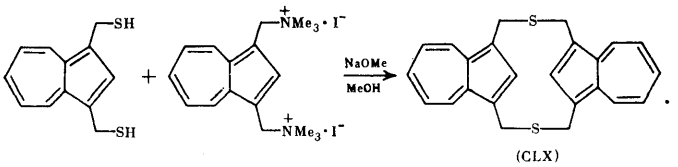
The structure of the cyclophane was demonstrated by electronic spectroscopy and ^{1}H NMR and also mass-spectrometry. Somewhat later, at the end of 1976, Japanese workers published yet another method of synthesis of the azulenocyclophane (CLV), illustrating the extensive possibilities of the intermediate transformations of azulene derivatives[83]. The protonation and electrophilic substitution of the azulenophane (CLV) by tetracyanoethylene have been recently investigated[84].

The syntheses of two types of [2.2]paracycloazulenophanes, (CLVI) and (CLVIII),[85] obtained by an intramolecular reaction involving the insertion of a carbene in [2.2]cyclophanes, have been published:



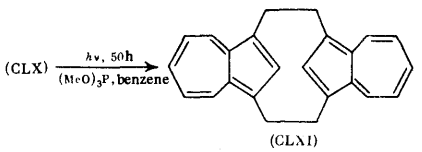
[2.2]Paracyclo(5,7)azulenophane (CLVIII) was obtained from 5-methyl[2.2]metaparacyclophane (CLVII) by a simpler procedure with an overall yield of approximately 2%:

(CLVII) (CLVIII), (2%)



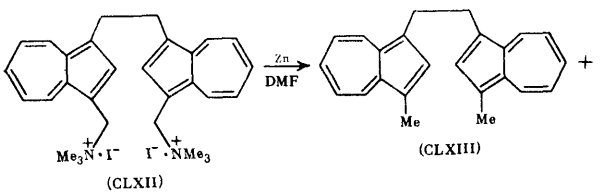
Simultaneously with the compounds indicated above, [2](1,3)azuleno[2]paracyclophane (CLIX) was also obtained[86]:

(CLIX), (70%)



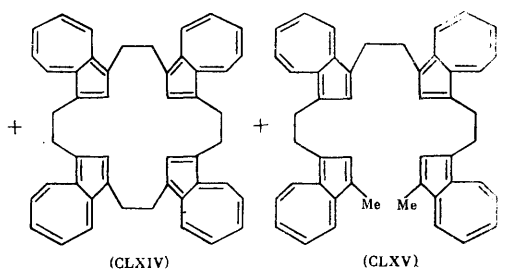
The condensation of 1,3-di(mercaptomethyl)azulene with 1,3-di(methyltrimethylammonia)azulene di-iodide in dry methanol with NaOMe (a high dilution technique is used) gives a

54% yield of 2,13-dithia[3.3]azulenophane (CLX):[87]



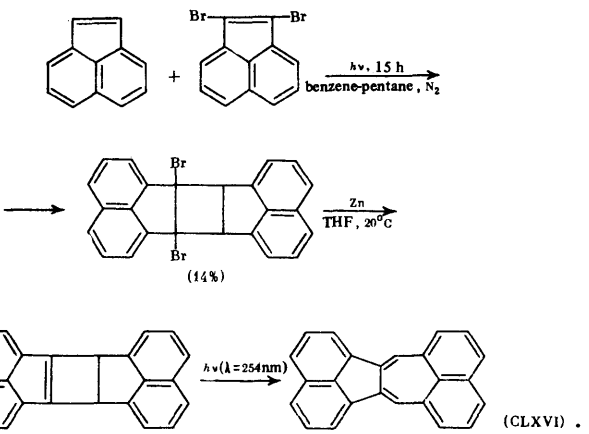
(CLX)

The photodesulphurisation of compound (CLX) in solution in trimethylphosphite–benzene gives rise to [2.2](1,3)-azulenophane (CLXI) in 16% yield:

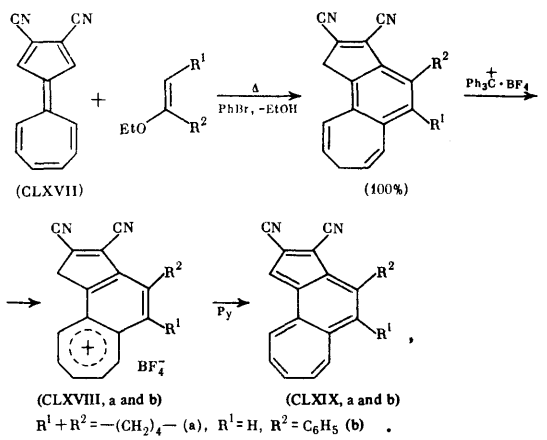


(CLXI)

Treatment of compound (CLXII) with zinc dust in dimethylformamide (DMF) under the conditions of high dilution leads mainly to polymeric products, but 3,3-diazulenyl-1,1-dimethylethane (CLXIII), [2.2.2.2](1,3)azulenophane (CLXIV), and an azulene tetramer with the structure (CLXV) have been isolated chromatographically in yields of 7, 0.1, and 1% respectively[88]:



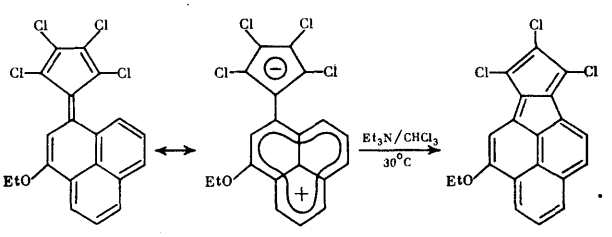
(CLXII) (CLXIII)



(CLXIV) (CLXV)

The extensive synthetic possibilities of the utilisation of azulene derivatives with functional groups are not exhausted by the carbocyclic systems presented here. Methods of synthesising polycyclic systems with condensed heterocyclic nuclei will be considered below. Before proceeding to these compounds, mention should probably be made of individual representatives of the kind of "non-classical azulenoid systems" obtained recently, in which the role of the seven-membered ring is assumed by another conjugated system, whose structure does not resemble that of the tropylium cation but which is capable of carrying a partial positive charge delocalised over the system. The hydrocarbon (CLXVI), obtained by a combination of photochemical and chemical methods[89], can serve as a representative of such "non-classical systems":

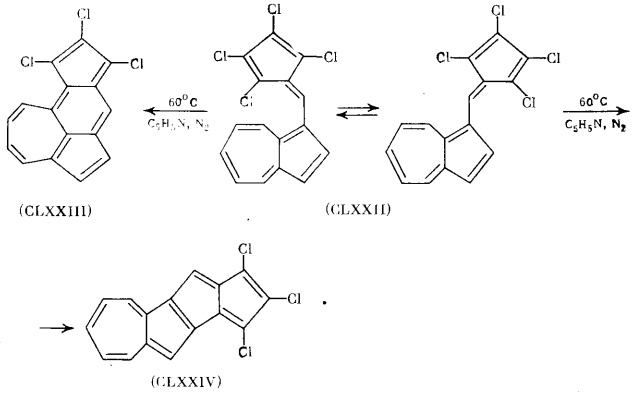
(CLXVI).



Stable derivatives of phenazulene (CLXIX, a and b), obtained by the [12 + 2] addition of ethoxycyclohexene or α-ethoxystyrene to 8,9-dicyanosesquifulvalene (CLXVII), have an intense blue-violet colour and are very weakly basic, but are protonated by concentrated H_2SO_4 in acetic acid to compounds (CLXVIII, a and b):[90]

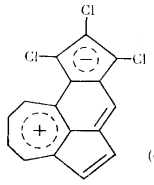
(CLXVII) (100%) (CLXVIII, a and b) (CLXIX, a and b)

$R^1 + R^2 = -(CH_2)_4-$ (a), $R^1 = H$, $R^2 = C_6H_5$ (b).



Japanese workers have reported[91,92] that the dehydrochlorination of 9,10,11,12-tetrachloro-2-ethoxypentaphenafulvalene (CLXX) by triethylamine leads to a new pentacyclic conjugated system—6,7,8-trichloro-4-ethoxypentaleno[1,2,3-*cd*]phenalene (CLXXI):

(CLXX) (CLXXI)



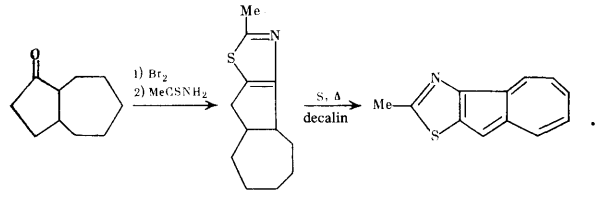
Depending on the nature of the solvent, the ring closure reaction takes place in acetone and n-heptane in 45 min and 10 h respectively. On the basis of these data, the authors proposed an ionic reaction mechanism. If the ionic reaction

does indeed occur, one can assume that a similar intramolecular cyclisation would occur in an alternative form of the molecule, which has a polar electronic structure and is sterically more preferable. The synthesis of the previously unknown tetracyclic conjugated π-electron system of cyclohept[*cd*]-*sym*-indacene (CLXXIII),[93] which can be regarded as an isomer of cyclohepta[*a*]phenalene,[94] was undertaken as an initial test of this hypothesis:

(CLXXIII) (CLXXII) (CLXXIV)

Both NMR data and LCAO-MO calculations for the carbon skeleton of compound (CLXXIII) suggest that the polar structure (CLXXIIIa), similar to that of sesquifulvalene, predominates in the true state of compound (CLXXIII):

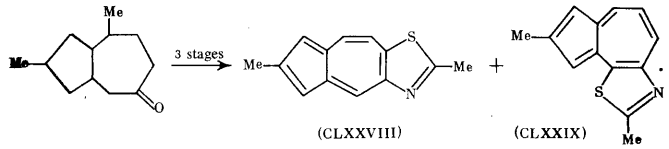
(CLXXIIIa)



The structure of the alternative product (CLXXIV) has not been finally established although the authors ascribe to it the structure indicated on the basis of mass-spectrometric data and the positions of the absorption bands in the electronic spectrum. Compounds (CLXXIII) and (CLXXIV) are unstable.

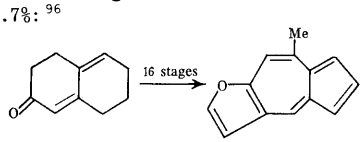
The chemistry of such azulene-like polycyclic systems, which sometimes do not obey the Hückel rule, is a matter for the future and is of great theoretical interest from the standpoint of synthesis, stability, and chemical and physicochemical properties.

III. STRUCTURES WITH CONDENSED NITROGEN-, SULPHUR-, AND OXYGEN-CONTAINING HETEROCYCLES



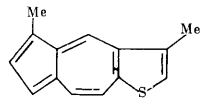
1. Total Syntheses Involving Dehydrogenation

As already mentioned, we include among the total syntheses methods whereby polycyclic azulenes are obtained employing starting materials which are not azulene derivatives and which usually involve a dehydrogenation stage. For example, the bromination of bicyclo[5.3.0]-1-decanone (CLXXV) and subsequent treatment of the resulting α-bromoketone with thioacetamide lead to the thiazole derivative (CLXXVI), which is dehydrogenated by sulphur to 2′-methylthiazole[4′,5′ : 1,2]-azulene (CLXXVII),[95] whose ultraviolet spectrum is close to that of 1,2-benzazulene:



(CLXXV) (CLXXVI) (CLXXVII)

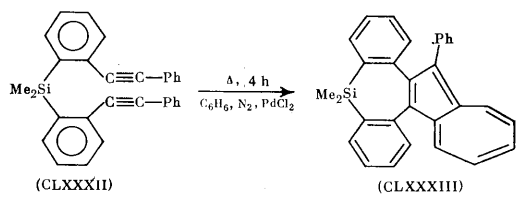
Similarly, 2,8-dimethylbicyclo[5,3,0]-5-decanone gives rise to the two isomeric compounds (CLXXVIII) and (CLXXIX) in proportions of 7 : 1 respectively:



(CLXXVIII) (CLXXIX)

The synthesis of 3,8-dimethylazuleno[6,5-*b*]furan (CLXXX) from naphthalene derivatives has been patented. The synthesis consists of 16 stages and the overall yield of compound (CLXXX) is 0.7%:[96]

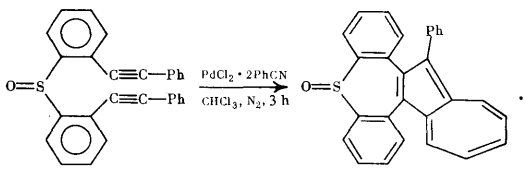
(CLXXX)



When the sequiterpene fraction of camphor oil is dehydrogenated with sulphur, a small amount of 3,5,8-trimethylazuleno[6,5-*b*]thiophen (CLXXXI) is formed together with *S*-guaiazulene and vetivazulene[97]:

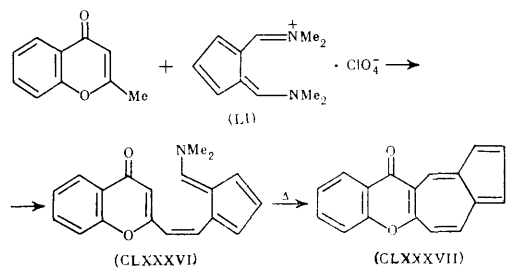
(CLXXXI)

2. Syntheses Based on Acetylenic Derivatives and Other Methods



The catalytic rearrangement of the silicon-containing acetylenic hydrocarbons (CLXXXII), leading to a 30% yield of 5,5-dimethyl-10-phenylazuleno[1,2-*d*]dibenzo[*bf*]silepin (CLXXXIII) has been reported[98]:

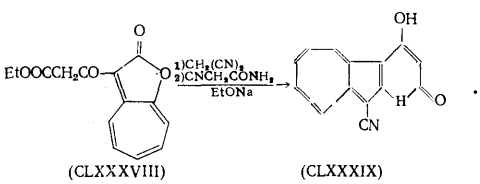
(CLXXXII) (CLXXXIII)



Later the same workers[99] published a synthesis of 5-oxo-10-phenylazuleno[1,2-*d*]dibenzo[*bf*]thiepin (CLXXXV), carried

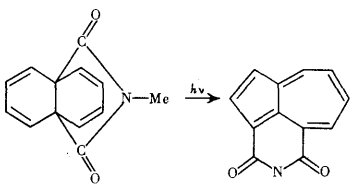
out by treating the diyne (CLXXXIV) with the complex catalyst $PdCl_2.2PhCN$:

(CLXXXIV) (CLXXXV)



2-Methylchromone has been condensed[50] with a heptamethinium salt (LI) in the presence of sodium methoxide in quinoline, the enamine (CLXXXVI) formed splitting off dimethylamine on heating and giving a 43% yield of azuleno-[6,5-*b*]chromen-12-one (CLXXXVII):

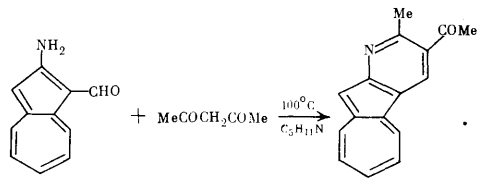
(LI)



(CLXXXVI) (CLXXXVII)

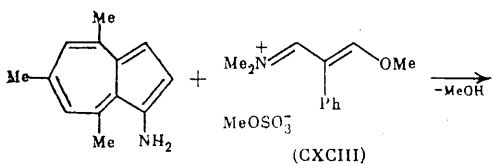
Japanese workers[100] obtained 10-cyano-4-hydroxyazuleno-[1,2-*e*]-2-pyridone (CLXXXIX) from the 2*H*-cyclohepta[*b*]-2-furanone derivative (CLXXXVIII) by multistage condensation with malononitrile and cyanoacetamide:

(CLXXXVIII) (CLXXXIX)



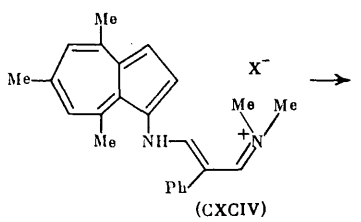
When propellane (CXC) is irradiated with ultraviolet light, the *N*-methylimide of azulene-1,8-dicarboxylic acid (CXCI) is formed in 4% yield together with a series of other compounds[101]. This reaction is of interest because in this case one of the carbocyclic rings contracts with the simultaneous expansion of the neighbouring heterocyclic and cyclohexadiene rings:

(CXC) (CXCI)

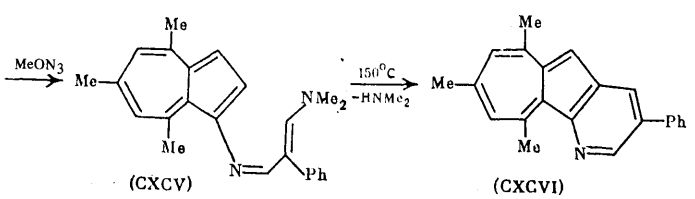


3. Azulene Derivatives in the Synthesis of Heterocyclic Azulenoid Systems

The application of azulenes with functional groups in the synthesis of polycyclic azulenoid systems, including nitrogen- and sulphur-containing heterocycles, constitutes at the present time the most universal method, which has led to the preparation of an extremely large number of a wide variety of compounds of this series. The presence of a free or an acyl-substituted amino-group in the azulene nucleus made it possible to obtain azulenopyridines of various structures as well as other nitrogen-containing derivatives. Thus the condensation of 2-amino-1-formylazulene with acetylacetone in the presence of piperidine makes it possible to obtain 3-acetyl-2-methylazuleno[2,1-*b*]pyridine (CXCII):[102]

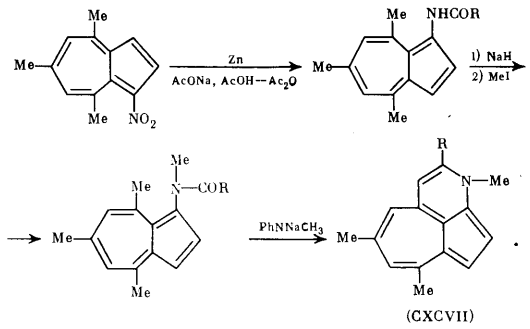


(CXCII)



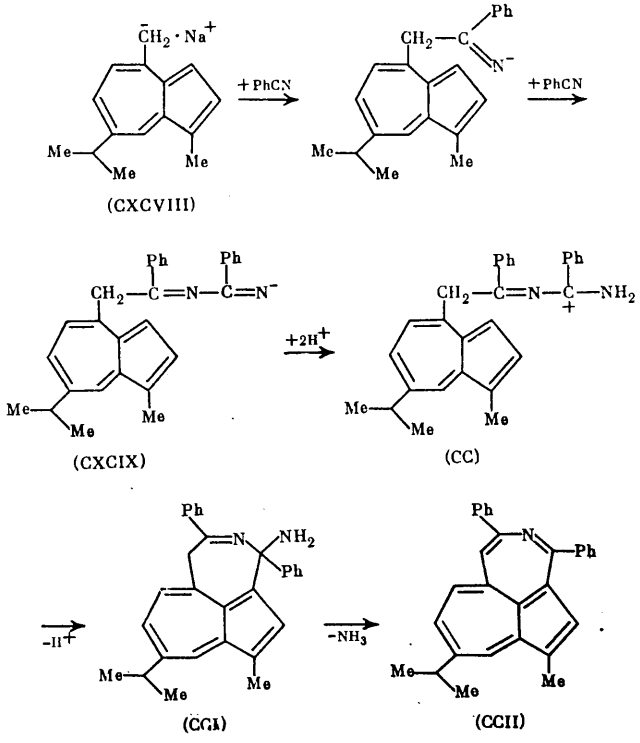
Another isomeric azulenopyridine derivative has been synthesised[57] by the condensation of 1-amino-4,6,8-trimethylazulene with the trimethinium salt (CXCIII). The azulenyltrimethinium salt (CXCIV) is formed initially and is then isolated in the form of the sparingly soluble perchlorate. On reaction with sodium methoxide, the salt splits off perchloric acid and is converted into the amidine (CXCV), which splits off dimethylamine at a temperature as low as 150 °C with formation of 6,8,10-trimethyl-3-phenylazuleno[1,2-*b*]pyridine (CXCVI):

(CXCIII)



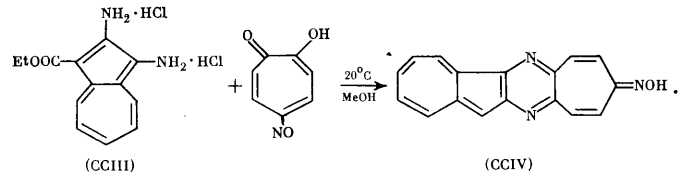
(CXCIV)

(CXCV) (CXCVI)



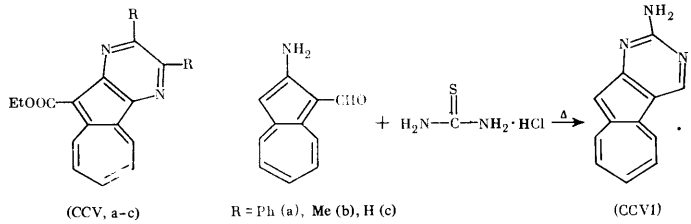
The mobility of the hydrogen atoms of the methyl groups in TMA can be used to synthesise a new pyridine ring condensed along the *cd* faces of the azulene nucleus. An example of this synthesis is provided by the preparation of 1,2,5,7-tetramethyl-1*H*-cyclohepta[*d*,*e*]-1-pyrindine or 1,5,7-trimethyl-2-phenyl-1*H*-cyclohepta[*d*,*e*]-1-pyrindine

(CXCVII) in accordance with the following scheme[103]:

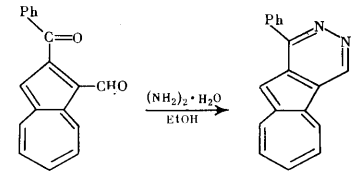


(CXCVII)

The sodio-derivative of guaiazulene (CXCVIII) condenses with benzonitrile to form the amidinium ion (CXCIX) (as the double accretion product), which forms in an acid medium the conjugated carbonium cation (CC), the latter cyclising intramolecularly to the unstable intermediate ketimine (CCI). As a result of the elimination of ammonia from the enamine (the ketimine–enamine tautomerism), the stable aromatic system of 6-isopropyl-8-methyl-2,10-diphenylazuleno[8,9,1-*de*]-azepine (CCII) is formed[104]:

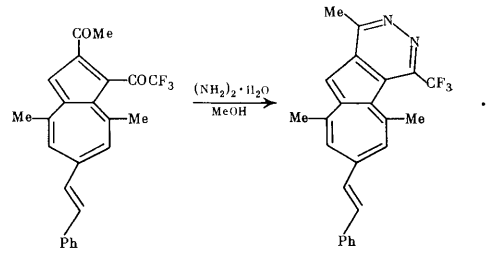


Heterocyclic azulene-containing systems with two nitrogen atoms in the heterocycle can be readily obtained from 1,2-diaminoazulenes. Thus the synthesis of a series of polycyclic derivatives based on 1,2-diamino-3-ethoxycarbonylazulene has been described[105]. When compound (CCIII) was condensed with 5-nitroso-tropolone in methanol, the tetracyclic tropone oxime (CCIV), containing the pyrazine ring in the system, was obtained:



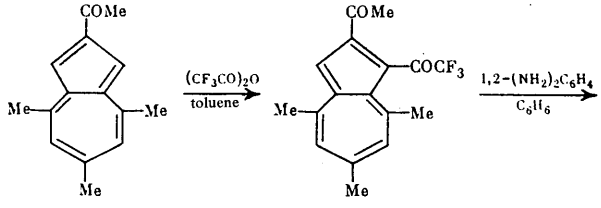
(CCIII) (CCIV)

The condensation of the same diamine with α-dicarbonyl compounds (benzil, diacetyl, or the bisulphite derivative of glyoxal) leads to the corresponding azulenopyrazines (CCV, a–c). The same workers described also the synthesis of the aminoazulenopyrimidine (CCVI):

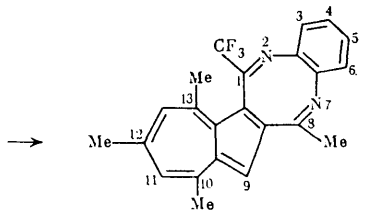


(CCV, a-c) R = Ph (a), Me (b), H (c) (CCVI)

In the presence of two carbonyl groups in the azulene ring, for example the ketone and aldehyde groups, condensation with hydrazine leads to the formation of the azulenopyridazine derivatives (CCVII) [59] and (CCVIII): [39]

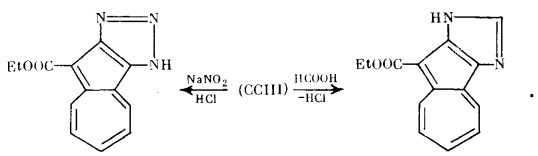


(CCVII)

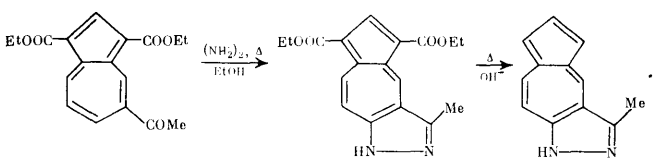


(CCVIII)

Trifluoroacylation of 2-acetyl-TMA (CCIX), obtained by the thermal reaction of TMA with malonic acid[106], results in the formation of the 1,2-diketone (CCX), whose condensation with *o*-phenylenediamine yields the new tetracyclic system 1-trifluoromethyl-8,10,12-14-tetramethylbenzo[*b*]azuleno-[2,1-*f*]-2,7-diazacyclo-octa-2′,4′,6′,8′-tetraene (CCXI): [39]

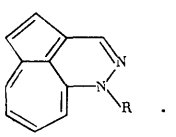


(CCIX) (CCX)



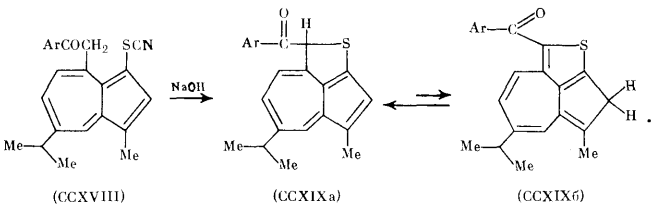
(CCXI)

Derivatives of 1,2-diaminoazulene of type (CCIII) can be readily converted into tricyclic systems containing pyrazole or triazole rings, by their condensation with formic acid or by the diazotisation of one of the amino-groups respectively[105]. The 3-ethoxycarbonyl derivatives of azuleno[1,2-*d*]imidazole (CCXII) and azuleno[1,2-*d*]triazole (CCXIII) have been obtained in this way:



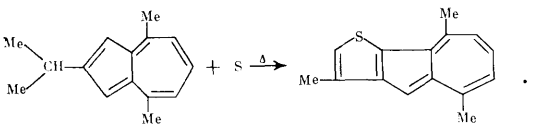
(CCXIII) (CCXII)

The presence of the electron-accepting ketone group in the seven-membered ring, particularly in azulenes in which the electron density is already reduced, such as, for example, 1,3-diethoxycarbonylazulene, the sensitivity of the seven-membered ring to nucleophilic addition increases so much that it permits the synthesis of a pyrazole system, condensed via one of the faces of the seven-membered ring, by the usual condensation of the corresponding derivatives with hydrazine. 5,7-Diethoxycarbonyl-3-methylazuleno[5,6-*d*]pyrazole was obtained in this way[107], the reaction evidently involving the intermediate formation of a hydrazone and its oxidation to the final product. At an elevated temperature the alkaline hydrolysis and decarboxylation of compound (CCXV) lead to 3-methylazuleno[5,6-*d*]pyrazole[108]:



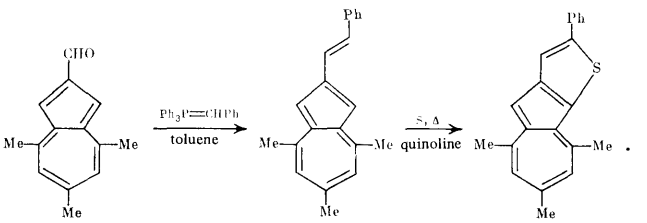
(CCXIV) (CCXV) (CCXVI)

Yet another new polycyclic structure, namely 1*H*-azuleno-[3,10,4-*de*]-1-R-pyridazine (CCXVII) has been obtained[109]:



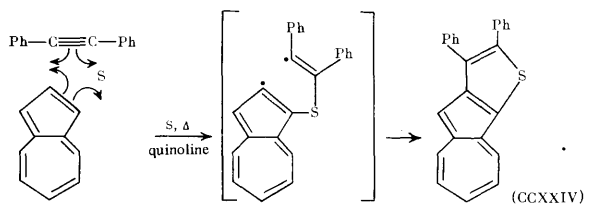
(CCXVII)

Several polycyclic systems incorporating condensed sulphur-containing heterocycles have been obtained from various azulene derivatives with functional groups. Thus the azulenocyclothiophen derivatives (CCXIX) is formed from the thiocyanatoazulenyl ketone (CCXVIII) and it has been established that the azulenodihydrothiophen tautomer (CCXIXa) is thermodynamically more favourable than the heptafulvenothiophen (CCXIXb):[110]



(CCXVIII) (CCXIXa) (CCXIXб)

The high electron density in the 1- (or 3-) position in various alkylazulenes makes it possible to arrive at the azulenothiophen system as a result of the usual dehydrogenation with elemental sulphur. For example, when vetivazulene is heated with sulphur at 200 °C for 4 h in nitrogen, 3,5,9-trimethylazuleno[1,2-*b*]thiophen (CCXX) is formed in 18% yield[111]:

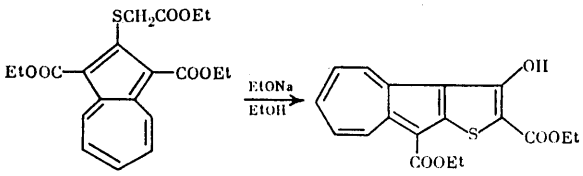


(CCXX)

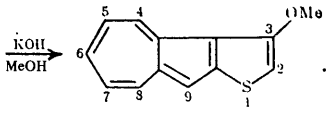
After it had been established that 1-formyl-TMA undergoes thermal isomerisation to the 2-formyl isomer (CCXXI),[112] a thienoazulene derivative was synthesised via 2-styryl-TMA (CCXXII):[39]

(CCXXI) (CCXXII) (CCXXIII), (22%)

When azulene is heated with sulphur in the presence of diphenylacetylene, dehydrogenation takes place with condensation of the reactants to 2,3-diphenylazuleno[1,2-*b*]-thiophen (CCXXIV) in 8% yield[39]:



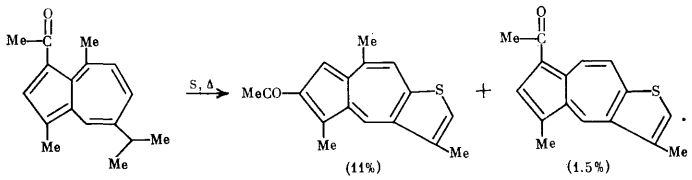
(CCXXIV)



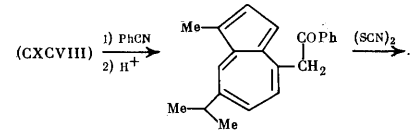
The authors explained the unusual condensation of azulene with diphenylacetylene by the formation of a five-centre intermediate state which is converted into a biradical, the latter recombining to the stable thienoazuleno system. The reaction is accompanied by the formation of a considerable amount of tetraphenylthiophen.

The presence of the thioglycolic residue in the 2-position in azulene made it possible to achieve the cyclisation of the ester (CCXXV) under the conditions of the Dieckmann reaction with its transformation via the hydroxyester (CCXXVI)

into 3-methoxyazuleno[2,1-*b*]thiophen (CCXXVII):[113]

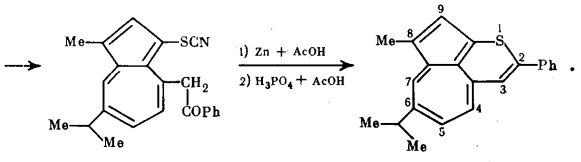


(CCXXV) (CCXXVI)



(CCXXVII)

The synthesis of 5- and 7-isopropylazuleno[2,1-*b*]thiophens has been described[114] and the cationic substitution of such systems has been investigated[115]. The thermal reaction of 3-acetylguaiazulene with sulphur, leading to the formation, apart from the 2-acetyl derivative, of azulenothiophens in which the thiophen ring is annellated along the *f* face of azulene [at the C(5) and C(6) atoms] is known[116]:

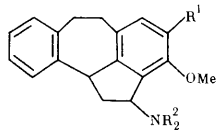


(11%) (1.5%)

The mobility of the hydrogen atoms in the 4-methyl group of guaiazulene makes it possible to obtain the sodio-derivative (CXCVIII), which condenses with benzonitrile to 7-isopropyl-1-methyl-4-phenacylazulene (CCXXVIII). The reaction of the latter with free thiocyanogen, the reduction of the thiocyanate (CCXXIX) with zinc in acetic acid, and intramolecular cyclisation of the intermediate mercapto-derivative, evidently with the enolic form of the phenacyl group, lead to a new azulenoid system—6-isopropyl-8-methyl-2-phenylazuleno[1,9,8-*bc*]thiapyran (CCXXX):[117]

(CCXXVIII)

(CCXXIX) (CCXXX)



Later a similar system was obtained from TMA.[104] Agreement between the theoretically predicted and experimentally observed mode of electrophilic substitution has been demonstrated for the condensed heterocyclic system (CCXXX).

Thus the Mannich reaction takes place exclusively in the 9-position (yield 79%); the Vilsmeier–Haack formylation of compound (CCXXX) gives rise to the 9-formyl derivative (39%) and the 4-formyl derivative (30%).[118]

The examples of the synthesis of polycyclic azulenes presented above do not exhaust all the possibilities of obtaining more highly condensed and complex carbocyclic and heterocyclic derivatives of this class. The employment of polyfunctional substituted azulenes with polyene residues and heterochain substituents is particularly promising in this field[39].

IV. PHYSIOLOGICAL PROPERTIES OF POLYCYCLIC AZULENES

Until recently, there has been virtually no information in the literature about the physiological activity of polycyclic azulene hydrocarbons and their derivatives, which can probably be accounted for by the fact that many representatives of this class are difficult to synthesise and have been obtained comparatively recently. It is only known that 3-acetyl-2-methylazuleno[2,1-*b*]pyridine as well as 5,7-diethoxycarbonyl-3-methylpyrazolo[4,3-*f*]azulene have been patented as preparations with antipyretic and anti-inflammatory activities[102,108]. 3-Methylpyrazolo[4,3-*f*]azulene has sedative and analgesic properties[108]. Azulene derivatives with analgesic, antidepressant, sedative, and hypotensive properties have been obtained [these derivatives should be more appropriately assigned to the class of hydrogenated azulenylamines of type (CCXXXI)]:[119]

(CCXXXI) R^1 = OH, OMe; R^2 = H, Me .

Certain other derivatives of the series of compounds (CCXXXI) possess similar properties[120]. *l*-3,5β,8β-Trimethyl-4,5,5aα,6,7,8,8aα,9-octahydroazuleno[5,6-*b*]furan[121], which possesses sedative, analgesic, and anticough properties, is known among hydrogenated azulene derivatives. A strong carcinogenic activity is attributed to aceazulenophenalene[49] and a group of other polycyclic azulenes[122]. The azulenofuran (CLXXX) has been patented as a preparation which is effective in the treatment of cancer and stomach ulcers[96].

Latest Advances and Trends in the Development of Catalysis on Zeolites

Ya.I.Isakov and Kh.M.Minachev

The most important advances in the utilisation of zeolites in catalysis in recent years (1977-1981) and the trends in the development of research in this field are examined.
The bibliography includes 252 references.

I. INTRODUCTION

Vigorous systematic studies on the utilisation of synthetic zeolites in catalysis have been prosecuted already for more than 20 years. During this period, the efforts of many teams of research workers have laid the scientific foundations for the creation and preparation of zeolitic and zeolite-containing catalysts; factors determining their activity, selectivity, and stability in various reactions have been found, effective ways of regulating the properties of a wide variety of catalysts have been devised, extensive possibilities in the application of zeolitic sytems in catalytic processes have been discovered, considerable advances have been made in the elucidation of the nature of the active centres and the mechanisms of the action of individual systems in reactions of different types, new effective catalysts, including polyfunctional catalysts, have been devised for many petroleum processing and petrochemical reactions, fundamentally new processes based on the utilisation of the characteristic features of the structure of zeolites (selecto-forming, deparaffinisation of oils, etc.) have been proposed, and the industrial manufacture and utilisation of zeolitic catalysts in many chemical processes have been achieved. A consequence of practical importance of the studies which have been carried out is also the formulation of recommendations for the suppresssion of the "parasitic" catalytic activity of zeolitic adsorbents, manifested when they were employed in the drying and purification of olefins and other reactive compounds (formaldehyde, etc.).

The results of studies in this field have been surveyed in a number of monographs, collections, and reviews[1-19]. Vigorous studies are being continued. New possibilities for the application of zeolites in catalysis are being discovered all the time. Specific search for and synthesis on zeolitic materials, necessary for the solution of the most important scientific and technical problems in modern chemistry, are being prosecuted. The research front is extremely broad; more than 250 papers are published annually and numerous patents devoted to various aspects of the synthesis, investigation, and application of zeolitic catalysts are taken out. The volume of information increases very rapidly, which makes it extremely desirable to examine periodically the accumulated data and to analyse the trends in the development of research and advances in the given field of heterogeneous catalysis, which has acquired great theoretical and practical importance. This review is devoted to such analysis of the results of studies published in 1977–1981. The results of earlier investigations are quoted only in so far as it is necessary.

II. EXPANSION OF THE APPLICATIONS OF ZEOLITIC AND ZEOLITE-CONTAINING CATALYSTS

The determination of the efficiency of zeolites as catalysts and components of various catalytic systems in a wide variety of chemical reactions (see, for example, Refs.1, 2, 5, and 8) as well as the discovery of reactions specific solely to crystalline aluminosilicates, such as, for example, the synthesis of ethyl and vinyl derivatives of aromatic compounds by the condensation of $ArCH_3$ with methanol or formaldehyde on the K-, Rb-, and Cs-forms of synthetic faujasites (X and Y zeolites)[20,23] and other reactions[2,5,8], stimulated the search for new applications of these materials in catalysis. The primary results of the research carried out in recent years has been a significant extension of the range of reactions accelerated by zeolitic systems.

1. Organic Reactions

It has been established[24-29] that the *oxidation of lower olefins to carbonyl compounds* can be achieved with a high selectivity on ion-exchange and impregnated zeolitic catalysts containing the Pd^{2+} and Cu^{2+} cations in the presence of water vapour:

$$RCH{=}CH_2 + 0{,}5O_2 \xrightarrow[115-120^{\circ}C]{H_2O} RCOCH_3 .$$

Features of the catalysis such as the necessity for the simultaneous presence in the catalyst of palladium and copper ions (the maximum efficiency is attained for the ratio[24] $Cu^{2+}:Pd^{2+} \cong 6:1$), the deactivation of PdCuNaY on treatment with hydrogen (at 400 °C) and on reduction of M^{2+} to the metal, the

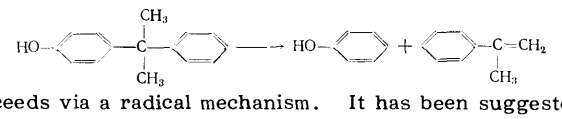
important role of water in ensuring the selectivity and stability of the catalyst, and the decrease of the rate of oxidation of olefins in the sequence ethylene > propene > but-1-ene > *cis*-but-2-ene ≅ *trans*-but-2-ene, which is the same as the analogous sequence in the homogeneous catalytic oxidation of C_nH_{2n} in the presence of $CuCl_2$–$PdCl_2$, etc.[24–29], led to the conclusion that the main stages of the oxidation reaction of olefins, in particular of ethylene to acetaldehyde, on zeolitic systems are similar to those found for solutions of palladium and copper salts[30]. On the basis of the data obtained, zeolitic catalysts for the oxidation of lower olefins to carbonyl compounds can be assigned to the class of heterogenised metal complex catalysts. This conclusion is of fundamental importance and gives rise to a new research field.

The synthesis of ethylene glycol from formaldehyde is catalysed by the zeolites NaX, CaA, and Na-mordenite[31]. The condensation is carried out in the presence of NaOH and proceeds in accordance with the mechanism

$$HCOH + HCOH \rightarrow HOCH_2CHO ;$$
$$HOCH_2CHO + HCOH + NaOH \rightarrow HOCH_2CH_2OH + NaOOCH .$$

This is accompanied by the simultaneous Cannizzaro reaction:

$$HCHO + HCHO + NaOH \rightarrow CH_3OH + NaOOCH .$$



The presence of NaOH in the reaction mixture prevents the formation of free formic acid, which decomposes the catalyst. In the case of Na-mordenite, the degree of conversion of HCOH was ~100% and the selectivity in the formation of glycolaldehyde was ~75% (~24% of HCOH was converted into CH_3OH and HCOOH and <1% was converted into sugars). The synthesis described is of interest as an example of typical base catalysis by zeolitic systems.

Another example of such catalysts is provided by *the crotonic condensation of n-butyraldehyde*, which the authors of the review investigated[32]:

$$C_3H_7CHO + C_2H_5CH_2CHO \rightarrow C_3H_7CH=C(C_2H_5)CHO + H_2O .$$

At atmospheric pressure and 100–200 °C on zeolites X and Y, butyraldehyde is converted with a high (97–100%) selectivity into 2-ethylhexenal and, in contrast to many other reactions (alkylation, disproportionation, oligomerisation, isomerisation, etc.)[33], in this case the M^+-forms of the faujasites are much less active than the specimens containing the M^{2+} and H^+ cations and exhibiting the properties of solid acids (Table 1). Carbon dioxide, which intensifies reactions of the carbonium type accelerated by zeolites[19], has a poisoning effect on the catalysts. These results and the earlier data[34] show that the activity of faujasites in the reaction under discussion is associated with their basic properties.

The efficiency of the NaX zeolite as a catalyst of *the decomposition of p-cumenylphenol with formation of phenol and α-methylstyrene* has been demonstrated[35]. The maximum degree of conversion of the initial substance was observed at 400 °C. It is believed[35] that the reaction

proceeds via a radical mechanism. It has been suggested that the dealkylation of *p*-cumenylphenol be used as a test in the study of catalysts with different types of active centres[35].

Interesting features of the catalytic action of zeolites were discovered in *the halogenation of aromatic compounds*. It has been established[36] that type X zeolites are able to accelerate the chlorination of toluene and halogenobenzenes with formation of *para*- and *ortho*-substituted derivatives whose ratio is significantly higher than for the usual chlorination catalysts, in particular $FeCl_2$. It has been shown[37] that zeolites Y are selective catalysts of the bromination of halogenobenzenes:

$$C_6H_5X + n\ Br_2 \xrightarrow[25-65°C]{CaY} C_6H_{5-n}Br_nX + n HBr$$
(X=F, Cl, Br; n = 1, 2)

Table 1. Dependence of the degree of conversion of n-butyraldehyde into 2-ethylhexenal (%) in the presence of type X and Y zeolites on their composition and the reaction conditions[32].

Zeolite	Without carrier gas	In stream of H_2	In stream of CO_2	Zeolite	Without carrier gas	In stream of H_2	In stream of CO_2
NaX (x=2.5)	45.5	42.2	29.8	0.13 HNaX	24.9	16.8	14.3
0.75 KNaX	53.0	48.2	41.6	0.13 BaNaX	27.8	24.2	19.1
0.65 RbNaX	49.0	46.4	44.6	0.13 NiNaX	34.8	29.5	23.7
0.65 CsNaX	51.6	48.1	46.9	NaY (x=4.4)	23.2	17.4	12.5
0.13 CaNaX	27.5	17.9	13.9	0.70 KNaY	35.8	33.0	28.5
0.81 CaNaX	17.2	13.7	9.1	0.70 RbNaY	35.3	30.4	30.0

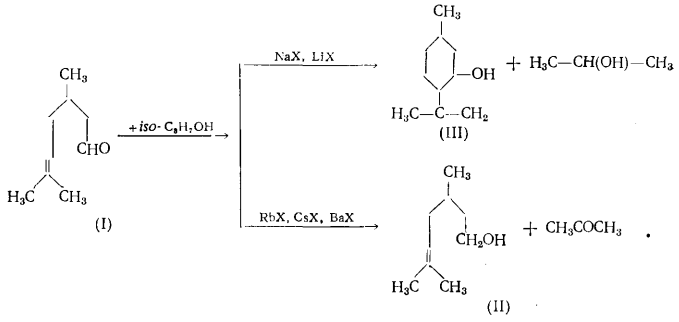
Note; $\nu = 1\ h^{-1}$; $C_4H_8O:H_2(CO_2) = 1:0.8$. For the reaction on the MNaX and MNaY zeolites, the temperature is 125° and 200 °C respectively. Here and henceforth the numerals in front of the cations in the formulae of the zeolites indicate the degree of exchange of Na^+ for M^{n+} expressed as a fraction; x is the molar ratio $SiO_2:Al_2O_3$ and ν is the volume flow rate (the ratio of the volumes of the liquid reactant supplied in 1 h to the volume of the catalyst); the molar reactant ratio is always quoted.

Under certain conditions in the preliminary treatment and when catalysts were employed, it was possible to obtain monobromination products enriched in the *para*-isomer. According to Huizinga et al.[38], *the gas-phase chlorination of benzene* (175 °C) on zeolites Y as well as amphoteric aluminosilicate (Al–Si) results in the almost exclusive formation of chlorobenzenes—the products of the substitution of H for Cl, whereas on the ZSM-5 and ZSM-11 catalysts, silicalite, H-mordenite, and SiO_2, mainly hexachlorocyclohexane—the product of the addition of Cl—is formed (Table 2):

$$C_6H_6 + Cl_2 \xrightarrow{ZSM\text{-}5} C_6H_6Cl_6$$
$$C_6H_6 + Cl_2 \xrightarrow{LnY} C_6H_{6-n}Cl_n .$$

The specificity of the catalytic action of high-silica zeolites and SiO_2 was explained by the fact that they promote the preferential homolytic dissociation of chlorine, which leads to the radical addition of Cl, whereas substances containing considerable amounts of aluminium (and acid OH groups) favour an ionic process with formation of electrophilic chlorination products[38].

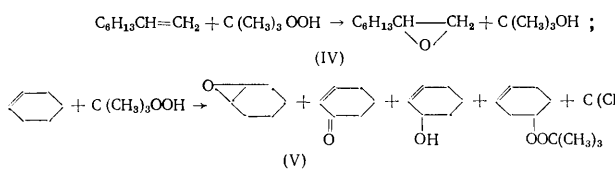
The efficiency of the MgY, AlY, GaY, and InY zeolites as catalysts of *the condensation of N-2-hydroxypropylethylenediamine with carboxylic acids* has been demonstrated:



$$RCOOH + H_2NCH_2CH_2NHCH_2CH(OH)CH_3 \xrightarrow[-H_2O]{MNaY} \rightarrow RCONHCH_2CH_2NHCH_2CH(OH)CH_3 \xrightarrow{H_2O} \rightarrow$$
$$\rightarrow \begin{array}{l} H_2C\text{—}CH_2 \\ | \quad\quad | \\ N \quad N\text{—}CH_2CH(OH)CH_3 \\ \diagdown\!\!\diagup \\ C\text{—}R \end{array} ;$$
$$R = C_nH_{2n+1},\ n = 9\text{—}17 .$$

The reaction results in the formation of 2-alkyl-1-hydroxypropylimidazolines and these are used to synthesise surfactants, which have found extensive applications[39]. The $M^{3+}NaY$ zeolites showed the highest activity; when they were employed, the yields of 1-hydroxypropyl-2-nonyl-2-imidazoline were 50–55% (at 160–220 °C). It was established that acid centres with $H_0 = -(3-8.2)$ are active in this reaction.

Table 2. Chlorination of benzene on zeolitic catalysts[38] (175° ± 5 °C, $Cl_2 : C_6H_6 = 5 : 1-10 : 1$).



Catalyst	Conversion of C_6H_6, %	Addition products, %	Substitution products, %
NaH-ZSM-5	98	90	10
H-ZSM-5	86	87	13
Ce-ZSM-5	90	81	19
NaH-ZSM-11	86	72	28
Silicalite	97	96	4
H-Mordenite	91	84	16
LnY (SK-500)	100	3	97
Al-Si	94	7	93
SiO_2	82	72	28

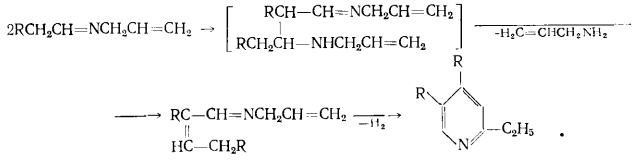
The results obtained in the study of the reaction of *citronellal (I) with isopropyl alcohol* led to important conclusions:

It was shown[40] that, depending on the catalyst, the interaction proceeds via two pathways: with formation of citronellol (II), the product of the reduction of the carbonyl group in compound (I), or of isopulegol (III), the product of the cyclisation of the initial aldehyde. The latter pathway obtains in the presence of the LiX and NaX zeolites, which are relatively coarsely porous and which enable the molecules of compound (I) to assume a configuration favourable for ring closure; the reaction proceeds with a selectivity S close to 100%. The introduction of the large cations Rb^+, Cs^+, and Ba^{2+} ($r > 1.3$ Å) into the faujasite leads to a narrowing of the channels in the aluminosilicate structure and this is believed[40] to force the molecules of compound (I) to assume preferentially a configuration which is relatively little bent; together with other factors, this promotes the selective (S = 85–90%) reduction of compound (I) to the unsaturated alcohol (II). Thus, by altering the dimensions and geometries of the "windows" and cavities in the zeolites as a consequence the steric factors governing the interaction of the reactants, it is possible to control the selectivity of the reactions on the corresponding catalyst.

The epoxidation of olefins by t-butyl hydroperoxide proceeds in accordance with the mechanism

Zeolites X and Y containing transition metal cations (Cu^{2+}, Co^{2+}, etc.) are active in these reactions[41]. At the same time, the initial hydroperoxide decomposes and other side reactions take place. The selectivity depends on many factors and can reach 50% [in the study of Bergk et al.[41] the selectivity S varied in the range 8.9–20.4% with respect to compound (IV) and 6.9–51.2% with respect to compound (V)]. The epoxidation takes place with participation of transition metal ions, evidently via a radical mechanism, which is analogous to the mechanism for the complexes of transition metals and their oxides[41].

Minachev et al.[42] determined the efficiency of zeolitic catalysts in *the oxidative acetoxylation of propene* to allyl acetate—the intermediate in many industrially important organic syntheses:



Bimetallic PdCu systems are best for this purpose. Their properties depend on the nature of the exchangeable cation in the zeolite and the type of structure of the aluminosilicate. The dependence of the activity and selectivity of metal-zeolitic catalysts (1% Pd, 0.6% Cu) in the propene acetoxylation reaction on their composition[42] at 1 atm, 180 °C, with a space velocity of the gas mixture of 2333 h^{-1}, and for the ratios $C_3H_6 : CH_3COOH : O_2 = 6 : 1 : 0.5$ is illustrated below:

Zeolite	LiY	NaY	KY	CsY	K, Na-Erionite	Na-Mordenite
Yield, g/litre cat. h	25.6	30.0	35.6	38.4	70.5	28.6
S, %	36.1	39.5	43.2	9.6	92.3	71.2

The catalysts prepared on the basis of K, Na-erionite have the highest activity. The productivity and selectivity parameters obtained with their aid are much better than those corresponding to other catalysts of this process.

In the presence of NiNaY, CoNaY, CrNaY, and FeNaY, *azaolefins undergo heteroaromatisation* with formation of alkylpyridines (yield up to 45–50% of theoretical)[43]:

The reaction proceeds with a high structural selectivity. The behaviour of the catalysts depends not only on their composition and the conditions under which they are employed (temperature and carrier gas—He or NH_3) but also on the initial azaolefin. In the reaction of propylideneallylamine the highest yields of 6-ethyl-3,4-dimethylpyridine were obtained at 350 °C on the 0.05 NiNaY (43% in an He stream) and 0.05 CrNaY (44.2% in NH_3) zeolites. Only 3-ethylpyridine was obtained from ethylideneallylamine on CrNaY. In the aromatisation of cyclohexylideneallylamine the MNaY zeolite showed a lower activity (tetrahydroquinoline was obtained in 8% yield in the presence of 0.05 CrNaY at 350 °C).[43]

Syntheses based on carbon monoxide have undergone further development as a result of the application of zeolitic catalysts. The possibility of converting CO + H_2 into aromatic hydrocarbons[44] and low-molecular-weight olefins[45,46] and CO + H_2O into methane[47,48] has been demonstrated:

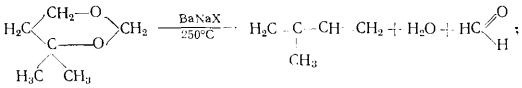
$$4CO + 2H_2O \rightarrow CH_4 + 3CO_2 \ .$$

The conversion of methanol (or dimethyl ether) into olefins is of great theoretical and practical value:

$$n\,CH_3OH \rightarrow (CH_2)_n + n\,H_2O \ ;$$
$$n = 2, 3, 4 \ .$$

Various catalytic systems (see, for example, Refs.49–57), including those based on type A and AW-500 zeolites[53], a type X zeolite in the Mn-form[51], dealuminated H-erionite[52], and the ZSM catalyst[49,50,57], are effective in this process. The reaction mechanism apparently depends on the nature of the catalyst. On H-ZSM-5, methanol can be converted with participation of the H^+-acid centres via the mechanism[57]

$$CH_3OH + CH_3OH \xrightarrow{H^+} CH_3OCH_3 + H_2O \ ;$$
$$CH_3OCH_3 + CH_3OCH_3 \xrightarrow{H^+} CH_2{=}CH_2 + 2CH_3OH \ ;$$
$$CH_3OCH_3 + H_2C{=}CH_2 \xrightarrow{H^+} CH_3CH{=}CH_2 + CH_3OH \ ;$$
$$CH_3OH + H_2C{=}CH_2 \xrightarrow{H^+} CH_3CH{=}CH_2 + H_2O \text{ etc.}$$



In the case of metal-zeolitic catalysts a reaction pathway involving the dehydrogenation of CH_3OH to formaldehyde, the condensation of the latter, and dehydration of the product is probable[53].

The following reactions in which zeolitic catalysts were shown to be effective are also of theoretical and practical interest:

(1) the synthesis of cyclopropyl methyl ketone from acetylpropyl acetate[58]:

$$CH_3COCH_2CH_2CH_2OCOCH_3 \rightarrow CH_3{-}CO{-}\langle\triangle\rangle + CH_3COOH \ ;$$

(2) the decomposition of 4,4-dimethyl-*m*-dioxan with formation of isoprene[59]:

(3) the addition of α-halogenoethers to asymmetric olefins[60]:

$$C_6H_5CH_2{-}CH{=}CH_2 + ROCH_2Cl \xrightarrow[25°C]{LaNaY} \begin{cases} \rightarrow C_6H_5CH_2CHClCH_2CH_2OR \\ \rightarrow C_6H_5CHClCH(CH_2OR)CH_3 \end{cases} \ ;$$

(4) the synthesis of higher alkanes from methane[61]:

$$n\,CH_4 \rightarrow C_nH_{2n+2} + (n-1)\,H_2 \ ;$$
$$n = 9{-}12 \ .$$

In addition zeolitic catalysts are effective in various oxidative dehydrogenation reactions[62] and in extensive oxidation reactions of organic chloro-compounds (CH_2Cl_2, $CH_2ClCH{=}CH_2$, $CH_2Cl{-}CH_2Cl$, CCl_4), which are important for the elimination of harmful substances from gaseous waste[63]. This, by no means complete list of reactions investigated in the presence of zeolitic systems in recent years, demonstrates very extensive possibilities in the application of zeolites to organic synthesis.

2. Inorganic Reactions

The considerable attention devoted to the study of the properties of zeolitic and zeolite-containing catalysts in inorganic reactions can be accounted for by the relative simplicity of many of the reactions and the convenience of their employment for the elucidation of the nature of the active centres and mechanisms of the action of various systems, the practical value of many of the reactions, in particular, in connection with the problem of the purification of the environment, and also the advances achieved in the industrial application of catalysts based on mordenite in the reduction of nitrogen oxides with ammonia[64,65].

Apart from the reactions involving the isotope exchange of H for D, the oxidation of H_2, CO, NO, NH_3, SO_2, H_2S, and NOCl, the synthesis of NH_3, the decomposition of hydrogen peroxide, ozone, hydrazine, and carbonyl sulphide, the interaction of CO with SO_2 to form COS and CO_2,[2] the ortho–para conversion of hydrogen[66], and the reduction of NO with ammonia[67–70], a number of new processes were discovered in recent years.

The reaction of CO with water vapour:

$$CO + H_2O \rightleftarrows H_2 + CO_2 \ .$$

This reaction is catalysed by the ruthenium complexes $[Ru(NH_3)_x(OH)_y(CO)_z]^{n+}$ with $n < 3$ in zeolites of the type of faujasite, the complexes being formed in the course of the activation of $[Ru(NH_3)_4]^{3+}NaX$ and $[Ru(NH_3)_4]^{3+}NaY$ in the presence of CO at 240–280 °C.[48] Their activity is higher than that of the industrial low-temperature catalyst based on copper.

The reduction of NO with carbon monoxide

$$NO + CO \rightarrow \begin{cases} \rightarrow N_2O + CO_2 \\ \rightarrow N_2 + CO_2 \end{cases}$$

is catalysed by zeolites containing transition metals—Ni, Co, Cu, Cr,[71] Rh,[71,72] and Ru.[73] Depending on the composition of the catalyst, the type of its preliminary treatment, and the conditions under which it is employed, the reaction can proceed with formation of either N_2O and CO_2 or of N_2 and CO_2. According to Minachev et al.,[71] there are at least three temperature ranges in which the characteristics of the reduction of NO are different. At low temperatures (200–300 °C) the product is N_2O and the catalysts are gradually deactivated. Above 350 °C, NO is fully reduced to N_2. It has been observed that the complex $[Rh^I(CO)_2(NO)]^+$, believed to be the reactive intermediate in the reduction of NO to N_2O, is formed from RhY.[72] It has been noted that the composition of the products of the reaction of NO with CO and the influence of temperature are significantly different for rhodium ions in the zeolite and in the case of deposited metallic rhodium[72].

The reduction of NO by molecular hydrogen

$$NO + H_2 \rightarrow N_2 + NH_3 + H_2O$$

is accelerated by the NiY zeolites and the phthalocyanine complexes of nickel in a faujasite matrix (PcNiY), while the CuY, CoY, PcCuY, and PcCoY zeolites are almost inactive[74]. The process selectivity is determined by the reaction temperature and the nature of the ligand environment of the transition metal cations. Only NH_3 is formed on PcNiY, while N_2 is the only product in the presence of the Ni^0/HNaY catalyst obtained by the reduction of NiNaY with hydrogen at 550 °C. In the presence of the NiY zeolite treated with H_2 for 3 h at 350 °C, the degree of conversion of NO at 100 °C was 100%, 62% NO being converted into NH_3 and 38% into N_2.

The synthesis of nitrosyl chloride from nitric oxide and chlorine, i.e.

$$2NO + Cl_2 \xrightarrow{250°C} 2NOCl \ ,$$

has been studied in the presence of catalysts obtained by heating NH_4NaY at 260°, 350°, 450°, and 550 °C.[75] The specimen heated at 550 °C showed the highest activity. A correlation was observed between the rate of reaction and the number of Lewis acid centres in the aluminosilicates.

The decomposition of nitrous oxide

$$2N_2O \rightarrow 2N_2 + O_2$$

is catalysed by type Y and L zeolites and mordenite containing transition metal cations[76–79]. CuNaY and CoNaY are more effective than NiNaY, while the atomic catalytic activity of NiKL is higher than for the NiNa–mordenite and NiNaY systems, in which the degrees of exchange of $Na^+(K^+)$ for Ni^{2+} are similar.

In the reduction of SO_2 with hydrogen sulphide (the Klaus reaction),

$$2H_2S + SO_2 \rightarrow 2H_2O + 3/n\,S_n$$

the activity of the NaX and NaY zeolites is comparable to that of an industrial catalyst (Al_2O_3), while the activity of NaX impregnated with 2% NaOH is higher[80,81]. The reaction is of zero order with respect to SO_2 and of 0.5 order with respect to H_2S. It has been established by infrared spectroscopy that H_2S dissociates heterolytically on the surface of the catalyst ($H_2S \rightleftharpoons HS^- + H^+$), which is consistent with an order of 0.5 with respect to hydrogen sulphide. According to George and Tower[81], the reaction proceeds on basic centres and not on the H^+-acid centres.

New evidence for extensive possibilities in the application of zeolitic catalytic systems to a wide variety of chemical reactions has thus been obtained.

3. Zeolites in Pyrolytic Processes

Pyrolytic processes constitute a promising field of application of zeolite-containing catalysts (ZCC). Thus the maximum yield of ethylene in the thermal decomposition of the propane fraction (40 wt.%) is attained at 850 °C, while in the presence of ZCC such yield is reached at 715 °C, i.e. at a temperature lower by 135 K, the yield of ethylene at 760 °C being 49.5 wt.%.[82] Furthermore, the selectivity of the process in relation to the formation of the desired product increases greatly under the influence of ZCC.

Similar results were obtained in pyrolytic processes involving low-quality petrols in the presence of zeolites and ZCC.[83,84] According to Minachev et al.[83], in the presence of the cationic forms of mordenite it was possible to obtain olefins in higher yields than on the NaA, NaX, and NaY zeolites, chabazite, or K, Na-erionite. The activity of the catalysts and the selectivity of their action depend significantly on the nature of the exchangeable cation M^{n+}. Table 3 shows that the greatest amount of gaseous products and C_2–C_4 alkenes are produced by Ni-mordenite and Co-mordenite. Among the Mn-, H-, and MnH-forms of the zeolite, for which the yields of gaseous products are similar, the decationated specimen has an outstanding selectivity in relation to the formation of olefinic hydrocarbons. These differences can probably be accounted for by the different locations of the Mn^{2+} cations in the Mn- and MnH-mordenites and by the different acid characteristics of the catalysts. The gasification of polyethylene in the presence of the CaX zeolite has also been achieved[85].

These initial studies laid the foundations of the important field involving the utilisation of zeolitic catalysts in pyrolytic processes, whose development is closely related to the synthesis of and research into new thermostable materials.

4. Zeolites as Catalysts and Adsorbents

We believe that a great future awaits the application of zeolites in catalytic processes as adsorbents (or as catalysts and adsorbents). This concerns the utilisation of the molecular sieve properties of zeolites for the selective adsorption of one of the reaction products and the displacement of the equilibrium in chemical reactions. The efficiency of this approach has been demonstrated in relation to the synthesis of esters of carboxylic acids and alcohols with the removal of water by the KA, NaA, and CaA molecular sieves[86–89], the transesterification of esters, $RCOOR^1 + ROH \rightleftharpoons RCOOR^2 + R^1OH$, with selective adsorption of R^1OH,[90–92] and in the synthesis of acetals and ketals[93,94]. The desired products were thus obtained in yields ≥90% (and in many instances in quantitative yields) even in the case of sterically hindered reactants. The adsorbent can be suspended in the reaction mixture or placed in the cartridge of the Soxhlet apparatus[90]. Comparison of the methods for the removal of H_2O or R^1OH. .(CH_3OH) by azeotropic distillation and adsorption on zeolites showed that in the latter case higher yields of products are obtained in a shorter time[7].

Table 3. Pyrolysis of high-quality petrol (O.N. = 42) on cationic forms of mordenite[83] (T = 600 °C, v = 1 h^{-1}).

Cationic form of zeolite	c_1, %	$[C_2-C_4]$, %	α	c_2, %
Li	25.0	57.2	1.44	8.1
Na	78.7	47.5	1.16	5.5
K	49.5	38.2	0.8	5.7
H	55.0	57.3	1.39	7.2
Co	80.0	66.6	3.37	7.0
Ni	81.2	68.8	2.63	6.0
Mn	40.6	51.7	1.29	6.6
MnH	50.4	75.9	3.6	5.7

Notation: c_1 and c_2 are the yields of gas and coke respectively, $[C_2-C_4]$ is the content of olefins in the gas, and α = olefin : paraffin ratio.

The use of zeolites as catalysts and adsorbents simultaneously (either of the same type or of different types and compositions in the two cases) is of special interest. Table 4 presents data[94] obtained for the synthesis of the diethyl acetal of cyclohexanone in the presence of the M^{n+}NaY zeolites as catalysts and the CeNaY and KA zeolites as adsorbents. Evidently, the reaction with KA goes to completion and at the same time the period during which cyclohexanone undergoes a quantitative conversion is shortened; KA is a more effective adsorbent than CeNaY.

5. Industrial Applications of Zeolitic Catalysts

Considerable advances have been made in recent years in industrial catalysis on zeolitic systems. New catalysts have been developed for the cracking[14,95–102], hydrocracking[18,103], and selective hydrocracking ("selecto-forming")[17,18,104–107] of petroleum fractions, the isomerisation of aromatic C_8 hydrocarbons ("octafining")[108,109], and the isomerisation of n-paraffins[110,111], in which zeolite-containing compositions have already been used. The scale of the manufacture and utilisation of catalysts has increased and their assortment

has been expanded. It has become possible to process new types of raw materials.

Catalytic cracking is the process involving the largest-scale consumption of catalysts. At the present time 220000 tonnes of zeolite-containing cracking catalysts are produced annually in the capitalist countries of which 200000 tonnes are employed in fluidised bed apparatus[18]. Catalysts have been devised which diminish the amounts of coke and gas formed and of the sulphur oxides discharged from the regenerator[98,99] and promote the oxidation of carbon monoxide in the smoke gases present in the fluidised bed cracking regenerators—this is achieved by introducing small amounts (<0.001%) of noble metals[95,96]. Compositions have been developed which are effective in the processing of heavy raw materials, are resistant to poisoning by metals, and increase the octane numbers (O.N.) of the fuels obtained[14,18,99]. They are all based on type Y zeolites, which are used in the ultrastable lanthanide (LnY) and magnesium-lanthanide modifications (MgLnY). Polyzeolitic systems incorporating, together with faujasites, also zeolites of other types (ZSM, mordenite, erionite, and ferrierite), which permit a finer control of the composition of the product formed, in particular they make it possible to increase the yields of propene and butenes, have been proposed recently[18]. Further developments in this field will evidently tend to increase the stability of the catalyst in relation to various influences, including the influence of admixtures in the raw material, to improve the selectivity of the catalyst, and to promote the maximum utilisation of these possibilities.

Table 4. Synthesis of cyclohexanone diethyl acetal using zeolitic catalysts and adsorbents[94].

Catalyst	t_a, °C	Adsorbent	$\tau_{50\%}$, min	η, %	τ, min
0.62 CeNaY	200	—	180	52	240
0.62 CeNaY	200	CeNaY*	14	71	60
0.62 CeNaY	200	KA	13	99.9	45
0.61 LaNaY	200	KA	19	99.9	60
LnY	200	KA	34	99.9	120
SK-500 (LnHY)	200	KA	11	99.9	45
0.67 NH_4NaY	340	KA	20	99.9	105
0.68 MgNaY	400	KA	—	3.1	150
0.75 CaNaY	400	KA	90	99.9	250

Note. A mixture of cyclohexanone (0.05 mol) and ethanol (0.2 mol) in n-hexane (75 ml) was stirred with the catalyst (4 g) and powdered KA (10 g) at 0 °C; t_a is the catalyst activation temperature, $\tau_{50\%}$ the time of attainment of 50% conversion of cyclohexanone and η the final conversion of cyclohexanone.

*In this case 14 g of the 0.62 CeNaY zeolite was taken in order to accelerate the reaction and displace the equilibrium.

Hydrocracking is the second process in which zeolitic catalysts are used on a wide scale (the annual consumption exceeded 1000 tonnes; approximately 50% of the starting material subjected to hydrocracking is processed with their aid[18]). They are all based on type Y zeolites and the hydrogenating components are Co, Mo, W, Pt, and Pd. The application of the catalysts is expanding continuously in a varied manner[103,112,113]. Radchenko et al.[103] described in greater detail the existing hydrocracking processes in the USSR and abroad, in which zeolite-containing catalysts are employed, as well as processes developed and designed for industrial use.

The selective hydrocracking (selectoforming) of n-paraffins (mainly C_5–C_9 paraffins) in mixtures with isoparaffins and aromatic hydrocarbons is designed to improve the quality (increase the O.N.) of reforming petrols with simultaneous formation of liquefied petroleum gas (a mixture of propane and butane). A catalyst exhibiting a molecular-sieve activity is used in this process. It is prepared from natural erionite (this is so far the only example of the industrial application of a catalyst made from a natural zeolite)[17,18] or from its synthetic analogue[104,105] and a metal (Ni or Mo). The possibility of employing also catalysts based on a narrow-pore synthetic mordenite has been demonstrated[114,115]. The selective hydrocracking of catalytic reforming petrol, refined petrol, and their mixture on a metal-zeolitic catalyst can yield a basic component with O.N. = 95, which on treatment with ≤15% of isopentane is converted into the non-ethylated petrol AI-93.[106] As a result of the involvement of low-octane refining products in the processing, the consumption of the straight-chain starting material is reduced (by ~20%) in the manufacture of AI-93 petrol[106].

The isomerisation of n-alkanes (the pentane–hexane fractions of petroleum and gaseous and light petrols) yields high-octane components of motor fuels—isoparaffinic hydrocarbons. According to Simoniak et al.[116], the complete isomerisation of normal paraffins in the fraction with a terminal boiling point of 71 °C in combination with catalytic reforming increases the O.N. of petrol by 20 points and yields a product balanced with respect to the O.N. of narrow fractions. A zeolitic isomerisation catalyst (H-mordenite containing a small amount of a noble metal) has been used since 1970 (the high isomer process[117]); at the present time it is already used in tens of different types of apparatus[18]. Various modifications of the Pt–zeolite Y catalysts[111] have also been developed and applied in industry. The Leuna-catalyst 8852 with the composition $Pt/LnCaY/Al_2O_3$ was introduced in 1980.[111]

The isomerisation of aromatic C_8 hydrocarbons (industrial mixtures of xylenes and ethylbenzene) is carried out under hydrogen pressure in the presence of metal-zeolitic systems. The Pt–dealuminated H-mordenite–Al_2O_3 catalyst has a high activity and stability in this process, whose aim is the maximum synthesis of *p*-xylene[108]. The latest catalysts are based on zeolites of type ZSM-5.[17,18,118] Their characteristic feature is a high ratio of their activities in the isomerisation and disproportionation of alkylbenzenes, which amounts to approximately 1000 (for mordenite catalysts, it is close to 70 and for faujasite catalysts it is 10–20).[118] This ensures the formation of *p*-xylene in hitherto unattainable yields and a diminution of the principal side reactions.

The industrial applications of zeolites and zeolite-containing catalysts in many of the other processes described below has begun.

In the alkylation of benzene by ethylene, designed to synthesise ethylbenzene which is converted into styrene and the latter is used in the manufacture of plastics and synthetic rubbers, aluminium chloride has been used as the catalyst hitherto. The problems associated with the application of $AlCl_3$ are generally known. Studies designed to replace $AlCl_3$ by solid catalysts which at the same time meet current requirements including those concerning the protection of the environment and the improvement of health conditions in the relevant industries, have been prosecuted for many

years. Many zeolitic catalysts have also been proposed[1,2,5,8]. However, it was not until 1977 that ethylbenzene was synthesised on an industrial scale in accordance with the technology of the "Badger" company using a catalyst based on the ZSM-5 zeolite developed by the Mobil Oil Corporation[119-121]. This catalyst does not cause corrosion of the equipment, is inert with respect to admixtures in the starting material, and does not require special storage conditions. The process does not involve the formation of harmful atmospheric and aqueous waste.

According to the results presented in Ref.121, the overall productivity of the existing and planned plant reaches 335000–465000 tonnes of ethylbenzene annually.

The catalytic deparaffination of distillates and oils is carried out on bifunctional metal-zeolitic systems and is used to prepare low-setting fuels and basic oils[122-125]. The best catalysts of the deparaffination of petroleum crude are platinum- or palladium-containing dealuminated H-mordenites[124]. They convert effectively only paraffinic hydrocarbons with normal or slightly branched structures, while sulphur and nitrogen compounds in aromatic hydrocarbons are changed little. Here it is important that predominantly the cleavage of alkanes with formation of gaseous products (principally propane, butane, and pentane), and not their isomerisation, takes place on the M^0/H-mordenites.

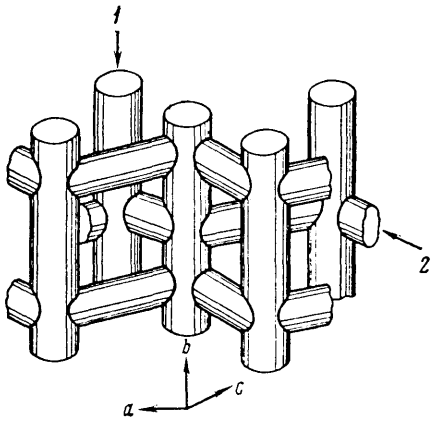
A process for the catalytic deparaffination of heavy distillates, whose application makes it possible to produce diesel and boiler fuels from heavy gas-oils, has been developed[122, 123]. The process is carried out on a stationary catalyst (based on the ZSM-5 zeolite) at 260–427 °C, a pressure of 21–42 atm, and with circulation of the hydrogen-containing gas. Fractions with setting points ranging from 6.7° to 54.4 °C and containing up to 50 wt.% of n-paraffins can be deparaffinated (by the selective hydrocracking of normal or weakly branched paraffins). The catalyst is resistant to the action of sulphur and nitrogen compounds, whose content in the starting material can reach 3 and 0.1 wt.% respectively. The period between the oxidative regenerations of the catalyst is 0.5–2 years. The yield of product which begins to boil at 165 °C is 54–91 vol.% with respect to the starting material and its setting point is greatly reduced[122]. The completion of the construction at the refinery of the Mobil Oil Corporation in Wilhelmshaven (Federal Republic of Germany) of a plant for the catalytic deparaffination of heavy gas-oil with output of 600000 tonnes per year has been reported[125]. The process is designed for the synthesis of furnace fuel (FF). Petrol and gas in the proportions FF : petrol : gas = 86 : 7 : 7 are formed together with the furnace fuel (400 °C, 40 atm). The application of this process increases the yield of the intermediate distillates from petroleum by ~5%.[125]

The synthesis of propane from butane[126] is based on the reaction $3C_4H_{10} + H_2 \rightarrow 4C_3H_8$. The catalyst (its composition is not reported) is a zeolite with a low content of an alkali metal, which exhibits hydrogenating properties although hydrogenating components are not specially introduced. The process conditions are as follows: temperature at the inlet to the reactor with a stationary catalyst bed 315–450 °C, pressure 12–23 atm, space velocity of liquid C_4H_{10} 1–3 h^{-1}, and the molar ratio $H_2 : C_4H_{10} = (3–6) : 1$. The highest yield of propane is obtained for a conversion of butane of ~90%. The industrial plant yielded 88.8% of propane and 12.8% of fuel gas for a hydrogen consumption of 1.6 wt.%.[126] The process makes it possible to overcome the shortage of propane and to smooth out the seasonal variations in the manufacture of individual hydrocarbons.

The disproportionation of toluene in the manufacture of benzene and xylenes can be achieved in the presence of various catalysts. When a lanthanide zeolite Y is used, the process is carried out in the liquid phase at 260–316 °C, 45 atm, and a weight velocity of the starting material of 1.5 h^{-1}. The degree of conversion of toluene per pass is ~45%, the yield of benzene is 19.7%, and the yield of xylenes is 23%. The life of the catalyst is 1.5 years[127]. The catalyst, based on the ZSM-5 zeolite, is highly selective and makes it possible to obtain disproportionation products enriched in *p*-xylene[17,18,118].

A series of catalysts for *the hydropurification of petroleum fractions*, based on the GO-115, GO-116, and GK-35 zeolites, have been developed[128-130]. Some results of the employment of the GK-35 catalyst on an industrial plant have already been examined[129].

The reduction of nitrogen oxides by ammonia is so far the only inorganic catalytic process in which zeolitic catalysts have found an industrial application. It is designed to make harmless the waste gases from a number of chemical industries (factories producing HNO_3, etc.). The H-forms of mordenite are effective catalysts of the reaction of NO_x with NH_3 to form N_2 and H_2O.[64,65] The Zeolon-200H catalyst is used in the USA and Canada in several types of plant. A new, cheaper, and more active NC-300 catalyst, having the following chemical composition (wt.%) has been developed recently: 72–80 SiO_2, 17–22 Al_2O_3, 1–4 Fe_2O_3, and <1.5 K_2O; its characteristic feature is the possibility of carrying out the process under milder conditions and in the presence of SO_2 as well as large amounts of water[64,65].



The conversion of methanol into petrol is included by some workers[17,18] among the industrial processes in which zeolitic systems are used. Such synthesis of motor fuel has been proposed by the Mobil Corporation[131-133]. Methanol is converted into a mixture of hydrocarbons having the following typical composition (wt.%): 1.7 C_1–C_2, 6.0 C_3, 16.4 C_4, 19.0 C_5, 16.4 C_6, 13.0 C_7–C_9, and 27.5 C_6–C_9 (aromatic); C_n with $n \geq 11$ are hardly formed, so that the composition (and characteristics) are close to those of petrol obtained from petroleum. This process has attracted attention as the final stage in one of the procedures for the synthesis of motor fuel from solid mineral fuels (or natural gas) in accordance with the scheme coal → synthesis gas ($CO + H_2$) → methanol → petrol. Its development has advanced to the stage involving the sale of licenses and demonstration plant is operating[17,134]. In November 1979 the government of New Zeland decided to manufacture petrol in accordance with the technology of the Mobil Corporation (the output of the plant is 1500 tonnes in 24 h).[17,134] Methanol can be obtained from natural gas. The design of the plant incorporates reactors with a stationary catalyst bed. The construction of a plant for the production of petrol from methanol in a fluidised bed is planned in the Federal Republic of Germany[134]. However, there is as yet no information as to whether the process is being applied on an industrial scale.

Thus the search for new applications of zeolites in catalysis is being prosecuted in several directions.

III. CATALYTIC SYSTEMS BASED ON ZEOLITES OF NEW TYPES

Hitherto approximately 150 structural types of zeolites have been described[135]. The catalytic activity has been studied only for certain types: A, X, Y, L, mordenite, erionite, chabazite, omega, clinoptilolite, offretite[1,2,5,6,8,10,12,15], and

ferrierite[136,137]. In recent years much attention has been devoted to zeolites of the pentasil family[138,139]: ZSM (the Soviet analogues are referred to as TsVK, TsVM, and ultrasil) and silicalite. These zeolites have an unusual structure[138–142], in which the dimensions of the windows and channels are intermediate between those of the windows and cavities in narrow- and wide-pore zeolites (see Figure), which ensures their unusual molecular-sieve properties; the zeolites are characterised by a high thermal stability, resistance to acids, and hydrophobic properties (combined with a low Al content); all these factors are responsible for the unusual nature of their interaction with various substances[141–144]. The SiO_2/Al_2O_3 ratio in the zeolites of the given families varies within wide limits, from approximately 20 to several hundreds and even thousands (specimens with $x = 8660$ have been investigated[144]); silicalite contains virtually no aluminium. Certain characteristics of ZSM-5 and silicalite are compared in Table 5.

Model of the porous structure of the ZSM-5 zeolite and silicalite: 1) linear channel with an elliptical cross-section (5.7 × 5.1 Å) formed by ten oxygen atoms; 2) zig-zag channel with a nearly circular cross-section (5.4 Å in diameter) formed by ten oxygen atoms.

Table 5. Comparison of the properties of the ZSM-5 zeolite and silicalite[46,139].

Property	ZSM-5	Silicalite
Chemical composition	$Na_2O \cdot Al_2O_3 \cdot x\ SiO_2$ ($x = 20 \div 1000$)	SiO_2
Number of Si and Al atoms in unit cell	96	96
Ion-exchange properties	Present	Absent
Crystal structure	Orthorhombic; $a = 20.1$ Å; $b = 19.9$ Å; $c = 13.3$ Å	Orthorhombic; $a = 20.6$ Å; $b = 19.80$ Å; $c = 13.36$ Å
Porous structure	Shown in Figure	Shown in Figure
Sorption of H_2O	Low in the presence of high SiO_2 content	Low
Thermal stability	Increases with increasing silicon content	High

During a short period, the catalytic properties of systems based on pentasils have been investigated in many reactions: in the cracking of hydrocarbons[143–149], in the oligomerisation[150–155] and aromatisation of C_2–C_4 olefins[143,152,153,155–159], in the dehydration of alcohols and other oxygen-containing compounds[160–163], in the conversion of methanol into petrol[17,131–133], olefins[49–57], and aromatic hydrocarbons[143,148,153,156,162,164], in the alkylation of aromatic compounds[145,153,165,166], in the chlorination of benzene[38], in the dehydrogenation of ethanol[161], in the synthesis of a wide variety of compounds from CO and H_2,[45,47,167,168] in the aromatisation of alkanes and cycloalkanes[169,170], in the disproportionation of aromatic hydrocarbons[165,171], in the selective hydrocracking of n-paraffins and methyl-substituted paraffins in mixtures of hydrocarbons of different compositions[122,123], in the isomerisation of n-alkanes[172,173], in the hydrolysis of ethyl acetate[174], and in others[15,138]. Detailed examination of the results is outside the scope of this review. We shall consider certain features of the catalytic action of systems incorporating pentasils.

In contrast to H-mordenite[175], in the presence of the H-form of TsVK n-pentane undergoes mainly hydrocracking and disproportionation with formation of C_1–C_4 alkanes and hexanes and not isomerisation (Table 6). The introduction of palladium into zeolites leads to catalysts in the presence of which isopentane is obtained with high yields and selectivity. Since the concentrations and strengths of the protic acid centres in H-ZSM-5 and H-mordenite are similar[16], the different behaviour of the H-TsVK and H-mordenite catalysts in the conversion of n-pentane can be accounted for by the different distributions of the active centres in the crystal structures of the zeolites and also by the characteristics of their structure.

Table 6. The conversion of n-pentane on catalysts based on TsVK zeolites of different compositions[173] [$p = 30$ atm, $v = 1\ h^{-1}$, $H_2 : n\text{-}C_5H_{12} = 3.2 : 1$ (moles)].

Catalyst	SiO_2/Al_2O_3 (moles)	t, °C	Conversion of $n\text{-}C_5H_{12}$, %	Yield, wt. %		
				iso-C_5H_{12}	C_1–C_4 alkanes	ΣC_6H_{14}
H-TsVK	33.3	250	42.7	9.0	27.0	6.7
H-TsVK	33.3	300	55.0	9.9	41.4	3.7
H-TsVK	83.0	250	37.2	10.0	21.9	6.3
0.5% Pd/H-TsVK	33.3	310	64.8	60.0	3.9	0.9
0.5% Pd/H-TsVK	83,0	330	61,8	59,5	1,4	0,9

Since the dimensions of the windows leading to the channels in the structure of pentasils are greater than in the wide-pore zeolites and smaller than in the narrow-pore zeolites, pentasils manifest a specific molecular sieve selectivity. Thus, according to Rabo[172], the isomerisation of n-hexane on the 0.5% Pt/H-silicalite catalyst yields mainly methylpentanes, while 2,2-dimethylbutane is formed only in insignificant amounts (Table 7). On the other hand, in the presence of the Pt/zeolite Y catalyst the fraction of 2,2-dimethylbutane in isohexanes is approximately 19%. Evidently, the fairly large molecules of 2,2-dimethylbutane (critical diameter $d_{cr} = 6.2$ Å) cannot be desorbed from the channels of silicalite (the latter also does not sorb substances whose molecular dimensions are close to d_{cr} for the neopentane, 2,2-dimethylbutane, and other molecules[172]). We may note that only methane and ethane were obtained from n-hexane in the presence of catalysts based on the H-forms of narrow-pore zeolites[172].

The hydrophobic properties of the ZSM specimens with a high SiO_2 and silicalite content combined with marked organophilic properties makes it possible to employ such catalysts

in reactions carried out in aqueous solutions, as shown in relation to the hydrolysis of ethyl acetate in the presence of H-ZSM-5 ($x = 93.2$).[174] This cannot be done for the majority of other zeolites.

Table 7. Isomerisation of n-hexane on the 0.5% Pt/vapour-stabilised zeolite Y and 0.5% Pt/silicalite catalysts at 15.3 atm and $H_2 : C_6H_{14} = 3:1$ (Rabo[172]).

Catalyst	0.5% Pt/zeolite		0.5% Pt/silicalite		
t, °C	272	262	327	339	351
Conversion of n-C_6H_{14}, %	81.44	77.39	74.74	75.58	76.88
c_1, %	55.42	56.53	68.26	66.22	64.41
c_2, %	18.97	14.84	0.64	2.0	3.67

Note. The silicalite contained 0.6 wt.% of Al_2O_3 as an impurity; it was converted into the H-form with a moderate acidity by ion exchange with NH_4^+ and subsequent heat treatment. The contents of methylpentanes (c_1) and 2,2-dimethylbutanes (c_2) in the C_6 product are quoted.

An important property of pentasils as catalysts and components of catalytic systems is their ability to retain a high activity for a long time (under certain operating conditions), which is significantly higher than for mordenites and other zeolites. Such ability is probably a consequence of the low degree of coke formation when pentasils are employed[16,143,145]. Indeed, using the tracer atom method, it has been established[176] that in the case of mordenite the "yield" of coke is higher by two orders of magnitude than for H-ZSM-5. It has been suggested[16,143,145] that mainly aromatic polyalkylhydrocarbons are a source of coke. They cannot be formed in the limited volume of the channels of pentasils, which limits the "yield" of coke. However, it is noteworthy that the stability of catalysts based on the ZSM, TsVK, and TsVM zeolites depends significantly on their composition and the conditions under which they are employed as well as on the nature of the reactants[143,167]. As a rule, the activity of the catalysts is maintained for a longer period the smaller their residual Na^+ content and the higher the SiO_2/Al_2O_3 ratio; process temperatures greater than or equal to 350 °C are favourable, so that the stability of the pentasil system is apparently determined not only by the rate of formation of coke but also by other factors.

The above examples (see also, the specific nature of the catalytic action of the type ZSM zeolite and silicalite in the chlorination of benzene[38] and a number of studies[46,57,143–145,159,166,167,170] described in Section I) demonstrate the likely usefulness of a comprehensive study of high-silica materials belonging to the pentasil family and others. Among the latest crystalline aluminosilicates, the Fu-1 and Nu-1 zeolites, obtained in systems involving tetramethylammonium compounds[177,178], and TsKF zeolites synthesised in the Na, Rb-, Na, Cs-, K, Rb-, and K, Cs-systems merit attention[179].

IV. CATALYSIS ON POLYZEOLITIC SYSTEMS

A natural development of studies involving different zeolites was the synthesis of polyzeolitic systems and the study of their catalytic properties. Such systems have been investigated in greatest detail in the cracking process[18,101,102]. It has been shown that, in the cleavage of a mixture of hydrocarbons on zeolite-containing compositions incorporating zeolites of the mordenite, erionite, ferrierite or ZSM types together with lanthanide or ultrastable faujasite Y, it is possible to achieve a fine control of the composition of the product formed, in particular the yields of propene and butenes as well as the octane number of the resulting petrol can be increased[18].

By combining the properties of different crystalline aluminosilicates, it is possible to "construct" a wide variety of polyfunctional catalysts of a new type. An example of the latter is provided by the bizeolitic alkylation catalysts which we investigated[180]. They consist of mixtures of zeolites, one of which is active only in the dimerisation of ethylene (NiNaA, NiNaX) and the other is active only in the alkylation of benzene by olefins (for example, CaNaY). In the presence of these catalysts the main product of the interaction of C_6H_6 with C_2H_4 is s-butylbenzene and both single- and two-bed systems are active. Their properties can be regulated by altering the contents of the individual components in the mixture[180]. The polyzeolitic compositions can include the crystallites of both a single type and different types. This application of zeolites in catalysis is very promising and merits further consideration.

V. POLYFUNCTIONAL CATALYSIS ON ZEOLITIC SYSTEMS

Catalysts with polyfunctional activity, which accelerate simultaneously several reactions coupled in a single process, make it possible to carry out in a single stage complex syntheses, including those which are difficult or impossible to achieve with the aid of monofunctional systems[181,182]. Their theoretical and practical importance is enormous. Special attention was devoted to this problem already in the first studies of Rabo and coworkers[183,184] and Minachev and coworkers[1,185,186], carried out during the initial period of the development of catalysis in the presence of synthetic zeolites. Subsequently new catalysts were devised for the hydrocracking and hydroisomerisation of hydrocarbons[6], the hydroalkylation of benzene to phenylcyclohexane[187], the isomerisation of ethylbenzene to xylenes[6,108,109], the hydrocondensation of carbonyl compounds[6,34], the single-stage synthesis of cyclohexane from toluene and H_2,[188] s-butylbenzene from C_6H_6 and C_2H_4 (see our earlier review[189]), and others[6,8].

The effective catalysts for hydropurification processes[128,129], the synthesis of aliphatic hydrocarbons from CO and H_2,[190–193], of olefins from CO and H_2 [45,46] or methanol[53–57], and of aromatic hydrocarbons from C_1–C_5 alkanes[168,194,195] and also from CO and H_2,[44] the disproportionation of paraffinic hydrocarbons[196], and other syntheses[168] were developed in recent years.

In the course of this research, a series of important data were obtained concerning the characteristics of zeolites of different types as components of polyfunctional catalysts, the formation of a wide variety of catalysts, the mechanism of their action, and the method and possibilities of the regulation of their activity, selectivity, and stability, etc. It has been shown[193], in particular, that the use of zeolite-containing systems makes it possible to obtain from CO and H_2 products containing larger amounts of high-molecular-weight hydrocarbons (ceresin) than those obtained on the industrial CO–MgO–ZrO_2–kieselguhr catalyst. On the other hand, it has been observed[192] that the structure of the zeolite can limit the growth of the hydrocarbon chain length. Thus mainly C_1–C_9 hydrocarbons have been obtained on the Ru/NaY ion-exchange catalyst reduced at 300 °C, while in

the presence of Ru/SiO_2 a mixture of C_nH_m, in which paraffins and $\geq C_{12}$ olefins predominated (60%), was obtained under the same conditions of the synthesis [250 °C, molar ratio $CO:H_2 = 3:2$, contact time (with respect to CO) 0.4 s].

The range of catalytic systems with polyfunctional activity has been expanded. It has been established that not only compositions of the metal/zeolite type in the form with H^+ acidity (the commonest catalyst[6]) can exhibit polyfunctional properties. In the alkylation of benzene and its homologues with ethylene, NiY faujasites and $NiO-H^+$–zeolite systems behave as bifunctional catalysts (the interaction of RC_6H_5 with C_2H_4 in their presence proceeds mainly with formation of the s-butylderivatives $RC_6H_4-C_4H_9$ [189]). Alkaline cationic modifications of zeolites X and Y containing Group VIII metals exhibit only a single function in the reactions of hydrocarbons, determined by the metal, catalysing the hydrogenation, dehydrogenation, or oxidation of C_nH_m.[6] On the other hand, they behave as bifunctional systems in the reaction of butyraldehyde with H_2, accelerating simultaneously the crotonic condensation and the hydrogenation of carbonyl compounds coupled in a single process (Table 8); here 2-ethylhexanal and iso-octyl alcohol are obtained in a single stage[32].

Table 8. Hydrocondensation of n-butyraldehyde on metal-zeolitic catalysts[32] (150 °C, $\nu = 1\ h^{-1}$, $C_4H_8O:H_2 = 1:1.5$).

Catalyst	Conversion of n-butyraldehyde, %				
	into butanol	into 2-ethyl-hexenal	into 2-ethyl-hexanal	into 2-ethyl-hexanol	Overall
0.5% Pt/NaX	16.8	10.8	13.0	6.1	51.0
0.5% Rh/NaX	8.4	4.9	29.2	2.8	46.0
0.5% Pd/NaX	1.6	1.6	58.8	1.9	67.0
1.0% Pd/KNaX	1.4	1.0	61.6	1.5	69.5
0.2% Pd/0.65 RbNaX	1.5	4.8	58.0	0.5	65.0
2.0% Ni/HNaX	21.8	1.1	16.1	7.3	47.0
2.0% Co/HNaX	21.5	22.2	20.5	2.7	72.0

Note. The content of the Group VIII metal is expressed in wt.%.

In the presence of Pd/CaY, it is possible to synthesise from C_6H_6 and H_2 either cyclohexane, by altering the temperature (to 200 °C), i.e. by merely hydrogenating benzene, or methylcyclopentane and cyclohexane (at 260–320 °C), i.e. benzene is made to undergo hydroisomerisation and as well as hydrogenation[186]. Thus a catalyst having the same composition can behave as monofunctional and polyfunctional depending on the nature of the reactant and the conditions under which it is employed. This leads to new research fields.

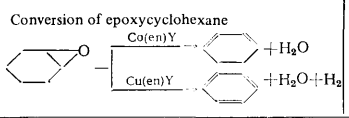
It is becoming increasingly obvious that the possibilities in the application of zeolites in catalytic polyfunctional systems have been by no means fully elucidated. The studies and developments in this field will undoubtedly continue.

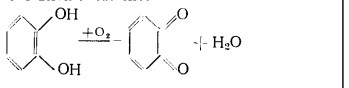
VI. ZEOLITIC METAL COMPLEX CATALYSTS

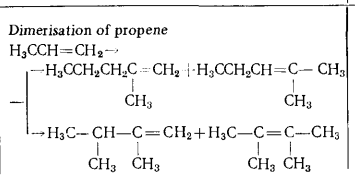
Yet another promising application of zeolitic materials in catalysis has been established—as a matrix for transition metal complexes (TMC) and components of hydrogenised metal complex catalysts. Such systems can be obtained by introducing the prepared complexes into crystallites having the appropriate composition or by synthesising the required compounds within the zeolite cavities (here it is necessary to distinguish cationic complexes and complexes of zerovalent metals[197–199]). The method involving the interaction of dehydrated zeolites containing transition metal cations with the corresponding compounds in the gas phase or solution is most common. It is used, in particular, in the synthesis of phthalocyanine[200], ethylenediamine[201,202], nitrosyl[197–199,203], carbonyl[204–207] and trimethylphosphine[208] transition metal complexes in zeolites X and Y. Catalysts of the TMC–zeolite type can also arise in the interaction of crystalline aluminosilicates with the components of the reaction mixture, as shown for the rhodium-[209–211] and iridium-zeolitic[16,212] catalysts for the carbonylation of methanol with carbon monoxide. The matrices are usually zeolites X and Y, which have the widest pores, ensuring the accommodation of the complex within the structural cavities and the possibility of the coordination of the reactant molecules.

Some characteristics of TMC and zeolites have already been considered[197–199,213]. Important results have been obtained[214–217]; it has been shown with the aid of X-ray photoelectron spectroscopy that the phthalocyanine complexes of nickel and cobalt in faujasite Y are formed mainly in the large cavities of the lattice, being uniformly distributed throughout the volume of the aluminosilicate crystals[214]. With increase of the degree of exchange of Na^+ for M^{2+}, the degree of binding of the cations to the phthalocyanine increases and reaches ~80% for 0.6 MNaY. The photoelectron spectra led to the conclusion that the zeolite behaves not only as a matrix but also as a ligand for complex formation, causing a charge redistribution over the nitrogen and meso-atoms in the phthalocyanine molecule[214,216].

The catalytic properties of TMC–zeolite systems have already been investigated in a fairly wide range of reactions, some of which are listed in Table 9. A number of characteristic features of the catalytic action of these systems have been discovered. According to Gusenkov et al.[225], in the presence of CuY the decomposition of epoxycyclohexane takes place non-selectively with vigorous coke formation. On the other hand, in the presence of copper-phthalocyanine in the zeolite, $C_6H_{10}O$ undergoes dehydration with formation of cyclohexadiene (100% selectivity). In the presence of the ethylenediamine complex of copper in faujasite, only benzene is obtained, i.e. the mode of reaction is determined by the nature of the ligand environment of the transition metal in the TMC in the zeolite[225]. Another example of an appreciable influence of the formation of complexes by M^{n+} in crystalline aluminosilicates on the selectivity of the corresponding catalysts may be provided by the dimerisation of propene in the presence of phosphine complexes of Ni^{2+} in zeolites X, namely $[R_3P.Ni]X$.[40] Depending on R, the main reaction products obtained are methylpentenes or 2,3-dimethylbutenes (when R is large; see Table 2); this is the result of the steric influence of the ligand PR_3, which determines the type of orientation of the π-bonded propene molecule in the olefin dimerisation stage. Thus new interesting possibilities have arisen for the regulation of the activity and selectivity of catalysts.







VII. MODIFICATION OF ZEOLITIC CATALYSTS

In view of the polyfunctionality and "universality" of the catalytic action of zeolites, there exists the acute problem of the controlled alteration of the selectivity of zeolitic catalytic systems and in particular of increasing their stability.

There are several ways in which the catalytic properties of zeolites can be regulated. The simplest and most frequently employed method involves varying the composition and conditions of the preliminary treatment of the catalyst[19].

The composition can be altered in the course of the synthesis of the zeolite by substituting the exchangeable cations, by extracting some of the aluminium atoms (dealumination) or silicon atoms from the skeleton, and by other procedures.

Table 9. Catalytic reactions in the presence of TMC–zeolite systems.

Complex, zeolite	Reaction	References
$[Cu(NH_3)_4]^{2+}$ $[Co(NH_3)_2]^{3+}$ in type Y zeolite	$NH_3+O_2\rightarrow N_2+H_2O$ $NO+NH_3\rightarrow N_2+N_2O+H_2O$	[217] [218]
Rhodium carbonyl complexes in type Y zeolite	Hydroformylation of olefins $RCH=CH_2 + CO + H_2\rightarrow RCH_2CH_2CHO + RCHCHO$ (CH$_3$)	[206]
Phthalocyanine complexes of Ni, Co, Fe, and Cu in type Y zeolites	Dehydrogenation of cyclohexane Dehydrogenation of isopropyl alcohol $NO+H_2\rightarrow N_2+NH_3+H_2O$ $CO+O_2\rightarrow CO_2$ Oxidation of cysteine Conversion of epoxycyclohexane  Hydrogenation of butanethiol $C_4H_9SH+H_2\rightarrow C_4H_{10}+H_2S$	[219–222] [220–222] [74] [223] [224] [225] [226]

Phosphine complexes of Ni^{2+} in type X zeolites: $[R_3P.Ni]X$	Dimerisation of propene 	[40]

Notation: en = ethylenediamine and trien = triethylenetetramine.

In the studies, carried out in recent years, many of these methods were developed further. In particular new methods were proposed for the dealumination of aluminosilicate zeolites, which make it possible to obtain high-silica materials with high chemical and thermal stability. One of these is based on the repeated ion exchange of the initial aluminosilicate with NH_4^+ ions and the hydrothermal treatment of the product in combination with the extraction of non-skeletal aluminium by inorganic acids (HCl or HNO_3).[228,229] Specimens of type Y zeolite in the ratio $SiO_2/Al_2O_3 \geq 100$, which retain their structure even after heat treatment at 1150 °C for several hours, were prepared by this method[228].

The method of dealumination with the aid of $SiCl_4$ is of great interest[230]. It is based on the reaction

$$M_{1/n}[AlO_2(SiO_2)_x] + SiCl_4 \rightarrow 1/n\ MCl_n + AlCl_3 + [(SiO_2)_{x+1}],$$

where M is a cation with a charge n. The process consists of a single stage and is carried out in the absence of water vapour. The zeolite (NaY, NH_4Y, etc.) is dehydrated in a vertical tubular reactor at ~380 °C in a stream of dry nitrogen, after which nitrogen saturated at room temperature with $SiCl_4$ is passed through it, while raising the temperature in the reactor to the specified value (460–560 °C) at a rate of 4 K min^{-1}. The treatment is continued for several hours (≥2 h). The aluminium is removed partly in the form of $AlCl_3$ and is partly converted into the complex $M[AlCl_4]$ {$Na[AlCl_4]$ in the case of NaY}, which is washed off with water. The degree of dealumination depends mainly on the reaction time τ and to a lesser extent on the final temperature of the treatment. In the case of NaY (x = 5.04) for τ = 2 h and 500–560 °C, products with x ranging from 40 to 100 and distinguished by a high crystallinity were obtained[230].

When $SiCl_4$ is used as the dealuminating agent, direct substitution of Al in the faujasite skeleton for Si is believed[230] to occur. The above method is inapplicable to narrow-pore zeolites, since $SiCl_4$ cannot penetrate into the cavities of the crystal structure[230].

Variation of the chemical composition, the method of preparation, and the type of preliminary treatment are only some of the procedures for the specific alteration of the activity, selectivity, and stability of zeolitic catalysts. "Secondary" modification methods are also used: the addition of various substances to the reaction zone (see the review of Minachev and Isakov[19]), complex formation with the exchangeable metal cations, and others (see below) which have more specific applications. The promoting effect of NO_2, SO_2, CO_2, HCl, H_2S, and Cl_2 on CaY in the catalysis of the dehydration of isopropyl alcohol[231], of SO_2 on the MNaX and MNaY zeolites in the isomerisation of butenes[232–236], and of H_2S on MNaY in the cracking of cumene, the disproportionation of toluene, the cracking and disproportionation of xylene, and the dehydration of isopropyl alcohol[237] has been established. The conclusion[19,238] that the application of systems in the presence of other substances permits not only the intensification of catalytic processes and a change in their selectivity but also a more complete determination and ultilisation of the possibilities of zeolites as catalysts has been confirmed. Valuable information about the nature of their activity and the mechanism of their action is obtained at the same time.

A procedure has been developed for the modification of catalysts comprising the ZSM and TsVK zeolites by phosphorus[17,165,166,171], boron[166,171], magnesium[165,171], antimony[239], and vanadium[159] compounds, whereby it has been possible to increase sharply the selectivity of the processes involving the disproportionation of toluene[17,165,171,239], the aromatisation of C_2–C_4 olefins[159], and the alkylation of toluene by methanol[166,239] to form p-xylene. Table 10 presents data obtained in the conversion of C_2–C_4 olefins. Evidently, in the presence of the TsVK zeolite without vanadium, the main component of the alkylbenzenes C_8H_{10} is m-xylene. The introduction of 5 wt.% V_2O_5 into the zeolite lowers the overall degree of conversion of C_nH_{2n} and the yields of the liquid catalytic reaction products and aromatic hydrocarbons (most pronounced in the case of C_2H_4) with a simultaneous marked increase of the fraction of p-xylene in the mixture of the alkylbenzenes C_8H_{10}. The p-isomer of ethyltoluene also predominated among the aromatic hydrocarbons C_9H_{12}.[159]

The causes of the observed effects have not yet been finally elucidated. It has been suggested[159,165,166] that they are associated with the partial blocking of the channels in

pentasils by the modifying compounds, which entails a decrease in the rate of diffusion of the molecules of *m*- and o-xylenes (in the general case *m*- and o-dialkylbenzenes) from the cavities in the crystal structure to the gas phase. However, the steric hindrance arising under these conditions is apparently not the only factor, particularly since the distribution in the catalysts of modifying agents of various types but inducing similar changes is unknown. According to Hughes[118], the modification of H-ZSM-5 with phosphorus (derived from phosphite) diminishes the strength of the acid centres, which explains the decrease of the activity of the catalyst usually observed[166,171] (see also Table 10), and can make a significant contribution also to their selectivity, for example, by altering the isomerising capacity of the catalysts. It is important to emphasise that the method of modifying the ZSM and TsVK zeolites described leads to the possibility of developing new stereospecific catalytic processes for the synthesis of *para*-substituted aromatic compounds.

Table 10. The influence of the composition of the catalyst on the aromatisation of C_2–C_4 olefins[159] [500 °C, v = 500 h^{-1}, $SiO_2 : Al_2O_3$ (in zeolite) = 70.5 : 1].

Initial olefin	η, %	W, %	c, %	Aromatic hydrocarbons, %				Composition of C_8 alkylbenzenes, %

Notation: η = conversion of C_nH_{2n}, W = yield of liquid catalytic reaction products, and c = content of aromatic hydrocarbons in catalytic reaction products.

*The contents of benzene and C_7–C_{10} alkylbenzenes are quoted.

In many instances the method involving controlled partial saturation of catalysts with coke has been effective[166,240]. It has been found that this procedure permits a significant increase of the selectivity and stability of catalysts and an increase in their useful life before regeneration. It has been shown, in particular, that the selectivity in the formation of *p*-ethyltoluene in the alkylation of toluene with ethanol increases with increasing degree of saturation of HNaY zeolites with coke[240].

The research in this field is being continued. Hitherto, much art is still involved in dealing with the problem although the contribution of science has become incomparably greater.

VIII. THE STRUCTURE OF ZEOLITIC CATALYSTS, THE NATURE OF THE ACTIVE CENTRES, AND THE MECHANISMS OF THEIR ACTION

A characteristic feature of the development of catalysis in the presence of zeolites at the present stage is the increasing contribution of studies devoted to a more extensive investigation of the structure, the nature of the active centres, and the mechanism of the action of catalysts using a set of various physical, physicochemical, and theoretical (computational) methods. This is a natural result of the accumulation of extensive experimental data on the catalytic properties of zeolitic systems and the development of methods for the investigation of solids and chemical processes. Many new valuable results have been obtained in studies carried out in recent years. Data concerning the location of the exchangeable cations in zeolites of different compositions not only as regards crystallographic sites but also throughout the bulk of the crystals are of great interest. In particular, it has been established by X-ray photoelectron spectroscopy[216] that, in contrast to NaY and HNaY, for which no significant deviations of the surface Na^+ concentrations from those in the bulk phase are observed, the outer layers of the crystals of Na-mordenite and the TsVK and TsVM zeolites are greatly enriched in sodium. The migration of metals, produced on reduction of transition metal ions, to the outer surfaces of zeolite crystals[241] and the formation of alloys in polycationic systems when the latter are treated with hydrogen[241,242] have been demonstrated on many examples. It has been found that the oxidation of the Cu–Ni alloy in the CuNiY zeolite is accompanied not only by the formation of the CuO phase but also by the diffusion of the Cu^{2+} ions within the zeolite structure with appearance of isolated Cu^{2+} cations (as in the initial zeolite before reduction with hydrogen)[242].

Data concerning the influence of zeolites on the electronic state of deposited platinum and palladium have been surveyed[243] and valuable information has been obtained concerning the interaction of the metal with the aluminosilicate in other metal-zeolitic systems[244,245]. The characteristics of the spill over of hydrogen on zeolitic catalysts have been investigated[246]. Quantum-chemical calculations have been made for the OH groups[247,248] and also for the location of cations in faujasites[249]. An inhomogeneous distribution of aluminium in ZSM-5 type zeolites has been established. In their study of 50–200 μm single crystals by scanning electron microscopy and scanning X-ray microanalysis, von Ballmoos and Meier[250] found that aluminium is invariably concentrated at the edge of the crystals, while its content in the bulk of the particles is smaller by an order of magnitude than in the surface layers. The above differences depend on the size of the aluminosilicate crystals and the smaller the crystals the smaller the differences. According to Derouane et al.[251], the distribution of aluminium in the ZSM-5 zeolites depends also on the conditions of their preparation and even on the reactants used in their synthesis. These results lead to the conclusion that, in comparing the properties of zeolites with their composition determined by chemical analysis (the "average" composition), some caution must be exercised.

The above lists of examples is by no means complete and could be extended. The results obtained permit not only a more complete and accurate explanation of the characteristics of the action of catalysts but also promote the development of new approaches to the modification of catalysts and the solution of individual problems in the application of zeolitic systems. They also form part of the foundations of novel ideas concerning the mechanisms of certain reactions occurring on zeolitic catalysts[252].

---o0o---

Such are the most important trends and the principal directions of development in catalysis on zeolites at the present stage. Zeolitic materials have aroused much promise for the solution of the important problem of the synthesis of artificial liquid and gaseous fuels and chemical products from coal and other mineral fuels. With their aid, much can be done not only in the field of the intensification of the processes and

the saving of energy and raw materials, but also in the solution of ecological and social problems.

Catalysis in Polycondensation Reactions

V.V.Korshak

The importance of catalysis in polycondensation processes is considered. It is suggested that the catalytic processes in polycondensation reactions be divided into four groups: cationic, anionic, ionic-coordination, and free-radical. Examples of catalysts for a number of reactions are presented and the mechanisms of the catalytic action in various types of catalysis in polycondensation processes are considered. Such types of catalytic reactions are cationic and anionic catalysis and catalysis with the aid of tertiary amines, stereoregular polycondensation and polycondensation in the presence of catalysts of the Friedel-Crafts type, and oxidative polycondensation. The side reactions due to the presence of catalysts and their influence on the properties of the polymers obtained are examined.
The bibliography contains 60 references.

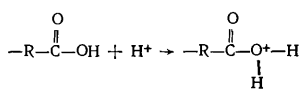
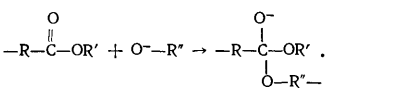
I. INTRODUCTION



Since polycondensaton is an important method of synthesis of polymers, studies on polycondensation processes are vigorously developing at the present time. Many polymers obtained by polycondensation methods are nowadays manufactured in amounts running into millions of tonnes: these are phenol-formaldehyde and carbamide polymers as well as polyurethanes, polyamides, and polyesters[1,2]. Many polymers obtained by polycondensation are manufactured in amounts of thousands of tonnes: these include polycarbonates, unsaturated polyesters, polysiloxanes, polyoxides, and others. Finally the third group of numerous polycondensation polymers includes those whose manufacture is on a small scale but which are irreplaceable since they possess a set of valuable properties. These include thermostable polymers such as polyimides, polyarylates, polybenzimidazoles and other polyheteroarylenes, and also various semiconducting and light-sensitive polymers, etc. The great variety and wide range of properties of the polymers account for the vigorous development of studies on the polycondensation reaction, which is also reflected in the numerous articles, reviews, and monographs[1-10].

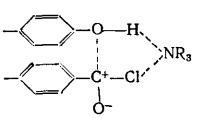
Catalysis plays a major role in polycondensation processes and the application of catalysts of all kinds is extremely widespread. The aim of the present review is to consider the literature data on catalysis in the polycondensation reaction[1,11,12].

II. TYPES OF POLYCONDENSATION PROCESSES



Depending on the nature of the catalyst and the starting materials employed, the polycondensation reaction can proceed as a cationic, anionic, polycoordination and even a free-radical process[3].

Thus the polycondensation of carboxylic acids with glycols in the presence of strong acids proceeds via a cationic mechanism with the intermediate formation of the product of the addition of a proton to the hydroxyl group of the acid:



(1)

An example of anionic polycondensation is provided by the reaction of dicarboxylic acid esters with glycols in the presence of alkali metal glycolates, which proceeds in accordance with the equation

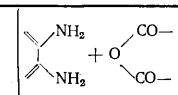
(2)

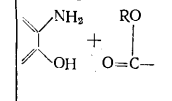
The polycondensation of dicarboxylic acid chlorides with bisphenols in the presence of catalysts such as tertiary amines is an example of the ionic-coordination polycondensation. This reaction leads to the formation of stereoregular polyarylates. Its mechanism can be accounted for by the formation of the following complex in its intermediate stage:

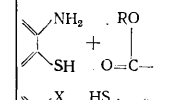
(3)

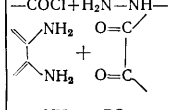
The formation of free radicals is an elementary step in the polyrecombination reaction [see reaction (4)], which is one of the instances of free-radical polycondensation[11]:

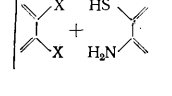
(4)

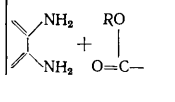












The examples presented illustrates the differences in the elementary step in polycondensation for each of the four types of polycondensation processes indicated above.

III. REACTIONS USED IN POLYCONDENSATION

An extremely significant feature of polycondensation processes, which has an appreciable influence on the process mechanism, is the great variety of types of initial monomers and hence differences between the structures of their active end groups whose reaction determines the course of the polycondensation process[1].

Table 1 lists the most important end groups and types of reactions used in polycondensation processes[12].

Table 1. The most important end groups and types of reactions used in polycondensation.

IV. CATALYSTS FOR THE POLYCONDENSATION REACTION

Among the catalysts for the polycondensation reaction involving an ionic mechanism, one encounters a wide variety of compounds such as oxides, salts, inorganic and organic bases, alkalis, complexes, inorganic and organic acids, amines, etc[13–15]. As an illustration, Table 2 lists the elements whose various compounds have been used as catalysts in the polycondensation reaction[13,15–19].

It is noteworthy that the polyesterification reaction is a process for which catalytic problems have been studied in greater detail compared with other reactions. It was established that both the nature of the metal and the nature of the anion of the catalyst used play a significant role. Table 3 presents the catalysts employed in polyesterification processes.

Table 3. Polyesterification catalysts.

Catalyst		References
cation	anion

Table 4. Dependence of the rate constant k for the polycondensation of bis(β-hydroxyethyl) terephthalate on the nature of the catalyst.

Catalyst	$10^{-2}k$, g mmol^{-1}s^{-1}	Catalyst	$10^{-2}k$, g mmol^{-1}s^{-1}
GeO_2	326	$Co(Ac)_3$	61
$Sb(Ac)_3$	156	$Mn(Ac)_3$	32
$Al(Ac)_3$	131	Without catalyst	0.156

In order to characterise the dependence of the activity of the catalyst on its structure, we present as an illustration Table 4, which shows how the activity of the catalyst in the polyesterification reaction of bis(β-hydroxyethyl) terephthalate depends on the polarity of the metal ion[24]. The Table shows that the rate constant for this reaction increases sharply under the influence of the catalyst and there is a significant variation in the presence of different metals[24].

The activity of the catalyst in a specific process also depends on the nature of the reaction investigated. Thus in the synthesis of polyamides the activity of the catalyst is much lower than in the polyester synthesis. However, substances such as boric acid[30], zinc chloride[31], phosphoric acid[31], magnesium oxide[30], tetraethyl pyrophosphate[32], and other compounds[12] were nevertheless shown in many instances to be catalytically active in the synthesis of polyamides.

The polycondensation of α-aminoacid esters is known to be very sensitive to the action of catalysts[33]. Various acids, among which carbon dioxide is particularly active, are active catalysts for this reaction. The mechanism of the catalytic action of carbon dioxide on the polycondensation of α-aminoacid esters has been explained by the formation of *N*-carboxyaminoacid esters in the first stage, the esters subsequently giving rise to carbamates,

$$R'OOCCHRNH_3 \cdot HOOCNHCHRCOOR' , \qquad (5)$$

which decompose at 55 °C with formation of polypeptides[33].

A large group of polycondensation reactions includes the interactions of aldehydes with phenols, amides, and other derivatives. All these reactions are sensitive to the pH of

the medium and to the action of catalysts of different kinds. Table 5 lists the catalysts used in the reactions of phenols with aldehydes[11,34].

Table 5. Catalysts used in the reactions of phenols with aldehydes.

		I_2

In many polycondensation reactions alkylation or acylation takes place in the presence of Friedel-Crafts catalysts such as aluminium chloride, aluminium bromide, zirconium chloride, boron fluoride, and others[11,12].

The above examples of catalysts illustrate fairly clearly their great variety in different instances of polycondensation. As will be shown below, a common property of all the catalysts is their ability to form intermediates with reactants and hence to increase their chemical reactivity. It is also noteworthy that in many instances the initial monomers act as catalysts and the reaction can then be regarded as an example of self-catalysis.

V. THE MECHANISM OF THE ACTION OF CATALYSTS

The great variety of the structures and types of catalysts complicates the consideration of the mechanism of their action from a single standpoint. We shall therefore attempt to consider mechanisms common to each group of reactions.

In considering catalysis in polycondensation processes as a general phenomenon we must, on the one hand, deal with specific instances of catalysis in individual processes, and, on the other hand, an attempt must be made to survey its overall importance. The polycondensation process can be represented by the equation

$$x\,aAa + x\,bBb \rightarrow a\text{—}(\text{—}AB\text{—})_x\text{—}b + (2x-1)\,ab \quad . \qquad (6)$$

The role of catalysis can be represented in general form as a process involving the formation of an intermediate active compound of the catalyst (K) with one of the monomers via the mechanism

$$\begin{aligned} &a\text{—}A\text{—}a + K \rightarrow (a\text{—}A\text{—}a)\,K \quad ; \\ &b\text{—}B\text{—}b + K \rightarrow (b\text{—}B\text{—}b)\,K \quad , \end{aligned} \qquad (7)$$

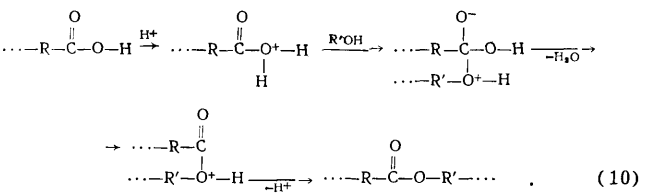
followed by the reaction of the intermediate with a molecule of the second monomer;

$$\begin{aligned} &(a\text{—}A\text{—}a)\,K + b\text{—}B\text{—}b \rightarrow a\text{—}A\text{—}B\text{—}b + ab + K \quad ; \\ &a\text{—}A\text{—}a + (b\text{—}B\text{—}b)\,K \rightarrow a\text{—}A\text{—}B\text{—}b + ab + K \quad . \end{aligned} \qquad (8)$$

A version is also possible in which both monomers form compounds with the catalyst and subsequent reaction takes place between these two active intermediate molecules via the mechanism

$$(a\text{—}A\text{—}a)\,K + (b\text{—}B\text{—}b)\,K \rightarrow a\text{—}A\text{—}B\text{—}b + ab + 2K \quad . \qquad (9)$$

These considerations apply to the general character of the action of the catalyst. Considering the mechanism of the latter in greater detail, we shall attempt a more detailed consideration of the mechanism of the action of catalysts of different chemical types in a wide variety of polycondensation reactions. In view of the fact that all ionic polycondensation processes take place with formation of ions and ionic systems, all the catalysts of such reactions can be divided into three groups[11,12].

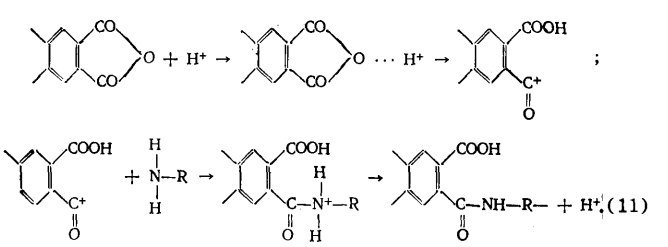


1. Catalysts which form reactive cations (cationic polycondensation).

2. Catalysts which form reactive anions (anionic polycondensation).

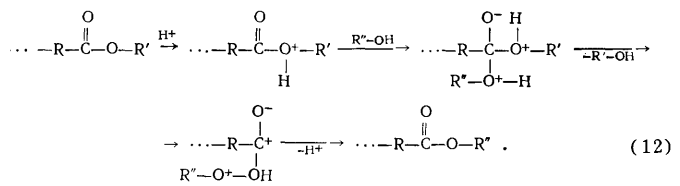
3. Catalysts which form reactive salt-like compounds (acceptor-catalytic polycondensation or stereospecific catalysis).

VI. CATIONIC CATALYSIS IN POLYCONDENSATION



We shall now proceed to a more detailed consideration of the individual examples of the action of catalysts in each of the groups indicated above. In the equilibrium polycondensation of dicarboxylic acids and glycols in the presence of acid catalysts, the cationic reaction mechanism can be represented schematically as follows:

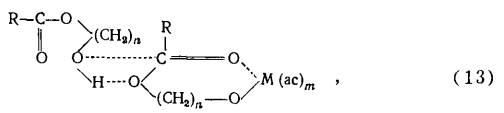
(10)



It is clearly seen from the above scheme that in the formation of oxonium compounds the addition of the acid proton to the hydroxyl group is an intermediate reaction in this process.

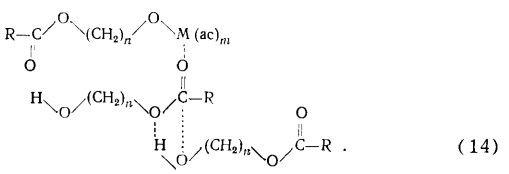
The carbonyl carbon atom becomes positively charged as a result and combines with the oxygen atom of the alcohol in consequence of nucleophilic attack. The reaction is accelerated in the presence of strong acids, since the initial glycol is a weak nucleophile and the initial dicarboxylic acid is a weak electrophile. However, the reaction can proceed via the above scheme also in the absence of a strong acid. Flory showed[35] that in this case the initial dicarboxylic acid plays the role of the catalyst. The catalytic action of carboxylic acids has also been demonstrated in the reactions of diamines and tetracarboxylic acid anhydrides, leading to the formation of polyamidoacids[36]. We believe that the reaction mechanism [see reaction (11)] can be represented schematically as follows:

(11)



The mechanism of cationic polycondensation can be also illustrated in relation to the formation of a polyester via the transesterification of a dicarboxylic acid ester with a glycol in accordance with the equation

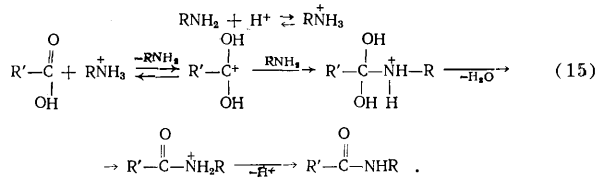
(12)



This reaction was investigated in particularly great detail in the synthesis of poly(ethylene terephthalate).[8,15,19,24,37,38]

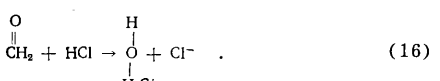
Reinisch and coworkers[24] proposed the following mechanism of the action of catalysts in this reaction based on the formation of cyclic complexes:

(13)



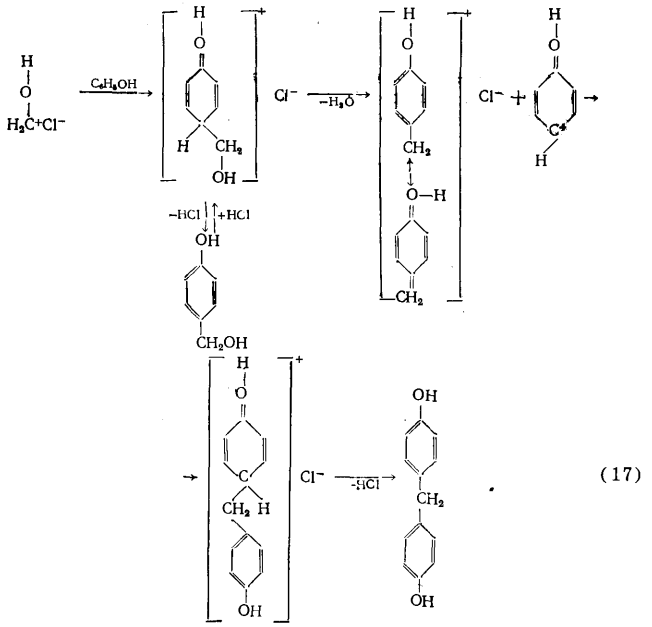
where M is a metal ion. There is a possibility of the simultaneous formation of linear complexes having the structure

(14)



Here it is assumed that the activity of the catalyst is proportional to its ability to form complexes of this kind[24].

In the formation of polyamides the catalysis involves protons[39] [see reaction (15)]. The following mechanism, which explains the action of the acid, has been proposed:



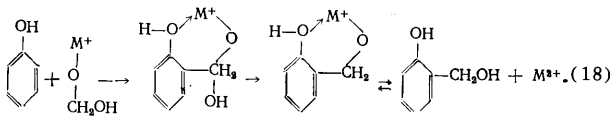
(15)

The reaction of phenols with aldehydes can proceed via a cationic mechanism in the presence of acids in accordance with the equation[40,41]

(16)

The ion pair formed in this process reacts further in the following manner:

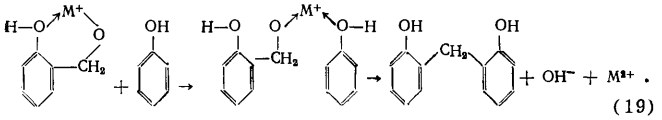
(17)



The first product is a quinone derivative, which is subsequently transformed into dihydroxydiphenylmethane. For this reason, phenol-alcohols are formed extremely rarely in an acid medium.

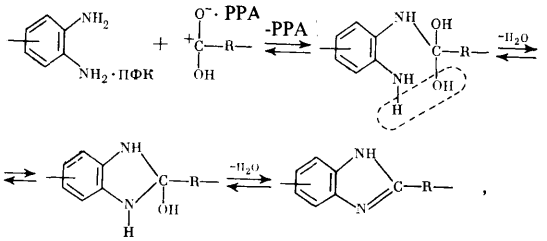
Bivalent metal ions accelerate the reaction of phenol with formaldehyde and at the same time exhibit a directing effect driving the hydroxymethyl groups in the *o*-positions relative to the hydroxy-groups. This results in the formation of phenolformaldehyde oligomers which contain predominantly *o*-substituted phenolic residues. These products are known as *ortho*-novolak or *ortho*-resol and are of interest as rapidly hardening materials.

Fraser et al.[42] described the catalytic action of bivalent metal ions in terms of the following scheme. The product of the reaction of the metal ion and methylene glycol is formed initially:



It then interacts with phenol to form *o*-salicyl alcohol

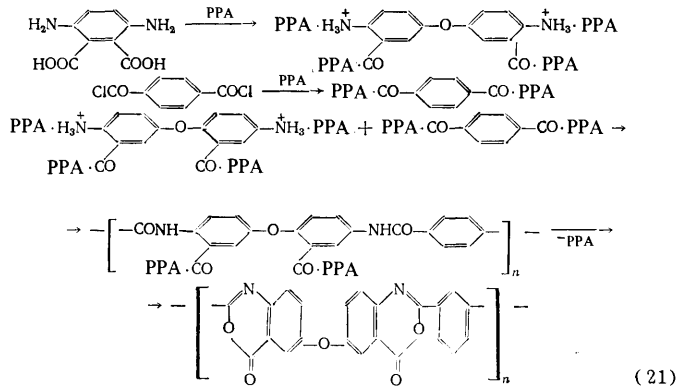
(18)



The last stage is the formation of di(*o*-hydroxyphenyl)methane:

(19)

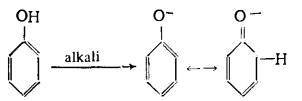
The catalytic action of polyphosphoric acid has been explained by the formation of an intermediate complex in the synthesis of polybenzimidazoles in accordance with the



scheme[43]

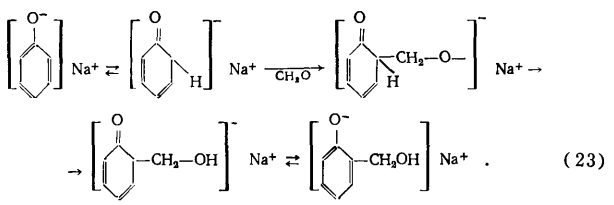
(20)

where PPA is polyphosphoric acid.



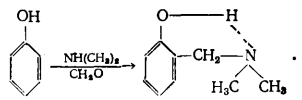
The formation of intermediate compounds with polyphosphoric acid has been demonstrated in relation to the formation of polybenzoxazinones from bisanthranilic acids[44]:

(21)



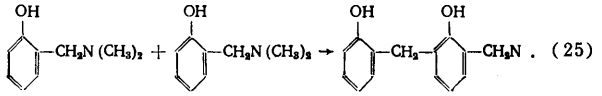
VII. ANIONIC CATALYSIS IN POLYCONDENSATION

The alkaline catalysts used in ionic polycondensation are extremely active, since in their presence phenol is converted into the phenoxide anion, which is accompanied by a redistribution of electron density in accordance with the following scheme:



(22)

As a result of this, alkaline catalysts facilitate the reaction of phenols with aldehydes[40]. Accordingly, the action of an alkaline catalyst in the polycondensation of phenol with formaldehyde can be represented schematically as follows:



(23)

When dimethylamine is used, the reaction of phenol with formaldehyde proceeds with formation of an intermediate Mannich base[45] via the mechanism

(24)

The Mannich base thus produced decomposes on heating into dimethylamine and a phenol-formaldehyde polymer in accordance with the equation

(25)

VIII. CATALYSIS WITH THE AID OF TERTIARY AMINES

The acylation of alcohols and phenols by carboxylic acid chlorides in solution is frequently carried out in the presence of tertiary amines (pyridine, triethylamine, etc) as catalysts. Depending on the nature of the tertiary amine and the initial phenol and acid chloride, the reaction can then proceed via one of the following two mechanisms:

(1) Via the general base catalytic mechanism:

(26)

(2) Via the nucleophilic catalytic mechanism:

(27)

The result of the reaction of a dicarboxylic acid chloride with a bisphenol depends on the amount of catalyst—triethylamine. Fig. 1 illustrates the variation of the yield and molecular weight of the polyarylate obtained by the polycondensation of terephthalic acid dichloride (AC) in solution in dichloroethane with the amount of triethylamine (TEA).[46] The maximum in the plot of the viscosity against the amount of the catalyst is also observed for the reaction of dian with terephthalic acid chloride at a catalyst concentration of 20 wt.% (Fig. 2).[47]

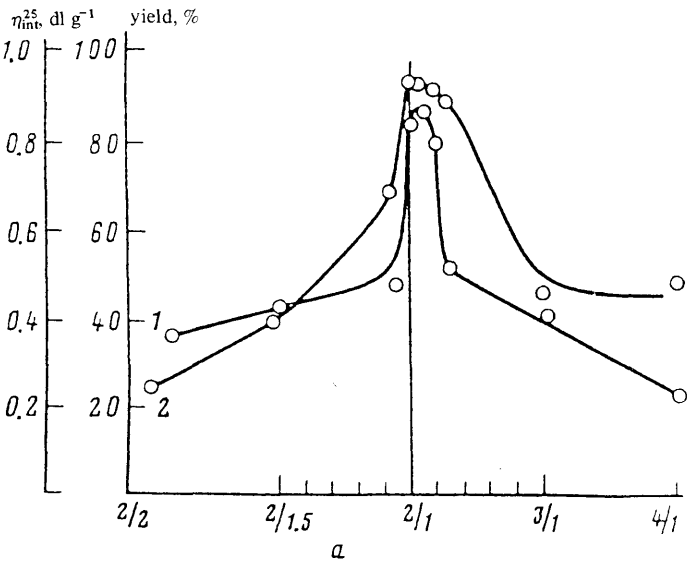


Figure 1. Dependence of the intrinsic viscosity (curve *1*) and the yield (curve 2) of the polyarylate on the molar ratio TEA:AC (*a*).

Tertiary amines not only accelerate the acylation reaction (for example, in the benzoylation of *p*-nitrophenol in the presence of triethylamine, the rate constant was higher by two orders of magnitude than for the same reaction in the presence of pyridine[48]) but also influence the steric structure of the polyester formed, as will be shown below[27,28,49].

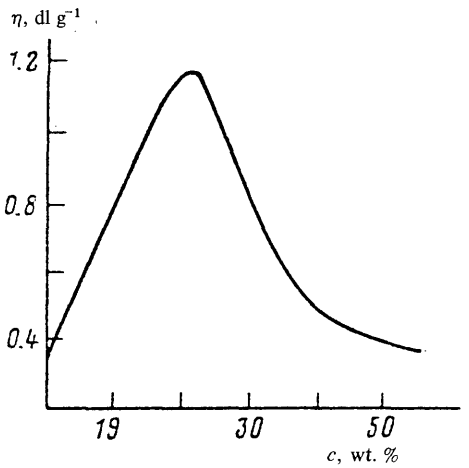

Figure 2. Dependence of the logarithmic viscosity of a solution of dian polyarylate and terephthalic acid on the amount of tetraethylammonium chloride (*c*) in the interfacial polycondensation reaction.

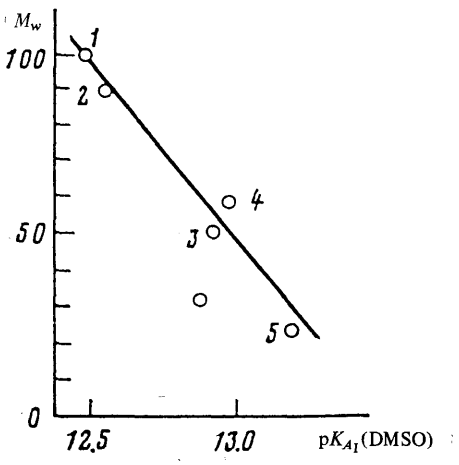

Figure 3. Dependence of the molecular weights of polyterephthalates M_W on the acidity of the bisphenol; bisphenol: *1*) 2,2-bis(3-chloro-4-hydroxyphenyl)propane; *2*) 3,3-bis-(4-hydroxyphenyl)phthalide; *3*) bis (4-hydroxyphenyl)methylphenylmethane; *4*) bis(4-hydroxyphenyl)phenylmethane; *5*) 9,9-bis(4-hydroxyphenyl)fluorene.

A characteristic feature of general base catalysis is also that, as can be seen from Fig.3, an increase of the acidity of the bisphenols entails an increase of the molecular weight of the polyarylates obtained from terephthalic acid chloride. Eqn.(26) shows that more favourable conditions for the acylation reaction are created with increase of the acidity of the phenol. Indeed an increase of the acidity of the hydroxy-component should entail an increase in its capacity for complex formation with the tertiary amine[48]. The increase of the activity of the hydroxy-component with increase of its acidity is indicated by the results of the joint acylation of a mixture of phenol and methanol with benzoyl chloride in the presence of triethylamine; it was found that the yield of phenyl benzoate was nine times greater than that of methyl benzoate. On the other hand, the reaction in the presence of a weak base such as pyridine led to the reverse ratio of the yields of phenyl and methyl benzoates, which was 0.35. This means that in the former case the general base catalysis predominates [reaction (26)], since the more acidic phenol is more reactive, whilst in the latter case nucleophilic catalysis predominates. This dependence of the rate of benzoylation of the mixture of the aliphatic alcohol and phenol on the basicity of the catalyst was confirmed by investigating the reactions using tertiary amines with different basicities as catalysts[49a]. It was found that the relative reactivity of the phenolic component increases with increasing basicity of the tertiary amine as can be seen from the curve in Fig.4.

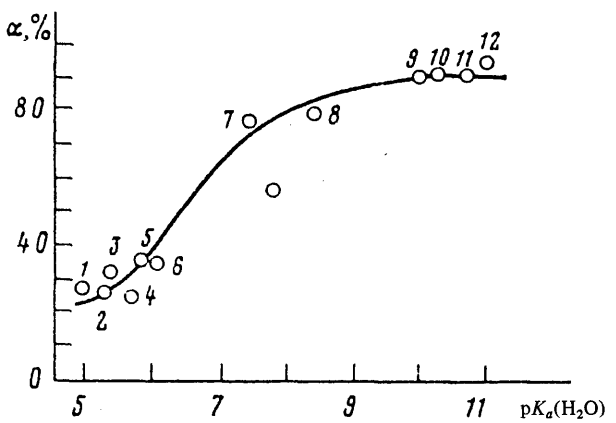

Figure 4. Dependence of the degree of conversion of phenol α on the basicity of the amine: *1*) quinoline; *2*) pyridine; *3*) isoquinoline; *4*) β-picoline; *5*) quinaldine; *6*) α-picoline; *7*) γ-collidine; *8*) triallylamine; *9*) ethyldimethylamine; *10*) cyclohexyldimethylamine; *11*) triethylamine; *12*) tributylamine.

These results confirm the above hypothesis that two catalytic processes can occur in acylation: general base catalysis and nucleophilic catalysis [reactions (26) and (27)].[49] The predominance of a particular catalytic process depends on the nature of the starting material and the tertiary amine[49]. The rate constants for the benzoylation of various phenols in the presence of triethylamine are presented in Fig.5. The left-hand part of the plot corresponds to phenols with pK_a ranging from 10 to 14. The sharp alteration in the form of the

plot starting from $pK_a > 14$ can be accounted for as a consequence of the change in the mechanism of the catalysis from the general base type to the nucleophilic type, as suggested above.

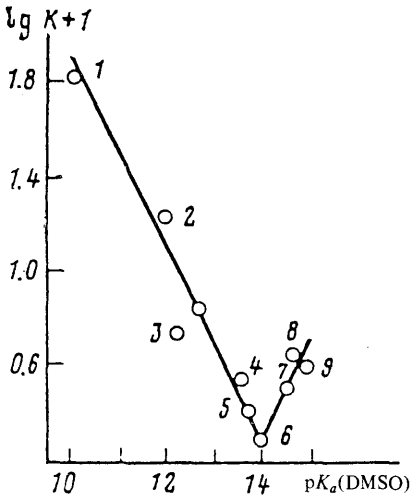

Figure 5. Dependence of the logarithms of the rate constants for the benzoylation of phenols on their acidity; phenol: *1*) *p*-nitrophenol; *2*) *p*-acetylphenol; *3*) *p*-chlorophenol; *4*) hydroquinone benzoate; *5*) phenol; *6*) *p*-t-butylphenol; *7*) *p*-cresol; *8*) *p*-methoxyphenol; *9*) hydroquinone.

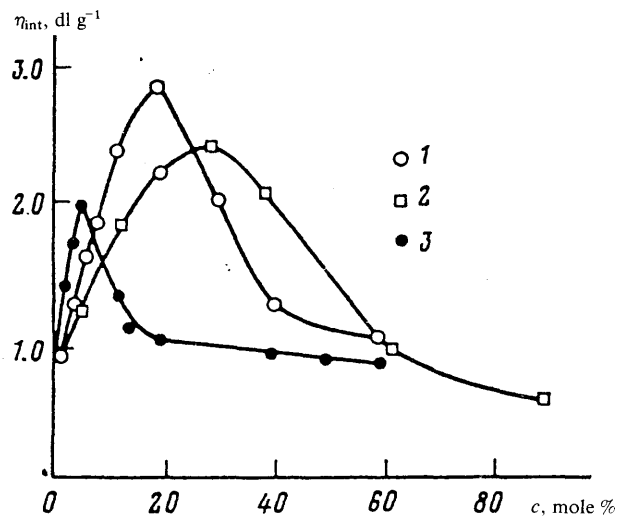

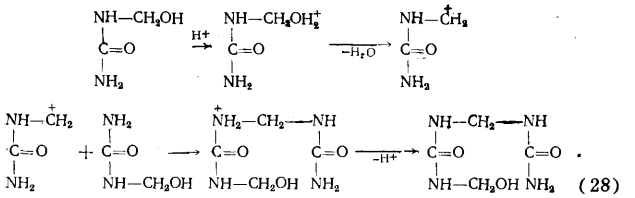

Figure 6. Dependence of the viscosity of the polyimide obtained by the reaction of the dianhydride of tricyclo [4.2.2.0]dec-10-ene-3, 4, 7, 8-tetracarboxylic acid with di(4-aminophenyl) ether on the catalyst concentration *c*: *1*) triethylamine; *2*) trimethylamine; *3*) tributylamine.[52]

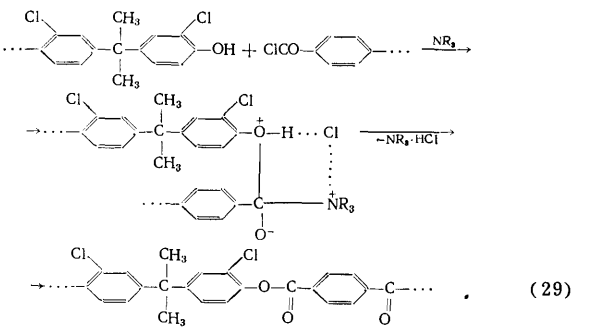
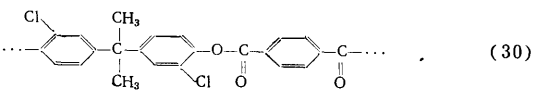


The reactions of diamines with dicarboxylic acid dianhydrides are extremely sensitive to the catalytic action of tertiary amines such as pyridine, triethylamine, and trimethylamine[50]. A maximum is then observed in the curves relating the viscosity of the product to the amount of the catalyst, as shown in Fig. 6.

The role of the acid catalyst in the reactions of amines and acid amides with aldehydes consists, according to Smets[51], in the formation of a carbonium ion in accordance with the equation



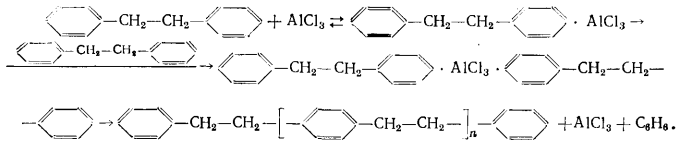
IX. CONFORMATIONALLY REGULAR POLYCONDENSATION

Stereoregular polycondensation was observed in the study of the polycondensation reaction in the presence of tertiary amines[27,28]. It proceeds as conformationally regular polycondensation on interaction of monomers capable of existing in several stereoisomeric forms [see reaction (29)]. The catalytic action of tertiary amines is manifested in the formation of polyarylates from bisphenols and dicarboxylic acid chlorides, which leads to the preferential formation of the *cis*- or *trans*-form of the polyester in accordance with the mechanism

In the presence of a weak base, for example, pyridine, the cisoid form of the polymer is formed. The use of a tertiary amine with strongly basic properties, for example, triethylamine, as the catalyst leads to the formation of the transoid form of the polyarylate:

The probable cause of the formation of conformationally regular polymers is the formation of stable conformations of the complexes of the starting materials with the tertiary amines.

X. POLYCONDENSATION IN THE PRESENCE OF FRIEDEL–CRAFTS CATALYSTS

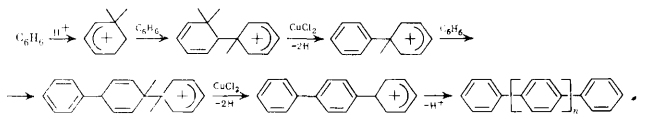


The polycondensation of aromatic hydrocarbons with halogen atoms in the side chain as well as the polycondensation of dihalogenoalkanes with aromatic hydrocarbons proceed only

in the presence of Friedel–Crafts catalysts. Aluminium chloride or the halides of cerium, boron, and other elements are most frequently used for this purpose.

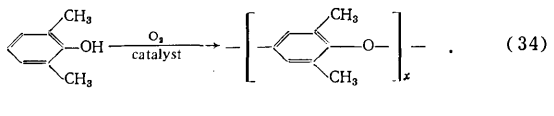
A ternary complex of the halogenohydrocarbon with aluminium chloride and the aromatic hydrocarbon is formed as the first reaction product in this instance. The formation of such a complex in the polycondensation of dichloroethane with benzene can be described by the equation[53]:

$$ClCH_2CH_2Cl \cdot Al_2Cl_6 + 2C_6H_6 \rightleftarrows ClCH_2CH_2Cl \cdot Al_2Cl_6 \cdot 2C_6H_6 \qquad (31)$$



Catalysts act similarly in *trans*-arylation[54]. This type of polycondensation leads to the formation of polyarylenealkyls in the following reaction accompanied by the formation of benzene[54]:

(32)

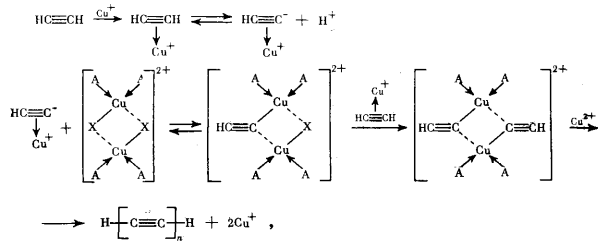


XI. OXIDATIVE POLYCONDENSATION

The oxidative polycondensation of benzene and other aromatic hydrocarbons, which leads to the formation of polyphenylenes according to Kovacic and Lange[55], takes place in the presence of iron(III) chloride or a mixture of copper(II) chloride and aluminium chloride[55]. The intermediate stage in this reaction is the formation of a σ-complex and the benzenium ion in accordance with the equation

(33)

An important instance of oxidative polycondensation is the synthesis of poly(2,6-dimethylphenylene oxide) by the oxidation of 2,6-dimethylphenol with atmospheric oxygen via the reaction



(34)

The reaction proceeds in the presence of various catalysts, among which the most important is the copper complex of pyridine[56]. The activity of this catalyst in the reaction depends on the ratio of the concentrations of pyridine and copper. With increase of this ratio, the number of ester linkages increases and the number of carbon–carbon bonds diminishes; when the ratio of the pyridine and copper concentration is 10:1, carbon–carbon bonds are not formed at all[57].

The copper complex of ammonia also proved to be an active catalyst of the oxidative polycondensation of acetylene, leading to the formation of a "carbyne"—a linear form of carbon—via the reaction[58]

$$HC \equiv CH \xrightarrow{+Cu^{2+}} -(-C \equiv C-)-_x \; . \qquad (35)$$

The mechanism of the action of the catalyst in this reaction can be described by the equation

where A = complexone residue.

XII. SIDE REACTIONS INDUCED BY THE PRESENCE OF CATALYSTS

In considering the problem of the action of catalysts, one must bear in mind the fact that catalysts can influence not only the main reaction involving the synthesis of polymers but can also induce or accelerate various side reactions, which can involve both the initial monomers and the polymer formed and this can be reflected in the molecular weight and structure of the reaction product and can influence the entire set of its physical and chemical properties. In certain cases catalysts accelerate the decomposition of the polymer in the course of its synthesis, impairing its properties[16].

As an example of the negative influence of side reactions, one may quote the synthesis of poly(ethylene terephthalate) from ethylene glycol and terephthalic acid in the presence of sulphuric acid[11]. A side reaction involving the elimination of water and the formation of diethylene glycol then takes place:

$$2HOCH_2CH_2OH \rightarrow HOCH_2CH_2-O-CH_2CH_2OH + H_2O \; . \qquad (37)$$

In addition, acetaldehyde and ethylene acetal are also formed. The diethylene glycol produced reacts with terephthalic acid, which results in the formation of a hetero-unit polymer containing diethylene glycol units:

(38)

Acetaldehyde can be readily removed from the reaction mixture, which alters the ratio of the starting materials and has a negative effect on the molecular weight of the polymer.

The use of certain catalysts, such as, for example, titanium and aluminium compounds, leads to the formation of dark-coloured products[16]. The occurrence of such reactions necessitates caution in the selection of catalysts[15]. It has been noted that even the material of the reactor can influence the process and the polycondensation product[19].

In addition, one should point out that in certain cases the presence of the catalyst influences the mode of reaction. Thus Murochochi et al.[32] observed that *N*-(γ-aminobutyryl)-γ-aminobutyric acid gives rise to the cyclic γ-pyrrolidinone on heating. However, if this monomer is heated to 100 °C in diethylphosphinic acid in the presence of tetraethyl pyrophosphate, polybutanamide is formed.

---oOo---

In conclusion of the review, we should like to emphasise that catalysis is a positive factor in polycondensation processes, since it accelerates the reaction, makes it possible to carry it out under mild conditions, and determines the microstructure of the polymer obtained. However, one should

note that theoretical studies of catalysis in polycondensation reactions fall short of the importance which they have for the development of this field. Therefore the problem of the selection of catalysts is still solved mainly empirically. The most important task for the future is the determination by extensive studies of the effective factors in the catalysis of polycondensation reactions, which should lead to the raising of the level of the relevant research and to advances in this field of polymer chemistry.
