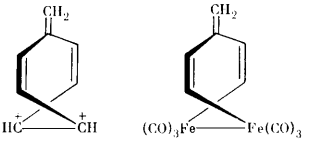
Isolobal analogy ensures a new methodological approach to the search for new non-classical organic structures which can be deduced by replacing the organometallic residues in the structures of π-complexes and clusters by isolobal organic groups (see Table). Thus the structure (XI) of the cation $(CH)_5^+$ might have been predicted on the basis of the structure of the η^4-cyclobutadiene complex of iron tricarbonyl established as early as 1960,[150] while the structure of the dication $(CH)_6^{2+}$ follows from the structure of ferrocene (LV, M = Fe), which became known as early as 1952.[125]



Bearing in mind the stability of the trimethylenemethane complex (XXVII) and the fact that the CH^+ and $Fe(CO)_3$ groups are isolobal, Chandrasekhar et al.[151] suggested the possibility of the existence of the 1-bicyclo[1,1,1]pentyl cation (LXXVIII) and confirmed this hypothesis by a direct MINDO/3 calculation:

(LXXVII) (LXXVIII) (LXXIX)

Although structure (LXXVIII) represents a local minimum on the PES, calculations predict an extremely low energy barrier (1.8 kcal mol^{-1}) in the rearrangement to the 1-methylene-3-cyclobutyl cation. This explains the finding that the intermediate formation of structure (LXXVIII) was not detected in experiments[152] on the distribution of an isotope label in the spiropentyl cation.

At the same time the suggestion that one should seek the bipyramidal dication (LXXIX), put forward by Hogeveen and Kwant[46], is not fruitful, since this structure does not satisfy the 10*e* rule. It must also be emphasised that, in connection with the method of constructing the valence orbitals of the organometallic residues, isolobal analogy should hold most completely for symmetrical compounds where the local symmetry axis of the group coincides with the symmetry axis of the molecule or ion as a whole. Otherwise the correspondence of the non-classical structure generated from a π-complex to a local minimum on the PES must be specially tested. Thus the hypothesis[153] that the dication (LXXX)—an analogue of the bisiron tricarbonyl complex (LXXXI)—can exist was not confirmed by detailed calculations[154], which failed to reveal the corresponding local minimum on the PES of $(CH)_8^{2+}$.

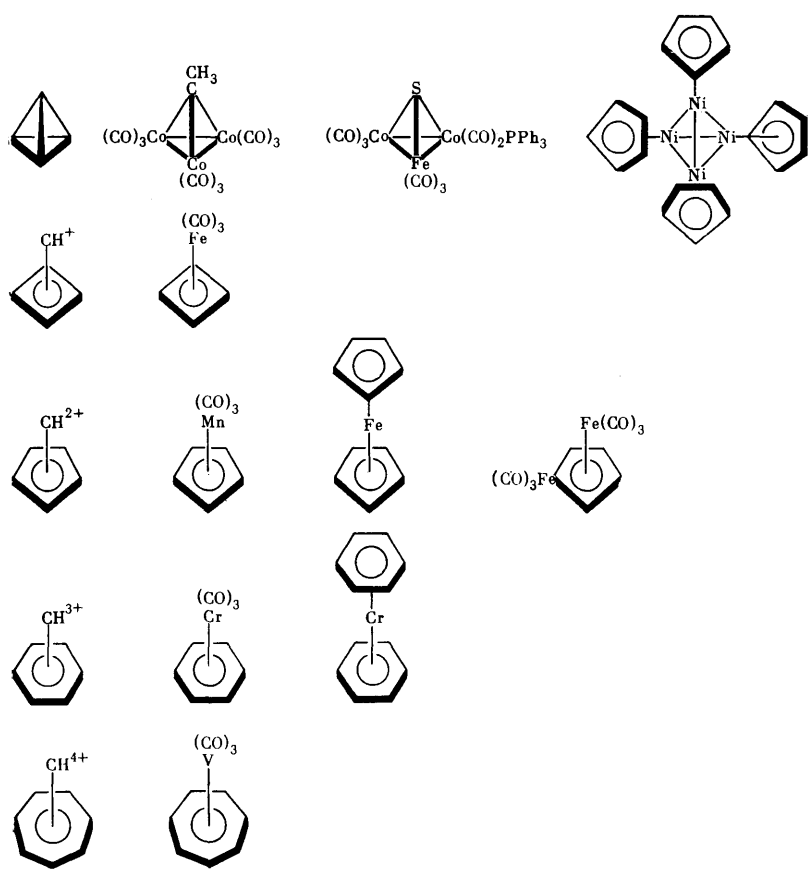
(LXXX) (LXXXI)

2. The Stability of Polyhedral Structures and the Skeletal Electron Count Rules

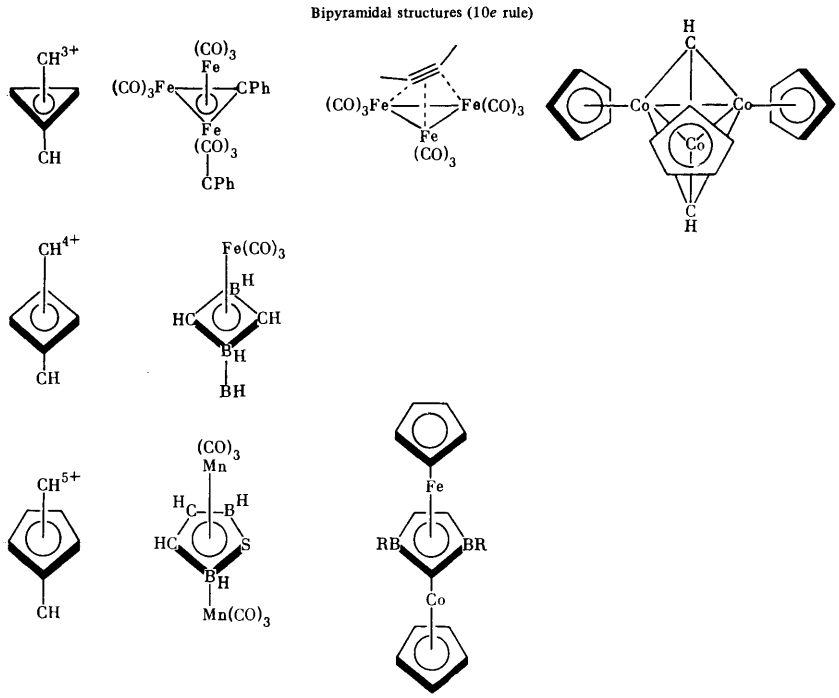
The stability of the non-classical polyhedral structures of organic molecules and ions examined above can be understood in the context of the general electron count rules developed for skeletal and cluster structures of boranes and heteroboranes and extended, taking into account the ideas of electronically equivalent groups, to the analogous organometallic compounds[2-5,155-157].

These rules are based on the count of skeletal electrons accommodated in the endocyclic orbitals of the skeletal bonds of skeletal and cluster compounds. The number of such electrons is $\nu + x - 2$, where ν is the number of valence electrons of the central atom of a non-transition element occupying one of the vertices and x is the number of one-electron ligands (the unshared electron pair behaves as a phantom ligand). For groups formed by transition metals, the number of skeletal electrons is defined as $\nu + x - 12$. A relation involving electronic equivalence with groups of non-transition elements is then established (see Table). Naturally the difference of 10*e* is in essence the difference

between the requirements for the filling of 8- and 18-electron shells for atoms of non-transition and transition elements.



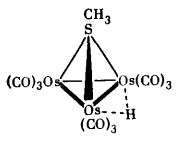
All the polyhedral structures formed by boranes, carbaboranes, heteroboranes, and organometallic compounds, differing by the presence of trigonal faces (deltahedra), can be generated[2-5,40] from the so-called *closo*(closed)-structures of a bipyramidal type for 5–7 vertices, from a trigonal dodecahedron for 8 vertices, etc., *nido*(nest)-structures are obtained from the *closo*-forms by truncating one vertex (for example, pyramids can be obtained from bipyramids). *arachno*(spider-like)-Structures are obtained similarly from *nido*-structures.



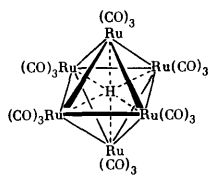
Qualitative analysis[1,2-5,155-158] and direct calculations on *closo*-structures lead to the conclusion that there are $n + 1$ bonding MO for the boranes B_nH_n, in which it is possible to accommodate $2n + 2$ skeletal electrons, i.e. the *closo*-structures of the dianions $B_nH_n^{2-}$ and of the isoelectronic carbaboranes $C_2B_{n-2}H_n$ are stable. The validity of this rule can be readily tested in relation to the bipyramidal compounds (LXXII)–(LXXV). At the same time the hydrocarbons (LXX) and (LXXI) contain respectively 3 and 4 excess electrons, which follows from both the $2n + 2$ and the 10*e* rules.

The $2n + 4$ rule holds for *nido*-structures. The tetraanions $B_nH_n^{4-}$, for example, (XXX), should be stable pyramidal boron hydrides. Finally, for the *arachno*-structure B_nH_n, the number of electrons which can be accommodated in the bonding MO is $2n + 6$, i.e. the hexa-anions $B_nH_n^{6-}$ are stable. For the *arachno*-structures of the hydrocarbons $(CH)_n$, generated by the truncation of the two vertices of bipyramids, i.e. for planar rings, this implies the stability of $(CH)_4^{2-}$, $(CH)_5^-$, $(CH)_6$, and $(CH)_7^+$, which is one of the consequences of the $4n + 2$ Hückel rule.

It is easy to show that the 8*e* and 10*e* rules obtained by reconstruction analysis are equivalent to the $2n + 4$ and $2n + 2$ rules for the skeletal electron count. Indeed in the pyramidal *nido*-structure of type (XXII), which has n vertices, $2(n-1)$ electrons of the $2n + 4$ skeletal electrons form the endocyclic σ-bonds in the basal ring and 2 electrons are used in the exocyclic bond (in the electron pair) of the apical group. The number of electrons binding the above fragments is thus $(2n + 4) - 2(n-1) + 2 = 8$ (the 8*e* rule). For the bipyramidal (*closo*) structure, we obtain analogously $(2n + 2) - 2(n - 2) + 2 + 2 = 10$ (the 10*e* rule).



Pyramidal structures (8*e* rule)



The rules for the counting of skeletal electrons can be readily extended to organometallic compounds, which can be done using the relations in the Table presented above. Other general formulations taking into account not only skeletal but also all valence electrons of skeletal and cluster structures, which are applicable to a wide range of metallic and organometallic structures with between 5 and 15 vertices[159,160] and also to skeletal and cluster electron-excess structures of the chalcogenides[161], have also been proposed.

Bridging groups, for example hydrogen atoms, can play the role of suppliers of skeletal and inner electrons. Thus the neutral *closo*-boranes B_nH_{n+2} correspond to the *closo*-dianions $B_nH_n^{2-}$, while the *nido*-borane B_nH_{n+4} [for example, B_5H_9 (XVI)] corresponds to the *nido*-tetra-anion $B_nH_n^{4-}$. In cluster (III) the carbon atom incorporated in the pyramidal skeleton contributes four additional electrons, with the aid of which the 8*e* requirement is met. We shall present further examples of the pyramidal [compound (LXXXII)][162] and bipyramidal [compound (LXXXIII)][163] clusters in which the bridging and endocyclic hydrogen atoms build up the inner electron shells to 8*e* and 10*e*:

(LXXXII)

(LXXXIII) $[H \cdot Ru_6(CO)_{18}]^-$

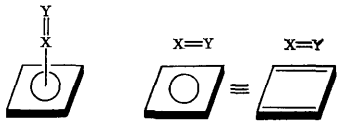
Using the technique of reconstruction analysis, it is possible to show that the bridging groups do not in fact alter the fundamental bonding pattern in polyhedral structures (Figs. 5 and 11). Analysis of the structures of the MO of a series of organometallic compounds with bridging hydrogen atoms has been described[164-166].

The importance of the electron count rules examined above is that they bring into direct correspondence the number of bonding MO and the type of polyhedral structure regardless of the nature of its constituent apical groups. These rules are topological in nature and clearly demonstrate the fact that inorganic and organic chemistry have common structural principles. This is confirmed also by the possibility of extending the relation

$$closo \underset{-2e}{\overset{+2e}{\rightleftharpoons}} nido \underset{-2e}{\overset{+2e}{\rightleftharpoons}} arachno \qquad (8)$$

which is familiar for boranes and carbaboranes, to polyhedral organic structures in the form

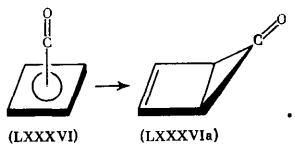
$$(n-2)\text{-gonal bipyramid } (10e) \underset{-2e}{\overset{+2e}{\rightleftharpoons}} (n-1)\text{-gonal pyramid}$$
$$(8e) \underset{-2e}{\overset{+2e}{\rightleftharpoons}} n\text{-gonal ring } (6e) \qquad (9)$$



The reaction whereby the dication (XIIb) is obtained from Dewar hexamethylbenzene[46] as well as the reaction (XXIX) $\rightleftharpoons$ (XXV, Y = S^{2+}) are examples where Eqn. (9) holds.

VII. [*n*]PRISMANES AND OTHER POLYHEDRA

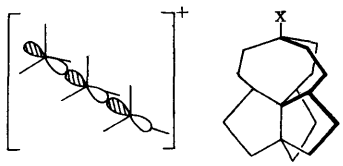
Apart from the combinations of structural units of polyhedra described above, there is also a possibility of edge–edge, edge–face, and face–face fusion.



The interactions of π-bonds and conjugated chains, which correspond to the type of edge–edge interaction, have been analysed[38,39]. Two topologically different perpendicular [structure (LXXXIV)] and parallel [structure (LXXXV)] orientations of the face and edge, ensuring the interaction of the entire system of ring orbitals with the orbitals of the π-bond, are illustrated below in relation to a four-membered

ring:

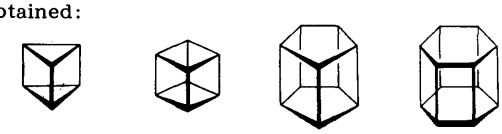
(LXXXIV) (LXXXV) (LXXXVa)



The valence orbitals of the groups X = Y (C≡O, N≡CH, N=O, S=O, O=O)[34,37] are similar in form to the CH group orbitals (Fig. 2), the antibonding π_x^*- and π_y^*-orbitals of the group XY corresponding to the pair of p_x- and p_y-orbitals. Since the *e*-level of these orbitals lies high above the *e*-level of the π-orbitals of the ring, this main type of interaction stabilising the pyramidal structures (LXXXIV) is weakened. Therefore, even in the most favourable case with XY=CO,[167] the above orbital interactions are sufficiently strong for the overall stabilisation of the (LXXXIV) system. Thus non-empirical (STO-3G)[168] and MINDO[169] calculations have shown that a local minimum in the PES of C_4H_4CO does not correspond to the C_{4v} structure (LXXXVI)[44] and the latter relaxes to the structure of bicyclo[2,1,0]pentenone (LXXXVIa):

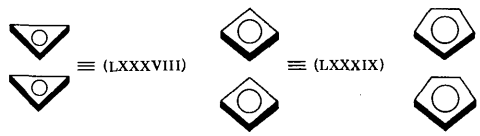
(LXXXVI) (LXXXVIa)

The hypothesis[65,171,172] of the intermediate structure (LXXXIV, XY=SO) in the topomerisation reaction of Dewar thiophen oxide, analogous to the rearrangement (XXIa) ⇌ (XXIb), has not been confirmed by calculations[170].



A more favourable orientation of the orbitals of the [*n*]-annulene ring and of the π-bond is attained in the configuration (LXXXV) predicted by calculations[168] for complexes of cyclobutadiene with C≡O, HC≡N, and CO_2. Discussion of the structures of these complexes has attracted considerable attention in connection with their intermediate formation in the photolysis and thermolysis of the precursors of cyclobutadiene derivatives[173–175]. The main type of orbital interactions in this configuration, namely $\pi_\sigma-\pi_\sigma$ interactions, has been considered recently with the aid of six different semi-empirical and non-empirical computational methods[176] in relation to the simple but structurally important model of the non-classical σ-allyl cation $(CH_3)_3^+$ (LXXXVII), in which the three methyl groups are bound together by the $p_\sigma-p_\sigma$ interactions of three *p*-orbitals:

(LXXXVII) (LXXXVIIa)



Since this type of interaction results in the formation of bonding, non-bonding, and antibonding MO, this configuration is stabilised in the two-electron case (cation). This suggests that fairly stable cations—analogues of the σ-allyl cation (LXXXVII)—can be generated from a suitable precursor, for example, propellane (LXXXVIIa).

The considerable role of the $\pi_\sigma-\pi_\sigma$ interactions between the orbitals of [*n*]annulene rings in the stabilisation of the polyhedral structure can be traced[177] in relation to [*n*]prismanes. The $(CH)_{2n}$ clusters with D_{nh} symmetry belong to this series. The first member of the series, namely [3]prismane (LXXXVIII) (triprismane according to Schultz's nomenclature[180] for compounds of this type) and tetraprismane (LXXXIX), also known as cubane, have been synthesised and studied in detail theoretically[14,37,100,178,179]. The higher representatives of the series of [*n*]prismanes, namely pentaprismane (XC), hexaprismane (XCI), etc., have not so far been obtained:

(LXXXVIII) (LXXXIX) (XC) (XCI)

The structures and the MO of prismanes can be formed by the parallel superposition of two identical [*n*]annulene rings (face–face interactions):

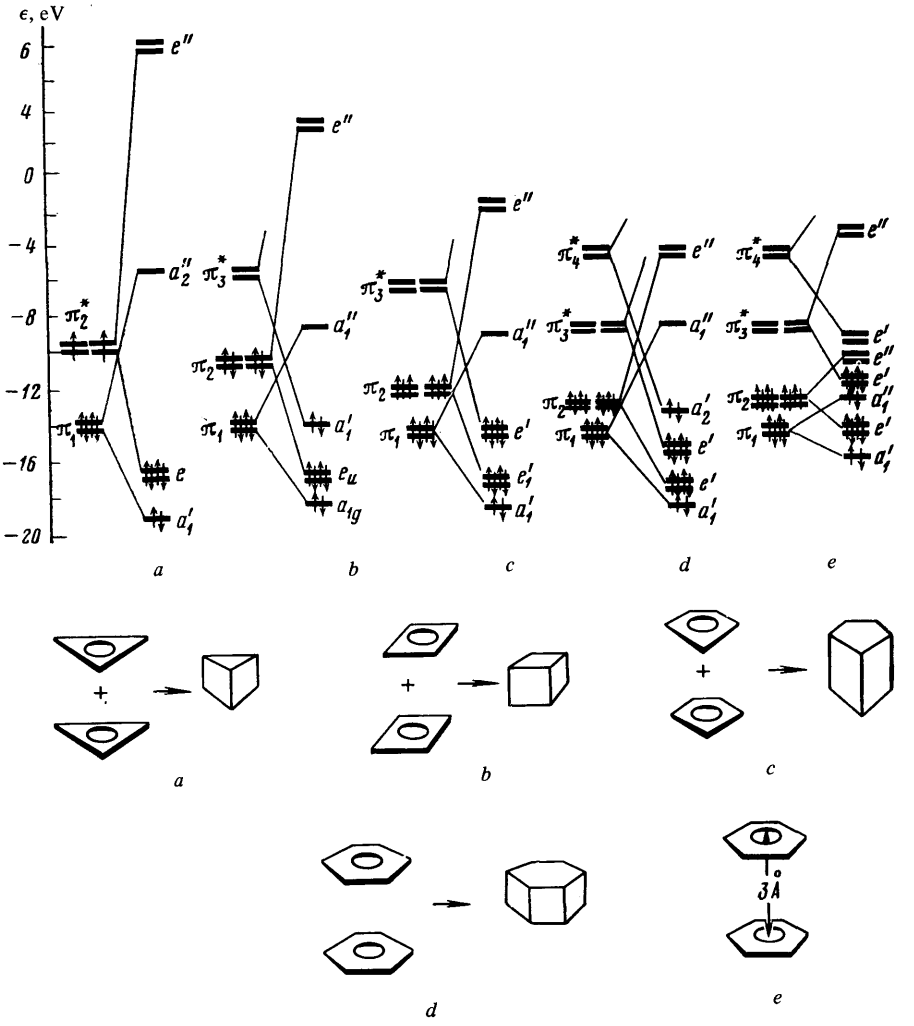
≡ (LXXXVIII) ≡ (LXXXIX) ≡ (XC)

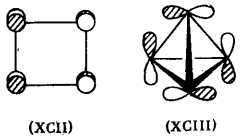
Two main types of interactions of the fragment orbitals can then be distinguished: π-overlap of a σ-MO of the Walsh type ($\sigma_\pi-\sigma_\pi$ interaction) and the σ-overlap of the π-MO ($\pi_\sigma-\pi_\sigma$ interaction). The above orbitals are illustrated in Fig. 4 in relation to [3]annulene. The interaction between the completely filled σ-MO are of the repulsive, destabilising type. However, the magnitude of this effect is comparatively small, since it is approximately proportional to the square of the overlap integral [see Eqns. (4) and (5)]. The $p_\pi-p_\pi$ overlap integral does not exceed 0.15 for equilibrium distances, while the $p_\sigma-p_\sigma$ overlap integral reaches 0.35. Because of this, the interaction (splitting) of the π-MO is significantly stronger. The main cause of stabilisation by such interaction is that the in-phase overlap of the identical antibonding π-MO of [*n*]annulenes leads to such a pronounced splitting of their levels that the lowest level becomes the bonding MO of [*n*]prismane (Fig. 13).

This result is obtained only under the conditions of a close parallel approach of the [*n*]annulene rings. For distances of the order of magnitude of the van der Waals contacts, the $p_\sigma-p_\sigma$ overlap integral is small and the splitting of the π-levels is insufficient to overcome the repulsive interactions (Fig. 13). This has been confirmed by direct calculations of the interaction energy of two benzene molecules[168,181] and also by structural data for benzene dimers obtained by the method of molecular beams[182], which show that the perpendicular orientation of the planes of the rings in the dimer is preferable.

The unfavourable nature of the [*n*]prismane structures for clusters of other elements can be understood from the correlation MO diagram in Fig. 13. The D_{2d} structure of the *closo*-dianion $(BH)_8^{2-}$ is more favourable by almost 400 kcal mol^{-1} than the cubic structure of the O_h type (LXXXIX)[183], since $(BH)_8^{2-}$ has only two electrons to fill all the bonding MO of the O_h structure (Fig. 13). On the other hand, the polychalcogenides S_8, S_8^{2+}, S_4N_4, and Se_{10}^{2+} [161] would have several antibonding MO populated by electrons in the [*n*]-prismane form. At the same time cluster (VI), which is isoelectronic with cubane (LXXXIX), has a structure similar to the latter.

The conditions for the stabilisation of the structure as a consequence of the formation of bonding MO, obtained by the in-phase combination of the antibonding MO of the fragments, which has been considered in relation to [*n*]prismanes, is fairly general for skeletal organic compounds. It is readily





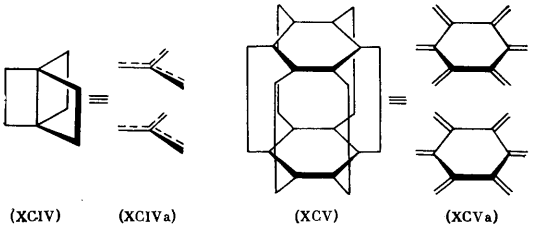


Figure 13. Schematic illustration of the formation of the MO of [*n*]prismanes as a result of the $\pi_\sigma-\pi_\sigma$ overlap of the π-MO of the [*n*]annulene fragments[177]. The energy levels of the annulenes and the overlap integrals of the π-MO for the equilibrium distances in [*n*]prismane have been obtained by calculations using the extended Hückel method (the $p_\sigma-p_\sigma$ overlap integral was assumed to be 0.3). The splitting of the levels following the approach of two benzene molecules to a distance exceeding the equilibrium distance in [6]prismane and equal to the sum of the van der Waals radii of the carbon atoms (the $p_\sigma-p_\sigma$ overlap integral is 0.1), for which the dimer is unstable, is shown on the right-hand side of the Figure. The correlation diagrams (*a*)–(*e*) correspond to structures (*a*)–(*e*).

seen that components of the highest occupied MO of cyclobutadiene (XCII) and tetrahedrane (XCIII) are made up of antibonding π*-MO of acetylenic fragments (cf. Fig.3):

(XCII) (XCIII)

The structures of the highest occupied MO of [2.2.2]propellane (XCIV)[44] and of the molecule of superphane (XCV) synthesised recently[184] also correspond to the case considered.

(XCIV) (XCIVa) (XCV) (XCVa)

On the other hand, the analogous parallel superposition of [5]- and [3]-annulenes does not lead, following their mutual approach in different relative orientations, to the appearance

of local minima of the biradical type on the PES of $(CH)_8$.[177] Analysis of the orbital interactions of the three-membered rings of $Fe_3(CO)_9$ and [5]annulene also leads to the conclusion that there is no stabilising effect. The structural consequences of the orbital interactions of the polyene chains and rings with the edges, faces, and individual vertices occupied by isolobal CH^{n+} groups and organometallic fragments have been examined in a number of studies[22,23,146].

---o0o---

The approach to the study of the nature of the stabilisation of molecules and ions with a strained or non-classical structure which has been considered here is applicable to the entire branched series of skeletal and polyhedral structures. The possibility of formulating electron count rules for inner, skeletal, or all valence electrons, which are valid for specific structural types regardless of whether the structure belongs to the series of organic, organometallic, or inorganic compounds, emphasises both the fact that the principles of electronic structure are common to these compounds and the decisive role of topological factors in their orbital organisation.

Like any broad generalisation, these rules have many exceptions. In the present review we did not concentrate attention on these, since the causes of the deviations from the predictions based on the electron count rules can be understood and foreseen on the basis of the same research techniques which have led to the formulation of the rules and also on the basis of more rigorous schemes for the fragmentation of structures.

The deviations from the rules formulated above are most frequently seen in the effect of substituents. Such are the sharp deviations from the classical structures of hydrocarbons where hydrogen atoms are replaced by lithium atoms or BH groups[98,185-187] and conversely the stabilisation of classical structures following the replacement of hydrogen atoms in carbaboranes by halogen atoms[188]. Direct allowance for the orbitals of the substituents within the framework of the scheme of reconstruction analysis explains the above effects.

The orbital approach to the analysis of complex structures has been recently extended as far as the field of the crystal chemistry of organic and inorganic compounds[189]. It has been shown that $\pi_\sigma - \pi_\sigma$ interactions of the orbitals of the A_6 and A_3X_3 hexagonal cells actually determine the structures of the crystal lattices of graphite, sphalerite, wurtzite, etc.

This approach has become a powerful instrument for the molecular design of new unusual organic structures and their organometallic analogues.

Molecules with a High Electron Affinity

L.N.Sidorov

Experimental values of the electron affinity of inorganic compounds reported between 1975 and 1980 are systematically examined. The following methods of measuring electron affinity are briefly reviewed: photo-extraction and photoelectron spectroscopy, electron impact, ion-molecule reactions, ionisation by alkali metal atoms, ion-molecule equilibria, and methods based on measuring the frequency for intramolecular charge transfer in the absorption spectra of complexes and on calculations using a thermochemical cycle. Classes of compounds having an electron affinity greater than that of halogen atoms are identified by analysing published data. 166 references.

I. INTRODUCTION

In the early 1970's very few substances with an electron affinity higher than that of the halogen atoms were known, and it was generally assumed that positive values of the electron affinity must lie in the range 0–4 eV. However, experimental methods of measuring electron affinity were being actively developed[1,2], and the first reports of compounds with very much higher electron affinities were beginning to appear[3]. These compounds are the strongest known oxidising agents, they readily form stable negative ions, and they lower the concentration of electrons in flames and plasmas.

In this paper we shall review experimental methods of measuring electron affinities, their validity when applied to substances with a high electron affinity, and the results obtained in the period 1975–1980. References to earlier work can be found in recent monographs[1,2]. Franklin and Harland's review[4] gives an account of experimental methods of studying negative ions and of the results obtained up to 1974, and it lists earlier reviews on negative ions (published since 1950). The most reliable information on the electron affinity of inorganic and of organic molecules published up to 1975 is summarised by Rosenstock and coworkers[5]. Between 1978 and 1980 four more reviews were published[6–9]; these contain more recent results and they partly overlap the present discussion.

Standard methods of determining electron affinities include the threshold methods, in which the affinities are calculated from the minimum energy of an impinging particle which will lead to the formation or breakdown of a negative ion. Among these methods are the photo-extraction and the electron impact method, and also methods based on the formation of negative ions by ion–molecule reactions or by collisions between neutral particles. Another large group of methods can be described as "equilibrium" methods, because the measurement consists in determining the temperature dependence (or the absolute value) of the equilibrium constant of a reaction involving the negative ion. This group includes the magnetron method and the surface ionisation method, and also the study of equilibria in gases, flames, and plasmas, and the classical effusion method, which was only very recently modified to deal with the special problems met in the determination of electron affinities.

Theoretical calculations of the electron affinity lie outside the scope of this review. The relevant methods are briefly outlined in Refs.1,2, and 7. Recent theoretical calculations of the electron affinity of hexafluorides are reported in Refs.10–12. Some of the more obscure methods which have been used to measure electron affinities are mentioned in Refs.1 and 2. In the latter part of this review we shall discuss two semiquantitative methods for estimating the electron affinity of complex molecules such as hexafluorides. The first is based on a calculation by the Born–Haber thermochemical cycle (see, for example, Ref.1), which includes the heats of reactions between charged particles and neutral particles. This method relies on theoretical calculations of the crystal lattice energy. The second method is based on a study of the absorption spectra of complex molecules, coupled with an experimental determination of the frequency of the transition corresponding to the intramolecular charge transfer process. Theoretically[13] this frequency is related to the ionisation potential of the electron donor and the electron affinity of the acceptor. The electron affinity of the acceptor molecule can therefore be estimated.

II. PHOTO-EXTRACTION AND NEGATIVE ION PHOTOELECTRON SPECTROSCOPY

For a more detailed discussion of the topics examined in this Section the reader is referred to recent monographs[1,2] and papers[14,15]. Both methods depend on a calculation of the energy balance in the photo-extraction of an electron from a negative ion:

$$AB^- + h\nu = AB + e \ .$$

Two distinct approaches have been used. In the first the frequency of the radiation is varied, and the threshold energy for the photo-extraction of the electron is found experimentally; in the second the radiation frequency is fixed and the kinetic energy spectrum of the emitted electrons is recorded. Since the kinetic energy spectrum characterises the energy levels of the negative ion, the term "negative ion photoelectron spectroscopy" has been proposed for

this variant. In the case of atomic anions the interpretation of the results is unambigous, and the experimental values of the frequency and energy of the emitted electrons can be used to calculate the electron affinity of the atom with high precision (Table 1): some workers[16] quote an uncertainty of ±0.0003 eV. For molecular anions the calculated value corresponds to a vertical transition, and in general this is not the same as the electron affinity of the molecule (defined as the energy difference between the ground states of the molecule and the ion). The difference between a vertical and an adiabatic transition can be large, especially in the case of molecules with a large electron affinity.

Table 1. Electron affinities determined by photo-extraction (PE) and photo-electron spectroscopy (PES) methods.

ZnH	0.95	PE	[20]

Experimental studies of the photo-extraction of electrons from negative ions are fairly complicated, and include a number of steps (not least, the generation of a strong beam of negative ions). The early work was carried out by the crossed beam method[1], in which the source of ions is a glow discharge and the ions emerge from a slit in the anode with an energy of ~ 300–500 eV and an energy spectrum 25–50 eV wide. The ion beam is accelerated, collimated, and after passing through the mass separator it enters the photon interaction region. The light source was either an argon ion laser working at 4880 and 5145 Å (2.5 and 2.4 eV) or a dye laser with a continuously swept frequency in the energy range 1.75–2.4 eV. The experiment consisted in recording the kinetic energy spectrum of the emitted electrons and measuring the threshold value of the photon energy (i.e. the minimum photon energy giving rise to photo-extraction).

Thus, Engelking and Lineberger[17] produced a strong beam of FeO^- and O^- ions in a low-pressure electric discharge, struck by burning iron pentacarbonyl in oxygen or nitrous oxide. The ions were accelerated to 680 eV and mass-separated in a Wien filter. The ion beam was crossed with a photon beam of 2.5 eV energy (4880 Å). The emitted electrons were energy-analysed, using an electrostatic monochromator with a resolution of 0.06 eV. The electron energy scale was calibrated by using the O^- ions present in the same discharge. As a result the electron affinity of the FeO molecule was found[17] to be $E(FeO) = 1.492 \pm 0.020$ eV.

In another type of apparatus ion–cyclotron resonance is used. This method does not require an accelerating voltage for mass separation, and the ions move from the source region to the analyser with near-thermal velocities. The time of residence of the ion in the apparatus is of the order of seconds: this is the most attractive feature of the "ion–cyclotron resonance + photo-extraction" method. The use of ion–molecule reactions to generate negative ions becomes possible. The primary negative ions are formed by collisions between neutral molecules and electrons (emitted by a thermionic cathode), and these ions take part in ion–molecule reactions during their subsequent slow drift within the source. The list of negative ions which can be studied has been greatly increased by the advent of this method. Janousek and coworkers[18] determined the electron affinity of the C_2H radical in an apparatus which included a V-5900 ion–cyclotron resonance spectrometer. The pressure in the drift region was 2×10^{-7} mmHg, the life time of the ions was ~ 0.5 s. The C_2H^- anions were obtained by the ion–molecule reaction $C_2H_2 + F^- \rightarrow C_2H^- + HF$. The source of F^- was the dissociative ionisation of nitrogen trifluoride by electron impact ($NF_3 + e \rightarrow NF_2 + F^-$). The electron affinity value obtained in these experiments was $E(C_2H) = 2.94 \pm 0.10$ eV.

A study of negative molecular ions relevant to the chemistry of the *D* layer in the ionosphere was carried out in the molecular physics laboratory of the Stanford Research Institute[19]. This work was aimed mainly at determining the photo-dissociation and photo-extraction cross-sections of ions such as $O_2^-.O_2$, $O_2^-.H_2O$, $O_3^-.H_2O$, CO_3^-, CO_4^-, HCO_3^-, $HCO_3^-.H_2O$, $NO.O_2^-$, $NO.O_2^-.H_2O$, and $NO_2^-.H_2O$. The measurements of cross-section could (in some cases) be interpreted in terms of the threshold values of the photo-extraction energy, and in these cases the electron affinity was calculated. The apparatus used in this work included a mass spectrometer with a drift tube. The negative ions were produced by collision with electrons emitted from a thorium–iridium cathode, and by the subsequent ion–molecule reactions in the drift tube. The ion source and the drift tube were filled with the gas (or gas mixture) at 0.05–1.0 mmHg pressure. The ions drifted (under the influence of a weak electric field) with an average velocity about an order of magnitude lower than the thermal velocity. During their drift time the ions undergo enough collisions with neutral particles to come to thermal equilibrium with the medium, and the excess energy acquired by the ions during their formation relaxes. This is one of the main advantages of the method, since it eliminates errors arising from the presence of ions in excited states and possessing an excitation energy much greater than the thermal energy. Approximately 2 mm beyond the exit slit of the drift tube the ions cross a modulated photon beam generated either by a dye laser with a continuous spectrum in the region of 4250–4600 Å or by an argon or krypton ion laser with a discrete set of lines at 4067–5309 Å. Beyond the exit slit the ions enter the high-vacuum region, which includes a quadrupole mass spectrometer. After mass separation the ions are recorded in a two-channel counter in the presence (I) and in the absence (I_0) of laser radiation. The percentage breakdown of the ions is small, and the I/I_0 ratio is close to unity. Therefore the signal needs to be integrated over a fairly long time: from minutes to hours, depending on the photo-extraction cross-section.

The method has been used also to determine the electron affinity of carbon trioxide[19]: the result was $E(CO_3) = 2.9 \pm 0.3$ eV. Electron affinity values obtained by the photo-extraction and photo-electron spectroscopy method and published between 1975 and 1980 are listed in Table 1.

III. ELECTRON IMPACT

Negative ions can be formed in several ways during electron impact. However, direct electron capture is not very effective because of the need to transfer the affinity energy to a third body, or to dissipate this energy among the internal degrees of freedom of the molecule. Processes leading to the formation of ion pairs have been successful, but only for atoms[1]. Therefore only the dissociative electron capture process has been widely used to measure electron affinities. The most recent review of dissociative electron attachment processes is given in Ref.38, and earlier work is discussed in Refs.4 and 39.

Table 2. Electron affinities determined by the electron impact method.

The dissociative electron capture process is described by the reaction $AB + e \rightarrow A + B^-$. The lower limit of the electron affinity of the molecule, $E(B)$, can be found from the threshold value of the electron energy, E_e, if the bond breaking energy $D(A-B)$ is known:

$$E(B) \geqslant D(A—B) - E_e + T ,$$

where T is the combined kinetic energy of the A and B residues. The inequality sign allows for the possible generation of the dissociation products in an excited state. Electron affinity values obtained in 1975—1980 by the electron impact method are listed in Table 2.

IV. ION—MOLECULE REACTIONS

When the collision between a negative ion and a neutral particle results in an endothermic reaction it is possible, in principle, to determine the enthalpy of formation of the negative ion and the electron affinity. In the simplest case, when the reaction consists simply in the exchange of an electron, the threshold value of the energy of the mutually repelling particles which leads to charge transfer gives the difference in electron affinity between the molecules taking part in the reaction. The electron affinities of halogen molecules[57] and oxygen compounds[58] have been obtained in this way:

Molecule	F_2	Cl_2	Br_2	I_2	O_2	O_3	NO	NO_2	NO_3
E, eV	3.08	2.38	2.51	2.58	0.48	1.96	0.09	2.04	$\geqslant 2.49$

The measurements consisted in determining the threshold energy of processes such as $F^- + F_2 \rightarrow F_2^- + F$, which corresponds to the difference in electron affinity between the atom and the molecule.

Charge transfer processes can be accompanied by chemical reactions leading to the formation of new ions and molecules. The threshold energy of the colliding particles gives the enthalpy of the reaction, and the possibility of calculating the electron affinity arises when the enthalpies of formation of all the other participants in the reaction are accurately known. A good illustration of this method is provided by an experimental determination[49] of the threshold energy (found to be 0.64 eV) for reactions of the type of

$$I^- + HNO_3 \rightarrow NO_3^- + HI .$$

This quantity is the enthalpy of the reaction, and since the enthalpies of formation of I^-, HNO_3, and HI are known, the enthalpy of formation of the NO_3^- ion can be calculated: $\Delta H_f^\circ(NO_3^-) = -3.04 \pm 0.09$ eV. In order to determine the electron affinity we must know $\Delta H_f^\circ(NO_3)$. Using the published value of this parameter the authors[49] obtained $E(NO_3) = 3.77 \pm 0.25$ eV.

Another example of the prospects of ion—molecule reactions is provided by a study[60] of the dissociation of negative ions by collisions with inert gas atoms. In this work a more complicated technique was used to produce the beam of negative ions. Whereas in the work described above[49] the range of negative ions was very limited, and only processes giving rise to a single type of negative ion could be used, in Ref.60 a mass separation of the negative ions was carried out as the first stage in the process. As a result, any method of ionisation could be used, including methods which yield a large number of different negative ions. After mass separation the ion beam passed through a 90° electrostatic analyser which selected the ions having a prescribed energy in the range 0.3—170 eV with an energy scatter of 0.2—0.3 eV. These ions have a known kinetic energy when they reach the collision chamber, where they undergo endothermic ion—molecule reactions to form new ions which are detected in a second mass spectrometer. The experiments consist in determining the minimum energy of the colliding ions for which reaction products are formed. The technique has been used[61] to study the dissociation of negative ions on the gases A (Xe, Kr, Ar, Ne, He, and N_2). The average value of the threshold energy for the reaction $N_2O^- + A \rightarrow N_2 + O^- + A$ was 0.43 eV, which can be combined with published data on the bond energy $D(N_2—O)$ and on $E(O)$ to give $E(N_2O) = 0.22$ eV.

Ion—cyclotron resonance apparatus is widely used in studies of ion—molecule reactions, usually for exothermic reactions which take place at thermal energies between the colliding particles. Hence the pair of particles on which the electron affinity is measured must be chosen so that the charge transfer reaction can proceed in one case but not in the other. This allows both the upper and the lower limit of the electron affinity of the given molecule to be determined. The electron affinity of tungsten hexafluoride has been determined in this way[62]. Charge transfer was shown to occur with fluorine but not with chlorine, and hence the value $E(WF_6) = 3.5 \pm 0.1$ eV was obtained.

In an earlier study[63] an attempt was made to measure the threshold energies of ion–molecule reactions directly. A beam of negative UF_6^- ions was produced by surface ionisation of uranium hexafluoride on a rhenium filament at 800–900 K, i.e. at a temperature giving a negligibly small electron emission current. The energy of the UF_6^- anions was varied between 0 and 40 eV, and the threshold values of the energy for the following reactions were identified[63]:

$$UF_6^- + UF_6 \rightarrow UF_7^- + UF_5$$
$$UF_6^- + BF_3 \rightarrow UF_5 + BF_4^- ,$$

leading to the affinities of uranium hexafluoride for electrons and for the fluoride ion shown in Table 3.

Another possible way of determining thermochemical quantities by using ion–cyclotron resonance apparatus involves measuring the equilibrium constants of ion–molecule reactions. Thus, in an experimental study[64] of the reaction

$$HCO_3^- + HNCO \rightleftarrows OCN^- + HCO_2H$$

the rate constants of the forward (k_f) and of the reverse (k_r) reaction were determined, and the equilibrium constant $K = k_f/k_r$ was calculated. The equilibrium constants obtained in this way agreed exactly with the values directly determined by measuring the concentration ratios of the ions and molecules under conditions giving long residence times of the ions in the reaction zone. By combining the result with published data on the enthalpy of formation of the reactants and products the authors[64] obtained $E(OCN) = 3.62 \pm 0.2$ eV for the electron affinity of the OCN radical.

A new method of calculating electron affinities from studies of electron extraction by glancing-angle impact has been proposed[65]. Negative ions (B^-) having a high kinetic energy (~ 6000 eV) can be converted into B^+ ions by glancing-angle collisions with neutral molecules:

$$B^- + N \rightarrow B^+ + N + 2e \cdot$$

If both B^- and B^+ are in their electronic ground state the difference in their kinetic energies is equal to the sum of the ionisation potential $I(B)$ and the electron affinity $E(B)$ of the B molecule. If $I(B)$ is known, we can calculate the electron affinity by measuring the difference between the kinetic energies of the B^- and the B^+ ion. For example, $E(CN) = 3.3$ and $E(S_2) = 2.15 \pm 0.5$ eV have been determined in this way[65], in good agreement with published data. Electron affinities obtained in 1975–1980 from studies of ion–molecule reactions are given in Table 3.

V. IONISATION BY COLLISION OF NEUTRAL PARTICLES

Collisions between neutral particles can lead to the formation of ion pairs, thus allowing electron affinities to be determined from the threshold value of the energy of the colliding particles. Under these conditions the threshold energy directly gives the difference between the ionisation potential and the electron affinity of the particles. The formation of ion pairs by collisions between neutral particles is discussed in Ref.78.

Table 4. Electron affinities determined by ionisation with alkali metal atoms.

* Estimated value.

In the collision of neutral particles the main problem is how to control the energy of the collision. In ion–molecule reactions this problem disappears, since the energy of charged particles is readily controlled by an electrostatic field, but in reactions between neutral particles a special solution of this problem must be found. Two different approaches have been used so far to prepare beams of neutral particles having energies of a few electron volts. The first relies on the application of supersonic flow technologies. The technique has been used[79,80] to study the formation of the ion pairs Cs^+ and Cl^-, Cs_2Cl^+ and Cl^-, and Cs^+ and $CsCl_2^-$ by collisions between the molecules CsCl or Cs_2Cl_2 and the atoms Ar, Kr, Xe (or the molecule SF_6) at energies which could be varied from thermal energy to 18 eV. These very high energies (for neutral particles) were obtained by gas-dynamic methods. No numerical values of the electron affinity of molecules have been obtained by this method so far: one possible reason is the formation of ion pairs at energies well in excess of the threshold energy of the reaction.

The second approach uses ionisation by collisions with alkali metal atoms. "Fast" alkali metal atoms can be obtained by transferring charge from M^+ ions which have been accelerated in an electric field to neutral M atoms. This method can yield atomic beams of alkali metals having a high and controlled (to ~ 0.1 eV) energy. Ionisation by alkali metals is widely used to measure the electron affinity of organic[81] as well as inorganic molecules. The method has been intensively developed by several groups of workers, and in recent years it has yielded important information on electron affinities (Table 4).

VI. EQUILIBRIUM METHODS

The electron affinity can be calculated by measuring the equilibrium constant of the reaction $A^- \rightarrow A + e$ at a known temperature T:

$$K_p = p_A p_e / p_{A^-} ,$$

where p_A, p_e, and p_{A^-} are the partial pressures of A molecules, of electrons, and of A^- ions in the system in thermodynamic equilibrium. The electron affinity, numerically equal to the heat ΔH_0° of the reaction at $T = 0$ K, is calculated by the equation

$$E(A) = \Delta H_0^\circ = RT \ln K_p + \Delta\Phi^\circ ,$$

where $\phi^\circ = S_T^\circ - (H_T^\circ - H_0^\circ)/T$ is the reduced Gibbs energy.

For gaseous molecules and ions the quantity ϕ° can be calculated by statistical thermodynamic methods from molecular constants. Unfortunately, very few data are available on the electronic states, structures, and vibration frequencies of negative ions, and practically none on polyatomic ions. Hence the calculations must be based on estimated molecular parameters, which lowers the precision of the results, but to an acceptable extent, since the entropy of the reaction is relatively insensitive to the uncertainty of the molecular parameters of the reactants and products.

In most cases the error in the estimated entropy of the gas-phase reaction is between 1 and 4 e.u., leading to an error of ~ 0.05–0.20 eV in the estimated electron affinity. The main difficulty in the use of this method lies in establishing an experimental procedure which gives reliable values of the equilibrium constant. Different methods have to be combined in order to obtain simultaneous measurements of the partial pressure of molecules, ions, and electrons. The neutral and the charged particles must be sampled from the same place, where local equilibrium is known to exist. The difficulty of simultaneously measuring the relative pressures of negative ions and electrons was solved by an apparatus which has been called the magnetron[101].

A method which avoids the need to measure the concentration of electrons can be based on surface ionisation, in which two ion currents are measured as a function of the surface temperature of the ion source. The result of this experiment is the difference in electron affinity between two atoms or molecules. If one of the electron affinities is known, the other is easily calculated. The surface ionisation method is widely known, and fully described in Ref.102. The latest developments in surface ionisation techniques in relation to the determination of electron affinities are discussed in Ref.103. The sample is evaporated from the surface of the ion source by means of a beam of positive ions rather than by a molecular beam (as in the conventional form of the method). This improvement offers very good control of the purity of the surface and of the thickness of the evaporated layer. The positive ions are neutralised, and the resulting molecules can undergo electron capture[103].

The most serious shortcomings of the magnetron method and of the surface ionisation method are due to the presence of temperature and concentration gradients between the bulk of the gas phase and the surface of the hot filament, and also to the large variations in the local value of the work function[104], which can lead to incorrect values of the electron affinity[1].

A more direct approach to the measurement of electron affinity relies on measuring the concentrations or pressures of ions, electrons, and molecules in a gas[64,105,106], vapour[107,108], flame[109], or plasma[110,111]. The experimental procedures developed for exploiting the drift of ions in a carrier gas have been used in studies of ion-molecule reactions and of the rate constant of electron removal by a bimolecular reaction such as $O_2^- + O_2 \rightarrow e + 2O_2$[105] or $NO^- + NO \rightarrow e + 2NO$.[106] At the same time the rate constants of the electron capture reactions in three-body collisions (i.e. in the reverse reaction) were also measured. Knowing the rate constants for the forward and the reverse reaction, the equilibrium constant and the electron affinity were calculated for the O_2[105] and the NO molecule[106]. Another example of the determination of equilibrium constants was mentioned in Section III above: the measurement of the rate constants of the forward and the reverse reaction by using ion–cyclotron resonance. The electron affinity of the OCN radical was calculated[64] from the equilibrium constant measured in this way.

A series of papers[112–116] describes ion–molecule equilibrium studies in flames consisting of hydrogen, nitrogen, and oxygen. The aim of the work was to study electron capture processes by additives assumed to have a very high electron affinity. Tungsten was introduced into the flame as $W(CO)_6$ or WF_6, chromium as $Cr(NO_3)_3$ or $Cr(CO)_6$, and rhenium as an aqueous solution of a rhenium salt or as ReF_6. Atomic potassium or caesium were also added as electron donors. The experiment consisted in measuring the equilibrium constants of the reactions involving molecules, ions, and electrons:

$$e + H_2WO_4 \rightarrow HWO_4^- + H$$

$$HWO_4^- + H \rightarrow WO_3^- + H_2O$$

$$WO_3 + e \rightarrow WO_3^- .$$

The concentrations of negative ions and of electrons were determined with a mass spectrometer and microwave resonator; the concentrations of neutral molecules or atoms were

calculated from standard thermodynamic formulae by using the heat of formation and the total concentration of the additive (i.e. the weights of chromium, molybdenum, tungsten, or rhenium introduced). From the equilibrium constants obtained in this way the heats of the reactions and the heats of formation of the negative ions were calculated. The electron affinities were determined as the difference between the heats of formation of the negative ion and those of the corresponding neutral molecule. The results are given in Table 5.

Some recent attempts to study electron affinities by measuring the electrical conductivity of plasmas have been reported[110-111]. The method depends on the large decrease in the electrical conductivity of the plasma caused by the formation of molecules and radicals with a high electron affinity. Model calculations suggest that the decrease can be as high as 10–40%, depending on the type and concentration of the additive: for example, oxides of iron, aluminium, and phosphorus lead to the formation of the ions FeO_2^-, PO_2^-, PO_3^-, and AlO_2^-.[110] The electrical conductivity of the plasma has been measured[111] as a function of the type and concentration of the additives. We see from the results (Table 5) that some hexafluorides have extremely high electron affinities (~ 5 eV).

The effusion method was first used in 1971–1974 to measure electron affinities[107,108,117] by studying the equilibrium between negative ions and neutral molecules in a Knudsen cell. The cell had to be heated to ~ 2000 K in order to give measurable concentrations of negative ions. The experimental substances were placed (at lower temperatures) in separate temperature-controlled compartments. By heating these compartments the experimental substances were transferred through connecting channels to the mixing chamber, where they underwent partial dissociation into neutral particles and charged particles. The neutral particles were monitored by conventional high-temperature mass spectroscopic methods. The negative ions present in the vapour of the experimental substances were also monitored mass spectroscopically after being "extracted" from the effusion cell by an electrostatic field.

* Calculated from published data[122].

The equilibrium constants of several ion–molecule reactions involving negative ions were successfully measured, and the electron affinity (eV) of the following molecules and radicals was determined: AlF_2 (2.30), BF_2 (2.20)[117]; BO (3.12), BO_2 (3.47)[107]; AlO (3.68), AlO_2 (4.11).[108] It was subsequently discovered that the use of very high temperatures (2000–2500 K) to obtain measurable concentrations of negative ions is not essential.

Negative ions were detected in the saturated vapour of a large number of inorganic salts and their binary systems at temperatures as low as 700–1200 K.[118-122] This observation led to the rapid development of studies of ion–molecule equilibria and to the determination of affinities for the electron and for the F^- anion. Many workers[110-123] have reported experimental tests of the existence of ion–molecule equilibrium under the conditions of a real effusion experiment and have developed methods of measuring the activity of neutral components from measurements of the partial pressures of negative ions. The fullest description of these techniques is given in Ref. 124 and 125, where the effect of the extracting field on the effusion process and on the electronic work function of the inner surface of the effusion cell is also discussed.

In the last two or three years the effusion method has been used to measure the affinity for the electron and for the F^- anion of a large number of inorganic fluorides (Tables 5 and 6). The most important of these results was the first experimental determination of the electron affinity of platinum hexafluoride: the highest electron affinity ever reported[126].

VII. CALCULATION OF ELECTRON AFFINITY FROM THERMOCHEMICAL DATA AND FROM THE ABSORPTION SPECTRA OF COMPLEXES

The difficulty of the direct experimental determination of electron affinity has led to the development of several methods by which the electron affinity can be estimated from measurements of related quantities. Typical of this approach is the calculation by a Born–Haber thermochemical cycle in which reactions involving both the charged and the neutral particles are included.

In order to calculate the electron affinity by this cycle we need to measure the heat of formation $\Delta H^\circ_{0f}(AB)$ of the crystalline compound AB from the gaseous components A and B, and to calculate theoretically the crystal lattice energy U of the compound. The energy U is equal to the heat of reaction (1) ($U = -\Delta H^\circ_0(1)$):

$$A^+(g) + B^-(g) \rightarrow Ab(cr) . \quad (1)$$

The heat of formation of the crystalline compound AB from gaseous A and B is equal to the heat of reaction (2), $\Delta H^\circ_0(2)$:

$$A(g) + B(g) \rightarrow AB(cr) . \quad (2)$$

The electron removal and addition reactions are written

$$A \rightarrow A^+ + e \quad (\Delta H^0_0(3) = I(A)) , \quad (3)$$

$$B + e \rightarrow B^- \quad (\Delta H^0_0(4) = -E(B)) , \quad (4)$$

where $I(A)$ is the ionisation energy (potential) of A and $E(B)$ is the electron affinity of B. The ionisation energy is usually known, and the electron affinity is calculated as the algebraic sum of the heats of reactions(1), (2), and (3):

$$\Delta H^0_0(4) = \Delta H^0_0(2) - \Delta H^0_0(1) - \Delta H^0_0(3) \quad (5)$$

or

$$E(B) = I(A) - U - \Delta H^0_0(2) .$$

Measurements of the heats of formation of molybdenum and tungsten pentafluorides and of the complexes MWF_6 and $MMoF_6$ (where M = Li–Cs) have been reported[134-136]. The crystal lattice parameters were determined, and used to calculate the energy of formation of crystalline MWF_6 and $MMoF_6$ from the M^+ and MoF_6^- (or WF_6^-) ions. By combining

the results with the known heats of formation of the pentafluorides, the electron affinities of the hexafluorides and the affinities for the F^- anion of the pentafluorides were calculated. In a more recent paper[136] an improved calculation of the crystal lattice energy is presented and a slightly different value of the electron affinity is obtained (see Table 7).

* Calculated from the absorption spectra of the complexes by using the most recent value[62] of the electron affinity of WF_6; $E(WF_6) = 3.5$ eV. The other entries are thermochemical calculations.

The first attempt to calculate the electron affinities of the transition metal (W, Mo, U, Re, Ir) hexafluorides from the absorption spectra of their complexes was reported[137] in 1978. New frequencies were observed in the visible and near u.v. regions of the absorption spectra of the crystals formed by the hexafluorides with xenon at liquid-nitrogen temperatures. They were assigned to intermolecular charge transfer between xenon and the hexafluoride:

$$Xe + MF_6 \xrightarrow{h\nu} Xe + MF_6^- .$$

The theory of charge transfer in complexes[13] leads to the expression

$$h\nu = I(Xe) - E(MF_6) + G ,$$

where $I(Xe)$ is the ionisation potential of the donor (Xe), $E(MF_6)$ is the electron affinity of the acceptor (MF_6), and G is a constant determined empirically by using a standard ($XeWF_6$ crystals). The energy $h\nu$ was determined experimentally, and the constant G was calculated by combining this value with published data on the ionisation potential of xenon and on the electron affinity of tungsten hexafluoride. From the G value, and the measured charge transfer frequencies of the xenon complexes, the electron affinities of five hexafluorides were calculated (Table 7). We note that the most recent value[62] of $E(WF_6)$ is 3.5 ± 0.1 eV, whereas the value 4.5 eV was used in Ref.137. Therefore all the results quoted in that paper should be lowered by ~ 1 eV.

VIII. COMPOUNDS HAVING AN ELECTRON AFFINITY GREATER THAN 3.0 eV

Each of our Tables (1–7) includes electron affinity values measured by one particular method. By comparing these results we can assess the relative merits of different approaches to the problems presented by the study of molecules with a high electron affinity.

Photo-extraction occupies a leading place among existing experimental methods of measuring electron affinity, and no other method can compete with the precision of its results. Measurements by negative ion photo-electron spectroscopy are usually claimed to have a precision of 0.01–0.02 eV, and in some cases (for example, for the carbon atom) the precision is as high as 0.0003 eV.[16] In photo-extraction experiments where the percentage breakdown of the anions is fixed a precision of 0.02–0.10 eV is usually quoted. The results are more difficult to interpret, since allowance is needed for the difference in energy between adiabatic and vertical transitions. Negative ion photo-electron spectroscopy gives a direct measurement of the lowest photon energy capable of generating a free electron. This energy corresponds to a vertical transition and is higher than the energy of the adiabatic transition which is equal (by definition) to the electron affinity. The numerical importance of these differences can be assessed only by comparing the results with those obtained by independent methods.

The photo-electron spectroscopy method can also be used to determine the enthalpies of formation of gaseous compounds having a high electron affinity. These compounds readily form stable negative ions in the gas phase, and it is experimentally easier to determine the enthalpy of formation of the negative ion than that of the corresponding neutral molecule or radical. Many examples can be quoted, and in some cases (e.g. AlF_4^- and HfF_4^- (Table 6), WF_7^- (Ref.62), and UF_7^- (Ref.63)) the enthalpy of formation of the negative ion is reliably determined while the existence of the corresponding neutral radical remains doubtful. Evidently, the enthalpy of formation of these radicals could be determined from measurements of the enthalpy of formation of the negative ions and the energy of extraction of an electron.

Consider the CO_3 molecule and the CO_3^- ion. The bond energy $D(O_2C-O^-)$ for the ion is accurately known, the most recent value[29] being 2.258 ± 0.007 eV. The electron affinity of the oxygen atom is known[5] to an even higher accuracy: $E(O) = 1.462 \pm 0.003$ eV. For the neutral CO_3 molecule the bond energy data are less reliable: $D(O_2C-O) = 0.46 \pm 0.17$ eV.[140] Since $E(CO_3) = D(CO_2-O^-) + E(O) - D(O_2C-O)$, we obtain $E(CO_3) = 3.26 \pm 0.17$ eV. Direct determination of the electron affinity by the negative ion photo-electron spectroscopy method should give a value of $E(CO_3)$ accurate to a few hundredths of an electron volt, and therefore a back-calculation should give a better value of the bond energy $D(O_2C-O)$ for the molecule. Unfortunately, the first attempt was unsuccessful[35], possibly because the intensity of the CO_3^- beam was insufficient, and the photo energy was adequate only for electron affinities lower than 3.1 eV.

There is little doubt that increasing the photo energy should provide the desired result and give more accurate values not only of the electron affinity but also of the heat of formation of the CO_3 molecule. Unfortunately, up to the present all the results obtained by the photo-extraction method lie between 0 and 3 eV (see Table 1). There are no fundamental obstacles to an extension of the measurements to higher energies, though of course some practical difficulties can be expected. The further development of the photo-extraction method and its application to the study of molecules with a high electron affinity should increase very substantially our understanding of the thermochemistry of negative ions and that of their related molecules and radicals.

The electron impact method occupies the second place in relation to the number of results obtained (see Table 2). Nearly all the results were derived from the appearance potentials of negative ions during dissociative electron capture

processes involving the molecules of interest. Inspection of Table 2 shows that in most cases uncertainty limits are not quoted, and occasionally only an upper limit is given. Some results obtained by the electron impact method have been criticised by Mathur and coworkers[90]. The dissociative electron capture method is applicable to the determination of electron affinity in compounds of higher valency only if the molecules undergoing ionisation are even more complex, e.g. $KMoF_6$ or KWF_6. In this case the electron affinity of MF_6 can be determined if MF_6^- ions are formed by dissociative electron capture. Unfortunately, no such results have yet been reported, and an attempt to prepare the AlF_4^- ion by dissociative electron capture from the $NaAlF_4$ molecule was unsuccessful.

Studies of ion–molecule reactions (Section IV) have revealed only 10 substances with an electron affinity higher than 3 eV. The affinity was calculated from the threshold energy of an endothermic ion–molecule reaction[59,61], from the threshold energies of two exothermic ion–molecule reactions[62], or by measuring the rates of the forward and the reverse reaction, i.e. from the equilibrium constant[64]. The latter variant is considered in Section VI, devoted to equilibrium methods. Studies of ion–molecule reactions have yielded relatively few electron affinity data, and the precision of the results usually lies in the range 0.1–0.3 eV (see Table 3).

Relatively few studies of ion–molecule reactions involving negative ions had been reported until recently. The limitation lay both in the method of producing negative ions and in the inadequacy of the available thermochemical data (mainly, on heats of formation). The position has shown a marked improvement in recent years, with a rapid increase in the number of negative ions which can be obtained in the gas phase and in the list of known heats of formation. A good example are the anions (Table 6) which are easily formed by heat treatment of complex salts of the $MAlF_4$ type, where M is an alkali metal[120]. The use of these anions in studies of endothermic ion–molecule reactions should make an important contribution to the acquisition of thermochemical data on fluorine compounds.

In Section V we examine a method based on the formation of an ion pair by the collision of a molecule with an alkali metal atom. Ionisation can be induced by collisions with Cs, K, and Na atoms, and the upper limit of the electron affinities measurable by this method is 5.14 eV, i.e. the ionisation potential of the sodium atom. There is effectively no lower limit. During the last 5 years this method has yielded the greatest number of results: 73 affinity values, 21 of which were higher than 3.0 eV. The method is being actively developed by several groups of workers (see Table 4), who claim a precision between 0.15 and 0.30 eV. There are a number of inconsistencies between the results reported from German and American laboratories, for example in the case of WF_6[93,100]. The high values of the internal excitation energy are surprising.[141] Unfortunately, for most of the hexafluorides the electron affinity is only given as "higher than 5.14 eV", since negative MF_6^- ions are formed even from sodium atoms at thermal energies.

The determination of thermochemical quantities from the absolute values of the equilibrium constants is one of the main experimental methods of chemical thermodynamics. In studies of equilibria involving the gas phase this is one of the principal methods, giving heats of reaction accurate to ~ 4–12 kJ $mole^{-1}$ (0.05–0.15 eV). Therefore experimental methods of measuring the constants of ion–molecule equilibria involving negative ions have been intensively developed during the past 10 years, including work on flames[109], plasmas[110,111], and on the formation of clusters on negative ions[142,143].

The application of the classical effusion method to these problems had only limited success at first, because of the high value of the work function of the inner surface of the Knudsen effusion cell and of the low concentration of negative ions[144]. However, in the case of molecules with a high electron affinity (i.e. for $E > 3$ eV) these problems are less important. A method of lowering the work function of the inner surface of the Knudsen cell during the effusion measurement was also discovered[125]. As a result, the effusion method can now be used to measure electron affinities $E > 3$ eV, and work now in progress may result in a lowering of this limit. The method has no upper limit, since the higher the electron affinity, the easier it is to obtain measurable concentrations of negative ions in the effusion cell.

During the period 1979–1981 this method has been used to determine the electron affinities of iron, manganese, platinum, uranium, and cerium fluorides, and the affinities for the F^- anion of a series of fluorides (see Table 6). The precision of the results is 0.1–0.3 eV, and is often limited by the uncertainty in the heats of formation of the corresponding neutral compounds. The range of substances suitable for investigation by this method can easily be widened to include other halides, oxide halides, oxides, and salts of oxygenated acids. This type of measurement can yield the affinity for other anions as well as the electron affinity. For example, the affinities of the BeF_2 molecule for the following anions have been measured[131]: F^-, BeF_3^-, $Be_2F_5^-$, AlF_4^-, and $BeAlF_6^-$. This work has much in common with the study of cluster formation on negative ions by the method which has been called high-pressure mass spectrometry[142]. Keesel and coworkers[142] determined the heats of formation of $A(SO_2)_n$ clusters on A ions (Cl^-, I^-, NO_2^-), with $n = 1$–4, and Nikitin and coworkers[131] determined the heats of formation of $F^-(BeF_2)_n$ clusters, where $n = 1$, 2, and 3.

We note that the Knudsen effusion cell in addition to its normal purpose (the generation of equilibrium conditions) can also be used as an efficient source of negative ions in methods such as photo-extraction, photo-electron spectroscopy, and other threshold methods of determining electron affinities. When used as an ion source the effusion cell offers the simplest way of applying such methods to the study of those negative ions, which play an important role in high-temperature systems.

The methods discussed in Section VII occupy a special position, because they cannot be classified among the direct experimental methods of determining electron affinities, and they are used mainly to obtain approximate estimates of the affinities. For this reason the results quoted in Table 7 are only tentative, but they are nevertheless of interest because of the increasing importance of this class of compounds in investigations of the reality of electron affinity values in the range 4–8 eV. At present the following values have been reliably established:

Molecule	WF_6	MoF_6	UF_6
E, eV	3.5 ± 0.1 [62] 3.7 ± 0.2 [100] 4.89 ± 0.25 [129]	3.6 ± 0.2 [72]	4.9 ± 0.5 [63] $\geqslant 5.14$ [99]

By comparing these values with those of Table 7 we note discrepancies often greater than 1 eV. The most serious inconsistencies arise with the data obtained from the absorption spectra of complexes. The disagreement affects not only the absolute values of electron affinities (which could be due to an incorrect choice of standard) but also their differences: for example, the difference $E(MoF_6) - E(WF_6)$ according to these data is 1.3 eV, as compared with only 0.1–0.3 eV according to the results obtained by other methods. We conclude that the data of Table 7 should only be used as a rough estimate of the electron affinity, with a precision not better than ~ 1.5 eV.

The experimental results summarised in Tables 1–7 characterise the electron affinity of a large number of inorganic molecules and allow us to identify the classes of compounds for which numerical values of the electron affinity higher than those of the halogen atoms can be expected. Inspection of Table 5 shows that higher-valency oxygen compounds have an electron affinity in the range 3.5–4.3 eV (the BO_2, PO_3, WO_3, HWO_4, $HMoO_4$, and ReO_4 radicals). Even higher values (5.25–5.40 eV) are obtained for the tetrafluorides of the transition metals (FeF_4, MnF_4, PtF_4). Measurements on cerium tetrafluoride gave a value of 3.6 eV, believed to be typical of the tetrafluorides of the lanthanum group. Still higher values were obtained in studies of the hexafluorides.

Bartlett's prediction[145], made in 1968, has been confirmed experimentally: the electron affinities of all the hexafluorides of transition metals in the second and the third series are higher than 3.5 eV, and in the case of platinum hexafluoride the electron affinity is higher than 6.8 eV. According to existing data, $E(PtF_6) = 8.0 \pm 0.3$ eV.[126] For the ReF_6 and IrF_6 molecules the reported value is $E > 5.14$ eV, and for WF_6 and MoF_6 values of 3.5,[62] 3.7,[100] and 3.6 eV[72] have been obtained. Hence the higher fluorides (and probably also the oxide fluorides) of the second and third series of transition metals are a class of compounds showing the highest electron affinity values so far reported. Uranium hexafluoride has an electron affinity of ~ 5 eV, and similar values can be expected for the hexafluorides of the transuranic elements. The high values of electron affinity in this class of compounds probably persist in halides (and oxide halides) other than the fluorides.

The data in Table 6 can be used to calculate the enthalpies of formation of the negative ions BeF_3^-, AlF_4^-, ScF_4^-, LaF_4^-, ZrF_5^-, and HfF_5^-. Similar data are available for the anions WF_7^-[69] and UF_7^-.[63] For the UF_7 radical the energy of addition of the seventh fluorine atom is positive[63], i.e. the potential energy curve of the UF_6–F system has a minimum. For the AlF_4, ScF_4, LaF_4, ZrF_5, HfF_5, and WF_7 radicals this information is not yet available, and the minimum in the potential energy curve may be absent in some of the systems. The enthalpies of formation of these radicals are not known, and only a rough estimate of their electron affinity is possible (5–8 eV[147,149]). Some estimates suggest even higher values of the electron affinity: the record is held by gold hexafluoride, for which a value of 10 eV has been proposed[93]. Of course, there are no direct experimental data, and the compound itself has not yet been synthesised. An analogous situation exists in many instances of high (expected) electron affinity. A good example are the hexafluorides of iron, cobalt, and nickel, whose synthesis has not yet been achieved in spite of repeated attempts.

The compounds with a high electron affinity are the strongest known oxidising agents. They have a strong influence on the concentration of free electrons in flames and plasmas, and they greatly simplify the problem of generating strong beams of negative ions.

---o0o---

New information on the affinity of compounds for electrons and for the F^- ion has appeared while the manuscript was being prepared for the press.

Photo-extraction and photo-electron spectroscopy methods have been used to obtain the electron affinities of the following compounds: $E(CH_2) = 1.055 \pm 0.0 \pm 5$,[148] $3.374 \leq E(C_2) \leq 3.408$,[166] $E(HO_2) = 1.19 \pm 0.01$,[150] $E(HS) = 2.314 \pm 0.003$ eV.[151] In addition to these experimental papers, a review entitled "Laser spectroscopy of negative ion beams" has also appeared[152]. The electron impact method has been used to show that $E(OF) \geq 2.2$, $E(NF) \cong 0.5$, $E(ClO_3) \geq 3.2$, $E(ClO_2F) \geq 2.3$ eV,[153] and also $E(CCl_2) = 2.5 \pm 0.3$ and $E(CCl_3) = 2.58 \pm 0.20$ eV.[154]

Studies of endothermic ion–molecule reactions have yielded values of the affinity for the electron and for the fluoride anion (E_F^-), and also of the energy of the removal of an oxide anion ($D(MO_n-O^-)$): $E(SF_5) \geq 3.70 \pm 0.3$, $E_F^-(SF_3) = 2.60 \pm 0.16$, $E_F^-(SF_4) \geq 2.60 \pm 0.16$, $E_F^-(SF_5) = 1.10 \pm 0.21$[155]; $D(N-O^-) = 5.0 \pm 0.1$, $E(NO) = 0.02 \pm 0.10$, $D(O-O^-) = 4.1 \pm 0.1$, $E(O_2) = 0.44 \pm 0.1$, $D(NO-O^-) = 4.0 \pm 0.1$, $E(NO_2) = 2.4 \pm 0.1$, $D(N_2-O^-) = 0.43 \pm 0.1$, $E(N_2O) = 0.22 \pm 0.1$, $D(CO_2-O^-) = 2.0 \pm 0.1$, and $E(CO_3) = 3.1 \pm 0.2$ eV.[156]

Ionisation by potassium atoms has been used to prepare negative D_2S^- and H_2S^- ions. The corresponding values of the electron affinity were found to be negative: $E(D_2S) = -1.5 \pm 0.2$ eV and $E(H_2S) = -1.6 \pm 0.2$.[157]

Measurements of the equilibrium constant of ion–molecule reactions have yielded additional information on the thermochemical characteristics of negative ions. Pyatenko and coworkers[158] have obtained $E(UF_5) = 3.78 \pm 0.40$ and $E(UF_6) = 6.33 \pm 0.50$ eV, and Chilingarov and coworkers[159] reported $E(RhF_4) = 5.0 \pm 0.3$ eV. The affinity for the F^- anion was measured, with the following results: $E_F^-(LaF_3) = 4.42$,[160] $E_F^-(VF_3) = 4.9 \pm 0.1$,[161] and $E_F^-(ThF_4) = 4.2 \pm 0.1$ eV.[162] Similar measurements have been reported also for the oxide fluorides of molybdenum and tungsten: $E_F^-(MoO_2F_2) = 4.08 \pm 0.17$ and $E_F^-(WO_2F_2) = 4.30 \pm 0.17$ eV.[163] A detailed description of the determination of the electron affinity of cerium tetrafluoride (including the procedure) is given in Ref. 165. It is interesting to compare these results with experimental data for the hexafluorides of molybdenum[72], tungsten[62], and platinum[126]. These experimental and theoretical results were obtained, independently, in the period 1979–1981, and it is very instructive to compare them with earlier data.

The Synthesis of Substituted Cyclopropanes and Cyclopropenes by the Reductive Cyclisation of Polychloroalkanes

R.Kh.Freidlina, A.A.Kamyshova, and E.Ts.Chukovskaya

The methods of synthesis of three-carbon rings—substituted cyclopropanes and cyclopropenes, obtained by the action of various metals on polychloroalkanes with chlorine-containing groups in the 1,3-positions relative to one another, are reviewed. Reductive cyclisation with zinc of compounds having the groups $-CCl_2CH_2CCl<$ or $CCl_3CH_2CCl<$ gives rise to new possibilities for the synthesis of substituted cyclopropanes. A new method of synthesising 1,2-disubstituted cyclopropenes from compounds with the group $-CCl_2CH_2CCl_2$ is examined.

The bibliography includes 87 references.

I. INTRODUCTION

The chemistry of compounds of the cyclopropane and cyclopropene series has attracted the constant attention of investigators. This is indicated particularly by the appearance of annual reviews of literature on the synthesis of these compounds[1-8]. During recent years, reviews have been published on individual methods of synthesis of substituted cyclopropanes: the carbene method[9,10], the Simmons–Smith method[11], synthesis with the aid of the copper-isonitrile complex[12,13], and the electrochemical method[14,15]. Cyclopropene compounds are usually obtained by β-elimination from halogenocyclopropanes, by the addition of carbenes to acetylenes, or by the intramolecular cyclisation of the corresponding unsaturated aliphatic compounds[16,17]. Reviews have been devoted to the properties and reactions of three-carbon rings[18-32].

The structures of these rings have been confirmed by infrared, Raman, and ^1H NMR spectroscopy[33-35]. ^{13}C NMR has been used with an increasing frequency in recent years for the solution of problems of the structure of cyclopropanes[36-40]. cyclopropanes with an exocyclic double bond[41,42], or cyclopropenes[43-45].

Among the numerous methods for the synthesis of three-carbon rings, our attention was attracted to the intramolecular cyclisation of aliphatic chloro-compounds, particularly the 1,3-elimination (or γ-elimination) reaction[46] involving the removal of two halogen atoms with formation of a new C–C bond. The 1,3-dehalogenation reaction permits the direct conversion of an aliphatic halogenohydrocarbon into cyclopropane homologues with the same number of carbon atoms. The stoichiometry of this process is represented by the following equation in a general form:

Metals are usually employed as electron donors.

The aim of the present review is a survey of studies devoted to the synthesis of three-carbon rings from polychloroalkanes with chlorine-containing groups in the 1,3-positions relative to one another. Examples of such reactions have been mentioned in certain reviews, but they have never been surveyed and examined from the standpoint of their suitability for the synthesis of compounds of cyclopropane and cyclopropene series. Furthermore, new possibilities for the synthesis of a wide variety of cyclopropanes and cyclopropenes by reductive 1,3-dechlorination have been discovered in recent years, which necessitates a special discussion of all the results concerning this field. This review deals with the literature data published up to January, 1981.

II. 1,3-DECHLORINATION OF DICHLOROALKANES AND DICHLOROALKENES

The synthesis of cyclopropane by the 1,3-dechlorination of 1,3-dibromopropane by sodium was first described by Freund[47]. Gustavson[48] showed that the application of zinc dust in alcohol as the dehalogenating agent is more convenient. Subsequently it was found that the Gustavson 1,3-dehalogenation is of general importance for the synthesis of compounds of the cyclopropane series[49,50]. However, it was discovered that, whereas the use of 1,3-dibromoderivatives gives rise to satisfactory results, 1,3-dichloroderivatives are less valuable[50,51].

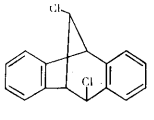
Without dwelling on numerous examples of the synthesis of substituted cyclopropanes from 1,3-dibromo-compounds, we shall consider below the 1,3-elimination of chlorine from organic polychloro-compounds.

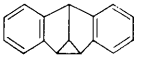
Table 1 presents all the examples of the synthesis of cyclopropane and cyclopropene derivatives from 1,3-dichloro-compounds known at the present time. It is seen that, in order to achieve a high yield of cyclopropane, Na_2CO_3 and NaI have been added[52] to the 1,3-dichloropropane (see No.1 in Table 1), coverting thereby the dichloro-compound into the more reactive di-iodo-derivative. n-Pentylcyclopropane has been obtained by the same method from 1,3-dichlorooctane (Table 1, No.6). It has been observed[54] that satisfactory results are obtained when 1,3-dichloropropane or 1,3-dichlorobutane is treated with the $Cr(ClO_4)_2$-ethylenediamine complex (Table 1, Nos.4 and 5).

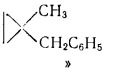
Magnesium in tetrahydrofuran can also be used successfully as the dechlorinating agent (Table 1, Nos.8 and 9). It has been shown[57] that the configuration of the dichloro-compound

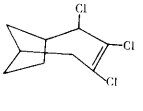
is very important in the dechlorination of bicyclic systems. Thus the 1,3-dechlorination of *anti*-8-*exo*-4-dichlorodibenzobicyclo[3.2.1]octadiene proceeds with formation of the cyclopropane ring (Table 1, No.9), while in the case of *syn-exo*- and *syn-endo*-dichloro-compounds the benzyl chlorine undergoes hydrogenolysis. The replacement of chlorine by hydrogen occurs also when the zinc–copper[57] or sodium–potassium[62] alloy is used as the dechlorinating agent. Furthermore, on treatment with sodium in ethanol, the dibromo-compound of analogous structure gives rise to a high yield of a hydrocarbon containing the cyclopropane ring[62]. Table 1 presents also examples (Nos.3, 7, 10, and 11) for which 1,3-dichlorination by a wide variety of reducing agents proceeds with low yields of cyclopropane derivatives.

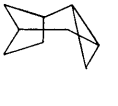
Proceeding to the synthesis of substituted cyclopropenes or their isomers with an exocyclic double bond from unsaturated 1,3-dichloro-compounds, one must note that attempts to obtain methylenecyclopropane by the dechlorination of 3-chloro-2-chloromethyl-1-propene by zinc proved unsuccessful[63]. The use of magnesium as the dechlorinating agent led to the formation of methylenecyclopropane in a low yield (Table 1, No.12). The electrochemical dechlorination of 1,3-dichloroalkenes, leading to substituted cyclopropenes (Table 1, No.13), has been achieved. Birch reduction, leading to cyclic compounds containing the 1,2,3-trichloroalkenyl group and a ring larger than that of cyclohexene, proceeds as reductive dechlorination with formation of bicyclo[*n*.1.0]alkanes (Table 1, No.14).











In conclusion of the examination of the 1,3-dechlorination of dichloroalkanes and dichloroalkenes, one should note that these reactions have been achieved in relation to a small number of examples and only some are suitable for the synthesis of three-carbon rings on a preparative scale; in the reviews published recently[7,8] the method of synthesis of three-carbon rings by 1,3-dechlorination is not mentioned at all. 1,3-Dichloro-derivatives containing functional groups are also without importance for the synthesis of cyclopropanes with functional substituents[64].

III. 1,3-DECHLORINATION OF COMPOUNDS WITH THE GROUPS $CCl_3CH_2CCl<$ or $-CCl_2CH_2CCl<$

1. The Interaction of Polychloroalkanes with $LiAlH_4$ and CH_3Li; Electrochemical Dechlorination

The 1,3-dechlorination of polychloroalkanes containing the $CCl_3CH_2CCl<$ or $-CCl_2CH_2CCl<$ groups by $LiAlH_4$ and CH_3Li or electrochemically, which leads to compounds of the cyclopropane series, has been described in relation to isolated examples. Thus treatment of 1,1,1,3-tetrachloro- or 1,1,1,3-trichloro-octane with $LiAlH_4$ in dioxan has been

Table 1. 1,3-Dechlorination of dichloroalkanes and dichloroalkenes.

found to result in the formation of n-pentylcyclopropane (up to 22%) together with the main reaction product—n-octane:[55]

$$XCCl_2CH_2CHClC_5H_{11} \xrightarrow[\text{dioxan}]{LiAlH_4} n\text{-}C_8H_{18} + \triangleright\!-C_5H_{11}\ .$$
X=H, Cl

The electrolysis of CCl_4 or ethyltrichloroacetate in the presence of compounds with polar double bonds (acrylonitrile, ethyl acrylate, etc.) can be classified as cyclisation with participation of geminal polyhalogenoalkyl groups[65]. Electrolysis at a mercury cathode leads to the two-electron cleavage of the added component. The anion, generated electrochemically, attacks the monomer with formation of the anionic adduct (I). The latter is converted into products via several pathways in accordance with the following scheme:

$$(C_2H_5CO_2CCl_2)^- + CH_2{=}CHX \rightarrow (C_2H_5CO_2CCl_2CH_2CHX)^- \rightarrow$$
$$\xrightarrow{a} C_2H_5CO_2CCl_2CH_2CH_2X$$
$$\xrightarrow{b} \text{Cl, } CO_2C_2H_5\text{-substituted cyclopropane, X}$$
$$\xrightarrow{c} C_2H_5CO_2CCl_2CH_2CHClX\ ;$$
X=CN, $CO_2C_2H_5$.

Stage *a* involves the protonation of the anionic adduct (I), stage *b* involves its cyclisation, including the intramolecular substitution of the halogen, and stage *c* involves the abstraction of the halogen from the initial polyhalogeno-compound. This reaction, carried out in dimethylformamide (DMF) in the presence of lithium chloride at room temperature, leads to a substituted cyclopropane (80%) and an adduct (20%). It must be emphasised that under the given conditions the second chlorine atom of the *gem*-dichloromethylene group is retained.

Mixed polyhalogeno-compounds containing chlorine and bromine, such as $CHBr_2CH_2CH_2Cl$ or $CHClBrCH_2CH_2Br$, undergo 1,3-dehalogenation by methyl-lithium[66]. Cyclisation then proceeds via the 1,3-elimination of bromine atoms and leads to a 45–50% yield of chlorocyclopropane. The presence of a chlorine atom in the γ-position relative to the geminal group sharply reduces the yield of the halogenocyclopropane. Thus in the case of 1,1-dibromo-3-chloropropane the yield of bromocyclopropane was 3–5% and the main product proved to be 1,6-dichlorohex-3-ene (40%).

Thus the 1,3-dehalogenation of *gem*-polyhalogeno-compounds with participation of bromine is also much easier than the reaction with participation of chlorine.

2. Reductive Cyclisation of Polychloro-derivatives

The ready availability of polychloroalkanes of the type of $CCl_3CH_2CClR^1R^2$ or $RCCl_2CClR^1R^2$, obtained by the addition of CCl_4 or $RCCl_3$ to the $>C=C<$ bond[67,68], makes it attractive to develop on their basis a method of synthesising compounds of the cyclopropane series. The study of chemical reactions of such polychloroalkanes suggested a new approach to the synthesis of cyclopropane and its substituted derivatives by the reductive cyclisation of the above compounds by zinc in boiling ethanol in a stream of HCl.[69]

In the present review reductive cyclisation is a term given to the process involving 1,3-dechlorination with formation of a new carbon–carbon bond (closure of a three-membered ring) and hydrogenolysis of one or two C–Cl bonds [mechanisms (2) and (3)]. It is noteworthy that the 1,3-elimination of two chlorine atoms from aliphatic compounds of the type of $RR^1CClCH_2CClR^2R^3$ with formation of the corresponding cyclopropane derivative is also sometimes referred to as reductive cyclisation[54] or reductive 1,3-elimination[5]. In the present review we shall refer to the reaction via mechanism (1) as 1,3-dechlorination in order to demonstrate its difference from reactions (2) and (3). Together with the above processes, hydrogenolysis, which does not lead to cyclopropane derivatives [reaction (4)], is also possible:

$$RCCl_2CH_2CClR^1R^2 \rightarrow \text{Cl, R, } R^1, R^2\text{-substituted cyclopropane}\ , \quad (1)$$

$$RCCl_2CH_2CClR^1R^2 \rightarrow \text{H, R, } R^1, R^2\text{-substituted cyclopropane}\ , \quad (2)$$

$$CCl_3CH_2CClR^1R^2 \rightarrow \text{H, H, } R^1, R^2\text{-substituted cyclopropane}\ , \quad (3)$$

$$RCCl_2CH_2CClR^1R^2 \rightarrow RCH_2CH_2CClR^1R^2 + RCH_2CH_2CHR^1R^2\ . \quad (4)$$

3. The Influence of the Nature of the Hydrogen Donor on the Yield of Cyclopropanes in the Reductive Cyclisation of Polychloroalkanes

The influence of various hydrogen donors on the yields of substituted cyclopropanes has been studied in relation to the compounds $(ClCH_2CH_2)_2CCl_2$ and $CH_3CCl_2CH_2CHClCH_3$ [70] (Table 2). In order to obtain comparable results, all the experiments, whose results are presented in Table 2, were performed up to ~100% conversion of the initial polychloroalkanes by heating the reaction mixture for 1–3 h.

Table 2. The yield of cyclopropanes in the reductive cyclisation of polychloroalkanes with zinc in various media[70].

Initial compound	Cyclopropane	Solvent				
		C_2H_5OH in stream of HCl	C_2H_5OH	CH_3CO_2H	$(CH_3)_2NCHO$	$[(CH_3)_2N]_3PO$
$(ClCH_2CH_2)_2CCl_2$	$\triangleright\!-CH_2CH_2Cl$	91	91	61*	53	70
$CH_3CCl_2CH_2CHClCH_3$	H_3C, CH_3 (*cis*:*trans*)	78 (7:1)	57 (6:1)	31 (4:1)	48 (10:1)	— —

*1,5-Dichloropentane (16%) was also obtained.

Table 2 shows that the best results have been obtained in experiments performed in boiling ethanol in a stream of HCl. Subsequently these conditions were used in the synthesis of a wide variety of cyclopropanes by the reductive cyclisation of polychloro-derivatives.

4. The Synthesis of Cyclopropane and Monosubstituted Cyclopropanes

Compounds having the structures CCl_3CH_2CHClR or $RCCl_2CH_2CH_2Cl$, containing the *gem*-polyhalogeno-group, readily react with zinc via one of the following mechanisms

$$RCCl_2CH_2CH_2Cl \xrightarrow[C_2H_5OH]{Zn} \triangleright\!\!-R \quad , \qquad (5)$$
$$R=(CH_2)_3\,Cl,\ (CH_2)_4\,Cl$$

$$CCl_3CH_2CHClR^1 \xrightarrow[C_2H_5OH]{Zn} \triangleright\!\!-R^1 \quad ; \qquad (6)$$
$$R^1=H,\ Alk.$$

The initial compound for the synthesis of cyclopropane is 1,1,1,3-tetrachloropropane [mechanism (6), $R^1 = H$], which can be readily obtained by the radical addition of CCl_4 to ethylene[67].

Reactions (5) and (6) involve both the *gem*-dichloromethylene and the *gem*-trichloromethyl groups. In both cases monosubstituted cyclopropanes are formed in high yields (Table 3). Under the chosen conditions, the formation of chlorocyclopropanes is not observed. Chloroalkanes [hydrogenolysis via mechanism (4)] have been obtained among the side products. Thus propyl chloride[71], 1,1,3-trichlorohexane[72], and 1,5-dichloropentane[69] have been isolated in low yields.

Table 3. The yields of cyclopropane and monosubstituted cyclopropanes* having the general formula $\triangleright\!\!-R$.

Initial compound	Yield, %	R	References
$CCl_3CH_2CH_2Cl$	75	H	[71]
$CCl_3CH_2CHClC_3H_7$	81	C_3H_7	[72]
$CCl_3CH_2CHClC_8H_{17}$	87	C_8H_{17}	[72]
$CCl_2(CH_2CH_2Cl)_2$	91	$(CH_2)_2Cl$	[69]
$ClCH_2CH_2CCl_2(CH_2)_4Cl$	86	$(CH_2)_4Cl$	[73]

*The reactions were performed in boiling ethanol with gaseous HCl passed for 1–3 h. The reactant ratio was polychloroalkane : zinc = 1 : 4.

5. The Synthesis of Monosubstituted Cyclopropanes with the Cyano- or Ester Group in the Aliphatic Chain

Polychloro-derivatives of the type $ClCH_2CH_2CCl_2CH_2.CClR^1X$ ($R^1 = H$ or CH_3; $X = CO_2CH_3$ or CN), containing a functional group in the α-position relative to the C–Cl bond, exhibit certain characteristic features in the reductive cyclisation reactions.

Table 4. The yields of monosubstituted cyclopropanes with functional groups in the side chain having the general formula $\triangleright\!\!-CH_2CHXR^1$ [74]*.

№	Initial compound	Yield, %	R^1	X
1	$ClCH_2CH_2CCl_2CH_2CHClCO_2CH_3$	67	H	CO_2CH_3
2	$ClCH_2CH_2CCl_2CH_2CCl(CH_3)CO_2CH_3$	63	CH_3	CO_2CH_3
3	$ClCH_2CH_2CCl_2CH_2CHClCN$	69	H	CN

*For the reaction conditions, see the footnote to Table 3.

The reaction proceeds selectively with respect to the $ClCH_2CH_2CCl_2$-fragment, while the chlorine atom in the α-position relative to the electron-accepting group (CN, CO_2R) is replaced by hydrogen and is not involved in the reductive cyclisation:

$$ClCH_2CH_2CCl_2CH_2CClXR^1 \xrightarrow[EtOH\ or\ MeOH]{Zn} \triangleright\!\!-CH_2CHXR^1 \ ;$$
$$R^1=H,\ CH_3;\ X=CN,\ CO_2CH_3 \ .$$

As a result, high yields of monosubstituted cyclopropanes with electron-accepting groups in the side chain are produced (Table 4).

Among the side reactions, mention may be made of the hydrogenolysis of the $\gtrdot CCl_2$ group. For example, $Cl(CH_2)_5CO_2CH_3$ has been obtained in a low yield from $ClCH_2CH_2CCl_2CH_2CHClCO_2CH_3$. The hydrolysis of the cyano-group on cyclisation of $ClCH_2CH_2CCl_2CH_2CHClCN$ to the acid with subsequent esterification, leading to cyclo-$C_3H_5CH_2CH_2CO_2C_2H_5$ with a low yield, has also been noted.

6. The Syntheses of Di-, Tri-, and Tetra-substituted Alkyl-, Chloroalkyl-, Phenyl-, and Chlorophenyl-cyclopropanes

If the substituents R, R^1 and R^2 in the initial polychloroalkanes $CCl_3CH_2CClR^1R^2$ or $RCCl_2CH_2CClR^1R^2$ are varied, it is possible to obtain disubstituted cyclopropanes (vicinal or geminal) as a result of reductive cyclisation and also tri- and tetra-substituted cyclopropanes by one of the following mechanisms:

$$CCl_3CH_2CClR^1R^2 \xrightarrow[C_2H_5OH]{Zn} \triangleright\!\!-R^1 + \triangleright\!\!-R^1 + \triangleright\!\!-R^1 \quad ; \qquad (7)$$
$$R^2 \qquad Cl\ R^2 \qquad Cl\ R^2$$

$$RCCl_2CH_2CClR^1R^2 \xrightarrow[C_2H_5OH]{Zn} \triangleright\!\!-R^1 + \triangleright\!\!-R^1 \quad ; \qquad (8)$$
$$R \quad R^2 \qquad R \quad R^2$$

$R=CH_3;\ R^1=H,\ CH_3;\ R^2=CH_3,\ C_6H_5.$

Examples of these reactions are given in Table 5.

Table 5. The yields and configurations of di-, tri-, and tetra-substituted cyclopropanes* .

		H_3C—$\triangleright$(CH_3)(Cl)—CH_3	—	13	

*For the reaction conditions, see the footnote to Table 3.
**The geometrical isomers are designated in terms of the nomenclature of Blackwood et al.[77], based on the concepts of the *E*- and *Z*-forms.

Evidently the chlorine atom at a secondary carbon atom is readily involved in the reductive cyclisation. We may note that the synthesis of vicinal dialkylcyclopropanes results in the preferential formation of the *cis*-isomer (Table 5, No.1). The secondary benzylic chlorine atom can also be involved in the reaction. A characteristic feature of the reductive cyclisation of compounds with a benzylic chlorine atom is the formation of chlorocyclopropanes (Table 5, Nos.2 and 3), which indicates the influence of the bulk of the substituent at a secondary carbon atom linked to a single chlorine atom on the hydrogenolysis of the C–Cl bond in the CCl_2 or CCl_3 group on cyclisation of compounds of the type $XCCl_2CH_2.CHClC_6H_5$ (X = Cl or alkyl). For examples under discussion, the formation of n-propyl- or n-butyl-benzenes (in low yields) as side products has been noted.

The chlorine atom at a tertiary carbon atom is also involved in the reductive cyclisation. The resulting *gem*-dimethylcyclopropane is insufficiently stable under the experimental conditions (Table 5, No.4) and isomerises with ring opening. This entails the formation of 2-methylbut-1-ene and 3-methylbut-1-ene with an overall yield of 36%. Chlorocyclopropanes have been obtained not only by the reductive cyclisation with involvement of a benzylic chlorine atom but also in the case where the chlorine atom is linked to a tertiary carbon atom (Table 5, No.5). This shows that the number of substituents at the carbon atom linked to the chlorine atom influences the hydrogenolysis of the C–Cl bond in the dichloromethylene group. Evidently in the instances indicated above such hydrogenolysis is hindered, which leads to the formation of chlorocyclopropanes.

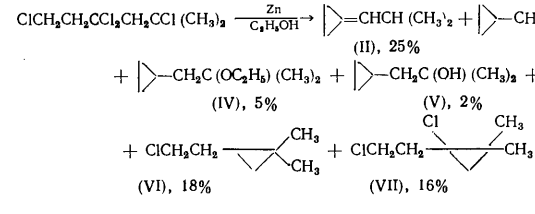
Consideration of the results of the reaction of 1,1,1,3-tetrachloro-3-phenylpropane with zinc shows that the overall yield of substituted cyclopropanes is 64% and that the products represent as it were all the stages in the reductive cyclisation: 1,1-dichloro-2-phenylcyclopropane, which is the 1,3-dechlorination product, and 1-chloro-2-phenyl- and 1-phenyl-cyclopropanes, which are the products of the successive substitution of chlorine by hydrogen. However, the chlorocyclopropanes formed are not intermediates whose hydrogenolysis leads to the formation of their hydrocarbon analogues, because it is known that chlorocyclopropanes are inert to reduction by zinc in alcohol[78]. Furthermore, special experiments have established that the interaction of 1,1-dichloro-2-phenylcyclopropane or 1-chloro-1-methyl-2-phenylcyclopropane with zinc under the conditions of reductive cyclisation leads to the formation of reduction products—1-chloro-2-phenylcyclopropane or 1-methyl-2-phenylcyclopropane—only in insignificant yields (2–7%).[70]

At the end of this discussion of the reductive cyclisation of polychloroalkanes with the $XCCl_2CH_2CCl<$ (X = Cl or alkyl) group, one may conclude that, in those cases where a single chlorine atom is linked to a primary or secondary carbon atom, the reaction proceeds smoothly and leads to the formation of mono- or di-substituted cyclopropanes in high yields. In those cases were a benzylic chlorine atom or a chlorine atom attached to a tertiary carbon atom is involved in the reaction, there is a possibility of the formation of a mixture of cyclopropane derivatives containing chlorocyclopropanes.

7. Competing Pathways in the Reductive Cyclisation of Polychloroalkanes with Several Chlorine-containing Groups

If there are several different chlorine-containing groups in the polychloroalkane molecule, the mode of reaction of this compound with zinc depends on the relative positions of the chlorine atoms. The study of the competing processes made it possible to establish the limits of the applicability of the given method of synthesis of cyclopropane compounds and to obtain data from which the reaction mechanism can be inferred. Certain examples of such reactions are given in Table 6.

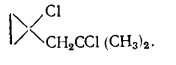
Table 6. The reactions of monofunctional polychloroalkanes*.



№	Initial compound	Products	Yield, %	References
1	$ClCH_2CH_2CCl_2CH_2CHClCH_3$		38	[75]
		 (*cis*)	32	
2	$ClCH_2CH_2CCl_2CH_2CHCl_2$		60 (72)**	[75]
			11 (2)	
3	$ClCH_2CH_2CCl_2CH_2CHClCH_2Cl$		60	[74]
4	$(ClCH_2CH_2CCl_2)_2$	$(ClCH_2CH_2CCl{=})_2$	92	[74]

*For the reaction conditions, see the footnote to Table 3.

**The yields of products obtained under the following reaction conditions are indicated in brackets: 25 °C, solvent—DMF.

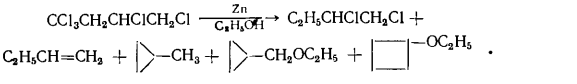


***The 1,2-dechlorination products, namely 6-chlorohex-1-ene and 3-cyclopropylpropene, were not detected.

Table 6 shows that, if the reductive cyclisation can proceed with participation of the chlorine atom at a primary or secondary carbon atom, then both possible pathways operate to approximately equal extents and a mixture of mono- and di-substituted cyclopropanes is obtained (Table 6, No.1). On the other hand, if there is a possibility of competition between 1,3-dechlorination with participation of the chlorine atom at a primary or tertiary carbon atom, the reaction is more complex[76] and a number of products are formed:

Compounds (II)–(V) are then produced as a result of reductive cyclisation with participation of the chlorine atom at a primary carbon atom, while compounds (VI) and (VII) result from 1,3-dechlorination involving the chlorine atom at a tertiary carbon atom. The overall yields of compounds formed on cyclisation via both competing pathways amounted to 41 and 34% respectively. This shows that the two processes take place to approximately equal extents. It is noteworthy that 1,3-dechlorination with participation of a single chlorine atom at a tertiary carbon atom leads to the formation of chlorocyclopropane (VII). Cyclopropane (II), having an exocyclic double bond, has been obtained with an

appreciable yield. Its formation is due to the 1,3-dechlorination of the $ClCH_2CH_2CCl_2$ fragment and subsequent transformations of the intermediate

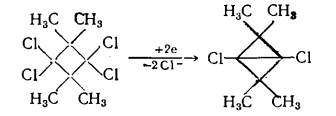


The $CHCl_2$ group in 1,1,3,3,5-pentachloropentane is involved in reductive cyclisation with much more difficulty than the $ClCH_2$ group (Table 6, No.2). Indeed, 60% of the reaction products were obtained by the cyclisation of the $ClCH_2CH_2CCl_2$ fragment. The formation of $CHCl_2(CH_2)_4Cl$ (5%) as a result of the hydrogenolysis of the CCl_2 group as well as the formation of a mixture of unsaturated chloroalkenes and the ethers $CH_2 = C(CH_2CH_2Cl)CH_2OC_2H_5$ and $CH_2 = C(CH_3)CH_2CH_2Cl$ (overall yield 12%) as a result of isomerisation with ring opening have also been noted. The formation of products of hydrogenolysis and isomerisation with ring opening does not occur if the reaction is carried out in DMF. The reductive cyclisation of the $CHCl_2CH_2CCl_2$ fragment is examined in greater detail below (see Section IV).

Results important for the understanding of the mechanism of the reductive cyclisation have been obtained in a study of polychloroalkanes which can undergo either 1,3- or 1,2-dechlorination. These compounds include $XCCl_2CH_2.CHClCH_2Cl$ (X = Cl, CH_3, or $ClCH_2CH_2$) and $(ClCH_2CH_2.CCl_2)_2$.

Table 6 shows that, when there is a possibility of the competitive 1,3-dechlorination of the $ClCH_2CH_2CCl_2$ group and the 1,2-dechlorination of single chlorine atoms, then the main reaction pathway is 1,3-dechlorination (Table 6, No.3). On the other hand, if 1,3-dechlorination of the same group or 1,2-dechlorination of vicinal dichloromethylene groups is possible, the only reaction pathway becomes 1,2-dechlorination of the $-CCl_2CCl_2-$group (Table 6, No.4). These results indicate unambiguously that the reaction begins with attack by the zinc atom on the $>CCl_2$ group.

Further confirmation of this has been obtained in the study of the interaction of polychloroalkanes of the type $XCCl_2.CH_2CHClCH_2Cl$ (X = Cl or CH_3) with zinc[71,74]. In relation to $CCl_3CH_2CHClCH_2Cl$, the reaction proceeds via the mechanism

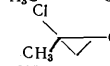


Similar results have been obtained in the study of the interaction of 2,2,4,5-tetrachloropentane with zinc in alcohol. The main products of these reactions are 1,2-dichloroalkanes and alk-1-enes—formed with an overall yield of 50–60% as a result of the hydrogenolysis of the CCl_3 or $>CCl_2$ groups. Cyclisation of the $CCl_2CH_2CHClCH_2Cl$ fragment containing the CH_2Cl group in the α-position relative to the single Cl atom is much more difficult (see also Table 6, No.3). The overall yield of cyclic products is only 6–9%.

Thus in these cases too the reaction begins with attack by zinc on the $>CCl_2$ group. The hydrogenolysis of the *gem*-polychloroalkyl group in the absence of the chlorine atom in the γ-position relative to this group becomes the only reaction pathway. Indeed, under the conditions of reductive cyclisation, mainly 1,1,5-trichloropentane is obtained from 1,1,1,5-tetrachloropentane[72].

IV. 1,3-DECHLORINATION OF COMPOUNDS WITH THE GROUPS $-CCl_2CH_2CCl_2-$ or $CCl_3CH_2CCl_2-$

1,3-Dechlorination of compounds with the $-CCl_2CH_2CCl_2-$group is known to occur in a few isolated examples. Thus, 1,1,3,3-tetrachloro-2,2,4,4-tetramethylcyclobutane has been reduced electrochemically at a mercury cathode in DMF:[79]



The reaction proceeds with formation of 1,3-dichlorotetramethylbicyclobutane.

Polychloroalkanes with two $>CCl_2$ groups in the 1,3-positions (of the type of $RCCl_2CH_2CCl_2CH_3$) can be readily achieved by adding $RCCl_3$ to 2-chloropropene[80,81]. It might be supposed that 1,2-disubstituted cyclopropenes would be formed from these compounds under the conditions of reductive cyclisation. However, it was found that the results of the reaction depend greatly on the structure of the geminal groups (CCl_3, CCl_2, or $CHCl_2$) and on the reaction conditions.

Table 7 presents data obtained for various polychloroalkanes when the latter are refluxed with zinc in ethanol. It was shown that the reaction proceeds in a complex manner with formation of a mixture of saturated and unsaturated cyclic and aliphatic compounds. Cyclopropenes have been obtained only from $CHCl_2CH_2CCl_2CH_3$; the formation of chlorocyclopropanes has also been noted[82]. The presence of branched unsaturated products in the mixtures can be explained by the fact that chlorocyclopropanes are apparently unstable under the reaction conditions and isomerise with ring opening. In all three examples in Table 7 products of the hydrogenolysis of the $>CCl_2$ group are formed.

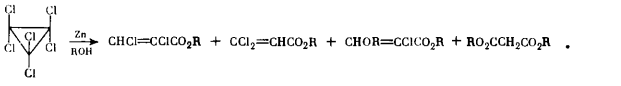


Table 7. The yields of the products of reductive cyclisation with participation of the $-CCl_2CH_2CCl_2-$group in C_2H_5OH (78 °C, 3 h).

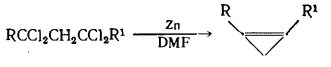
Initial compound	Cyclic compounds	Yield, %	Aliphatic compounds	Yield, %	Refs.
$CHCl_2CH_2CCl_2CH_3$		30	$CHCl_2CH_2CH_2CH_3$	12	
		4	$CH_2=C(CH_3)CH_2OC_2H_5$	19	[75]
		10	$CH_2=C(CH_3)_2$	9	
$CH_3CCl_2CH_2CCl_2CH_3$		4	$CH_2=C(CH_3)CH(CH_3)OC_2H_5$	30	
			$CH_2CH=C(CH_3)CH_2OC_2H_5$	3	
		9	$CH_3(CH_2)_3CH_3$	1	[82]
		4	$CH_3CH=CHC_2H_5$ / $CH_2=C(CH_3)C_2H_5$	11	
			$CHCl_2CH_2CH_2Cl$	38	
			$CHCl_2CH_2CH_2OC_3H_7$	21	[74]
$CHCl_2CH_2CHCl_2$*	—	—	$CHCl_2CH_2CH_3$	20	
			$Cl(CH_2)_3Cl$	4	

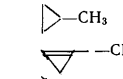
*The reaction was carried out in $n\text{-}C_3H_7OH$ at 100 °C for 3 h.

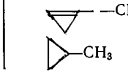


$CHCl_2CH_2CHCl$ does not react with zinc in boiling ethanol. On the other hand, in boiling propanol the hydrogenolysis of the $CHCl_2$ group, and not 1,3-dechlorination, takes place with subsequent alkoxylation.

The formation of a complex mixture of products has been observed in a study of the action of zinc in ethanol on hexachlorocyclopropane[83]. Instead of the expected 1,2,3,3-tetrachlorocyclopropene, a mixture of unsaturated esters was obtained, the esters being formed, according to the authors[83], as a result of isomerisation with opening of the cyclopropane ring:

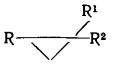
1. The Synthesis of Substituted Cyclopropenes





Reduction of the reaction temperature and especially the use of a different solvent (replacement of C_2H_5OH by DMF) enabled Kamyshova et al.[84] to propose a new method of synthesis of substituted cyclopropenes. The reaction proceeds via the mechanism

The availability of compounds of the type $RCCl_2CH_2CCl_2CH_3$ noted above leads to the possibility of synthesising the corresponding 1,2-disubstituted cyclopropenes; examples of such reactions are given in Table 8. Evidently, when R,R^1 = alkyl, the reaction leads to the formation of 1,2-dialkylcyclopropenes in high yields (Table 8, Nos.1 and 2). In those cases where the molecule contains only one CCl_2 group and the second geminal group is either CCl_3 (R = Cl, Table 8, No.3) or $CHCl_2$ (R = H, Table 8, No.4), the reaction is more complex and leads to a mixture of monosubstituted cyclopropanes and cyclopropenes.



The synthesis of cyclopropenes from polychloroalkanes with the $-CCl_2CH_2CCl_2$-group by the action of zinc in DMF is extremely promising, since cyclopropenes are formed under mild conditions and in high yields.

Table 8. The synthesis of cyclopropenes by the dechlorination of compounds of the type $RCCl_2CH_2CCl_2CH_3$ with zinc in DMF at 25 °C.

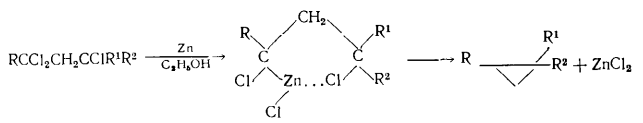
V. THE PROBLEM OF THE MECHANISM OF THE REDUCTIVE CYCLISATION OF POLYCHLOROALKANES WITH FORMATION OF THREE-CARBON RINGS

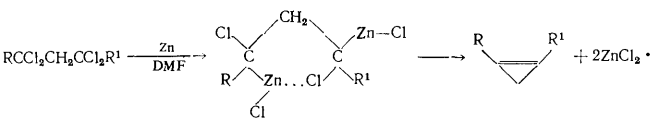
The mechanism of the dehalogenation of 1,3-dihalogenoalkanes to compounds of the cyclopropane series by metals or salts of metals in the lowest valence state has been the subject of a series of studies (see, for example, Refs.54, 58, 66, 86, 87). It was found that the process is complex and consists of two or three stages[86,87]. In almost all the studies the possibility of the intermediate formation of a γ-halogeno-substituted organometallic compound was considered. For example, the cyclisation of 1,3-dihalogenopropane under the influence of the $Cr(ClO_4)_2$–ethylenediamine complex entails, according to Kochi and Singleton[54], the intermediate formation of $HalCH_2CH_2CH_2Cr^{II}en$, where en = ethylenediamine. The cyclisation of 2-benzyl-1,3-di-iodo-2-methylpropane by $LiAlH_4$ in ether is also believed[58] to involve the intermediate formation of the organoaluminium compound $PhCH_2C(CH_3).(CH_2I)CH_2LiAlH_3$. It is believed[66] that 1,1,3-dehalogenation of 1,1,3-trihalogenoalkanes with methyl-lithium proceeds via the intermediate formation of organolithium compounds of the type $RCHBrCH_2CHHalLi$. As regards the reductive cyclisation of compounds of the type $RCCl_2CH_2.CClR^1R^2$ by the action of zinc, which involves both 1,3-dechlorination and the hydrogenolysis of the C–Cl bond, one may claim that the hydrogenolysis of the CCl_2 group with formation of the fragment $\rangle CClCH_2CCl\langle$ is not the first reaction stage, since this fragment is dechlorinated with much more difficulty (see Section II), than the $-CCl_2CH_2CCl\langle$ group. One may also claim that the formation of the cyclopropanes

does not proceed via the intermediate chlorocyclopropanes



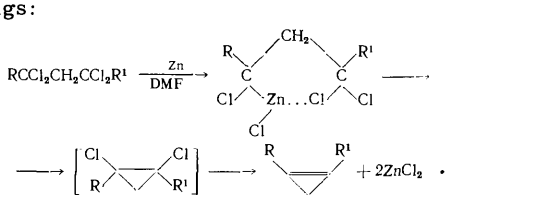
because, as already stated above, under the conditions of reductive cyclisation the hydrogenolysis of the chlorine atom linked to the ring proceeds to an insignificant extent (see Section III).

One may quote much evidence in support of the fact that reductive cyclisation with participation of *gem*-polyhalogeno-groups begins with attack by the zinc atom on such a group (CCl_2 or CCl_3). Thus there are two vicinal CCl_2 groups and the $ClCH_2$ group in the compound $(ClCH_2CH_2CCl_2)_2$; the reaction proceeds solely with the participation of the $-CCl_2CCl_2$-group, while the CH_2Cl group is not involved at all. On the other hand, the 1,3-dechlorination of the $ClCH_2CH_2CCl_2$ fragment in the $ClCH_2CH_2CCl_2CH_2CHClCH_2Cl$ molecule takes place much more readily than the 1,2-dechlorination of single chlorine atoms. The main reaction pathway for compounds of the type $XCCl_2CH_2CHClCH_2Cl$ (X = Cl or alkyl) is the hydrogenolysis of the $XCCl_2$ group. It has also been shown that $AlkCCl_2CH_2CHCl_2$ is 1,3-dechlorinated, whereas $CHCl_2CH_2CHCl_2$ is not involved in cyclisation. All these findings indicate the necessity for the presence in the molecule of the dichloromethylene or the trichloromethyl group for the reaction under consideration to occur. Finally reductive cyclisation proceeds just as readily when it involves a single Cl atom linked to a primary, secondary, or tertiary carbon atom.



By analogy with the examples of the 1,3-dehalogenation of dihalogenoalkanes by metals with the intermediate formation of organometallic compounds, which were examined above, one can postulate that the reductive cyclisation of polychloroalkanes of the type $RCCl_2CH_2CClR^1R^2$ also proceeds via the intermediate formation of an organozinc compound. This hypothesis makes it possible to account for the ready

hydrogenolysis of the C–Cl bond in the α-position relative to the C–Zn bond:



This hypothesis is also confirmed by the preferential formation of *cis*-1,2-disubstituted cyclopropanes mentioned above. The stereoselectivity of the process shows that an organozinc compound is formed as an intermediate in a specific conformation ensuring the coordination of zinc to γ-chlorine. The elimination of $ZnCl_2$ leads to the closure of the three-carbon ring.

1,2-Disubstituted cyclopropenes are apparently formed by a similar mechanism:

An alternative reaction involves the initial 1,3-dechlorination to 1,2-dialkyl-1,2-dichlorocyclopropane followed by 1,2-dechlorination of the vicinal chlorine atoms of the three-carbon rings:

Thus compounds with the groups CCl_3CH_2CCl <, $-CCl_2CH_2CCl$ <, or $-CCl_2CH_2CCl_2-$ can find extensive applications in the synthesis on their basis of a wide variety of three-carbon rings via dechlorination or reductive cyclisation reactions.

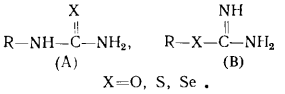
Derivatives of Carbohydrates with Carbamide Fragments

V.A.Afanas'ev, Zh.A.Dzhamanbaev, and G.E.Zaikov

A systematic account is given of the results of experimental studies on the synthesis, structures, and properties of carbohydrate-containing derivatives of urea and its analogues—thiourea, selenourea, and iminourea (guanidine). The possibility of using them in the preparative chemistry of carbohydrates and in certain branches of the national economy is demonstrated. The prospects for the development of the chemistry of sugars with ureido-groups are outlined.



The bibliograph includes 123 references.

I. INTRODUCTION

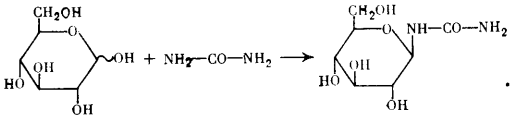
The products of the substitution of the hydroxy-groups of the carbohydrate chain, including the glycosidic hydroxyl $C_{(1)}$–OH by the residues of derivatives of urea and its analogues—thiourea, selenourea, and guanidine (iminourea)—must be included among ureidosugars, which form part of the large class of aminosugars and *N*-glycosylamines (*N*-glycosides).[1-4] A series of structural and chemical features make it possible to combine these compounds into a separate group among nitrogen-containing sugar derivatives. Among these features, one should include in the first place the polyfunctional nature of the carbamide fragments, manifested particularly by the effects involving neighbouring functional groups of the sugars. The presence of the carbonyl group in the immediate vicinity of the amino-group reduces markedly the basicity (pK_a) of the amino-group and hence the reactivity of the carbamide fragment in acid-catalysed nucleophilic addition and substitution reactions. In this respect the *N*-glycosidic linkage in *N*-glycosyl derivatives of carbamides approaches in its properties the glycosidic linkages in nucleosides. The fact that both the amino-group (A) and the oxygen, sulphur, and selenium atoms (B) can participate in the formation of a bond with the carbohydrate residue R must be regarded as one of the characteristic features of ureidosugars, the stability of derivatives with the iso-structure (B) increasing with increase of the nucleophilicity of the atom X. Stable iso-structures of carbohydrate derivatives of urea are unknown.

X=O, S, Se.

In terms of certain structural and chemical features, ureidosugars resemble carbamic acid esters (carbanilates) and amides derived from sugars as well as *N*-acylation products. The preparative value of these derivatives in carbohydrate chemistry has been discussed in a number of studies[1-5] and they are not considered in the present review.

Different aspects of the technical employment of ureidosugars are limited mainly to *N*-glycosylureas, which have been used, for example, to obtain non-shrinking and crease-resistant cotton fabric[6], in compositions designed to increase the strength of paper[7], as detergents with improved disinfecting properties[8,9], and as feed preparations with a high content of *N*-glycosylurea to make good the protein nitrogen deficiency in the diet of animals[10,11]. A significantly more important trend towards their application in pharmacology, medicine, the health service, bio-organic chemistry, and molecular biology has arisen recently. The likelihood of the development of research into the chemistry of ureidosugars is associated primarily with the problem of the synthesis of carbohydrate-containing physiologically active substances with a low toxicity, a high solubility in water, and with selective action on the living organism.

As a preparation for medical purposes, urea has extremely modest possibilities[12]. Urea derivatives, the various pharmacological properties of which can be illustrated by examples of their utilisation as soporific, narcotic, antipyretic, analgesic, and anticonvulsant agents and in the treatment of diabetes, glycaemia, and in helminthiasis, are of significantly greater interest in this sense[12-14]. The fact that the carbamide residue is extremely common in nature and enters into the structures of biologically important substances of the pyrimidine series also merits special attention. Nitroso-derivatives of urea, guanidine, and biuret have acquired great practical importance for the treatment of malignant neoplasts[15-19]. An exceptionally high mutagenic activity and the ability to overcome the haematoencephalic barrier must be included among the characteristic features of *N*-nitrosoalkylureas.



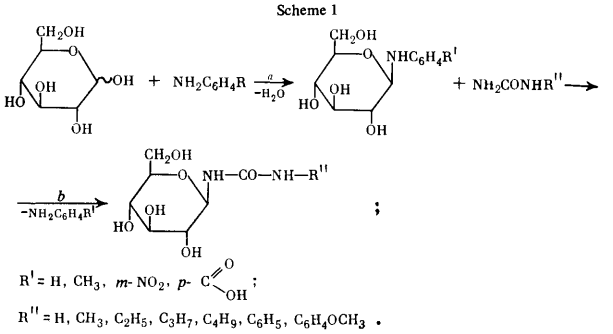
Bearing in mind the above considerations, it is to be expected that the development of experimental and theoretical studies in the field of carbohydrate-containing derivatives of urea and its analogues will lead to the discovery of ways of synthesising new effective medicinal drugs and intermediates for their preparation.

II. METHODS OF SYNTHESIS OF UREIDOSUGARS

Two main approaches are used in the synthesis of ureidosugars: direct interaction of carbohydrates with carbamides and their analogues under the conditions of acid catalysis and the formation of carbamide groups in the carbohydrate molecule on the basis of known reactions leading to the formation of derivatives of urea, thiourea, selenourea, and guanidine. The first pathway is suitable for the synthesis of derivatives involving the glycosidic centre. Among the methods of the second type, the iso(thio)cyanate

method has become most widely used, permitting the introduction of the carbamide residue into virtually any position in the carbohydrate ring.

The synthesis of *N*-glucosylurea (II) by the direct condensation of unsubstituted D-glucose (I) with urea in the presence of an inorganic acid as the catalyst was first achieved by Schoor[20]:



(I) (II)

The reaction was followed by measuring the optical rotation of the reaction solution. The crystalline product was obtained only after enzymatic cleavage of the unreacted D-glucose. Subsequently, the direct condensation method was improved somewhat[21-29] and extended to other mono- and di-saccharides, but no fundamental changes were introduced into the method of synthesis. Thus in the synthesis of *N*-β-D-glucopyranosylurea[21] a 1:1 mixture of glucose and urea is kept at 50 °C for seven days, evaporated, and the 1:2 adduct of glucosylurea and urea is crystallised. In order to isolate glucosylurea, the product is treated with boiling absolute ethanol for three days. In the synthesis of *N*-β-D-ribopyranosylurea[23] the reaction mixture is kept at 50 °C for ten days and the anomeric forms of the condensation product are isolated by preparative chromatography; the final yield does not exceed 15–20%.

A new, more effective method of synthesis of *N*-glycosylurea, using unprotected *N*-arylglycosides, has been discovered in recent years[30-32]. Kinetic studies have shown[2] that the replacement of the glycosidic hydroxyl by an *N*-arylaglycone increases the reactivity of $C_{(1)}$ in nucleophilic addition and substitution reactions as a result of which it is possible to facilitate the introduction of weakly basic aglycones under the conditions of acid catalysis. The set of reactions involving the $C_{(1)}$ atom in the synthesis of *N*-glycosylureas can be represented by the following scheme incorporating stages (*a*) and (*b*):

Scheme 1

R^{I} = H, CH_3, *m*-NO_2, *p*-$C(=O)OH$;

R^{II} = H, CH_3, C_2H_5, C_3H_7, C_4H_9, C_6H_5, $C_6H_4OCH_3$.

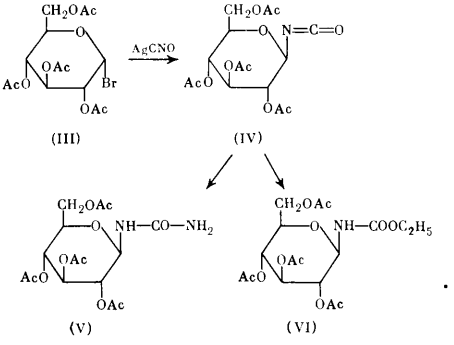
In order to obtain *N*-glycosylureas by the *N*-transglycosylation reaction, it is sufficient to heat for a very short time (10–30 min) a mixture of urea and the *N*-arylglycosides with an aglycone of moderate basicity in the presence of small amounts of added inorganic acid until the mixture becomes completely homogenised. The initial *N*-glycoside is sometimes precipitated on crystallisation together with the required product, but it can be readily removed by washing the precipitate with hot ethanol. Subsequent recrystallisation of the product from aqueous alcoholic solutions leads to chromatographically homogeneous *N*-β-D-glycopyranosylurea.

Scheme 1 shows that the arylamine plays in essence the role of a nucleophilic catalyst of the direct condensation of the monosaccharide with urea derivatives. To simplify the preparative procedure, *N*-glycosylureas can therefore be synthesised without the preliminary preparation of the corresponding *N*-arylglycoside and catalytic amounts of the arylamine can be used.

In the synthesis of glycosylureas by the direct condensation of unprotected sugars with urea, *N*,*N'*-diglycosylureas are always formed, their relative content in the reaction mixture depending on the ratio of the concentrations of the initial components:

$$2\rangle HC_1{-}OH + NH_2{-}CO{-}NH_2 \rightarrow \rangle HC_1{-}NH{-}CO{-}NH{-}C_1H\langle + 2H_2O .$$

N-Alkylureas do not condense with sugars at the site where the alkyl group is substituted.

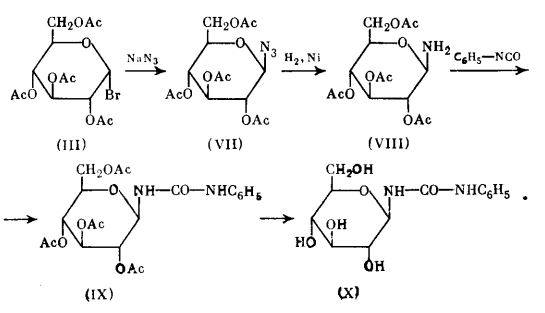


The *N*-triglycosylation method is nowadays the most promising for the synthesis of *N*-glycosylureas on a large scale. By altering the nature of the *N*-aglycone, it is possible to vary the rate of the substitution reaction and to synthesise anomeric forms at the kinetically controlled stages.

The isocyanate method, developed by Fischer[33] in 1914 and based on the interaction of acetyl-substituted glycosyl isocyanates with amines, proved to be effective in the synthesis of *N*-glycosylureas:

$$\rangle HC_1{-}N{=}C{=}O + NH_2R \rightarrow \rangle HC_1{-}NH{-}CO{-}NHR .$$

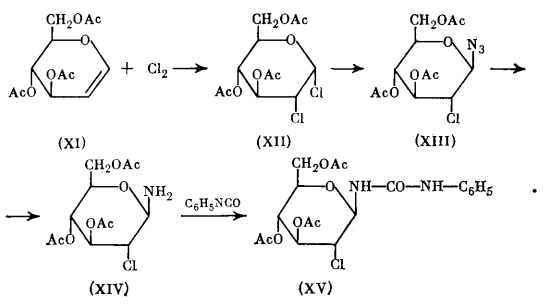
Thus, in the synthesis of *N*-β-D-glucopyranosylurea, treatment of tetra-*O*-acetyl-α-D-glycopyranosyl bromide (III) with silver cyanate in anhydrous xylene gives the glucosyl isocyanate (IV) which is converted into the final product (V) by teatment with an aqueous solution of ammonia. On the other hand, when compound (IV) is heated in an alcoholic solution, the glucosylurethane (VI) is formed (see the scheme below):



Scheme 2

(III) (IV) (V) (VI)

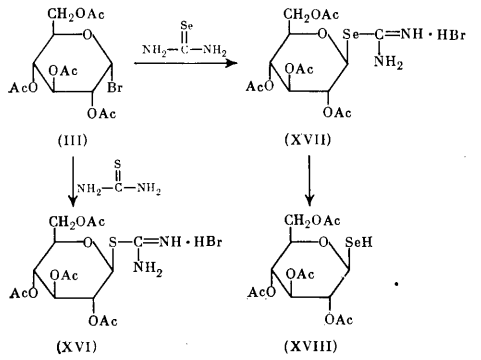
The carbamide residue can be formed at $C_{(1)}$ also by the reaction of *N*-glycosylamine with isocyanates, as shown for the formation of *N'*-phenyl-*N*-β-D-glucopyranosylurea (X) (see the scheme below):



Scheme 3

(III) (VII) (VIII) (IX) (X)

The Fischer method has been improved[34-41] and its applicability in the synthesis of glycosylureas has been greatly extended. An an illustration, one may quote the synthesis of 2-chloro- and 2-bromo-derivatives of glycosylureas from acetylglycols[42]:

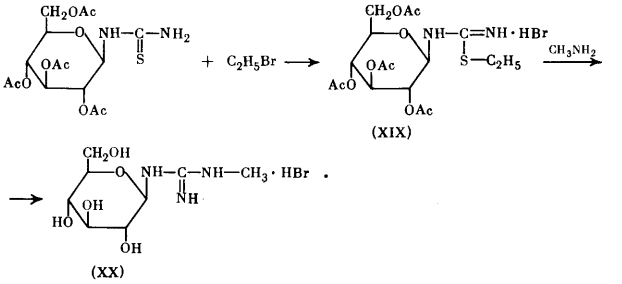


Scheme 4

Similarly sugar isothiocyanates with protected hydroxy-groups readily undergo addition reactions with amines and give rise to the corresponding *N*-glycosylthioureas.

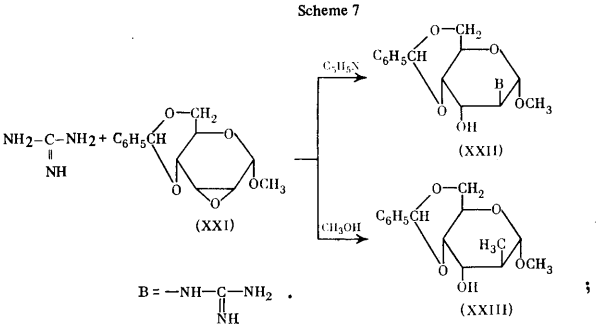
The interaction of thiourea with acetylhalogeno-sugars leads to the formation of thioureido-sugars with the iso-structure. Thus treatment of acetobromoglucose (III) with thiourea results in the formation of tetra-*O*-acetyl-β-D-glucopyranosylisothiourea (XVI)—the so-called "isothiouronium salt":[48-51]

Scheme 5



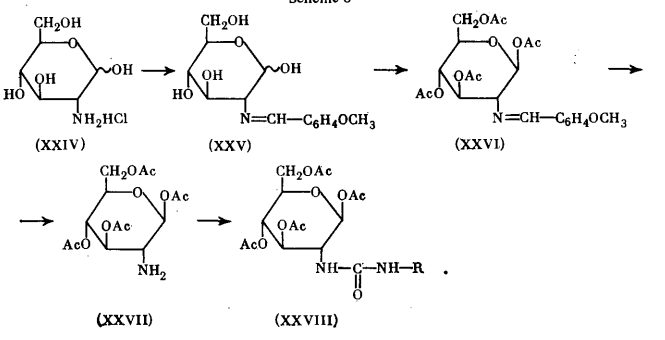
Derivatives of isothiourea are unstable and readily decompose under the influence of bases with formation of thioaldoses. A method of synthesis of alkylthioglycosides has been developed on this basis[52].

Selenourea behaves analogously[53-56]. On interaction with acetobromoglucose, it gives rise to tetra-*O*-acetyl-β-D-glucopyranosylisoselenourea (XVII), which decomposes on treatment with KOH solution to form the selenoglucoside (XVIII), which subsequently condenses to bis(tetra-*O*-acetyl-β-D-glucopyranosyl) diselenide.

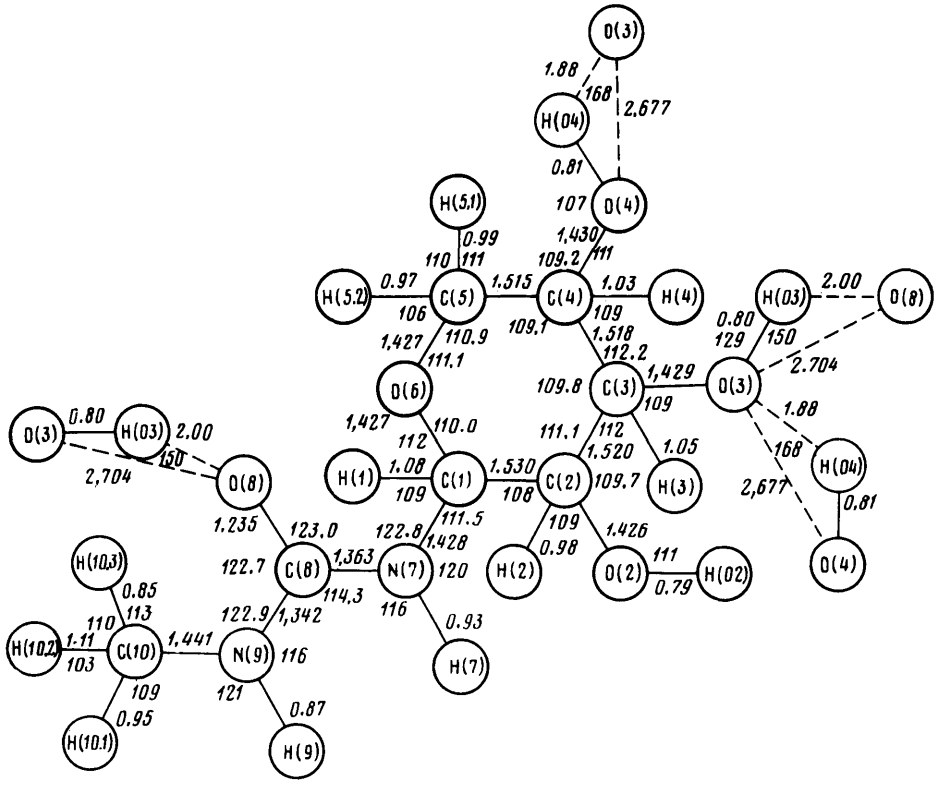


In contrast to urea and thiourea, guanidine does not undergo condensation reactions with unsubstituted sugars[4]. Guanidine-containing sugars can be conveniently obtained by the method involving the transformation of the thiourea fragment into a guanidine fragment by treatment with amines[57-59]. This procedure can be illustrated in relation to the synthesis of *N*-β-D-glucopyranosylguanidine (XX) from *S*-ethyl-substituted *N*-β-D-glucopyranosylthiourea (XIX) obtained by the reaction of *N*-β-D-glucopyranosylthiourea with ethyl bromide and subsequent treatment with methylamine[57,58]:

Scheme 6



It has been possible[60-62] to introduce the guanidino-residue into the $C_{(2)}$ position by the direct treatment of 2,3-anhydro-4,6-*O*-benzylidene-α-D-methylallopyranoside (XXI) with guanidine, the mixture being subjected to prolonged heating in pyridine. When the treatment with guanidine was carried out in methanol, the methyl derivative (XXIII) was formed via the following scheme:



Scheme 7

The Fischer iso(thio)cyanate method, which is universal and preparatively simple, is mainly used to introduce carbamide or thiocarbamide fragments into positions in the carbohydrate ring other than the glycosidic centre at $C_{(1)}$. The applicability of this method of synthesis is determined by the practical availability of aminosugars with a specified position of the amino-group. The method of synthesis can be illustrated by the synthesis via Scheme 8 of *N*-substituted derivatives of 2-ureido-2-deoxysugars in which it is possible to isolate the following principal stages[63]: protection of the amino-group with the aid of anisaldehyde, exhaustive *O*-acetylation with acetic anhydride in pyridine, removal of the anisidine protection group, and condensation of the acetyl-substituted aminosugar with alkyl or aryl isocyanates. Treatment of the *O*-acetyl-substituted condensation products with an ammoniacal solution of methanol permits smooth deacetylation and the preparation of the unsubstituted derivatives of 2-ureido-2-deoxysugars:

Scheme 8

The bond lengths (Å) and valence angles (degrees) in *N*-methyl-*N*-β-D-xylopranosylurea. The oxygen atoms of the neighbouring groups forming hydrogen bonds with the given molecule (dashed lines) are also shown.

III. THE STRUCTURE AND PROPERTIES OF *N*-GLYCOSYLUREAS

The structure and properties of *N*-glycosylureas have been most thoroughly studied among ureidosugars. The structures of *N*-glycosylureas, demonstrated with the aid of traditional methods of carbohydrate chemistry—periodate oxidation, exhaustive acrylation, acid hydrolysis, and specific synthesis by the isocyanate method—have been described in a review[4]. In the vast majority of the known ureidosugars the carbohydrate residue exists in the cyclic, principally the pyranose form with a 1,2-*trans*-glycosidic linkage[24].

An X-ray diffraction study of *N*-methyl-*N'*-β-D-xylopyranosylurea showed[64] that the carbohydrate ring is in the $C_{(1)}$ conformation, while the carbamide residue has an almost planar trigonal structure (see Figure). The plane of the carbamide residue forms a dihedral angle of 4.5° with the plane of the carbohydrate ring. The valence angles at the atoms of the pyranose ring are close to the tetrahedral value, while the bond lengths are close to the standard $C(sp^3)$–$C(sp^3)$ and $C(sp^3)$–O bond lengths. The $C_{(8)}$–$N_{(7)}$ bond in the urea residue is somewhat lengthened, while the $C_{(8)}$–$N_{(9)}$ bond is somewhat shortened compared with the corresponding bonds in ureas.

The crystals of *N*-methyl-*N'*-β-D-xylopyranosylurea belong to the orthorhombic system ($P\ 2_12_12_1$ group): $a = 6.707$ Å; $b = 8.670$ Å; $c = 15.944$ Å; $\alpha_{calc} = 1.48$ g cm^{-3}; $Z = 4$. In the crystal lattice the molecules are "cross-linked" by hydrogen bonds and give rise to a two-dimensional network in the *ac* plane. Each molecule is involved in four intermolecular hydrogen bonds of the type O–H...O with participation of the OH groups at the $C_{(3)}$ (two bonds) and $C_{(4)}$ atoms as well as the C = O group of the urea residue. The hemiacetal oxygen ring atom and both NH groups are not involved in the system of hydrogen bonds. The hydrogen bonds apparently make the main contribution to the energy of the crystal[64].

The range 1400–1800 cm^{-1}, free from the absorption bands of the carbohydrate residues, is suitable for the identification of *N*-glycosylureas with unprotected OH groups on the basis of absorption spectra[65]. In this region there are characteristic "amide" absorption bands, which frequently make it possible to determine the nature of the substituents at the nitrogen atom (see Table). The band near 1560 cm^{-1}, which is associated with the deformation vibrations of the N–H bond ("the amide-II" band), is a reliable spectroscopic characteristic of the *N*-glycosidic linkage in *N*-glycosylureas. The absorption bands of free urea (at 1625 and 1680 cm^{-1}) do not change significantly when urea is incorporated into a monosaccharide. An absorption band at 1635–1645 cm^{-1} is characteristic of *N*,*N'*-diglycosylureas, while bands at 1630–1640 cm^{-1} (C = O) and 1585–1590 cm^{-1} (N–H) are characteristic of *N*-alkyl-substituted 2-ureido-2-deoxysugars[66]. The replacement of an alkyl substituent in these derivatives by a phenyl group shifts the stretching vibration frequency of the C = O group to 1690 cm^{-1} and lowers the frequency of the deformation vibrations of the N–H

bond to 1540 cm^{-1}. The introduction of a nitroso-group in the *N*-position results in a still greater shift (to 1710 to 1720 cm^{-1}) of the frequency of the C = O group in the -NH-CO-NHR fragment; at the same time the absorption band of the *N*-nitroso-group appears in the range 1450 to 1500 cm^{-1}. Acetylation of ureidosugars results in a marked levelling of the infrared spectra.

The characteristic signals of the anomeric proton and of the protons at the other carbon atoms of the carbohydrate skeleton in the NMR spectra are in general retained for *N*-glycosylureas and 2-ureido-2-deoxy-derivatives. The signal of the hydrogen atom linked to $C_{(1)}$ in the β-anomers of ureidosugars has a chemical shift δ = 6.00–6.34 p.p.m.; as a result of the interaction with the hydrogen atom at $C_{(2)}$, this signal is a doublet and the spin–spin coupling constant J = 9 Hz. The signals of the protons in the carbamide residue (-NH-CO-NH-) are in the range δ = 4.2–5.5 p.p.m. and, together with the signals of the protons of the carbohydrate ring, give rise to an extremely complex group whose complete analysis is possible at working frequencies of spectrometers in excess of 100 mHz.[66]

The "amide" absorption bands of certain *N*-glycosylureas and their derivatives.

Compound	Frequencies, cm^{-1}

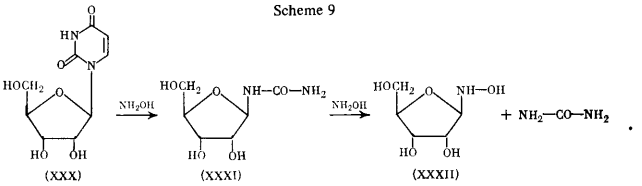
N,N-Dimethylurea	1530, 1634, 1680

The introduction of the carbamide *N*-aglycone leads to an appreciable decrease of the reactivity of the glycosidic centre in relation to nucleophiles without altering significantly the properties of the OH groups of the carbohydrate skeleton and the functional groups of the urea residue. Glycosylureas are stable in dilute solutions of acids and alkali and hydrolyse only in a highly acid medium.



Glycosylureas give a negative response on treatment with reagents for the aldehyde group. In contrast to *N*-glycosides with aglycones of moderate and high basicity ($pK_a \cong 2-10$), glycosylureas do not enter into transamination (*N*-transglycosylation), osazone formation, and anomerisation reactions and do not undergo the Amadori rearrangement under the conditions of the acid–base catalysis typical for these reactions[2,3]. However, it has been shown[27] that heating of tetra-*O*-acetyl-*N*-β-D-glucopyranosylurea in glacial acetic acid leads to the formation of an equilibrium mixture of anomers with approximately 14.5% of the α-anomer.

The reactivity of the glycosidic centre in sugars in relation to nucleophiles is determined by the effective positive charge on the $C_{(1)}$ atom, so that all the factors promoting an increase of the positive charge favour nucleophilic addition and substitution reactions. Such factors include acid catalysis, whose mechanism is described satisfactorily on the basis of the idea that the heteroatom in the glycosidic linkage is protonated.

The rate of the acid-catalysed nucleophilic reaction involving $C_{(1)}$ should increase with increasing basicity (pK_a) of the *N*-aglycone, which agrees with the results of kinetic studies[2]. The replacement of the oxygen atom in monosaccharides and *O*-glycosides by the more basic nitrogen atom in the *N*-glycosidic linkage increases, other experimental conditions being equal, the probability of the protonation of the glycosidic linkage and hence also the rate of nucleophilic reactions involving the $C_{(1)}$ atom. As regards glycosylureas, the pK_a for the basicity of the nitrogen atom involved in the *N*-glycosidic linkage is very low ($pK_a \cong 0.1$) compared with *N*-aryl- and *N*-alkyl-glycosides. The probability of its protonation in moderately acid media is therefore very low. Furthermore, calculations have shown[67,68] that the most probable site of the protonation of urea is the oxygen atom. The protonation of the oxygen atom is energetically favourable, but it does not promote and actually lowers the reactivity of the $C_{(1)}$ centre owing to the decrease of the probability of the protonation of the nitrogen atom of the *N*-glycosidic linkage.

The above factors can account for the relatively high hydrolytic stability and low reactivity of glycosylureas in nucleophilic substitution reactions. In this respect the $C_{(1)}$–N bond in glycosylureas has properties approaching those of the *N*-glycosidic linkages in pyrimidine nucleosides and their analogues. For example, it is instructive that, in the hydroxylaminolysis of cytosine and uracil nucleosides, the heterocycle is the first to be cleaved, the *N*-aglycone being displaced from *N*-β-D-ribofuranosylurea (XXXI) only in the concluding stages of the reaction under fairly severe conditions (see the scheme below):[69]

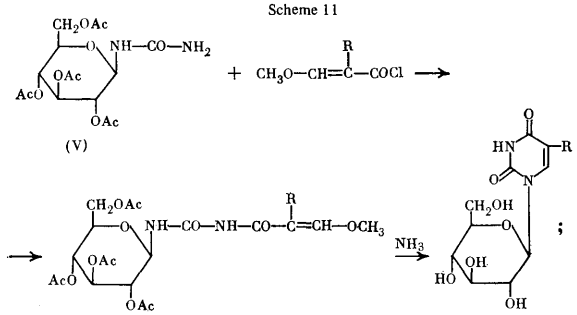
IV. THE REACTIONS OF UREIDOSUGARS AND THE SYNTHESES ON THEIR BASIS

1. The Synthesis of Nucleosides and Their Analogues

Glycosylureas and glycosylthioureas can serve as the starting materials for the synthesis of *N*-glycosides of the pyrimidine series by the cyclisation of the carbamide aglycone on the basis of the known reactions for the formation of pyrimidine systems. One of the first studies in this field was that of Goodman[70], who described the synthesis of 6-amino-*N*-β-D-glucopyranosyluracil (XXXIV) by the Trauber reaction involving the treatment of tetra-*O*-acetyl-β-D-glucopyranosylurea (V) with cyanoacetic acid and subsequent deacetylation of the condensation product (XXXIII) with an ethanol solution of ammonia. The removal of the acetyl protecting groups resulted also in the simultaneous cyclisation of the *N*-aglycone. Goodman obtained in this way a series

of alkyl- and aryl-substituted glucosyl derivatives of 6-aminouracil:

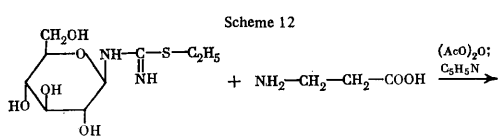


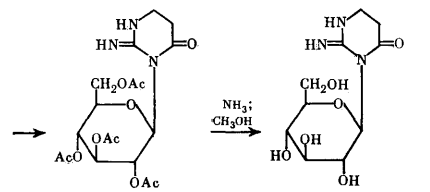
Scheme 10

(V) (XXXIII) (XXXIV)

Japanese investigators[71-76] synthesised pyrimidine *N*-glycosides by the condensation of fully *O*-acetylated *N*-glycosylureas and glycosylthioureas with the chlorides of acrylic and methacrylic acids. Thus β-D-glucopyranosylthymine (XXXVI) has been obtained by the reaction of tetra-*O*-acetyl-β-D-glucopyranosylurea (V) with 3-methoxy-2-methacrylic acid chloride and treatment of the condensation product, tetra-*O*-acetyl-β-D-glucopyranosyl-3-(3-methoxy-2-methylacryloyl)urea (XXXV), with a 3.3% solution of ammonia at 80 °C for 2 h. Under these conditions, the carbohydrate residue is deacetylated and the *N*-aglycone cyclises via Scheme 11. β-D-Arabinopyranosylthymine has been obtained analogously.

Scheme 11



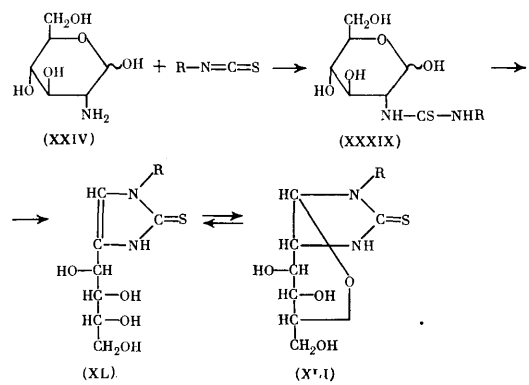


(V) (XXXV) R = CH_3. (XXXVI)

In these syntheses the yields of products reach 60–70% in the stage involving the condensation of the acid chloride with *O*-acetylated glycosylureas and 60% in the stage where the intermediate is deacetylated and cyclises. In terms of efficiency, the above method of synthesis of glycosylthymines is comparable to the method of Ralph and Shaw, which is based on the interaction of α-cyano-β-ethoxycarbonylacrylamide with glycosylamines (see Shabarov's review[77]).

Micheel and coworkers[57,58] synthesised analogues of nucleosides and *N*-glycosides with heterocyclic aglycones using *N*-glycosylthioureas. Thus the glycosyl derivative of hexahydropyrimidine (XXXVIII) has been obtained from *S*-ethyl-*N*-β-D-glucopyranosylthiourea via the following scheme:

Scheme 12



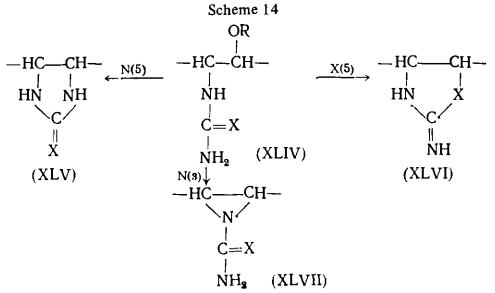
(XXXVII) (XXXVIII)

2. Reactions Involving Neighbouring Groups

In modern carbohydrate chemistry reactions with neighbouring group participation are used to invert the configuration of the carbon atoms and for the stereospecific synthesis of glycosides[1-5,78,79]. Under the conditions of acid catalysis, the collaboration effects frequently lead to migration of the functional groups to neighbouring carbon atoms via intermediate stages involving the formation of acetoxonium, oxazoline, and other heterocycles in the carbohydrate chain. An analogous picture has been observed also for ureidosugars.

The effect of the collaboration of the neighbouring groups in *O*-substituted sugars has been examined in detail[80] in relation to nucleophilic reactions of $C_{(1)}$-acetyl derivatives of sugars. Subsequently the ideas concerning the mechanism of the intramolecular reactions of neighbouring groups were developed by Lemieux[78], but, long before these studies, Neuberth and Wolf[81] established in 1901 that the reaction of D-glucosamine with allyl and phenyl isothiocyanates leads to the formation of stable derivatives of imidazoline-2-thione (XL) (see Scheme 13). It was later shown[82,83] by periodate oxidation and acetylation methods that the condensation product exists in the glucopyranose form (XLI) and it has been observed[84] that in alcoholic solutions the interaction of D-glucosamine with isothiocyanates leads initially to the formation of derivatives of 2-thioureido-2-deoxy-D-glucose (XXXIX), which then undergo an intramolecular cyclisation on treatment with glacial acetic acid with formation of the heterocycle (XL). The interaction of isothiocyanates with products of the Amadori rearrangement leads to analogous derivatives[85].

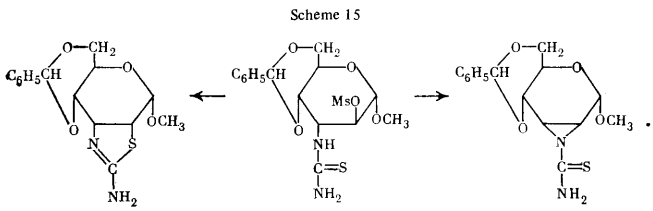
Scheme 13



(XXIV) (XXXIX) (XL) (XLI)

Intramolecular cyclisation of the carbamide and thiocarbamide fragments in a series of alkyl(or aryl)-2-thioureido(or 2-ureido)-2-deoxy-D-glucopyranose yielded[63] a large number of derivatives of 3-alkyl(aryl)-1-aryl-4-(D-arabinotetrahydroxybutyl)-imidazolin-2-ones (imidazoline-2-thiones) (XL).

The mechanism of the collaboration process can be represented by a scheme which provides for intramolecular nucleophilic attack by the heteroatom of the functional group on a neighbouring carbon atom linked to a readily removed substituent (see Scheme 14). The carbamide substituents in general possess three potentially active nucleophilic centres capable of involvement in intramolecular substitution processes. Depending on which of the three centres attacks a neighbouring *trans*-substituent, there is a possibility of $N_{(5)}$-cyclisation with formation of the imidazole ring compound (XLV), $X_{(5)}$-cyclisation accompanied by the formation of heterocyclic structures of the type of (XLVI), and $N_{(3)}$-cyclisation leading to the closure of the aziridine ring (XLVII).



Scheme 14

(XLV) (XLIV) (XLVI) (XLVII)

In a series of studies[86-93] on the synthesis of analogues of nucleosides, reactions with involvement of carbamide[90-92], thiocarbamide[89,92-93] and guanidine[88-91] fragments were investigated in detail and empirical rules were formulated for the determination of the preferential mode of intramolecular cyclisation as a function of the positions of the attacking and leaving (sulphonate ester) groups and the basicity of the medium. As an example, one may quote reactions involving intramolecular substitution in the molecule of methyl 4,6-*O*-benzylidene-3-deoxy-2-*O*-methanesulphonyl-3-thioureido-α-D-altropyranoside (XLVIII). When compound (XLVIII) is kept in boiling pyridine for 1 h, a product with the thiazoline structure (XLIX) is formed in yields up to 70%. When it is treated with sodium methoxide, cyclisation with formation of the aziridine structure (L) takes place:

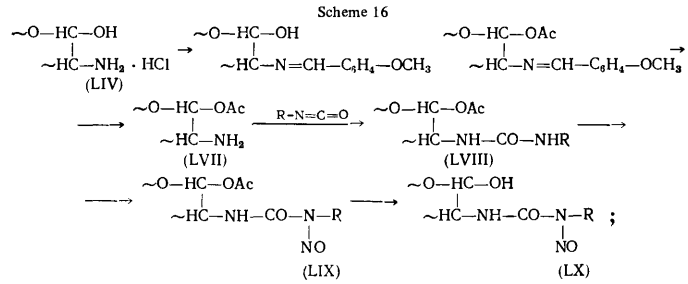
3. Carbohydrate Derivatives of *N*-Alkyl-*N*-Nitrosoureas

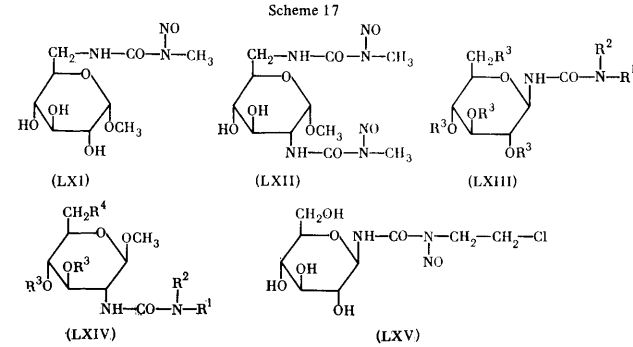


Sugar derivatives with *N*-alkyl-*N*-nitrosocarbamide fragments merit special consideration in view of their exceptionally important role in the chemotherapy of cancer[15,94]. Interest in compounds of this class arose at the beginning of the 1960s after the discovery of the high antileukaemic activity of 1-methyl-1-nitroso-3-nitroguanidine (LI) [95] and 1-methyl-1-nitrosourea (LII).[96] During the same years, the antibiotic streptozotocin was isolated from the culture liquid of streptomycin[97-101] and its structure was then readily demonstrated by specific synthesis from tetra-*O*-acetyl-D-glucosamine and methyl isocyanate with subsequent nitrosation and deacetylation of the condensation product[101]:

(LI) (LII) (LIII)

The preparative syntheses of a number of *N*-alkyl-substituted analogues of streptozotocin via Scheme 16 have been achieved[66,101,102].

Scheme 16



(LIV) (LVII) (LVIII) (LIX) (LX)

R=CH_3, C_2H_5, C_3H_7, C_4H_9 .

The discovery of streptozotocin and the determination of the spectrum of its therapeutic activity (antibiotic, antitumour, etc.) stimulated experimental research into the synthesis of a wide variety of carbohydrate-containing *N*-nitrosoureas as well as tests on their biological activity. In the search for syntheses of selectively acting antitumour agents with a high solubility and a low toxicity, methods of synthesis were developed during a comparatively short time for *N*-nitroso-derivatives of ureidosugars with various locations of the *N*-nitroso-carbamide fragments in the carbohydrate ring and with a wide variety of substituents and carbohydrate residues[103-117].

Japanese investigators achieved considerable successes in this field[104-111]. Derivatives of α-methyl-D-glucopyranoside with one [compound (LXI)] and two [compound (LXII)] methyl-*N*-nitrosocarbamide fragments, *N*-alkyl-*N*-nitroso-derivatives of *N*-β-D-glucosylurea (LXIII), and 1-methyl-β-D-glucosamine (LXIV) have been synthesised and their pharmacological activities have been largely tested (Scheme 17). The derivatives were synthesised by a fairly general method involving the interaction of glucosamine with alkyl isocyanates and nitrosation of the condensation products with sodium nitrite in acetic acid solutions.

Scheme 17

(LXI) (LXII) (LXIII) (LXIV) (LXV)

R′—CH_3, C_2H_5, C_3H_7, C_4H_9; R^2=H, NO; R^3=OH, OAc;
R^4=H, OH, OAc, OMs, NH—CO—N (NO) CH_3 .

It has been shown[118] that the replacement of the CH_3 group in *N*-methyl-*N*-nitrosurea by the 2-chloroethyl fragment increases the antitumour activity in relation to leukaemia; later, monosaccharide derivatives of 1-(2-chloroethyl)-3-(D-glucosyl)urea (LXV) were synthesised and preliminary tests on their antitumour activities were performed[110,119–122].

Comparative pharmacotoxicological studies established[123] that the addition of *N*-methyl-*N*-nitrosourea to the glycosidic centre in unprotected monosaccharides leads to a sharp decrease of the toxicity of the antitumour preparation and to a change of the spectrum of its action in relation to a number of experimental tumour models. It has also been shown that the toxicity and selectivity of the action of carbohydrate analogues of methylnitrosourea depend significantly on the nature of the monosaccharide carrier of the cytotoxic agent. This leads to the possibility for the specific regulation of the pharmacological properties of anticancer preparations by altering the structure of the carbohydrate unit.

Aminoacids as the Amine Component in the Mannich Reaction

A.G.Agababyan, G.A.Gevorgyan, and O.L.Mndzhoyan

The review is devoted to the aminomethylation of the CH-, NH-, and the PH-acid residues by aminoacids. Data are presented on the biological activities of certain Mannich bases derived from aminoacids.
The bibliography includes 132 references.

CONTENTS

I. Introduction 387
II. Aminomethylation of CH-acid residues 387
III. Aminomethylation of NH-acid residues 391
IV. Aminomethylation of PH-acid residues 393
V. Biological properties of Mannich bases derived from α-aminoacids 393

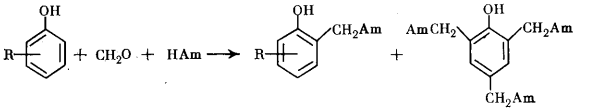
I. INTRODUCTION

Mannich aminomethylation consists in the compensation of the substrate R–H containing at least one active hydrogen atom (alkyl ketones, phenols, various heterocycles, etc.) with formaldehyde (more rarely with other aldehydes) and primary or secondary amines (or ammonia):

$$R{-}H + CH_2O + HN\langle \rightarrow R{-}CH_2{-}N\langle \quad .$$

The great flexibility in the choice of reagents, the wide variety of possibilities for other reactions of the Mannich bases, and mild conditions have made the Mannich reaction one of the important methods of modern organic chemistry.

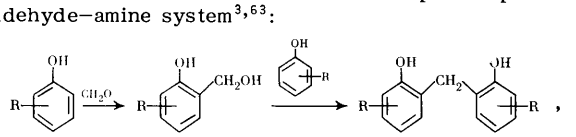
There is an extensive literature on studies of the Mannich reaction, in particular fundamental reviews and monographs[1-7]. However, aminomethylation by aminoacids as a special case of this comprehensively investigated reaction has so far been inadequately dealt with in the literature.



It is known that Mannich bases have a wide spectrum of biological activity[8]. Many of them have found applications in medicine. Thus the hydrochlorides of 4-(n-propoxy)- and 4-(n-butoxy)-β-piperidinopropiophenones (falicaine and dyclonine) are used as local anesthetics[9-11] and the hydrochloride of 4,α-dimethyl-β-piperidinopropiophenone (mydocalm) serves as an anticonvulsant[12]. Certain aminomethyl derivatives of tetracycline (morphocycline, glycocycline, lymecycline) are used in medical practice together with other tetracyclines[13,14]. Antibacterial activity has been observed also in many other Mannich bases[15-19].

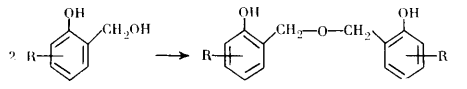
The results of studies during the last 10–15 years indicate anti-inflammatory and pyretic[20,21], spasmolytic[22], adrenolytic[23], H-cholinolytic[12,23-25], and analgesic[26-28] properties of aminomethyl derivatives of ketones, phenols, and various heterocycles. Certain coumarin derivatives stimulate the activity of the respiratory and nervous systems[29]. On the other hand, aminoacids, being an inseparable component of the living organism, have become recently the subject of profound investigation from the standpoint of biological properties. Among synthetic derivatives of aminoacids, anti-inflammatory, antipyretic[30-38], antiviral and antibacterial[32,34,39-46], hypotensive[47-53], anti-tumour[32,36,38,46,54-57], and analgesic[33] substances as well as substances acting on the surface nervous system[34,58,59] have been found. As a consequence of this, the biological properties of Mannich bases obtained when the amino-residue is replaced by an aminoacid residue are of special interest.

The aim of the present review is to survey the available literature data on the aminomethylation of various organic compounds by aminoacids in particular CH-, NH-, and PH-acid residues as well as the data on the biological activity of certain Mannich bases derived from aminoacids.



II. AMINOMETHYLATION OF CH-ACID RESIDUES

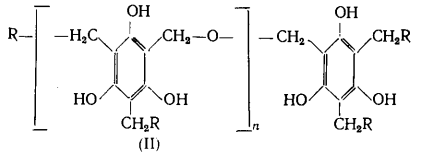
The first communications on aminomethylation by aminoacids refer to phenols[60,61].† When phenols were condensed with formaldehyde and aminoacids, both the usual aminomethyl derivatives of phenols (I, a and b) and polymeric compounds with benzene rings linked by methylene groups were obtained[60]:



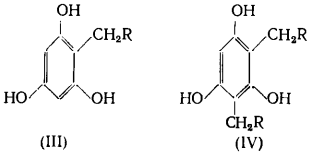
Am = Gly, Ala, Leu, and other aminoacids.

Bearing in mind that phenols are capable of condensing with formaldehyde, apart from the Mannich reaction it is necessary to consider a further two possible pathways [reactions (1) and (2)] in the three-component phenol–formaldehyde–amine system[3,63]:

(1)



(2)

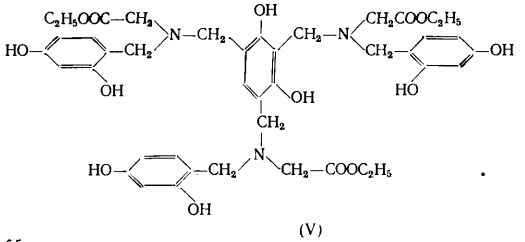


† The Mannich reaction between phenol, iminodiacetic acid, and formaldehyde has also been investigated[62].

Scheme (1) explains the formation of polymeric compounds described in a patent[60].

Later a reaction between aminoacids[64] (particularly glycine), polyhydric phenols, and formaldehydes was investigated#. It has been shown on the basis of ultraviolet and infrared spectroscopic data that the most probable structure of the condensation product is (II):

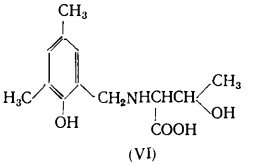
(II)



(III) (IV)

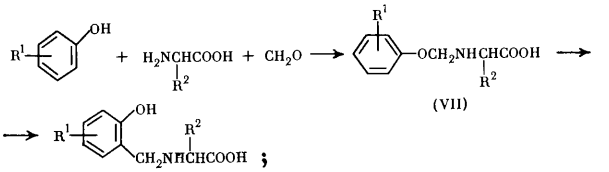
R=NHCH$_2$COOH

Structure (II) corresponds to the condensation product of phloroglucinol, glycine, and formaldehyde taken in proportions of 1:2:6. The possibility of the formation of products (III) and (IV) has also been demonstrated.



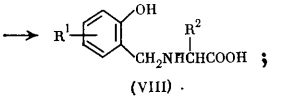
Apart from glycine, other aminoacids as well as di- and tri-peptides have also condensed with phloroglucinol. Thus, according to Gringras and Sjostedt[64], glycine and lycine react with phloroglucinol and formaldehyde to the extent of 90%, the degree of reaction of aspartic acid is 70%, while alanine and leucine react to the extent of 50%.

Data have been published[61] on the aminomethylation of resorcinol by both amines and aminoacid derivatives. In contrast to piperidine and morpholine which led to trisaminomethyl derivatives of type (Ib), ethyl glycinate reacts with resorcinol and formaldehyde to form a product with the tentative structure (V):



(V)

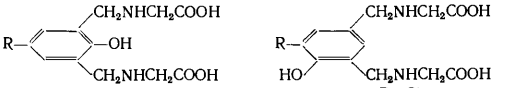
Blass[65] reported the synthesis of the Mannich base (VI)—a derivative of threonine and 2,4-dimethylphenol (yield 67%):



(VI)

As expected, substitution takes place at the *o*-carbon atom of the benzene ring. It has been suggested[66-68] that the aminomethylation takes place initially at the phenolic hydroxyl with formation of the product (VII), which subsequently, on heating to 80–100 °C or under the influence of inorganic acids at 50–60 °C, isomerises to the *C*-aminomethyl derivative (VIII):

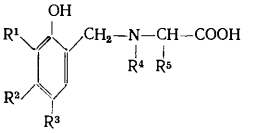
(VII)



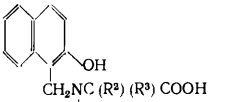
(VIII).

R^2=H; R^1= *p*-Cl, *p*-Br, or *o*-(*m*-, *p*-)OH;
R^2=CH$_3$; R^1=H, *o*-(*m*-, *p*-)CH$_3$, *p*-iso-C$_3$H$_7$, *p*-t-C$_4$H$_9$, or *p*-t-C$_5$H$_{11}$.

However, this mechanism was not confirmed in subsequent studies[69,70].



In the presence of a twofold excess of formaldehyde and glycine, 2,6- and 4,6-bis(carboxymethylaminomethyl)phenols (IX) were obtained[68]:

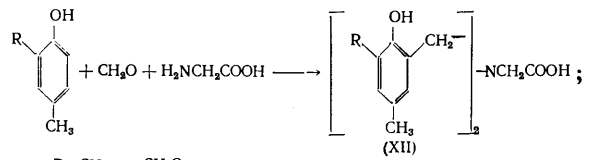


(IXa), R=Br, or F (IXb), R=Cl, or I

2,4,6-Trihalogenophenols and *o*-nitrophenol do not undergo the Mannich reaction with aminoacids under these conditions[68].

The synthesis of Mannich bases derived from phenols, naphthols, and certain aminoacids has been described[71]:

(X)



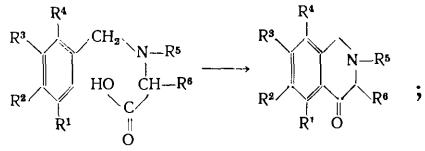
(XI)

(a) R^1=H, R^2=CH$_3$O; R^3=OH; R^4=H, or CH$_3$; R^5=H, or CH$_2$CH$_2$SCH$_3$;
(b) R^1=CH$_3$; R^2=H; R^3=CH$_3$; R^4=H, or CH$_3$, R^5=H, CH$_3$, CH$_2$COOH, CH$_2$OH, or CH$_2$CH$_2$SCH$_3$;
(c) R^1=CH$_3$O; R^2=R^5=H; R^3=CH$_3$, CHO, COOH, or CH$_3$O; R^4=H, or CH$_3$;
(d) R^1=Cl; R^2=R^5=H; R^3=Cl, R^4=CH$_3$.

(a) R^1=H; R^2=CH$_3$, or CH$_2$OH R^3=H, or CH$_3$;
(b) R^1=CH$_3$; R^2=R^3=H.

The authors showed that 2,4-dimethylphenol reacts with formaldehyde and a number of aminoacids (glycine, glutamic acid, alanine, serine, and methionine) to form *N*-benzyl derivatives. Sarcosine condenses successfully with formaldehyde and 2,4-dimethyl-, 2-methoxy-4-methyl-, and 2,4-dichlorophenols.

The reaction of glycine and formaldehyde with 2,4-dimethyl- and 2-methoxy-4-methyl-phenols leads to *N*,*N*-bisbenzyl derivatives (XII)[71]:

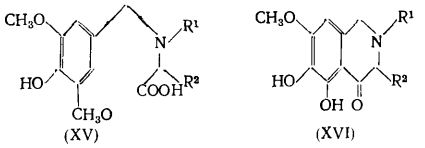


(XII)

R=CH$_3$, or CH$_3$O.

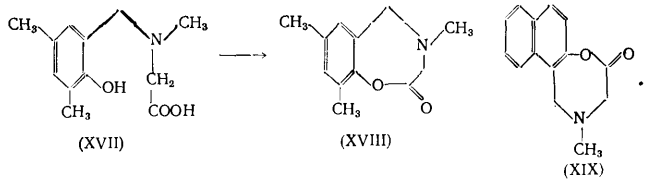
N-Benzylaminoacids (XIII) have been cyclised to derivatives of 1,2-dihydro-4(3*H*)-isoquinolone (XIV)[72]. In particular *N*-(2-hydroxy-3-methoxy-5-methylbenzyl)sarcosine (XIII)

On the basis of the similarity of the ultraviolet spectra of "cross-linked" ("bridged") products formed from gelatin and the products of the Mannich reaction involving aminoacids and peptides, the authors[64] concluded that the reaction mechanisms are similar.



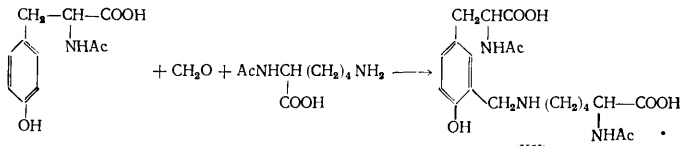
readily cyclises in the presence of sulphuric acid to form 1,2-dihydro-8-hydroxy-7-methoxy-2,5-dimethyl-4(3*H*)-isoquinolone (XIV):

(XIII) (XIV)



$R^1=R^5=CH_3$; $R^2=R^6=H$; $R^3=CH_3O$, $R^4=OH$.

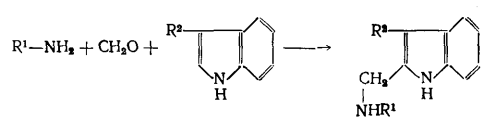
In the cyclisation of *N*-(4-hydroxybenzyl-3,5-dimethoxy)-sarcosine (XV, $R^1 = CH$, $R^2 = H$) and *N*-(4-hydroxybenzyl-3,5-dimethoxy)alanine (XV, $R^1 = H$, $R^2 = CH_3$) the methoxy-group in the 3-position hydrolyses simultaneously with formation of compound (XVI):



(XV) (XVI)

ortho-Substituted phenolic Mannich bases of type (XVII) are capable of being lactonised in the presence of thionyl chloride with formation of benzoxazepins (XVIII). 1,2-Dihydro-2-methylnaphtho[1,2-*f*]-1,4-oxazepin-4(3*H*)-one (XIX) has been obtained in a similar fashion to compound (XVIII)[72]:

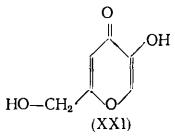
(XVII) (XVIII) (XIX)



Sometimes the aminoacid itself can serve as the CH-acid component. Thus tyrosine, being a phenol derivative, condenses with formaldehyde and lycine to form the "bridged" compound (XX): Lys-CH_2-Tyr[73] (the α-amino-groups of both aminoacids are protected):

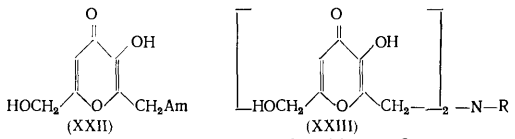
(XX)

The above interaction of aminoacids with formaldehyde and phenol[65] can be regarded as a model of this type of reaction (aminoacid-1-formaldehyde-aminoacid-2). A series of model "cross-linked" systems have been obtained[74,75]. 2,4-Dimethylphenol (model of tyrosine), 3-methylindole§ (model of tryptophan), and alkylamides¶ (models of glutamine and asparagine) have been used as models of aminoacids.



§ However, the indole fragment of tryptophan undergoes the Mannich condensation predominantly as the CH-acid component[77]:

¶ See the next Section for the details of the interaction of aminoacids with amides.

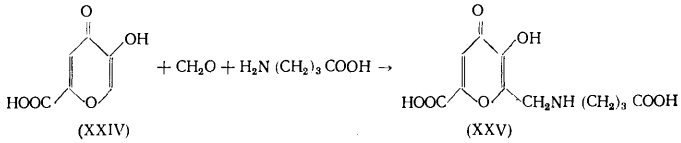


The position of the methylene group has been determined by ^{13}C NMR, which constitutes a convenient non-destructive method for the determination of the location of cross links in peptides treated with formaldehyde.

Thus the possibility of using the Mannich reaction for the synthesis of *C*-aminomethyl compounds in which the amino-fragment is an aminoacid has been demonstrated in relation to phenols. However, it has been suggested[76] that the aminomethylation of phenols by aminoacids involves experimental difficulties (long reaction time and the difficulty of isolating the final products) and cannot be used to synthesise the corresponding aminomethyl derivatives. Nevertheless it was shown[76] that kojic acid (5-hydroxy-2-hydroxymethyl-4*H*-pyran-4-one) (XXI), which is structurally similar to phenol, can be successfully condensed with formaldehyde and a number of aminoacids: glycine, sarcosine, valine, leucine, isoleucine, methionine, and taurine.

(XXI)

The formation of the mono-derivative (XXII) has been noted for all the aminoacids investigated; glycine and taurine, in which both amino-hydrogen atoms are substituted with formation of compound (XXIII), are an exception:

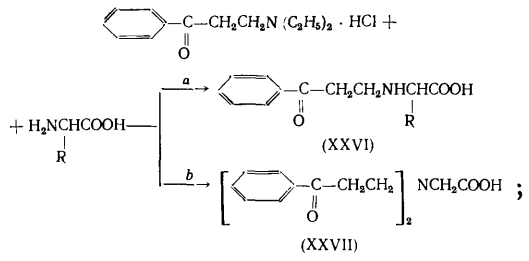


(XXII) (XXIII)

R=CH_2COOH, or $(CH_2)_2SO_3H$.

As was to be expected, aminoacids of different structures condense with formaldehyde and CH-acid components with different degrees of ease. The best results have been achieved in the aminomethylation of kojic acid by valine: heating for 50 min leads to an 80% yield of the final product[76]. This finding and also the lack of differences in the aminomethylation with leucine and isoleucine can be readily accounted for by steric factors.

O'Brien et al.[76] were unable to obtain the aminomethyl derivatives of kojic acid with asparagine, glutamine, aspartic, and glutamic acids, phenylalanine, and tyrosine. They believe that the main reason for the failure of the reaction with phenylalanine and tyrosine is their insolubility in the reaction mixture. In the case of dibasic acids (glutamic and aspartic) the second carboxy-group apparently exerts an inhibiting influence.

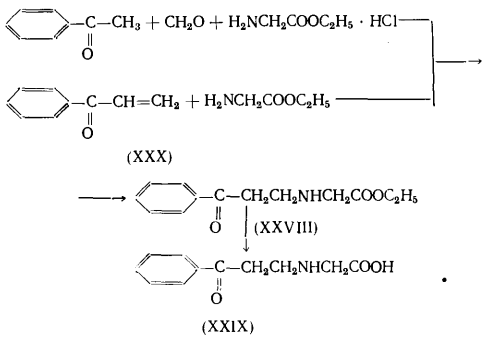


The aminomethyl derivative (XXV) has been obtained by the condensation of γ-aminobutyric acid with formaldehyde and comenic acid (XXIV)[78]:

(XXIV) (XXV)

There are contradictory data in the literature on the aminomethylation of acetophenones. Thus it has been suggested[79] that the Mannich reaction with acetophenones and α-aminoacids hardly occurs and the corresponding aminomethyl

derivatives (XXVI) and (XXVII) have been obtained by the reaction

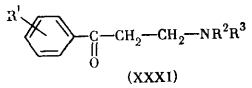


(XXVI)

(XXVII)

a:R=CH_3, CH_2COOH, CH_2CONH_2, $CH_2C_6H_5$;
b:R=H.

However, the ethyl ester[80] of *N*-β-benzoylethylglycine (XXVIII) has been obtained (albeit with a low yield) by the direct condensation of acetophenone, formaldehyde, and the hydrochloride of ethyl glycinate:



(XXX)

(XXVIII)

(XXIX)

N-β-Benzylethylglycine (XXIX) has been obtained by the hydrolysis of compound (XXVIII). Both products have also been synthesised by specific synthesis from acrylophenone (XXX) and glycine or its ethyl ester[80].

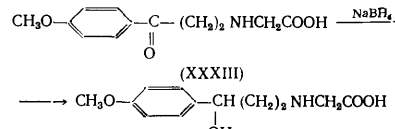
Although one of the convenient methods of synthesising β-aminoketones (derived from α-aminoacids) is in fact the Mannich reaction, many β-substituted aminopropiophenones having the general formula (XXXI) have been obtained by an exchange reaction[81]. The possibility of the aminomethylation of acetophenones by aminoacids via the Mannich reaction has been demonstrated only in relation to *N*-[β-(*o*-hydroxybenzoyl)ethyl]glycine[81]:

(XXXI)

(a) R^2=H; R^3=CH_2COOH; R^1 = *o*-HO, *o*-NH_2, *o*-CH_3O, *o*-C_3H_7O, *o*-iso-C_3H_7O, or *o*-(*m*-, *p*-)C_4H_9O;
(b) R^2=H; R^3=CH (CH_3) COOH (L-, DL-), CH ($CH_2CH_2SCH_3$) COOH (D-, L-, DL-), or CH (CH_2OH) COOH (L-, DL-); R^1 = *o*-HO; *o*-NH_2^*,
(c) R^2=H; R^3=CH [CH (CH_3)$_2$] COOH (D-, L-); R^1=*o*-HO (DL-); *o*-HO, *o*-CH_3O, *p*-Cl, *o*-(*m*-, *p*-)NH_2^*, CH_3CONH^*, *m*-(*p*-)CH_3NH^*, *p*-$C_4H_9NH^*$, *p*-CH_3COO^*, or *o*-(*m*-)Cl^*;
(d) R^2=H; R^3=C (CH_3) ($CH_2CH_2SCH_3$) COOH (DL-); R^1 = *o*-HO, or *p*-HO^*;
(e) R^2=H; R^3=CH [CH_2CH (CH_3)$_2$] COOH (D-, L-); R^1=*o*-HO, *p*-CH_3CONH^*, or *p*-$C_3H_7CONH^*$;
(f) R^2=H; R^3=CH [CH (OH) CH_3] COOH (D-, L-, DL-); R^1 = *o*-HO, *o*-NH_2^*, or *p*-iso-$C_3H_7O^*$;
(g) R^2=H; R^3=CH (CH_2) $CH_2SCH_2CH_3$) COOH (DL-); R^1 = *o*-HO, or *o*-CH_3O^*;
(h) R^2=CH_3; R^3=CH_2COOH; R^1 = *o*-(*m*-)HO, *m*-C_2H_5O, or *p*-C_3H_7COO;
(i) R^2=CH_3; R^3=CH [CH (CH_3)$_2$] COOH; R^1 = *p*-CH_3O^*;
(j) R^2=CH_3; R^3=CH [CH_2CH (CH_3)$_2$] COOH; R^1 = *o*-HO^*;
(k) R^2=C_2H_5; R^3=CH_2COOH; R^1 = *o*-HO;
(l) R^2 = iso-C_3H_7; R^3=CH [CH_2CH (CH_3)$_2$] COOH; R^1 = *o*-HO^*;
(m) R^2=C_4H_9; R^3=CH_2COOH; R^1 = *o*-HO.

† The optical forms of the aminoacid residues are not indicated.

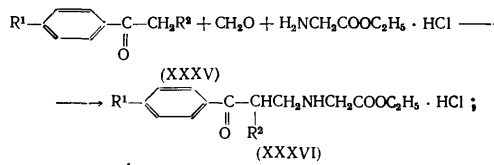
Certain β-aminoketones (XXXII) derived from glycine, alanine, and valine have been synthesised by the Mannich condensation[71]:



(XXXII)

(a) R^1=R^2=H, R^3=C_2H_5;
(b) R^1=4-CH_3O, R^2=H, CH_3, or (CH_3)$_2$ CH, R^3=H;
(c) R^1=4-HO-3-CH_3O, R^2=H, R^3=C_2H_5;
(d) R^1=3-NO_2, R^2=H, R^3=CH_3;
(e) R^1=3, 4, 5-(CH_3O)$_3$, R^2= H, R^3=C_2H_5 .

The authors achieved the best results using a mixture of cyclohexane and t-butyl alcohol as the solvent.

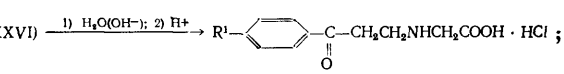


N-[β-(*p*-methoxybenzoyl)ethyl]glycine (XXXIII), obtained by the hydrolysis of the ethyl ester (XXXII, R^1 = 4-CH_3O, R^2 = H, R^3 = C_2H_5), was reduced with sodium tetrahydroborate to the corresponding alcohol (XXXIV)[71]:

(XXXIII)

(XXXIV)

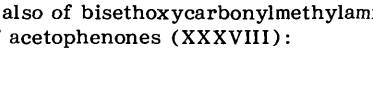
The ethyl esters of *N*-(β-benzoylethyl)-, *N*-[β-(*p*-alkoxybenzoyl)ethyl]-, and *N*-[β-(*p*-halogenobenzoyl)ethyl]-glycines (XXXVIa, R^2 = H) and α-phenyl derivatives of some of them (XXXVIb, R^2 = C_6H_5) have been obtained by the condensation of 4-substituted acetophenones and benzyl phenyl ketones (XXXV) with formaldehyde and ethyl glycinate[82,83]:



(XXXV)

(XXXVI)

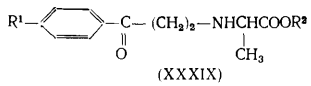
R^1 = H, Alkyl, Cl, or Br.



A number of *N*-[β-(*p*-alkoxybenzoyl)ethyl]glycines (XXXVII) have been synthesised by the hydrolysis of the corresponding ethyl esters (XXXVI)[82]:

(XXXVII)

R^2=H, R^1=H, or alkoxy.

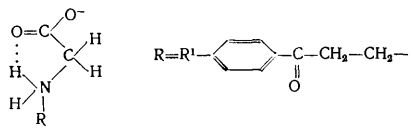


The authors[82] concluded that the aminomethylation of acetophenones with free glycine, as shown by Cymerman-Craig et al.,[79] does not in fact occur. However, condensation with the hydrochloride of ethyl glycinate instead of the free acid takes place in 20–30% yield. It has been shown that, apart from compound (XXXVI), the reaction leads to the formation also of bisethoxycarbonylmethylaminomethyl derivatives of acetophenones (XXXVIII):

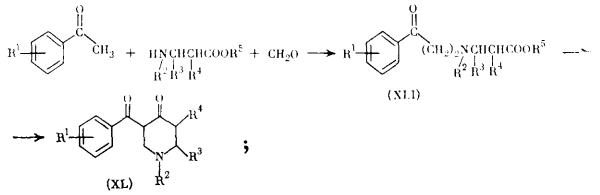
(XXXVIII)

Agababyan et al.[83] published data on the aminomethylation of 4-substituted acetophenones with α-alanine. It was shown that, depending on the reaction conditions and the

reactant ratio, the yields of the aminoketones (XXXIX) vary significantly:



(XXXIX)

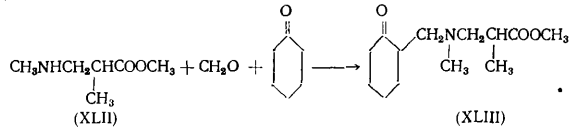


(a) R^2=H; R^1=H, CH_3O, C_2H_5O, C_3H_7O, iso-C_3H_7O, C_4H_9O, Cl, or Br;
(b) R^2=C_2H_5; R^1=C_3H_7O.

Thus, after refluxing for 10 h in ethanol (1:1:1 ratios of the reactants comprising 4-substituted acetophenone, paraformaldehyde, and alanine) at pH 6–7, the yield of the reaction product does not exceed 10–12%, whereas at pH 1–2 and for the same reaction time the yield increases to 28–30%. A change in the reactant ratios (twofold excess of acetophenone and formaldehyde) increases the yields to 30% (at pH 6–7) and 50% (pH 1–2). The replacement of ethanol by dioxan and the use of iron(III) chloride as the catalyst did not increase the yield of the final product. Certain aminoketones (XXXIX, R^1 = H, Br, iso-C_3H_7, or n-C_4H_9) have also been obtained by an exchange reaction[83].

The infrared spectra of *N*-[β-(p-alkoxybenzoyl)ethyl]glycines, their hydrochlorides (XXXVII), and ethyl esters (XXXVIa) have been investigated[84]. It has been established that the secondary amino-group is present only in the esters. In the hydrochlorides (XXXIX) the ketone oxygen forms an intermolecular hydrogen bond with the hydroxy-group of the carboxyl. It has been shown that the length of the alkoxy-group does not affect the intramolecular and intermolecular interactions. It has been suggested that the aminoacid fragment has a cyclic structure:

The Mannich reaction between acetophenones and α-aminoacid esters has been described[85]. The condensation products were further cyclised with sodium hydride to 3-benzoyl-4-piperidinones (XL):

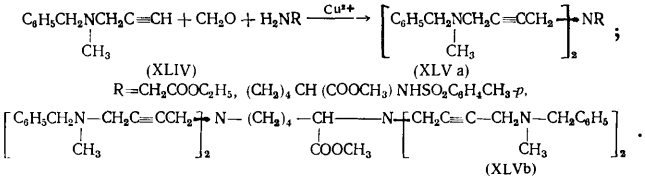


(XLI)

(XL)

(a) R^1=H, or CH_3O; R^2=CH_3, or C_2H_5; R^3=H, or CH_3; R^4=H, or CH_3; R^5=CH_3, or C_2H_5;
(b) R^1=CH_3; R^2=R^4=R^5=CH_3; R^3=H;
(c) R^1=Cl; R^2=R^3=CH_3; R^4=H; R^5=C_2H_5.

The stability of the ketoaminoesters (XLI) varies with their structure; *N*-methyl-substituted Mannich bases are more stable than the *N*-ethyl-substituted derivatives. It has been shown that esters with the methyl group in the α-position cyclise more readily than the esters with the methyl group in the β-position[85].

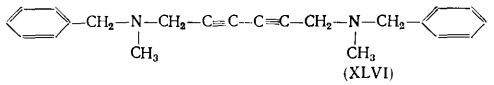


For comparison, a Mannich base has also been obtained from cyclohexanone and methyl β-methylaminopropionate (XLII)[85]:

(XLII) (XLIII)

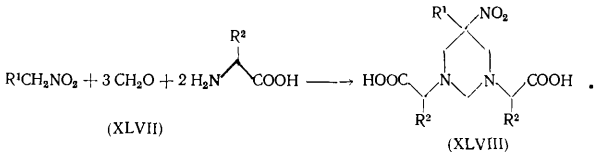
However, the aminomethylation product (XLIII) could not be cyclised.

Acetylene derivatives have also been used as the CH-acid residues in the Mannich reaction. Aminomethylation of pargyline (*N*-methyl-*N*-propargylbenzylamine) (XLIV) with glycine or lysine derivatives yielded the corresponding Mannich bases (XLV)[86]:



(XLIV) (XLV a)

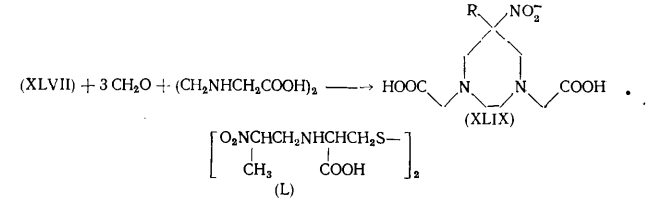
R=$CH_2COOC_2H_5$, $(CH_2)_4CH(COOCH_3)NHSO_2C_6H_4CH_3$-*p*,



(XLVb)

The reaction was carried out at pH 6 in the presence of a catalyst—copper(II) chloride. At pH 9 or 4 pargyline does not react with the amino-component and formaldehyde, being oxidised to compound (XLVI):

(XLVI)



An interesting example of the Mannich reaction is that with nitroalkanes and aminoacids[87]. The hydrogen atoms in compound (XLVII) next to the nitro-group are very mobile, which promotes the cyclocondensation of this compound with two aminoacid molecules and three formaldehyde molecules to form the hexahydropyrimidine (XLVIII):

(XLVII) (XLVIII)

Glycine, β-alanine, valine, leucine, isoleucine, serine, threonine, phenylalanine, and methionine have been used successfully in this reaction (the lowest yield, in the reaction with phenylalanine, is 20%; in the remaining cases it is 60–80%).

In an analogous cyclisation reaction, Roth and Ergenzinger[87] obtained 6-nitro-1,4-diazacycloheptane-1,4-dicarboxylic acids (XLIX) from ethylenediamine-*N*,*N*′-diacetic acid. On the other hand, cysteine condenses with nitroethane and formaldehyde like a normal diamine, with formation of compound (L)—the "normal" Mannich base:

(XLIX)

(L)

However, cysteine does not undergo the Mannich condensation, since the reaction with formaldehyde leads to a cyclic product—thiazolidinecarboxylic acid[87,88].

III. AMINOMETHYLATION OF NH-ACID RESIDUES

Numerous studies[89–95] have been made on the interaction of aminoacids with formaldehyde and compounds containing nitrogen and mobile hydrogen atoms. This applied initially to the amine–formaldehyde–amide and amine–formaldehyde–guanidine coupling reactions, which have been studied by Fraenkel-Conrat and Olcott[91]. It was shown that, over a wide pH range at room temperature, formaldehyde can form

methylene bridges between the amino-group and the primary amide or guanidine NH_2 groups:

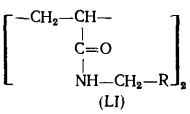
$$R^1{-}NH_2 + CH_2O + H_2N{-}C(=O){-}R^2 \longrightarrow RNH{-}CH_2{-}NH{-}C(=O){-}R^2 \ ;$$
$$R^1{-}NH_2 + CH_2O + H_2N{-}C(=NH){-}NHR^2 \longrightarrow RNH{-}CH_2{-}NH{-}C(=NH){-}NHR^2 \ . \qquad (3)$$

Neutral or acid media are preferable for reaction (3) between aminoacids and amides and between amines and amides respectively. The authors[91] explain this difference by the rapid formation of the cyclic trimers of the amines and formaldehyde in alkaline media. In order to confirm finally the condensation of aminoacids with formaldehyde and amides, the products of the interaction of alanine and proline with formaldehyde and acetamide were isolated.

Before the communication of Fraenkel-Conrat and Olcott[91], the mechanism of reaction (3) was studied inadequately. The authors[91] believe that, like the Mannich reaction, reaction (3) can be regarded as the condensation of a primary or secondary amine (in relation to alanine and proline), formaldehyde, and the NH-acid component—the primary amide group. According to Einhorn[96], an amidohydroxymethyl compound is formed initially. However, according to Fraenkel-Conrat and Olcott[91], despite the fact that the addition of formaldehyde to the primary amide group does indeed occur (this is also indicated by other data[94,95]), it is much slower than the "cross-linking" reaction, i.e. the formation of a methylene "bridge". It has been shown experimentally that the amidohydroxymethyl compound is incapable of subsequent condensation with the amine[91]. Thus reaction (3) proceeds in two stages:

$$R^1{-}NH_2 + CH_2O \xrightarrow{a} R^1NHCH_2OH \ ;$$
$$R^1NHCH_2OH + H_2NCOR^2 \xrightarrow{b} RNHCH_2NHCOR^2 + H_2O \ .$$

The interaction of the amino-group and the aminoacid with formaldehyde# is proved by a number of facts: the decrease of the pH of the reaction mixture and the change in the optical rotation of solutions of the L-aminoacid mixed with formaldehyde. The above two-stage mechanism is also confirmed by the change in the optical rotation of the mixture consisting of an optically inactive amide, an optically active amine, and formaldehyde[89].



Whereas primary amide groups react with formaldehyde comparatively readily[94], secondary amides as well as peptide groups do not react with amines and formaldehyde under similar conditions[91,95].

On the basis of indirect data, some workers have also concluded that the methylene bridge is formed via a reaction of the Mannich type when proteins are treated simultaneously with formaldehyde and glycine[97] or other aminoacids[98]. The tanning effect of formaldehyde is mainly associated with similar reactions. It has been shown that, in a mixture with formaldehyde, aminoacids with a longer molecule act as less active tanning agents than glycine[98].

Apart from the free amide or guanidine groups, the NH group of indole is involved in the "cross-linking" reactions[73] (the aminomethylation of the α-carbon atom of indole was mentioned above[77]).

As already mentioned, aminoacids undergo a Mannich type reaction with NH-acid substrates such as amides; a number of studies have been made on reactions of this kind[106-110].

In particular, a number of communications report the synthesis of polymeric Mannich *N*-bases of type (LI) from *N*-hydroxymethylacrylamide, a free aminoacid, and methylenebisacrylamide[107] or from the acrylamide–methylenebisacrylamide copolymer, formaldehyde, and an aminoacid[108]:

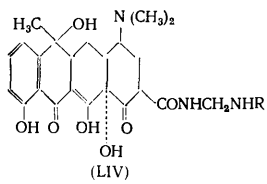
(LI)

Here R is a residue of the optically active aminoacid, including L-proline and L-phenylalanine.

Complexes of polymeric Mannich *N*-bases with copper(II) or nickel(II) salts have been suggested for the resolution of aminoacids into optical isomers[106-108]. The synthesis of alanine derivatives (LII) has been reported[109]:

(LII)

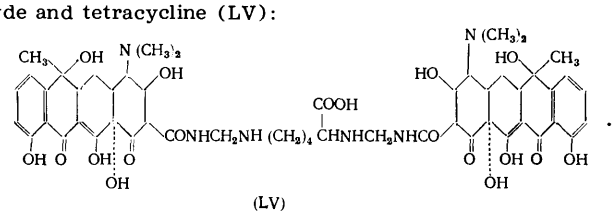
R=CH_3, C_6H_5, 4-$O_2NC_6H_4$, 2-HOC_6H_4, 2,5-$(HO)_2C_6H_3$, or $C_6H_5CH(OH)$.



Aminomethyl derivatives of acetamide (LIII) have been obtained by the reaction of the latter with formaldehyde and certain aminoacids, namely valine [R = $CH(CH_3)_2$], norvaline (R = $CH_2CH_2CH_3$), phenylalanine (R = $CH_2C_6H_5$), and α-aminobutyric acid (R = CH_2CH_3)[110]:

(LIII)

Under these conditions, glycine, β-alanine, and α-aminobutyric acid form a mixture of products which has not been separated.

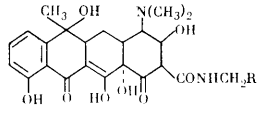


The majority of studies on the aminomethylation of NH-acid compounds have dealt with tetracyclines[14,111-116]. Condensation of aminoacids with formaldehyde and tetracyclines involves the amide group (the Einhorn reaction) with formation of aminomethyl derivatives of tetracycline (LIV):

(LIV)

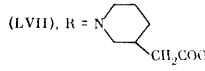
R=CH_2COOH, CH (CH_3) COOH, CH $(CH_2C_6H_5)$ COOH, CH $[(CH_2)_3NH_2]$ COOH, CH $[CH_2CH(CH_3)_2]$ COOH, CH $[CH(CH_3)CH_2CH_3]$ COOH, CH $[(CH_2)_4NH_2]$ COOH, CH $\left[(CH_2)_3NH{-}C(=NH){-}NH_2\right]$ COOH, CH $(CH_2CH_2SCH_3)$ COOH, or $(CH_2)_nCOOH$ (n=3—10).

The results of the aminomethylation of tetracycline by aminoacids such as glycine, α-alanine, phenylalanine, ornithine, and arginine indicate unambiguously the formation of monoaminomethyltetracyclines (LIV)[111,112]. However, it has been shown for lysine that the condensation involving the second amino-group is also possible[113] and that the bis-derivative (LV) is formed in the presence of an excess of formaldehyde and tetracycline (LV):



(LV)

The authors[113] emphasise that not more than two formaldehyde molecules react with lysine.



Numerous studies on this problem have now been carried out[99-105].

Among aminomethyl derivatives of tetracycline, compounds (LIV) with R = $(CH_2)_nCOOH$ and n = 3–10 have been obtained in high yields (up to 87–94% for n = 3–5)[114]. A derivative of γ-aminobutyric acid (n = 3) has also been described[115,116]. A synthesis of aminomethyl derivatives of tetracycline (LVI) and (LVII), in which the amino-fragment consists of residues of piperidine-3(4)-carboxylic and piperidine-3-acetic acids, has been proposed[116]:

(LVI), R =

(LVII), R =

IV. AMINOMETHYLATION OF PH-ACID RESIDUES

PH-acid residues—phosphorus and organophosphorus acids and their derivatives—are also used in the condensation reaction with aminoacids and formaldehyde. Like α-aminomethylphosphonic acids[117], *N*-phosphonomethylglycines have been obtained by a reaction of the Mannich type[118–122]. The *N*-phosphonomethylglycines widely used in practice as herbicides are largely obtained by other procedures[123–126].

N-Phosphonomethylglycine (LVIII) has been obtained by the condensation of dialkyl phosphonate [dialkyl halogen phosphite?] with formaldehyde and glycine followed by the hydrolysis of the resulting dialkyl ester of *N*-phosphonomethylglycine (LIX)[118]:

$$(RO)_2P(O)H + CH_2O + H_2NCH_2COOH \xrightarrow{NaOH} \underset{(LIX)}{(RO_2)P(O)CH_2NHCH_2COOH} \xrightarrow{H_2O(H^+)} \underset{(LVIII)}{(HO)_2P(O)CH_2NHCH_2COOH}.$$

The reaction between phosphorous acid, formaldehyde, and glycine taken in proportions of 2:2:1, leads to the formation of *N*,*N*-bis(phosphonomethyl)glycine (LX) (the authors used a different name—*N*-carboxymethyl-*N*,*N*-bismethylphosphonic acid)[119]. In contrast to compound (LIX), obtained at a low temperature in an alkaline medium[118], compound (LX) was synthesised at 110 °C in the presence of hydrochloric acid:

$$2H_3PO_3 + 2CH_2O + H_2NCH_2COOH \xrightarrow{HCl} \underset{(LX)}{HOOC-CH_2N[CH_2P(O)(OH)_2]_2}.$$

The mechanism of the acid dissociation of *N*-carboxymethyl-*N*,*N*-bismethylphosphonic acid has been studied and the structure of its anionic forms has been established[119].

N-Protected glycines condense with phosphorous acid and formaldehyde to form compounds of the type of Mannich bases. Thus *N*-hydroxy-*N*-phosphonomethylglycine (LXI) has been synthesised from *N*-hydroxyglycine[120]:

$$HO-NHCH_2COOH + H_3PO_3 \xrightarrow{CH_2O} \underset{(LXI)}{HOOCCH_2-\underset{\displaystyle OH}{\underset{|}{N}}-CH_2P(O)(OH)_2}.$$

The condensation of the ethyl ester of *N*-benzylglycine takes place analogously. Having removed the benzyl group, *N*-phosphonomethylglycine (LXIII) can be obtained from *N*-benzyl-*N*-phosphonomethylglycine (LXII)[121]:

$$C_6H_5CH_2NHCH_2COOC_2H_5 + CH_2O + H_3PO_3 \xrightarrow{H_2O} \underset{\displaystyle CH_2P(O)(OH)_2}{\underset{|}{C_6H_5CH_2NCH_2COOH}} \xrightarrow{HBr} \underset{(LXIII)}{HOOC-CH_2-NHCH_2P(O)(OH)_2}.$$
(LXII)

Di(carboxymethylaminomethyl)phosphinic acids have also been synthesised by the Mannich reaction[127]:

$$2C_6H_5CH_2NHCH_2COOH + 2CH_2O + H_2P(O)OH \longrightarrow \underset{(LXV)}{\left[HOOC-CH_2-\underset{\displaystyle CH_2C_6H_5}{\underset{|}{N}}-CH_2\right]_2P(O)OH} \longrightarrow \underset{(LXIV)}{[HOOC-CH_2NHCH_2]_2P(O)OH}.$$

Compound (LXIV), obtained by the debenzylation of the condensation product (LXV) with palladium, was converted into various salts.

Using iminodiacetic acid as the amino-component in the Mannich reaction, compound (LXVI) has been obtained by the mechanism[128]

$$CH_3-P(OH)(CH_2-N(CH_2COOH)_2) \xrightarrow[3)\ \text{ion-exchange resin}]{1)\ H_2SO_4,\ 2)\ H_2O_2} \underset{(LXVI)}{CH_3-P(=O)(OH)(CH_2NHCH_2COOH)}.$$

V. BIOLOGICAL PROPERTIES OF MANNICH BASES DERIVED FROM α-AMINOACIDS

It has been shown[81] that many β-aminoketones derived from aminoacids such as glycine, alanine, valine, serine, methionine, leucine, threonine, ethionine, and α-methylmethionine as well as various salts based on the carboxy- and amino-groups exhibit a high bactericidal activity. The broad spectrum of the bactericidal activity (against both gram-positive and gram-negative micro-organisms) as well as their fungicidal activity suggest the possibility of using this group of β-aminoketones in various branches of industry (for example, the textile and paper industries).

The anti-inflammatory and antipyretic properties of *N*-[β-(*p*-substituted benzoyl)ethyl]glycines, alanines, and the ethyl esters of some of them have been investigated[82,83]. Comparison of the antipyretic and anti-inflammatory properties of the hydrochlorides of the ethyl esters of *N*-[β-(*p*-substituted benzoyl)ethyl]glycines[82] showed that the hydrochloride of ethyl *N*-[β-(*p*-isobutoxybenzoyl)ethyl]glycinate, introduced intra-abdominally in a dose of 50 mg kg^{-1}, exhibits an anti-inflammatory and an antipyretic activity. However, these properties of the preparation were not shown after peroral administration in doses of 50, 100, and 200 mg kg^{-1}.[82]

It has been noted that compounds (XXXVI), (XXXVII), and (XXXIX) have a low toxicity.

The influence of β-aminoketones derived from alanine and glycine, compounds (XXXIX) and (XXXVI) with R = Cl or Br, on the coronary blood circulation has also been studied[83]. Among these, only *N*-[β-(*p*-nitrobenzoyl)ethyl]alanine (XXXIX, R = NO_2) exhibits a weak coronary artery expanding activity. Compared with a series of *N*-[β-(*p*-alkoxybenzoyl)ethyl]- and *N*-[β-(*p*-halogenobenzoyl)ethyl]-alanines (XXXIX, R = alkoxy-group, Cl, or Br) shows that the introduction of the nitro-group in the *p*-position in the benzene ring leads to the appearance of vasodilatory activity.

Three compounds of the series of *N*-[β-(*p*-alkoxybenzoyl)-ethyl]glycines with various substituents (XXXVI, R = C_3H_7O, C_4H_9O, or iso-C_4H_9O) have been tested for their anti-tumour activities. The last two compounds exhibit an anti-tumour activity against Erlich adenocarcinoma (53 and 50% suppression of tumour growth respectively has been observed).

Like tetracycline itself, its aminoacid derivatives are of considerable interest as antibacterial agents. In contrast to other antibiotics of the tetracycline group, the aminomethyl

derivatives (*N*-pyrrolidino- and *N*-morpholino-methyltetracyclines, known as reverin and morphocycline) and, particularly, the aminoacid derivatives (glycino- and lysino-methyltetracyclines—glycocycline[13] and lymecycline§) dissolve much more readily in water. Thus lymecycline is 5000 times more soluble than tetracycline[130]. In terms of their antibacterial activity, aminomethyl derivatives are similar to tetracycline[129–132]. Furthermore parenteral administration of lymecycline does not give rise to local secondary responses, frequently observed when tetracycline is administered[14]. Comparison of reverin and glycocycline showed that, while their therapeutic effects (following intravenous administration) are similar, the latter is preferable because of the absence of side effects[131].

As stated above, *N*-phosphonomethylglycines were used as highly effective herbicides[121–126], fungicides, and plant growth regulators[127].

The Interaction of Metals with Proteins

M.G.Bezrukov, A.M.Belousova, and V.A.Sergeev

Various types of interactions in metal-protein systems are examined, the co-ordinate bonds between metals and proteins and their influence on various levels of organisation in protein molecules are specially considered, and examples of practical applications of metal-protein systems are presented.
The bibliography includes 132 references.

CONTENTS

I. Introduction 397
II. Biological functions and types of interactions in metal-protein systems 397
III. Coordinate bonds between metals and proteins 399
IV. The effect of metals on various levels of the organisation of the protein 401
V. Practical aspects of the applications of metal-protein systems 403

I. INTRODUCTION

There is now a multiplicity of both novel experimental communications as well as reviews concerning various aspects of the interaction of proteins with metal cations (for example, Refs.1–10). However, most of the published studies deal with specific and comparatively narrow aspects of metal–protein interactions. For example, a number of experimental publications exist in the Soviet literature[11–13] reflecting purely structural aspects of the problem, but a distinct deficiency of review publications is felt.

Reitel[14] believes that a protein can be regarded as a system involving interactions characteristic of linear polypeptides containing between 100 and 1000 aminoacid residues. We think that one cannot limit the treatment merely to interactions of polypeptide chains with one another; one must take into account the entire set of interactions of polypeptide chains with one another, with the solvent, and with high-molecular-weight and low-molecular-weight components and the protein must be regarded as polypeptide chains in a system of interactions. One of the significant types of interaction is that with metal cations.

In the present review an attempt is made to follow a combined approach to the consideration of the interaction of proteins with metals against the background of other types of interactions and to assess the role of metals at various levels of the organisation of the protein. This approach has not so far been realised in published reviews; it can promote both a better understanding of the theoretical aspects of the functioning and properties of protein systems and the solution of practical problems which are important for medicine, biology, and biochemistry as well as a new branch of chemical industry—the technology of the isolation and processing of proteins.

II. BIOLOGICAL FUNCTIONS AND TYPES OF INTERACTIONS IN METAL–PROTEIN SYSTEMS

Historically the interest of investigators in metal–protein interactions has been associated primarily with the biological activity of metal ions[15,16]. In 1973 a collected volume of review articles was published under the title "Metal Ions in Biological Systems", in which biological, chemical, and medical aspects of the role of metals *in vivo* are discussed; they include (as a rule in relation to individual specific examples) also the problems of the interaction of metals with proteins (for example, the role of zinc in the functioning of enzymes[19], the importance of vanadium for the vital activity of plants and animals[20], and the role of copper in haemocyanine[21]).

Proteins incorporating a metal in their composition play an important role in biocatalysis and in the metabolism of all living organisms. These proteins have come to be divided into four groups[22,23]: enzymes, redox proteins, transport proteins, and storage proteins. The activity of many enzymes depends on the presence of cofactors, which frequently consist of metal ions; for example, the activities of arginase and carbonic anhydrase depend on the presence of manganese(II) and zinc(II) ions respectively[24].

Table 1. The role of metal ions in biological processes[17].

Metal	Form of location in organism	Strength of binding to protein	Function
Na, K	mobile	low	charge transfer, osmotic equilibrium, transmission of nerve pulse
Mg, Ca	partly mobile	moderate	formation of structures, "trigger" (initiating) reactions, hydrolysis, transfer of phosphate, regulation of cell functions
Mn, Fe Co, Cu, Mo	static	high	catalysis of oxidation-reduction reactions, formation of active centres in enzymes
Zn	static	high	"superacid" catalysts

The group of redox proteins, which are involved in oxidation-reduction processes whereby electrons are transferred in photosynthesis, in the fixation of nitrogen, in mitochondrial respiration, and in the introduction of an oxygen atom into the molecule or in the elimination of a hydride ion, consists of cytochromes and iron- and sulphur-containing proteins (ferredoxin, rubredoxin).[22] Transport proteins—transferrin, ceruloplasmin, iron–porphyrin oxygen-transferring agents (haemoglobin, myoglobin), non-haemin iron-proteins (haemerythrin), and copper-proteins (haemocyanine), and storage proteins (ferritin) regulate the concentration of metals and substrates in the organism, ensuring their presence at the sites where they are needed[25,26].

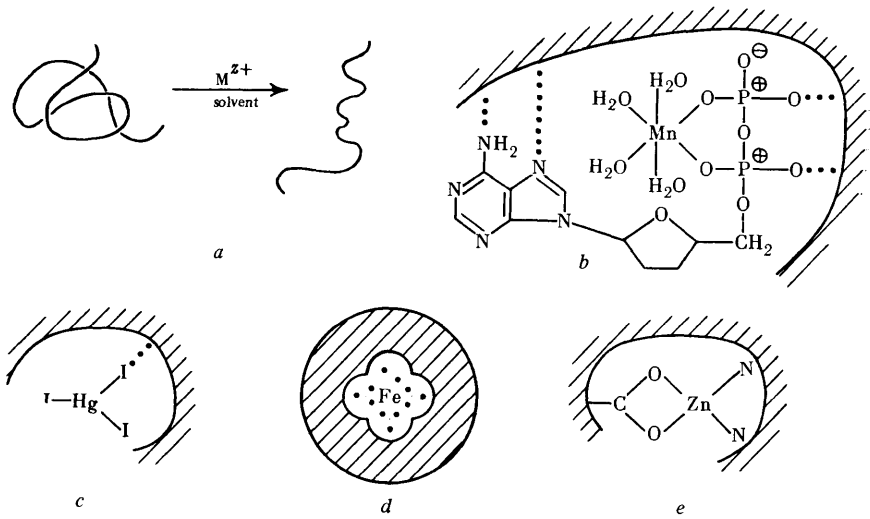

Figure 1. Classification of metal–protein interactions: *a*) indirect interaction via the solvent (lyotropic effect);[27,28] *b*) indirect interaction via an organic ligand[35–37]; *c*) indirect interaction with hydrophobic regions via an inorganic ligand[6,38]; *d*) supermolecular clathrate compounds[39–42]; *e*) coordination interactions with the functional groups of aminoacid residues[19,43].

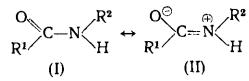
It is also possible to differentiate a fifth group of metal-proteins—kidney proteins responsible for the binding and elimination of heavy metals from the organism, although so far in the literature they are not combined in a separate class and there is no complete information about their physiological role.



In Table 1 [17] an attempt is made to treat systematically the role of metals in biological processes. Evidently the biological activity of metals is not always determined directly by the strength of their interaction with the protein.

Various types of interactions occurring in metal–protein systems are presented below (Fig. 1). The suggested five types of interactions are fairly conventional and do not exhaust all theoretically possible cases. Nevertheless this scheme, which is not free from internal contradictions, permits a systematic treatment of most of the experimental data available at present.

The first type of interaction—mediated by the solvent—involves the interaction of metal ions and proteins (the lyotropic effect, Fig. 1*a*). Since an aqueous medium is most characteristic of natural systems, we shall consider the influence of metal ions on the protein in such media. The stability of the structure of such protein molecules in solution is usually determined by the hydrogen bonds formed by peptide groups, dipole–dipole interaction of polar groups, and hydrophobic interaction[27,28]. The lyotropic effect of metal ions is of a combined type and includes the following versions: interaction with charged groups, interaction with dipoles (including the peptide bond), and weakening of the hydrogen bond[29].

The interaction of metal salts with charged groups of the protein has a significant influence on the solubility of the latter, since association of the cationic and anionic groups on the surface of the protein with counterions leads to the neutralisation of these groups and weakens the electrostatic attraction between protein molecules. As a result, when salts in low concentrations are added, the solubility of the protein increases.

Proteins contain various readily polarisable functional groups capable of interacting with ions and consisting of dipoles. Most of these dipoles are formed by peptide bonds, which can exist in two *meso*-forms (I) and (II):

(I) (II)

By virtue of the double bond between the carbonyl carbon and the nitrogen in form (II), the rigidity of the structure, necessary for the arrangement of the polypeptide chains in native proteins, is ensured. The addition of metal ions can influence the contribution of mesomeric forms (I) and (II), can weaken the double bond character, and can promote free rotation[30].

Under the influence of metal ions, hydrogen bonds can weaken and even fully rupture if the affinity of the polar group for the ion is comparable to the affinity for its analogue in the hydrogen bond. The rupture of the hydrogen bond, which is an element of the native conformation of the protein, leads to the uncoiling of the peptide chain.

Hydrophobic interactions differ from all other lyophobic interactions by the fact that their energy relations are determined by two factors: firstly, the dispersion forces between the non-polar molecules in contact and, secondly, by the change in the structure of the solvent (water) on interaction with non-polar molecules. Contacts between non-polar molecules and water diminish the entropy as a result of the increase of the fraction of ordered elements in water. The minimisation of such contacts (the transfer of molecules to a non-polar environment or their association) is therefore accompanied by an increase of entropy and a shift of the system to a more favourable energy state[31].

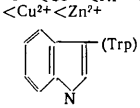
The arrangement of the polypeptide chain in space is such that the hydrophobic aminoacids form the nucleus of the globules, while the hydrophilic aminoacids are distributed on its surface. As a result of electrostatic interaction, the metal ions exert a considerable influence on the structure of

water[32,33], altering the difference between the energies of the water aggregates on the hydrophobic surface of the protein molecule and disturbing the thermodynamic equilibrium in such a way that the aminoacid residue, previously oriented inwards, can become oriented outwards, i.e. the protein molecule with a compact arrangement can uncoil (become denatured). The uncoiling of the molecules results in their aggregation and the reduction of the solubility of the protein. Such increase of the energy of the interaction of protein molecules with one another and the so-called salting out usually occur at high metal salt concentrations in solution[34].

Interactions of the second type are also indirect (via the organic ligand) and occur in bridged complexes (Fig. 1*b*). Such binding is characteristic of many enzymes and transport proteins, including porphyrin-containing proteins[35–37]. In Fig. 1*b* this type of interaction is illustrated schematically for the binding of manganese(II) to creatine kinase via the nucleotide substrate and the formation of a ternary complex: manganese–adenosine diphosphate–creatine kinase[35].

Interactions of the third type are characterised by the addition of heavy metal ions to the protein molecule in hydrophobic pockets (Fig. 1*c*). The addition product is stabilised by van der Waals forces acting between the inorganic readily polarisable ligand and the hydrophobic region of the protein molecule[6,38]. Such addition is characteristic of mercury and gold iodides. In addition, there is a possibility of a direct interaction of certain metal cations with these regions, which is accounted for by the structure of the electron shell of these cations, responsible for their hydrophobic character and the extremely low affinity for water molecules. A high affinity for hydrophobic regions explains the accumulation of Hg^{2+}, Ag^{+}, and Cu^{+} ions in fatty tissues[6].

Interactions of the fourth type involve the formation of supermolecular clathrate compounds formed by storage proteins, a characteristic representative of which is ferritin (Fig. 1*d*). A ferritin species contains 24 identical protein subunits, within which is incorporated an inorganic nucleus approximately 73 Å in diameter containing up to 4500 iron(III) atoms in the form of a basic hydrogen phosphate gel[39–42]: $(FeOOH)_8(FeO{-}OPO_3H_2)$.



Finally, interactions of the last type, which have been most thoroughly investigated, involve the formation of coordinate bonds between the metal and the functional groups of the aminoacid residues in the polypeptide chain. In Fig. 1*e* these are illustrated schematically for the interaction of zinc with a glutamic acid residue and two histidine residues in the enzyme carboxypeptidase A.[19] Interactions of this type play the most significant role in the structure and functioning of metal–protein systems and must be considered in greatest detail.

III. COORDINATE BONDS BETWEEN METALS AND PROTEINS

Metal complexes with aminoacids and peptides have served for many years as model systems for the investigation of the reactions between metals and proteins. An exhaustive review of the literature up to 1968 was published in 1969;[44] in recent years a multiplicity of novel investigations of new metal complexes with aminoacids and of their practical applications have been published[45,46].

However, despite the extensive literature data, on the basis of results of the binding of metals to aminoacids, it is difficult to draw inferences about metal–protein compounds, since the binding of the metal to the functional groups of the protein differs significantly from its binding to the same groups in small peptides and aminoacids, where the cooperative nature of the interaction of the functional groups, which may have approached one another in the tertiary structure of the protein, is very important. On the other hand, the functional groups in the polypeptide chain are separated by tens of aminoacid residues and act comparatively independently of one another, obeying the geometrical requirements imposed by the structure of the protein. This steric structure can change on coordination of the metal ion, which complicates the study of this process still further. The active centres of enzymes are located as a rule in non-polar pockets within the protein structure where the metal ion is coordinated in fact under the conditions of a non-aqueous medium. Furthermore, the number of coordinating groups in the protein is greater than required to bind the metal, so that the metal ion has a "choice". The protein contains groups with unlike charges which can facilitate or hinder the approach of the cation to the potential ligand without being directly involved in complex formation.

Table 2. Classification of metals and ligands in terms of the HSAB theory[6,47–49].*

Type of compound	Class A (hard)	Intermediate	Class B (soft)
Acids	Ca^{2+}, Mg^{2+}, Mn^{2+}, Fe^{3+}, Cr^{3+}, Co^{3+}	$Fe^{2+}<Co^{2+}<Ni^{2+}<Cu^{2+}<Zn^{2+}$	Cu^{+}, Ag^{+}, Hg^{2+}, Pd^{2+}, Pt^{2+}
Bases	H_2O, $RCOO^-$ (Asp, Glu),	 (Trp),	R_2S (Met), RS^- (Cys),
	ROH (Ser, Thr), RNH_2 (Lys, Arg)	$-C_6H_4OH$ (Tyr)	 (His)

*Preferred coordination series: $RCOO^- > RNH_2 > RS^- > H_2O$ in class A and $RS^- > RNH_2 > ROH \gg H_2O$ in class B.

When one comes to consider the probable centres of the interaction of metals with the functional groups of the proteins, one usually begins with the concept of hard and soft acids and bases (HSAB, Table 2).[47–49]. In terms of this concept, all metal ions have acid properties and are divided into hard (class A) and soft (class B). Hard metal ions have a low polarisability as a consequence of their small radii and a high positive charge. They form the most stable complexes with donor atoms which have a high electronegativity, a low polarisability, and small radii and are difficult to oxidise, i.e. with hard bases (for example, N, O, or F). Soft metal ions have a low positive charge and are readily polarised and form the most stable complexes with readily oxidised and polarised ligands—soft bases (for example, S, P, or I). There exist also intermediate acids and bases exhibiting both hard and soft properties depending on the conditions.

In relation to protein systems, hard metal ions endeavour to combine with hydroxy- and carboxy-groups and water molecules. Coordination to sulphur-containing groups and the imidazole residue of histidine is preferred for soft metal ions. Since certain metal ions occupy an intermediate position in this classification, their softness or hardness depends on the bases surrounding them. The arrangement of the metal cations and ligands in the hardness–softness series makes it possible to predict qualitatively the relative strengths of the possible metal–protein coordinate bonds.

Table 3 presents the stability constants of the complexes of certain cations with aminoacids in model experiments and with aminoacid residues in peptides and proteins. Comparison of

the stability constants of metal complexes with aminoacids in Table 3 and the hardness series in Table 2 shows that the majority of cations behave as intermediate species even in the simplest model systems, while the experimental constants for peptide and even more so protein complexes are inconsistent either with the HSAB theory or with the stability constants of the aminoacid complexes. The quantities obtained experimentally in the study of metal–protein equilibria can be referred to as constants only as a matter of convention—the vast majority of the constants published in the literature are stoichiometric quantities calculated for individual complexes within a narrow range of concentrations of both the protein and the cation. The data presented in Tables 4 and 5 show that, in different concentration ranges and at different ionic strengths, different experimental constants can be obtained[57–59].

Table 3. The stability constants of metal complexes of aminoacids ($\lg K$) and aminoacid residues in peptides and proteins ($\lg K'$).*

Aminoacid	Fe^{2+} [51]	Fe^{3+}	Co^{2+}	Ni^{2+}	Cu^{2+}	Zn^{2+}
	lg K					
Glycine	—	7.8	8.9	11.0	15.4	9.3
Aspartic acid	11.4	8.5	10.7	12.7	15.4 [52]	10.4
Glutamic acid	12.1	—	8.1	10.3	14.4 [53]	3.5
Arginine	8.7	—	6.9	9.1	13.8	8.1
Cysteine	—	—	—	—	—	9.9 [55]
Methionine	9.1	—	—	—	—	—
Histidine	4.7	9.3	12.7	15.9	—	12.0
			lgK′			
Cysteine	—	—	—	—	—	7.0 [56]
Histidine	—	—	—	—	3.1—4.4 [54]	2.5 [55]

*Unless otherwise stated, the results were taken from Albert[59].

Note. The numbers in square brackets denote references (Ed.of Translation).

Table 4. The coordination binding of zinc(II) ions to bovine serum albumin.

pH	Medium	t, °C	lg K	References
5—9	0.15 *M* KCl	25	2.9	[57]
6.5	0.2 *M* $NaCH_3COO$	30	3.9	[58]
6.8	0.5 *M* $NaClO_4$	25	9.6	[59]

The scatter of the experimental quantities can be accounted for by many factors. The constant for the binding of a cation by a protein molecule depends on the change of the hardness of the metal in the course of its desolvation and coordination, the changes in the ionic strength of the system, the pH, and the size of the solvation shell, and the conformational changes in the protein. Apart from these factors, account must be taken of the fact that the change in the concentration of the metal ion in a protein solution leads to the binding of the metal at new sites and gives rise to the possibility of oligomerisation or even polymerisation of the protein species, which alters the stability constants. It is at present impossible to take into account all the factors enumerated above in the experimental determination of the binding constant. Thus the determination of the true constant for the binding of the cation to the protein or a specific fragment of the polypeptide chain is very difficult both experimentally and mathematically.

Formally the interaction with the protein can be represented by the equation[6]

$$pM^{z+} + qH^+ + rA^{y-} = M_pH_qA_r^{(zp+q-ry)} ,$$

where p, q, and r are the numbers of metal ions (M^{2+}), protons, and protein molecules (A^{y-}), which form the complex. Here A^{y-} is the base of the polynuclear protein molecule in which all the dissociable protons have been split off.

Despite all the difficulties, significant advances have been made in the quantitative estimates for coordination interactions. As an example, one may quote a study[60] in which the coordination interaction of copper with ribonuclease was considered (Table 5); the sites where copper(II) is coordinated at the functional groups of the aminoacid residues of ribonuclease have been determined exactly.

Table 5. Coordination interaction of copper(II) with ribonuclease[60].

Ligands and their positions in primary structure	Degree of saturation of coordination centre, %		
	pH 5.5; 10^{-5} M $CuCl_2$	pH 5.5; 5 × 10^{-5} M $CuCl_2$	pH 7.0; 3.5 × 10^{-5} M $CuCl_2$
α-NH-R, Lys^{-1}; carboxyl, Lys^{-1}; γ-carboxyl, Glu^{49}; hydroxyl, Ser^{80}	37 ± 4	98 ± 8	24 ± 5
Imidazole, His^{119}; γ-carboxyl, Glu^{111}; H_2O bound to γ-carboxyl, Glu^7	28 ± 4	86 ± 7	33 ± 7
Hydroxyl, Ser^{21}, hydroxyl, Ser^{22}; hydroxyl, Ser^{23}; α-NH-R, Ser^{24}; guanidine, Arg^{39}	27 ± 4	72 ± 11	42 ± 5
Imidazole, His^{105}	14 ± 3	67 ± 8	29 ± 5
γ-Carboxyl, Glu^{86}	13 ± 4	44 ± 8	—
Imidazole, His^{119}, H_2O bound to γ-carboxyl, Asp^{121}	—	—	47 ± 6
Guanidine, Arg^{10}; hydroxyl, Ser^{50}; β-carboxyl, Asp^{53}	6 ± 3	22 ± 7	—

In the study of the interaction of zinc(II) ions with serum albumin (L) various workers observed and demonstrated the existence of several forms of the complex having the general formula Zn_pL_r: ZnL, Zn_2L, Zn_6L_2, $Zn_{16}L_4$ and $Zn_{26}L_6$.[57–59] The formation of $Zn_{16}L_4$ and $Zn_{26}L_6$ is accompanied by the formation of two new bridges comprising zinc(II) ions with a zinc–imidazole binding constant of approximately $10^{3.3}$.

It is of particular interest to note that, although fairly numerous cations can be bound by any protein molecule, there exist certain protein–cation pairs, exhibiting a specific affinity for one another, whose interaction constants, corresponding to certain physicochemical parameters of the medium, are higher by several orders of magnitude than the binding constants for other pairs. This applies primarily to the so-called "metal-dependent" enzymes and the cations participating in the formation of their active centres, for example, zinc(II) in alcohol dehydrogenase[61] and manganese(II) in pyruvate carboxylase[62]. Furthermore, there exist in nature proteins without enzymic activity and having a hitherto unelucidated biological function, which bind selectively certain cations: the Ag-binding protein in rat

liver[63], the Au-binding protein in rat kidneys[64], the Zn-binding factors in rat liver and muscles[65] and in cow's milk[66], and the Cd-binding proteins in the lymph of earthworms[67].

The most probable metal coordination centres in the polypeptide chain are presented in Table 6. The terminal amino-groups (No.1 in Table 6) are the most usual sites for the binding of metals despite their high pK, since the nitrogen atoms of the amino-groups are strongly electron-donating, while the oxygen atoms of the carboxy-group are separated from them by not more than four atoms and can form a chelate ring[50,68]. Coordination to the terminal amino-groups without chelate formation is a much rarer phenomenon and is characteristic of silver and platinum[69,70]. Carboxy-groups (No.2 in Table 6) either participate in chelate formation together with the terminal groups or interact with metals capable of monodentate coordination[19,71,72].

Table 6. Preferred centres for the coordination of metal ions in proteins.

No.	Functional group	Metal	Example of coordination	Refs.
1	Terminal amino-groups	Zn(II), Ag(I), Pt(II)	Pt with α-chymotrypsin	68
2	β,γ-Carboxy-groups (Asp, Glu)	Fe(II), Ag(I), Cu(II), Zn(II), Ca(II), Mn(II)	Zn(II) with Glu residue in carboxypeptidase A	19
	ditto	ditto	Mn with Asp and Glu residues in concanavalin A	69
3	Phenolic OH (Tyr)	—	$(UO_2)^{2+}$ with Tyr residue in tosyl elastase	73
	ditto	—	Fe with Tyr residue in haemerythrin	74
4	Imidazole (His)	Cu(II), Zn(II), Co(II), Fe(II), Ni(II), Cd(II)	Cu(II) with imidazole residue of haemocyanine	75,76
	ditto	ditto	Zn(II) with imidazole residue of insulin	91,23
5	Sulphydryl (Cys)	Ag(I), Hg(II), Mn(II) Fe(II), Co(II), Ni(II), Zn(II), Pb(II), Cu(II)	Cu(II) with Cys residue in "blue" copper-containing proteins	77
	ditto	ditto	Fe with Cys residue in rubredoxin	23
6	Thioester (Met)	Pd(II), Pt(II), Ag(I), Cu(I), Hg(II)	Pt(II) with Met residue in ferricytochrome *c*	80
	ditto	ditto	Cu(II) with Met residue in azurin	23
7	Peptide	Na(I), Ca(II), Co(II), Hg(II), Cu(II), Zn(II), Ni(II), Co(III), Pd(II), Pt(II)	Co(II) and Hg(II) with amide oxygen in biuret	82
	ditto	ditto	Zn(II) with glycylglycine	83

Coordination to metal ions is not very typical for the hydroxy-group of tyrosine (No.3 in Table 6) and the examples in Table 6 [73,74] are perhaps some of the few instances known at the present time. Serine and threonine are more often involved in coordination via the nitrogen atom of the amino-group and the carboxyl oxygen[50,58].

The nitrogen atoms of the imidazole group of histidine are the most important centres for the binding of metals (No.4 in Table 6). The coordination activity of this group can be explained by the fact that the nitrogen of the imidazole groups is an effective electron donor capable of forming stable covalent bonds at the physiological pH.[75,76] The sulphur atoms of methionine, cystine, and cysteine interact preferentially with soft cations (Nos.5 and 6 in Table 6). The sulphur atom is highly polarised in the field of metal ions and is a powerful electron donor. Either monodentate coordination only to the sulphur atom or bidentate complex formation with participation of a nitrogen or oxygen atom in addition to sulphur are usually encountered[77,78,80]. Coordination with participation of a bivalent sulphur atom may be complicated by the oxidation of sulphur to the quadrivalent state and the corresponding reduction of the metal ion[79].

The oxygen of the peptide group (No.7 in Table 6) has weakly basic properties and interacts with metals when chelate formation with participation of a neighbouring amino-group is possible. The oxygen of the peptide group interacts with alkali or alkaline earth metals and this interaction is apparently ionic[81]. The peptide nitrogen binds metals only when the process is accompanied by its deprotonation[84].

IV. THE EFFECT OF METALS ON VARIOUS LEVELS OF THE ORGANISATION OF THE PROTEIN

It may be regarded as firmly established that any local microchemical changes in the protein macromolecule (addition of a low-molecular-weight compound, addition or elimination of the metal, change in the valence of the added metal) [19,29,59,85–96] can lead to significant conformational and configurational rearrangements in the biopolymer. Up to the present time, there is no information about the inclusion in the polypeptide chain of the protein molecule of any fragments other than aminoacids. The question of whether one can assume that the coordination of the functional side groups of the aminoacid and of α-peptide groups to metal cations entails a change in the primary structure is more in the nature of a philosophical-methodological kind and its answer is outside the framework of this review.

The effects of metals on the secondary structure has been most fully studied in relation to collagen[29]. The structural unit of collagen is the cylindrical tropocollagen molecule which consists of three helically intertwined polypeptide chains. The stepwise (with a displacement corresponding to 1/4 of the length) parallel arrangement of the triple helices of tropocollagen ensures the construction of the collagen fibrils. The addition of metal ions to the system can lead either to the stabilisation of the native helical structure of the polypeptide chains of collagen or to their uncoiling and the denaturation of the protein. A series of cations are given below in order of their increasing denaturing effects on collagen[29]:

$$\underset{\text{helix}}{\longleftarrow} \qquad \underset{\text{coil}}{} \qquad WO_4^{2+} < Al^{3+} < NH_4^+ < Rb^+,\ K^+,\ Na^+,\ Cs^+ < Li^+ < Mg^{2+} < Ca^{2+} < Ba^{2+}.$$

The uncoiling of the polypeptide chains of collagen is associated with the increase in the number of groups bearing like charges in the protein under the influence of the metal cations. The repulsion of like charges leads to swelling, an increase in the volume of the molecule, and a rearrangement of the helical chain into a more ordered configuration (coil).

The above series of "dehelicising" activities of cations is valid only in relation to collagen; for other proteins, series of this kind have not yet been set up and may not correspond at all to that illustrated above, particularly since in the organisms of animals (*in vivo*) the coordination of collagen to calcium actually promotes the formation of helices and an increase of the rigidity of the supermolecular formations[85].

The dependence of the catalytic properties of enzymes on the presence of metal cations in solution is a sensitive indicator of the changes in the tertiary structure of the protein. In the case of "metal-independent" enzymes the change in catalytic activity may be caused by the effect of cations,

mediated by the solvent, which induces changes in the physicochemical parameters of the medium. This type of interaction was examined above in Section I. In the case of "metal-dependent" enzymes the change in catalytic activity is associated with configurational changes occurring as a result of the direct coordination of the metal to the protein. The change in configuration and the loss of catalytic activity occur either as a result of the removal of the metal from the active centre, of the competitive replacement of one cation by another, or as a result of the addition of a further metal ion even to one side of the active centre[19].

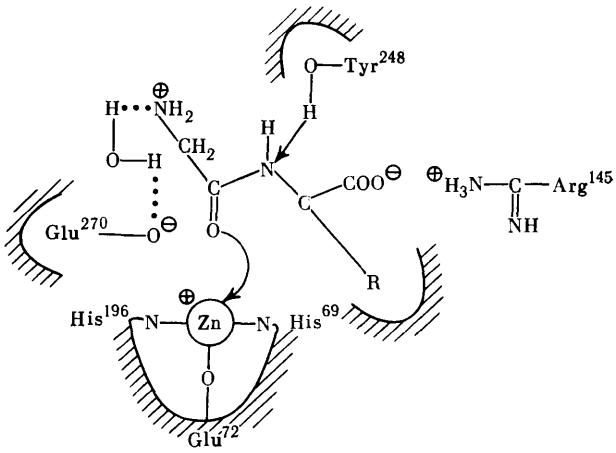


Figure 2. Orientation of the substrate on the surface of carboxypeptidase A.[87]

The optimum catalytic activity, i.e. the existence of the enzyme in the conformational state most favourable for the reaction, is ensured over a comparatively narrow range of concentrations of the added cations. For example, in carboxypeptidase A the Zn^{2+} ion is involved in the orientation of the substrate on the surface of the enzyme molecule (Fig. 2). The removal of the metal leads to a shift of the glutamine (Glu^{270}) and tyrosine residues, subsequent changes in the molecular configuration, and loss of activity[19,86]. An increase of the concentration of the zinc ions in solution is accompanied by the addition of further cations to the enzyme, uncoiling, and polymerisation of the protein molecules via hydrophobic interactions and the formation of salt bridges[59].

In the light of the foregoing considerations, "metal-independent" enzymes strictly speaking do not exist—all enzymes respond to the presence of cations in the system. The only difference is in the concentration of cations giving rise to this effect: Na, K, and Li act indirectly via the solvent and their activity is manifested at high concentrations; Zn, Cd, and Mn, which are coordinated directly to the protein molecule, are active in microamounts.

It is frequently impossible to draw a clear boundary between the changes in the secondary, tertiary, and higher-order structures, since the changes in one of the levels of the organisation of the protein molecule entail the rearrangement of the protein in all its structural levels. This can be well illustrated in relation to the oxygenation of haemoglobin[88,89]. Oxygenation begins with the addition of the O_2 molecule to one of the four haemoglobin sub-units with formation of the O–Fe bond, the iron atom of certain aminoacid residues being displaced from the initial position (Fig. 3). These changes are responsible for further transformations of the tertiary and quaternary structures. After the oxygenation of two sub-units, the molecule as a whole assumes the oxy-configuration, while the two remaining sub-units retain the previous tertiary structure and the latter is now strained, which subsequently facilitates their oxygenation.

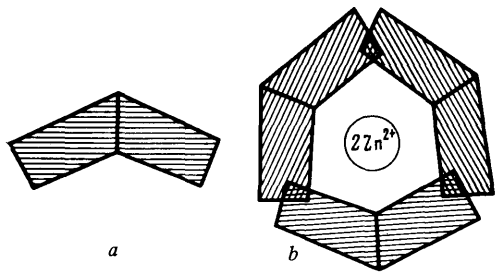

Figure 4. The interaction of insulin with zinc: *a*) dimer; *b*) hexamer.

The change in the quaternary structure has been studied most thoroughly for the interaction of proteins with zinc[90–92]. For example, in the case of insulin, which consists of a dimer comprising two polypeptide chains in solution, the addition of zinc ions results in the formation of a hexamer, in which three dimers are linked to two zinc ions. The coordination

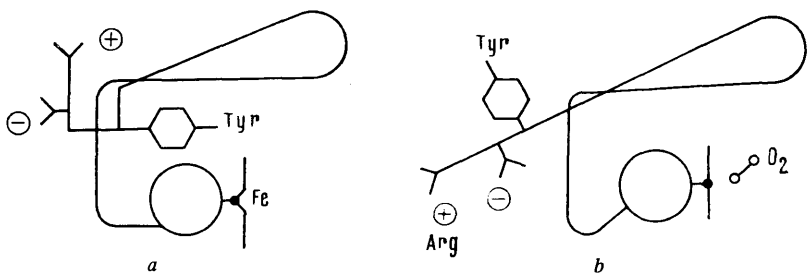

Figure 3. Change in the structure of haemoglobin in the oxygenation process[88]: *a*) deoxy-form; *b*) oxy-form.

of zinc to insulin alters the packing density of the polypeptide chains in the hexamer—they are virtually intertwined with one another (Fig. 4). An increase of the concentrations of the protein and zinc ions in solution increases the size of the aggregates.

In the general case the phenomenon of the aggregation of the protein under the influence of cations is characteristic of solutions of all proteins. The nature of the aggregation depends on the properties and concentration of the protein and the cations. It has been observed[93] that X-ray diffraction by metmyoglobin crystals begins to change when the Zn^{2+} : protein ratio becomes $\geq 3:1$. A further increase of the concentration of zinc ions leads to the disruption of the crystal and the appearance of a brown deposit of the insoluble zinc proteinate. Polymerisation and subsequent precipitation with increase of the concentration of zinc ions have been observed for bovine serum albumin[99]. The interaction of copper(II) ions with insulin also results in the formation of a polymeric protein complex[94].

Table 7. The types of possible steric structures in the aggregation of protein under the influence of cations: $pM^{z+} + rA^{y-} + qH^{+} \rightarrow M_pH_qA_r^{(pz+q-yr)}$.

Type of coordination	Metal	Protein	p	r	Structure
1	Zn^{2+}	Insulin	2	3	soluble species
2	Ca^{2+}, Mn^{2+}, Ni^{2+}	Actin	2	2	fibril formation
3	Ca^{2+}, Mg^{2+}	Casein	3	2	three-dimensional network (gel)
4	Fe^{3+}	Casein	3	1	coagulate
	Zn^{2+}	Metmyoglobin	4	1	coagulate

When actin reacts with calcium, manganese, strontium, and nickel ions, a linear polymer is formed; the interaction with zinc[95] and lanthanum[96] ions leads to non-linear polymerisation. The type of three-dimensional structure produced by the protein as a result of the formation of salt bridges between the protein species is determined by the number of cations which can be bound by the protein species and by the packing density of the species linked by salt bridges (Table 7 and Fig. 5).

When calcium ions are coordinated to actin, each protein species binds not more than two cations and can become aggregated via two salt bridges with not more than two other protein species—aggregates with a linear structure and soluble in water are formed (Table 7, type 2). When calcium ions are coordinated to casein, each casein micelle can bind several ions, which interact with the carboxyl and phosphate groups located on the surface of the caseine micelle. At a protein concentration of 12–15% and a calcuim ion concentration of 0.02–0.1 *N*, a continuous three-dimensional network of protein molecules is formed throughout the volume of the system (Table 7, type 3), which leads to gel formation[97,98]. A decrease of the protein concentration and an increase of the calcium ion concentration lead to closer packing of the protein species, the flocculation of the protein, and the formation of a deposit. Magnesium acts similarly[99]. Iron cations are coordinated to a much greater set of functional groups of the protein molecule than calcium and magnesium, so that the addition of iron to the protein solution gives rise to a closer packing of the protein species owing to a disordered aggregation (Table 7, type 4), which results in precipitation over a wide range of protein and metal concentrations[99].

V. PRACTICAL ASPECTS OF THE APPLICATIONS OF METAL–PROTEIN SYSTEMS

Historically, the practical applications of metal–protein interactions began long before the principal concepts of the chemistry of proteins were formulated. The traditional employment of metal–protein interactions for the conservation of food products and in the leather industry constitute a negligible proportion of the modern applications. Their use is developing most successfully in fields such as biotechnology, the food industry, medicine, and others.

The coordination interaction of polyvalent cations with collagen constitutes the basis of the processes involved in the tanning of leather and furs by aluminium and chromium salts[100–105]. The tanning of collagen-containing material by salts makes it possible to regulate its practically important properties such as resistance to moisture, elasticity, and mechanical strength. Treatment of leather and wool by fluorozirconates[106,107] increases the stability of the material without diminishing its elasticity.

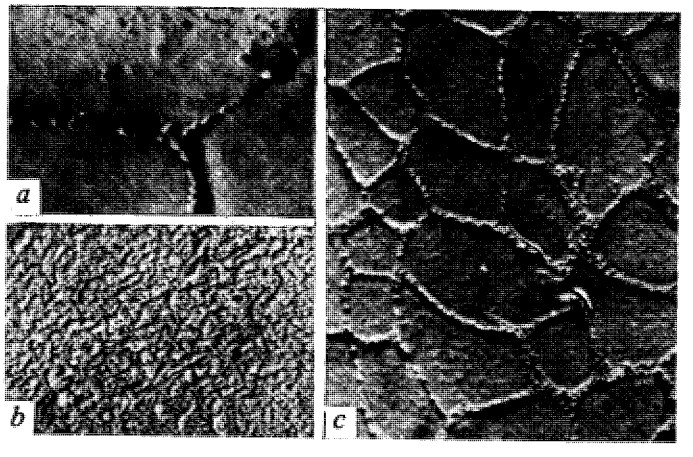

Figure 5. The aggregation of proteins under the influence of metal ions: *a*) fibril-formation; *b*) three-dimensional network (gel); *c*) coagulated material.

Regulation of the solubility of proteins as a result of interaction with salts has found extensive applications in the food industry, in the conversion of isolated protein mixtures into food products. The addition of magnesium and calcium salts to solutions of milk and plant proteins makes it possible to obtain structured systems imitating the fibrous structure of meat products[108,109] and gel-like systems[97,98]. Calcium salts are used to precipitate the lipoprotein complex (the cheese clot) in cheese making[110]. Aluminium salts are used to prepare artificial protein skins for sausages[111] and iron(III) salts serve to increase the mechanical strength of the skins on artificial protein caviare[112,113].

Bivalent and tervalent iron salts are used to precipitate food proteins from very dilute solutions[114–117], which is the most economical method of concentrating and isolating proteins. The converse process is also known—the elimination of heavy metal ions (mercury, copper, lead, tin, etc.) from water by coprecipitation with proteins[118].

Isomorphous complexes of proteins with heavy metals are widely used in electron microscopy[119] and in the X-ray diffraction analysis of proteins[120]. Selective complex formation with certain cations is employed in affinity chromatography for the fractionation and preparative isolation of pure proteins[121,122]. It may be hoped that communications concerning the application of rigorously selective complex formation to the converse problem—the isolation of certain cations from mixtures and dilute solutions—will appear in the immediate future.

Coloured protein complexes of metal cations are used not only for analytical purposes (the biuret reaction with copper salts) [123] but also for the preparation of food dyes (the red colour of the bivalent iron complexes of proteins in the presence of ascorbic acid).[124]

Sodium chloride, which is used traditionally to conserve food products, suppresses the activity of the majority of enzymes at high concentrations. At a certain concentration specific to each enzyme system sodium chloride can activate enzymes. This property has been used in biotechnology for the autolytic processing of the biomass of micro-organisms[125]. Calcium, magnesium, and zinc cations are used to induce the autolysis of micro-organisms[126]. The use of zinc is of greatest interest. The addition of its salts at low concentrations makes it possible to activate selectively enzymes in different groups—for example, one can activate nucleases, leaving proteases in an inactive state[127].

The application of metal–protein interactions in medicine is only just beginning. Quite recently reports have appeared of the detection of antibacterial activity in heavy metal complexes (silver, mercury, and gold) of plant proteins[128]. These studies are extremely promising for the creation of new medicinal preparations with a narrowly specific activity. Peroral administration of the coordination compounds of metal cations and proteins has been suggested for the treatment of disorders caused by the deficiency in the organism of microelements such as zinc, copper, iron, chromium, and manganese[129]. The most promising results have been obtained in the treatment of deficiency of iron[130] and zinc[65].

Supermolecular, colloidal metal–protein compounds, similar to natural clathrate compounds, are also used in medicine. Thus a microdisperse insoluble complex of Fe_3O_4 with serum albumin has been administered intravenously as a special contrasting substance for X-ray studies[131]. Analogous colloidal compounds of CaO and MgO with plant proteins are used to regulate the activity of gastric juice[132].

* * *

Many problems of the structure and functioning of metal–protein systems still await solution. Nevertheless practical necessity requires the employment of metal–protein interactions in various branches of industry, medicine, and science. Each year new applications are being discovered for these systems, while the theoretical problems are still not fully investigated and are hardly likely to be solved in the immediate future.

Most attractive are the prospects for the employment of metal–protein interactions in medicine—for the regulation of enzyme activity and the creation of new drugs with a narrowly specific activity, in metallurgy—for the concentration, isolation, and purification of rare and non-ferrous metals in complex mixtures and dilute solutions (sea water), and in the food industry.

The Chemical Properties of Singlet Molecular Oxygen and Its Importance in Biological Systems

N.V.Shinkarenko and V.B.Aleskovskii

Typical chemical reactions of singlet molecular oxygen with organic substances as well as its disruptive influence on biological systems (the photodynamic effect) are described. The involvement of singlet oxygen in carcinogenesis is demonstrated. A new (luminescence) method of detecting singlet oxygen in solution is discussed. The role of singlet molecular oxygen as an oxidant in polluted city air is noted.
The bibliography includes 232 references.

I. CHEMICAL REACTIONS OF SINGLET OXYGEN WITH ORGANIC SUBSTRATES

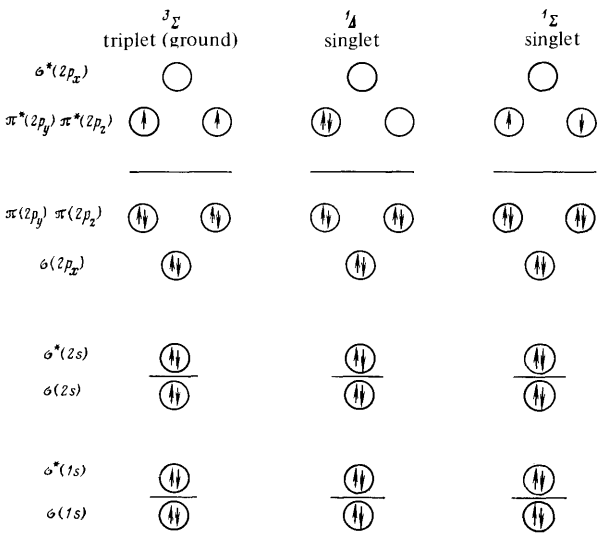
The oxygen molecule has three possible lowest electronic states which differ in the population of their highest-lying molecular orbitals (Fig.1). The first state ($^3\Sigma$) has the lowest energy, since the two electrons in the highest orbitals are located in different regions of space and consequently their mutual repulsion is minimal. The second state ($^1\Delta$) has a higher energy, since greater interelectron repulsion corresponds to two electrons in the same orbital $\pi^*(2p_y)$. The energy of the third state ($^1\Sigma$) is higher still, since its attainment requires the expenditure of a fairly large amount of energy in order to reverse the spin of the electron in one of the π^* orbitals.

The first state is the ground triplet state and the other two are excited singled states. The singlet states $^1\Delta$ and $^1\Sigma$ lie 22.5 and 37.5 kcal mol^{-1} above the ground state[1]. Singlet molecular oxygen is in general designated by $^1O_2$ in contrast to ordinary oxygen which is designated by $^3O_2$ (or simply by O_2). Fig.1 shows that oxygen in the ground state or "triplet" oxygen has two unpaired electrons; it is a stable biradical of the type $^{\cdot}O-O^{\cdot}$ and its chemical reactions are of the free radical type[2]. As an example, one may quote the radical chain autoxidation of isopropyl alcohol:

$$HOC(Me)_2H \xrightarrow[-\dot{O}_2H]{^3O_2} HO\dot{C}(Me)_2 \xrightarrow{^3O_2} HOC(Me)_2O-O^{\cdot} \xrightarrow[-HO\dot{C}(Me)_2]{HC(Me)_2OH} HOC(Me)_2OOH.$$

It was initially postulated[3-6] that the $^1\Sigma$ state must exhibit a similar reactivity. However, it has been established[7] that the $^1\Sigma$ state relaxes in solution to the $^1\Delta$ state over a period of approximately 10^{-10} s and the authors[8,9] therefore concluded that the reactions of $O_2(^1\Sigma)$ cannot be detected. Additional experimental data, confirming this conclusion, have

been obtained[10]; the author of the above study, who used a wide range of photosensitisers to investigate the reactions of singlet oxygen, established that the proportions of the reaction products do not change when the energy of the triplet state of the sensitiser is below the energy required for the formation of $O_2(^1\Sigma)$. Furthermore, according to the theory $O_2(^1\Sigma)$ cannot undergo concerted addition reactions[11], whereas the reactions of singlet oxygen are concerted[12-14]. We shall therefore consider below only the reactions of the $O_2(^1\Delta)$ form.



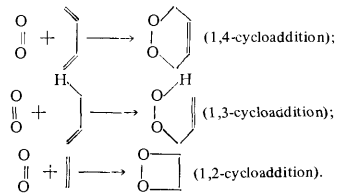


Figure 1. Possible electronic states in the oxygen molecule.

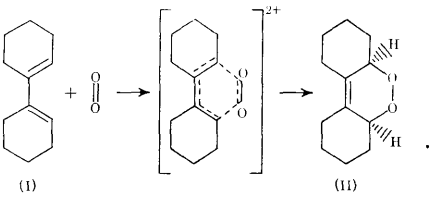
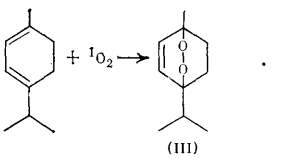
Singlet oxygen in the $^1\Delta$ state is extremely reactive, since, apart from the fact that it has an excess of energy, its lifetime is anomalously long (2700 s in the gas phase at a low pressure and approximately 10^{-5} s in solution).[15,16] The molecule of singlet oxygen in the $^1\Delta$ state can be represented by O=O (Fig.1), i.e. in its electronic structure it resembles ethylene and behaves in reactions as a dienophile[17-19].



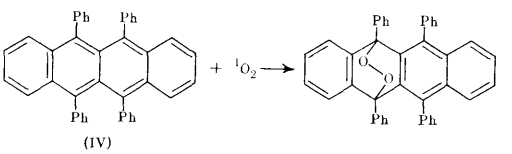
Thus the chemical properties of singlet oxygen in the $^1\Delta$ state are completely different from those of oxygen in the ground state. For example, the characteristic reactions of $O_2(^1\Delta)$ are 1,4-cycloaddition of the Diels–Alder type and 1,3- and 1,2-cycloaddition[11,20-28]:

These three types of reactions give rise to simple methods for the introduction of the peroxy-linkage into organic substrates and are important for the synthesis of new compounds. There is a multiplicity of examples of each type of cycloaddition, only some of which are presented below. More detailed data on the chemistry of singlet oxygen can be found in various reviews[10,11,17,21,22,28-31].

1. 1,4-Cycloaddition (the Endoperoxide Pathway)



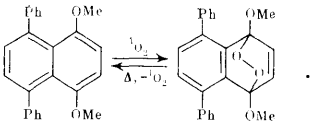
The concerted nature of the reaction involving cycloaddition to dienes has been observed in the addition of oxygen to 1,1'-bicyclohexenyl (I) in the *cis*-conformation. The reaction yields exclusively the *cis*-peroxide (II):[21]



The addition of singlet oxygen proceeds via the formation of a six-membered cyclic transition state, as in the Diels–Alder reaction[10,17].

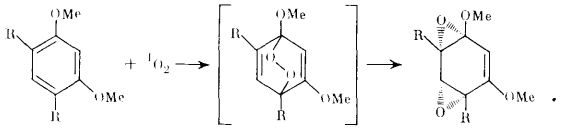
In the study of the effect of temperature on the rate of reaction of singlet oxygen with a series of dienes, it was found that the activation energy varies from zero for the more reactive dienes to approximately 6 kcal mol^{-1} for comparatively inert dienes[32]. The concerted nature of the reaction and the low activation energy for the addition of singlet oxygen to dienes agree with the theoretical results[11].

Numerous studies have been made on the reactions involving the addition of $^1O_2$ to dienes[21,27]. The *endo*-peroxide (III) (ascaridole) was isolated already in the first half of this century from chenopodium oil and was subsequently found to be formed in plant leaves in the course of the chlorophyll-sensitised oxidation of α-terpinene:[33,34]



In the laboratory this reaction was discovered in connection with a fundamental study of the photochemical conversion of steroids into vitamin D,[35] where it was shown that ergosterol gives rise to an *endo*-peroxide on oxidation with a dye sensitiser. Extensive studies on the photochemical oxidation of steroid dienes were subsequently carried out[21] and it was observed that aromatic hydrocarbons, for example rubrene (IV), are converted into *endo*-peroxides under similar conditions:[36]

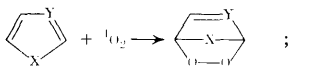
Later numerous studies were made on the photochemical oxidation of polycyclic aromatic and heteroaromatic compounds[21,27,37]. It was found that 9,10-di-substituted anthracenes and polycyclic aromatic compounds which are large molecules react with singlet oxygen almost quantitatively[21,27,37,38]. One should note that, in the photochemical oxidation of hydrocarbons of the acene series, there is no need to employ special sensitiser dyes, since acenes are themselves capable of acting as sensitisers; this also applies to rubrene.



Activated derivatives of naphthalene and benzene also enter into the 1,4-cycloaddition reaction with singlet oxygen; for example, compound (V) can be converted into the *endo*-peroxide (VI):[39]

(V) (VI)

A series of di-, tri-, tetra-, hexa-, and octa-methylnaphthalenes have also been converted into *endo*-peroxides under the influence of $^1O_2$.[40,41]

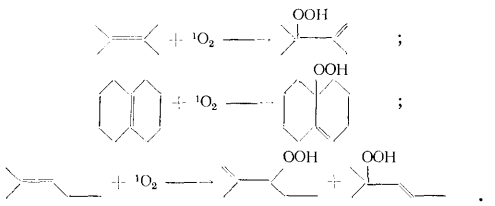


It has been shown that a derivative of resorcinol (VII) is converted into the *endo*-peroxide (VIII) on interaction with $^1O_2$, which results in the formation of the diepoxide (IX):[42]

(VII) (VIII) (IX)

R = t-Bu

A very large series of heterocyclic compounds, particularly five-membered compounds such as furans, thiophens, pyrroles, oxazoles, thiazoles, and imidazoles, undergo the 1,4-cycloaddition reaction with singlet oxygen[21,27]:



X = O, S, NH, NR; Y = CH, N .

endo-Peroxy-products are unstable and are converted into other compounds or are solvolysed.

2. 1,3-Cycloaddition (the Allylic Hydroperoxide Pathway)

In reactions of this type singlet oxygen adds to olefins, forming allyl hydroperoxides, as in the Alder reaction. The 1,3-cycloaddition mechanism has not so far been established exactly; nevertheless this process is of great synthetic importance, particularly for the series of terpenes, which are the main constituents of various essential oils isolated from flowers, fruits, leaves, and other parts of plants[28]. The reduction of allyl hydroperoxides to allyl alcohols can be achieved on an industrial scale in order to obtain synthetic perfumes.

Numerous studies have been made on 1,3-cycloaddition[10,15,17,22,30,43-49]. Some examples of reactions of this type are presented below:

The experimental observations concerning these reactions can be summarised as follows[11]:

(1) Oxygen is always introduced into the part of the molecule from which hydrogen is removed and the double bond always migrates[10,17,22,29,30,50].

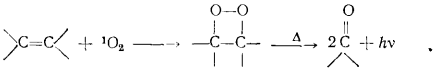
(2) The reaction cannot be inhibited by adding radical trapping agents[50].

(3) For substituted olefins, the ratio of secondary and tertiary hydroperoxides is approximately 1 : 1.[10,17,22,29,30,51]

(4) Groups of substituents which shield the double bond prevent attack by singlet oxygen[52].

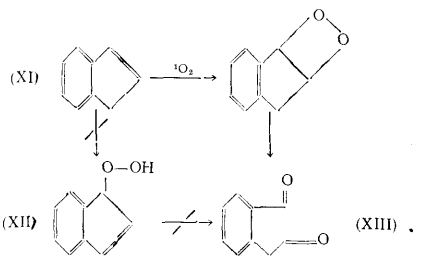
(5) There is no loss of optical activity in the oxidation of optically active olefins[50,53]. Furthermore, comparison of the photochemical oxidation reactions of *cis–trans* olefin pairs has shown that *cis–trans* isomerisation does not occur in the course of the reaction[51].

(6) The reactivity of olefins intensifies after the introduction of alkyl substituents (by a factor of approximately 10 per CH_3 group).[19]



(7) For the majority of olefins, the nature of the solvent has very little influence on the proportions of the products or on the rate of reaction with singlet oxygen[10,17,22,29,30].

(8) There is a satisfactory correlation between the relative rates of reaction of olefins with peracids and with singlet oxygen[19].



(9) There is a large difference between the rates of reaction of various substituted olefins with singlet oxygen and with free radicals. In the case of singlet oxygen the relative reactivity varies by four orders of magnitude depending on the structure of the olefin, while in the case of trifluoromethyl radicals the variation is only by a factor of two.[19]

3. 1,2-Cycloaddition (The 1,2-Dioxetan Pathway)

One of the most interesting achievements in the chemistry of singlet oxygen has been the discovery of a method for the 1,2-cycloaddition of singlet oxygen to olefins, which leads to the formation of "high energy" 1,2-dioxetans, which emit light and decompose into the corresponding carbonyl products[22]:

The first successful synthesis of a stable dioxetan was reported in 1968.[54,55] This was important, since it had been postulated earlier that carbonyl fragments, which frequently appear in photochemical oxidation reactions, arise as a result of secondary reactions of the unstable allyl hydroperoxides formed initially[17] and not as a result of the cleavage of the intermediate dioxetan. In the same year Foote and Lin[56] and also Huber[57] put forward the hypothesis that dioxetan is one of the three possible intermediates in the reaction of singlet oxygen with enamines. The role of dioxetan as an intermediate in the reactions of singlet oxygen with electron-rich olefins was finally established in a study[58], where it was shown that the dialdehyde (XIII), the only product of the sensitised photochemical oxidation of indene (XI), does not arise as a consequence of the rearrangement of the unstable allyl hydroperoxide (XII):[58]

(XI) (XII) (XIII)

There are many examples of rapid reactions of singlet oxygen with olefins despite the fact that the latter are unable to split off hydrogen atoms in allyl positions[59], which may indicate the formation of dioxetans.

Nitrogen-activated olefins such as enamines, bisacrylidylenes[60,61], indoles[62,63], and dipyrrylmethylenes[64] enter into the 1,2-cycloaddition reaction with $^1O_2$. Alkylthio-substituents are just as effective in activating the ethylene bond with respect to oxidation by singlet oxygen. For example, tetrathioethylenes, which are extremely stable in relation to the usual electrophiles and dienophiles, readily combine with $^1O_2$ to form dioxetans[65,66]. Even monothioethylenes undergo 1,2-cycloaddition[67] rather than attack on the sulphur atom by singlet oxygen[68,69].

II. BIOLOGICAL IMPORTANCE OF SINGLET OXYGEN

1. The Photodynamic Effect

Numerous studies have established[70–79] that virtually all types of biological systems, ranging from the simplest unicellular organisms to multicellular plants and animals, can be damaged by the simultaneous operation of the following three factors: light, oxygen, and a photosensitiser (it is usually a dye); this phenomenon was first discovered in 1900 and was called the photodynamic effect[71,72]. The photodynamic effect can lead to the damage of viruses, fungi, algae, and the simplest unicellular organisms, causing mutations, membrane defects, disturbance of metabolism, etc. (up to the lethal outcome). A number of reviews have been devoted to this effect[70,73–81]†.

The photodynamic effect is based on the photosensitised oxidation of the substrate during which the sensitiser molecule S absorbs a light quantum and passes to an excited singlet state ^1S:

$$S + h\nu \rightarrow {}^1S \quad .$$

From the ^1S state, the sensitiser can pass to an excited triplet state ^3S, which has a lower energy but is longer-lived:

$$^1S \rightarrow {}^3S \quad .$$

This state is in fact involved in the majority of photochemical and photophysical processes. Two main types of reactions of sensitisers in the triplet state have been discovered[17,30]. In reactions of type (I) the sensitiser interacts directly with the substrate, the process involving the abstraction of a hydrogen atom or the transfer of an electron, which leads to the oxidation of the substrate and the reduction of the sensitiser[30]. In reactions of type (II) the triplet sensitiser interacts with oxygen.

According to Kautsky's mechanism[82], which is generally accepted nowadays, the interaction of a sensitiser in the triplet state with oxygen in the ground state involves energy transfer from the sensitiser to oxygen, which results in the formation of singlet oxygen $^1O_2$:

$$^3S + {}^3O_2 \rightarrow S + {}^1O_2 \quad .$$

The singlet oxygen formed then attacks the substrate; in biological systems such substrates are, for example, certain aminoacid residues in proteins, the bases in nucleic acids, and the lipids in membranes. The rate constants for processes of type (I) are $\leq 10^7$ litre mol^{-1} s^{-1}, while those for processes of type (II) are greater by two orders of magnitude and amount to 1×10^9 litre mol^{-1} s^{-1}.[79] In this review only type (II) processes will be considered#. The range of the possible photosensitisers is extremely wide; it consists of dyes (Bengal Pink, Methylene Blue, acridines, etc.), natural pigments (chlorophyll, haematoporphyrin, flavins, etc.), and aromatic hydrocarbons (certain anthracenes, rubrene, etc.). The main condition governing the suitability of the compound as a sensitiser for the reactions considered is that the energy of its triplet state should be not less than 22.5 kcal mol^{-1}, i.e. the energy required for the transition of the oxygen molecule to the singlet state.

It is noteworthy that many medicinal substances such as antibiotics, phenothiazines, and sulphonamides are photosensitisers and can therefore give rise to photodynamic damage in the human organism. For example, it has been observed[84] that the antiobiotics tetracycline, oxytetracycline, and griseofulvin cause a pathological sensitivity of human skin to light.

(a) Protection of organisms against the destructive influence of the photodynamic effect. At the end of the 1960's, it was established that carotenoids can protect organisms against the destructive influence of the photodynamic effect[85]. It was shown on model systems[86] that the oxidation of the substrate by singlet oxygen is effectively inhibited by β-carotene.

The hypothesis that carotenoids can protect photosynthesising systems against the photodynamic effect (when they are sensitised by their own chlorophyll) was put forward as early as 1959 on the basis of experiments with carotenoid-free mutants of photosynthesising bacteria[87]. It was observed that these mutant bacteria are rapidly destroyed in the presence of light and oxygen with sensitisation by their endogenic chlorophyll, while normal bacteria, containing carotenoids, are completely stable under these conditions. Cells without carotenoids, obtained by being grown in the presence of diphenylamine, behave similarly to the carotenoid-free mutant[88].

Experiments on the protecting action of carotenoids have been performed also on animals. Thus haematoporphyrin was administered to mice with and without the addition of β-carotene before exposure to light. It was found that β-carotene affords a significant protection against the photodynamic effect[89].

---

† An erroneous lifetime of $O_2(^1\Delta)$ is quoted in the paper of Merzlyak and Sobolev[80] (p.137) (apparently fortuitously); the lifetime of $O_2(^1\Delta)$ generally accepted at the present time is 2700 s (i.e. 45 min).

Bobrovskii and Kholmogorov[83] investigated sensitised photochemical dehydrogenation reactions in model organic systems with the aim of discovering the mechanism of the photodynamic dehydrogenation of the substrates studied (ionol, phenothiazine, and diphenylamine): the question was whether the dehydrogenation is due to singlet molecular oxygen or takes place as a consequence of the direct interaction of the sensitiser in the excited triplet state with the substrate and subsequent dehydrogenation of the reduced sensitiser by oxygen (Santamaria and Prino[84] rule out the electron transfer mechanism because it presupposes the decomposition of the sensitiser, which has not been confirmed experimentally). Tetrapyrrole pigments (chlorophyll, methyl chlorophyllide, phaeophytin, etc.) were used as sensitisers. The authors established that molecular oxygen in the excited singlet state is in fact the active agent responsible for the dehydrogenation of the substrates employed.

These results led to the conclusion that the destructive agent in the photodynamic effect is singlet oxygen and β-carotene protects living organisms against the photodynamic damage by deactivating ("quenching") singlet oxygen. This deactivation takes place via the transfer of the excess energy of excited singlet oxygen to β-carotene, which results in the formation of oxygen in the ground state and β-carotene in the excited triplet state[22,86,90]:

$$^1O_2 + \beta\text{-carotene} \rightarrow O_2 + {}^3\beta\text{-carotene}.$$

Next it was observed that the quenching takes place effectively when carotenes having nine or more conjugated double bonds are used, while quenching by carotenes having seven or fewer double bonds takes place ineffectively or not at all[91].

Another endogenic quenching agent for singlet oxygen is α-tocopherol. The high efficiency of the quenching of $^1O_2$ by α-tocopherol led many investigators to the conclusion that the biological role of this compound consists in protecting the lipid components of biological membranes against oxidation by a singlet oxygen[92–99] (Section II, 1d and II, 3). It was established that there is a correlation between the activity of α-, β-, γ-, and δ-tocopherols as vitamin E and the efficiency of quenching of singlet oxygen by the latter[92,93].

There exist also exogenic quenching agents for singlet oxygen, for example, certain nickel complexes, which are more stable as a function of time than carotenes, since the latter are gradually consumed in the reaction with $^1O_2$.[100] These complexes can be obtained in forms which are soluble either in water or in lipids. 1,4-Diazabicyclo[2,2,2]octane (DABCO) is a very effective quenching agent. However, it was found that this compound is also an effective trapping agent for hydroxy-radicals ($k \cong 2.5 \times 10^9$ mol^{-1} s^{-1}).[101] Sodium azide is also an effective quenching agent, which is readily soluble in water. (For singlet oxygen quenching agents, see also Section II, 3 below.)

Singlet oxygen can be deactivated not only by a quenching agent but also by a chemical trapping agent ($^1O_2$ acceptor); such deactivation gives rise to the corresponding oxidation products in $^1O_2$ cycloaddition reactions. The trapping agent must then satisfy the following criteria[11,102]: a fairly high rate of reaction with $^1O_2$, specificity in relation to $^1O_2$, the absence of complicating side reactions, and ease of analysis of products. Furthermore, the trapping agent must not participate in the generation of $^1O_2$.

Furans are widely used as trapping agents in biology, but, as has been noted by Foote[100], they are not in practice specific, because many othe oxidants, apart from oxygen, oxidise furans to dicarbonyl compounds. Aromatic hydrocarbons giving rise to *endo*-peroxides are more specific[100]. Dimethylcyclohexane gives rise to a characteristic pair of products of interaction with $^1O_2$; it is not very soluble in water, but may be useful in lipid systems[100]. Limonene, which forms six characteristic products of interaction with $^1O_2$, is analogous to the above compound.

According to Foote[100], the best of the probes for $^1O_2$ known at present is the cholesterol system, proposed by Smith and Stroud[102], who concluded that, among the numerous common cell components which might serve as endogenic trapping agents of $^1O_2$ subject to the criteria mentioned above, only unsaturated aliphatic acids and sterols are promising. They showed that cholesterol (cholest-5-en-3β-ol) as well as two other sterols, namely 5α-cholest-7-en-3β-ol and 5α-lanost-8-en-3β-ol, which are present in mammalian tissues, are effective trapping agents for $^1O_2$, satisfying all the criteria enumerated above. The oxidation of sterols by singlet oxygen give rise to hydroperoxides which are completely different from the hydroperoxides obtained in oxidation by normal oxygen (see also Subsections 1c–1e below).

(b) Photodynamic effect on cells and subcellular components. Many types of photodynamic phenomena have been investigated at the cellular level, for example, the loss by the cell of the ability to form colonies, the arrest and anomalies in cell division, the induction of mutations, a decrease of mobility, a change in the permeability of the membrane and in active transport, the loss of ability to maintain the growth of a bacteriophage, etc.[103] These studies were carried out mainly with unicellular organisms such as bacteria[103–108]. In addition, the photodynamic effect has been investigated on cultured mammalian cells. The cessation of growth and destruction of cell enzymes[109], the cessation of mitosis[110], and destruction of cells[111] were observed. There have been reports of damage to cell organelles, but most of the damage is in the nucleus. Many of the mutagenic and lethal effects investigated, manifested in the presence of photo-sensitisers, are due to conformational changes and the breakdown of strands or the destruction of bases in nucleic acids[112].

Depending on which sensitiser participates in the photodynamic effect, the inactivation of the cell can be of three types[113]: (1) when the cell is attacked from the outside and the sensitiser remains outside the limits of the cell; (2) when the cell is attacked from the inside and the sensitiser is located mainly in the cytoplasm; (3) when the cell is attacked from the inside and the sensitiser is bound preferentially to DNA. In these types of inactivation the sites of damage are respectively the cell surface, the cytoplasm (enzymes, RNA, and other subcellular structures), and DNA. An example of a sensitiser of the first type is provided by the dye Toluidine Blue; many thiazine dyes also belong to this category. The second type consists of xanthenes. Acridine dyes, which can cause genetic changes, belong to the third type.

(c) Genetic effects. The photodynamic effect on biological systems in many instances causes damage to genetic material, resulting in mutation or destruction of the system[112]. Genetic effects (more precisely mutations and chromosomal aberrations) have been observed in many biological systems—from viruses and bacteriophages to higher plants and organisms[112,114–118]. The study of the photodynamic inactivation of bacteriophages has shown that the nucleic acid of the bacteriophage is the target for $^1O_2$:[115,116] it was found that guanine is mainly decomposed[117].

The penetration of the sensitiser (dye) into nucleic acid and its attachment are the necessary stages in this effect[118]. Certain acridine dyes, for example, Acridine Orange, are of special interest in the study of the photodynamic mutagenesis in micro-organisms, viruses, and bacteriophages in view of their high affinity for DNA [119] and the ability of being incorporated between neighbouring bases in the DNA helix.[120]

Before the dye is able to exhibit a sensitising effect, it must initially penetrate through the pellicle of the virus. Incubation with a dye in the dark increases the subsequent effect in the light; consequently the penetration of the dye takes place over an appreciable period[112]. It has been shown[121] that only a dye bound within the virus particle is effective. It has also been demonstrated[118] that the molecules of dyes ineffective in inactivating the bacteriophage can also be bound to the active sites of the nucleic acid. When mixtures of effective and ineffective dyes are used, competition for binding by the ineffective dye lowers the degree of inactivation caused by the effective dye[112].

On photodynamic treatment of DNA, many physiochemical changes in its molecule take place in addition to the selective degradation of guanine. The decomposition of DNA after extensive photodynamic treatment using Acridine Orange has been reported[122]. The authors of this study observed a decrease of the melting point of DNA, which indicates

changes in its conformations. They noted that the decrease of the melting point is proportional to the guanine content in the DNA. A decrease of the thermal stability of the DNA of the T4 phage has been observed[117]; the heat-denatured DNA then underwent photochemical oxidation more readily than the native DNA.

The damage to the skeleton of the DNA molecule on treatment has been investigated[123] by noting the changes in viscosity. The authors[123] suggest that the degradation of neighbouring guanine residues leads to the weakening of the bonds in the DNS skeleton.

(d) Photodynamic damage of membranes. The ability of $^1O_2$ to react with lipids has been confirmed in a number of studies[124–128]. The damage to membranes is believed to be caused by the oxidation of lipids as a result of the photodynamic effect[70,73–80]. It has been shown that aliphatic acid derivatives[129] and cholesterol[130] give rise to photochemical oxidation products in which the double bond has been appreciably displaced towards the allylic position, i.e. the interaction of $^1O_2$ with lipids is a 1,3-cycloaddition with formation of hydroperoxides. The rate of reaction of $^1O_2$ with unsaturated aliphatic acids is approximately 1.5×10^3 times higher than for oxygen in the ground state. The non-conjugated hydroperoxides formed in this reaction indicate the involvement of $^1O_2$ in the peroxide oxidation[102,131,132].

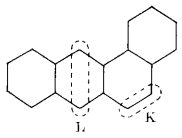
The photochemical oxidation of cholesterol in erythrocytes in the hereditary disease "erythropotic protoporphyria" is a particularly important instance of the peroxide oxidation of lipids by singlet oxygen[94,133]. In this disease 10–100 times more protoporphyrin is observed in the erythrocytes of the patients than under normal conditions. Being an effective sensitiser, protoporphyrin produces singlet oxygen, which damages the erythrocyte membranes. Irradiation of the blood of patients suffering from erythropoetic protoporphyria in the presence of oxygen leads to haemolysis. Singlet oxygen then interacts with the erythrocyte cholesterol, forming cholesteryl hydroperoxide, which induces further haemolysis of the erythrocytes[94,133,134]. It has been observed that internal administration of β-carotene constitutes an extremely effective treatment of this disease[135]. α-Tocopherol also exhibits a protective effect in photohaemolysis[94].

(e) Photodynamic effect on proteins. The first communication about the photodynamic effect on proteins appeared as early as 1903.[136] It was shown that enzymes such as diastase, invertase, and pepsin are inactivated in the light in the presence of eosin. Since then numerous investigations of the photodynamic degradation of proteins, particularly enzymes, have been made[76,77,137]. In all the instances studied the photodynamic damage to the proteins is manifested by a change in the side chains of the aminoacids, but there is no dissociation of peptide or disulphide bonds[76,138].

Of the twenty aminoacids encountered in typical proteins, only five are sensitive to singlet oxygen: histidine, tryptophan, methionine, tyrosine, and cysteine, the first three reacting with $^1O_2$ particularly rapidly[139,140]. The aminoacid residues incorporated in proteins are usually oxidised photochemically more slowly than the same aminoacids in a free state in solution. The incorporation of an aminoacid even in a small peptide can alter profoundly its sensitivity to photochemical oxidation as well as the chemistry of the process[77].

Photodynamic treatment entails a series of physicochemical transformations of proteins as a result of a change in the sensitive aminoacid residues. Changes in solubility[141], surface tension[142], viscosity[143], polarographic behaviour[144], diffusion properties[145], light scattering properties[146], the type of sedimentation[147], optical rotation[147], capacity for assimilation under the influence of proteases[148], binding to metals[149] and coenzymes[150], binding to haem[151], etc. have been noted. The majority of enzymes lose their catalytic activity as a result of photodynamic treatment[76,137], hormones lose their activity[149,152], antigenic properties disappear[137], and the reactivity of antibodies is lost[153].

The aminoacid residues sensitive to photodynamic oxidation change at different rates depending on the reaction conditions and on the protein in which they are incorporated. Thus it is possible to carry out the selective photochemical oxidation of only one type of residue or of a series of residues in proteins using specific sensitisers or reaction conditions. Histidine residues in proteins are known to be sensitive to photochemical oxidation only when the imidazole ring of histidine carries no charge[77]. Thus histidine residues are hardly oxidised photochemically at low pH.[76] Consequently at high pH there is a possibility of the selective oxidation of histidine residues, while at low pH other residues can be oxidised[153–155]. The photochemical oxidation of methionine or histidine forming part of the active centre can be used to investigate the mechanism of enzyme action[156].



Photochemical oxidation has been used in the conformational analysis of proteins[156–158]. By virtue of the three-dimensional structure of the protein, the residues located on its surface are photo-oxidised at a higher rate than those located at different depths within the molecule. It has been established that the rate constants for the photochemical oxidation of histidine and methionine residues on the surface of the protein are 14 times higher than for those located in the bulk of the molecule[159].

If the sensitiser is associated with the protein, a very high degree of selectivity of the photochemical oxidation of aminoacid residues, located in close proximity to one another as a result of the three-dimensional folding of the protein molecule, is ensured. Chromophores can be bound covalently to specific sites in the protein molecule where they can sensitise the photochemical oxidation of sensitive neighbouring residues. Certain proteins can contain chromophores which are capable of sensitising the photochemical oxidation of aminoacid residues nearby. The required proximity of the sensitiser in the residue depends on the photochemical oxidation mechanism. The photodynamic effect then depends on the distance over which singlet oxygen can diffuse in the course of its lifetime[77]. It has been noted[113] that the possibility of different sites for the generation of $^1O_2$ and for its attack is a unique property of singlet oxygen in the photodynamic effect. Thus the migration of $^1O_2$ through a layer of stearate up to 500 Å thick has been demonstrated[160]. The $^1O_2$ molecule can therefore transport electronic energy over fairly long distances[113].

2. The Involvement of Singlet Oxygen in Carcinogenesis

Numerous attempts have been made to find a correlation between the carcinogenic activity of a compound and molecular electronic factors: charge density[161], electron affinity[162], the ability to form charge-transfer complexes[163], the ability to fluoresce[164], and the energy of the lowest triplet state[165]. The correlation proposed by Schmidt[161] and expressed quantitatively by Pullman and Pullman[166] proved to be best. Pullman and Pullman[166] calculated the charge densities for different carcinogens and observed that carcinogenic activity is

related to the charge density in the K and L regions in polycyclic hydrocarbons:

The K region corresponds to addition to two neighbouring carbon atoms, while the L region corresponds to addition to carbon atoms located in the *para*-positions in the ring. The ease of electrophilic addition in the K and L regions is determined by the charge density at the atoms indicated. The K region can be the site of attachment of the hydrocarbon molecule to the components of the cell[167]. It has been shown experimentally that 1,2 : 5,6-dibenzoanthracene is fixed on the protein of the skin precisely via the K region[168].

It has been demonstrated that the L region of polycyclic hydrocarbons could also be involved in binding to the cell protein[168].

On the basis of the discovery that singlet oxygen can be generated on quenching the excited states of organic molecules (sensitisers) by ordinary molecular oxygen[82,169–171] and bearing in mind the properties of $^1O_2$ as an effective oxidant[12], Khan and Kasha[172] proposed a mechanism of carcinogenesis involving the intermediate participation of singlet oxygen.

According to the model of Pullman and Pullman[166], the two necessary conditions for the carcinogenic properties of polycyclic hydrocarbons are the presence of an active K region and the absence of an active L region. On the basis of their calculations, Pullman and Pullman predicted, for example, the carcinogenic activity of 3,4 : 9,10-dibenzopyrene before this was demonstrated experimentally[173]. Pullman and Pullman were forced to introduce very complex indices into their model in order to account for many experimental observations; nevertheless complete success in predicting carcinogenic activity was not achieved. For example, contrary to the model, 2',3' : 3,4 : naphthopyrene is carcinogenic[172], despite the presence of a very active L region.

According to the theory of Khan and Kasha[172], the initiation of photocarcinogenesis requires that the molecule of the bound polycyclic hydrocarbon should continue to absorb natural sunlight. This type of hydrocarbon molecule, altered as a result of binding to the cell (i.e. the part of the molecule remaining after binding—see Fig. 2), has been called[172] the "optical residue". Thus the bound hydrocarbon molecule plays in this model the role of a bound sensitiser generating singlet oxygen. This mechanism of carcinogenic activity can be represented schematically as follows.

(1) Preliminary binding of the hydrocarbon molecule M to a specific component of the cell Q:

$$^1M + Q \rightarrow {}^1M{-}Q \quad .$$

(2) The excitation by light of the molecule formed:

$$^1M{-}Q \xrightarrow{h\nu} {}^1M^*{-}Q \quad .$$

(3) Intersystem crossing to the triplet state:

$$^1M^*{-}Q \rightarrow {}^3M^*{-}Q \quad .$$

(4) Photosensitised formation of singlet oxygen:

$$^3O_2 + {}^3M^*{-}Q \rightarrow {}^1M{-}Q + {}^1O_2 \quad .$$

(5) The reaction of singlet oxygen with DNA bases initiating the carcinogenic process.

In this model there must be a satisfactory rate of intersystem crossing of the residual molecule from the singlet excited to the triplet state and the energies of the electronic states of the residual molecule must be favourable for the photosensitised formation of singlet oxygen (i.e. the energy of the triplet state of the residual molecule must be $\gg$22.5 kcal mole^{-1}).

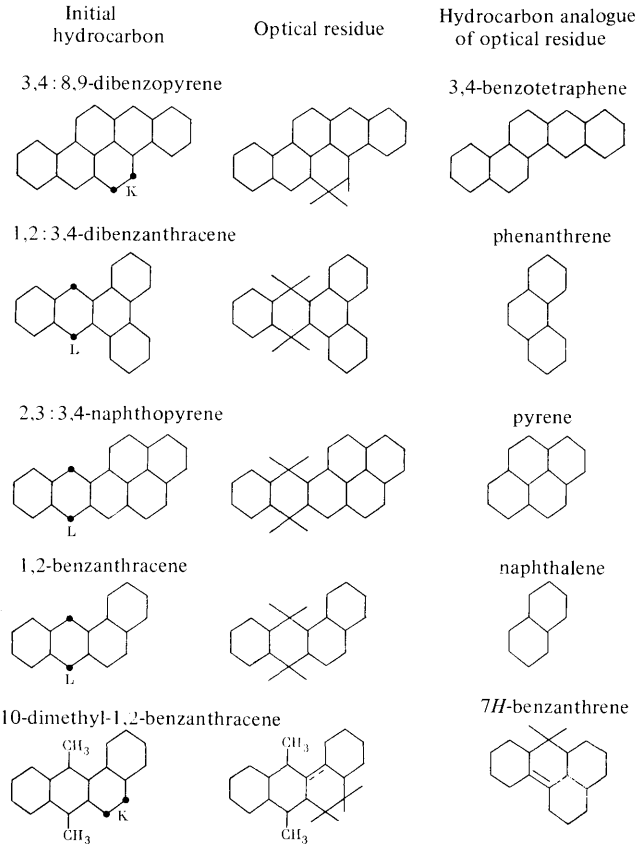


Figure 2. Schematic representation of the optical residues and their hydrocarbon analogues for certain polycyclic hydrocarbons.

Table 1. The absorption of polycyclic hydrocarbons and the analogues of their optical residues after covalent addition to the K or L region[172].

Initial hydrocarbon	λ, nm	Analogue of optical residue	λ, nm
3,4 : 8,9-Dibenzopyrene	480	3,4-Benzotetraphene	410
1,2 : 3,4-Dibenzanthracene	375	Phenanthrene	350
2,3 : 3,4-Naphthopyrene	480	Pyrene	375
1,2-Benzanthracene	390	Naphthalene	317
9,10-Dimethyl-1,2-benzanthracene	390	7*H*-Benzanthrene	350

Khan and Kasha stated that the attachment of the molecule M to the residual cell components via the K or L region shifts two ρ,π orbitals away from the delocalised π-electron system of the polycyclic hydrocarbon molecule as a result of which the optical excitation of the bound molecule requires a higher energy (Table 1), i.e. a blue shift should be observed in the

absorption spectra. The addition via the L region leads as a rule to a more pronounced blue shift of the absorption bands compared with the addition via the K region. This can explain why the presence of an active K region usually favours carcinogenesis, while an active L region normally prevents it. It is noteworthy that the presence of an active L region in the model[172] does not guarantee the absence of carcinogenic activity. Khan and Kasha do not attribute any preferred role to the K or L regions in the induction of cancer; in their model the difference between these regions is determined solely by the optical properties of the residual hydrocarbon from the standpoint of the possibility of the sensitisation of the formation of singlet oxygen.

For example, according to Pullman and Pullman, 3,4 : 8,9-dibenzopyrene (Fig. 2) is a powerful carcinogen, since it has an active K region and has no active L region. Khan and Kasha suggest that the molecule has a carcinogenic activity on the grounds of its optical behaviour, since its addition to a cell component gives rise to an optical residue capable of absorbing sunlight (Table 1). Experimental tests revealed that 3,4 : 8,9-dibenzopyrene is indeed an active carcinogen[172].

The molecule of 1,2 : 3,4-dibenzoanthracene (Fig. 2) has only an active L region and according to the model of Pullman and Pullman should not be carcinogenic. Since addition should displace the absorption spectra to the ultraviolet, Khan and Kasha predicted an insignificant photocarcinogenic activity of this molecule and confirmed this experimentally[172].

The 2′,3′ : 3,4-naphthopyrene molecule (Fig. 2) has no active K region but has a highly active L region and, according to the model for Pullman and Pullman, should not exhibit carcinogenic activity. However, it has been shown experimentally[173] that this compound is a powerful carcinogen. According to the Khan–Kasha model, the residual molecule formed after the addition of the initial molecule via the L region exhibits an optical absorption in the region corresponding to the solar spectrum (Table 1) and for this reason 2′,3′ : 3,4-naphthopyrene should exhibit carcinogenic activity.

Substitution can induce the appearance of carcinogenic activity in molecules which were previously inactive. For example, 1,2-benzoanthracene (Fig. 2) is non-carcinogenic, since the most likely site of the addition of its molecule to the cell component is in the 9,10-positions of the anthracene moiety; such addition shifts the absorption spectrum of the residual molecule to an energically inaccessible region (Table 1). However, the addition of substituents in the 9,10-positions (9,10-dimethyl-1,2-benzoanthracene—Fig. 2) results in the addition of the molecule via the K region rather than the L region and the residual hydrocarbon absorbs sunlight (Table 1). Indeed, 9,10-dimethyl-1,2-benzoanthracene exhibits carcinogenic activity[174].

It is of interest that these planar molecules of polycyclic hydrocarbons—both carcinogenic and non-carcinogenic—are incorporated in DNA molecules[175,176]. Khan and Kasha therefore suggest that the long-lived form of singlet oxygen generated by the residual polycyclic hydrocarbon can diffuse causing oxidation in a very remote section of the DNA chain or can add to certain specific enzyme sites in the cell.

The first experimental test of the theory of photocarcinogenic properties of Khan and Kasha was carried out by its authors[172]. Mice from two colonies (the C_3H breed resistant to cancer of the skin) were smeared with a dilute acetone solution of 3,4-benzopyrene in the standard procedure of the carcinogenic test and were left alone for 5½ months, one colony being placed in a dark room. Twice as many skin tumours appeared in mice living in the normally illuminated room compared with those in the dark room. Control animals living in the dark and normally illuminated rooms did not exhibit this effect.

On the basis of the foregoing, one can conclude that the molecules which are believed to be non-carcinogenic under daylight illumination (the usual wavelength range of solar radiation) can become carcinogenic on irradiation with ultraviolet light.

3. Luminescence in Biological Systems. A New Method of Detecting Singlet Oxygen in a Condensed Phase

Vladimirov[177] began in 1958 studies on ultraviolet luminescence in biological systems; measurements were made with the aid of a photomultiplier cooled with liquid nitrogen and working in the photon counter regime. In 1961 extensive investigations were initiated on the ultraweak glow of tissues and homogenates as well as the glow appearing on oxidation of aliphatic acids (see, for example, Tarusov and Veselovskii[178]).

Among these studies, reactions associated with the action of hydrogen peroxide on biological substrates are especially interesting. An ultraweak glow accompanying the enzymatic decomposition of hydrogen peroxide by catalase, peroxidase, liver homogenates, and yeast and erythrocyte suspensions was observed; the luminescence spectrum was in the range 420–530 nm with maxima at 460 and 510 nm.[177,179] Somewhat later Kachanova and Purmal'[180] confirmed these results, having observed chemiluminescence in the decomposition of H_2O_2 by catalase and metal–amine complexes serving as models of catalase; the emission maximum was observed at approximately 510–520 nm.

In 1966 it was reported[181] that singlet oxygen is formed in the decomposition of hydrogen peroxide by catalase. However, it is claimed[79,182] that singlet oxygen constitutes not more than 0.5% of the entire oxygen formed in this reaction under these conditions. Nevertheless, one can apparently assume that the emission of singlet oxygen is involved in the ultraweak glow occurring in the decomposition of hydrogen peroxide indicated above. The observed region of the $^1O_2$ spectrum includes an emission band at 478 nm, corresponding to the dimolecular transmission[7]:

$$O_2(^1\Delta) + O_2(^1\Sigma) \rightarrow 2O_2(^3\Sigma) + h\nu \quad .$$

Singlet oxygen can then also behave as an intermediate transmitting its excitation energy to other fluorescent molecules[183,184] and can thus participate in luminescence indirectly. There exists yet another mechanism of luminescence involving singlet oxygen. As stated above, $^1O_2$ 1,2-cycloaddition reactions result in the formation of dioxetans, which then decompose into carbonyl-containing fragments, approximately 15% of the fragment molecules being formed in the excited state[185]. This excitation energy can be emitted directly by the fragment or transferred from the latter to a fluorescing molecule[79].

Unfortunately the photomultipliers used to detect the ultraweak glow of plant and animal tissues are insensitive to radiation at wavelengths in excess of 650 nm,[178] while the most characteristic and most intense band in the spectrum of singlet oxygen is at 1270 nm;[11,31,169–171,186] this band corresponds to the $O_2(^1\Delta) \rightarrow O_2(^3\Sigma)$ transition.

The 1270 nm band has been detected by a number of workers in the study of gas-phase systems in the quenching of triplet states of organic compounds by molecular oxygen[11,31,169–171,187,188]. However, in solution it could not be detected for a long time because the lifetime of singlet oxygen in the condensed phase is reduced by eight orders of magnitude compared with the gas phase[7,15,16,184,189,190]. This luminescence band was detected in 1976 by Krasnovskii, Jr.,[191] in air-saturated solutions of various photosensitiser pigments

generating singlet oxygen. The above study[191] was followed by a whole series of investigations by the same author[192–199] who used a sensitive photoelectric technique and solvents (CCl_4, CS_2, and Freon-112) which interact comparatively weakly with $^1O_2$. Aromatic hydrocarbons (anthracene and naphthacene), porphyrins, chlorophylls, bacteriochlorophylls, and phaeophytins were used as photosensitiser pigments. It was found that the spectral region of the flow is independent of the nature of the solvents and pigments.

In all cases a maximum was observed at 1271 ± 1 nm; the emission half-width in spectra recorded using narrow slits (~4 nm) was 18 ± 1 nm, i.e. the glow corresponds to the $^1\Delta$ state of O_2. The luminescence excitation spectra coincided in all cases with the absorption spectra of the photosensitiser pigments. According to Krasnovskii's measurements[192–194], the lifetime of $^1O_2$ in carbon tetrachloride is 28 000 μs, which greatly exceeds the values obtained previously by other workers[202].

Using Krasnovskii's method, it was found that the $^1O_2$ luminescence can be observed in virtually all organic solvents[203] and also in D_2O and H_2O.[195] It is noteworthy that the luminescence quantum yield in D_2O is 400 times smaller than in CCl_4 and amounts to approximately 1.2×10^{-7} and measurement of the $^1O_2$ luminescence in H_2O involves considerable difficulty and a distinct emission maximum could not be observed in H_2O; however, this maximum has been observed largely on diluting D_2O with ordinary water up to the 1 : 1 ratio.

In the study of the above systems Krasnovskii concluded that two processes compete in solutions: photosensitised generation of $^1O_2$ and its quenching in collisions with non-excited sensitiser molecules[192]. He showed that porphyrins, their complexes with zinc, magnesium, and cadmium, chlorophylls, phaeophytins, and retinals effectively generate singlet oxygen[191–198]. Krasnovskii used the quenching of the $^1O_2$ luminescence as a method for investigating the reactivity of $^1O_2$ with respect to various compounds. This method is undoubtedly more accurate than the chemical methods employed hitherto and based on measurements of the rate of consumption of $^1O_2$ trapping agents introduced into the system investigated.

In the course of these experiments it was observed that porphyrins, chlorophylls, and phaeophytins are also effective quenching agents[192–198]. Metal complexes of porphyrins proved to be still more effective quenching agents than metal-free porphyrins; the activity of the quenching agent depends on the nature of the central metal atom and on the structure of the porphyrin ligand. In terms of their activity in the quenching processes, the metals can be arranged in the following sequence:

$$Cu^{2+} < Zn^{2+} < Cd^{2+} \leqslant Mg^{2+} < Fe^{3+} \simeq$$

Porphyrin complexes with Fe^{3+}, Ni^{2+}, and Co^{2+} proved to be the most effective. The quenching rate constant k_q for these compounds are independent of the nature of the ligands and in all cases approach the rate constant for a diffusion-limited process (k_d).

In order to elucidate the quenching mechanism, Krasnovskii measured the rate constants (k_{ox}) for the chemical reaction between $^1O_2$ and quenching agents, which lead to the decomposition of the latter[194,197]. It was found that $k_{ox} \ll k_q$ for porphyrins, chlorophylls, and carotenoids, i.e. the quenching is determined by the physical energy transfer process without the destruction of the quenching agent. For lipids and naphthacene (an aromatic hydrocarbon), $k_{ox} \cong k_q$, i.e. quenching is also determined by the degradative process. On the basis of a comparison of these data, Krasnovskii put forward the hypothesis that two mechanisms of physical quenching are most probable; either direct energy transfer from $^1O_2$ to low-lying levels of the quenching agents or rapid electron exchange in the exciplex between $^1O_2$ and the quenching agents. The first mechanism is possible for quenching agents having energy levels at ≲1 eV (for example, for carotene, bacteriochlorins, and cobalt, nickel, and iron complexes of porphyrins). The second mechanism is more probable for quenching agents without such levels.

The fact that retinals, chlorophylls, and porphyrins are able to generate and quench $^1O_2$ is extremely important for the understanding of photobiological processes such as photosynthesis and vision[197,199]. It is known that the photoreceptors of the retina always contain free retinal which has been shown[197,199] to be an effective photogenerator of single oxygen and can therefore be the cause of the damage of the retina by light. It has been suggested that in the system protecting photoreceptors from singlet oxygen the leading role is assumed by α-tocopherol,[204] whose content in the outer segments of the rods in the retina is 5–10 times higher than in the other biomembranes.

Somewhat later than Krasnovskii's investigations, Khan and Kasha also detected the $^1O_2$ luminescence at 1270 and 1580 nm in liquid solutions[200,201]. They used an extremely sensitive infrared spectrometer with a thermal electrically cooled PbS detector. A much weaker band at 1580 nm corresponds to the $^1\Delta(v' = 0) \rightarrow {}^3\Sigma(v'' = 1)$ transition. $^1O_2$ was generated via photosensitisation of the solution and also chemically in the reaction of hydrogen peroxide with sodium hypochlorite. Benzophenone, haematoporphyrin, etc. were used as the sensitisers, while the solvents were perfluorohexane, Freon, CCl_4, and water.

The $^1O_2$ photoluminescence can be used to detect the ability of various substances to generate $^1O_2$ photochemically and also to estimate the efficiency of this generation process. Thus this new method of detecting singlet oxygen can be very important not only for the study of natural biological processes but also for the investigation of the effect on natural systems of exogenic components, which is associated particularly with problems involving the care of public health.

III. SINGLET OXYGEN IN POLLUTED CITY AIR

The possibility that singlet oxygen plays a decisive role in the formation of photochemical smog in the lower atmosphere was first examined in the 1960's.[205,206] Later this problem was studied in greater detail[207–209]. As a result of prolonged studies of the mechanisms of the formation and decomposition of photochemical smog, Pitts and coworkers[210,211] concluded that singlet oxygen $O_2(^1\Delta)$ and (or) $O_2(^1\Sigma)$ in polluted city air participates in chemical processes as an oxidant. These authors suggested that certain hitherto inexplicable atmospheric chemical and possibly biological effects could be attributed to singlet oxygen.

The ways in which singlet oxygen is formed in polluted city air are examined below. Five mechanisms, explaining the formation of singlet molecular oxygen in polluted city air have been proposed[207]. The first four mechanisms as well as the contribution of each to the production of singlet oxygen are illustrated in Table 2.

1. Direct Absorption of Sunlight

After a series of experiments on a mixture of air and tetramethylethylene in an apparatus with a long optical path, Pitts and Coomber[207,208] concluded that the direct absorption

of visible radiation in the range 550–770 nm by normal oxygen leads to the formation of singlet oxygen $O_2(^1\Sigma)$ (the $^3\Sigma + {}^1\Sigma$ transition at 762 nm), which is rapidly deactivated to the $^1\Delta$ state. $O_2(^1\Delta)$ then reacts with tetramethylethylene and the corresponding hydroperoxide is formed. Furthermore, the absorption at 1270 nm leads to the formation of $O_2(^1\Delta)$. However, since these transitions are formally forbidden, the contribution of this mechanism to the overall production of singlet oxygen in the atmosphere is very small.

Table 2. The formation of $^1O_2$ in polluted city air[220].

Source of $^1O_2$	w^*, 10^{-8} h^{-1}
Direct optical absorption	$<9.2\cdot10^{-3}$
Photosensitisation	80
$O_3+h\nu\rightarrow{}^1O_2+O$ *	0.1
$NO+O_3\rightarrow NO_2^*+{}^1O_2$	1140

*Here w is the rate of production of $^1O_2$.

2. Energy Transfer from Organic Molecules in the Triplet State to Oxygen in the Normal State (Photosensitisation)

A considerable amount of singlet oxygen is obtained by the direct transfer of electronic energy to the oxygen molecule from the molecules of an organic pollutant in the triplet state[207,210,212]. This mechanism is identical with Kautsky's mechanism of laboratory photosensitised oxidation reactions[82]. Spectroscopic studies by a number of workers showed that $O_2(^1\Delta)$ is produced by the gas-phase energy transfer to oxygen from irradiated gaseous aromatic hydrocarbons with (π,π^*)-triplet states (for example, benzene and naphthalene)[169,171,213] and carbonyl compounds with (n,π^*)-triplet states, for example benzaldehyde[208,214]. Energy transfer has also been observed for heterogeneous gas–solid and gas–liquid systems[215].

3. The Photolysis of Ozone

When ozone is irradiated with ultraviolet light, it undergoes photodissociation to an electronically excited oxygen atom $O(^1D)$ and an oxygen molecule in the singlet state[216,217]:

$$O_3 + h\nu_{260\ nm} \rightarrow O(^1D) + O_2(^1\Delta \text{ or } {}^1\Sigma) \quad .$$

This mechanism is particularly important in the upper layers of the atmosphere[218]. In the lower layers it is less important than the energy transfer mechanism[219,220].

A significant consequence of the formation of $O(^1D)$ atoms in this reaction is its involvement in the subsequent energy transfer process:

$$O(^1D) + O_2 \rightarrow O_2(^1\Sigma) + O(^3P) \quad .$$

This results in the formation of two oxidising species; singlet molecular oxygen and atomic oxygen in the ground state[207].

4. Exothermic Chemical Reactions

An important exothermic reaction in a polluted atmosphere giving rise to $^1O_2$ is that between nitric oxide and ozone[207], the rate constant for which is $k = 1.2 \times 10^7$ litre mol^{-1} s^{-1}:[221]

$$NO + O_3 \rightarrow NO_2^* + {}^1O_2 \quad .$$

Furthermore, it has been suggested[222,223] that ozone might react similarly with a series of other substances polluting the atmosphere, such as sulphides, with formation of singlet oxygen. It is known that similar processes in the condensed phase do lead to the formation of singlet oxygen[207].

The high reactivity of peroxyacetyl nitrate (PAN) in chemical and biological systems *in vitro* and *in vivo* is known. It has been shown that PAN is one of the main causes of the irritation of the eyes and the damage to plants by polluted city air[224–226]. Studies on simpler systems have shown that PAN can act both as an oxidising and an acetylating agent[227,228]. Alkaline hydrolysis of this compound leads to the formation of singlet molecular oxygen[207,229,230]:

Thus singlet oxygen must be regarded not only as a possible oxidant acting on the environment but also as an intermediate in the oxidation process.

5. Charge-Transfer Complexes between a Hydrocarbon and Oxygen

Coomber and coworkers[208,209] proposed a fifth way leading to the formation of singlet molecular oxygen, which is as follows. When ultraviolet light is absorbed by short-lived olefin–oxygen or aromatic hydrocarbon–oxygen collision complexes, charge-transfer complexes are formed between the electronically excited hydrocarbon (electron donor) and oxygen (electron acceptor) in the ground state. These complexes can then decompose, giving rise to singlet oxygen and the triplet hydrocarbon[207–209].

When a charge-transfer complex is formed between a hydrocarbon and oxygen, an additional intense absorption band, corresponding to charge transfer, appears in the absorption spectrum of the hydrocarbon, which results in an increase of the intensity of the long-wavelength edge of the hydrocarbon absorption band and in addition the band undergoes a shift towards longer wavelengths ("red shift") (see, for example, Tsubomura and Mulliken[231] and Shinkarenko[232]). The fact that the long-wavelength edge of the absorption band of hydrocarbons becomes more intense and undergoes a bathochromic shift in the presence of oxygen under illumination is extremely important for atmospheric photochemistry. It was believed previously that the presence of many of the polluting compounds in the environment is unimportant because they do not absorb light in the region corresponding to the solar spectrum. However, the red shift of the absorption band suggests that some of these compounds do indeed absorb in the visible region and therefore participate in the photochemistry of polluted city air.

Structure of Polymeric Carbon

V.M.Mel'nichenko, A.M.Sladkov, and Yu.N.Nikulin

Experimental results and model ideas on the structural organisation of different forms of condensed carbon are critically reviewed from the standpoint of polymer science. Stress is laid on the role of chemical bonds between molecules (branching points) and of lamellar and other supermolecular formations in the multi-step process leading to a three-dimensional development of the polymeric carbon structure. Many crystalline forms of carbon (in addition to diamond and graphite) are shown to exist as regular polymers of the carbyne or transitional types. 297 references.

I. INTRODUCTION

Existing views on the molecular and supermolecular organisation of condensed carbon are not universally held. Different schools of workers apply different treatments to their experimental results, and unfortunately even the terminology varies as between laboratories. Published papers contain a profusion of suggested models of the structure of carbonaceous materials which are often mutually incompatible.

Although the original tentative classifications of solid carbon as a type of polymer were soon followed by extensive articles and monographs, the development of the structural physics of carbon lags at least 25 years behind the present level of polymer science. The structure of the various three-dimensionally cross-linked carbon polymers is still largely unexplained, even in broad terms: even the nature of the interatomic C–C bonds, i.e. the structural chemistry of these materials, is far from clear. Typical of this state of affairs are the various coals, carbynes, and carbon thin films. This is true also of the more highly organised carbonaceous materials such as blacks, cokes, graphites, coals, vitreous carbon, pyrolytic carbon, carbyne, schungite, anthracite, diamond, carbon fibres, microporous adsorbents, composite materials, etc. There is hardly any concept in the materials science of carbon which could not benefit from critical re-examination. Our knowledge is still largely empirical, and much more work is needed before a theoretical understanding can be achieved. The problems lie in many different areas of technology. The present period of detailed studies of the properties of different types of polymeric carbon, aiming to establish a large fund of varied experimental data, must now be followed by a period of constructive thought and generalisation. The most urgent need in the physical chemistry of carbon at present is to generalise and unify the existing information.

All structural methods comprise two basically different aspects: the mathematical formalism, with its system of axioms, and the interpretation needed to apply it to specific problems. The two aspects must be carefully distinguished before the structural method can be successfully applied to structurally indefinite and varied materials such as the different forms of polymeric carbon. Unless this is done we cannot be sure that the conclusions from an experiment stem from the theoretical basis of the method rather than from the far more indeterminate interpretation rules.

In setting up the theoretical basis of a method we should avoid, if possible, terms already loaded with connotations, such as crystallite, phase, graphitisation, interplanar spacing, amorphous carbon, defect, and so on. The mathematical results should preferably be formulated in a neutral language, in order to avoid pre-conceived interpretation. The general theory should be, as far as possible, independent of *a priori* assumptions as to the structure of the unknown system. The initial postulates should be clearly stated, they should have the greatest possible generality, and they should not be biassed towards a specific model of the material under study.

A common mistake in the analysis and interpretation of experimental information is to tackle prematurely the most difficult and interesting question: the selection of a suitable working model. The alternative (and more cautious) approach, adopted in this review, concentrates initially on a pragmatic and inductive study of the model.

II. COORDINATION CHEMISTRY OF CARBON. LENGTH OF C–C BONDS

We have a fairly unambiguous criterion for deciding whether or not a chemical bond exists between two carbon atoms, i.e. whether the two atoms belong to the same molecule: the distance (r) between their nuclei. When an interatomic bond is present, r(C–C) = 120–170 pm.[1–3] Distances shorter than 120 pm between carbon atoms are inadmissible, owing to mutual repulsion. The range 120–170 pm, called the "valence bond" region, is followed by a "forbidden gap", from 170 to 280 pm, beyond which comes another band of allowed carbon–carbon distances: r(C–C) > 280 pm. This is the intermolecular interaction band.

The term molecule applies, in principle, to any sub-assembly of atoms in which each atom is chemically bound to one or more atoms of the same sub-assembly[4]. From this point of view a diamond crystal is a single three-dimensionally cross-linked giant macromolecule. Similarly, an atomic layer in an ideal graphite crystal is a single two-dimensionally cross-linked polymeric macromolecule.

According to the modern structural chemistry of carbon a C atom can be chemically bound to two, three, or four nearest neighbours (not necessarily equidistant from it). Stoichev's rule, well known in the stereochemistry of organic compounds, relates the length of the C–C bond to the number of bonds or atoms attached to this bond:

$$r(\text{C—C}) = 129.9 + 4.0\,n \text{ (pm)}.$$

In this expression $n = 2–6$ is the sum of the coordination numbers of the two carbon atoms forming the bond, less 2:

$$n = z_1 + z_2 - 2\,.$$

Other coordination numbers such as $z = 0$ (clathrate bond), $z = 1$ (end-atom in a radical), and $z > 4$ (e.g. in carborane-like fragments), though possible in principle, are not typical of polymeric carbon.

The coordination chemistry of carbon is still far from being fully developed: the chemical behaviour of a carbon atom is usually described in terms of its valence states (sp, sp^2, sp^3 hybridisation of hydrogen-like wave functions). However, a recent review[3] has shown that the coordination number can be used to reveal new facets of the changes in interatomic C–C distance. Thus, though coordination numbers greater than 4 are not normally considered in the structural chemistry of polymeric carbon[1,2,5,6], it is now well established[3] that in carboranes the C atom can have coordination numbers of 4, 5, and 6, so that

$$r(\text{C—C}) = 107.4 + 5.8\,n \text{ (pm)}; \quad n = 6, 8, 9, 10.$$

The longest C–C bond experimentally found in carboranes[3] is 171 pm.

III. COPOLYMERIC NATURE OF CONDENSED CARBON

The term polymeric has been used[7] exclusively for non-graphitising carbon. However, this usage is terminologically incorrect: it would be more exact to treat the concepts of "condensed" and "polymeric" states of carbon as synonymous.

Polymeric (or, more strictly, copolymeric) carbon is an open lattice or network of atomically cross-linked chains (one-dimensional), tapes (two-dimensional), and diamond-like, polyhedral (carborane) fragments, i.e. three-dimensionally linked rod-like, lamellar, and globular fragments. They form[8] a fairly rigid and oriented three-dimensionally cross-linked structure penetrated from all directions by a system of pores which can be open or closed, in the shape of cylinders or disks, lens-like, needle-like, or spherical. Coal has been likened[9–11] to a conglomerate of linear, branching, and cross-connected amorphous polymers, interlinked by intermolecular interaction forces. It is impossible, in general, to identify individual molecules or pores: this explains the failure of various attempts[12–14] to describe the structure of solid condensed carbons and coals in molecular terms (the "small molecule" theory[15]).

The impossibility of describing solid carbon as a molecular substance (like water, benzene, etc.) is now well recognised[16–21]. Thus, according to Biryukov[22], most of the constituents of natural forms of carbon can be classified as high-molecular compounds (HMC). Coals are mixtures of different HMC, with a three-dimensional heteropolycondensed (hydroaromatic) structure and a low level of polycondensation (2–5 rings). The aromatic rings contain substituents in the form of radicals or aliphatic groups. The number of these substituents decreases as the degree of metamorphism of the coal increases. The rings can be interconnected (cross-linked) by methylene bridges, ether bridges, or bridges of the alicyclic, heterocyclic or biphenyl type.

It has been said[9] that the description of coal as a high-molecular compound with a three-dimensional structure destroys the relevance of studies of its molecular structure, since the concept of "a macromolecule" is now known to be physically meaningless in the chemistry of HMC. Nevertheless a clearer knowledge of the individual molecular constituents (segments, fragments, branches) between the branching or cross-linking points is not useful but essential to a better understanding of the organisation of carbonaceous materials.

IV. THE PACKET AND FRINGE MODEL

The most characteristic X-ray diffraction feature of carbonaceous substances is a set of several more or less diffuse maxima corresponding to the graphite structure superimposed on a continuous background. The most important is the first reflexion, in the region of scattering angles (2θ) between 18 and 32° (for $\lambda = 154$ pm), corresponding to the Bragg periods $d = 280–500$ pm. The reflexion is found in various forms in almost any form of carbon, and it is always the strongest. It is usually ascribed to the presence of small crystallites of graphite[23,24], and the spacing d is interpreted as the distance between plane-parallel layers of carbon atoms or aromatic molecules. It is assumed that carbon atoms have a strong tendency for two-dimensional condensation to give aromatic molecules (graphitisation).

The presence of 2–4 diffuse reflexions in positions close to those from the (002), (100,101), (004), and (110) graphite planes has been quoted[25] as evidence that the basic structural unit in coals is the graphite network. However, it is now becoming clear that this assertion is misleading, and that the "coincidence" of reflexions from "amorphous" carbons (coal, schungite, vitreous carbon, carbon blacks, etc.) and from crystalline graphite is in many ways fortuitous[26]. Nevertheless, Warren's turbostratic model[23] of two-dimensionally ordered structures has been increasingly applied to amorphous carbons. The size of the graphite blocks (condensed "aromatic macromolecules") and their mutual orientations were inferred from the width of the reflexion and from the approximate "interplanar spacings". The aromatic model was extended to all forms of carbon, including those which yield a different (non-graphitic) diffraction pattern.

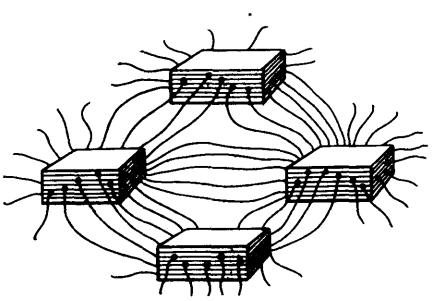

Figure 1. The packet and fringe model of the structure of polymeric carbon.

It is claimed[27] that the presence of graphitic reflexions is direct evidence of the formation of blocks (clusters, packets) of two-dimensional layers of aromatic molecules. On this

evidence the presence of "crystallites" (graphite-like particles, or micelles) having fairly sharp boundaries and immersed in an amorphous matrix has been postulated (Fig. 1). In this model the carbonaceous material is treated as a two-phase system (even without allowing for the presence of pores[27]).

All forms of carbon can be arbitrarily classified into two types[16-20,28-34]: 1) organised (ordered, aromatic, nucleated, crystalline, contained in crystallites) and 2) not organised (amorphous, non-aromatic, peripheral, disordered, lying between crystallites in the amorphous matrix).

The position of the reflexions was assumed to be determined by the internal layer structure of the crystallites, and their width by the external dimensions of the crystallites. The crystallite size was treated as the most important of the structural characteristics, and in most cases it was found to be 1–100 nm. The background continuum of the diffraction picture was ascribed to the amorphous matrix. Several structural models of carbon were proposed, all of them based on an aromatic macromolecule (or layer) surrounded by aliphatic, hydroaromatic, and other atomic groups. The basic structural transformation during carbonisation and heat treatment was assumed (*a priori*) to be the growth and ordering of aromatic macromolecules and crystallites as a result of the rearrangement of atomic groupings with bonds of different types. This approach led to the structural model of carbon which we can call the packet (or micelle) and fringe model by analogy with the now superseded fringed micelle model in the structural physics of linear polymers[35,36].

In this model (the "spider" model) the primary structural fragments were thought to be: 1) a two-dimensional aromatic layer in the crystallite, usually assumed to be planar, i.e. absolutely rigid, and 2) a carbon chain with side-groups of hetero-atoms interconnecting the crystallites.

The bundle of chains terminating on any one crystallite is treated as its fringe[37]. The block (or packet, crystallite, micelle, cluster) is a secondary, supermolecular formation in which the distance between the plane parallel carbon layers varies between 335.4 and 344 pm depending on the degree of correlation (three-dimensional order) in the mutual arrangement of these formations. The lower limit was identified with the ideal graphite structure, and the upper limit with the turbostratic structure, i.e. with a fully uncorrelated disposition of the layers[23,24,30]. However, Ruland has shown[38] that even the spacing d = 344 pm implies some degree of correlation in the disposition of the layers. Thus one of Franklin's fundamental assumptions[30] appears to be incorrect.

The packet and fringe (micelle and fringe, or crystallite) model of the carbon structure was proposed independently in the early 1950's by Franklin[29-32] and by Kasatochkin[16-19,33], and was subsequently developed by many workers[5,14,20,27,34,38-51]. The model has been used to interpret all types of experimental result[1,2,37]: even a method of determining the fractional amount of aromatic carbon was based on it[52]. Numerous models of the disorder (or partial amorphousness) of polymeric carbon have been proposed[23,24,50-57]: in most cases the amorphousness was ascribed to disordered translation, rotation, and bending of the layers[24,58-68], non-identical valence bonds in some of the atoms (Pauling's quinoid structure[63-65]) or non-identical states of the different surfaces of the same (or of different) two-dimensional aromatic molecules[50,51], or to the presence of two phases in the system (the crystallite packet phase + the amorphous fringe carbon phase). It was suggested[5,20,37] that the amorphous carbon can display every possible level of hybridisation of the states of the four outer electrons in each C atom. In spite of the emphasis on a more or less regular packing of the aromatic layers in the packet (or crystallite), the presence of some regularly packed chain-like fragments was implicitly accepted. No other way of interpreting the mass of experimental facts could be found, especially those derived from X-ray diffraction measurements.

However, the position of the first reflexion often corresponds to d > 344 pm,[42-49] and this cannot be explained within the framework of the packet and fringe model[66,67]. Furthermore the intensities of some of the reflexions, in particular the (002) and (004), are often anomalous and do not correspond to the graphite structure[66]. Also, the presence of coherent scattering regions of finite size does not in itself imply that the system must be two-phased, or micro-heterogeneous, as has been recognised in the case of chain (linear) polymers[68,69].

Indeed, high-resolution (~0.3 nm) electron microscopy, interference microscopy (to reveal the periodicity of atomic layers), and phase contrast methods[70] have all been unsuccessful in the search for discrete crystallite particles[67,71-88]. It was found that the size of the bent, twisted, and tangled bundle (micro-fibril), consisting of several tape-like layers (or molecules), can greatly exceed the normal values of L_a and L_c, reaching several micrometres[71-73,81-86]. The finding that not only individual layers (tapes) but also bundles (micro-fibrils) are quite pliable was most unexpected[71-77,87].

The conclusion was that the basic microstructural units include large, distorted graphite layers and long narrow ribbons rather than small three-dimensional crystallites (as suggested by the original X-ray diffraction experiments). Polymeric (rigid, non-graphitising) forms of carbon have been described[7] as a highly distorted form of graphite consisting of tapes rather than layers.

The adherents to the crystallite (micellar fringe) model have now started to describe the crystallite as an assembly of approximately parallel layers without identifiable boundaries between the crystallite and its surroundings, rather than as a normal particle (or micelle)[34,42,66,74-76]. This treatment stems from the belief that the intensity of the reflexion is a measure of defect concentration rather than of the size of the "scattering particle". However, these stipulations amount to admitting the failure of the micellar fringe model of the carbon structure.

V. THE MOLECULAR-TAPE FELT MODEL

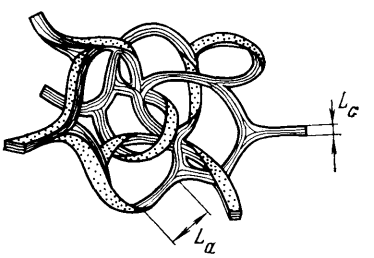

Figure 2. The molecular tape carbon felt model.

The micellar fringe model was followed by the tangled tape model[74,75], in which any carbonaceous substance (from vitreous carbon[72-76] to carbon fibre[7,34,81-88]) is held to consist of a uniform molecular-tape felt without any discrete

supermolecular formations (Fig.2). In this case the difference between vitreous carbon and carbon fibre lies only in the degree of preferred macroscopic (visible) orientation of the ribbon bundles as they diverge, intersect, and come together again[7,44,67].

This model of the structure of carbon was quickly adopted in many published papers and text-books[27,66,89,90]. Nevertheless, in spite of its apparently firm experimental foundations, the model is incompatible with physical reality in two respects. Firstly, by postulating that all the carbon atoms are trigonal (in an exclusively sp^2 hybrid valence state[42]) the felted tape model ignores the possible existence of carbon chains, diamond-like regions with tetrahedral bonds, chemical cross-links, sharp bends, and the intermingling and spiralisation (twisting) of chains, tapes, and layers. Secondly, while rejecting crystallites as real structural elements[73,91], this model also rejects every other discrete structural unit having a higher (supermolecular) level of organisation.

Evidently, in real systems the organisation of the carbon must be less uniform than this model suggests, both from the chemical point of view (interatomic bonds) and from a higher-level standpoint. Recent extensive structural investigations have demonstrated the formation of ordered structures at both the molecular and the supermolecular level not only in crystalline but also in amorphous carbonaceous materials. The formation of these structures is responsible for the loss of three-dimensional homogeneity in carbonaceous materials: it is accompanied by the appearance of interfacial boundaries and localised non-uniformities such as cracks, graphitised regions, and local concentrations of low-molecular compounds.

Johnson and coworkers[92] have proposed a complex model of the fish-scale structure of a high-molecular carbon fibre (HTT† = 3100 K), including intersecting (even at right angles) and longitudinal bundles of aromatic tapes, pores with sharp angles, regions of imperfect packing of the tapes, sharp bends, and twists in the tapes.

Numerous variants of the two basic structural models (the packet and fringe and the felted molecular tape model) of condensed (copolymeric) carbon are described in recent monographs[7,12,15,20,22,27,66,73,90] and reviews[6,8,40–42,48,51,56,89,93]. In principle they do not contradict, but they complement each other, and therefore all can claim some validity. Each variant focusses attention on certain aspects of the structural hierarchy and of the amorphousness of carbon, while other aspects are ignored. In reality the structure of polymeric carbon is infinitely more rich and varied than even the most complex model suggests.

VI. DIRECT EXPERIMENTAL OBSERVATIONS OF THE NON-UNIFORM MOLECULAR STRUCTURE OF POLYMERIC CARBON.

It is widely assumed that all non-crystalline forms of carbon consist of graphitoids: localised packets of aromatic two-dimensional macromolecules. However, in many cases the shapes of the observed diffraction peaks are not described satisfactorily by this model. For example, even Franklin[31] met this difficulty in a study of the carbonisation products of poly(vinylidene chloride) (PVDC) at 1300 K. From an analysis of the X-ray reflexion profiles [mainly of (110) index] Franklin concluded that 65% of the carbon atoms in this material are accommodated in highly perfect, flat graphitic layers, and 35% in an amorphous phase which gives diffuse scattering. Other workers also reported similar observations[14,40,41].

Kirda and coworkers[57] have shown that the average length of the C–C bonds in anthracite, calculated from the position of the first peak on the atomic radial distribution curves, decreases from 145 to 128 pm if the sample is ground for 20 min in a vibro-mill. They concluded[57] that 66.5% of the carbon in the initial sample exists as flat graphitic layers ~2 nm in diameter, and 33.5% can be classified as amorphous, i.e. not organised in ordered packets. During the grinding operation the relative amount of amorphous carbon in anthracite increases from 33.5 to 43%, and the area of the aromatic layers decreases, but the inter-layer spacing d_{002} remains constant (356 pm). Like the earlier workers[14,29–32,40–41], Kirda and coworkers[57] failed to define the material which they termed amorphous carbon.

An analysis of the atomic radial distribution functions[94,95] has led to the conclusion that regions (or domains) of two types are present in vitreous carbon: graphitic, and tetrahedrally bonded (or diamond-like). Similar views were put forward by other workers[45–49,96–102], though others have doubted the presence of diamond-like regions in vitreous carbon. Ergun and coworkers[45–59] concluded from measurements of hardness and density combined with a determination of the width of the diffraction lines that non-graphitising (rigid) carbons contain different crystalline forms of carbon including a substantial amount of micro-structures in which the atoms are tetrahedrally coordinated.

According to the polyadamantane hypothesis[103,104] different carbon atoms in natural coals have different electronic states and different coordinations: ~50% of the atoms are in structural fragments of the complex cycloalkane (polyadamantane) type, ~10% in alkane chains, and only 26–30% in condensed benzene rings.

Another study of atomic radial distribution functions[105,106] has established that practically no condensed aromatic systems are present in vitrinites from bituminous coals containing 77–90% of carbon. It has also been stated[25] that the structure of the vitrinites from anthracite cannot be described by models based on a condensed aromatic macromolecule. It is assumed that all possible types of carbon bond are found in vitrinites from anthracite (as they are in schungite). At least two methods of carbonising coal are known: those tending towards graphitisation, and those tending towards anthracitation (schungitisation) or, more accurately, carbynisation, i.e. the formation of straight or branching chains, ladders, or tapes of three-dimensionally cross-linked macromolecular fragments.

A combination of physical, physicochemical, and petrological studies[9–11] has shown not only that glubular polymeric structures with linear or branching chains are present in the vitrinite part of coal, especially in natural coals in an intermediate state of metamorphism, but also that linear macromolecular fragments are predominant in these structures.

The view that coals are mainly aliphatic has been put forward by several workers[103,107,108]. Aromatic fragments are thought to be present in small numbers, the coal consisting mainly of linear alkane chains. A study[109] of the acetylation of coals of different levels of metamorphism using the chloro-anhydrides of various aliphatic acids (the Friedel–Crafts reaction) has shown that even in the lean coal stage a three-dimensional network has not yet been formed. The volume of graphitoids in natural coal is estimated[110–112] to be less than 10%: the main bulk consists of linear carbon polymers. A mass spectrometric and gas chromatographic analysis of the products of the oxidation of coals by a 40% aqueous solution of nitric acid at 333 K has shown[113] that up to 38% of the carbon exists as linear alkane chains up to 23 C–C bonds in length.

†HTT is the heat treatment temperature.

Thus, in spite of the lack of quantitative agreement on the carbon chain content of natural coals and anthracites, the presence of such chains is accepted by many workers, including adherents to the micellar fringe model. As was pointed out in Ref.111, the make-up of spatially inhomogeneous, structured natural carbons (coals, semi-cokes, anthracites, carbon blacks, vitreous carbon, carbon fibre, schungite, etc.) is complicated by the enormous number of cross-bonds and branching chains, which make it impossible for the material to soften and be converted into a liquid. Being vitreous, this gelled material can only be converted into a highly elastic state by an increase in temperature.

Whittaker and Tooper[114,115], using electron diffraction, found that most of the fragments in vitreous carbon (with HTT up to 3500 K) give diffuse diffraction patterns containing several rings, but a significant proportion gives only spots and rings or even (in 10% of the cases) a sharp pattern consisting only of spots and corresponding to a single-crystal region in the sample. Unexpectedly, the crystalline fragments between 0.1 and several micrometres in size did not have the graphite structure: in most cases their structure was that of carbyne (chaoite, carbon-VI), diamond, lonsdalite, and other previously unknown forms of carbon. On the other hand, patterns corresponding to crystalline graphite were often twinned (with a rotation of approximately 28.5°), suggesting the presence of two crystalline regions in the same fragment (for example, of the lamellar or platelet type).

From these recent and detailed investigations we may draw the following conclusions.

1. The characteristic size of the uniform regions in vitreous carbon is 10–1000 nm, i.e. much greater than the typical crystallite size calculated from the broadening of the X-ray reflexions (L_a, L_c = 1–20 nm).

2. Though a proportion of the carbon atoms is accommodated in aromatic fragments consisting of 1–3 rings[96], a much larger number of C atoms adopts different types of cooperative arrangement (coordination).

3. The presence of different crystalline forms of carbon causes a broadening of the "graphitic" X-ray lines, additional to the "size" effect, since many of the reflexions for these forms lie close to the characteristic graphite reflexions. This interpretation of the broadening of the (002) band and of the enhanced background near this band was suggested in 1965 by Ruland[116], who tried to analyse the intensity of the band not in terms of the distribution of crystallite sizes L_c but in terms of the distribution of intermolecular distances d. This approach was put forward[116] as an alternative to Franklin's artificial postulate of single atomic layers (macromolecules) and of atomically amorphous carbon, assumed to scatter X-radiation incoherently, in a system as close-packed as polymeric carbon. However, this approach was not developed further, and the broadening of the (002) band is now almost invariably ascribed to the crystallite size L_c.

Early work[12–14,28,117,118] on the structure of natural carbons referred also to the γ-band, corresponding to a structure with a periodicity d = 400–500 pm. Abnormally high values of d_{002} are found in many forms of carbon: for example, the values d_{002} = 360–420 pm are typical of carbon blacks[119], and in carbynes the predominant periodicity is 430–480 pm. On the other hand, for polymeric diamond structures consisting of cross-linked atomic layers the typical intermolecular distances d are much smaller. It has been suggested[12,18,117,118] that the γ-band in coals is determined by the intermolecular distance in a packet ~2 nm in diameter consisting of several small aromatic units (the "bitumen" molecules). The high values of d_{002} in other types of carbon have been ascribed to imperfections (curvature) in the aromatic layers, though the existence of these layers was uncritically accepted. The 430 pm periodicity in carbonised polyacenaphthylene (HTT = 460–570 K) was explained in this way[116].

However, an alternative explanation is possible, treating the γ-band as an indicator of the existence of carbon in chains and ribbons[25,26]. This treatment assumes not only the existence of distinct chain fragments, but also whole regions of close and partly ordered packing. For example, the diffraction pattern[120] of amorphous poly(vinyl alcohol) ($-CH_2-CHOH-$, $M \cong 40000$), known to be a chain polymer[36], consists of a single broad peak (with d = 437 pm) for different structural and morphological forms of the polymer (powdered, gelatinous, thin-film, fibrous, vitreous, mesomorphic) at 430–480 K. In spite of the difficulty of formulating a fully convincing interpretation[120], this peak must somehow be a measure of the distance between chains, possibly in a state of free or partially hindered rotation (torsional vibrations). The intensity ratio of the bands with d = 350 and 520 pm has been used[121] to calculate the degree of aromatisation (cross-linking of chains) as a function of time during the thermal oxidation of polyacrylonitrile (PAN) fibres.

The period d = 460–480 pm of the broad band observed[7] in the products of the low-temperature carbonisation of phenolic resins (HTT < 1140 K) has been interpreted[7] as the average distance between narrow tapes of aromatic carbon. This period decreased continuously from 480 to 350 pm as the heat-treatment temperature was increased, i.e. as the degree of aromatisation (cross-linking) of the carbon was increased, and as the narrow tapes and chains grew into two-dimensional atomic layers. This process results in the formation of a three-dimensional network structure. ESR spectral results and measurements of the electrical conductivity for carbonised polyacrylonitrile (HTT = 470–1370 K) were successfully interpreted[122] by a two-phase micro-heterogeneous model which describes the semiconductor as a random mixture of a highly conducting (polyconjugated) phase and an insulating (non-cyclised PAN) phase. The size of these regions in relation to one paramagnetic centre (PMC) was estimated to be ~1.5–20 nm.

A specially wide spectrum of molecular structures and supermolecular formations is observed in the condensation (whether homogeneous or heterogeneous) of carbon from its vapour[123–141], from a plasma[142–151], from a molecular-ion beam[151–156], or from solutions[157–161]. The products (in the form of globules, films, whiskers, etc., depending on the rate of the formation process) may contain any of the known (and some previously unknown) forms of crystalline or amorphous carbon: graphitic (two-layer polytype or normal hexagonal graphite), three-layer cubic or rhombohedral graphite, four-layer diamond, and carbyne. The substructure and some properties of evaporated carbon films are discussed in recent review articles[151,162–164].

VII. CARBYNE AND TRANSITIONAL FORMS OF CARBON

The term carbyne denotes a system consisting only of carbon chains held together by van der Waals forces to form a crystal[165–172]. The chains are assumed to be straight, since the electronic state of each C atom is described by *sp* hybrid wave functions (poly-yne $-C\equiv C-$ or polycumulene $=C=C=$ form). In the total absence of chemical intermolecular bonds (or cross-links) between the chains we obtain the originally postulated carbyne structure: an assembly of linear carbon chains without any chemical bonds between them. To confirm the existence of carbyne in this form we

require material as a single crystal of a size sufficient for extensive structural studies: such single crystals are not available at present. Though a liquid consisting of isolated carbon chains can exist, in principle, it has never been prepared.

Evidently, in real samples the carbon chains are chemically cross-linked by bonds showing various periodicities[173]. Whereas in the description of diamond and graphite systems the concept of intermolecular chemical bonds and associated branching systems (three- or four-function branching) is relatively unimportant, this concept becomes vitally important in the description of carbon chain polymers. Though these systems can be formally classified as transitional forms of carbon[5,6,37], we shall apply the concept of a real carbyne form of carbon (as opposed to the ideal carbyne) to a partially cross-linked three-dimensional polymer having a more or less regular (crystalline) structure and predominantly composed of extensive fragments of linearly polymerised carbon.

This wider definition of the carbyne forms of carbon is more general as well as methodologically more accurate. It includes, in addition to two-function (linear chain) lattice positions, the three- and four-function positions associated with branching (chemical cross-linking). From this point of view the graphitic atomic layers (molecules) and the diamond crystals are the limiting cases of network and chain structures respectively, ideally cross-linked by three- and four-function branching points.

Whittaker[174] interprets the graphitic monolayer in exactly this way: as an assembly of ideally cross-linked (in one plane) carbon chains. It has been suggested[175] that a diamond crystal consists of equal numbers of right and left screw axes, i.e. of helically twisted carbon chains.

In the presence of chemical cross-links between chains of linear carbon polymers the relative position of the chains may not be parallel. This is another important new aspect of the treatment of the carbyne structure. We note that the primary structural fragment is now no longer the two-dimensional layer of sp^2 hybridised carbon, but the chain connecting two nearest lattice points (i.e. the cross-link).

In principle the existence of carbon chains cannot be doubted (see, however, Refs.176 and 177). It has been demonstrated by various methods[178–192], including electron and X-ray diffraction[166–171 193–208].

The fundamental maximum of the energy loss spectrum during electron diffraction (in the 20–50 eV range) by evaporated carbon films prepared by various methods is found[187] to lie near 23 eV, i.e. slightly below the value for amorphous carbon and well below the value for graphite and diamond (27 and 34 eV respectively). The position of this maximum is thought[187] to be a characteristic structure parameter of this type of film. In some samples weak peaks were observed at ΔE = 7 and 33 eV. Annealing and storage of the films causes changes in structure (or, more exactly, changes in the energy loss spectrum).

A peak near 23 eV has been observed[186] for carbyne (in reality, a complex mixture of chain, ring, diamond, and other fragments). However, this result was reported only tentatively, and as possibly due to the presence of traces of oxygen. All the carbons examined (graphite, plasma black, carbyne, diamond) gave a broad band near 17 eV. The carbyne spectrum included two sub-bands, at 16 and 17 eV, reminiscent of the sub-bands found in diamond.

The Raman resonance spectra for poly-yne are interpreted[184] as a clear indication of one-dimensional chains with alternating bonds: the chain length is estimated to be 30 ± 20 C≡C bonds.

The Raman spectrum of natural graphite[180,181] consists of one (Stokes) absorption line at 1570–1580 cm^{-1}. In vitreous carbon, coal, pyrolytic carbon, and carbon black[182] two lines are seen (at 1360 and 1580 cm^{-1}), and in evaporated and white carbon (chaoite, carbyne) three lines[180,181]: at 1360, 1580, and 2140 cm^{-1}. The additional broad line at 2140 cm^{-1} in the carbyne spectrum is ascribed to conjugated acetylene bonds, $(-C\equiv C-)_n$.

Thus all the polymeric carbons show a sharp absorption band at 1570–1580 cm^{-1}, corresponding to a system of conjugated C=C bonds. The i.r. spectra of some samples of paracyanogen $(CN)_x$ also show a single, sharp absorption band at 1570 cm^{-1},[209,210] typical of the C=N bond[211], and therefore this band cannot be used to establish the electronic structure of our systems. It has been suggested[210,211], from X-ray diffraction results, that paracyanogen also has a layer lattice of the graphite type, with alternate C atoms replaced by N atoms, and the black colour and high stability of paracyanogen have been ascribed to resonance interactions involving electron transfer. The C–N interatomic distance in paracyanogen (136 pm) and the C–C distance in graphite (142 pm) are not very different: the difference between the interplanar spacings (~450 and 335 pm) is much greater[210,211]. On the other hand the colour of crystalline carbyne particles is white.

Obviously, all possible electronic states in condensed carbon atoms cannot be reduced to three types, with sp, sp^2, and sp^3 hybridisation. For example, s^2p^2 hybridisation is also possible (bivalent carbon model[7,212]), as well as multi-step hybridisation of already hybridised states, etc. Theoretical calculations suggest that the following structures are relatively stable: four-coordinated planar carbon (singlet biradical)[213], diamond-like three-coordinated amorphous carbon[135], pentagonal pyramids (a half-sandwich, positively charged in the cyclopentadienyl ring base of the pyramid[214]), and other electronic states[215,216].

Even the electronic structure of graphite is still being discussed[49,63–65,217], and doubts have been expressed on the dynamic equivalence of the σ-bonds in the layer, on their planarity, and their hexagonal symmetry. An orthorhombic elementary cell has been suggested[49,63,64], with a = 240.9, b = 433.9, c = 670.8 pm: the so-called quinoid structure, in which two-thirds of the C–C bonds are 145.3 pm long and the remaining one-third 135.7 pm, the bond angle being 112, 124, and 124°.

It has also been shown that the specific heat $C = f(T)$ curves of different polymeric carbons lie in the following (increasing) sequence: diamond, graphite, anthracite (and schungite), carbyne, and heat treated polyfurfural (HTT = 790 K, a mainly linear polymer)[178,179]: the heat of combustion of carbyne, Q = 84.54–88.80 kcal $mole^{-1}$, is significantly lower than those of graphite (94.05 kcal $mole^{-1}$) and of diamond[173]. The conclusion is that carbon in chains is thermodynamically more stable than graphite or diamond[173].

The specific heat of these materials at very low temperatures (0.44–4.5 K) has been found[218], surprisingly, to obey the law $C = \alpha T^3 + \gamma T$. The linear term almost certainly denotes the presence of a one-dimensional phonon spectrum. After neutron irradiation the coefficient γ increases, and α decreases (in parallel with degradation of the vitreous carbon)[219].

X-Ray and electron diffraction studies[220–226] of natural or artificial graphites had shown (even in the 1930's and 1940's) anomalous reflexions which could not be assigned to known crystalline modifications of carbon. In order to account for these reflexions various graphitic superstructures had to be postulated, though they could not be independently confirmed.

The observation[102] in the electron diffraction patterns from similar vacuum-evaporated films (of density 2.4 g cm^{-3}) of eleven diffuse haloes could only be explained by assuming that the intensity maxima were neither from graphite nor from diamond structures.

An electron diffraction camera (ER-100) has been used[227–230] also to study carbon films evaporated by an electron beam under the following conditions: vacuum ~5 × 10^{-7} mmHg, substrate NaCl or $BaCl_2$, T = 310–340 K, angle of incidence of the electron beam on the substrate 60°, rate of condensation 0.2–0.3 nm s^{-1}, film thickness δ = 10 or 80 nm. The electron diffraction patterns showed six haloes, the strongest being for d = 455 pm with δ = 10 nm and d = 485 pm with δ = 80 nm. The authors conventionally assumed that these large "interlayer spacings" are due to the insertion of carbon atoms between the graphite nets, giving distorted and highly supersaturated interstitial solid solutions of carbon in carbon. The regions of coherent electron scattering for which L_a = 1.2 nm and L_c = 0.8 nm were identified with strongly distorted graphite crystals in which the regularity of the mutual orientation of neighbouring graphite nets had been lost.

The atoms in evaporated films are often assumed to be grouped in diamond-like and graphite-like fragments[102,133,163,231]. In recent years it has become clear that thin carbon films (usually graphite-like[162–164,232,233]) can be in a polycrystalline cubic (diamond) phase completely free from graphite impurities when prepared under special conditions[143–159,234], the individual diamond crystallites reaching 5 μm dimensions[152–156]. However, the possible carbon structures in evaporated films are not limited to graphite and cubic diamond[187,235]. Fragments of lonsdalite and other unidentified ("intermediate") phases have been detected[149,236] in substantial amounts in carbon deposits, together with the cubic diamond phase. These phases were believed to be chaoite (α-carbyne). Cubic graphite also has been observed in condensed deposits[237,238]. But in most cases the investigators were "forced to discover" new crystalline forms of carbon[170,171,194–208,237–246].

Thus Aust and Drickamer[237] reported preliminary data on the synthesis of a new crystalline (high-pressure) carbon phase, formed by compressing a single crystal of graphite to 150 kbar. They described the crystal as cubic (a = 554.5 pm), with n = 24 atoms in the elementary cell and a density ρ = 2.80 g cm^{-3}. Later work, however, showed that these results were erroneous.

There are reports[241,242] that the condensation of a carbon plasma in a vacuum on a freshly cleaved KCl single crystal gives, in addition to a finely divided diamond-like deposit of particle size 1–2 nm (giving diffuse electron diffraction rings corresponding to d = 209, 115, 74, and 59 pm), also a scattering of faceted microcrystallites between 10 and 300 μm in size, giving electron diffraction patterns of the monocrystalline and the polycrystalline type. These crystals were indexed in the body-centred cubic lattice: a = 427.9 pm, n = 16, ρ = 4.1 g cm^{-3}. This new crystalline carbon phase, with a density 15% higher than that of diamond, is thought[241,242] to consist of close-packed slightly distorted tetrahedra.

The carbyne family continues to grow. At least six varieties of carbyne (polytypes) are known at present[169–171,194–201,207,208]: according to Whittaker[174] there may be eight.

A recent paper describes the synthesis of chaoite[247] ("a new hexagonal allotropic form of carbon") from vitreous carbon wafers compressed by a shock wave to 100 GPa. The structure was identified by electron diffraction (a = 893.7 ± 4.0 pm). The possibility of homogeneous nucleation and selective growth of diamond and other forms of carbon had been suggested[129–133], including carbyne phases, if conditions in the gas phase are optimised for a particular form: for example, laser irradiation of liquid hydrocarbons was found to favour the formation of microscopic diamond and carbyne granules.

Crystalline carbon in the carbyne form has been detected in thin lamellar streaks and in graphitic deposits[248]. As Whittaker points out[248], carbynes are not a rare form of carbon: their natural distribution is relatively wide.

We should stress that carbynes are not necessarily always crystalline. Their degree of order (or crystallinity) can be arbitrary.

The "rediscovery" of carbon has continued, at an increasing rate, during the past few years. We can expect, as a result, new and truly "polymeric" concepts to be developed in the structural physics of carbon. Thus, it has been established[245] in principle that carbon can exist in new crystalline structures showing sp^2 hybridisation of the atomic orbitals and topologically different from known modifications (diamond, graphite, and carbyne). These structures can arise through the formation of covalent bonds (regular cross-links) between helical carbon chains. Though the formation of these carbon polymers is kinetically hindered, the chains are thermodynamically stable owing to the presence of high energy barriers which prevent the conversion of the system into graphite or diamond.

Further new and surprising properties of carbon in thin films has been observed. For example, the colour of vacuum-evaporated films previously heat treated at 550 K slowly changes (at ~1 mm min^{-1}) from black to grey after a localised pin-prick has been applied[249]. The thicker the film, the faster is the motion of the colour-change front (within the range δ = 15–200 nm). Simultaneously with the colour change, the electrical conductivity increases by an order or more. Heat treatment has a similar effect. After this structural change the carbon films become amorphous, or are converted into a mixture of interpenetrating fine particles of graphite and diamond phases.

The instability of the electron distribution (for example, in a fixed configuration of the nuclei) occasionally manifests itself as the reversible memory switching effect shown by many disordered oxide and glass systems[250] in evaporated carbon deposits[251], in vitreous carbon[252], etc. The electrical resistance of these systems suddenly falls, following the application of a voltage above some threshold value (2–10 V), by several orders of magnitude (for example, from 450 to 1.8 kOhm). Both states (high-resistance and low-resistance) are metastable, and can be "remembered" for several days[250–253]. This means that the electronic subsystem of the material can be in one of several metastable states (energy levels), i.e. the material shows non-equivalence of the C atoms (in particular, a variable degree of ionicity), alternation of the interatomic bonds, and changes in the type of localisation and distribution of the electrons surrounding the atomic cores. It is suggested[252] that in the presence of an electric field thin needle-like conducting channels are formed in the film, as in the development of low-temperature trans-polarisation in ferroelectric materials[254]. (The same explanation has been applied to the switching effect in filamentary Sb_2S_3 single crystals[255].) However, the nature of the low-resistance state is still under discussion[250,256].

The ESR absorption of different forms of carbon is due to the presence of at least two types of PMC, differing in geometric configuration and in internal structure. The narrow ESR signal is assigned[257] to unpaired, delocalised electrons, located in the aromatic regions of cyclically polymerised carbon, whereas the origin of the broad signal is thought to be a set of PMC localised in the "amorphous" phase of the system: small oxygen-containing or (more probably) carbon radicals with planar or linear π-conjugation. Samples of vitrinite from Donets gas carbon[258] previously heat treated

for 30 min at 900 K (i.e. having a maximum concentration of PMC) give a vacuum ESR signal (at 10^{-4} mmHg) whose intensity varies steeply and reversibly with the measurement temperature: it falls about 10-fold when the sample is cooled to 290 K, and returns to its initial value when the sample is re-heated *in vacuo* within the resonator of the spectrometer. As the intensity of the broad signal increases, a narrow ESR signal appears, and grows. On the other hand, if the heating and cooling cycles in the cavity are carried out under ordinary conditions (rather than in a vacuum) the intensity of the ESR signal becomes a maximum at 470–570 K. The increased intensity of the ESR absorption of heat treated vitrinite samples on cooling has been explained[258] not by the formation of free radicals or by irreversible rearrangements of the molecular structure, but by changes in the collective state of the electronic subsystem (possibly, of π-associations) under the influence of temperature.

More recent work[122,257–261] has tended to rely on improved methods of analysing the ESR spectra, using the entire spectrum rather than the shape of a single line, and allowing for complex, polymodal spectra, in order to extract information on the size of the structure fragments (radicals) of various types. The concept of clustering of paramagnetic centres has been firmly established in a recent paper[261].

Whittaker and Kintner[197] showed that the high-temperature emission (sublimation) of carbon at $T = 2800–4000$ K occurs mainly as graphite and carbyne particles, giving a visible Tyndall effect. In all types of carbon examined (graphite, coke, and carbon black compositions with spectroscopic carbon, pyrolytic carbon, or vitreous carbon as a binder) the weight of sample lost through the emission of particles was 60–90% of the total weight loss. Particle size varied from molecular (1–100 nm) to 60 μm.

Cypres and coworkers[262] have reported a thermogravimetric study of the hydrogenation kinetics ($C \rightarrow CH_4$) of high-purity (nuclear) graphite, i.e. of the gasification of graphite at atmospheric pressure in a stream of pure hydrogen at 1220 K in the presence of finely divided metallic iron as a catalyst. The rate of gasification was directly proportional to the concentration of iron in the sample. Graphite and α-iron were detected in partially gasified samples by X-ray diffraction. The diffraction patterns included three anomalous lines which could not be assigned to any known carbide. By using electron diffraction the following structural periods d_{hkl} (in pm) were observed for the new phases in different orientations:

214.0; 123.9; 106.3; 75.4; 70.0; 348.7; 238.9; 118.0; 79.4; 461.5; 261.5; 174.3; 152.8; 132.6; 98.1; 88.0.

The periods corresponding to the strongest reflexions are underlined. No attempt was made to discuss the nature of these new phases, though the correlation between some of the periods and those given by Whittaker and Wolten[198] for carbon-VI (carbyne) is striking ($a = 924$ pm, $c = 1224$ pm). Carbyne forms of carbon, more stable towards hydrogen, may be formed from graphite in the H–C–Fe system.

Carbynes are only beginning to gain general acceptance. They have tended to be ignored in the technical as well as in the scientific literature because of the reluctance to accept the exaggerated concept of an artificially graphitised polymeric carbon[16–20,23–25,28–34] (highly dispersed, turbostratic, defective, fine-, crypto-, or paracrystalline, etc.).

In spite of these difficulties approximately 100 papers on the structure, synthesis, properties, and even possible applications of carbyne have already been published, including several reviews[166–168,172,263,264]. Nevertheless carbyne remains a chemical curiosity: so far no atomic structure calculations have been carried out for any of its many modifications, nor have electron distribution calculations been attempted. The history of the discovery and of the gradual acceptance of carbyne (from the scientific and the practical point of view) is itself a fascinating study. By now the preparation of carbyne and the problems arising from its structure and properties have been integrated into the general problem of elemental (polymeric) carbon.

VIII. CONDENSATION OF CARBON AND LAMELLAR FORMATIONS

In general, graphite, carbon black, diamond, and carbyne can be formed from the gas phase (including plasmas and ionic–molecular beams). Evidently, the type of carbon formed is determined by kinetic rather than by thermodynamic factors: the intensity of the flow of carbon atoms being deposited, their energy, the degree of clustering (cooperation) in the flow, the structure and temperature of the substrate, the pressure and composition of the gaseous medium, etc.

In a d.c. arc carbon whiskers up to 3 cm long and ~10 μm in diameter can be formed[53]. According to recent evidence a whisker is a scroll of coaxial, helical carbon layers oriented normally to the substrate, i.e. parallel to the growth direction (axis) of the whisker. Surprisingly, a thin "leader", ~20 nm in diameter, grows first, and is subsequently thickened[265].

Characteristic spirals have been observed in synthetic and in natural graphites[266]. It was suggested[267] that graphite crystals grow by the addition of atoms or atomic groups to the edges of crystal faces. Though several crystallisation centres are thereby buried, some growth steps ~10 nm high are also formed. These spirals are easily seen in an electron microscope: they point to the pyramidal growth of layers in artificial graphite single crystals[268,269]. Conical graphite crystals consisting of thin packets of graphite layers successively wrapped round the *c* axis have also been observed. Their formation is interpreted as evidence of a spiral growth mechanism of the crystal.

Growth from acetylene-containing gases[124,141] on molybdenum disks heated by radiation from an LG-25 laser has yielded hollow carbon whiskers having a "bamboo" morphology, i.e. with a longitudinal periodicity. Straight, bent, or helically shaped whiskers have been obtained. According to diffraction measurements the graphite basal planes are stretched along the growth direction of the whiskers, which explains their high tensile strength. Electron diffraction measurements showed that the whiskerisation of carbon filaments 6 μm in diameter produces, in addition to graphite, also carbyne and other unidentified carbon phases having periods $d = 455$, 390, 340, 283, 262, 247, 213, 158, 147, and 123 pm.

The formation of hollow carbon whiskers with cylindrical internal cavities 2–50 nm in diameter has been reported also from other laboratories[270]. The filament body consists of two coaxial parts. One, adjacent to the axial cavity, is composed of long carbon layers extending along the axis, which apparently grew during the early stages of the process. The second (external) part of the filament is probably formed by pyrolytic deposition of "amorphous" carbon during a subsequent stage.

The graphitoid model of the growth mechanism and of the inner structure of carbon whiskers is probably far from correct. Thus, filamentary diamond crystals can also be grown from a vapour–gas mixture containing carbon[124,271,272]. In general the initial stages of the heterogeneous condensation (polymerisation) of carbon and the inner structure and morphology of the resulting product (carbon black, diamond,

graphite, carbyne, and "hybrid" forms) have not yet been studied systematically.

In this respect it is interesting to note[273] that the "hexagonal planar nets" in carbon deposits obtained by the decomposition of *p*-xylene in a glow discharge are rotated by 90° and oriented with their plane at right angles to the deposition surface. Growth from the gas phase of graphite scales with their basal plane normal to the deposition surface has also been reported[140].

High-resolution electron microscopy has been used to study partially graphitised film[70]. The films were found to contain vertically oriented one-, two-, and three-layer "graphite platelets", with their *c* axis perpendicular to the primary electron beam. The micrographs of the two- and three-layer graphite platelets showed that the inter-layer spacing in these very thin crystallites is significantly greater than in larger crystals. Convincing evidence was obtained that this observation is not a photographic artefact, but is genuinely due to a weakening of the van der Waals forces between layers in very thin crystals.

Similar features have been observed[274] in the growth of diamond-like films from the gas phase. The films were either fully microcrystalline, with randomly oriented grains, or well textured, with the (110) texture axis perpendicular to the substrate (consisting of the (111) face of a natural diamond crystal). However, deposition from ionic beams on polycrystalline substrates gave mainly diamond crystals with a (111) orientation[152-153].

Samples prepared by static compression of powdered graphite were recently found[275] to contain ~70% of lonsdalite, up to 20% of diamond, and up to 10% of graphite. One-dimensional disorder effects in the disposition of the (001) basal planes of lonsdalite have been detected. The powders were found (by transmission electron microscopy) to consist of flat particles, reflecting the platelet structure of the initial graphite. The textures observed on the electron diffraction patterns indicated (111) diamond planes and (001) lonsdalite planes perpendicular to the surface of the particle (which before the phase transition consisted of a (001) graphite plane). The observed orientations could have been caused by a martensitic transformation of the graphite by the mechanism known as longitudinal layer bending. During the graphite → lonsdalite transition equivalent systems of (100) graphite planes are transformed into (001) lonsdalite planes, and the [001] direction in graphite becomes the [100] direction in lonsdalite.

The block size of the lonsdalite, revealed by dark-field electron microscopy in the (103) reflexion, was about 4 nm, and that of the diamond in the (111) reflexion was 10–15 nm. The lattice parameters were: $a_l = 251.6 \pm 0.5$ pm, $c_l = 418 \pm 2$ pm, $a_d = 355.8 \pm 0.5$ pm. The latter value is substantially lower than the corresponding value for perfect, large diamond crystals ($a = 356.70 \pm 0.01$ pm).

Lastly, there are many reports[168-170,198,207,208,248] of individual crystalline carbyne particles with well developed facets and a platelet shape (lamellar or scale-like). It is thought that the partially cross-linked carbon chains are oriented at right angles (or at an angle which can vary by discrete amounts) to the basal face of the lamella. It follows that, as in the crystallisation of organic macromolecular chains (for example, polyethylene), the fundamental and simplest morphological unit in polymeric carbon is a thin, transparent particle (lamella) ~10 nm thick. The size of the lamella in the two other dimensions (i.e. in the direction of the basal plane) can be much greater: up to several tens or even hundreds of micrometres. The surface of these faces is fairly even, flat, and smooth, without any visible steps. The lamella as a whole can be sharply bent, folded, and twisted (Fig.3). Several lamellae stacked together produce piles, pyramids, and aggregates of the fan and bundle type (Fig.4). In general carbyne particles are conglomerates of separate lamellae, showing varying degrees of complexity.

Figure 3. Lamellar particle of α-carbyne (×20000).

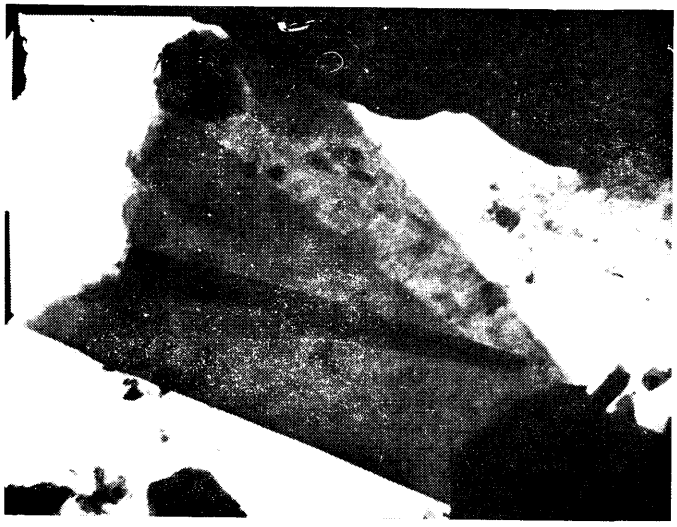

Figure 4. Aggregate of lamellar carbyne particles (×10000).

If carbon vapour is condensed on a cold substrate sufficiently slowly the product consists mainly of carbyne forms of carbon. The deposit is an assembly of fragment, mostly platelet-like. The thicker particles (stacks of lamellae,

Fig. 5) break up into several thinner particles, like schungite, when fractured by compression[276]. This observation convincingly demonstrates that large carbyne particles have a layered inner structure.

Figure 5. Layer structure of a condensed carbon particle (×2000).

Figure 6. Typical electron diffraction pattern of a carbyne lamella (with Au reference rings).

It has also been observed that under the influence of the electron beam an initially sharp diffraction pattern (spots and rings, Fig.6) often becomes gradually more diffuse, and after some time (~1 min) disappears. Amorphisation by electrons has been observed also in organic chain polymers[35], but not in diamond or graphite crystals. After irradiation the basal surface of the lamella develops pits ("sores") of various shapes. Similar fibrillar "vacuoles" have been observed by other workers[198,274]: the former were produced by radiation, but the latter were present in the sample as deposited from the gas phase, and they had almost invariably a regular conical shape.

Filamentary particles are occasionally detected in the scanning electron microscope[207]. This has led to the suggestion that individual carbon chains (molecules) become associated into a bundle of uniform composition[173,263]: a kind of primitive fibril. In this case dense particles are formed by the combination of submicroscopic filamentary particles[207]. Obviously these are the fragments which can be observed experimentally (to a varying extent) in all forms of condensed carbon, and they are the main structural units at the second (supermolecular) organisation level.

By combining dark-field contrast techniques with scanning electron microscopy in the transmission mode (which can sample a region only 0.24 nm in diameter) Isaacson and coworkers[277] have studied the structure of carbon films 0.68 nm thick condensed from the vapour phase, i.e. consisting of only 2–4 atomic layers. Both stepped and smooth regions over 3 nm in diameter were observed.

Figure 7. Lamellar microstructure of heat treated anthracite (HTT 3200 K): *a*) electron micrograph (×25000), *b*) electron diffraction pattern.

Carbon particles obtained by reducing polytetrafluoroethylene with sodium amalgam[278] consist of lamellae reminiscent of those found in polytetrafluoroethylene spherulites, a few tens of nanometres thick.

In anthracites the layer structure can be observed at all levels[111,112], from the optical (platelet shaped deposits) to the molecular. An electron micrograph and the corresponding selected-area diffraction pattern of thermo-graphite particles[279] prepared at 3100 K are shown in Fig.7. Platelets 10–30 nm thick are clearly visible. The individual lamellae consist of a parallel stack of aromatic layers parallel to the large faces. On the other hand the chains in the carbyne lamellae are oriented (apparently) at right angles to these faces, since most of the selected-area electron diffraction patterns have hexagonal symmetry.

A very unusual structure has been observed[280,281] in pitch cokes: ultrasonic dispersion can split off platelets (lamellae) thin enough to be transparent to the electron beam. The boundaries of the lamellae are clearly visible because the optical density is uniform within a single stack but it changes in discrete steps over the micrograph as a whole. Selected-area electron diffraction patterns from lamellar particles of unheated petroleum coke have shown[282] (002) and (004) reflexions from planes oriented almost normal to the planes responsible for the (110) and (100) reflexions, as in the case of mesophase particles. Hence the electron beam was aligned almost parallel to the atomic layers. These results were interpreted by assuming an oblique exposure, with the particles oriented preferentially at right angles to the substrate.

It has been shown[283] that irradiation of a thin carbon film with an Ar ion beam of 1.2 MeV energy produces surface corrugations, revealed by the appearance in the electron diffraction pattern of "three-dimensional" reflexions of the (112) and (002) type in addition to the basal ($hk0$) reflexions. It was also noted[284] that graphite single crystals are degraded in discrete steps rather than continuously when irradiated with neutrons: polygonisation into smaller crystals is the most likely mechanism.

Local electron diffraction patterns from lamellar particles in a single crystal of carbyne (Fig.8) can show a large number of weak but quite sharp rings corresponding to basal reflexions from graphite (probably deposited epitaxially on the large faces of the carbyne lamellae). In this case the system is evidently two-phased: carbyne, and a thin but extensive layer of relatively well ordered graphite. We should note that even Franklin[31] often observed one or two sharp lines corresponding to the periods d = 342.6 and 336 pm against the background of a diffuse (002) line in non-graphitising forms of carbon (from poly(vinylidene chloride) or sugar charcoal, 83.1% C, HTT = 2300–3300 K). A sharp peak against a diffuse (002) background is clearly visible also in heat treated wood charcoal[285], and in neutron-irradiated graphite[286,287]. Two-phase graphitisation is examined in depth in Refs.288 and 289.

This phenomenon clearly suggests the presence of relatively extensive crystalline regions ("islands") within the main, more amorphous material, and has been interpreted as heterogeneous graphitisation of the carbon vy evaporation and condensation on crystallisation centres, by transport of the carbon in the form of volatile compounds with hetero-atoms, and by other mechanisms[27,31,37,290–292]. However, an alternative agency leading to "heterogeneous graphitisation" is the presence of internal surfaces, and in particular the large faces of lamellar formations. By analogy with organic polymers we may assume that the lamellar structure in carbon is relatively labile, and easily destroyed. In a styrene–isoprene copolymer the largest period (60 nm) begins to increase quite rapidly[293] at temperatures as low as ~470 K, reaching 120 nm at 520 K: at the same time the number of low-angle reflexions decreases from 10 to 3. Above 520 K the low-angle diffraction pattern disappears completely. This behaviour suggests that the lamellar structure is not re-established when the molten polymer is cooled.

Brief (10–20 s) heating of oriented polyethylene samples 4.5 K above the melting point was also found[294] to cause a substantial increase in the large period: from 32 to 90 nm.

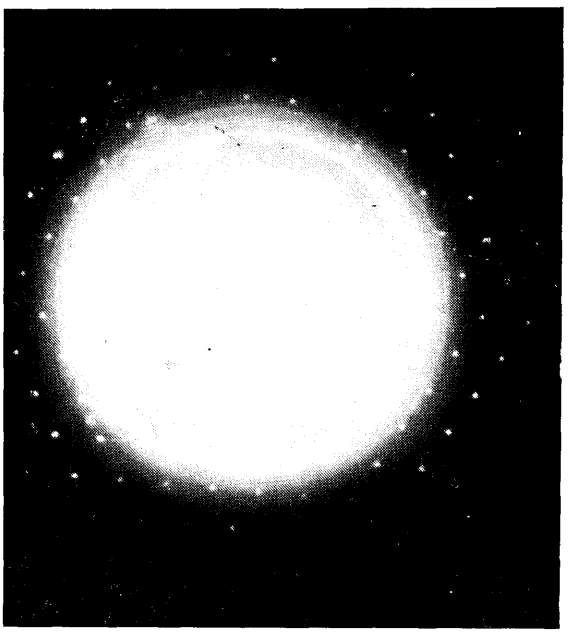

Figure 8. Selected-area electron diffraction pattern of a lamellar particle of deposited α-carbyne.

Experiments on the "pure" condensation (polymerisation) of elemental carbon under fully controlled conditions so far reported are few. Nevertheless the following conclusions are legitimate.

1. White carbyne deposits are obtained, apparently, under the milder condensation conditions: fairly high vacuum, low flux and energy of the atoms or groups of atoms (or ions) impinging on the substrate, low rate of deposition. The chains appear to grow normally to the surface without developing cross-links. Univalent hetero-atoms (e.g. hydrogen) in the surrounding medium may stabilise the chain and prevent cross-linking. These conditions occur during laser irradiation (in a vacuum) of pyrolytic graphite platelets, followed by condensation of the vapour on another platelet[204,207] or near the rim of the resulting crater[180–183,199,200]. They also occur during the normal evaporation (emission) of carbon from the hotter parts of the surface and condensation on the cooler parts[198], during the evaporation of spectroscopically pure carbon in an electric arc in a vacuum evaporator, followed by free crystallisation of the vapour on a freshly cleaved rocksalt crystal[208], during the synthesis of carbyne from organic compounds in a glow discharge[244], in a low-temperature plasma[142,241,242], etc.

2. Diamond (lonsdalite), on the other hand, is obtained under less mild condensation conditions: high energy of the impinging atoms or ions (which thus penetrate deep into the already deposited film and perturb its structure, "mingling"

the carbon atoms and favouring chemical cross-linking). The substrate in this case plays only a minor role. This probably explains the fact that diamond rather than carbyne films are almost invariable obtained from molecular (or ion) beams in a vacuum[143-156]. It is also found[295] that the bombardment of thin graphite films partially ordered (in three dimensions) with Ar^+, N^+, He^+, and Ne^+ ions of average energy 50–80 keV converts the sample into a new modification of carbon which has a low electrical conductivity, a high hardness, and a face-centred cubic lattice of period $a = 369$ pm (as compared with $a = 356.70$ pm for diamond). A chemically active surrounding atmosphere and a high pressure also favour the cross-linking of carbon atoms and chains into diamond forms of carbon[236]: this is probably the mechanism of the synthesis of diamond from the gas phase by Deryagin and Fedoseev's method[124-133,136-139]. Pressures (under shock tube conditions) up to 120 GPa have also been shown to convert graphite into diamond, and diamond into a metallic carbon phase[296,297]. Vitreous carbon under shock compression is converted into an ordered state (probably a diamond phase[296]).

3. Under ordinary (moderate) conditions, with a fairly high concentration of gas-phase atoms of not too high energy, layer polymers of carbon are formed: pyrolytic graphite, carbon black, and pyrolytic carbon, with a high or a low concentration of inter-chain and inter-layer chemical bonds (cross-links) in a regular arrangement.

IX. CONCLUSIONS

Solid carbonaceous materials had traditionally been classified into three categories: diamond (lonsdalite), crystalline graphite, and amorphous carbons.

According to well established classical views substances such as blacks, coals, cokes, schungite, pyrolytic carbon, evaporated layers, etc. are systems consisting of small graphite fragments (crystallites) embedded in random orientations in the amorphous material. The basic component of all forms of carbon (except diamond and lonsdalite) was thought to be the aromatic two-dimensional layer (or macromolecule). The difference between different substances was purely quantitative, depending on the difference in size and shape of these layers, as well as on their degree of perfection (flatness) and the order of their mutual orientation. Obviously, diamond and lonsdalite are an exception to the general rule. The diamond type of lattice forms a special subgroup among the symmetry space groups defined in crystallography and in crystal chemistry.

The temptation to fit all the multitude of non-diamond polymeric forms of carbon into the Procrustean bed of graphite is still strong. The discovery of long tape-like aromatic fragments and diamond-like inclusions, the amorphous fringe concept (i.e. carbon chains and extensive layers (macromolecules) connecting different graphite crystallites), the concept of coexisting atoms of different types (with sp, sp^2, or sp^3 hybridisation of the atomic orbitals) in the so-called transitional forms of carbon, even the discovery of new crystalline (carbyne) forms of carbon have rocked the foundations of the graphitoid conception of the artificial graphitisation of polymeric carbon but have failed to destroy it. The sharpest criticism of this conception arose from studies of the nature of coals, in which linear carbon polymers were suggested as an alternative to the graphitons (or aromatic layers).

In this review we have tried to demonstrate the limitations of the graphitoid ideas as applied not only to coals but to all forms of carbon by analysing experimental data and theoretical models. Crystalline graphites and diamonds (in two, three, or many layers) are only a few of the forms in which polymeric carbon can exist: they may be the commonest, but not necessarily the most stable. This conclusion is no longer in doubt. Crystalline carbyne, which contains carbon chains between branching points, has as much physical reality as graphites and diamonds. Whereas in the traditional approach the very suggestion of transitional forms of carbon in a crystalline state (regular type) appears absurd, experiment shows the opposite, namely that an immeasurably large number of crystalline forms of carbon can exist. This phenomenon is yet another illustration of the many unique aspects of carbon as an element: it is not surprising that life on earth should have developed through the biochemistry of its compounds.

The electronic subsystem of a cooperative system of carbon atoms is very labile. It is characterised by a large number of metastable states: transitions between these states are possible, giving switching effects, even for a given (fixed) configuration of the atomic nuclei. Equally numerous are the possible types of electronic state of the atomic "loggias". The coordination (cooperation) between atoms can differ, the coordination number z usually varying between 2 and 4, though other values are possible. In this sense a one-component substance consisting of single carbon atoms should more correctly be treated as consisting of atoms of different types, since the atoms are not identical. The possible combinations of even three kinds of carbon atom (in reality, far more than three) are very numerous and varied. They amount to a set of systems of indeterminate composition and both regular and non-regular structure.

Some crystalline forms of carbon may have very unusual electrophysical, magnetic, or mechanical properties: they can be superconductors, conductors, semiconductors, or insulators. The strategic objectives of current carbon research include the development of a systematic approach to a unified scientific description of cooperative phenomena in elemental carbon, the controlled synthesis of carbon crystals having prescribed properties, and the study of the structure and properties of these crystals.

Diamond has long been used as a super-hard material, and graphite also has found widespread practical applications. Carbyne is now beginning to establish itself. Polymeric carbon, in its enormous variety of forms and modifications, will undoubtedly become a leading technological material. The strong tendency of carbon towards localised cooperation (polymerisation), increasing with temperature, gives it an advantage over all other polymers, which are degraded by heat.

The general progress in carbon science and the developments in the carbon industry have created new prospects for the application of different types of carbon in electronics, the aircraft industry, space technology, medicine, constructional materials, etc.

Highly Anisotropic Molecular Solids

V.A.Starodub and I.V.Krivoshei

The physicochemical properties of quasi-one-dimensional crystals formed by charge-transfer complexes, radical-ion salts, and coordination and organometallic compounds are examined. The characteristics of the electrophysical, optical, and mechanical properties of these compounds due to the crystal structure and the nature of the movement of the electrons and (or) holes in them are discussed.
The bibliography includes 230 references

I. INTRODUCTION

The development of the physics and chemistry of the solid state involves at the present stage the study of new classes of substances. The greatest advances are associated with the investigation of low-dimensional molecular solids—quasi-one-dimensional and quasi-two-dimensional. By quasi-one-dimensional systems, one understands systems exhibiting a high anisotropy of their physical properties: electrical resistance, magnetic susceptibility, reflection coefficient, Young's modulus, and others. The electrons in such systems can move mainly along one direction (filament) crossing from one filament to another only in rare instances either as a result of jumps or by tunnelling. Such systems are attractive because one can neglect to a first approximation the interaction between the filaments and one can consider one-dimensional movement for which there exist a whole series of many-particle models susceptible to exact solution.

The problem of quasi-one-dimensional systems arose after the publication of the interesting although erroneous study by Little[1]. This was associated with the problem of high-temperature superconductivity, namely the possibility of the operation of the exciton—electron mechanism of superconductivity. Little put forward a specific version of this mechanism (known as the Little model) comprising a polymeric highly conducting organic linear molecule containing side chains—monomers with a high polarisability. On the basis of the one dimensional model, Little applied the Bardeen—Cooper—Schrieffer (BCS) theory, which constitutes a satisfactory approximation in the three-dimensional case, to the calculation of the critical temperature of a superconducting junction and obtained the fantastic value $T_{cr} = 2200$ K. In other words, a system satisfying Little's model must be a superconductor over the entire temperature range of its existence.

The results of this study were subjected to a thorough and just criticism (see, for example, Refs.2–4), but it created such an enormous impression that a search was immediately begun for systems formally satisfying Little's model. The initial aim was to increase the critical temperature for superconduction: this led to the creation of new branches of the physics and chemistry of the solid state—the physics and chemistry of quasi-one-dimensional systems. Substances with a high anisotropy in physical properties were discovered primarily among the class of molecular complexes—charge-transfer complexes (CTC) and radical-ion salts (RIS). As early as 1962, the radical-anion salts of 7,7',8,8'-tetracyanoquinodimethane (TCNQ) with simple and complex compositions [Kt^+TCNQ^-, $Kt^+(TCNQ)_2^-$, and $Kt_2(TCNQ)_3^{2-}$, where Kt is the metal or organic base action], were described in a review[5]. A characteristic feature of systems of this kind is an unusual quasi-one-dimensional nature of the packing of the salt components in the crystal in which the TCNQ molecules form infinite columns of interleaved and non-interleaved types (Fig.1).[6,7]

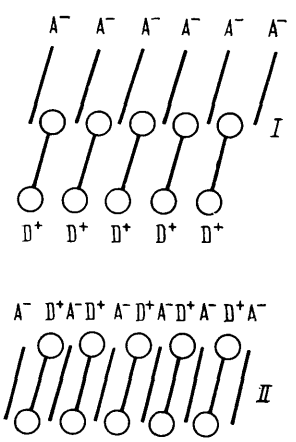

Figure 1. Types of molecular packing of CTC: II) interleaved type; I) non-interleaved type; A = acceptor; D = donor.

In 1968 Krogmann obtained planar mixed valence complexes with metal—metal bonds based on platinum cyanide (Krogmann salts)[8,9]. These salts have the composition $K_2Pt(CN)_4.X_{0.3}\cdot nH_2O$ (X = Cl or Br) and exhibit a distinct anisotropy of their

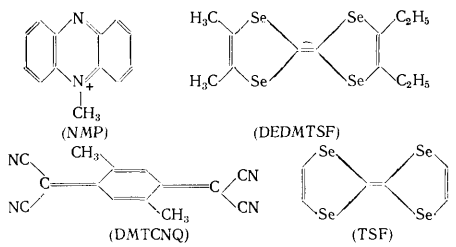
electrical, magnetic, and optical properties[10-12]. Compounds with a similar structure were obtained by Krogmann on the basis of complex platinum oxalates, for example, $Mg_{0.82}\cdot[Pt(C_2O_4)_2].5.3H_2O$ and $K_{1.6}[Pt(C_2O_4)_2].2H_2O$.[13,14] Highly conducting compounds with a quasi-one-dimensional structure, based on iridium carbonyl halides having the composition $K_n[Ir(CO)_4Cl_m]$, have been described[15]. The physical properties of the above compounds have been examined in detail in a review[16] and therefore not discussed here. Particular attention has been devoted to the properties of organic conductors, their synthesis, and purification in the review of Khidekel' and Zhilyaeva[17].

The present review surveys the results of experimental and theoretical studies on highly anisotropic molecular solids (excluding polymers) obtained after the publication of previous reviews[16,17].

II. THEORY OF LINEAR CONDUCTING SYSTEMS

Numerous studies have been made on the nature and stability of the metallic state in quasi-one-dimensional systems. It was therefore necessary to develop new methods of calculation taking into account the interaction between one-dimensional filaments, which is very significant for phase transitions in quasi-one-dimensional crystals (phase transitions are impossible in a rigorously one-dimensional crystal[4]).

In order to explain the electrical properties of charge-transfer complexes (CTC), many different models have been proposed. The most natural model is that of bilinear organic conductors in which the conductivity of the crystal is assumed to be additive to a first approximation. On the basis of this model, Phillips[18,19] explained the characteristics of the electrical properties of organic conductors by the appearance of domains with a Peierls structure. It is assumed that the sizes of the Peierls energy gaps are different for donor and acceptor columns and the lattice periods are therefore also different. The domains with a Peierls structure are formed when the difference between $E_A(T)$ and $E_D(T)$ is small. This type of structure disappears in a first order-phase transition. The Phillips model is applicable to TCNQ complexes; in particular, it explains the observed temperature dependence of the electrical conductivity $\sigma(T)$, which varies in proportion to T^{-n} $(n>1)$ when $T>T_D$. The domains alternate with metallic regions whose length is of the order of hundreds of angstroms. The charge can migrate not only along the chains but also between them—via jumps.



The structure of the CTC depends significantly on the Coulombic electrostatic interaction, on the elucidation of the role of which numerous studies have been carried out[20-27]. The charge transfer in the formation of the CTC leads to a considerable increase of the electrostatic energy owing to the repulsion of the charges of the neighbouring molecules in the column. This energy decreases either owing to the formation of complex salts or as a result of incomplete charge transfer. The possibility then arises of a resonance electron transfer via a relay mechanism:

$$\text{—}A^-\text{—}A^0\text{—}A^-\text{—}A^0\text{—} \rightarrow \text{—}A^0\text{—}A^-\text{—}A^0\text{—}A^-\text{—} .$$

In the tetrathiofulvalene—tetracyanoquinodimethane (TTF–TCNQ) complex there is not only incomplete charge transfer but charge density waves (CDW) are generated with a wave vector $4k_F$ ($\hbar k_F$ is the Fermi-quasi-momentum)[20]. The instability as regards the formation of the CDW is the only type of instability occurring at finite temperatures in the one-dimensional chain of a quasi-one-dimensional conductor and is due to the Coulombic electrostatic interaction and the interaction between the electrons and phonons of the three-dimensional crystal[21]. On decrease of temperature, a phase transition takes place in systems of this kind to a state with CDW, accompanied by the distortion of the lattice with a period $(4k_F)^{-1}$. In an ordered state non-linear CDW excitations constitute solitions with a gap in the excitation spectrum. Analogous collective states of a one-dimensional electron gas, which can be interpreted as isolated or bound solitons, can conduct an electric current[22,23]. The dependence of the current transmitted by solitons on temperature is of the activated type. The soliton model has been discussed in connection with the attempt to interpret the electrical conductivity peak in the TTF–TCNQ crystals[24].

The interaction of a rarefied electron gas with a highly polarised background can lead to an effective electron—electron repulsion. There is then a possibility of the Wigner "crystallisation" of the electron gas either in the form of individual electrons or in the forms of pairs[25-27]. The presence of such a generalised lattice makes it possible to interpret the optical spectra of TCNQ salts and to explain the satellite reflections on X-ray diffraction patterns[28]. The structure arising in the TTF–TCNQ complex is of the antiferroelectric type.

In systems containing components with a low symmetry there is a possibility of instability due to orientation disorder. The symmetry of planar centrosymmetric molecules can decrease as far as C_S following the introduction of one of two substituents. Examples of such compounds are provided by the complexes NMP–TCNQ, DEDMTSF–TCNQ (contain only asymmetric cations), TSF–DMTCNQ (contains only asymmetric anion), and others†.

One of the alternative possibilities in the packing of asymmetric fragments in the column is orientationally disordered packing. The influence of such disorder on the instability of the Peierls type has been examined[29]. The breakdown of translational symmetry on orientational deformation merely modulates, in contrast to shear deformation, the local energy of the electron, leaving unchanged the transition integrals. The gap in the electronic spectrum is then absent and the Peierls transition does not arise. Allowance for the interaction of the electrons of the one-dimensional chain with the rotational vibrations of the organic molecules (librons) demonstrated the possibility of the existence of states with the so-called chiral charge density waves (CCDW). A lattice instability with a wave vector $\mathbf{Q}=4\mathbf{k}_F$ corresponds to these. The transition to the state with CCDW can account for the continuous variation of the superstructure period from a to $2a$ and then to $4a$ in the TTF–TCNQ crystals, which occurs in the range 54–38 K. The electron–libron interaction is also very significant in TSF–TCNQ and $(TTF)_7I_5$.[30]

† Notation: NMP = *N*-dimethylphenazinium ion; DEDMTSF = diethyldimethyltetraselenofulvalene; DMTCNQ = dimethyltetracyanoquinodimethane; TSF = tetraselenofulvalene.

The lattice instability of the quasi-one-dimensional crystals is due in the general case to two fundamentally different contributions-dimerisation of the Peierls type via electron–phonon interaction and spin-Peierls dimerisation due to the spin–lattice interaction. The two different contributions have been estimated[31] using the self-consistent field approximation. Intermediate values of the interelectron interaction constants for which the electronic states are still delocalised, i.e. $t \propto U$, were taken. Here t is the integral for the transition of an electron between two nearest electronic states and U is the energy of the interaction of two electrons at a single site. By virtue of the quadratic relation between the exchange integrals and the transition integrals ($J \propto t_2$), the spin–lattice interaction is more effective than the electron–lattice interaction for intermediate values of t/U and for this reason the spin-Peierls transition is more probable than the Peierls transition.

The radical-anion salt $K^+TCNQ^{-\cdot}$, which undergoes a phase transition at 396 K, formally satisfies this model. Here there is a change in the energy gap and a complex rearrangement of the one-dimensional chain takes place and is accompanied by a rearragement of the spin structure. For this reason $K^+TCNQ^{-\cdot}$ is a spin system which exhibits Peierls instability in the vicinity of Tp.[32]

Ideas about the spin-Peierls instability have been used[33] to account for two Konno anomalies in quasi-one-dimensional TCNQ salts with the wave vectors $\mathbf{k}_1 = \mathbf{b}^*\rho$ and $\mathbf{k}_2 = \mathbf{b}^*\rho/2$, where $\mathbf{b}^*$ is the inverse lattice vector along the chains and ρ is the number of conductivity electrons per molecule ($\rho < 1$). For $\rho = 1/2$, the anomaly with $\mathbf{k}_1$ is caused by the electron–phonon interaction in which pairs of molecules containing one electron are combined into diads. The anomaly with $\mathbf{k}_2$ corresponds to the Peierls transition, i.e. the transition to the antiferromagnetic state in which the electrons of neighbouring diads form singlet pairs (it is assumed that $T_1 > T_2$). The lattice period is then quadrupled.

Studies on the infrared spectra of conducting quasi-one-dimensional crystals of TCNQ salts, initiated by Kaplunov et al.[34] and Kondow and Sakata[35], revealed their fundamental difference from the spectra of other molecular crystals. A characteristic feature is the presence of a broad absorption band associated with intermolecular charge transfer along the TCNQ column, beginning on the high-frequency side in the visible part of the spectrum and embracing the low-frequency infrared region to a greater extent the higher the electrical conductivity of the complex. This band covers the region of the low-frequency intramolecular vibrations (IMV) of the TCNQ molecules. The observed spectrum is not a simple sum of the electronic and vibrational spectra and has a more complex form: anomalously broadened asymmetric lines correspond to the intramolecular vibrations of TCNQ and the polarised spectra of the single crystals contain lines corresponding to the IMV with A_g symmetry, i.e. to electrical dipolar transitions which are prohibited for an isolated molecule.

The important role of the interaction of the electron system with IMV in the interpretation of the electronic, kinetic processes in TCNQ crystals has been established in a number of theoretical studies[36–42]. Allowance for the interaction is also necessary, according to Epstein and Conwell[43], in the analysis of temperature variation of the electrical conductivity and the electron mobility in crystals of TCNQ salts. We may also note that the study of the interaction of electrons with high-frequency IMV in organic conducting crystals is of interest in connection with the problem of high-temperature super-conductivity via the phonon mechanism. The first determination of the electron–phonon interaction constants for TCNQ salts by analysing the infrared spectra of the $TEA(TCNQ)_2$ salt (TEA = tetraethylammonium) has been carried out by Belousov et al.[44]

On the basis of a phenomenological model the above workers[44] obtained a formula for the component of the dielectric constant tensor along the conducting filaments:

$$\varepsilon_{\parallel}(\omega) = \varepsilon_{\parallel}^{\infty}\left[1 + \frac{(\omega_{le}^2 - \omega_{tl}^2)}{\omega_{te}^2 - \omega^2 - ig_e\omega - \sum\limits_k \gamma_k^2/(\omega_k^2 - \omega^2 - ig_k\omega)}\right],$$

incorporating the background dielectric constant $\varepsilon_{\parallel}^{\infty}$, the longitudinal frequency ω_{le}, the intrinsic frequency ω_{tl} of a one-dimensional harmonic oscillator describing the electronic transition with a decay coefficient g_e, the frequency ω_k and the decay coefficient g_k of IMV of type k, and the interaction constant γ_k.

This formula describes effects associated with the frequency shift and the occurrence of forbidden transitions known for Fano resonance[45]. The optical conductivity $\sigma(\omega) = \omega \mathrm{Im}\varepsilon_{\parallel}(\omega)$ spectrum differs significantly from the sum of the electronic and vibrational spectra. The spectrum illustrated in Fig. 2 is a result of the interference of the electronic and vibrational states and corresponds to the antiresonance of a continuous spectrum with a set of discrete vibrational levels. For example, the ω_k vibration, located on the low-frequency slope of the electronic band is manifested by an asymmetric band (with a width much greater than g_k), beginning with a shallow minimum on the high-frequency side, at a frequency close to ω_k. The vibration

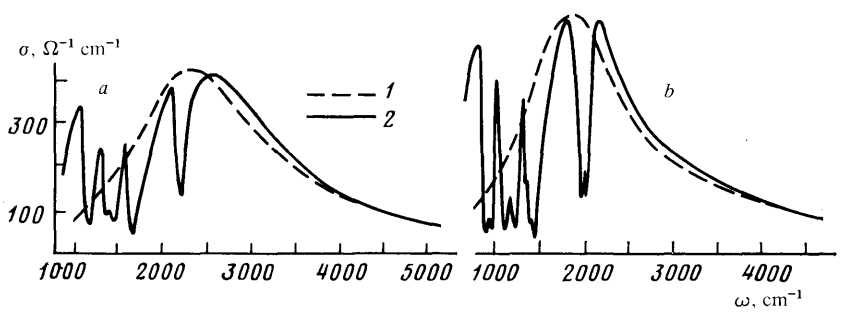


Figure 2. Spectroscopic relations for the optical conductivity of $TEA(TCNQ)_2$ crystals with E polarisation[44]: *1*) unperturbed electronic band; *2*) the same band with allowance for the interaction with intramolecular vibrations: *a*) 300 K; *b*) 100 K.

occurring in the region of the maximum of the electronic band is manifested by a "crossing-over point".

It has been shown[46] that the high dielectric constant of the salt TEA $(TCNQ)_2$ is due to the interaction of the low-frequency intramolecular TCNQ vibrations with electrons, leading to the formation of mixed electron–phonon states with a high oscillator strength.

The theoretical studies undertaken to elucidate the relation between the temperatures of the superconducting transition (T_c) and the Peierls transition (T_p) are important. It is known[47] that, to a first approximation, $T_c \cong T_p$ or the two temperatures are very similar, from which it follows that in such systems the superconductivity is fundamentally unobservable (the superconducting transition is suppressed by the dielectric transition). The two temperatures T_c and T_p increase monotonically with increase of the electron–phonon interaction constants and for low constants $T_c > T_p$, while for high constants, $T_c < T_p$.[48] This means that T_c for quasi-one-dimensional systems are hardly likely to be high, but they may nevertheless be appreciably higher than for a three-dimensional highly anisotropic metal[49]. Exciton shielding does not apparently exert a decisive influence on the electronic properties of radical-ion salts[50].

The problem of the influence of impurities in quasi-one-dimensional conductors on T_c and T_p has been studied[51,52]. For a weak electron–electron interaction, the impurities suppress the three-dimensional phase transition and increase the superconductivity fluctuation in unit chains. Marked scattering by the impurities fully suppresses the dielectric Peierls transition and, after the attainment of a certain critical concentration of impurities, the superconducting transition is also suppressed.

III. THE TETRATHIOFULVALENE–7,7,8,8-TETRACYANOQUINODIMETHANE COMPLEX

The attention of investigators has been mainly directed to a detailed study of the phase transitions in TTF–TCNQ crystals. Numerous precise measurements of the physical properties over a wide temperature range have now been carried out. The resistance R along conducting columns has been measured to within 10^{-5}. A sharp negative discrepancy at 53 K, associated with a second-order transition, has been observed in the relation between dR/dT and T.[53] The temperature dependence of the electrical conductivity in the range 20–300 K and at pressures up to 6×10^8 Pa exhibits two anomalies[54]. The temperature of the first (the metal–dielectric transition) (54 K and $p = 0$) increases with increasing pressure, while that of the second (38 K and $p = 0$) decreases slowly. Since the width of the conductivity band in the TTF–TCNQ complex increases with pressure in the experimental range of the latter, these results are difficult to interpret within the framework of the existing theory of the Peierls transition. The transitions have been interpreted[55] as independent transitions in the donor and acceptor columns, namely the transition at 54 K corresponds to ordering in the TCNQ chains while that at 38 K is associated with further ordering in the TTF chains, which leads to the appearance of a gap in the TTF column. Only one transition, at 29 K, is observed in TSF–TCNQ crystals, which can be accounted for by an intense interchain interaction.

The ability of the TTF–TCNQ and TSF–TCNQ complexes to form solid solutions makes it possible to obtain TTF_xTSF_{1-x}·TCNQ single crystals ($0 \leq x \leq 1$).[56–58]. Studies on the electrophysical properties of such crystals showed that the conductivity of the TTF–TCNQ crystal is determined by TCNQ chains in the range 300–58 K and by TTF chains in the range 58–38 K. The conductivities of the donor and acceptor columns in the TSF–TCNQ crystals are of the same order of magnitude. It therefore appears likely that both donor and acceptor columns are responsible for the transition at 38 K in TTF–TCNQ. The simple phase transition in TSF–TCNQ splits into two components after the addition of small amounts of TTF–TCNQ (<2%). The temperature of the high-temperature transition increases rapidly with increasing TTF concentration, while that of the low-temperature transition diminishes slowly, but the region of the anomaly in the resistance associated with this transition is markedly broadened.

Measurements of the velocity of sound in the range 0–300 K established[59,60] that Young's modulus is anistotropic ($E_a > E_b$, where b is the maximum conductivity axis), increases with decrease of temperature, and diminishes by several per cent in the vicinity of the transition point (54 K), the decay of sound at this temperature passing through a maximum. The increase of the velocity of sound by 1.5% at $T < 52$ K is due to the freezing of the conductivity electrons. A singularity is observed in the vicinity of T_p in the relation between the change in the magnetic susceptibility $d\chi/dT$ and T: $d\chi/dT \propto (T - T_p)^{1/3}$ and $\chi \propto \Delta^2$, where Δ is the width of the dielectric gap. There are no singularities on the $\chi(T)$ and $(d\chi/dT)(T)$ curves near the second transition[61], but they are manifested clearly on the $\chi(T)$ curve after the isolation of the contribution by the background (Fig. 3).[62]

Precise measurements of the heat capacity of the TTF–TCNQ crystals revealed four phase transitions, at 52.6, 48, 46, and 37 K,[63] while precise measurements of Young's modulus in the range 54–38 K led to the differentiation of five phase transitions[64]. These transitions can be regarded as martensite transformations in which the effects of the elastic interaction and of the ordering of microdomains, leading to one- and three-dimensional distortions of the lattice, play a significant role. The anomaly at 46 K is associated with a phase transition in the surface region, corresponding to the transition at 49 K in a massive specimen.

Measurements of neutron scattering in the range 38–54 K revealed the existence at $T < 38$ K of a three-dimensional structure with modulation of long-range order along the a and b axes in the initial monoclinic lattice with periods of $4a$ and $3.4b$.[65] The magnetoresistance of the TTF–TCNQ crystals $\Delta\rho/\rho = [\rho(50\text{ K}) - \rho(0)]/\rho(0)$ is smaller by 0.1% in the temperature range $T > 54$ K,[66] while at $T = 52.8$ K there is a magnetroresistance peak of 1.4%. The temperature T_p decreases in a magnetic field in accordance with the law

$$\Delta T \propto (\mu_B H)^2 (2k_F)^2 T_p$$

The results of Cooper et al.,[67] who investigated the influence of the isotope substitutions $^2H \rightarrow {}^1H$ and $^{15}N \rightarrow {}^{14}N$ on the transitions at 52.5 K (T_1) and 37.7 K (T_2), confirmed the view that the transitons in the TTF and TCNQ columns are independent. When both chains are deuterated, T_1 increases by 0.75 K, while the substitution of ^{14}N results in an increase by 0.6 K. When only TTF is deuterated, T_1 remains unchanged, but T_2 is altered. On the other hand, when only TCNQ is deuterated, T_1 increases by 0.7 K, while T_2 remains unchanged. This result can be explained by the fact that all molecular vibrations contribute to the Peierls instabilities; their relative contributions are determined by the binding constants. In TCNQ chains the instability is determined mainly by the intramolecular vibrations[68].

Several theoretical models have been proposed to account for the phase transitions in the range 38–54 K.[69–74]. The transitions at 54, 49, and 38 K can be accounted for on the basis of the Ginzburg–Landau theory. In contrast to the generally accepted interpretation, it has been claimed[73] that

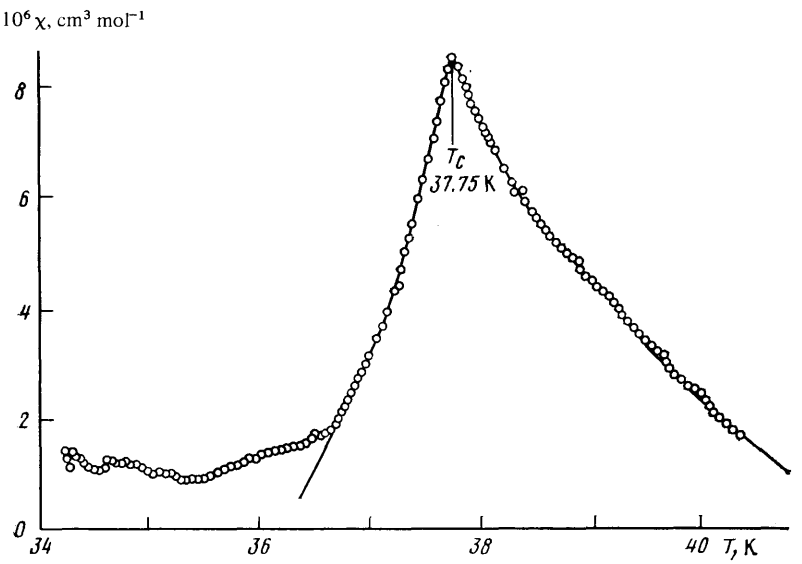

Figure 3. The anomaly in the magnetic susceptibility of the complex TTF–TCNQ near 38 K after the isolation of the background, giving rise to an exponential $\lambda(T)$ relation[62].

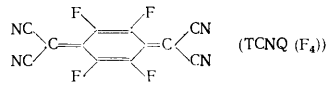
the transition at 54 K is associated with ordering in both filaments and not only in the TCNQ column. Experiments on X-ray scattering[72] made it possible to relate the transition at 54 K to the condensation of the anomaly with the wave vector $2\mathbf{k}_F$ in the form of the $2a \times 3.4b \times c$ superstructure, while the transition at 49 K can be related to the condensation of both longitudinal anomalies with the vectors $2\mathbf{k}_F$ and $4\mathbf{k}_F$.

In order to explain the microanomalies of Young's modulus in the range 38–52 K, a model based on the idea of the domain structure of the metallic and dielectric phases has been proposed[70]: it is believed that the column consists of conducting and non-conducting sections separated by domain walls consisting of a separate phase. The transition at 47 K corresponds to the formation of tetrads made up of metallic domains, while the transition at 38 K corresponds to their ordering. The transition at 34 K corresponds to the disappearance of metal–dielectric microdomain transitions from the TCNQ columns[70,71]. The transitions at 49–54 K have also been interpreted using the concept of phasons—excitations of the ground state with CDW which infringe the symmetry as a consequence of the phase shift of the CDW of the neighbouring chains[69]. The transition at 49 K corresponds to the instability of the phason mode. In this model there is a linear (in terms of the phason amplitude) interaction with a deformation of the crystal and the transition can therefore be suppressed by the application of an appropriate pressure. Thus, despite the abundance of experimental data, the theoretical interpretation of the results is not yet clear mainly due to the lack of a general theory of quasi-one-dimensional systems.

A series of detailed experimental studies have been made on the influence of the purity and perfection of TTF–TCNQ crystals on their electrophysical properties as well as the influence of the methods of measurement. One of the possible ways of taking into account the influence of the direction of the crystals is statistical analysis of the results of different workers. Such analysis, based on a survey of 600 measurements in 18 world laboratories[75], shows that the hypothesis of superconducting fluctuations is superfluous. The temperature T_P is in the range 54–58 K;[76] the scatter of the values is determined mainly by the degree of perfection of the single crystals and to a lesser extent by the concentration of the impurities.

This has been shown for TTF–TCNQ crystals with impurity concentration not exceeding 10^{-6}.[77,78] As a consequence of the low value of the disproportionation energy of the $TCNQ^-$ and TTF^+ radical-ions, the TTF–TCNQ crystals possess an internal source of contamination and, according to Haddon's data[79], the concentration of the impurities formed on disproportionation via the mechanisms



$$2TCNQ^{\cdot-} \rightarrow TCNQ^0 + TCNQ^{2-},$$
$$2TTF^{\cdot+} \rightarrow TTF^0 + TTF^{2+},$$

can reach 12%. Crystals grown from the gas phase are not free from such contamination either. This follows from the scatter of the values of σ_b (at 300 K) for such crystals, which are in the range $(2\text{–}6.7) \times 10^4\ \Omega^{-1}\ m^{-1}$.[80] A very great change in σ in the region of 58 K has not been observed either for large TTF–TCNQ crystals whose dimensions were $7 \times 0.5 \times 0.24$ mm and $30 \times 6 \times 0.7$ mm.[81] The concept of the anisotropy of σ arises from measurements of its principal values for a series of crystals: $\sigma_b = (4.40 \pm 0.15) \times 10^4$, $\sigma_a = (1.30 \pm 0.05) \times 10^2$, and $\sigma_c = (12.6 \pm 30.0) \times 10^2\ \Omega^{-1} m^{-1}$.[82] The scatter of the values of σ_c is due to the small thickness of the crystals in the direction of the c axis and the possible diffusion of the current-conducting silver paste through the crystal.

The magnitude of the transferred charge Δq in TTF–TCNQ crystals is important for the construction of a theoretical model for the latter. It has been determined by various methods and the scatter of its values proved to be small. Direct numerical integration in terms of X-ray structure factors yields $\Delta q = (8.55 \pm 0.95) \times 10^{-20}$ C.[83] Experiments on Raman scattering by TTF, TTF–TCNQ, and $(TTF)_7I_5$ crystals[84] in the temperature range 4–77 K yielded $\Delta q = 7.92 \times 10^{-20}$ C.[85] Two peaks of the $N1s$ levels have been observed

in the X-ray photoemission spectra, which corresponds to two TCNQ charge states (neutral and singly ionised)[86]. The ratio of the intensities of these peaks, proportional to Δq, yields the estimate $\Delta q \cong (8.87-10.61) \times 10^{-20}$ C.

Silverman[87] suggested that Δq for CTC is always smaller than unity, while for TTF–TCNQ it amounts to 9.35×10^{-20} C. All the results quoted above confirm the conclusion[88] that the optimum value of Δq, necessary for the preparation of highly conducting CTC, is $(9.50-12.67) \times 10^{-20}$ C per molecule. This is associated with two opposed factors: an increase of q entails an increase of the concentration of the conductivity electrons (and hence also of σ) and at the same time an increase of the Coulombic repulsion of the electrons, leading in the limit to the splitting of the conductivity band and the formation of localised electronic states. In fact, the value of Δq estimated by X-ray electronic spectroscopy for the TTF–TCNQ complex

(TCNQ (F_4))

with a low conductivity is $(15.04 \pm 3.17) \times 10^{-20}$ C.[89] A high value of Δq is obtained as a result of the high electron affinity (higher by 0.4 eV than that of TCNQ).[90] TCNQ(F_4) can therefore be used to obtain highly conducting CTC employing weaker donors.

Complexes of TTF with TCNQ having a different stoichiometry are also known: $(TTF)_3(TCNQ)_2$ and $(TTF)_2TCNQ$.[91] These complexes are obtained by the low-temperature exchange method.

IV. CHARGE-TRANSFER COMPLEXES AND RADICAL-ION SALTS BASED ON 7,7,8,8-TETRACYANOQUINODIMETHANE

Simple radical-anion salts based on TCNQ have attracted the interest of both experimenters and theoreticians in connection with the fact that they exhibit two types of instability of the metallic state: the Mott and Peierls instabilities. In both of these salts a structural Peierls transition takes place at certain temperatures with retention of the Mott gap. Such a transition has been investigated[92] by X-ray diffraction for the salt Na^+TCNQ^-. In the low-temperature phase ($T < 353$ K) the distances in the $TCNQ^-$ column alternate: 3.212×10^{-10} and 3.429×10^{-10} m, while in the high-temperature phase all the distances are equalised: 3.385×10^{-10} m. The analogous transition at 396 K in K^+TCNQ^- crystals[93] is accompanied simultaneously by a rearrangement of the spin structure and K^+TCNQ^- is therefore a system which exhibits spin-Peierls instability in the vicinity of T_P. According to structural and magnetic data[94], the spin-Peierls instability is also characteristic of the violet ($T_P = 301$ K) and bluish-violet ($T_P = 215$ K) NH_4TCNQ^- phases.

According to electrophysical measurements, heating results in phase transitions in TCNQ salts not only with alkali metals (Li, Na, and K) but also with transition metals (Mn, Fe, Co, Ni, Cu, and Zn).[95] The plot of $\lg \rho$ against $1/T$ in the range 300–500 K consists of two linear sections and of a transition region between them, the latter corresponding to a gradual accumulation of the high-temperature phase within the limits of the low-temperature phase, i.e. the transition is diffuse. In alkali metal salts of TCNQ these transitions have also been observed by infrared spectroscopy[96] from the sharp increase of the intensities of the lines corresponding to the vibrations of TCNQ molecules with A_g symmetry. The Coulombic interaction in these salts makes the main contribution to the dielectric gap, since at T_P the latter decreases insignificantly.

The report[97] of the preparation of the radical-ion salt $(DEPE)^{2+}(TCNQ)_4^{2-}$, where DEPE = bisdiethylpyridiniaethylene

has aroused much interest among investigators. In this salt the metallic state persists up to ~0.03 K. The above communication led to a flood of publications[98-104] devoted to studies on this and similar radical-ion salts. Values of σ_{300} in the range $(1.5-22) \times 10^4\ \Omega^{-1}\ m^{-1}$ have been quoted in a number of studies[98,105,106] for the above radical-ion salt; $\sigma_{0.03}/\sigma_{300} \cong 3.7$. The thermo-e.m.f. is 35×10^{-6} V K^{-1} and is independent of temperature. However, according to Somoano et al.[99], σ_{300} of the monoclinic phase is $\sim 5 \times 10^3\ \Omega^{-1}\ m^{-1}$ and the $\sigma(T)$ relation is of the semiconducting type with an activation energy $E_a = 0.10 \times 10^{-19}$ J; the thermo-e.m.f. is saturated at high temperatures, reaching 6×10^{-5} V K^{-1}, which corresponds to a quarter-filled conductivity band. The erroneous nature of the conclusions reached in several studies[97,98,105,106] may be associated with the employment of thin $DEPE(TCNQ)_4$ single crystals, which might have resulted in the short-circuiting of the contacts owing to the diffusion of the current-conducting paste. Indeed, a semiconducting relation with $E_a = (0.32-0.48) \times 10^{-19}$ J has been obtained for a series of similar TCNQ salts[98-104], which were isolated in the form of larger crystals.

Interesting data concerning the influence of the symmetry of the cation on the electrophysical properties of the radical-ion TCNQ salts have been obtained[107]. The properties of the TCNQ radical-ion salts with symmetrical (4,4′-bipy) and asymmetric (2,2′-bipy) cations

(2,2′-bipy)

(4,4′-bipy)

are markedly different. The salt with the symmetrical cation is a semiconductor while that with the asymmetric cation is metal-like, in which the metal–dielectric transition occurs on cooling. The studies by Mihaly and coworkers[108,109] of the influence of the dipole moments of the donors are related to the above investigations. If the dipole moments are small, there is a possibility of a metallic state in which these moments are oriented at random. Scattering by the inhomogeneities of the electric field suppresses the dielectric transition and the salts behave as disordered metals. For large dipole moments, there is a possibility of the occurrence of an ordered charge state in which the salts behave as narrow-band conductors with a low conductivity.

The electrophysical properties of the TCNQ salt depends significantly also on the method of preparation (the specimens contain different amounts of $TCNQ^{2-}$ impurity ions). For example, a change in the concentration of the $TCNQ^{2-}$ ions in the salt $Qn(TCNQ)_2$ (Qn = quinolinium) alters E_a from 0.37 to 0.60×10^{-19} J, while σ is reduced by a factor of 10.[110] In addition, in the course of the preparation of the TCNQ salts, the molecules of many solvents can be incorporated in the crystal lattice of the complex; this usually decreases the resistance[111]. The influence of the solvent is manifested particularly effectively in the complex $(NMeQn)(TCNQ)_2$.[112, 113] A phase transition, accompanied by a sharp decrease of σ in the high-temperature phase occurs in this complex at 390 K. The transition is due to the decrease of the content of acetonitrile in which the complex was obtained. Its evaporation increases the structural disorder in the conducting

phase. The acetonitrile molecules act as a shield preventing the interaction of neighbouring chains and stabilise the thermodynamically unstable phase.

An unusual metal–dielectric phase transition occurs on heating crystals of the salt DECA $(TCNQ)_2$ (DECA = diethylcyclohexylammonium[114]). It is an irreversible first-order transition in which the initial column, consisting of TCNQ tetrads, is converted into one consisting of diads in the high-temperature phase. Sharp anomalies are observed on curves for the temperature variation of χ and the specific heat $\rho(T)$ (Fig. 4). The temperature of the transition depends greatly on the pressure ($dp/dT \cong 16 \times 10^4$ kg m^{-2} K^{-1}).

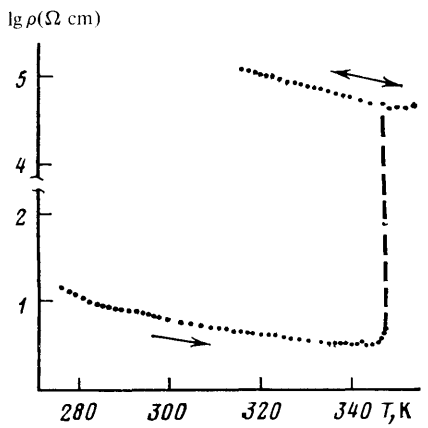


Figure 4. Temperature variation of the resistivity of DECA$(TCNQ)_2$ crystals[114].

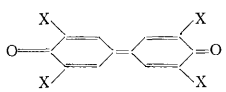
When the salt $(NMe_3H)TCNQ$ was oxidised with iodine[115], a one-dimensional complex with a one-third filled band, having the composition $(NMe_3H)^+(I_3)^-_{1/3}(TCNQ)^{(2/3)-}$, was isolated. The anistropy of the electrical conductivity, measured by Montgomery's method, is ~400 and the conductivity $\sigma_{300} = 2000\ \Omega^{-1}\ m^{-1}$ increases up to 240 K, decreasing sharply at 160 K. The EPR line width decreases monotonically up to 160 K, after which it increases sharply. This transition is reversible and, according to the data of Delhaes et al.[116], is a Peierls transition.

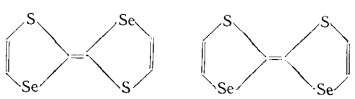
Complexes formed by derivatives of dipyranylidene and its dithio-analogue, isoelectric with TTF, are of interest[117,118]. Such donors have low ionisation potentials and high polarisability. In particular, tetraphenyldiphyranylidene



and tetraphenyldithiodipyranylidene form complexes with TCNQ; the conductivity of the first complex $\sigma_{300} \cong (2.4–4.0) \times 10^3\ \Omega^{-1}\ m^{-1}$ and decreases with decrease of temperature in accordance with an activation law ($E_a = 6.41 \times 10^{-21}$ J); the conductivity of the second complex $\sigma_{300} \cong (2.5–3.0) \times 10^4\ \Omega^{-1}\ m^{-1}$ and increases with decrease of temperature up to 145 K; below this temperature, the dielectric phase is stable. A reversible phase transition, in which σ decreases by two orders of magnitude, has also been observed in the tetraphenyldipyranylidene complex.

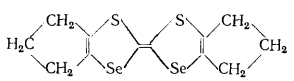
V. ORGANIC CONDUCTORS BASED ON CHARGE-TRANSFER COMPLEXES

Highly conducting compounds based on CTC were isolated as early as 1965 [119] using tetrathiotetracene (TTT) as the donor. *o*-Chloranil (*o*-CA), *o*-bromanil (*o*-BA), and tetracyanoethylene (TCNE) form complexes with the compositions $(TTT)_3$(*o*-CA), $(TTT)_3$(*o*-BA), and $(TTT)_3(TCNE)_2$. The resistances of the powdered specimens vary in accordance with an activation law ($E_a \cong 1.6 \times 10^{-20}$ J) and have the following values at 300 K:



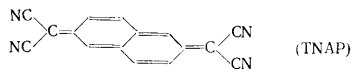
Acceptor	*o*-CA	*o*-BA	TCNE
$10^2\rho_{300}$, Ωm	2.4	6—8	15

Tetrahalogenodiphenoquinones have high electron affinities:



In particular 4.49×10^{-19} J, which is identical with the electron affinity of TCNQ, has been obtained for TCDQ and TBDQ.[90] The quinonoid structures of these complexes suggest a high polarisability. A series of TCDQ and TBDQ radical-ion salts have been described[120,121]. Salts containing cations, such as that of *p*-phenylenediamine (a Wurster radical-cation), ferrocenium, and cobaltocenium (0.2–0.8 Ωm, pelletted specimens) have low resistivities. Highly conducting complexes $TTT(TCDQ)_2$ and $TTT(TBDQ)_2$ are also formed by tetrathiotetracene[122] ($\sigma_{300} \cong 1.7$ and 8 Ω^{-1} m^{-1} respectively). It follows from infrared spectra that these complexes are radical-ion salts. Unfortunately, as a consequence of the extremely limited solubility of the RIS based on TCDQ and TBDQ, it is virtually impossible to isolate the salts in the form of single crystals.

Complexes of substituted derivatives and analogues of TTF with TCNQ and its derivatives have now been investigated in detail. As a rule, the weak asymmetry of the donor or acceptor stabilises the metallic phase of the complex, in which the latter behaves as a disordered metal. For example, mixed *cis–trans*-diselenodithiofulvalene (DSDTF)



forms with TCNQ a complex having $\sigma_{300} = (7 \pm 3) \times 10^4\ \Omega^{-1}\ m^{-1}$, [123] which behaves as a disordered metal. Its dicyclopentano-derivative

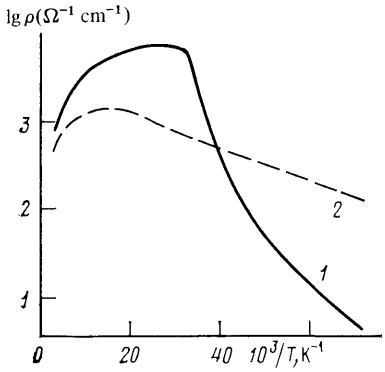
(HMDSDTF)

forms with TCNQ and TNAP (11,11',12,12'-tetracyanonaphtho-2,6-quinodimethane)

(TNAP)

highly conducting RIS with the 1:1 composition ($\sigma_{300} \cong 10^4\ \Omega^{-1}\ m^{-1}$). [124] The complex of TMTTF (tetramethyltetrathiofulvalene) with 2,5-dimethyl-TCNQ has the conductivity $\sigma_{300} \cong 5 \times 10^4\ \Omega^{-1}\ m^{-1}$ with a sharp maximum at 50 K ($\sigma_{50}/\sigma_{300} = 10$) followed by the transition to the dielectric phase[125]. The addition of MTCNQ (methyl-TCNQ) to the complex TSF–TCNQ gives rise to the mixed complex $TSF(TCNQ)_{1-x}$-$(MTCNQ)_x$,

whereupon the peak in the $\sigma(T)$ relation shifts towards higher temperatures (from 40 to 75 K) and the gap in the electronic excitation spectrum in the region below the transition temperature diminishes so much that $\sigma_{4.2}$ for the mixed complex exceeds $\sigma_{4.2}$ for the initial complex by a factor of 10^4 (Fig.5). The complexes of TTF with 2,5-diethyl-TCNQ and 2,5-dimethyl-TCNQ are also disordered conductors, but the Peierls transition occurs at higher temperatures ($Tp \cong 180$–210 K) and the increase in σ amounts to only 50 and 20% respectively[125] (Fig.6). According to thermo-e.m.f. measurements the isostructural series of the CTC of TCNQ with TTF and *cis-trans*-DSDTF exhibits the properties of semiconductors at high temperatures, while in the range 40–60 K there is a transition to the dielectric phase[127]. For example, the conductivity maximum in DSDTF–TCNQ crystals is observed at 60 K.[128] The complexes# of OMTTF, OMDSDTF, DBTTF, and DBDSDTF with TCNQ and TNAP are dielectrics[124,129]. Possibly the reason for this is the appreciable difference from the planar structure of the dicyclohexano-derivatives, on the one hand, and the high ionisation potentials of the dibenzo-derivatives, on the other.



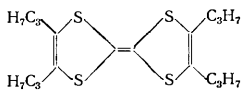


Figure 5. The electrical conductivity of TSF–TCNQ (curve *1*) and $TSF(TCNQ)_x(MTCNQ)_{1-x}$ (curve *2*) crystals[126].

Similarly the complex of the tetrapropyl derivative of TTF with TCNQ

(TPTTF)

is a dielectric having a structure of the interleaved type[130], while the magnetic and dynamic properties of the complex TMTTF–TCNQ (TMTTF = tetramethyl-TTF) are similar to those of TTF–TCNQ.[131] Apparently the main reason for this is the presence of a bulky substituent and hence an insufficiently effective overlap in the column consisting of TPTTF molecules alone.

#Notation: OMTTF = octamethylene-TTF, OMDSDTF = octamethylene-DSDTF, DBTTF = dibenzo-TTF, DBDSDTF = dibenzo-DSDTF, TNAP = tetracyanonaphthoquinodimethane, and HMTTF = hexamethylene-TTF.

However, the complex HMTTF–TCNQ (it contains a non-planar cation) exhibits a metallic type of conductivity up to ~75 K, after which it is converted into the dielectric phase[132]. The two sharp transitions at 49 ± 1 and 43 ± 1 K have been related to the rearrangement of the HMTTF and TCNQ columns respectively. Furthermore, the complex HMTSF–TCNQ (where HMTSF = hexamethyltetraselenofulvalene) retains the metallic type of conductivity up to 0.06 K. Apparently the deviations from the planar structure of these donors are not sufficiently significant to prevent an effective overlap of the donor orbitals in the column. The interaction between the HMTSF and TCNQ columns, manifested by short-circuited intermolecular contacts, has also been observed in the complex HMTSF–TCNQ.[133] In all probability this effect stabilises the metallic phase. Measurements of the anisotropy of the conductivity of organic semiconductors[134] (see Table) have shown, however, that the HMTSF–TCNQ crystal is far from being isotropic. To some extent, it can be regarded as an anisotropic quasi-two-dimensional conductor formed by layers oriented along the *a* and *b* axes.

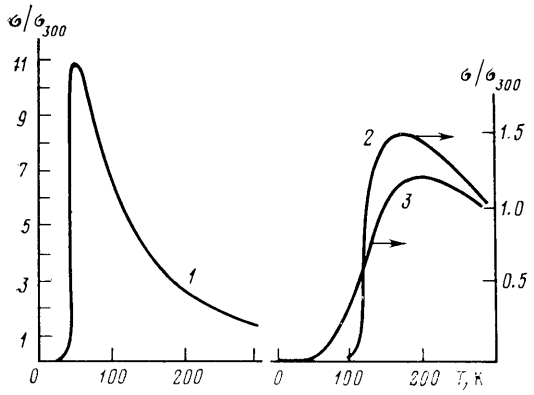

Figure 6. Temperature variation of the electrical conductivity of CTC containing low-symmetry acceptors: *1*) TMTSF–DMTCNQ; *2*) TTF-DETCNQ: *3*) TTF–MTCNQ.[125]

The anisotropy of the conductivity of organic conductors at 300 K.

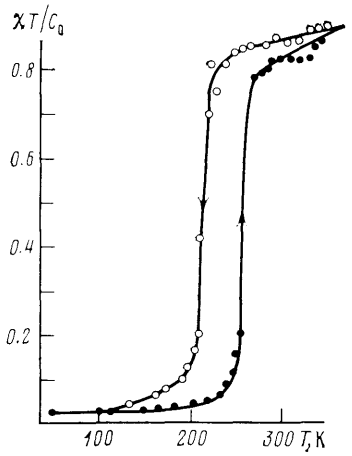
Conductor	σ_b/σ_a	σ_b/σ_c	$10^4\sigma_{b_{300}}$ Ω⁻¹ m⁻¹
TTF—TCNQ	300—500	120	4±1
TSF—TCNQ	150—300	130—280	8±1
HMTSF—TCNQ	30	450	18±2

The high anisotropy of the conductivity of the complexes TMTSF–TCNQ, TMTTF–TCNQ, and DEDMTSF–TCNQ has been observed by Andersen[135]. In interpreting these results, one may conclude that, in compounds containing sulphur, the current flows via both donor and acceptor columns, while in compounds containing selenium it flows only via acceptor columns. Two phases—conducting and dielectric—are known for the complex TMTSF–TCNQ.[136]

In general, polymorphism is a very common phenomenon for CTC. Polymorphism is possible for identical compositions and can be due to different contents of the solvent. Polymorphism of type P_1 is known for NMP–TCNQ, Et_2TCl. $.(TCNQ)_2$ (Et_2TCl = 3,3′-diethylthiazolinecarbocyaninium ion), RbTCNQ, TMPD–CA, and K^+CA^-.[137] The two forms can crystallise simultaneously; they can be frequently distinguished even visually and in other cases a difference is observed when the optical or electrophysical properties are investigated.

The incorporation of solvent molecules in the CTC lattice (P_2 polymorphism, i.e. polymorphism of the second kind) can alter markedly the physical property of the complex. The complex $TTT(TCNQ)_2$ incorporates acetonitrile, chlorobenzene, or nitrobenzene molecules, which leads to a highly disordered structure. The complex benzidine–TCNQ incorporates methylene chloride or benzene.

Cooling of K^+CA^- crystals, containing a one-dimensional chain of radical-ions CA^-, leads to a phase transition, which is clearly manifested on the $\chi(T)$ curve (Fig.7).[138] The susceptibility of the low-temperature phase is described equally satisfactorily by the singlet–triplet excitation model and the Ising model. The hydrated form of the salt is diamagnetic in the range 70–300 K, which is associated with the stabilisation of the singlet ground state (in the hydrated form the CA^- chain consists of singlet dimers).



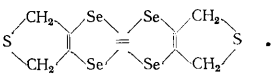


Figure 7. Temperature variation of the magnetic susceptibility of K^+CA^- crystals; $\chi T/C_0$ = dimensionless parameter; C_0 = Curie constant.

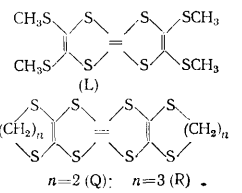
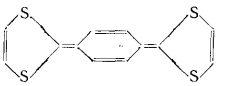


An idea about the influence of the nature of the donor on the electrophysical properties of the CTC is provided by the temperature Tp determined[139] from measurements of the dielectric susceptibility:

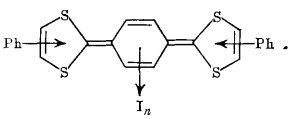
CTC	TTF–TCNQ	DSDTS–TCNQ	TSF–TCNQ	$TTF_{0.97}TSF_{0.03}TCNQ$	TMTTF–TCNQ
T_P, K	53	50	29	50	40

The metallic phase becomes more stable both on replacement of sulphur by selenium and after the introduction of a substituent with a small bulk. In both cases the intermolecular contacts between the donor and acceptor columns are improved. A series of donors, which are analogues of TTF but are superior to the latter as regards their electron-donating capacity, have been synthesised; for example, di-2,5-dihydrothieno-1,4,5,8-tetraselenofulvalene is structurally similar to HMTSF:[140]



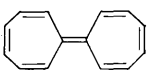
It forms a 1:1 complex with TCNQ, whose conductivity $\sigma_{300} = 6 \times 10^4\ \Omega^{-1}\ m^{-1}$. A series of TTF derivatives with a still higher sulphur content, namely alkylthioderivatives, have been obtained:

(L)



n=2 (Q); n=3 (R).

These donors form with TCNQ CTC having the composition L(Q,R)TCNQ in the form of black crystals. The conductivities σ_{300} of the complexes Q–TCNQ and R–TCNQ are higher than that of TTF–TCNQ, while σ_{300} for L–TCNQ is lower[141]. Finally the derivative of a superdonor, namely tetrathioquinodimethane



(TTQ)

was isolated in the form of diphenyl-TTQ iodide:

This iodide exists in the form of an equilibrium mixture of the RIS and the CTC.[142] The neutral TTQ has been obtained only in the form of a red solution in benzene which is extremely unstable as regards oxidation.

The study of the electronic absorption spectra of solutions of heptafulvalene

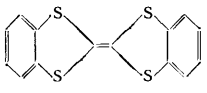
and TCNQ showed that the application of this donor (isoelectronic with TTF) is promising for the synthesis on its basis of CTC and RIS.[143] Unfortunately the complex was not isolated from solution.

Thus the only CTC retaining metallic properties at helium temperatures is the complex HMTSF–TCNQ)conductivity of the metallic type is retained by this complex at pressures $p > 2.5 \times 10^8$ Pa and temperatures up to 2×10^{-2} K).[144] At low temperatures it exhibits a high and anisotropic magnetoresistance and a high mobility of carriers (~$4 \times 10^8\ m^2\ V^{-1}\ s^{-1}$ for electrons and $1.2 \times 10^8\ m^2\ V^{-1}\ s^{-1}$ for holes). The disappearance of magnetoresistance at temperatures above 80 K indicates the one-dimensional nature of the system at these temperatures. The magnetic susceptibility increases with temperature. A considerable Hall e.m.f. was observed for the first time for quasi-one-dimensional conductors in the complex HMTSF–TCNQ.[145,146] The possibility of this effect in quasi-one-dimensional conductors was predicted by Lyo[147]. In the two-band model of the CTC the Hall mobility is caused either by a jump mechanism (when the bands do not overlap) or by resonance tunnelling (overlapping or coinciding bands). The Hall constant R_H for HMTSF–TCNQ crystals is positive at

high temperatures, increases on cooling down to 50 K, and then changes sign at 32 K, which implies an increase of the contribution of electrons to conductivity compared with holes on cooling.

The Hall effect has also been observed in TTF–TCNQ crystals by means of d.c. measurements[148] and by the ultrahigh frequency method[149]. At room temperature the value of R_H measured using a direct current is $-(4.2 \pm 0.6) \times 10^{-5}$ V Wb^{-1} m^{-1}, which agrees with the conclusion[55] that the acceptor columns make a dominant contribution to the electrical conductivity of the complex TTF–TCNQ.

VI. ORGANIC CONDUCTORS BASED ON RADICAL-CATION SALTS



Conductors based on radical-cation salts with simple, mainly inorganic anions possess hole type conductivity. At the present time such conductors have been obtained from derivatives and analogues of TTF, TTT (tetrathiotetracene), and TST (tetraselenotetracene). Their composition can be expressed by the formula DY_n (where D = TTF, TTT, or TST and Y is an inorganic anion), n being as a rule non-integral.

The methods of synthesis of the radical-cation salts have been discussed in a review[17]. The halides are frequently obtained by the direct oxidation of solutions of donors by solutions of the corresponding halogens. The donor : halogen ratio, which can be varied within wide limits, determines the composition of the salts.

Direct oxidation of TTF with iodine and bromine yields salts having the composition $TTF(I)_{0.71}$ and $TTF(Br)_{0.71}$.[150, 151] The conductivity of the bromide is (300–350) $\times$ 10^2 Ω^{-1} m^{-1}, changes little in the range 180–300 K, and rapidly decreases below 180 K with an activation energy of 0.13×10^{-19} J. The electrical conductivity of the iodide crystals is $\sigma_{293} = (1.0–4.5) \times 10^4$ Ω^{-1} m^{-1} and diminishes sharply at 240 K, exhibiting a considerable hysteresis. In the region of the transition there are anomalies both in the thermo-e.m.f. and in the intensity of the EPR lines. All these features are associated with a strong interaction of the one-dimensional chains in the salt crystals and also with the change in the interaction of iodine with the TTF columns in the region of the metal–dielectric transition[152].

The thiocyanates of those donors whose composition depends on the initial reactant ratio and the structure of the donors have been obtained by the direct oxidation of TTF and TMTTF by solutions of dithiocyanogen $(SCN)_2$: TTF forms the salts $TTF(CNS)_{0.5}$ and TTF(SCN), while TMTTF gives rise to salts with the compositions TMTTF.$(SCN)_{0.5}$ and TMTTF$(SCN)_2$ (the latter is a dielectric[153]). When the donor : halogen ratio was varied in the range from 1 : 0.5 to 1 : 8, a series of TMTTF salts with the following compositions were obtained: $(TMTTF)I_n$ (n = 0.5, 1.3, 2.6, and 3.7) and $(TMTTF)Br_n$ (n = 0.5, 0.8, and 6.0).[154]

A series of radical-ion salts have been obtained by oxidising TTF with copper(II) chloride and the composition of these salts depends on the nature of the solvent. The purple complex $(TTF)_3(CuCl_2)_5$, containing $TTF^{\ddagger}$ and TTF^{2+}, was isolated from ethanol[155]. After recrystallising from acetonitrile, a black acicular salt $(TTF)_2CuCl_4$ is obtained, while direct oxidation in acetonitrile yields the yellow product $TTF^{2+}(CuCl_4)^{2-}$.[155] A series of organic conductors based on dibenzotetrathiofulvalene

(DBTTF)

have been isolated on oxidation of the latter with metal salts. In particular, the salts $D(SnCl_6)_{0.375}$, $D_4Ti_2Cl_9$, $D_8Pt_2Cl_9$, D_2PtCl_5, $D_7Pt_2Br_9$, $DPtBr_5$, D_2FeCl_4, $DFeCl_4$, $D(PtCl_6)_{0.375}$, $D(SnCl_6)_{0.375}$, and $D_{2.5}FeCl_4$ (here D = DBTTF) were obtained[156–159]. The salts $D(MCl_6)_{0.375}$ (M = Pt or Sn) and $D_{2.5}FeCl_4$ are conductors, passing to the state of a Peierls dielectric at 180–200 K. They contain DBTTF with a formal degree of oxidation of 0.75–0.8, which is most favourable for the occurrence of the metallic state[88].

The method of synthesis of radical-cation salts by an exchange raction is effective in many instances. For example, the thio- and seleno-cyanates of TTF having the compositions $(TTF)_{11}Y_6$ (Y = SCN or SeCN)[160,161] and $(TTF)_7I_5$ have been isolated. They are all isomorphous, but the iodide is a semiconductor, while the thio- and seleno-cyanates are conductors up to 220 K. Somoano et al.[162] quoted a different composition of the thio- and seleno-cyanates, namely $(TTF)_{12}Y_7$. The thermo-e.m.f. of these salts is positive and decreases linearly as the temperature is reduced, which confirms the metallic type of their conductivity and implies that the current carriers are holes.

One of the effective methods of synthesis of radical-cation salts involves oxidation with hydrogen peroxide in the presence of the corresponding acid. The oxidation of DBTTF in the presence of HBF_4 in benzonitrile yields the salt $DBTTF(BF_4)_{0.80}$.[163] The conductivity of compressed salt specimens ($\sigma_{300} \cong 80$ Ω^{-1} m^{-1}) changes little on cooling to 180 K, after which there is a sharp transition to the dielectric phase. The substance then remains in the paramagnetic phase and for this reason the transition can be due to Mott instability. TMTTF tetrafluoroborates have the compositions $TMTTF(BF_4)_{0.5}$ (conductor) and $(TMTTF)_x.(BF_4)_y$ ($x/y \cong 1$, dielectric, $\sigma_{300} \cong 2 \times 10^3$ Ω^{-1} m^{-1}).[164]

All the TTF halides contain a more or less large amount of impurities of internal origin due to the disproportionation of the $TTF^{\ddagger}$ radical-cation via the mechanism

$$2TTF^{\ddagger} \rightleftharpoons TTF^0 + TTF^{2+} \quad .$$

The random temperature-dependent distribution of impurities stabilises the metallic state[165].

The radical-cation salts of TTT and TST are perhaps of greatest interest at the present time. A whole series of TTT iodides, formed on direct oxidation of TTT with iodine, have been isolated. The iodide (TTT)I is a conductor up to 200 K, while the iodide $(TTT)I_{1.5}$ is a conductor up to 50 K.[166] Studies of the electronic spectra of the crystals and solutions of $(TTT)I_{1.5}$ showed that this salt is the tri-iodide $(TTT)_2^{+}I_3^{-}$,[167] i.e. the degree of oxidation of TTT in this substance is 0.5. The metal–dielectric transition in the salt $(TTT)_2I_3$ has not been observed[168] up to 3.3 K. At 50 K the quantity $\sigma(T)$ passed through a maximum, but the system remained in a conducting state. Subsequently the isolation of the iodide $(TTT)I_{1.6}$ [single crystals, $\sigma_{300} = (7.0–15.0)$ 10^4 Ω^{-1} m^{-1}] was reported[169]. The degree of disorder in this substance is such that the dielectric Peierls transition is suppressed. The situation was clarified after the publication of a study[170] in which it was shown that in reality one should consider the phase $(TTT)I_x$, where x varies from 1.5 to 1.55. With increase of x, the quantity I_{max} diminishes and σ_{max} is greater the smaller the value of T_{max}. At low temperatures there is nevertheless a metal–dielectric transition whose temperature depends significantly on the iodine content. The same workers described a new iodide $(TTT)I_3$ ($\sigma_{300} \cong 50$ Ω^{-1} m^{-1}).

Crystals of the iodide $(TTT)_2I_3$ can be obtained also in the gas phase[171,172], but its structure is not the same as that quoted by Buravov et al.[166] and $T_{max} = 35 \pm 3$ K. Interesting results have been obtained in the calculation of

the Madelung energy of the iodide $(TTT)_2I_3$.[173] Depending on the relative shift of the I_3 ions, this energy has two minima separated by a maximum with $E_a = 4.8 \times 10^{-20}$ J, which gives rise to the possibility of a relative slip of the ions in the $(I_3)_x$ chain with increase of temperature and this leads to structural disorder.

The joint oxidation of TTT with iodine and bromine makes it possible to isolate the mixed salt $(TTT)_2I_xBr_{3-x}$.[174] Qualitatively the $\sigma(T)$ relation is similar to that observed for the pure iodide, but T_{max} is higher, amounting to 150–180 K.

Khidekel' and coworkers[175] obtained TST iodides having the compositions $(TST)I_{0.7-0.8}$, $(TST)I_{1.80-1.85}$, and $(TST)I_{2.2-2.4}$ and an iodide of unknown composition $(TST)I_x$. Khidekel' and Yagubskii and coworkers[176,177] described TST chloride and bromide having the compositions $(TST)_2X$ (X = Cl, Br, or CSN). They are obtained when TST is oxidised by one-electron oxidants (TCNQ, TCNE) in the presence of Cl^-, Br^-, or CSN^- ions. The chloride and bromide are conductors, while the thiocyanate is a semiconductor. Subsequent studies in Shchegolev's laboratory[178,179] on $(TST)_2Cl$ crystals led to the discovery of a phase transition at 25 K of the metal (I)–metal (II) type and of a high-pressure phase at $p > 6 \times 10^8$ Pa, which is also of the metallic type [metal (III), $\rho_{10K} \cong 1.1 \times 10^{-7}$ Ω m]. According to a remark by Shibaeva and Kominskii[133], a common feature of the structures of the complexes (HMTSF)TCNQ and $(TST)_2Cl$ is the interaction between the columns manifested by shortened intermolecular contacts.

The study of the magnetoresistance and the anisotropy of the conductivity of $(TST)_2Cl$ [180] leads to the analogous conclusion, namely that, although, the low-temperature state is strongly anisotropic, its anisotropy is not uniform.

VII. CONDUCTORS BASED ON ORGANOMETALLIC AND COORDINATION COMPOUNDS

Mixed valence platinum complexes have already become traditional objects of study. Apart from the thoroughly investigated platinum cyanide, partly oxidised with chlorine or bromine, highly conducting compounds based on complex oxalates have also been isolated. At the same time conductivity of the metallic type have also been observed, for example, in the compounds $(H_3O)_{1.6}[Pt(C_2O_4)_2]_n.H_2O$ [181] and $K_{1.6}[Pt(C_2O_4)_2].1.2H_2O$; the latter contains, like the complex cyanide $K_{1.75}[Pt(CN)_4].1.5H_2O$ [182,183], a quasi-one-dimensional zig-zag chain of platinum atoms in which there are three crystallographically non-equivalent platinum atoms (Fig. 8). The groups $Pt(C_2O_4)_2$, located at a distance $c/2$, are in the eclipsed configuration and those at a distance $c/4$ are in the staggered configuration. Analogues of the Krogmann salt, namely $(NH_4)_2[Pt(CN)_4]Cl_{0.3}3.2H_2O$ and $(NH_4)_{2.2}.[Pt(CN)_4]Cl_{0.5}.3H_2O$, in which the dielectric Peierls transition occurs at 150 K,[184] and the salt $[C(NH_2)_3]_2[Pt(CN)_4].Br_{0.23}.H_2O$, which exists in the state of a Peierls dielectric even at room temperature[185], have been obtained by exchange reactions. The soliton conduction mechanism is possible for the last salt.

The electrochemical oxidation of the salts $M_2[Pt(CN)_4]$ in the presence of F^- or HF_2^- ions led to the isolation of the following salts from aqueous solutions:

$$K_2[Pt(CN)_4](HF_2)_{0.30} \cdot 3H_2O \ (I), \quad Rb_2[Pt(CN)_4](HF_2)_{0.40} \ (II),$$
$$Rb_2[Pt(CN)_4](HF_2)_{0.26} \cdot 1.7H_2O \ (III), \quad Cs_2[Pt(CN)_4](HF_2)_{0.39} \ (IV),$$
$$Cs_2[Pt(CN)_4](HF_2)_{0.23} \ (V), \quad [C(NH_2)_3]_2[Pt(CN_4)](HF_2)_{0.26} \cdot H_2O \ (VI).$$

The conductivities of salts (II), (IV), and (V), measured on single crystals at room temperature, are respectively 1.6×10^5, 2×10^5, and $(2.5–3.5) \times 10^4$ Ω^{-1} m^{-1}.[186,187] The temperature dependence of the conductivities of certain platinum complexes is illustrated in Fig. 9.

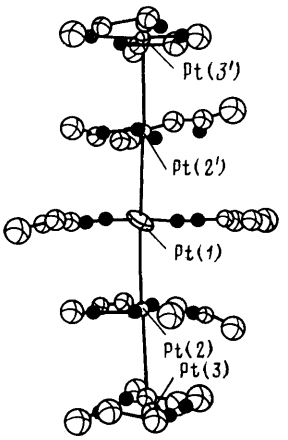


Figure 8. One-dimensional chain of $[Pt(C_2O_4)_2]^{1.6-}$ ions containing three crystallographically non-equivalent Pt atoms[182].

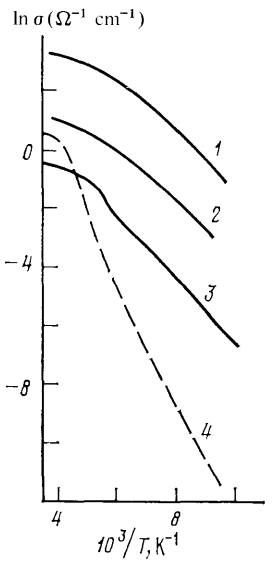

Figure 9. Temperature variation of the electrical conductivity of crystals of complex platinum cyanides: *1*) $K_2[Pt.(CN)_4Cl_{0.3}.3.2H_2O$; *3*) $(NH_4)_2[Pt(CN)_4Cl_{0.3}.3.2H_2O$; *4*) $(NH_4)_{2.2}[Pt(CN)_4]Cl_{0.5}.3H_2O$.[184]

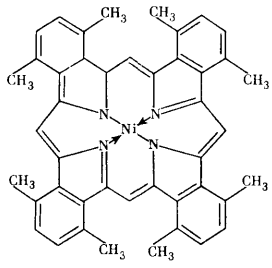
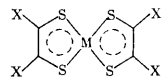


Partially oxidised phthalocyanines and porphyrins form a new class of highly conducting quasi-one-dimensional organic metallic compounds[17,188–191]. Such compounds are obtained, for example, on partial oxidation with iodine of

transition metal (Fe, Co, Ni, Cu, Zn, Pt) complexes of phthalocyanine (Pc):

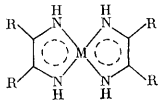
$$MPc + \frac{x}{2} I_2 \rightleftharpoons (MPc) I_x \quad .$$



The iodine is present in these compounds mainly in the form of the ion I_3^-; $0.5 \leqslant x \leqslant 3.0$. The conductivity of some of these compounds ($CuPcI_{1.71}$ and $PtPcI_{0.93}$) is comparable to that of the complex $Qn(TCNO)_2$.

The resistance of thin PbPc films decreases with decrease of temperature down to 50 K and remains constant at lower temperatures. Hence the conductivity of porphyrins partly oxidised with iodine increases slightly as the temperature is reduced from 380 to 300 K. After the oxidation of the nickel complex of 1,4,5,8,9,12,13,16-octamethylenetetrabenzoporphyrin, i.e. Ni(OMTBP)

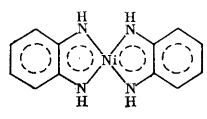
with iodine, the compounds $Ni(OMTBP)(I_3)_y$ with $y = 0.35 \pm 0.03$ and 0.97 ± 0.10 were isolated. The conductivity of the complex with $y = 0.35$ has a maximum at $T \cong 300$ K [$\sigma_{max} = 1.5 \times 10^3\ \Omega^{-1}\ m^{-1}$ (Fig.10)], while for the complex with $y = 0.97$ the maximum is displaced to $T = 340$ K.



Another interesting class of organometallic compounds forming crystals with a quasi-one-dimensional structure consists of transition metal olefindithiolates with the general formula $M(ODT)_2$ (ODT = olefindithiolate ion having a planar structure with D_{2h} symmetry):

Here M is a transition metal atom and x = alkyl, aryl, CN, CF_3, or H. A characteristic feature of the olefindithiolates is the ease of their one- and two-electron reduction with retention of the planar structure:

$$M(ODT)_2 \overset{+e}{\underset{-e}{\rightleftharpoons}} M(ODT)_2^- \overset{+e}{\underset{-e}{\rightleftharpoons}} M(ODT)_2^{2-} \quad .$$



Similar properties are characteristic also of transition metal olefin di-iminates of the same composition:

Five degrees of oxidation are known, for example, for nickel o-phenylene di-iminate:

$$Ni(Pda)^{2+} \overset{+e}{\underset{-e}{\rightleftharpoons}} Ni(Pda)^{+} \overset{+e}{\underset{-e}{\rightleftharpoons}} Ni(Pda) \overset{+e}{\underset{-e}{\rightleftharpoons}} Ni(Pda)^{-} \overset{+e}{\underset{-e}{\rightleftharpoons}} Ni(Pda)^{2-}$$

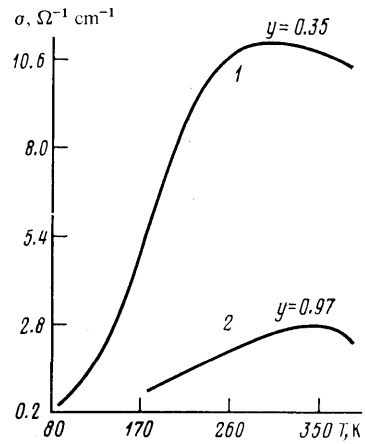
Ni(Pda) =

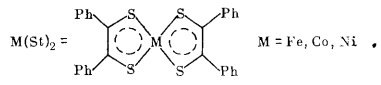
All its forms have a planar structure[192].

The use of olefindithiolates and olefin di-iminates for the synthesis of CTC and RIS based on them is doubly interesting, since there is a possibility, in principle, of the formation in such compounds of conducting acceptor or donor columns by the overlap of the d_{z^2} orbitals of the transition metal partly filled as a result of charge transfer. In this sense, they can combine the properties of the mixed valence platinum cyanides (radical-cation salts) and CTC based on TCNQ or TTF.

Some of the complexes of this type which have been isolated do indeed exhibit a high conductivity. For example perylene (PE) forms conducting complexes with nickel, copper, and palladium maleodinitriledithiolates (mnt) having the composition $(Pe)_2^+[M(mnt)_2]^-$ and a thermally activated conducting state [$E_a \cong (1.6\text{–}3.2) \times 10^{-21}$ J].[193] According to Bray and coworkers[194,195], the complex $(TTT)_{1.2}NiS_4C_4H_4$, isolated in the form of black crystals ($\sigma_{298} \cong 3 \times 10^3\ \Omega^{-1}\ m^{-1}$) is a quasi-one-dimensional conductor. Its crystals are formed by one-dimensional TTT chains separated by $[NiS_4C_4H_4]^-$ ions. The degree of filling of the electronic band in this substance is 1/6. The activated nature of the conductivity of the complex ($E_a \cong 1.76 \times 10^{-20}$ J) is due to the presence of the Peierls gap. The electronic and magnetic properties are fully analogous to those of a radical-cation salt.

The complex $(TTF)_2NiS_4C_4H_4$ has been isolated. The complexes of TTF with olefindithiolates have interesting magnetic properties. The magnetic susceptibility of the complexes $TTF[PtS_4C_4(CF_3)_4]$ and $TTF[NiS_4C_4(CF_3)_4]$[196,197] is described by a model consisting of a one-dimensional ferromagnetic with antiferromagnetic interaction between the chains. The peak in the $\chi(T)$ relation at a temperature below 12 K corresponds to the antiferromagnetic ordering. The complex $(TTF)_2[NiS_4C_4H_4]$ is a paramagnetic with single unpaired electrons per molecule.





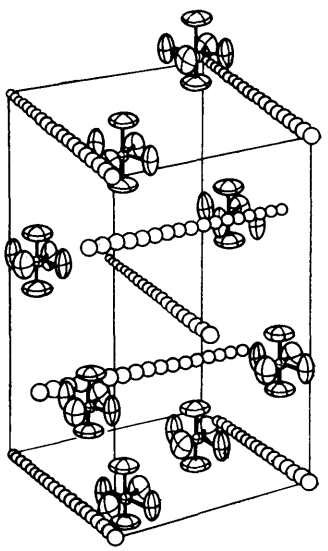


Figure 10. The conductivity of $Ni(OMTBP)(I_3)_y$ crystals: *1*) $y = 0.35$; *2*) $y = 0.97$.[191]

The possibility of the replacement of the central atom in the molecules of olefindithiolates makes it possible to vary their magnetic properties within wide limits. This has been demonstrated in relation to transition metal stilbenedithiolates[198],

Nickel stilbenedithiolate is a diamagnetic; the Curie-Weiss law is valid for the susceptibility of $Co(St)_2$ in the range 4–300 K ($\Theta < 1$ K, $\mu_{eff} = 2.06\ \mu_B$), while the susceptibility of the complex $Fe(St)_2$ is described by a model consisting of a one-dimensional Heisenberg antiferromagnetic with a low-temperature increase of $\chi(T)$ due to the finite chain length[198].

The study of the magnetic properties of the complexes $TTF[MS_4C_4(CF_3)_4]$ (M = Cu or Au) led to the discovery of a fundamentally new phenomenon—the spin-Peierls transition[199–201], theoretically predicted by Pytte[202]. The susceptibilities of both complexes have a broad maximum at $T \approx 50$ K; for $T = 12$ K (M = Cu) and 2.1 K (M = Au), the quantity $\chi(T)$ diminishes smoothly. This decrease is described satisfactorily by the theory of the one-dimensional Peierls transition in an antiferromagnetic Peierls chain. At $T < Tp$ new crystalline phases of the complexes contain paired TTF groups with a spin $S = 1/2$.

○ Hg atom ⊕ As atom ⊕ F atom

Figure 11. The crystal structure of $Hg_{2.86}AsF_6$.

Perhaps the most interesting properties among inorganic highly anisotropic compounds are shown by mixed-valence mercury salts[203–210]. In liquid sulphur dioxide direct interaction of mercury with stoichiometric amounts of AsF_5 yields the salts $Hg_3(AsF_6)_2$ and $Hg_4(ASF_6)_2$. The two salts contain linear discrete mercury polycations Hg_3^{2+} and Hg_4^{2+} respectively. The Hg_3^{2+} cation is also present in the salt $Hg_3.(AlCl_4)_2$.[211] Golden crystals with the composition $Hg_{2.85}.AsF_6$ sparingly soluble in SO_2 are formed in the initial stage of the interaction of mercury with AsF_5. The same compound is a product of the disproportionation of the salt $Hg_4(AsF_6)_2$ on slow cooling of its solution in SO_2:

$$5.44Hg_4(AsF_6)_2 \rightarrow 3.44Hg_3(AsF_6)_2 + 4Hg_{2.86}AsF_6 \downarrow .$$

A compound with a similar cation is also obtained on oxidation of mercury with antimony pentafluoride; it has the composition $Hg_{2.91}SbF_6$. The formal degrees of oxidation of mercury in these salts are 0.35 and 0.34 respectively. A characteristic feature of the crystal structures of the two salts is the presence of infinite intersecting linear chains of mercury atoms arranged in two mutually perpendicular directions (Fig.11). A consequence of this structure is the quasi-one-dimensional behaviour of the salt crystals at the macroscopic level. The bond length in the Hg–Hg chain (2.64×10^{-10} m) is much shorter than in metallic mercury (3.005×10^{-10} m) and is not comparable to the lattice period of the salt. However, the distance between the mercury chains is only 3.085×10^{-10} m, which gives rise to the possibility of an appreciable interaction between the chains.

Thus the systems described possess all conditions for the establishment of the one-dimensional metallic state. The conductivities in the basal planes of the $Hg_{2.86}AsF_6$ and $Hg_{2.91}SbF_6$ crystals σ_{ab} (300 K) are respectively 8.7×10^5 and $\sim 10^5\ \Omega^{-1}\ m^{-1}$. The anisotropy of the conductivity of the $Hg_{2.86}AsF_6$ crystal is $\rho_{ab}/\rho_c \approx 70$ at room temperature. The quantity ρ_{ab} for this salt decreases unusually rapidly on cooling and $\rho_{ab} \approx 10^{-9}\ \Omega$ m already at 4.2 K, which is less than the limit of the measurement. Extrapolution of the $\rho_{ab}(T)$ relation to the absolute zero reveals the absence of a residual resistance. The resistance ρ_c at 4 K decreases abruptly (over a range of 0.2 K) virtually to zero. The disappearance of this transition in magnetic fields directed both parallel to the basal plane and at right angles to it makes it possible to classify it as a superconducting transition. The critical field is minimal if it is directed along the c axis and at $T = 1.4$ K it amounts to 3.8×10^{-2} Wb m^{-2}. In the "normal" state at temperatures less than 30 K and in a field of 10^{-3} Wb m^{-2} the magnetoresistance increases sharply. For $H \neq 0$, a residual resistance appears in the $\rho_{ab}(T)$ relation. The magnetic susceptibility is almost constant in the range 4–300 K; the specific heat C in the range 1.8–5 K is described by the equation $C = \gamma T + \beta T^3$ with an unusually high value of γ.

The study of the elastic and non-elastic reflection of neutrons in the range 10–300 K reveals a phase transition at 120 K corresponding to the ordering of the rigid chains of mercury atoms. At room temperature the salt crystals consist of a network of one-dimensional chains, in the range 300–120 K parallel chains are ordered, and at 120 K order is established between orthogonal systems of chains. At $T < 120$ K the system is three-dimensional.

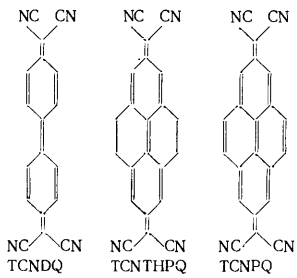
VIII. CONCLUSION

The study of the quasi-one-dimensional molecular solids examined in this review, which was begun comparatively recently, has developed so effectively that over a short period it has led to the creation of a new scientific field—the chemistry of quasi-one-dimensional metals, including CTC and RIS as well as inorganic, organometallic, and coordination compounds. The number of new objects increases continuously. During the preparation of the manuscript for the press, communications on the synthesis of olefindithiolates with conductivity of their metallic type were published. The conductivity σ_{300} of $Li_{0.75}[Pt(mnt)_2].2H_2O$ crystals is 30–200 Ω^{-1} cm^{-1} and increases slightly up to 250 K.[212] The electrical conductivity of the complex of perylene with

$[Pt(mnt)_2]$, having the composition $(Pe)_2[Pt(mnt)_2]$ increases on cooling, reaching a maximum at 15 K, $\sigma_{300} = 9 \times 10^3\ \Omega^{-1}\,cm^{-1}$,[213] after which it decreases sharply.

The radical-cation salts are being investigated most vigorously at the present time. This was greatly stimulated by the discovery of the superconductivity of the $(TMTSF)_2PF_6$ crystals[214]. As in the series of the isomorphous salts $(TMTTF)_2^+X^-$, where $X^- = BF_4^-$, ClO_4^-, SCN^-, PF_6^-, or Br^- (examined in detail in a review[215]), which undergo the Peierls transition at $T < 100$ K, in the analogous salts $(TMTSF)_2^+X^-$ ($X^- = NO_3^-$, ClO_4^-, BF_4^-, PF_6^-, AsF_6^-, SbF_6^-, or TaF_6^-) the metal–dielectric transition is observed at lower temperatures ($T < 20$ K) or is not observed at all [for example, for $(TMTSF)_2ClO_4$].[216–222] The metallic phase can be stabilised by the application of an appropriate pressure. In the metal–dielectric transition, there is an unusually marked increase of conductivity—up to $10^5\ \Omega^{-1}\,cm^{-1}$.[222]

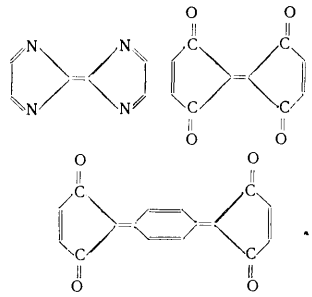
Studies of nuclear magnetic resonance and magnetism established that the transition to the dielectric phase in $(TMTSF)_2PF_6$ is associated with spin density waves. Consequently we have here a new example of the spin-Peierls instability. The set of numerous experimental facts—the unusual increase of σ, a very high magneto-resistance, and non-linear voltage—current characteristics—suggest the occurrence of one-dimensional superconductivity fluctuations in the salts $(TMTSF)_2X$ at $T < 40$ K.[221] In the salt $(TMTSF)_2 \cdot PF_6$ the transition to a superconducting state has been observed at pressures $p > 9 \times 10^8$ Pa and $T_c = 0.9$ K.[218] This is a superconductor of the second kind with very low critical magnetic fields $H_{C_1}^{\perp} = 3 \times 10^{-3}$ Wb m^{-2} and $H_{C_2}^{\perp} = 3.3 \times 10^{-2}$ Wb m^{-2}.[216] The transition temperature diminishes fairly rapidly with increasing pressure; thus at $p = 2.4 \times 10^9$ Pa it is $T_c = 0.19$ K.[219] The $T_c(p)$ relation is approximately linear: $\partial T_c/\partial p = -8 \pm 1$ K Pa^{-1}. At $p = 6.5 \times 10^8$ Pa the superconducting and dielectric phases coexist, since the metal–dielectric transition temperature at this pressure is 6 K.[223]



The superconductivity of $(TMTSF)_2AsF_6$ crystals has been observed at $p \geq 1.2 \times 10^9$ Pa and $T_c \leq 1.1$ K.[218] When the pressure is reduced, it is possible to attain $T_c = 1.4$ K at $p = 6.5 \times 10^8$ Pa for the salt $(TMTSF)_2PF_6$ and $p = 10^9$ Pa for the salt $(TMTSF)_2AsF_6$.

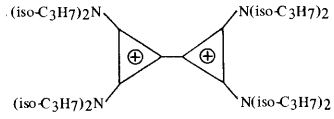
The superconductivity of $(TMTSF)_2ClO_4$ ($p = 3 \times 10^8$ Pa), $(TMTSF)_2SbF_6$ ($p = 10^9$ Pa), and $(TMTSF)_2TaF_6$ ($p = 1.1 \times 10^9$ Pa) crystals has been observed[222]. At $p = 10^5$ Pa the superconducting transition in $(TMTSF)_2ClO_4$ is observed at 1.3 K.

Even on the basis of aromatic hydrocarbons, highly conducting radical-cation salts have been obtained and isolated. They have the composition $(Arene)_2^+X^-$, where $X^- = PF_6^-$, AsF_6^-, SbF_6^-, BF_4^-, or ClO_4^- and Arene = naphthalene, fluoranthene, pyrene, perylene, and triphenylene[224]. The salt $(naphthalene)_2^+(PF_6^-)$ exhibits the highest conductivity ($\sigma_{293} = 0.12\ \Omega^{-1}\,cm^{-1}$). Typical conductivities of other salts are in the range 10^{-2}–$10^{-3}\ \Omega^{-1}\,cm^{-1}$.



Highly conducting salts of a new donor—tetratellurotetracene (TTeT),—having the composition $(TTeT)_2X$ (X = Cl or Br), were isolated recently[225]. The conductivity σ_{293} of the pelleted specimens is 1–2 $\Omega^{-1}\,cm^{-1}$. The authors were unable to isolate single crystals suitable for the measurement of the electrical conductivity and it is therefore not clear whether the electrophysical properties change significantly following the replacement of sulphur or selenium ions by tellurium.

Publications on the synthesis of new acceptors—tetracyanodiphenoquinodimethane (TCNDQ), tetracyanotetrahydropyrenoquinodimethane (TCNTHPQ), and tetracyanopyrenoquinodimethane (TCNPQ) —have appeared recently[226,227].



These acceptors form dianions and radical-anions and are apparently stronger acceptors than TCNQ as far as one can judge from their electrochemical potentials. They form CTC with TTF in the form of fine black crystals. However, in our view, acceptors of this kind can hardly be used for the synthesis of compounds with interesting electrophysical properties. It is difficult to select for TCNTHPQ and TCNPQ a donor close to them in linear dimensions, which is one of the conditions for the preparation of CTC of the non-interleaved type[228]. Low solubility is also an obstacle to the preparation of single crystals. Furthermore, in connection with the discovery of the superconductivity of radical-ion salts, the problem of the synthesis of organic superconductors with the highest possible T_c has now become urgent. Apart from the requirements formulated by Krivoshei[228], the components of the CTC or the RIS must satisfy yet another significant condition in order to achieve this[229]: they must exhibit a high polarisability for small linear dimensions.

The synthesis of the acceptors illustrated below is of interest in this sense:

The ways of synthesising such acceptors are being sought nowadays by the authors of the review. The study[230] in which the salt $\{[(iso\text{-}Pr)_2N]_4TF\}^{2+}(ClO_4^-)_2$ (TF = triafulvalene)

was isolated merits attention. The salts of TF and of its substituted derivatives can be used to prepare CTC by exchange reactions (with partial reduction) for the synthesis of RIS.

Halogen Derivatives of 1,4-Dioxan

A.V.Dombrovskii

Methods for obtaining mono-, di-, and poly-chlorinated derivatives of 1,4-dioxan by the direct substitution of hydrogen atoms by chlorine are surveyed, together with synthetic reactions yielding fluoro-, chloro-, and bromo-dioxans. Methods of obtaining halogenoalkylated dioxans containing fluorine, chlorine, or iodine atoms are described. Consideration is given to reactions of halogenodioxans making possible their use in organic synthesis, in particular of solvents for polymers. A list of 110 references is included.

IV. Halogenoalkyldioxans 464

I. INTRODUCTION

1,4-Dioxan (usually termed simply *dioxan*) continually attracts the attention of chemists because it is a specific and perhaps universal solvent meriting the name "organic water". Furthermore, it forms molecular compounds (dioxanates) with many inorganic and organic substances. Such dioxanates are often used in organic synthesis[1]. Dioxan itself and its derivatives also occupy an important position in organic synthesis. The halogen derivatives, in particular chlorodioxans, are especially valuable.

Halogeno-derivatives of dioxan and their reactions have been only partly dealt with in recent monographs and reviews[2-4]. A considerable number of predominantly experimental studies on halogenodioxans and their use in various types of organic syntheses have been reported during past decades.

Direct chlorination of dioxan is the chief method for obtaining chlorodioxans, with replacement of any hydrogen atom forming an α-chlorinated ether. Direct fluorination and iodination of dioxan have not been reported, the corresponding derivatives being obtained by indirect procedures. Iodinated dioxans are completely unknown. Chloro- and bromo-dioxans are extraordinarily reactive: they are used to obtain alkyl- and aryl-dioxans, alkoxy- and aryloxy-dioxans, dihydrodioxin, dioxin, dioxanone, and other compounds based on the dioxan ring.

II. CHLORODIOXANS

Chlorine does not form stable dioxanates, in contrast to bromine and iodine, which at and below room temperature form with dioxan molecular compounds $C_4H_8O_2.X_2$ (X = Br,I). The direct action of chlorine on dioxan involves a vigorous exothermic reaction accompanied by evolution of hydrogen chloride. If the temperature is not controlled, the reaction may terminate in an explosion. The chlorination of dioxan is strongly accelerated by light and by catalysts such as Lewis acids. Chloro-derivatives of various degrees of substitution right up to octachlorodioxan $C_4Cl_8O_2$ can be obtained by the direct chlorination of dioxan. Chlorodioxans having a specified number of chlorine atoms in the ring can be prepared by maintaining a definite régime of chlorination.

Certain difficulties arise in establishing the structure of chlorodioxans. The chlorination of dioxan may lead to the simultaneous formation of many structural isomers and stereoisomers as well as conformers. Furthermore, the reaction is accompanied by chlorolysis with fission of the dioxan ring. Among 45 possible chlorodioxans (counting optical isomers) only 16 are known. The Table gives data on the numbers and properties of possible isomers.

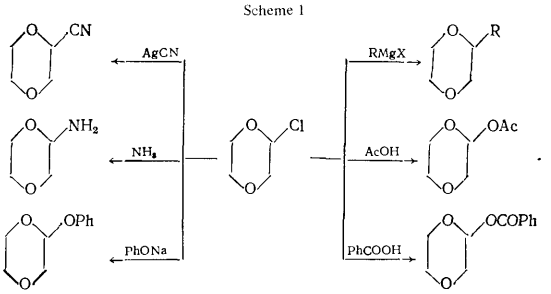
** Structure not established.

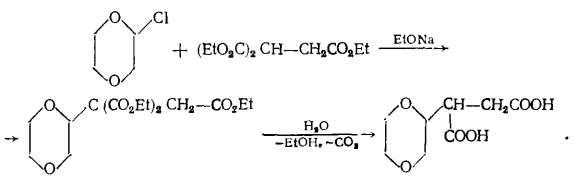
1. Monochlorodioxan

Monochlorodioxan (2-chloro-1,4-dioxan, dioxanyl chloride) cannot be obtained by the direct action of chlorine on dioxan.

The unstable compound is apparently further chlorinated to dichlorodioxans[5-7]. Monochlorodioxan is usually obtained by the addition of hydrogen chloride to dihydrodioxin in the cold[5]:

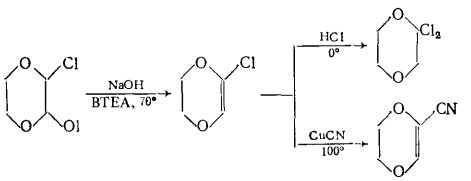


(I) (II)

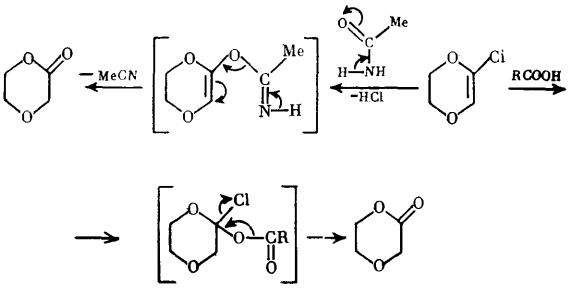


Use of a solvent in this reaction lowers the yield[8]. Nuclear magnetic resonance spectral data have shown[9] that, in virtue of the anomeric effect†, monochlorodioxan exists predominantly in the axial conformation (I), with the position of the conformational equilibrium (I) ⇌ (II) almost unaffected by the polarity of a solvent, (II) being the equatorial isomer.

Monochlorodioxan is unstable and gradually decomposes, especially in the presence of moisture, evolving hydrogen chloride and resinifying. Its instability and great reactivity are explained by the activating influence of ethereal oxygen on the α-chlorine atom. It can be used to obtain other monosubstituted dioxans. Thus heating with silver cyanide yields cyanodioxan, which in turn serves as starting material for the preparation of other monosubstituted derivatives[11]. A series of nucleophilic substitutions of the chlorine atom have been described:

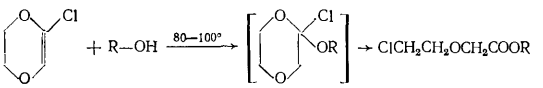


Scheme 1



Monochlorodioxan does not form the usual Grignard compounds with magnesium, but it gives 2-alkyldioxans with alkylmagnesium halides RMgX (R = C_2H_5, n-C_4H_9, etc.; X = Cl, Br, I).[8] Amino-, phenoxy-, acetoxy-, and benzoyloxy-dioxans have been obtained in 70–80% yields[12,13]. In the presence of sodium ethoxide monochlorodioxan reacts with triethyl ethane-1,1,2-tricarboxylate to form the 1-dioxanyl triester, which on hydrolysis followed by decarboxylation is converted into dioxanylsuccinic acid[14]:

An important chloro-derivative is 5-chloro-2,3-dihydro-1,4-dioxin, which is usually obtained by the dehydrochlorination of 2,3-dichlorodioxan when heated with dimethylaniline[15] or on pyrolysis[16]. A proposed effective method of dehydrochlorination is the use of 40% caustic soda under the mild conditions of phase-transfer catalysis in the presence of benzyltriethylammonium chloride (BTEA), which gives a 65–68% yield of the chlorodihydro-derivative[17]:



5-Chloro-2,3-dihydrodioxin exhibits the typical properties of a chlorovinyl ether: vigorous addition of hydrogen chloride takes place in the cold in conformity with Markovnikov's rule to give 2,2-dichlorodioxan[15], and it reacts comparatively readily with copper cyanide to form 5-cyanodihydrodioxin[18]. Vigorous reaction takes place also with carboxylic acids to give high yields of dioxan-2-one and the corresponding acid chlorides[16]. This reaction is of practical interest (in the case of acetic acid), since dioxanone has proved a valuable solvent for certain polymers; similar results are obtained with acetamide[19]:

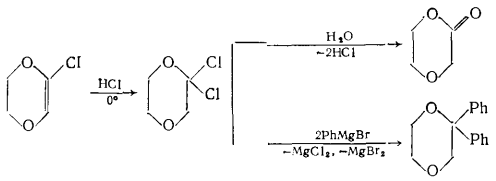
R = Me (84), CH_2Cl (100), Ph (62), *p*-$O_2NC_6H_4$ (38)[2] ‡.

When 5-chloro-2,3-dihydrodioxin is heated with a primary alcohol or a phenol, however, a vigorous reaction leads to fission of the ring and formation of a 2'-chloroethoxyacetic ester, apparently also involving addition at the double bond[16]:

R = Me (54), Et (71), n-Bu (81), Ph (91.5), *p*-MeC_6H_4 (87).

2. Dichlorodioxans

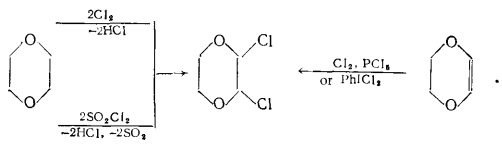
Three of the seven possible structural isomers of dichlorodioxan are known.



(a) 2,2-Dichlorodioxan

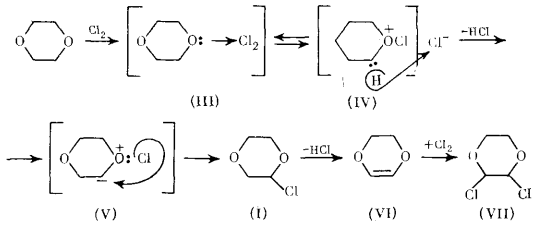
Small quantities of 2,2-dichlorodioxan are detected among the products of the direct chlorination of dioxan, but this reaction is unsuitable for preparative purposes. As already noted, 2,2-dichlorodioxan is obtained in entirely satisfactory yields by the addition of hydrogen chloride to 5-chloro-2,3-dihydrodioxin in the cold[15]. It is not very stable and is

† The anomeric effect is the predominance of the axial conformation of an α-substituent relative to a heteroatom as a consequence of steric or electronic effects, dipole–dipole interaction, the state of hybridisation of the atoms, etc.[10]



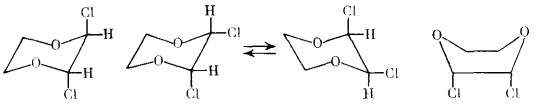
‡ Parentheses enclose percentage yields of dioxanone.

readily hydrolysed to dioxan-2-one, but it reacts normally with phenylmagnesium bromide to give 2,2-diphenyldioxan[15]:



(b) 2,3-Dichlorodioxan

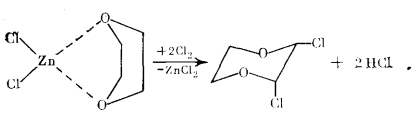
The readily accessible 2,3-dichlorodioxan, which is prepared by the direct chlorination of dioxan, is most important and interesting for the chemistry of the latter, and was first obtained in 1931.[20] It was later shown that chlorination is catalysed by addition of a chloride of copper, iron, manganese, nickel, tin, or iodine[8,21], to give a yield of ~ 90%. The patent literature indicates[22,23] that good yields are obtained by the action of chlorine on dioxan in the vapour phase (120 °C) in the presence of phosphorus(III), phosphorus(V), or antimony(V) chloride as catalyst. Sulphuryl chloride can also be used as chlorinating agent[24], with which an effective procedure has been developed to give an 80% yield[25]; 2,3-dichlorodioxan can be obtained from dihydrodioxin by the addition of chlorine[11,26] and also by the action of phosphorus pentachloride or dichloroiodobenzene[19]:



Incidentally, the latter reactions serve as proof of the positions of the chlorine atoms.

The mechanism of the direct chlorination of dioxan to 2,3-dichlorodioxan at 90 °C and at higher temperatures, when polychlorodioxans are obtained, apparently comprises a series of consecutive primary reactions[2,5,6]:

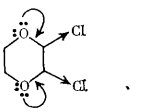
Chlorine acts on dioxan to form an unstable dioxanate (III), which in the presence of Lewis acids is strongly polarised and converted into the ionic dioxanate (IV). The latter eliminates a molecule of hydrogen chloride to form the carbanion (V), which is converted into unstable monochlorodioxan (I). At high temperatures this undergoes dehydrochlorination to dihydrodioxin (VI). Lastly, this product adds a molecule of chlorine to give the final reaction product—stable 2,3-dichlorodioxan (VII).



2,3-Dichlorodioxan is known in the form of two isomers (VIII) and (IX), which differ in melting point, infrared spectrum, and dipole moment[15]:

	(VIII) ($Cl_{ax,ax}$)	(IX) ($Cl_{ax,eq}$)	(X) ($Cl_{eq,ax}$)	(XI)
M.p., °C	31	53		
Infrared, cm^{-1}	875	948		
μ, D	0	1.6		

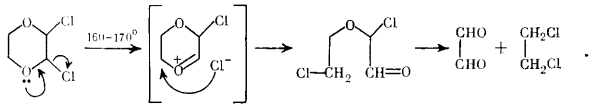
Polarity, polarisability, and n.m.r. spectral data at and below room temperature (down to −42 °C) indicate that both isomers have a chair conformation[27-34]. The more stable *trans*-isomer (VIII) has the diaxial chair conformation ($Cl_{ax,ax}$). The less stable *cis*-isomer (IX) also has a chair conformation, with an axial–equatorial arrangement of the chlorine atoms ($Cl_{ax,eq}$), which undergoes inversion to form an equilibrium mixture with the conformation (X) ($Cl_{eq,ax}$)[31,34]: the statement that it is present as the rigid boat (XI)[29] is incorrect. Chlorination of dioxan in the absence of a solvent gives predominantly the isomer (VIII) with a little (~ 4%) of isomer (IX); in boiling tetrachloromethane a mixture of almost equal quantities of (VIII) and (IX) is obtained, which can be separated by crystallisation. The less stable isomer (IX), when heated with aluminium chloride or sulphuryl chloride, is rapidly and almost quantitatively converted into the *trans*-isomer (VIII)[15].



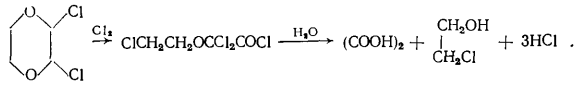
The almost pure isomer (IX) can be prepared by chlorinating dioxan in the presence of zinc chloride[34]. The stereochemistry of the reaction can be attributed to formation of the dioxanate $C_4H_8O_2.ZnCl_2$, in which the dioxan ring is in the boat conformation[35], with the oxygen atoms coordinated with the zinc atom:

Chlorination of such a dioxanate becomes sterically preferred for the formation of *cis*-2,3-dichlorodioxan (IX)[34].

2,3-Dichlorodioxan is toxic: contact with the skin or inhalation of its vapour leads to dizziness, headache, nausea, and inflammation of the mucous membrane of the eye, symptons which may continue for several days. Partial alleviation is provided by the inhalation of ammonia[15].

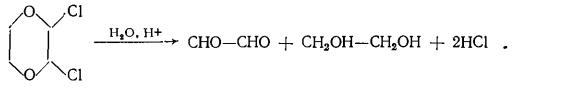


The chemical properties of 2,3-dichlorodioxan are consistent with electronic effects arising from the strong polarisation of the carbon–chlorine bonds and displacement of the *p*-electrons of the ethereal oxygen atoms conjugated with those bonds



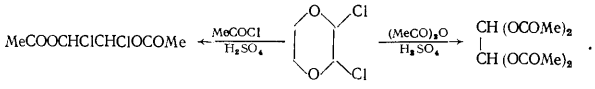
This explains the poor aqueous solubility and the inability to form dioxanates. 2,3-Dichlorodioxan is extremely reactive, mainly in three directions—cleavage of the dioxan ring, nucleophilic replacement of chlorine atoms, and elimination of the elements of hydrogen chloride.

Under the influence of various factors the ring in substituted dioxans is generally opened more readily than is the extremely stable ring of dioxan itself. Thus ring fission

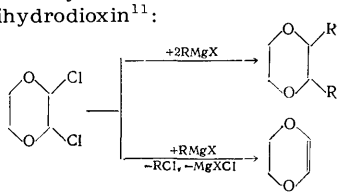


occurs readily when 2,3-dichlorodioxan is heated. Thermal decomposition of this compound is assumed to involve ionisation of one of the chlorine atoms and its migration across the ether link, with intermediate formation of 2,2′-dichloroethoxyacetaldehyde, which then decomposes into glyoxal and 1,2-dichloroethane[36]:

The dioxan ring undergoes cleavage also in the chlorolysis of 2,3-dichlorodioxan to the extremely reactive 2,2,5-trichloro-3-oxavaleryl chloride, which can be hydrolysed to oxalic acid, 2-chloroethanol, and hydrogen chloride[37]:

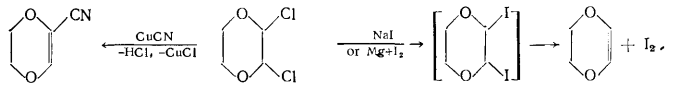


2,3-Dichlorodioxan is comparatively readily hydrolysed when heated with acidified water, being converted into equal quantities of glyoxal and ethylene glycol[20,38]:

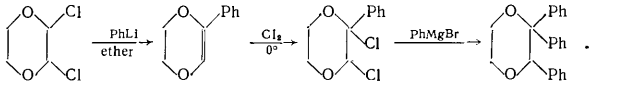


The *cis*-isomer is hydrolysed more rapidly than the *trans*-isomer by a factor of 14.[15] Hydrolysis of this compound has been proposed for the preparation of glyoxal[36,38].

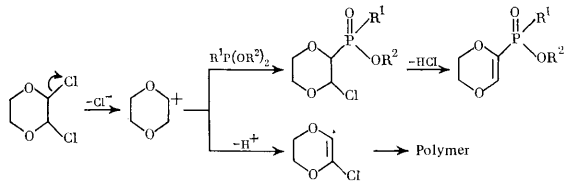
Heating 2,3-dichlorodioxan with excess of acetic anhydride or acetyl chloride mixed with concentrated sulphuric acid also opens the dioxan ring, with the formation respectively of ethanediylidene tetra-acetate (in 70% yield) or 1,2-dichloroethylene diacetate[18]:



The chlorine atoms in 2,3-dichlorodioxan undergo nucleophilic substitution with rather greater difficulty than do those in the usual α-halogenated ethers. However, several reactions are known in which under certain conditions both chlorine atoms are replaced by various groups to give 2,3-disubstituted dioxans. Thus 37–44% yields of 2,3-dialkyldioxans are obtained by the action of Grignard reagents catalysed by additions of ethereal solutions of anhydrous zinc or cadmium chloride[8,39]. Similarly, arylmagnesium halides yield *trans*-diaryldioxans[26,40–42], substitution in this case being accompanied by elimination of chlorine atoms with the formation of dihydrodioxin[11]:

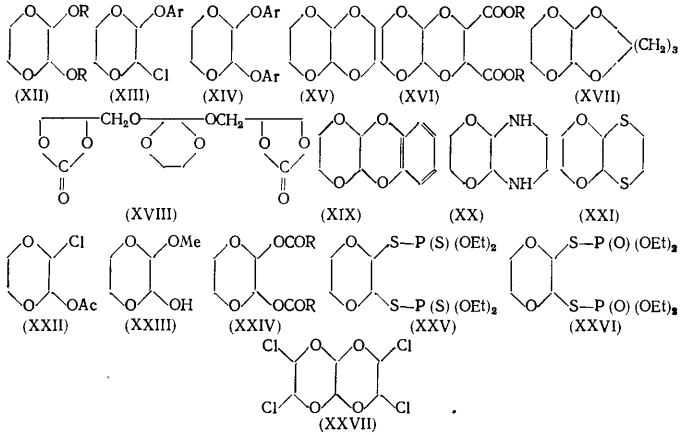


R=Me, Et, n-Pr, n-Bu, CH_2=CH—CH_2, Ph, *p*-ClC_6H_4, *p*-BrC_6H_4; X=Cl, Br .



2,3-Dichlorodioxan also undergoes dechlorination when heated with sodium iodide[8] or with a mixture of magnesium and iodine[7], the yield of dihydrodioxin reaching 81% in the latter case. These reactions apparently involve intermediate formation of unstable 2,3-di-iododioxan, which immediately breaks down into dihydrodioxin and molecular iodine. 2,3-Dichlorodioxan reacts quite smoothly with copper cyanide, when 5-cyanodihydrodioxin is formed as a consequence of dehydrochlorination and substitution of the remaining chlorine atom[18]:

Phenyl-lithium reacts similarly to form unstable 2,3-dihydro-5-phenyldioxin (in 31% yield), which on cautious chlorination gives 2,3-dichloro-2-phenyldioxan; the latter can be converted by phenylmagnesium bromide into 2,2,3-triphenyldioxan (yield 54%)[43]:

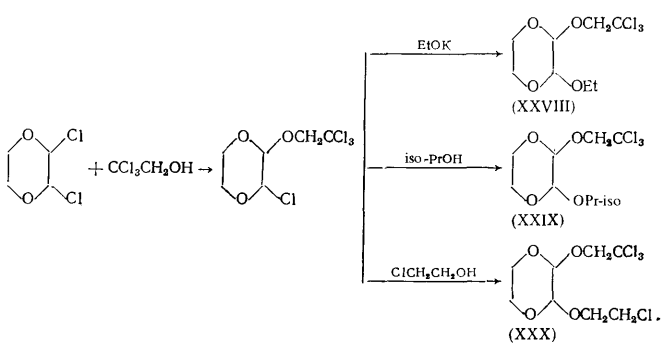


Application of the Michaelis–Becker reaction to 2,3-dichlorodioxan and a sodium dialkyl phosphite yields small quantities (< 20%) of phosphonylated derivatives of dihydrodioxin[44]. The same work showed[44] that the 2,3-dichloro-compound undergoes the Arbuzov reaction with difficulty, and only under comparatively severe conditions does it form with esters of tervalent phosphorus *C*-phosphonylated derivatives of dioxan in relatively low yields (< 40%):

R^1 = Me, Et, *p*-ClC_6H_4, EtO, n-PrO, n-BuO etc.;
R^2 = Et, n-Pr, n-Bu, etc.

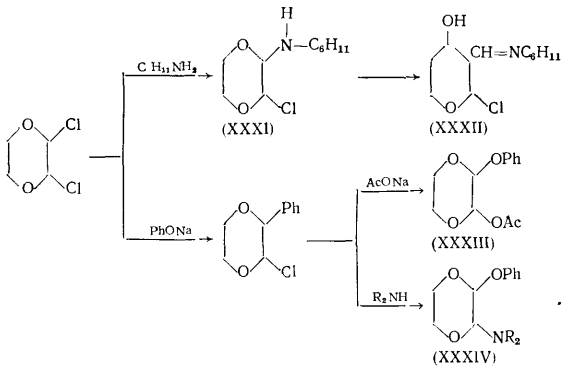
The low reactivity of 2,3-dichlorodioxan is most probably due to steric hindrance.

Many nucleophilic substitutions of the chlorine atoms in 2,3-dichlorodioxan have been reported, yielding various 2,3-disubstituted dioxans



Thus alcoholic sodium ethoxide forms 2,3-diethoxydioxan (XII: R = C_2H_5),[20] but heating with benzyl alcohol gives crystalline 2,3-dibenzyloxydioxan (XII: R = $C_6H_5CH_2$).[45] A monoalkyl ether of ethylene glycol, e.g. 2-ethoxyethanol, forms 2,3-bis-(2-ethoxyethyl)dioxan (XII: R = $C_2H_5OCH_2CH_2$), which has been proposed as a high-boiling solvent for polymers and as a softening agent conferring antistatic properties on films[46]. Under certain conditions the chlorine atoms can

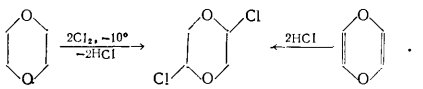
be replaced in stages. Thus heating 2,3-dichlorodioxan with a phenol ArOH (Ar = C_6H_5, o-$CH_3C_6H_4$, p-$CH_3C_6H_4$, 2,4-$Cl_2C_6H_3$) gives 45–52% yields of 2-aryloxy-3-chlorodioxans (XIII)[18,47], in which the second chlorine atom is readily replaced to form 2,3-diaryloxydioxans (XIV) (yields 40–60%)[18]. Heating 2,3-dichlorodioxan with ethylene glycol gives decahydro-1,4,5,8-tetraoxanaphthalene (XV)[18,45,48], the yield of which reaches 77% when the reaction is conducted in pyridine[49]. With the dimethyl or diethyl ester of (+)-tartaric acid 2,3-dichlorodioxan forms the corresponding ester of (−)-decahydro-1,4,5,8-tetraoxanaphthalenedicarboxylic acid (XVI: R = CH_3, C_2H_5), which after saponification and decarboxylation is converted into decahydrotetraoxanaphthalene (XV)[45,50]. Heating 2,3-dichlorodioxan with propane-1,3-diol forms 2,3-trimethylenedioxydioxan (XVII)[51], but 3-hydroxypropylene carbonate gives crystalline dioxan-2,3-bisoxypropylene dicarbonate (XVIII), used for the preparation of water-insoluble resins, which have been suggested as additives for the sizing of yarn and in papermaking[52]. When 2,3-dichlorodioxan is heated with pyrocatechol in xylene, crystalline decahydro-2,3-benzo-1,4,5,8-tetraoxanaphthalene (XIX) is obtained[40,41,45]. Ethylenediamine resembles dihydric alcohols in forming a bicyclic heterocycle, decahydro-1,4-dioxa-5,8-diazanaphthalene (XX)[19], and ethanedithiol forms decahydro-1,4-dioxa-5,8-dithianaphthalene (XXI)[53]. Heating with acetic acid in toluene initially forms 3-chlorodioxanyl acetate (XXII)[54], which with methanolic sodium methoxide gives 3-methoxydioxanol (XXIII)[18]. Diesters (XXIV: R = CH_3, C_2H_5) are obtained when 2,3-dichlorodioxan is heated with potassium acetate in acetic acid or with silver acetate in benzene, and in still higher yields (80–90%) with ammonium carboxylates[18].



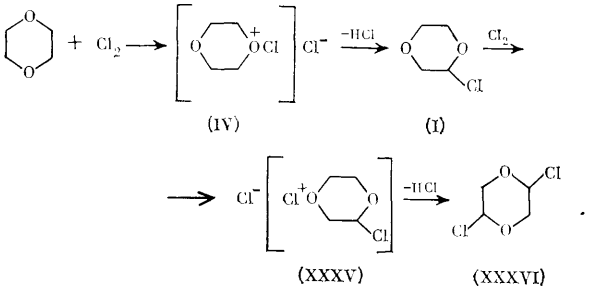
Dioxan rings are present in insecticides having practical value. For example, the diphosphorodithioate (XXV) (Delnav) is obtained by heating 2,3-dichlorodioxan with *OO*-diethyl hydrogen dithiophosphate in the presence of catalytic quantities of zinc chloride or a tertiary amine[55,56]. Delnav exists as *cis*- and *trans*-isomers, the former being considerably more toxic. Another product is Delnav-P-*O* (XXVI), obtained similarly from *OO*-diethyl hydrogen thiophosphate[56]. When *trans*-2,3-dichlorodioxan is dissolved in concentrated sulphuric acid and kept at 40 °C for 24 h, hydrogen chloride is evolved and a compound $C_6H_6Cl_4O_4$ is obtained, to which the structure 2,3,6,7-tetrachlorodecahydro-1,4,5,8-tetraoxanaphthalene (XXVII) was attributed[57].

As already remarked, the chlorine atoms in 2,3-dichlorodioxan can be replaced in stages, with the formation of 3-substituted 2-chlorodioxans, which can be isolated as individual compounds. Such monochlorinated dioxan derivatives undergo further vigorous nucleophilic substitution of the remaining chlorine atom. Thus heating 2,3-dichlorodioxan in benzene with 2,2,2-trichloroethanol gives crystalline 2,2′2′,2′-tetrachloro-3-ethoxydioxan (yield 50%), which on treatment with potassium ethoxide, propan-2-ol, and 2-chloroethanol forms compounds (XXVIII)–(XXX) respectively[58]:

(XXVIII) (XXIX) (XXX)



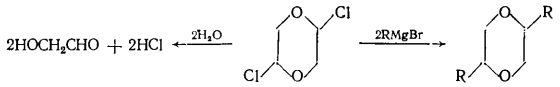
In the absence of atmospheric moisture 2,3-dichlorodioxan undergoes an exothermic reaction with cyclohexylamine, forming 2-chloro-3-*N*-cyclohexylaminodioxan (XXXI), which when heated undergoes fission of the dioxan ring and conversion into the azomethine (XXXII)[19]:



2-Chloro-3-phenoxydioxan, obtained from 2,3-dichlorodioxan and sodium phenoxide, gives 3-phenoxydioxanyl acetate (XXXIII) when heated with sodium acetate, and forms 2-amino-3-phenoxydioxans (XXXIV) with secondary amines[18].

(c) 2,5-Dichlorodioxan

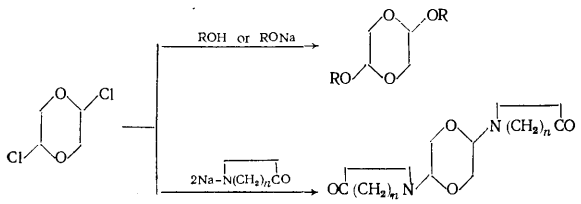
2,5-Dichlorodioxan is obtained by chlorinating dioxan in the cold (between −47 and −5°), when ~ 25% of the crystalline *trans*-isomer is isolated from the complicated mixture that results[6,59]; this product is obtained also by the addition of hydrogen chloride to dioxin[60];



Chlorination of dioxan at low temperatures[2,5,6] also gives initially the chlorodioxanate (IV) and monochlorodioxan (I). In contrast to chlorination at high temperatures, e.g. 90 °C, elimination of hydrogen chloride from chlorodioxan (I) is greatly retarded. As a consequence, a second chlorine molecule is able to form the unstable dioxanate (XXXV) with the second ethereal oxygen atom in chlorodioxan, and 2,5-dichlorodioxan (XXXVI) results from (XXXV) by known reactions:

(IV) (I) (XXXV) (XXXVI)

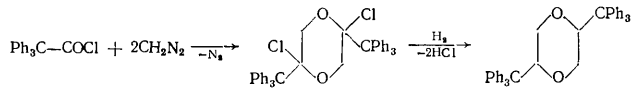
2,5-Dichlorodioxan is a typical α-chloro-ether, but as a consequence of its molecular symmetry is more stable than the 2,3-dichloro-isomer. Nevertheless, it is gradually hydrolysed by moisture, evolving hydrogen chloride, and when boiled with water the dioxan ring opens to give an almost quantitative yield of glycollaldehyde, which is proof of the structure of 2,5-dichlorodioxan[60]; with alkyl- and



aryl-magnesium bromides mixtures of *cis*- and *trans*-2,5-disubstituted dioxans are formed[6,61]:

R=Me, n-Bu, Ph, *p*-MeC_6H_4 .

In the reaction with phenylmagnesium bromide the yield of 2,5-diphenyldioxan reaches 95%.[6]



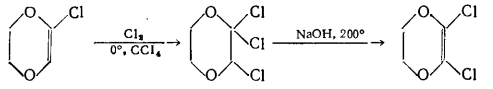
Dioxan derivatives containing substituents at positions 2 and 5 are obtained by the action of nucleophilic reagents on 2,5-dichlorodioxan[62–64]:

n=3–5

R=$CH_2CH{=}CH_2$, CH_2CH_2Cl, $CH_2CH_2CH_2Cl$, CH_2CH_2Br, CH_2CH_2CN, CH(CN)Me, Ph, 2,4-$Cl_2C_6H_3$, $PhOCH_2CH_2$, 4-$ClC_6H_4OCH_2CH_2$, 1-$C_{10}H_7$.

It was reported[65] that reaction between triphenylacetyl chloride and diazomethane gives crystalline 2,5-dichloro-2,5-bistriphenylmethyldioxan (m.p. 133 °C), which on reduction is converted into 2,5-bistriphenylmethyldioxan:

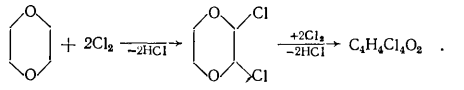
3. Polychlorodioxans



Tri-, tetra-, hexa-, hepta-, and octa-chlorodioxans have been obtained by the direct chlorination of dioxan and also indirectly, and their properties have been described. No report has yet appeared of the existence of pentachlorodioxan.

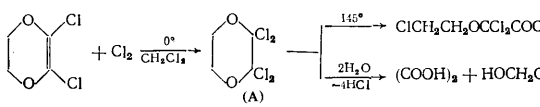
The results of the direct action of chlorine on dioxan exhibit a peculiar temperature dependence[2]: after the predominant formation of 2,5-dichlorodioxan at subzero temperatures[6,59], another one or two hydrogen atoms are replaced with every additional 10-deg rise in temperature, so that tetrachlorodioxans are formed at +10 °C, but hexachlorodioxans at +20 °C. To obtain heptachlorodioxan the temperature must be raised to 30–40 °C. The yields of polychlorodioxans obtained by low-temperature chlorination are usually small. Further action of chlorine at temperatures above 40 °C leads to gradual chlorolysis with degradation of the ring. When 80 °C is reached, a violent exothermic reaction suddenly begins, with swelling, charring, and even ignition of the reaction mixture. In this case the instability of the various chlorination products makes it very difficult to isolate individual compounds. Under reaction conditions under which this peculiar temperature barrier in the region of 80–90 °C has been surmounted, and especially in the presence of a catalyst such as iodine, tin(II) chloride, etc., the chlorination of dioxan again proceeds comparatively smoothly with, as already noted, the formation predominantly of 2,3-dichlorodioxan. At 110–170 °C highly chlorinated polychlorodioxans are obtained. The high-temperature chlorination of dioxan also yields complicated mixtures, including not only chlorodioxans but also chlorolysis products; its mechanism has remained almost uninvestigated, but is assumed to involve radical reactions.

The stability of polychlorodioxans towards hydrolysis and other chemical actions increases with the number of chlorine atoms in the ring. Thus tetrachlorodioxans (other than the 2,2,3,3-isomer) and more highly chlorinated dioxans can be steam-distilled without appreciable decomposition[62]. Polychlorodioxans exert an insecticidal action similar to that of DDT.[19]



(a) 2,2,3-Trichlorodioxan

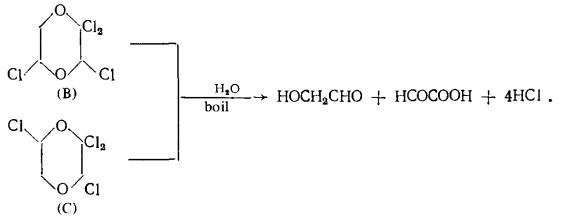
2,2,3-Trichlorodioxan has not been obtained by the direct chlorination of dioxan: it can be prepared by the addition of chlorine to 5-chloro-2,3-dihydrodioxin[37]. Thermal alkaline dehydrochlorination converts 2,2,3-trichlorodioxan into 5,6-dichloro-2,3-dihydrodioxin (yield 52%):



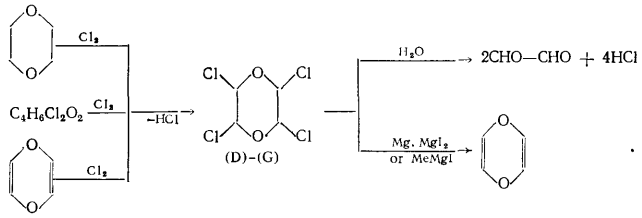
(b) Tetrachlorodioxans

Seven of the possible isomeric chlorodioxans are known (Table, A–G), formed in small quantities in the preparation of 2,3-dichlorodioxan by the chlorination of dioxan at 90 °C.[60] The yields increase with rise in the temperature of the reaction (to 135–140 °C) and increase in its duration[38,41]. It is assumed that the production of tetrachlorodioxans is preceded by the formation of 2,3-dichlorodioxan[21,38,41,45,62]:

The chlorination of 2,3-dichlorodioxan at 135 °C does indeed give an 85% yield of a mixture of isomers, from which individual tetrachlorodioxans have been isolated[37,41,62]. Some have been prepared by other methods.



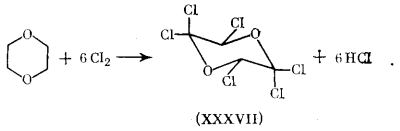
The report[66] that 2,2,3,3-tetrachlorodioxan (A) could be obtained by chlorinating 2,3-dichlorodioxan at 155–160 °C proved incorrect. As shown later, only chlorolysis products of dioxan are obtained, but (A) can be prepared in quite good yield by the addition of chlorine to 5,6-dichloro-2,3-dihydrodioxin[37]. The tetrachloro-isomer (A) is a quite stable compound, decomposing only when heated above the melting point, to form 2,2,2'-trichloroethoxyacetyl chloride, but on prolonged boiling with water it is hydrolysed and converted into oxalic acid, ethylene glycol, and hydrogen chloride:



(A)

The structures of tetrachlorodioxans (B) and (C), isolated in small quantities from the products of the chlorination of 2,3-dichlorodioxan, have not been accurately established: the liquid isomer (B) is assumed to be 2,2,3,5-tetrachlorodioxan, and the crystalline isomer (C) 2,2,3,6-tetrachlorodioxan. Both compounds also resist the action of water, being hydrolysed only after prolonged boiling with water (for

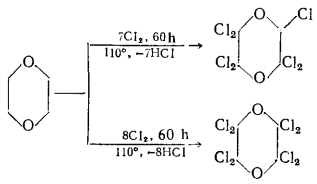
5–6 h), which converts them quantitatively into glycollaldehyde, glyoxylic acid, and hydrogen chloride[21,38,41]:



The symmetrical 2,3,5,6-tetrachlorodioxans are especially interesting, with five possible stereoisomers depending on the disposal of the chlorine atoms. The four crystalline stereoisomers that have been prepared and characterised (D)–(G) differ in melting point. Tetrachlorodioxans (D)–(F) are obtained by the chlorination respectively of dioxan[21,38], 2,3-dichlorodioxan[21,41], and 2,5-dichlorodioxan[62,67]; the isomer (G) results from the addition of chlorine to 1,4-dioxin[21,38,60]:

Compounds (D)–(G) are also stable towards water, and can be distilled in steam without appreciable hydrolysis[60], but on being boiled with water for 2–3 h decompose quantitatively into glyoxal and hydrogen chloride[38]. When heated with magnesium, magnesium iodide, or methylmagnesium iodide they are dehydrochlorinated to 1,4-dioxin. Both reactions provide evidence of the positions of the chlorine atoms in these tetrachlorodioxans[60].

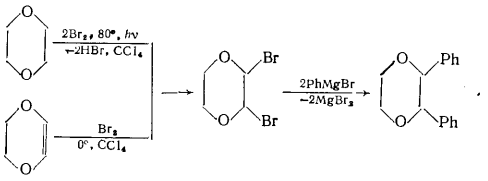
(c) Hexachlorodioxans



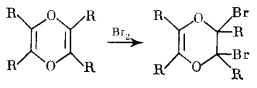
When chlorine is passed into dioxan at 110 °C for a long time (~ 50 h), two isomeric hexachlorodioxans differing in melting point can be isolated from the reaction mixture in a total yield of 25%.[45,62] The one melting at 94 °C and having zero dipole moment was regarded[48] as 2,2,3,5,5,6-hexachlorodioxan (XXXVII):

(XXXVII)

(d) Hepta- and octa-chlorodioxans



Still more prolonged chlorination of dioxan (at 110 °C for ~ 60 h) gives a good yield of two stereoisomeric heptachlorodioxans, which differ considerably in melting point. Introduction of the eighth chlorine atom into the dioxan ring takes place slowly and with difficulty. The octachlorodioxan isolated from the reaction mixture crystallises well[62,63]:

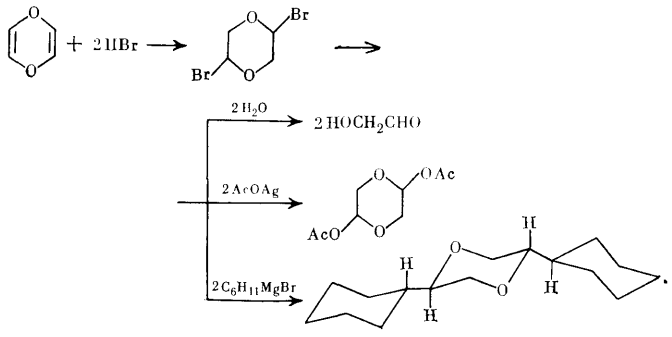


Heptachlorodioxan is so stable that it begins to evolve hydrogen chloride only when heated with concentrated sulphuric acid to 150 °C, without darkening of the reaction mixture. It does not split off hydrogen chloride when heated with aqueous alkalis or with aqueous–alcoholic silver nitrate solution, and a mixture of concentrated sulphuric acid and potassium permanganate has hardly any effect[62]. Heptachlorodioxan possesses well developed insecticidal properties, surpassing the γ-isomer of DDT in its action on individual species of ants[2].

III. BROMO- AND FLUORO-DIOXANS

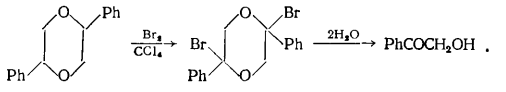
Bromodioxans have been far less studied than have chlorodioxans. In the cold dioxan forms with bromine a dioxanate $C_4H_8O_2.Br_2$[1,68–70], which when heated decomposes with opening of the dioxan ring and formation of bromoethane, hydrogen bromide, etc.[38,71]. On ultraviolet exposure in tetrachloromethane dioxan is smoothly brominated[72] to crystalline 2,3-dibromodioxan (yield 75%, m.p. 71.5–73.5 °C); this dibromide is obtained also in good yield (92%) by the addition of bromine to dihydrodioxin in tetrachloromethane in the cold[5,26]:

Similarly, 2,3-dihydro-5-phenyldioxin adds bromine to give 2,3-dibromo-5-phenyldioxin[43]. It is interesting that under the same conditions 1,4-dioxin[60] and 2,3,5,6-tetraphenyl-1,4-dioxin[73] add only one bromine molecule to form substituted dihydrodioxins:



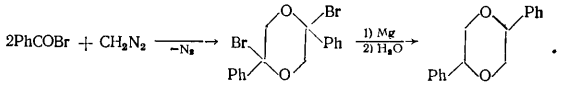
R = H, Ph .

2,3-Dibromodioxan is unstable, and is gradually decomposed by atmospheric moisture, with the evolution of hydrogen bromide. Its structure has been proved by its reaction with phenylmagnesium bromide, when 2,3-diphenyldioxan is obtained[5].

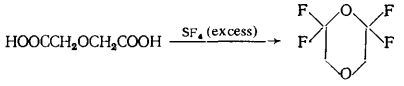


2,5-Dibromodioxan has been obtained in good yield (90%) by passing anhydrous hydrogen bromide into a cold chloroform solution of 1,4-dioxin. It is thermally unstable, darkening at 104 °C, and decomposing at 134 °C. Its structure has been confirmed by hydrolysis: brief boiling with water readily gives a quantitative yield of glycollaldehyde. When 2,5-dibromodioxan is heated with silver acetate in toluene,

both bromine atoms are replaced by acetoxy-groups to form dioxan-2,5-ylene diacetate[74]:



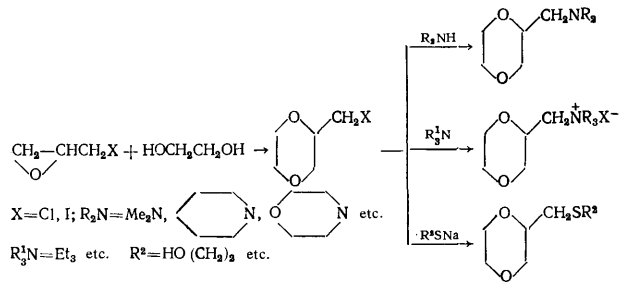
With cyclohexylmagnesium bromide 2,5-dibromodioxan forms (in 20% yield) 2,5-dicyclohexyldioxan as the *trans*-diequatorial conformer (according to n.m.r. spectral data)[75].



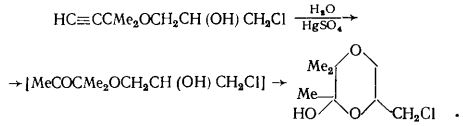
2,5-Diphenyldioxan is readily brominated to 2,5-dibromo-2,5-diphenyldioxan, which on hydrolysis is converted into hydroxymethyl phenyl ketone[6]:

As with the chloro-derivative, the action of diazomethane on benzoyl bromide gives 2,5-dibromo-2,5-diphenyldioxan, which is converted by the successive action of magnesium and water into 2,5-diphenyldioxan (yield 62%)[65]:

The action of sulphur tetrafluoride on a diglycollic ester forms the extremely stable liquid 2,2,6,6-tetrafluorodioxan[76,77]:

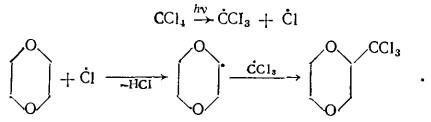


IV. HALOGENOALKYLDIOXANS

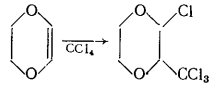


A considerable number of dioxans halogenated in side-chains are known. The halogen atoms usually undergo ready nucleophilic substitution with preservation of the dioxan ring. The best known and most thoroughly studied are the chloro- and iodo-derivatives.

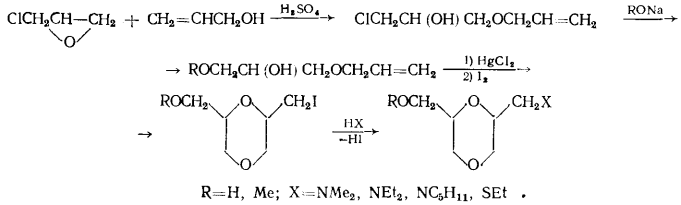
1. Halogenoalkyldioxans



Condensing epoxypropyl chloride and iodide respectively with ethylene glycol in the presence of concentrated sulphuric acid yields 2-chloromethyl- and 2-iodomethyl-dioxans[78], which react readily with secondary and tertiary amines and also with thiols to give alkylated dioxans containing nitrogen or sulphur atoms in the alkyl groups[79,80]:

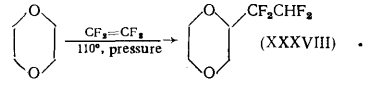


Under the conditions of the Kucherov reaction 1-chloro-5,5-dimethyl-4-oxahept-6-yn-2-ol undergoes hydration and cyclisation to 6-chloromethyl-2,3,3-trimethyldioxan-2-ol[81]:

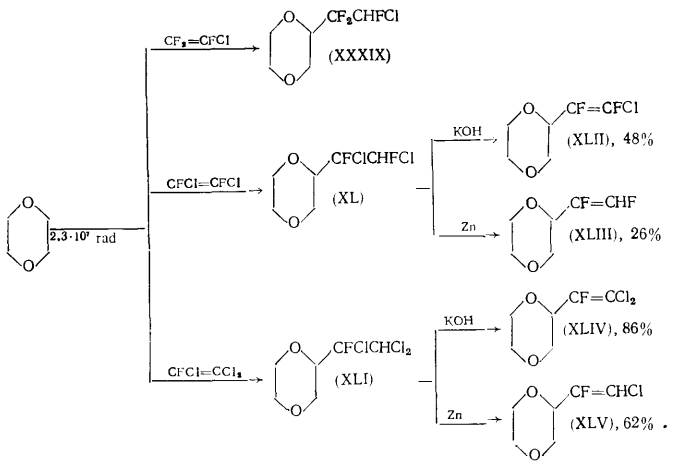


Prolonged (~ 100 h) ultraviolet exposure of a solution of tetrachloromethane in dioxan results in radical reactions, the products of which include crystalline trichloromethyldioxan (m.p. 136–138 °C) together with hydrogen chloride, chloroform, and hexachloroethane[78]:

An analogous mechanism is involved in the addition of tetrachloromethane to dihydrodioxin in the presence of azoisobutyronitrile to form 2-chloro-3-trichloromethyldioxan[82]:

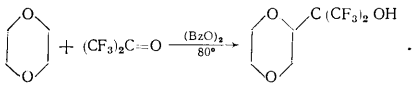


Several 6-substituted iodomethyldioxans have been obtained from epoxypropyl chloride and allyl alcohol, in which the iodine atom is readily exchanged by the action of nucleophiles, as expected, usually forming mixtures of *cis*- and *trans*-2,6-disubstituted dioxans[83–85]:

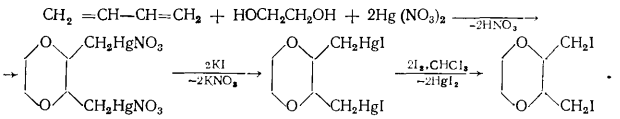


R=H, Me; X=NMe_2, NEt_2, NC_5H_{11}, SEt .

Some interest attaches to fluoroalkyldioxans, obtained from dioxan and organofluorine compounds by free-radical reactions initiated by exposure to ultraviolet radiation or γ-rays, as well as in the presence of peroxy-compounds. According to a patent[86] dioxan reacts with tetrafluoroethylene when heated in the presence of benzoyl peroxide under pressure, with the formation of 1′,1′,2′,2′-tetrafluoroethyldioxan (XXXVIII):

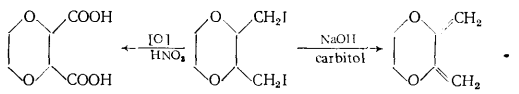


Dioxan reacts with equimolecular proportions of chlorofluoroalkenes on exposure to γ-rays to form liquid chlorofluoroethyldioxans (XXXIX)–(XLI) in yields of ~ 55%[87]:



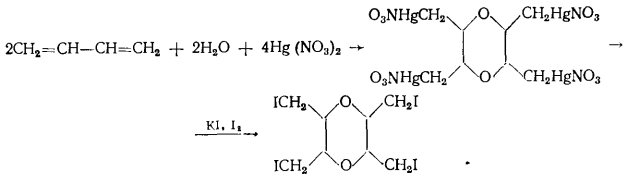
Treatment of the products (XL) and (XLI) with potassium hydroxide or zinc dust converts them into the chlorofluorovinyldioxans (XLII)–(XLV)[88].

Dioxan condenses with hexafluoroacetone on ultraviolet irradiation or on heating with benzoyl peroxide to form crystalline dioxanylbistrifluoromethylmethanol (yield 25%)[89]:



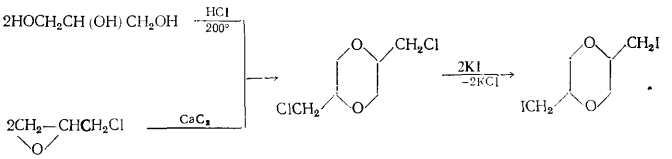
2. Bishalogenoalkyldioxans

Application of Nesmeyanov and Lutsenko's method[92] to buta-1,3-diene and ethylene glycol gave by a series of consecutive reactions 2,3-bisiodomethyldioxan (yield 56%) as a mixture of *cis*- and *trans*-isomers (m.p. 77 and 90 °C) with the latter predominating[90,91]:



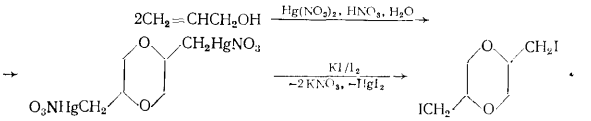
If the reaction is conducted in a strongly acid medium, e.g. in nitric acid, the quantity of the *trans*-isomer is greatly increased.

This *trans*-isomer served as starting material for obtaining a series of 2,3-disubstituted dioxans. Thus oxidation of the di-iodide with nitric acid gives dioxan-*trans*-2,3-dicarboxylic acid (m.p. 175 °C), and heating with alkali in an inert solvent forms a readily polymerisable conjugated diene:

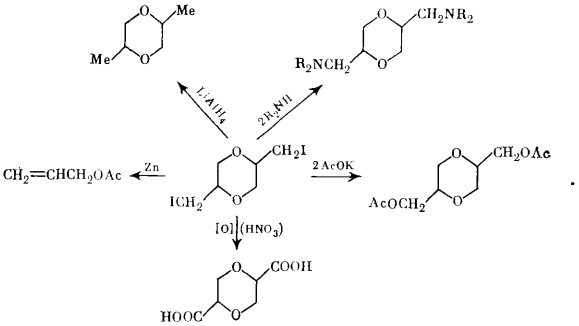


The latter product, 2,3-dimethylenedioxan, forms a crystalline adduct with maleic anhydride (m.p. 82 °C).

If the reaction between butadiene and aqueous mercury(II) nitrate is conducted in the absence of ethylene glycol, and the product is then treated successively with potassium iodide and iodine, 2,3,5,6-tetrakisiodomethyldioxan is obtained, apparently with intermediate formation of 2,3,5,6-tetrakisnitratomercurimethyldioxan[91]:

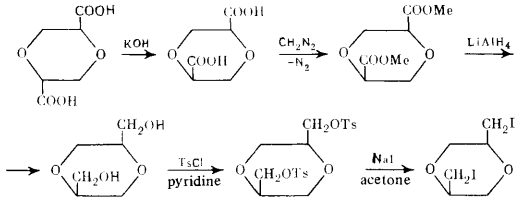


Early papers[93–95] described 2,5-bishalogenomethyldioxans under the names "diepichlorhydrin" and "diepi-iodohydrin". The former was obtained by heating glycerol with hydrochloric acid, and the latter from the former by heating with alcoholic potassium iodide:

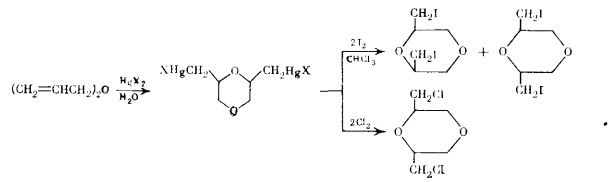


The structure of these compounds was later reliably established as *trans*-2,5-bishalogenomethyldioxans[90,97,98]. According to a patent[99] a 90% yield of *trans*-2,5-bischloromethyldioxan can be obtained by heating epoxypropyl chloride with calcium carbide in the presence of hexacarbonylbistributylphosphinecobalt as catalyst. The resulting dichloride reacts with alcoholic potassium iodide to form crystalline *trans*-2,5-bisiodomethyldioxan (m.p. 158 °C).

The bisiodomethyl derivative can be synthesised also by condensing two molecules of allyl alcohol in the presence of mercury(II) nitrate in aqueous nitric acid and then treating the products with iodine and potassium iodide[90,93,95,96]. In these stereospecific reactions *trans*-2,5-bisnitratomercurimethyldioxan is obtained initially in almost quantitative yield, and with potassium iodide and iodine gives a 90% yield of the di-iodide:

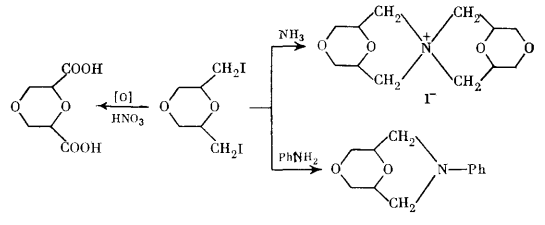


2,5-Bisiodomethyldioxan is of interest in view of the many S_N reactions involving the two reactive iodomethyl groups and yielding *trans*-2,5-dimethyldioxans in which the methyl groups are substituted. Thus heating with concentrated ammonia forms 2,5-bisaminomethyldioxan[93,97], and with morpholine and 2,6-dimethylmorpholine the 2,5-dimorpholino- and 2,5-bis-2′,6′-dimethylmorpholino-dioxans respectively[100]. Brief heating of the di-iodide with potassium acetate in acetic acid involves initial replacement of one iodine atom by an acetate group, but on longer heating two iodine atoms are substituted to give dioxan-2,5-ylenedimethyl diacetate[97]:

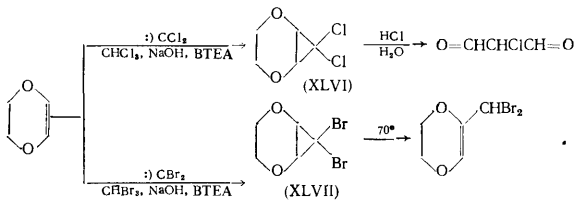


An attempt to reduce the di-iodide with zinc in acetic acid or in alcohol opens the dioxan ring and forms allyl acetate or alcohol respectively, but lithium tetrahydroaluminate in ether reduces it to 2,5-dimethyldioxan[101].

Heating the *trans*-di-iodide with concentrated nitric acid oxidises it to dioxan-*trans*-2,5-dicarboxylic acid[90,98], which when heated with potassium hydroxide isomerises into the *cis*-dicarboxylic acid. This last product can be converted by a series of consecutive reactions into *cis*-2,5-bisiodomethyldioxan (m.p. 97 °C)[97]:

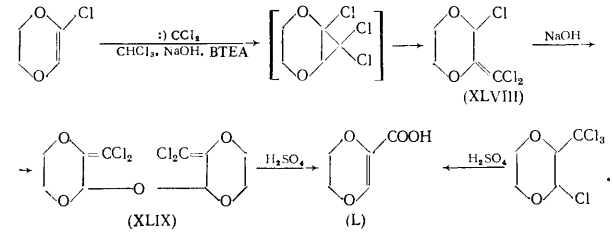


Diallyl ether condenses extremely readily with mercury(II) acetate or chloride in aqueous solution to give an 85% yield of 2,6-bischloromercurimethyldioxan, which on treatment with iodine or chlorine is smoothly converted into respectively 2,6-bisiodomethyl- or 2,6-bischloromethyl-dioxan[92]:



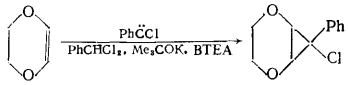
It was established by chemical methods that 2,6-bisiodomethyldioxan is a mixture of *cis*- and *trans*-isomers[98,102]. It is interesting that the former has the higher melting point (90 and 70 °C). The relative stability of the *cis*-isomer is attributed to its greater molecular symmetry, the possibility of its existing as a conformation with a diequatorial arrangement of the iodomethyl groups. In the *trans*-isomer one iodomethyl group occupies an axial position[98].

Here the known facts concerning the greater stability of *cis*- than of *trans*-1,3-disubstituted cyclohexanes can be appropriately compared in terms of the equatorial–polar concept[103]. For steric reasons the former isomer, unlike the latter, forms morpholine derivatives on reaction with ammonia or aniline[98,102]; both isomers are oxidised by hot nitric acid, being converted into the corresponding isomeric dioxan-2,6-dicarboxylic acids without change in the geometric configuration[98]:

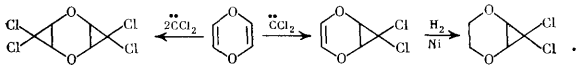


3. Reactions of Halogenocarbenes with Dioxins and Dihydrodioxins

Halogenocarbenes react readily with dioxin and with dihydrodioxin. The adduct of the latter with dichlorocarbene was described first in 1974[104] and then in subsequent papers[105,106]. Detailed investigation showed[107] that, with dichlorocarbene generated from chloroform by the action of 50% caustic soda under conditions of phase-transfer catalysis in the presence of benzyltriethylammonium chloride, dihydrodioxin gives a very good yield (> 90%) of 7,7-dichloro-2,5-dioxabicyclo[4,1,0]heptane (XLVI), which is relatively unstable and is converted into chloromalonaldehyde when boiled with dilute hydrochloric acid[105]:



Under analogous conditions dibromocarbene generated from bromoform yields the thermally unstable 7,7-dibromo-2,5-dioxabicyclo[4,1,0]heptane (XLVII), which on moderate heating is converted (with cleavage of the cyclopropane ring) into 5-dibromomethyldihydrodioxin[107].



With 5-chlorodihydrodioxin dichlorocarbene does not give a stable adduct at the double bond under conditions of phase-transfer catalysis[108,109]. The bicyclic adduct formed in the course of the reaction is apparently converted into 2-chloro-3-dichloromethylenedioxan (XLVIII), which in an alkaline medium gives the bisdichloromethylenedioxanyl ether (XLIX) (yield 37%), from which dihydrodioxin-5-carboxylic acid (L) is obtained (yield 60%)[108], as also by heating 1-chloro-2-trichloromethyldioxan with sulphuric acid:

The reaction of dihydrodioxin with chlorophenylcarbene generated from benzylidene dichloride and potassium t-butoxide gives 7-chloro-7-phenyl-2,5-dioxabicyclo[4,1,0]heptane[106,110]:

1,4-Dioxin also reacts vigorously with dichlorocarbene generated from methyl trichloroacetate by the action of sodium methoxide[106]. Addition takes place at either one or two double bonds depending on the proportions of the reactants. In the former case 7,7-dichloro-2,5-dioxabicyclo-[4,1,0]heptene is obtained (yield 56%), which on hydrogenation is reduced to the known adduct of dihydrodioxin with dichlorocarbene; in the latter case a double adduct is formed—4,4,8,8-tetrachloro-2,6-dioxatricyclo[5,1,0]octane (yield 34%):

---oOo---

In conclusion it can be stated that halogenodioxans form a group of compounds of interest to organic chemists that has been by no means completely investigated. Individual representatives have a well defined physiological effect and possess insecticidal properties. Among dioxan derivatives the most valuable are those containing chlorine atoms in the ring. Further development of methods of preparation and study of their reactions will undoubtedly give valuable new information for the theory and practice of organic synthesis.

Reactions of Pyrylium Salts with Nitrogen-containing Nucleophiles

E.A.Zvezdina, M.P.Zhadonva, and G.N.Dorofeenko (deceased)

New data on reactions of pyrylium salts with nitrogen-containing nucleophiles, occurring both with retention of the pyrylium ring and with recyclisation, are considered. The extensive possibilities for the employment of pyrylium salts in the synthesis of many functional compounds of the aliphatic and aromatic series and of different nitrogen- and oxygen-containing three-, five-, six-, and seven-membered heterocycles, including condensed heterocycles, are demonstrated.
The bibliography includes 184 references.

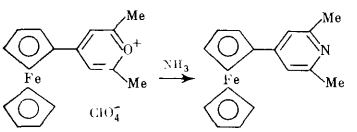
I. INTRODUCTION

The vigorous development of the chemistry of pyrylium salts observed in recent years is associated not only with the enormous theoretical interest in the reactions of the carboxonium cation but also with the possibility of using such salts for the synthesis of many aliphatic, aromatic, and heterocyclic compounds, which sometimes cannot be obtained by other procedures. In this sense, the cyclisation reactions of pyrylium salts under the influence of nitrogen-containing nucleophiles are of particular interest. They lead to compounds among which effective biologically active substances, dyes, metal corrosion inhibitors, emulsifying agents, etc. have been found[1,2].

Pyrylium salts, which have a positive charge in the heterocycle, are exceptionally reactive to nucleophiles. The presence of a sextet of π electrons is responsible for the aromatic properties of the pyrylium cation. However, the electronegative oxygen heteroatom promotes a non-uniform electron density distribution in the ring. A high positive charge is therefore concentrated at the 2-, 4-, and 6-carbon atoms, whilst the charge at C(3) and C(5) atoms is quite insignificant, or these atoms are even negatively charged[3,4].

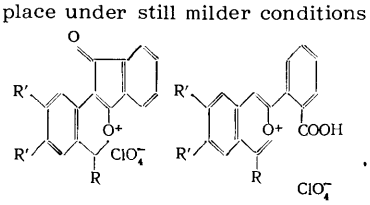
The first stage in the reaction of pyrylium salts with nucleophiles is the addition of the nucleophiles to C(2) or more rarely to C(4). The attack on the 2-position in the pyrylium ring is accompanied by ring opening and recyclisation (the S_NANRORC mechanism). The structure of the reaction product depends on the nature of the nucleophile, the substituents in the pyrylium ring, and the process conditions.



The reactions of pyrylium salts with ammonia, ammonium carbonate and acetate, and certain amines have been partly considered in other reviews[5-8] covering the literature up to 1972. The review of Plas and Streef[9], which deals with the recyclisation of various heterocycles, also presents several examples of the above reactions.

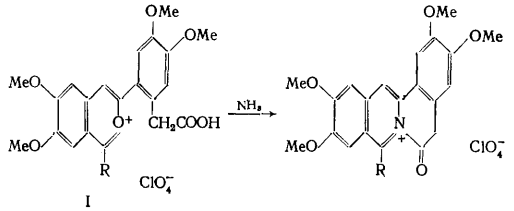
In the present review an attempt has been made to survey the extensive experimental data on the reactions of pyrylium salts with a wide variety of nitrogen-containing nucleophiles, which have accumulated in recent years (up to 1980 inclusive). Some attention has also been devoted to studies published up to 1972 but not included in the reviews quoted above.

Apart from the reactions of monocyclic pyrylium structures, the behaviour of the benzo- and heterocyclic analogues has also been considered, which we believe makes it possible to assess more fully the problem of the reactivity of heteroaromatic cations with *N*-nucleophiles in general.



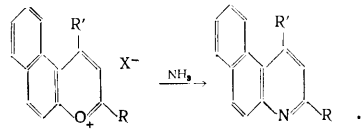
II. INTERACTION OF PYRYLIUM SALTS WITH AMMONIA AND THE SIMPLEST AMINES

In recent years the interaction of pyrylium salts with ammonia led to the synthesis of new compounds of the pyridine series otherwise difficult to obtain[10-23], for example:

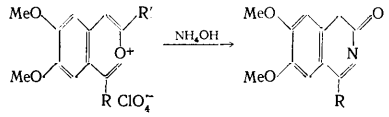


2-Benzopyrylium as well as pyrylium salts condensed with N-, O-, S-, and Se-containing heterocycles react with ammonia to give respectively isoquinoline bases of pyridines condensed with heterocycles. Hitherto unknown isoquinolines or isoquinolines difficult to obtain[24,25], pyridines with condensed cycloalkene rings[26-32] and steroids[33], disteroidopyridines[34], indolo[2,3-*c*]pyridines[35], benzofuro[3,2-*c*]pyridines[36,37], thionaphtheno[2,3-*c*]pyridine[38], selenopheno[3,2-*c*]pyridines[39,40], selenopheno[2,3-*c*]pyridines[41,42], and pyrido[2,3-*d*]pyrimidines[43] have been obtained by this method.

1-Alkyl(aryl)-3,4-diaryl-2-benzopyrylium salts are converted by ammonia into isoquinolines more readily[44] than the 1-alkyl(aryl)-3-aryl-substituted derivatives[45]. The exchange of the ring oxygen atom for nitrogen in 3-aryl-substituted 2-benzopyrylium salts without a substituent in the 1-position[46] and in salts with the electron-accepting carbonyl group[30] takes place under still milder conditions:



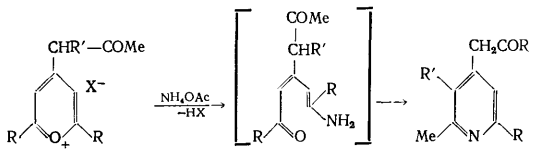
When the salts (I) interact with ammonia, the replacement of the oxygen hetero-atom by nitrogen is accompanied by the formation of a new ring[47]:



I

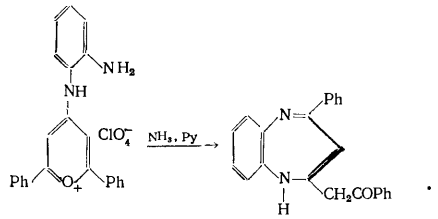
1-Benzopyrylium and xanthylium salts cannot be converted into quinolines and acridines by treatment with ammonia[48], but naphtho[*b*]pyrylium salts have been converted into benzoquinoline derivatives in satisfactory yield by reaction with ammonia[49]:

The reactions of 5,6,7,8-tetrahydrochromylium and symmetrical octahydroxanthylium salts with ammonia, leading to 5,6,7,8-tetrahydroquinolines and octahydroacridines, take place under mild conditions[27].



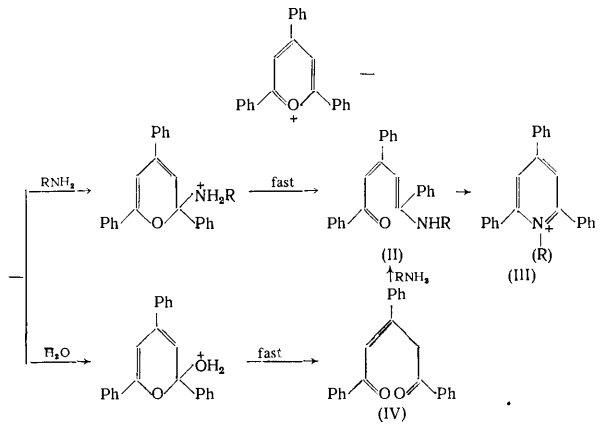
The reaction of 2-benzopyrylium salts containing the 3-OCH_3 group with aqueous ammonia results in the hydrolysis of the intermediate ether and subsequent cyclisation to 3-oxo-4*H*-isoquinoline[50]:

R=Alk, R′=OMe, $PhCOCH_2O$, EtCOO, R″CONH .

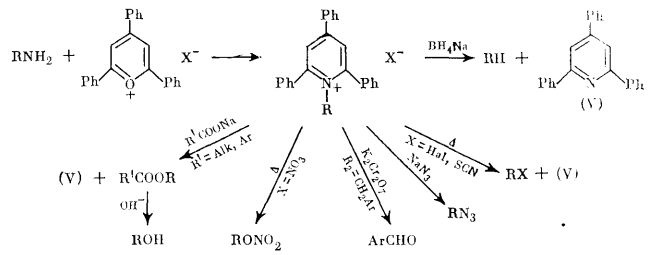


Isoquinolones are formed in high yields also in the reactions of 1-alkyl-3-phenacyloxy-[51] and 1-alkyl-3-acylamino-2-benzopyrylium salts[52] with ammonia. Similarly 1-alkyl-3-methoxy-5,6,7,8-tetrahydro-2-benzopyrylium salts are converted by reaction with ammonia into 1-alkyl-5,6,7,8-tetrahydroquinolones[53]. Pyrylium salts with a free 4-position react with ammonia to form 2,6-disubstituted pyridines[54]. 2-Ethoxyvinylpyrylium salts recyclise to pyridines on reaction with ammonia[55] and the ethoxyvinyl group is simultaneously hydrolysed to the β-hydroxyvinyl group.

The conversion of 4-acetonylpyrylium salt into pyridine with participation of the keto-group of the substituent in the intramolecular cyclisation of the intermediate enamine is of interest[56]:

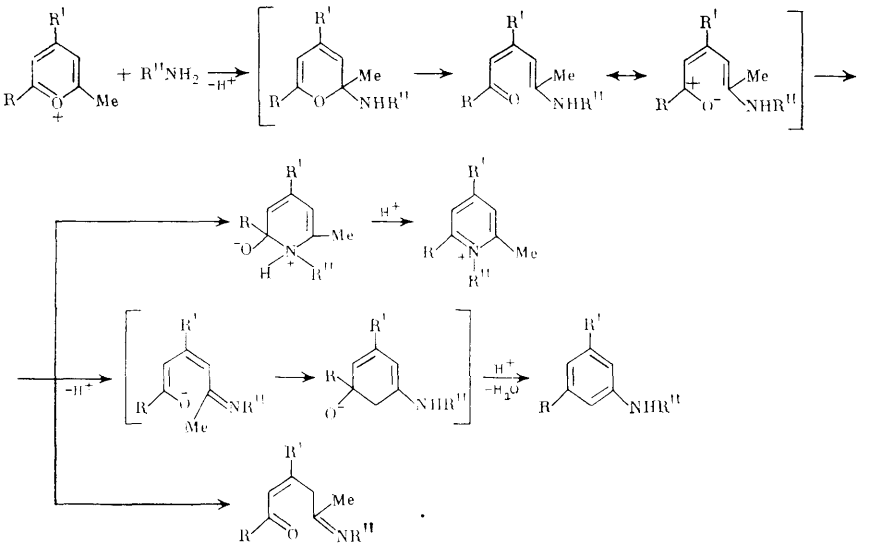


The presence of the electron-donating amino-group in 4-*p*-aminophenylpyrylium salts diminishes somewhat the electrophilicity of the pyrylium ring, but the reaction of these salts with ammonia take place more readily and leads to pyridines[57]. The reaction of *N*-substituted aminopyrylium salts with ammonia proceeds under more severe conditions[19,58]. As a consequence of a still greater delocalisation of the positive charge in the vinylogues of aminopyrylium salts, the ring oxygen heteroatom is not substituted by nitrogen[55].

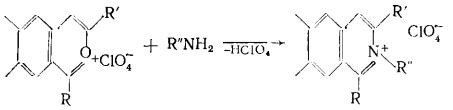


4-(*o*-Aminoanilino)-2,6-diphenylpyrylium perchlorate remains unchanged on being refluxed with ammonium acetate in acetic acid, but the reaction of the salt with ammonia in pyridine leads to its conversion into substituted 1*H*-benzo-1,5-diazepine[59]:

The reactions of arylpyrylium salts with aliphatic amines proceed under mild conditions and with high yields of *N*-alkylpyridinium salts[60,61]. Recent kinetic studies on this reaction by ^{13}C NMR and ultraviolet spectroscopy showed that the rate-limiting stage is the closure of the pyridine ring (II) → (III), which can be catalysed by acids[60,62]:

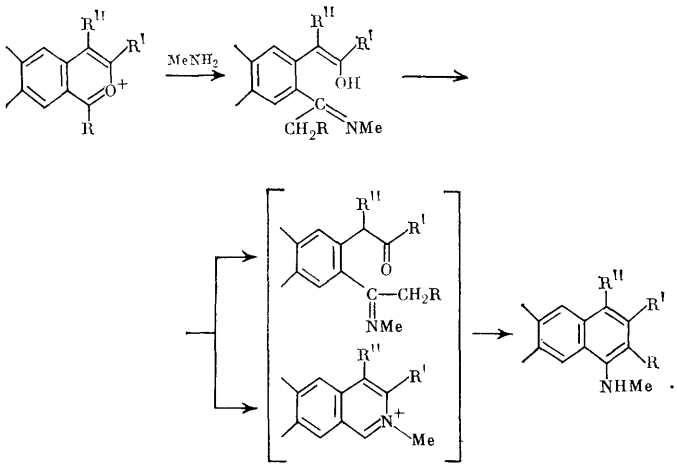


It has also been shown that, together with the main reaction, the diketone (IV) is formed under the influence of traces of water. The diketone (IV) reacts with the amine, giving rise to the pyridinium salt (III), possibly via the aminoketone (II)[60,62]:

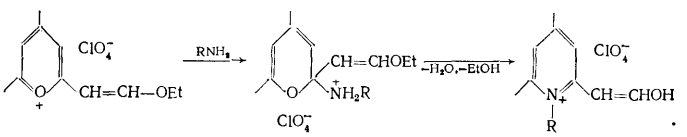


The salts (III) readily split off 2,4,6-triphenylpyridine on being subjected to mild pyrolysis or on treatment with nucleophiles, which makes it possible to employ the reaction of primary amines with pyrylium salts as an intermediate stage in the conversion of amines into hydrocarbons, ethers, alcohols, alkyl halides, thiocyanates, aldehydes, azides, and other derivatives[60].

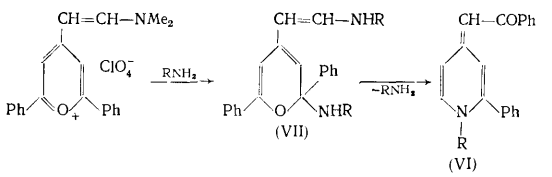
Substituted xylidines may be formed in the reaction of 2-methylpyrylium salts with aliphatic amines together with the conversion into pyridinium salts[63]:



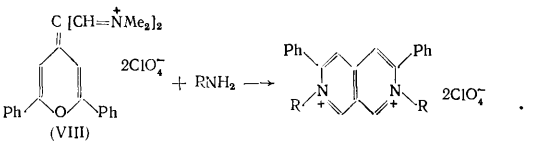
The ratio of the amounts of pyridinium salts and xylidines depends on the nature of the amine. In the case of aliphatic amines and benzylamines the predominant product is pyridinium salts. Cyclohexylamine reacts with 2,4,6-trimethylpyrylium salts to form xylidine, while amines with C_2–C_5 aliphatic groups form xylidines in yields of 30–40%. The interaction with t-butylamine stops at the stage involving the formation of *N*-butylketodienamine, which is the third possible reaction pathway[63].



The reaction of 2-benzopyrylium salts with primary amines results in the formation of isoquinolinium salts. Nucleophilic attack by the amine is directed to the most electron-deficient C(1) atom with formation of benzo-1*H*-pyran, which recyclises via an enamine to an isoquinolinium salt[64,65]:

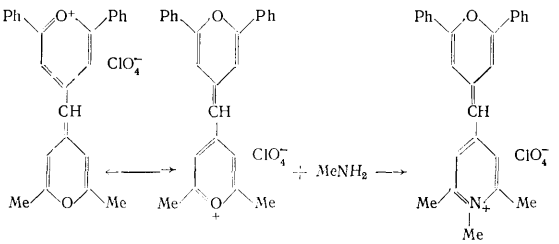


1-Alkyl-3-aryl-substituted 2-benzopyrylium salts, which form α-naphthylamines in the presence of an excess of methylamine, constitute an exception[66,67]. In this case either the second possible version of the cyclisation of the intermediate enamine takes place or the isoquinolinium salt formed recyclises under the influence of the excess amine via the Kost–Sagitullin mechanism[68]:

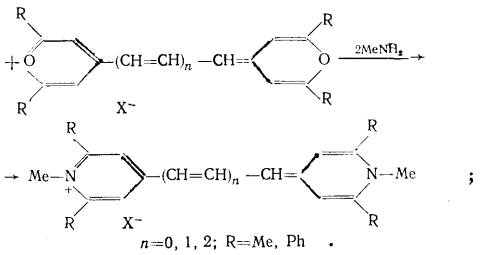


4-Methoxy-2,6-dimethylpyrylium salt reacts with methylamine to form a 4-methoxy- or 4-methylamino-pyridinium salt, depending on the reactant ratio[69]. 2-Benzopyrylium salts with the 3-methoxy-group react with an alcoholic solution of methylamine to form quaternary *N*-methylisoquinolinium salts[50]. Ethoxyvinylpyrylium salts react with aliphatic amines via the mechanism[55]

4-Dimethylaminovinyl-2,6-diphenylpyrylium perchlorate interacts with primary aliphatic amines to form pyridines (VI), which is a result of the recyclisation of the intermediate aminovinylpyran (VII)[70]:



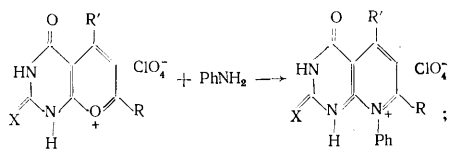
The bisiminium salt (VIII) leads to diquaternised copyrines in an analogous reaction[70]:



The positive charge in pyrylocyanines is delocalised over the entire mesomeric cation, which diminishes their electrophilicity. Nevertheless, even in alcohol the reaction with

ethylamine leads to pyridopyrylocyanine and in the asymmetric cyanine (IX) the oxygen in the dimethylpyrylium ring is the first to be substituted[71]:

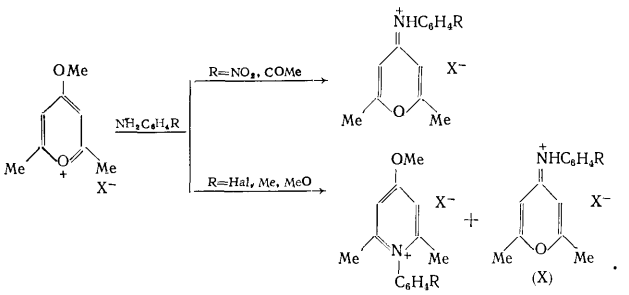
The substitution of the second oxygen atom by nitrogen does not occur in methanol[72,73]. In an aprotic solvent—dimethylformamide (DMF)—it is possible to obtain symmetrical tetramethyl(phenyl)pyrido-derivatives of mono-, tri-, and penta-methinecyanines[71]:



n=0, 1, 2; R=Me, Ph .

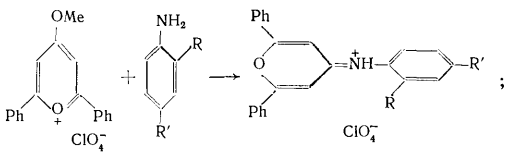
Isopropylcyanines exchange only the oxygen heteroatom for the methylamino-group in DMF, while t-butylcyanine does not react with methylamine at all[74].

The conversion of pyrylium and 2-benzopyrylium salts under the influence of aromatic amines into the corresponding *N*-arylpyridinium and isoquinolinium salts has been thoroughly investigated[64,65]. Analogously to their reaction with ammonia, chromylium and xanthylium salts are not converted into quinolinium and acridinium derivatives on reaction with anilines. Nucleophilic attack on the xanthylium salt is directed to the 9-position, which results in the formation of aminoarylxanthenes[48].



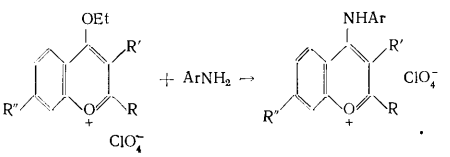
Naphtho[1,2-*c*]- and naphtho[2,1-*c*]-pyrylium salts were made to react with *p*-aminophenol, which yielded benzoquinolinium salts[49]. In contrast to 1-benzopyrylium salts, the condensed pyrylia[2,3-*d*]pyrimidine systems react with aniline to form *N*-phenylpyridinium salts[43]:

X=O, S .



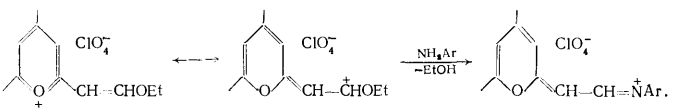
5,6,7,8-Tetrahydrochromylium and symmetrical octahydroxanthylium salts give rise to 5,6,7,8-tetrahydroquinolinium and symmetrical octahydroacridinium salts on treatment with primary amines[75,76].

The reaction of 4-methoxy-2,6-dimethylpyrylium salts with an equimolar amount of *p*-substituted anilines results in the formation of an iminopyran salt (X) together with the 4-methoxypyridinium salt[77]:



Anilines with electron-accepting substituents form only the products resulting from the attack on the 4-position of the pyrylium ring, i.e. an iminium salt (X). More basic amines with electron-donating substituents attack preferentially the 2-position of the pyrylium cation forming a greater amount of the alkoxypyridinium salt the more pronounced the electron-donating effect of the substituent[77].

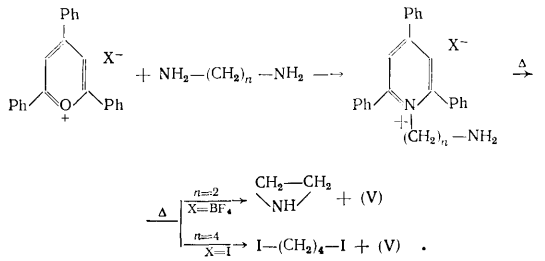
It is noteworthy that 4-methoxy-2,6-diphenylpyrylium perchlorate is converted exclusively into pyran iminium salts in the reaction with anilines[59]:



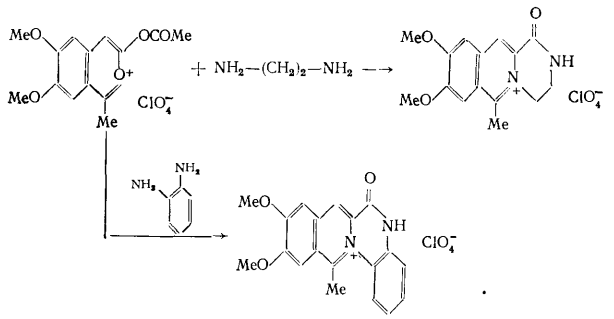
R=H, NH_2, OMe, R′=H; R=H, R′=NH_2, NMe_2, NHCOMe .

The reaction of 4-ethoxychromylium salts with primary amines proceeds analogously[78,79]:

Ethoxyvinylpyrylium salts react with aromatic amines, retaining the pyran ring[55]:



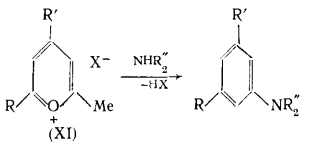
p-Aminophenylpyrylium salts react with aniline only on refluxing in DMF[57].



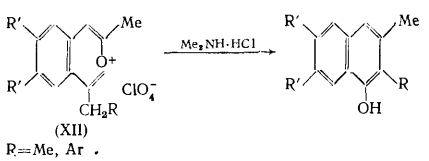
The reactions of pyrylium and 2-benzopyrylium salts with aliphatic and aromatic diamines in molar proportions of 2:1 give rise to bispyridinium salts[65,80-82]. The interaction of pyrylium perchlorate with an equimolar amount of an arylenediamine results in the formation of *N*-aminoarylpyridinium salts[83,84], which react with pyrylium perchlorates to form *m*- or *p*-arylenebispyridinium salts[84] and it is possible to obtain by this procedure compounds with pyridine rings substituted in different ways. *o*-Phenylenediamine reacts with pyrylium salts only via one amino-group, probably owing to steric hindrance. *N*-(*o*-Aminoaryl)pyridinium salts do not form bispyridinium derivatives probably for the same reason[84].

The reactions of equimolar amounts of 2,4,6-triphenylpyrylium salts and aliphatic diamines lead to *N*-aminoalkyl-2,4,6-triphenylpyridinium salts, which have been suggested

for the preparative synthesis of aziridine[85] and di-iodobutane[86] via their pyrolytic decomposition:

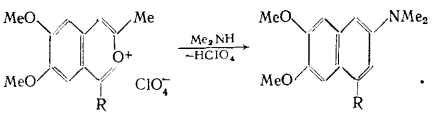


It is of interest that 2-benzopyrylium salts with the 3-methoxycarbonyl group react with certain diamines via two reaction centres[87]:



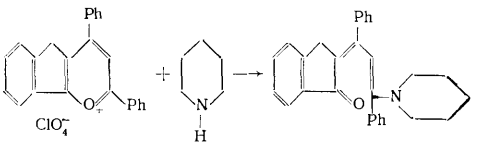
The same pyrylium salts react with *p*-phenylenediamine or 1,8-diaminonaphthalene and are converted into *N*-aminoaryl-substituted quaternary isoquinolinium salts[87].

Pyrylium salts having a 2-methyl or methylene group [compounds (XI)] react with secondary amines and are converted under mild conditions into *N*-substituted anilines[88-90]:



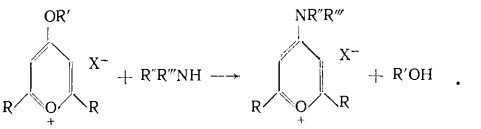
The basicity of the amine plays a significant role in this process. Thus the reaction with highly basic dialkylamines takes place vigorously without heating[88,89]. The reaction of the less basic indoline with the salt (XI, X = ClO_4^-, R = R′ = 4-$MeOC_6H_4$) does not result in the formation of the corresponding *N*-arylindoline[89].

1-Methyl-2-benzopyrylium salts react with cyclic and aliphatic secondary amines to form dialkylaminonaphthalenes[65]. An anomalous reaction of 1-ethyl(benzyl)-substituted 2-benzopyrylium salts (XII) with dimethylamine in ethanol, resulting in the formation of α-naphthols, was discovered recently[91]:

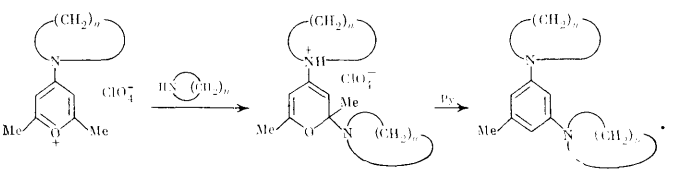


The same reaction takes place when the perchlorate (XII) is acted upon by alkali[92], i.e. the dimethylammonium salt has a catalytic effect on the recyclisation of the 2-benzopyrylium cation with participation of the water present in the alcohol.

The perchlorates (XII, R = H or Me) react with gaseous dimethylamine and recyclise to tertiary β-naphthylamines, which can be accounted for only by the initial attack of the nucleophile on the C(3) position[93]:

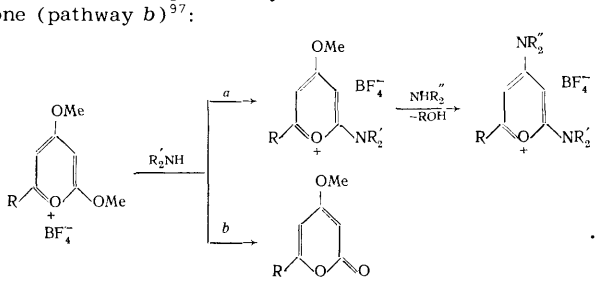


Thieno- and seleno-[2,3-c]pyrylium salts react analogously with dimethylamine[94].

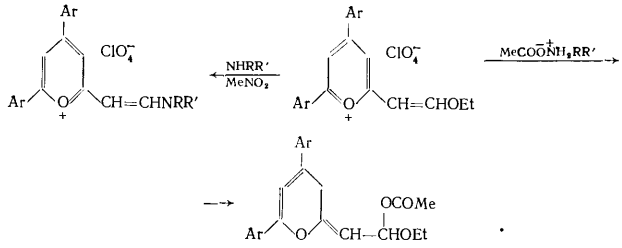


Arylpyrylium salts without an alkyl group in the 2-position are quantitatively converted into dialkylaminoketones on treatment with two equivalents of a secondary aliphatic amine[32,62], for example:

2- or 4-Alkoxypyrylium salts react with secondary aliphatic and heterocyclic amines, retaining the pyrylium ring[58,69,88,95,96]:

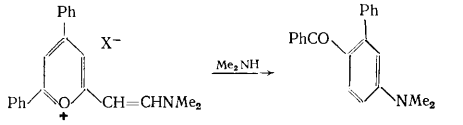


An excess of the amine as well as an increase of temperature promote the formation of the product of the addition of two moles of the secondary amine, which, on heating in pyridine, recyclises to an *m*-diaminobenzene derivative[58]:

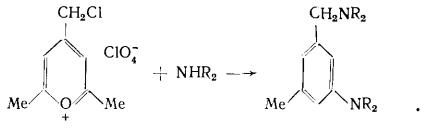


2-Phenylpyrylium salts do not form similar bisadducts.

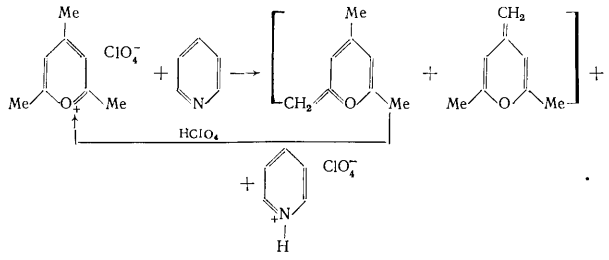
The reactions of 2,4-dimethoxypyrylium salts with secondary amines proceeds via two pathways: the main pathway involves nucleophilic substitution of the C(2) atom (pathway *a*), while the minor pathway involves the methylation of the amine, i.e. the attack on and dissociation of the O–CH_3 bond with formation of a quaternary ammonium salt and an α-pyrone (pathway *b*)[97]:



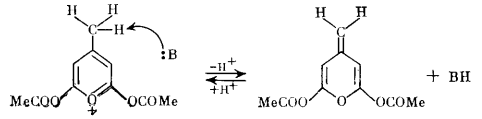
The reaction of an excess of a secondary amine results in the conversion of a 2-amino-4-ethoxypyrylium salt into a 2,4-diaminopyrylium salt[98].



2-Ethoxyvinylpyrylium salts react with secondary amines to form either aminovinylpyrylium salts or acetal-acylals, depending on the solvent employed[55]:

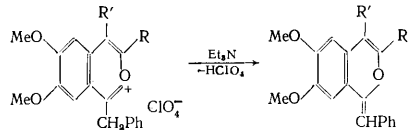


The reaction of aminovinylpyrylium salts with secondary amines can involve the substitution of one amino-group by the other[70]. 2-Dimethylaminovinyl-4,6-diphenylpyrylium is converted into a benzoylaniline on reaction with dimethylamine[99]:

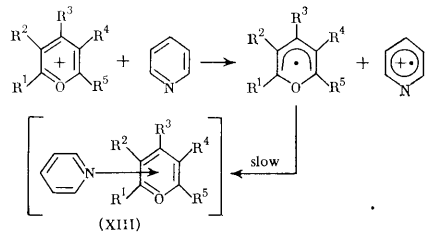


The halogen in 4-halogeno-2,6-diphenylpyrylium salts is readily substituted on reaction with secondary cyclic and alicyclic amines, various 4-dialkylaminopyrylium perchlorates being formed[100]. 4-Chloromethyl-2,6-dimethylpyrylium perchlorate reacts with secondary amines both in the 2-position of the pyrylium ring and via the substituent in the methyl group, forming aromatic diamines[101]:

The reaction of 2,4,6-trimethylpyrylium perchlorate (TMPP) with triethylamine, pyridine, benzimidazoles, imidazoles, quinoline, and pyrazoles takes place with deprotonation of the methyl group of the pyrylium cation[102-104]:

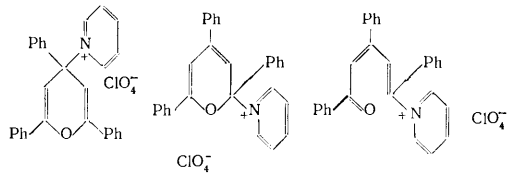


The study of the infrared spectra of the pyridinium perchlorates formed in the reaction with selectively 2- or 4-deuterated TMPP showed that the proton is split off from both the 2-CH_3 and 4-CH_3 groups[102]. The resulting methylenepyrans, which are extremely reactive, undergo further transformation into methylenepyran hexamers, whose structure could not be determined[103]. Comparatively stable methylenepyrans can be obtained only in the presence of effective electron-accepting substituents in the pyran ring. Thus a methylenepyran has been isolated and spectroscopically characterised in the reaction of a 2,6-dimethoxycarbonyl-4-methylpyrylium salt with pyridine[105]:



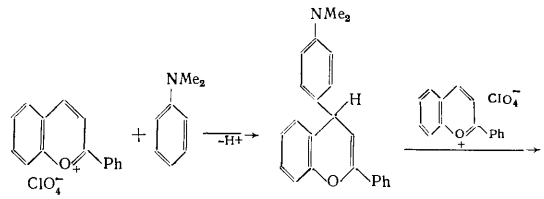
It is of interest that aniline acts on this salt similarly to pyridine.

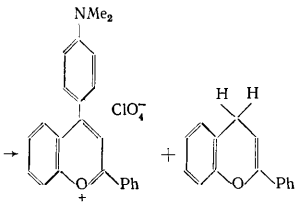
The dimerisation of 4-methylflavylium perchlorate in pyridine is also believed[106,107] to proceed via the intermediate formation of methylenepyran.



On treatment with triethylamine in an anhydrous medium, 1-benzyl-2-benzopyrylium salts give rise to stable benzylideneisochromenes[108]:

On dissolution in anhydrous pyridine, polyarylpyrylium salts generate pyranyl radicals[109], the EPR spectra of which are identical with those of the radicals formed on reduction of the corresponding pyrylium salts with zinc[110,111]:

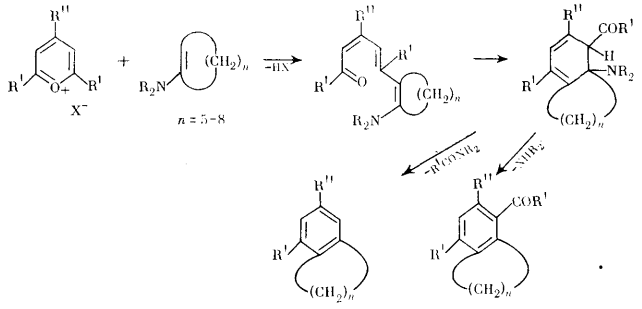


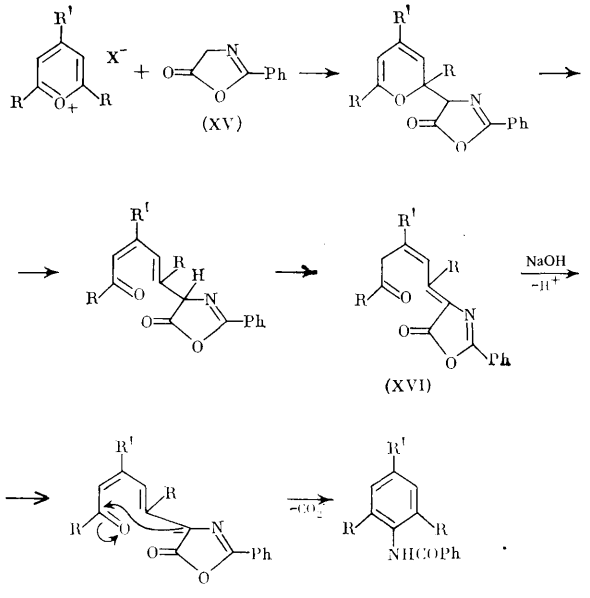


The pyranyl radicals react slowly with pyridine to form donor–acceptor complexes (XIII). It has been established that a small amount of products of the addition of pyridine to the 4- or 2-position of the pyrylium ring and an acyclic valence isomer of the latter are present in the pyridine solution of 2,4,6-triphenylpyrylium perchlorate (TPPP) in addition to the complex (XIII, $R^1 = R^3 = R^5 = Ph$; $R^2 = R^4 = H$)[112]:

It has been shown that TPPP forms charge-transfer complexes also with triphenylamine and its derivatives[113].

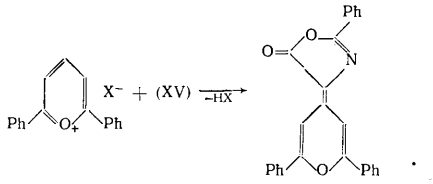
Pyrylium and 1-benzopyrylium salts with a free 2- or 4-position react with aryl-substituted tertiary amines and heterocyclic compounds having an excess of electrons to form aminoaryl or heteroaryl-pyrylium salts[15,114-116], for example compound (XIV):





(XIV)

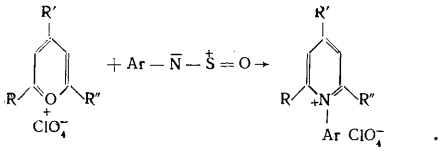
Heteroarylpyrylium salts are also formed when 2- and 4-methoxy-, 2- and 4-methylthio-, and 2- and 4-chloro-pyrylium salts react with nitrogen-containing heterocycles[100,116-121].



In the reactions of pyrylium salts with enamines containing a tertiary nitrogen atom (NR_2-pyrrolidinyl or NO_2-morpholinyl derivatives) the role of the amino-group split off in the process consists in increasing the nucleophilicity of the double bond[122]:

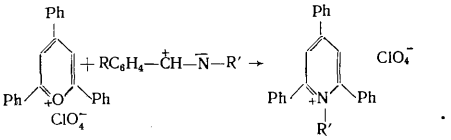
The interaction of the azlactone (XV) with 2,4,6-trisubstituted pyrylium salts proceeds via nucleophilic attack on the 2-position of the pyrylium ring, leading to the formation of the oxazolinones (XVI). After brief treatment with aqueous alkali, the latter are converted into *N*-benzoylanilines[123]:

The interaction of compound (XV) with 2,6-diphenylpyrylium salts leads to pyranylideneoxazolinone[123]:



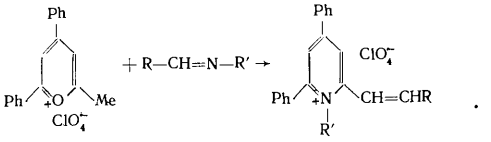
Pyranylidenethiazolinones have been obtained analogously[124].

Thus, nitrogen-containing non-aromatic heterocycles react with pyrylium salts via the most nucleophilic carbon atom.

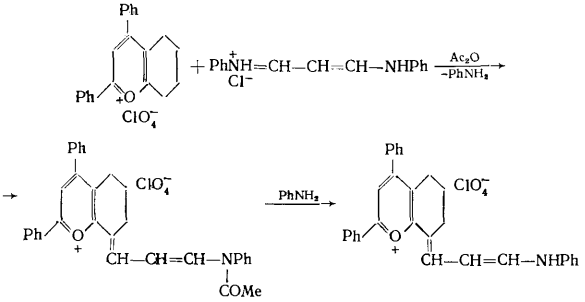


III. REACTIONS WITH COMPOUNDS CONTAINING THE S = N, C = N, AND N_3 GROUPS

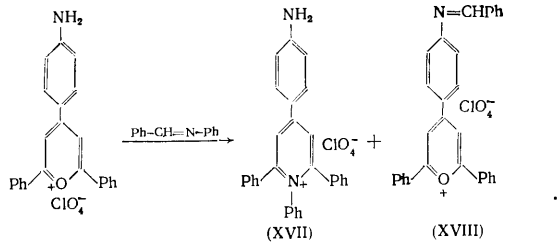
The reaction of pyrylium salts with thionylanilines in DMF leads to *N*-arylpyridinium salts[125]. The author suggests that it begins with the addition of thionylaniline to the C(2) atom of the pyrylium ring with subsequent opening of the pyran ring via the intramolecular 1,2-cycloaddition and the elimination of the SO_2 molecule:



Since the reaction was carried out under conditions ruling out the hydrolysis of thionylanilines, the alternative reaction mechanism involving the hydrolysis of thionylaniline and the reaction of aniline with the pyrylium salt was excluded.



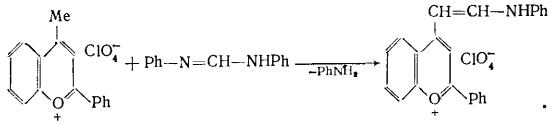
The interaction of TPPP with azomethines in DMF with formation of pyridinium salts[126,127] probably proceeds via a similar mechanism:



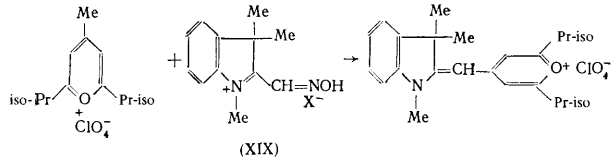
A pyrylium salt with a 2-methyl substituent gives rise to α-styrylpyridinium perchlorate[127]:

The reaction with the dianilide of malonic dialdehyde takes place via the methylene group in the 2-position of the pyrylium cation[128]:

The reaction of 4-(*p*-aminophenyl)pyrylium perchlorate with benzylideneaniline yields two salts—(XVII) and (XVIII)[57]. The reaction takes place preferentially in the 2-position of the initial perchlorate, resulting in the formation of pyridinium salts (XVII), while the benzaldehyde produces the azomethine (XVIII) on reaction with the initial salt[57]:



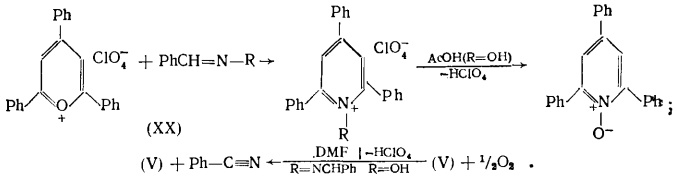
(XVII) (XVIII)



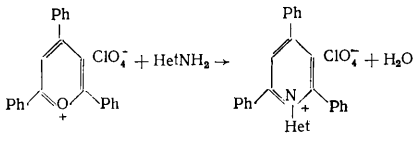
It has been shown separately that compound (XVII) does not react with benzaldehyde under these conditions.

The reaction of substituted 2-benzopyrylium salts with monobenzylidene-*o*-(or *p*-)phenylenediamines proceeds preferentially via the —CH=N— group and not the amino-group[84].

The reaction of 4-methylflavylium perchlorate with diphenylformamidine leads to an aminovinylpyrylium salt[129]:

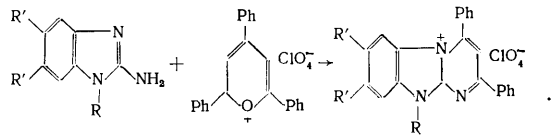


The reaction of 2,6-di-isopropyl-4-methylpyrylium perchlorate with the aldoxime (XIX) also involves the methyl group[72]:



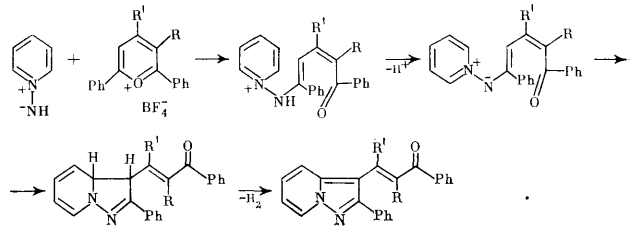
(XIX)

The reactions of TPPP with benzaldoxime (XX, R = OH), benzylidenephenylhydrazine (XX, R = —NHPh), and benzylideneazine (XX, R = —N=CHPh) have been investigated. The reaction with benzaldoxime in acetic acid yielded 2,4,6-triphenylpyridine *N*-oxide, while the reaction with benzylidenephenylhydrazine resulted in the formation of an *N*-anilinopyridinium salt[127]:



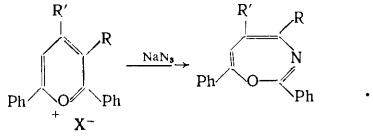
The pyridinium salts formed split off the pyridine (V) in boiling DMF. The reaction with benzylideneazine can be regarded as a method for the synthesis of benzonitrile.

In subsequent years it was found that the reaction of TPPP with heterocyclic amines leads to the formation of *N*-heteroarylpyridinium salts[103,130] (Het = heteroaryl):



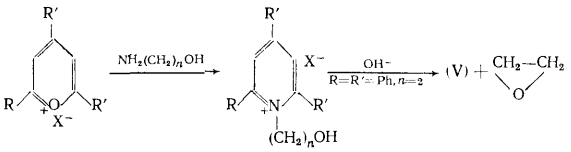
Analogous heteroarylpyridinium salts were obtained from 4-*p*-aminophenyl-2,6-diphenylpyrylium perchlorate[131] and TMPP[60,80,132,133]. However, only the amines whose basicity constants in acetonitrile are $pK_a \geq 5$ react with TMPP via this pathway[103]. The presence of the pyridine nitrogen atom in the heterocycle promotes the elimination of a proton from the methyl group of the pyrylium salt, which, as already mentioned, leads to the formation of a hexamer[103]. Heterocyclic amines in which the basicity of the amino-group is significantly reduced as a result of the significant contribution of the charged resonance form with the positive charge on the nitrogen of the amino-group interact via this pathway.

The condensation of *N*-aminoheterocycles with 2,4,6-substituted pyrylium salts yielded N—N linked heteroarylpyridinium salts[134]. Both nucleophilic centres of the aminoheterocycle molecule (the amino-group and the pyridine nitrogen atom) are involved in the reaction of TPPP with 1-alkyl-2-aminobenzimidazoles, which leads to the formation of pyrimido-[1,2-*a*]benzimidazolium salts[135,136]:

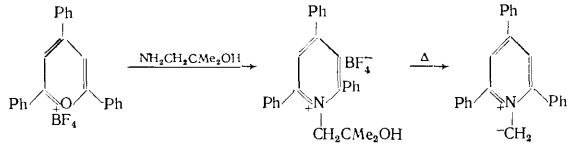


TPPP also forms the condensed pyrimido[1,2-*a*]naphthimidazolium system on reaction with 2-amino-3-benzylnaphtho-[1,2-*d*]imidazole[131,136]. However, the reaction of the above perchlorate with the azomethines of the above heterocyclic amines proceeds similarly to the reactions of benzylideneanilines, which leads to the formation of *N*-heteroarylpyridinium salts[127]. Thus it has been found that, if the heterocyclic amine does not form a quaternary pyridinium salt on reaction with TPPP, it can be obtained from the azomethine derived from the above amine.

The interaction of arylpyrylium salts with *N*-pyridinium imine proceeds via a non-standard pathway, where the 2-position of the pyridine reactant is involved in intramolecular 1,5-dipolar cyclisation. This results in the formation of a derivative of a pyrazolo[1,5-*a*]pyridine[137]:

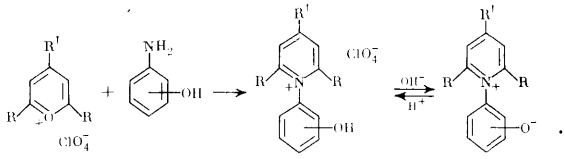


Monocyclic pyrylium salts recyclise to 1,3-oxazepines under the influence of sodium azide[138]:



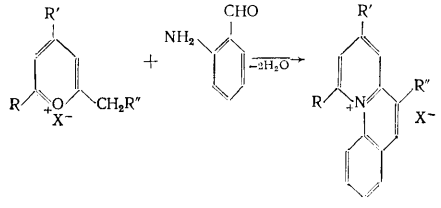
The reaction of 1-benzopyrylium perchlorates with sodium azide, leading to the formation of benzo[*f*]-1,3-oxazepines, proceeds analogously[139].

IV. INTERACTION WITH AMINES CONTAINING OTHER FUNCTIONAL GROUPS



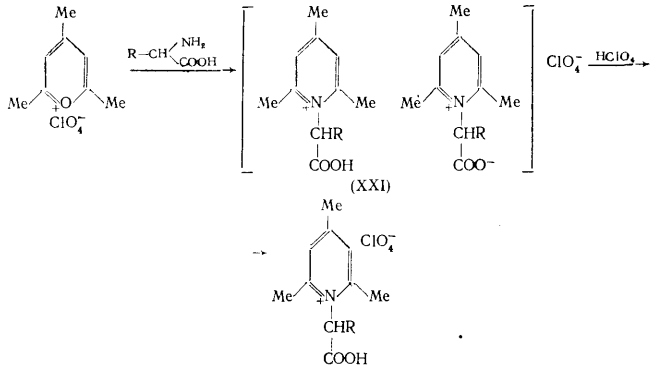
The interaction of pyrylium salts with aliphatic aminoalcohols yielded *N*-hydroxyalkylpyridinium salts[85,140,141]; some of their reactions have been investigated[85,140]:

A novel method has been discovered for the synthesis of 2,4,6-triphenylpyridinium methylide[85]:

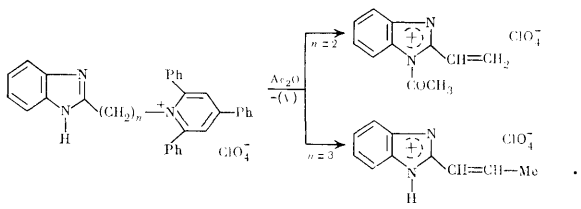


Pyrylium salts readily interact with *p*-, *m*- and *o*-aminophenols and their derivatives with the nitro-group in the *m*-position relative to NH_2, forming 1-hydroxyarylpyridinium derivatives, which are deprotonated on treatment with alkali to O^-–N^+-pyridinium betaines[142,143]:

The symmetrical octahydroxanthylium perchlorate is readily converted into *N*-substituted octahydroacridinium salts by reaction with *o*-, *m*- and *p*-aminophenols and ethanolamine[76].



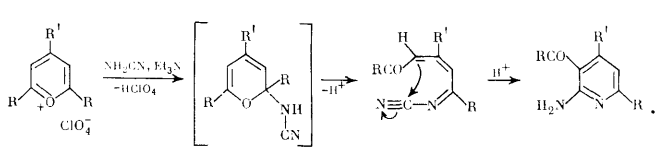
Both functional groups of *o*-aminobenzaldehyde are utilised in its reaction with 2-methyl(or methylene)-substituted pyrylium salts and derivatives of the condensed benzo[*c*]-quinolizinium system were obtained by simple single-stage synthesis[144]:



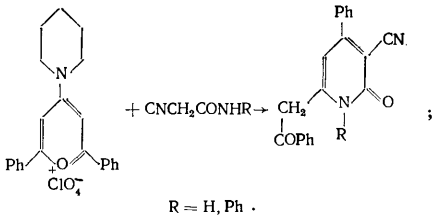
The reaction of pyrylium salts with aromatic aminoacids proceeds with formation of *N*-carboxyphenylpyridinium derivatives[130,145], which are deprotonated by ion-exchange resins, forming stable compounds with a zwitterionic structure[130].

The ethyl esters of glycine, phenylalanine, and glycylglycine readily react with TMPP, TPPP, and 5,6,7,8-tetrahydrobenzopyrylium and *sym*-octahydroxanthylium perchlorates to form *N*-alkoxycarbonyl derivatives of quaternary pyridinium, tetrahydroquinolinium, and octahydroacridinium salts[146,147].

The condensation of TMPP with α-aminoacids and peptides proceeds under less severe conditions than the condensation with their esters, giving rise to the dimeric products (XXI). On treatment with $HClO_4$, the latter are converted into pyridinium salts[145,148]:



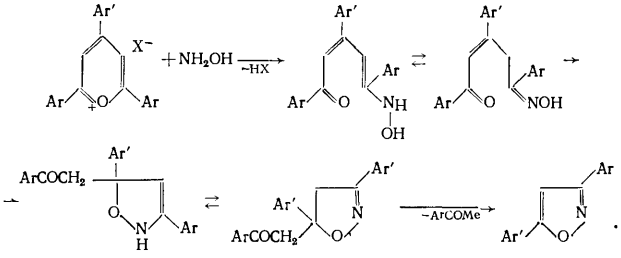
It has been shown that the reaction of TPPP with α-aminoacids does not give rise to condensation products[81]. The interaction of TMPP and TPPP with β-alanine and γ-aminobutyric acid takes place readily, resulting in the formation of the corresponding carboxypyridinium perchlorates. By reaction with *o*-phenylenediamine, the latter were converted into *N*-benzimidazolylalkylpyridinium salts, which underwent thermal decomposition on refluxing in acetic anhydride[81]:



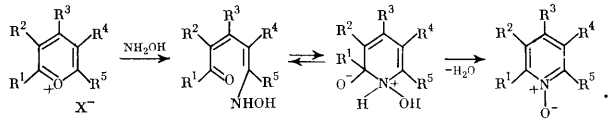
These reactions can be regarded as a simple method of synthesising 2-alkenylbenzimidazoles.

Diaminomonocarboxylic acids (lysine and ornithine) interact with TMPP and TPPP via the ε- or δ-amino-group, forming aminoacids with a pyridinium substituent[149]. On the other hand, pyrylium salts do not react with aminodicarboxylic acids (aspartic and glutamic). The above studies have demonstrated the possibility, in principle, of reactions of pyrylium salts with the free amino-groups of proteins; it has been suggested that the mutagenic action of TMPP is based on this factor[150,151]. The same pyrylium salt has been used as a selective reagent for the chemical modification of α-chymotrypsin[152].

2,4,6-Triarylpyrylium salts interact smoothly with cyanamides in the presence of triethylamine, forming 2-amino-3-aroylpyridines[153]. The reaction with cyanamide belongs to the class of rare reactions in the chemistry of pyrylium salts in which cyanamide behaves initially as the nucleophile and then as the electrophile:



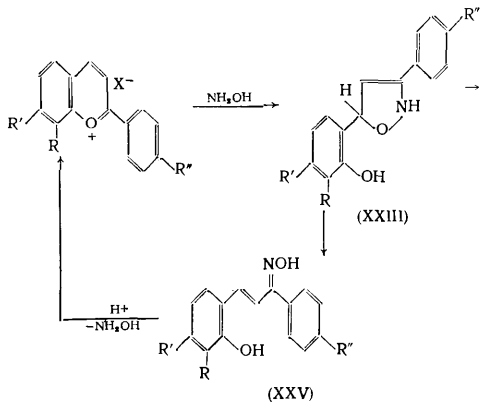
The reaction with cyanoacetamide and cyanoacetanilide in the presence of bases proceeds without the involvement of the cyano-group in the formation of the pyridine ring[58]:



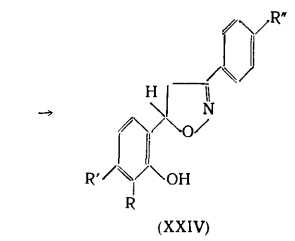
R = H, Ph .

Triarylpyrylium salts react with hydroxylamine in neutral or basic media to form phenacyl derivatives of isoxazolines (XXII), which decompose on heating into acetophenone and 3,5-diphenylisoxazoles[154,155]:

(XXII)



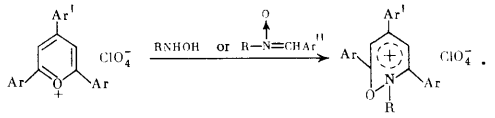
In an acid medium arylpyrylium salts react with hydroxylamine and are converted into the *N*-oxides of arylpyridines[156]:



Together with the *N*-oxides, the reactions of 2,4,6-triarylpyrylium salts give rise under these conditions to isoxazolines (XXII) and their oximes. In the presence of even one additional substituent in the 3- or 5-position in the pyrylium ring the reaction proceeds exclusively with formation of pyridine *N*-oxides. The formation of 2,4,6-trimethylpyridine *N*-oxide in the reaction of TMPP with hydroxylamine takes place in both acid and basic media.

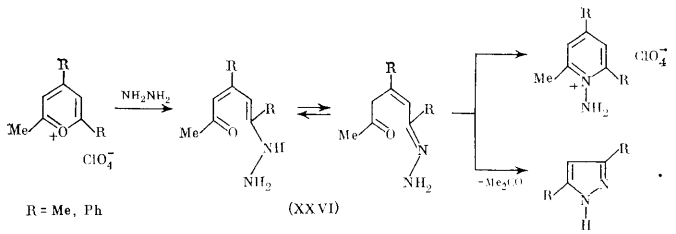
The reaction of heteroarylpyrylium salts with hydroxylamine yielded isoxazoles[15,16,157], while isoquinoline *N*-oxide was obtained from 1,3-dimethyl-2-benzopyrylium perchlorate[65].

The reaction of flavylium salts with hydroxylamine leads to *o*-hydroxyphenylisoxazolines (XXIII), which can be made to undergo a thermal rearrangement to isoxazolines (XXIV) or can be converted in acid media into oximes (XXV), which recyclise to the initial flavylium salt by eliminating a hydroxylamine molecule[158]:



(XXV)

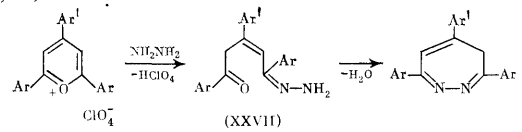
(XXIV)



4-Ethoxyflavylium perchlorate reacts with hydroxylamine to form flavone oxime[79].

The reaction of substituted arylhydroxylamines with 2,4,6-triarylpyrylium salts in DMF is accompanied by ring expansion, which leads to the synthesis of a new seven-membered cation with eight π electrons—1,2-oxazepinium[159]:

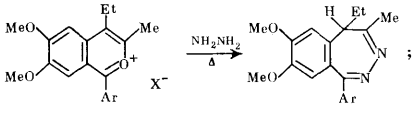
The same cations have been obtained by the reaction of 2,4,6-triarylpyrylium salts with aldonitrones[159].



In the presence of a 2-alkyl substituent, pyrylium perchlorates react with hydrazines (1:1 reaction ratio) to form *N*-aminopyridinium salts[160]:

R = Me, Ph (XXVI)

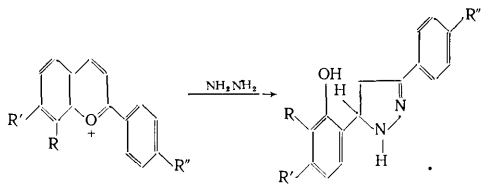
1-Amino-octahydroacridinium[161], 1-amino-2,6-dimethyl-4-(2-benzothiazolyl)pyridinium[16], and 12-amino-11,13-dimethyl[9]-(2,6)pyridinophanium[22] salts have been obtained analogously. The intermediate hydrazone (XXVI) can split off an acetone molecule under mild conditions on treatment with an excess of hydrazine and cyclise to a pyrazole derivative[161].



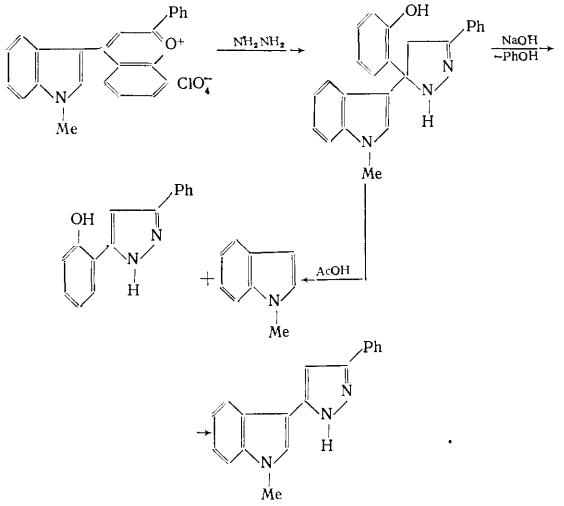
The reaction of arylpyrylium salts with hydrazine is accompanied by ring expansion with formation of 4*H*-1,2-diazepines[57,154,162-164]:

(XXVII)

It has been possible to isolate the intermediate monohydrazone (XXVII), whose intramolecular condensation leads to 1,2-diazepine[165]. 1,2-Diazepines with t-butyl[166] and methyl[58] substituents in the 3- and 7-positions have also been obtained.



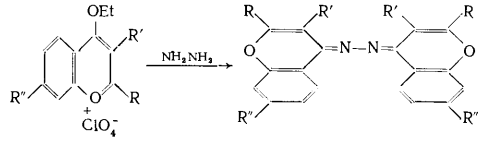
1-Aryl-2-benzopyrylium salts react with hydrazine and are converted into 5*H*-2,3-benzodiazepines[167]:



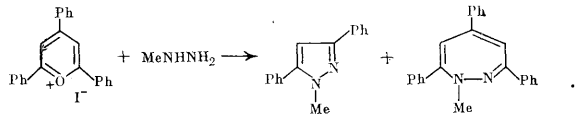
Ar = 3,4-dimethoxyphenyl; X = Cl, Br, HSO_4, ClO_4 .

Flavylium salts with the free 4-position are attacked by hydrazine exclusively in the 2-position. The addition product then isomerises with the opening of the pyran ring and

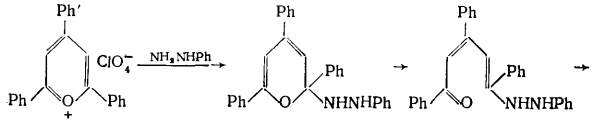
cyclises to 4,5-dihydro-1*H*-pyrazole[158]:



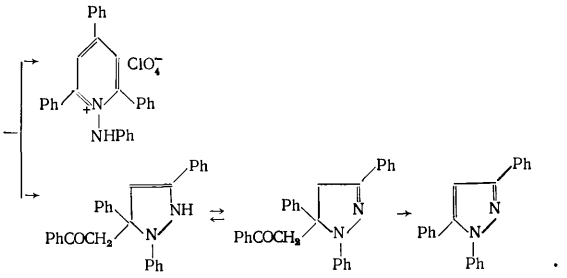
4-Indolylflavylium salts react with hydrazine analogously, but in the presence of a base pyrazoline splits off the phenolic substituent, forming 3-(5-pyrazolo)indole[166]:



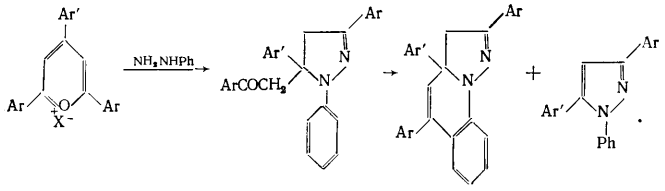
On being refluxed in acetic acid, pyrazoline is cleaved to 1-methylheteroindole and 5-*o*-hydroxyphenyl-3-phenylpyrazole.



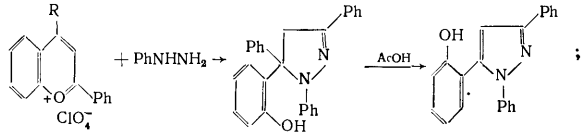
On reaction with hydrazine, 4-ethoxy-1-benzopyrylium salts give rise to chromone azines[79]:



The reaction of 2,4,6-triphenyl- and 2-methyl-4,6-diphenylpyrylium salts with methylhydrazine results in the formation of substituted pyrazoles and a small amount of phenacylmethylpyrazolines, 1-methyl-3,5,7-triphenyl-1*H*-1,2-diazepine having been obtained in 4% yield only from 2,4,6-triphenylpyrylium iodide[168]:



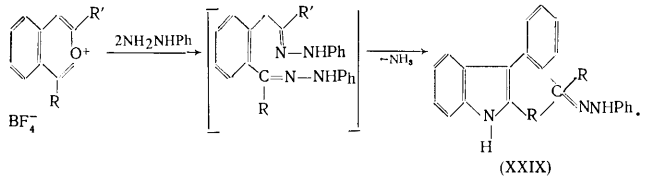
The reaction of 2,4,6-trisubstituted pyrylium salts with an equimolar amount of phenylhydrazine leads to *N*-phenylaminopyridinium salts[169]. On reaction with twice the amount of phenylhydrazine, TPPP recyclises to phenacylpyrazoline, which can split off acetophenone, being converted into pyrazole[154]:



In the presence of a large excess of phenylhydrazine, the resulting phenacylpyrazolines are capable of intramolecular condensation to 4*H*-pyrazolo[2,3-*a*]quinoline[170]:

At the same time the pyrazoline is aromatised to pyrazole, while eliminating acetophenone.

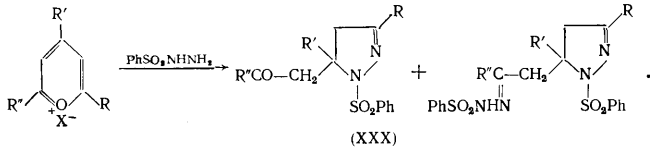
The corresponding pyrazoles have been isolated in the reaction of 4-(2-benzothiazolyl)-2,6-dimethyl-[16] and 4-(1-alkyl-3-indolyl)-2,6-diphenylpyrylium salts[171] with phenylhydrazine.



1-Benzopyrylium[166] and pyrylia[2,3-*c*]indole salts[157] react with phenylhydrazine to form pyrazolines, for example (XXVIII):

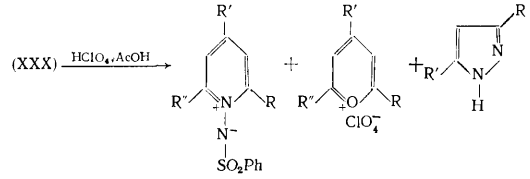
(XXVIII)

R = 1-methyl-3-indolyl.



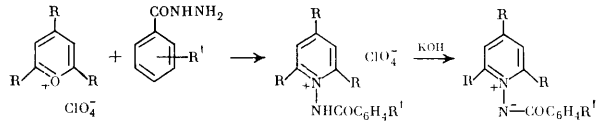
The reaction of 2-benzopyrylium salts with phenylhydrazine gives rise to substituted indoles (XXIX), probably via an intermediate bisphenylhydrazone, as in the Fischer synthesis of indoles[49]:

(XXIX)



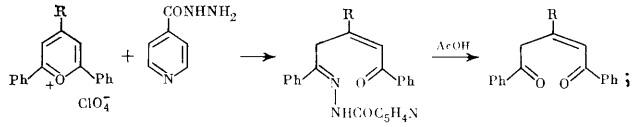
Examples of the conversion of pyrylium salts into 1-phenyl-1*H*-1,2-diazepines are as yet unknown.

Benzenesulphonyl hydrazide reacts with arylpyrylium salts to form pyrazolinylacetophenones (XXX) or a mixture of the latter with their benzenesulphonylhydrazones[172]:



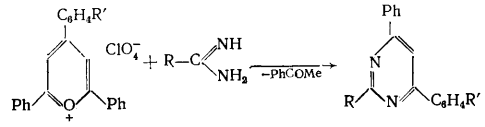
(XXX)

It is of interest that treatment of the pyrazolines (XXX) with $HClO_4$ in acetic acid can effect their recyclisation either to *N*-pyridiniabenzenesulphimide or a pyrylium salt, depending on the nature of the aryl substituent[173]:



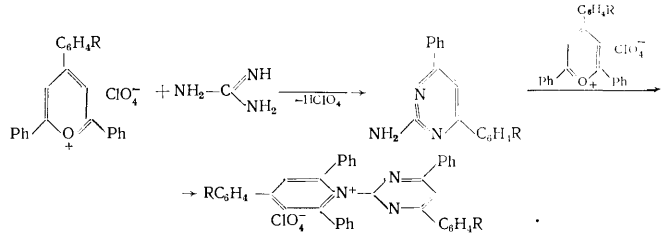
For R′ = R″ = Ph and R = *p*-$NO_2C_6H_4$, a mixture of three products is obtained, for R′ = R″ = Ph and R = *p*-BrC_6H_4, only the pyrylium salt is formed, and for R″ = Me and R = R′ = *p*-$NO_2C_6H_4$, the only product is a betaine.

The reactions of substituted benzoyl hydrazides with pyrylium salts proceed similarly to the reactions with aromatic amines, giving rise to the formation of 1-acylaminopyridinium salts, whose treatment with alkali leads to acyliminopyridinium betaines[161,174,175]:



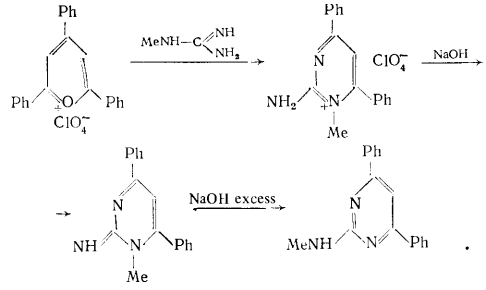
When arylpyrylium perchlorates are refluxed in DMF with twice the amount of benzoyl or isonicotinoyl hydrazide, pentene-1,5-dione monobenzoyl- or monoisonicotinoylhydrazones are formed and are then hydrolysed to the 1,5-diketones on refluxing in acetic acid[171]:

R = 1-benzyl-3-indolyl, 1-methyl-3-indolyl, or phenyl.



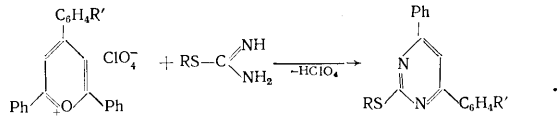
V. REACTIONS WITH POLYFUNCTIONAL AMINES CONTAINING THE N—C—N GROUP

It has been observed recently that the reactions of 2,4,6-triarylpyrylium perchlorates with amidines involve both amino-groups of the latter, which leads to the formation of 2,4,6-triarylpyridines[176,177]:

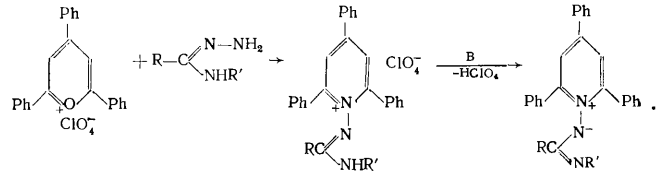


Pyrylium salts unsubstituted in the 4-position interact with amidines similarly, forming 2,4-diarylpyrimidines[177]. Methylpyrylium salts are not converted into pyrimidines on treatment with amidines.

The recyclisation of 2,4,6-triarylpyrylium perchlorates on reaction with guanidine leads to the intermediate 2-aminopyrimidines, which react with the initial pyrylium salt[178,179]:

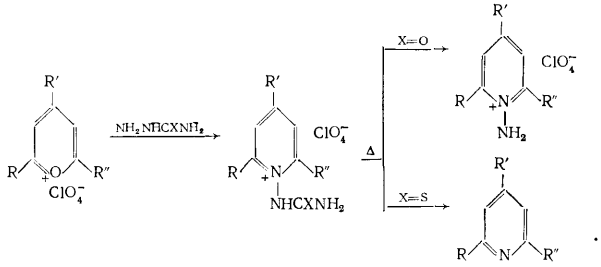


When the same pyrylium salts react with methylguanidine, the pyrylium cation is attacked preferentially by the more basic methylamino-group of the nucleophile. The structure of the resulting unstable 2-iminodihydropyrimidine has been confirmed by the Dimroth rearrangement to 2-methylamino-4,6-diphenylpyrimidine[179]:



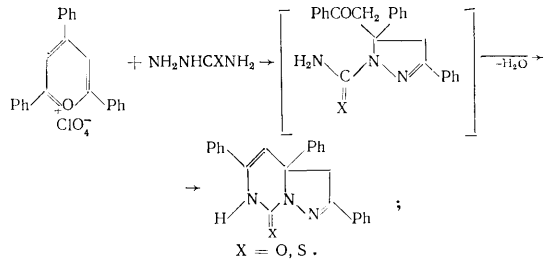
TMPP and TPPP react with sulphanilylguanidine via one amino-group of the guanidine fragment, forming the corresponding pyrimidinium salts[179]. The formation of the pyrimidine ring might have been expected also in the reaction of pyrylium salts with urea or thiourea. However, the interaction of these compounds and of *N*-substituted ureas with TPPP in DMF leads to pyridine (V)[180].

In contrast to ureas and thiourea, S-substituted isothioureas react readily with pyrylium salts, forming 2-alkylthio-4,6-diarylpyrimidines[180,181]:



2-Methyl-4,6-diphenylpyrylium perchlorate and TMPP are converted into the corresponding pyridines by reaction with *S*-benzylisothiourea. Evidently, the electrophilicity of the C(4) atom in these salts is insufficient for cyclisation to pyrimidine.

In the reaction with TPPP under mild conditions, amidrazones form 2,4,6-triphenylpyridinium salts, which are readily deprotonated in the presence of bases to substituted pyridinium *N*-ylides[182,183]:



The reactions of 2,4,6-trisubstituted pyrylium salts with semi- and thiosemi-carbazides in ethanol involve one amino-group of the hydrazine fragment and lead to *N*-carbamido- and *N*-thiocarbamido-pyridinium salts[180]:

N-Carbamidopyridinium salts undergo thermal cleavage in DMF, which constitutes a convenient method of preparing *N*-aminopyridinium salts. *N*-Thiocarbamidopyridinium salts undergo thermal degradation in boiling DMF via a different mechanism involving the elimination of the corresponding pyridines[180].

When TPPP is refluxed with semi- and thiosemi-carbazides in DMF, the reaction involves the second amino-group of the hydrazine fragment of the latter and a pyrazoline ring is formed. Subsequent intramolecular condensation of the amino-group with the carbonyl group of the phenacyl substituent completes the formation of a new bicyclic system—7-hydroxy(mercapto)-2,3a,5-triphenyl-3*H*-pyrazolo[1,5-c]-pyrimidine[184]:

Thus the interaction of arylpyrylium and 2-benzopyrylium salts with nitrogen-containing nucleophiles takes place via the attack of the latter on the carbon next to the oxygen atom and subsequent recyclisation if this is possible. In pyrylium salts with functional and alkyl substituents and also in the salts with an unsubstituted electron-deficient position, an additional electrophilic centre appears and the reactions proceed via one pathway or another depending on the reactant and the process conditions.

Under the influence of the condensed benzene ring, 1-benzopyrylium salts lose their ability to exchange the heteroatom.

---o0o---

The data presented in this review demonstrate the likely usefulness of pyrylium salts as synthons in organic chemistry, since numerous aliphatic, aromatic and heterocyclic functional derivatives as well as pyridines, pyridinium salts, pyrazoles, isoxazoles, pyrimidines, diazepines, 1,3-oxazepines, 1,2-oxazepinium salts, and various condensed heterocyclic compounds can be obtained from them.

Preparation and Properties of Carbodi-imides and Cyanamides Containing Silicon, Germanium, Tin, and Lead

A.S.Gordetsov, V.P.Kozyukov, I.A.Vostokov, S.V.Sheludyakova, Yu.I.Dergunov, and V.F.Mironov

Information on methods of preparation and properties of carbodi-imides and cyanamides containing Group IVB elements is summarised and systematised. Reaction schemes are discussed, and several aspects of their practical application are examined. A list of 221 references is included.

I. INTRODUCTION

Carbodi-imides and cyanamides are genetically interrelated and are functionally closely similar, but for compounds containing Group IVB elements isomeric transitions are observed between the two groups of compounds. In many cases methods of preparation and reactivities are the same. This is why hetero-organic cyanamides and carbodi-imides are considered together in this Review.

Progress in the chemistry and application of organic carbodi-imides has been repeatedly and exhaustively discussed in reviews[1-3], but information on hetero-organic carbodi-imides and cyanamides has not been fully systematised. There exist only a survey of organosilicon carbodi-imides and cyanamides[4] and a review[5] which considers organotin carbodi-imides together with other compounds containing tin–nitrogen bonds. A considerable number of papers have appeared recently which, together with earlier information, are worthy of special discussion.

The present Review aims to systematise published information on the preparation, reactivity, physicochemical properties, and applications of carbodi-imides and cyanamides containing silicon, germanium, tin, and lead. Monographs, periodical literature, and patents appearing up to 1980 are covered.

II. METHODS OF PREPARATION

1. Interaction of Cyanamide and its Derivative with Hetero-organic Compounds

The first example of a hetero-organic carbodi-imide, disilylcarbodi-imide, was obtained[6] in 25% yield by passing gaseous iodo- or bromo-silane over silver cyanamide, in conformity with the general equation

$$Ag_2N{-}C{\equiv}N + R_3MX \rightarrow AgX + R_3M{-}N{=}C{=}N{-}MR_3 \qquad (1)$$

in which M = Si, R = H, and X = Br, I. It was originally supposed that the product was the cyanamide $N{:}C.N(SiH_3)_2$. However, infrared and Raman spectral data[7-9] and also investigation of a deuterated derivative[8] showed that it had the carbodi-imide structure $H_3SiN:C:NSiH_3$. The yield of bistrimethylsilylcarbodi-imide obtained by this reaction (M = Si, R = CH_3, X = Cl) is not appreciably influenced by use of a solvent[10-12]. More severe conditions are required in the absence of a solvent (170 °C for 5 h, yields 90%) [10,11] than in ether (20 °C for 10 h, yield 80%) [12] or in benzene (yield 90%).[13]

The potential danger of explosion with dry silver cyanamide creates great difficulties in carrying out preparations[6,11,14,15]. Individual organosilicon carbodi-imides have therefore been obtained from the corresponding chlorosilanes in boiling benzene or in acetonitrile [Eqn.(1): M = Si, R_3 = $(C_2H_5)_3$, $(C_3H_7)_3$, $(C_6H_{13})_3$, $CH_3(C_6H_5)_2$, $(CH_3)_2C_6H_5$, $(C_6H_5)_3$, $(C_6H_5)_2CH_2:CH$, $(C_2H_5O)_3$; X = Hal]. The reaction in acetonitrile is accelerated by adding small quantities of water[15], but the catalytic effect decays rapidly.

Use of a mixture of two different trialkyl- or triaryl-chlorosilanes yields three different carbodi-imides[15]:

$$Me_3SiCl + Ph_3SiCl + Ag_2NCN \xrightarrow[-AgCl]{} Me_3SiN{=}C{=}NSiMe_3 + Me_3SiN{=}C{=}NSiPh_3 + Ph_3SiN{=}C{=}NSiPh_3$$

However, the unsymmetrical carbodi-imide cannot be isolated, because it disproportionates when distilled[15]:

$$Me_3SiN{=}C{=}NSiPh_3 \rightarrow Me_3SiN{=}C{=}NSiMe_3 + Ph_3SiN{=}C{=}NSiPh_3$$

Silver cyanamide is used to obtain several symmetrical organosilicon and organogermanium carbodi-imides of general formula $C[:NM(CH_3)_nH_{3-n}]_2$ (M = Si, Ge; $n = 0-3$). The corresponding chloro- or iodo-silanes and bromo- or iodo-germanes have been used as the second reactant[16]. Reaction (1) is suitable also for the preparation of symmetrical organotin carbodi-imides[17-19].

Application of an analogous reaction to silver cyanamide has enabled polymeric carbodi-imides containing silicon to be synthesised from dialkyl- and diaryl-dichlorosilanes[20]. A tetramer of dibutylbiscarbodi-imidostannane has been obtained similarly from di-n-butyltin dichloride[21]:

$$n Ag_2NC{\equiv}N + nRR'MCl_2 \rightarrow -(-MRR'-N{=}C{=}N-)_n- + 2nAgCl$$

M = Si; RR' = Me_2, Ph_2, MePh, MeVin, $(EtO)_2$;
M = Sn; RR' = Bu_2; $n = 4$.

In view of the high cost and explosiveness of silver cyanamide it is advisable to replace it by sodium, calcium, zinc, or lead cyanamide[15,16,22-24]. Thus bistrimethylsilylcarbodi-imide can be obtained[22] in 76% and 46% yields by passing trimethylchlorosilane through technical disodium and calcium cyanamides respectively in a lithium–potassium chloride melt:

$$Na_2NC{\equiv}N + R_3MX \rightarrow R_3MN{=}C{=}NMR_3 + NaCl \qquad (2a)$$

$$M'NC{\equiv}N + R_3MX \rightarrow R_3MN{=}C{=}NMR_3 + M'X_2 \qquad (2b)$$

where M = Si, M′ = Ca, R = CH_3, X = Cl. It has recently been shown that carbodi-imides can be obtained in high yields (80–90%) without the use of molten salts by a modified technique[6] involving passing gaseous iodides over anhydrous lead cyanamide at 25 °C [Eqn.(2b): M = Si, Ge; M′ = Pb; $R_3 = (CH_3)_nH_{3-n}$; $n = 0-3$; X = I].[16–24] Bistrimethylsilyl- and bistrimethylgermyl-carbodi-imides have been prepared by the action of trimethylchlorosilane and trimethylbromogermane respectively on lead cyanamide at 100 °C for 5 h [Eqn.(2b): M = Si, Ge; M′ = Pb; R = CH_3; X = Cl, Br].[16] The action of triphenyltin iodide on disodium cyanamide [in benzene at 80 °C for 23 h; Eqn.(2a): M = Sn, R = C_6H_5, X = I] [25] and on monosodium cyanamide[26] and that of triethyltin chloride on the latter (in ether at 0–25 °C) [27] give high yields of the corresponding organotin carbodi-imides:

$$Et_3SnCl + NaNHC{\equiv}N \xrightarrow{-NaCl} Et_3SnNHCN \rightarrow Et_3SnN{=}C{=}NSnEt_3 + H_2NCN$$

The above reactions can be successfully used to synthesise various symmetrical and unsymmetrical hetero-organic carbodi-imides and the isomeric cyanamides. Interaction of organic halides of silicon, germanium, tin, and lead with appropriate cyanamide derivatives of silver, potassium, calcium, barium, or strontium has yielded in particular $R_3SiN:C:NC_6H_5$ (R = CH_3, C_6H_5),[28] $(C_6H_5)_2Si(N:C:NC_6H_5)_2$,[28] $(C_6H_5)_3SnNCNC{\vdots}N$,[29] $R_3SnN(C_6H_5)C{\vdots}N$ (R = CH_3, C_6H_5),[30] $(C_2H_5)_3SnOC(CH_3)NCN$,[31] $R_2Sn(OCR'NCN)_2$ (R = CH_3, C_2H_5, C_4H_9, C_6H_5, $C_6H_5CH_2$; R′ = CH_3, C_6H_5),[31] $[(C_4H_9)_3SnS]_2C:N.C{\vdots}N$,[32] $(C_4H_9)_2Sn\langle S \rangle C:N.C{\vdots}N$,[32–34] $R_3MN(CN)_2$ (M = Ge, Sn, Pb; R = CH_3, C_6H_5),[35–37] and $R_2Sn[N(CH)_2]_2$ (R = CH_3, C_6H_5).[36,37].

N-Phenyl-*N*′-trimethyl[phenyl]silylcarbodi-imides can also be synthesised in 55–79% yields from phenylcyanamide[28,38–41]. The same method has since been used to obtain several other unsymmetrical organosilicon carbodi-imides[4,38–41]:

$$R_3MX + R'NHC{\equiv}N + Et_3N \rightarrow R'N{=}C{=}NSiR_3 + Et_3N{\cdot}HX$$
M = Si; R = Me, Ph; R′ = Me, Et, t-Bu, Ph, Ph_3C, EtOCO; X = Cl.
M = Sn, R = Ph, R′ = Ph_3C, X = I .

The compounds $RN:C:NSi(CH_3)_3$ are found to exist in tautomeric equilibrium with the corresponding cyanamides $RN(C{\vdots}N)Si(CH_3)_3$.[4,40,41]

Cyanamide itself also proved useful for the synthesis of carbodi-imides[12]. Thus with trimethylchlorosilane in the presence of triethylamine in ethereal solution (at ~20 °C for 1 h) a high yield of bistrimethylsilylcarbodi-imide is formed:

$$H_2NC{\equiv}N + 2R_3MX + 2Et_3N \rightarrow 2Et_3N{\cdot}HX + R_3MN{=}C{=}NMR_3 \quad (3)$$
M = Si, R = Me, X = Cl .

The first organogermanium carbodi-imide, bistributylgermylcarbodi-imide, was obtained by heating an ethereal solution of cyanamide, sodium ethoxide, and tributylgermanium chloride (yield 24%).[43] When triphenylgermanium bromide is heated with cyanamide in the presence of triethylamine in isopropyl ether, a 66% yield of bistriphenylgermylcarbodi-imide is obtained [Eqn.(3): M = Ge, R = C_6H_5, X = Br].[44]

Organotin carbodi-imides have been obtained similarly. Thus heating ethereal solutions of triethyltin chloride or triphenyltin iodide with cyanamide and triethylamine gave high fields of bistriethyl[phenyl]stannylcarbodi-imides respectively[17,25] [Eqn.(3): M = Sn, R = C_2H_5, C_6H_5; X = Cl, I].

Silylation of cyanamide with a mixture of trimethylchlorosilane and lithium in oxolan also yields bistrimethylsilylcarbodi-imide. When the duration of the reaction is increased, however, tristrimethylsilylamine and trimethylsilyl cyanide are formed[42]:

$$H_2NC{\equiv}N + 2Me_3SiCl + 2Li \xrightarrow[0-10^\circ]{\text{oxolan}} Me_3SiN{=}C{=}NSiMe_3 + 2LiCl + H_2$$
$$Me_3SiN{=}C{=}NSiMe_3 + 2Me_3SiCl + 2Li \xrightarrow{\text{oxolan}} (Me_3Si)_3N + Me_3SiCN + 2LiCl .$$

The next step in simplifying the preparation of heteroorganic carbodi-imides was to use organoelementary oxides and hydroxides as metallating agents, which made it unnecessary to introduce acceptors for hydrogen chloride and ultimately diminished the number of chemical operations. Furthermore, the yields of the final products remained high, and in isolated cases approached theoretical. Thus reaction of cyanamide with bistriethylgermyl[45], bistriethylstannyl[27,46], bistributylstannyl[47], bistriphenylstannyl[25,48], and bistris(trimethylsilylmethyl)stannyl[49] oxides gives the corresponding carbodi-imides in 80–95% yields:

$$R_3MOMR_3 + H_2NCN \rightarrow R_3MN{=}C{=}NMR_3 + H_2O$$
M = Ge, R = Et; M = Sn, R = Et, Bu, Ph, CH_2SiMe_3 .

Cyanamide reacts similarly with tin- and lead-containing hydroxides[27,46,49]:

$$R_3MOH + H_2NCN \rightarrow R_3MN{=}C{=}NMR_3 + H_2O$$
M = Sn, R = Et, Ph; M = Pb, R = Ph .

Despite the simplicity of the scheme, the reaction mechanism is quite complicated. It is assumed (in the case of organotin compounds[27]) that an organometallic cyanamide is formed initially, whose disproportionation yields the corresponding carbodi-imide and cyanamide:

$$R_3SnOSnR_3 + H_2NCN \rightarrow R_3SnNHC{\equiv}N + H_2O \quad (4a)$$

$$R_3SnNHCN \rightarrow R_3SnN{=}C{=}NSnR_3 + H_2NCN \quad (4b)$$

$$H_2NCN \rightarrow HN{=}C(NH_2)NHCN . \quad (4c)$$

It was shown later that trimethyltin, tributyltin[50], and triphenyltin[25] cyanamides could be obtained in conformity with Eqns.(4a: R = C_4H_9, C_6H_5) and

$$R_3MOH + H_2NCN \rightarrow R_3MNHC{\equiv}N + H_2O \quad (5)$$

(M = Sn, R = CH_3), and then underwent disproportionation.

Another possible mechanism in that the metallating agent may interact with the active (acidic) hydrogen atom present in the trialkyltin cyanamide $R_3SnNHCN$ formed initially, and the resulting bistrialkylstannylcyanamide may then isomerise to the corresponding carbodi-imide. Metallation may also occur with migration of the reaction centre, when the bistrialkylstannylcarbodi-imide is formed directly.

Reaction (5) has been used also for the preparation of trimethyl-lead cyanamide with alcohol as solvent[51].

Attempts to obtain silicon-containing cyanamides of type $R_3SiNHCN$ have proved unsuccessful. Thus, instead of the expected mono- and bis-trimethylsilylcyanamides, bistrimethylsilylcarbodi-imide was isolated independently of the reaction conditions[12]. It has now been shown that existence is possible only for substituted organosilicon cyanamides of type $(CH_3)_3SiN(CN)COOC_2H_5$ [52] and $RR^1R^2SiCH_2NR^3C{\vdots}N$ (R = CH_3, Cl; R^1, R^2, R^3 = Alk, Ar, AlkO).[53] Cyanamides $(CH_3)_3SiNRC{\vdots}N$ have also been synthesised, in tautomeric equilibrium with the corresponding carbodi-imides $(CH_3)_3$.SiNCNR (R = Alk, Ar).[4,40,41,54,67,68].

Cyanamide reacts with methoxytributyltin to give an 89% yield of bistributylstannylcarbodi-imide[55], the reaction being regarded as reversible:

$$H_2NCN + Bu_3SnOMe \rightleftarrows MeOH + Bu_3SnN{=}C{=}NSnBu_3 .$$

When methoxytributyltin is replaced by tributyltin isocyanate, reaction occurs only in the presence of triethylamine (at 80 °C for 48 h), and up to 68% yields of the carbodi-imide are

obtained[56]:

$$Bu_3SnN{=}C{=}O + H_2NC{\equiv}N \xrightarrow{Et_3N} Bu_3SnN{=}C{=}NSnBu_3 + HNCO .$$

A method has been proposed[57] for preparing disilylcarbodi-imide from cyanamide:

$$H_2NCN + H_3SiPH_2 \rightarrow H_3SiN{=}C{=}NSiH_3 + PH_3$$
$$H_2NCN + (H_3Si)_2S \rightarrow H_3SiN{=}C{=}NSiH_3 + H_2S .$$

Cyanamide is silylated also by hexamethyldisilazane, when the yield of bistrimethylsilylcarbodi-imide is 95%:[58,59]:

$$H_2NCN + (M_3Si)_2NH \rightarrow Me_3SiN{=}C{=}NSiMe_3 + NH_3 .$$

This method—the reaction of cyanamide and its derivatives with hetero-organic compounds—nevertheless has several important disadvantages: cyanamide is difficultly accessible, toxic, and unstable, its silver salts are explosive, large quantities of solvents are used, and in several cases the yields are comparatively low. They are almost all eliminated by replacing cyanamide by its dimer, dicyanodiamide[58-62]. The procedure is to heat the latter to 110–200 °C with a hetero-organic compound containing a bond between the heteroatom and nitrogen or oxygen, and gives very high yields of carbodi-imides containing silicon, germanium, or tin:

$$HN{=}C(NH_2)NHCN \rightarrow \begin{cases} \xrightarrow{(Me_3Si)_2NH} Me_3SiN{=}C{=}NSiMe_3 + NH_3 \\ \xrightarrow{Et_3GeNEt_2} Et_3GeN{=}C{=}NGeEt_3 + Et_2NH \\ \xrightarrow{(Bu_3Sn)_2O} Bu_3SnN{=}C{=}NSnBu_3 + H_2O \end{cases} .$$

Silylating agents used in the preparation of bistrimethylsilylcarbodi-imide have been hexamethyldisilazane, silylamines of the type $Z[NHSi(CH_3)_3]_2$ ($Z = CH_2C_6H_4CH_2$, $CH_3C_6H_3$), *N*-cyclohexyltrimethylsilylamine, tristrimethylsilylmelamine, and tristrimethylsilyl cyanurate[58-62]. Polysilylcarbodi-imides have been synthesised from dicyanodiamide and polysilazanes[62], and *N*-tributylplumbylcarbodi-imide has been obtained by the use of tributyl-lead hydroxide as metallating agent[51].

In conclusion we may state that reactions of the above type have the greatest preparative value at present because of their universality.

2. Preparation from Compounds containing Heteroatom–Nitrogen Bonds

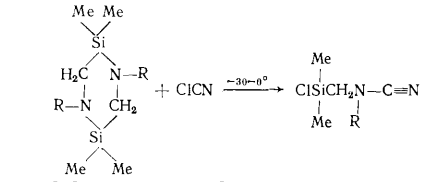
The reactions involved comprise mainly those of cyanogen halides with silicon-containing amino-derivatives. In the preparation of organosilicon carbodi-imides cyanogen halides react with primary and secondary silylamines under milder conditions[4,63-68] than with the tertiary amines (at 50–100 and 200 °C):

$$Et_3SiNH_2 + ICN \rightarrow Et_3SiN{=}C{=}NSiEt_3 + NH_4I$$
$$(Me_3Si)_2NH + XCN \rightarrow Me_3SiN{=}C{=}NSiMe_3 + Me_3SiX + NH_4X$$
$$X = Cl, Br$$
$$(Me_3Si)_3N + ClCN \rightarrow Me_3SiN{=}C{=}NSiMe_3 + Me_3SiCl .$$

With organosilicon amines of types $RNHSi(CH_3)_3$ [R = CH_3, C_2H_5, iso-C_3H_7, $(CH_3)_3C$, C_6H_5] [40,60] and $RN[Si(CH_3)_3]_2$ (R = CH_3, C_4H_9, $CH_2{:}CHCH_2$) [4,40,66-68] cyanogen chloride forms unsymmetrical carbodi-imides in tautomeric equilibrium with the corresponding cyanamides:

$$RN(SiMe_3)_2 + ClCN \xrightarrow[-Me_3SiCl]{20-35^\circ} RN{=}C{=}NSiMe_3 \rightleftarrows Me_3Si(R)N{-}C{\equiv}N . \quad (6)$$

The action of cyanogen chloride on silicon-containing amides of carboxylic acids gives high yields of *N*-acyl-*N'*-trimethylsilylcarbodi-imides[4,66-68]:



$$RC(O)N(SiMe_3)_2 + ClCN \xrightarrow{20-50^\circ} RC(O){=}N{=}C{=}NSiMe_3 + Me_3SiCl$$
$$R = Me, Ph .$$

These products have been obtained also by cross synthesis—reaction between acyl chlorides and bistrimethylsilylcarbodi-imide—and are shown by infrared, nuclear magnetic resonance, and mass spectral data to exist in the three tautomeric forms[4,66-68]

$$PhC(O){=}N{-}C{=}NSiMe_3 \rightleftarrows PhC(O){-}N(SiMe_3){-}C{\equiv}N \rightleftarrows PhC(OSiMe_3){=}N{-}C{\equiv}N \quad (7)$$
(a) (b) (c)

Cyanamides containing silicon and an organic function were first obtained by the reaction of cyanogen chloride with linear and cyclic *CN*-disilylalkylamines[53,66]:

$$MeSi(R')(R'')CH_2NSiMe_3 + ClCN \xrightarrow{20-60^\circ} MeSi(R')(R'')CH_2N{-}C{\equiv}N + Me_3SiCl$$

$$+ ClCN \xrightarrow{-30-0^\circ} ClSi(Me)(R)CH_2N{-}C{\equiv}N$$

(R, R' = Me, MeO, EtO; R'' = iso-Pr and iso-Bu, Ph).

An organosilicon cyanamide is formed also by the action of cyanogen chloride on *NN*-dimethyl-*N'*-trimethylsilylhydrazine[69]:

$$Me_2N{-}NHSiMe_3 + ClCN \xrightarrow{-Me_3SiCl} Me_2N{-}N(SiMe_3){-}C{\equiv}N .$$

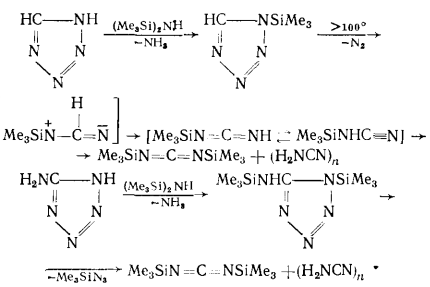
Silylamines of types $(CH_3)_2NSiH_3$, $CH_3N(SiH_3)_2$, and $(H_3Si)_3N$ apparently[70] do not form silylcarbodi-imides on treatment with cyanogen chloride.

Unsymmetrical carbodi-imides containing silicon, germanium, or tin can be obtained also from organometallic amines. Investigation of the reaction of benzoyl-t-butylcarbodi-imide with amines of types $(CH_3)_3M.N(CH_3)_2$ (M = Si, Ge, Sn) and $[(CH_3)_3M]_2NCH_3$ (M = Si, Sn) established[71,72] that the equimolecular insertion products when heated to 150 °C decomposed with the formation of unsymmetrical organo-silicon and -germanium carbodi-imides (yields 68–82%):

$$PhC(O)N{=}C{=}NCMe_3 + Me_3MN(R){-}Me \rightarrow$$
$$\rightarrow PhC(O)N(R){-}C(MMe_3){=}NCMe_3 \xrightarrow{150^\circ} Me_3MN{=}C{=}NCMe_3 + PhC(O)N(R){-}Me$$
$$M = Si, R = Me, Me_3Si; M = Ge, R = Me .$$

High yields of unsymmetrical organotin carbodi-imides have been obtained[73] by the action of isothiocyanates on tristrimethylstannylamine:

$$(Me_3Sn)_3N + RN{=}C{=}S \rightarrow R{-}N{=}C{=}NSnMe_3 + (Me_3Sn)_2S$$
$$R = t\text{-}Bu, C_6H_{11}, Ph .$$



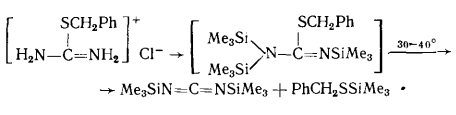
Bistrimethylsilylcarbodi-imide can be obtained in 80% yield by reaction between heptamethyldisilazane and *N*-sulphinylcyanamide[74-76], in ether at −70 °C since the latter reactant

decomposes explosively:

$$N{\equiv}C{-}N{=}S{=}O + (Me_3M)_2NMe \rightarrow$$
$$\rightarrow Me_3MN{=}C{=}NMMe_3 + MeN{=}S{=}O$$
$$M = Si, Sn .$$

Bistrimethylstannylcarbodi-imide has been obtained similarly[76].

Bistrimethylsilylcarbodi-imide can be isolated as either the main product or a by-product when certain compounds are heated with hexamethyldisilazane. Thus a high yield is obtained from tetrazoles[76-82]:



Heating hexamethyldisilazane with the polyurethane $[CONHRCH_2RNHCO_2CH_2CH_2O]_n$ ($R = p\text{-}C_6H_4$) at 197 °C for 21 h yields a mixture of bistrimethylsilylcarbodi-imide, trimethylsilyl isocyanate, hexamethyldisiloxane, and other products[83-85]. Bistrimethylsilylcarbodi-imide is formed as a by-product in the thermolysis of a mixture of the isocyanate and hexamethylenediamine[86,87]. It is obtained in good yield (85–90%) by heating isothiocyanatobistrimethylsilylamine[88]:

$$(Me_3Si)_2N{-}N{=}C{=}S \xrightarrow{110^\circ} Me_3SiN{=}C{=}NSiMe_3 + S_8 .$$

3. Reactions with Urea and Thiourea

Substituted ureas, thioureas, and isothioureas are the traditional and principal starting materials for the preparation of carbodi-imides[1,3]. However, the usual methods of dehydration of hetero-organic ureas and elimination of hydrogen sulphide from hetero-organic thioureas are unacceptable owing to the great reactivity of the resulting hetero-organic carbodi-imides[1]. Furthermore, urea and thiourea cannot be completely silylated with trimethylchlorosilane or hexamethyldisilazane[89]. An attempt to silylate urea and biuret with triethylsilane[90] was also unsuccessful, owing to the low yields and the difficulty of separating the products (triethylsilyl isocyanate, bistriethylsilylcarbodi-imide, and bistriethylsilyl ether). Therefore this route to the synthesis of hetero-organic carbodi-imides has not been developed. An exception is the direct silylation of isothiourea derivatives with a mixture of trimethylchlorosilane and triethylamine, which gives a 76% yield of bistrimethylsilylcarbodi-imide[91].

Isothiouronium salts can also be used as starting materials for the preparation of silylated carbodi-imide[91]:

There have been reports of the direct conversion of thiourea and its organic derivatives into organotin carbodi-imides[25,48], excess of the initial triphenyltin oxide being used as dehydrosulphurising agent:

$$Ph_3SnOSnPh_3 + H_2NCNH_2 \rightarrow Ph_3SnN{=}C{=}NSnPh_3 +$$
$$+ Ph_3SnSSnPh_3 + H_2O$$
$$Ph_3SnOSnPh_3 + Ph_3CNHCNH_2 \rightarrow$$
$$\rightarrow Ph_3SnN{=}C{=}NCPh_3 + Ph_3SnSSnPh_3 + H_2O .$$

This process is assumed to involve intermediate formation of triphenylstannylcyanamide, which disproportionates into the organotin carbodi-imide and dicyanodiamide (Eqns. 4b, 4c).[25] Replacement of triphenylmethylated thiourea by its phenyl analogue yields an organotin cyanamide instead of the expected carbodi-imide[30]:

$$Ph_3SnOSnPh_3 + PhNHCNH_2 \rightarrow Ph_3SnNC{\equiv}N + Ph_3SnSSnPh_3 + H_2O .$$

This result was attributed[30] to differences in the steric characteristics of the phenyl and triphenylmethyl groups.

Examples of the synthesis of silylcarbodi-imides from organosilicon ureas are very few[10,11,92]. Thus reaction of bistrimethylsilylurea with phenyl-lithium followed (after boiling) by trimethylchlorosilane gives an 80% yield of bistrimethylsilylcarbodi-imide[11]:

$$(Me_3SiNH)_2CO \xrightarrow[2)Me_3SiCl]{1)PhLi} Me_3SiN{=}C{=}NSiMe_3 .$$

Replacement of phenyl-lithium by sodamide lowered the yield to 12%.[11]

Use of the silver salt of imidazole to desulphurise bistrimethylsilylthiourea gave a 50% yield of bistrimethylsilylcarbodi-imide[12]:

$$Me_3SiNHC(S)NHSiMe_3 + AgC_3H_3N_2 \rightarrow Me_3SiN{=}C{=}NSiMe_3 + Ag_2S + C_3H_4N_2 .$$

An organosilicon carbodi-imide containing an organic function has also been obtained from a thiourea derivative[91]:

$$Me_3SiOCH_2CH_2NHC(S)NHCH_2CH_2OSiMe_3 \xrightarrow{MeI} \rightarrow$$
$$\rightarrow [Me_3SiOCH_2CH_2NHC(SMe){=}NHCH_2CH_2OSiMe_3]^+ I^- \rightarrow$$
$$\xrightarrow{Me_3SiCl/Et_3N} [Me_3SiOCH_2CH_2N(SiMe_3)C(SMe){=}NCH_2CH_2OSiMe_3] \rightarrow$$
$$\xrightarrow{80^\circ} Me_3SiSMe + Me_3SiOCH_2CH_2N{=}C{=}NCH_2CH_2OSiMe_3 .$$

4. Reactions with Metallated Silylamines

This differs from the preceding methods in being applied exclusively to the preparation of organosilicon carbodi-imides. Reaction of the sodium and lithium derivatives of bistrimethylsilylamine $[(CH_3)_3Si]_2NM$ with carbonyl chloride[10,11,92], carbon dioxide[10,11,93-95], carbon disulphide[93,95], silicon-containing isocyanates and isothiocyanates[10,11,96-98], cyanogen halides[12,65,99], dithiocyanogen[100], trifluoroiodomethane[93], cyanuryl chloride[13], and isocyanide dichlorides [e.g. $C_6H_5.NCCl_2$][101,102] yields organosilicon carbodi-imides. Thus on phosgenisation of the sodium derivative in boiling benzene bistrimethylsilylcarbodi-imide was isolated in 60% yield[10,11,92]. It is of interest to note for comparison that the corresponding reaction with non-metallated silazane results in isolation of another heterocumulene–trimethylsilyl isocyanate[11]:

$$(Me_3Si)_2NH + COCl_2 \rightarrow Me_3SiN{=}C{=}O + Me_3SiCl + HCl .$$

The reaction of sodium bistrimethylsilylamine with carbon dioxide has a complicated course. The gas is rapidly absorbed by a benzene solution of the sodium derivative

even at room temperature to form bistrimethylsilylcarbodi-imide[93]. By analogy with the reactions of other hetero-organic compounds it would be expected that the alkali-metal silicon-containing carbamate or its decomposition products would be formed:

$$(Me_3Si)_2NNa + CO_2 \rightarrow (Me_3Si)_2NCOONa\ .$$

Nuclear magnetic resonance spectroscopy showed that actually the reaction involved a series of consecutive processes with initial formation of a salt of carbamic acid, which broke down into sodium trimethylsiloxide and trimethylsilyl isocyanate. When carbon dioxide was passed through molten sodium bistrimethylsilylamine at 200 °C the isocyanate could be isolated before it underwent further reactions[94]. The complete series of reactions can be represented by the overall equation[93]

$$(Me_3Si)_2NNa + CO_2 \rightarrow Me_3SiN{=}C{=}NSiMe_3 + (Me_3Si)_2O + NaOCN + Na_2NCN + Na_2CO_3\ .$$

Carbon disulphide reacts similarly with sodium trimethylsilylamine[93]:

$$CS_2 + (Me_3Si)_2NNa \rightarrow NaSCN + Na_2S + (Me_3Si)_2S + Me_3SiN{=}C{=}NSiMe_3 + (Me_3Si)_3N\ .$$

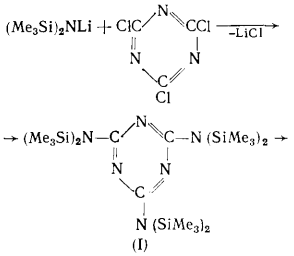
Reaction of sodium bistrimethylsilylamine with silicon tetra-isocyanate and with trimethylsilyl isocyanate and isothiocyanate results in all cases in the formation of bistrimethylsilylcarbodi-imide, but there is a difference in behaviour between isocyanato- and isothiocyanato-silanes: whereas the isothiocyanato-group in organosilicon isothiocyanates can act in these reactions as either a pseudohalogen or a thiocarbonyl group, isocyanates behave as typical carbonyl compounds without displaying any of the pseudohalogen properties so characteristic of most of their reactions. In particular, trimethylsilyl isocyanate undergoes solely the second possible type of reaction[98]:

$$Me_3SiNCO + (Me_3Si)_2NNa \rightarrow NaOCN + (Me_3Si)_3N$$
$$Me_3SiNCO + (Me_3Si)_2NNa \rightarrow (Me_3Si)_2O + Me_3SiN{=}C{=}NSiMe_3 + NaOCN\ .$$

Trimethylsilyl isothiocyanate reacts with the sodium derivative considerably less vigorously than does the isocyanate, the proportions of the parallel reactions being respectively 65–70% and 25%:[98]

$$Me_3SiNCS + (Me_3Si)_2NNa \rightarrow \begin{cases} Me_3SiN{=}C{=}NSiMe_3 + (Me_3Si)_2S + NaSCN \\ (Me_3Si)_3N + NaSCN\ . \end{cases}$$

The preparative value of this reaction is limited by the difficulty of separating the product mixture due to the only slight difference in boiling point between bistrimethylsilylcarbodi-imide and bistrimethylsilyl sulphide.



The action of sodium bistrimethylsilylamine on cyanogen halides[12,65,99], trifluoroiodomethane, and dithiocyanogen[93,100] gives high yields of bistrimethylsilylcarbodi-imide:

$$(Me_3Si)_2NNa + XCN \rightarrow Me_3SiN{=}C{=}NSiMe_3 + NaX \quad (X = Cl, Br, I)$$
$$(Me_3Si)_2NNa + ICF_3 \rightarrow NaI + NaF + Me_3SiF + Me_3SiN{=}C{=}NSiMe_3$$
$$(Me_3Si)_2NNa + (SCN)_2 \rightarrow Me_3SiN{=}C{=}NSiMe_3 + NaSCN + (Me_3Si)_2NSSN(SiMe_3)_2\ .$$

As in the case of carbon dioxide, formation of the carbodi-imide in the last reaction is unexpected. It was assumed[100] to involve the series of reactions

$$(Me_3Si)_2NNa + NCS{-}SCN \rightarrow (Me_2Si)_2N{-}SCN + NaSCN$$
$$(Me_3Si)_2N{-}S{-}C{\equiv}N \rightarrow Me_3SiN{=}C{=}NSiMe_3 + (Me_3Si)_2NSS{-}CN$$
$$NC{-}S{-}\underset{\displaystyle SiMe_3}{\overset{\displaystyle |}{N}}{-}SiMe_3$$
$$(Me_3Si)_2N{-}S{-}SCN \rightarrow (Me_3Si)_2N{-}S{-}S{-}N(SiMe_3)_2 + (SCN)_2\ .$$

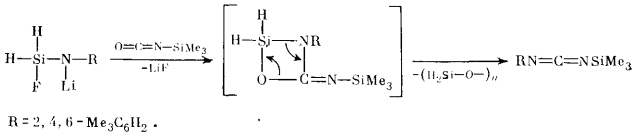
Reaction between lithium bistrimethylsilylamine and cyanuryl chloride in boiling oxolan gives a 25% yield of bistrimethylsilylcarbodi-imide[13] accompanied by 2,4,6-trishexamethyldisilazanyl-1,3,5-triazine, tristrimethylsilylamine, traces of hexamethyldisilazane, and an insoluble product of high melting point, which according to the infrared spectra is a lithium derivative of trimethylsilylcarbodi-imide. The reaction mechanism[13] involves initial formation of an organosilicon 1,3,5-triazine (I), its thermal decomposition, obviously to *NN*-bistrimethylsilylcyanamide, and rapid isomerisation of the latter to the carbodi-imide:

(I)

$$[(Me_3Si)_2NC{\equiv}N] \rightarrow Me_3SiN{=}C{=}NSiMe_3\ .$$

Heating pure (I) to 100 °C does actually give the carbodi-imide (85%). Formation of tristrimethylsilylamine and the lithium derivative $(CH_3)_3SiN:C:NLi$ was attributed[13] to partial interaction of lithium bistrimethylsilylamine with (I) or with bistrimethylsilylcarbodi-imide:

$$Me_3SiN{=}C{=}NSiMe_3 + (Me_3Si)_2NLi \rightarrow (Me_3Si)_3N + Me_3SiN{=}C{=}NLi\ .$$



This process, like all the preceding methods, can be used to obtain unsymmetrical organosilicon carbodi-imides. Thus treatment of phenyl dichloroisocyanide with an equimolecular quantity of lithium bistrimethylsilylamine at 100 °C gives a 65% yield of *N*-phenyl-*N'*-trimethylsilylcarbodi-imide[101,102]:

$$PhN{=}C\begin{matrix}Cl\\Cl\end{matrix} + (Me_3Si)_2NLi \xrightarrow{LiCl} \left[PhN{=}C(Cl){-}N(SiMe_3){-}SiMe_3\right] \xrightarrow[-Me_3SiCl]{} PhN{=}C{=}NSiMe_3\ .$$

The same compound was obtained as a by-product from the reaction of phenyl isocyanate or isothiocyanate with methyldiphenyltrimethylsilyliminophosphorane $(C_6H_5)_2P(CH_3):NSi(CH_3)_3$.[103] *N*-t-Butyl-*N'*-trimethylsilylcarbodi-imide has been prepared from t-butyl isocyanate and lithium bistrimethylsilylamine[54]:

$$t\text{-}BuN{=}C{=}O + (Me_3Si)_2NLi \rightarrow t\text{-}BuN{=}C{=}NSiMe_3 + LiOSiMe_3\ .$$

An unsymmetrical organosilicon carbodi-imide has been obtained also by reaction between the lithium derivative of a fluorosilylamine and trimethylsilyl isocyanate[104]:

$R = 2,4,6\text{-}Me_3C_6H_2$.

Low yields of bistrimethylsilylcarbodi-imide result from the thermal decomposition of the nitrogen-containing lithium complexes[88]

$$(Me_3Si)_3N_2Li\cdot COS,\ (Me_3Si)_3N_2Li\cdot CS_2,$$
$$(Me_3Si)_2N_2Li_2\cdot COS,\ (Me_3Si)_2N_2Li_2\cdot CS_2,$$
$$(Me_3Si)_3N_2Li\cdot TsNCS\ .$$

5. Decarboxylation of Isocyanates

The decarboxylation of isocyanates is an important and most convenient method for obtaining organic carbodi-imides[1,3]. It is suitable also for preparing hetero-organic carbodi-imides, although very few papers have appeared on this topic. Thus, when trimethylsilyl isocyanate is passed through a quartz tube heated to ~600 °C, it undergoes partial decarboxylation to bistrimethylsilylcarbodi-imide[105,106]:

$$Me_3SiNCO \xrightarrow[-CO_2]{\Delta} Me_3SiN=C=NSiMe_3 .$$

At temperatures up to 200 °C this and other silyl isocyanates do not undergo the reaction even in the presence of decarboxylation catalysts[105,106]. In contrast, silicon-containing aromatic carbodi-imides

$$n\text{-}XC_6H_4N=C=NC_6H_4X\text{-}n \quad (X=HMe_2Si,\ Me_3Si,\ Me_3SiO)$$

have been obtained in 82–93% yields by heating the corresponding isocyanates in the presence of organo-phosphorus catalysts to 150–180 °C.[107,108].

The decarboxylation of organotin isocyanates is considerably more complicated. Thus triphenylstannyl isocyanate gives only a 19% yield of bistriphenylstannyl-carbodi-imide[109,110], which is attributed to the possibility of simultaneous disproportionation of the isocyanate to diphenylstannanediyl di-isocyanate and tetraphenyl-stannane[109–111]:

$$Ph_3SnN=C=O \begin{cases} \xrightarrow{-CO_2} Ph_3SnN=C=NSnPh_3 \\ \longrightarrow Ph_2Sn(NCO)_2 + Ph_4Sn \end{cases} .$$

Tributylstannyl isocyanate is extremely stable to heat, being only 4% decomposed when kept at 200 °C for 6 h; at 250 °C it breaks down into butane, butene, carbon monoxide, nitrogen, metallic tin, and an unidentified solid residue[109]. The course of the reactions is uninfluenced by the usual decarboxylation catalysts (water, hydroquinone, urea, etc.).[112] Tris(trimethylsilylmethyl)stannyl isocyanate is still more stable, breaking down at 275 °C after 6 h (yield 12%):[49]

$$(Me_3SiCH_2)_3SnNCO \rightarrow (Me_3SiCH_2)_3SnN=C=NSn(CH_2SiMe_3)_3 + CO_2 .$$

Triphenylplumbyl isocyanate is converted into the corresponding carbodi-imide $C[:NPb(C_6H_5)_3]_2$, but the yield is comparatively small[113]; the scheme of thermal decomposition has been subjected to detailed thermographic investigation[110].

Thus decarboxylation of isocyanates has at present limited value for the preparation of hetero-organic carbodi-imides.

6. Other Methods

Several papers have recently appeared on the formation of hetero-organic carbodi-imides and cyanamides by trans-metallation:

$$R_3MN=C=NMR_3 + 2R'_3M'X \rightarrow 2R_3MX + R'_3M'N=C=NM'R'_3$$

$M = M' = Si$; $R = Me$; $R' = Et$, Ph; $X = Cl$. $M = Si$; $M' = Ge$;
$R = Me$; $R'_3 = Me_nH_{3-n}$, $n = 0-3$; $X = F$. $M = Si$; $M' = Sn$;
$R = Me$; $R' = Ph$; $X = OH$. $M = Ge$; $M' = Si$; $R = R' = H$; $X = Br$.
$M = Ge$; $M' = Sn$; $R = Et$; $R' = Ph$; $X = Cl$; $M = Sn$. $M' = Si$;
$R = Bu$; $R' = Me$; $X = Cl$. (8)

Interaction of bistrimethylsilylcarbodi-imide with triphenyl-chlorosilane at 245–250 °C [14,15] gives a 75% yield of a new carbodi-imide. The action of fluorogermane on the former reactant at room temperature results in a 95% yield of digermylcarbodi-imide[14,114]. This method has been used also to obtain organogermanium carbodi-imides of general formula $C[:NGe(CH_3)_nH_{3-n}]_2$ (yields up to 90%).[16]

Digermylcarbodi-imide in turn reacts with bromosilane at room temperature to give a quantitative yield of germyl bromide and disilylcarbodi-imide[114]. Bistrimethylsilyl-carbodi-imide has been obtained from bistributylstannyl-carbodi-imide and trimethylsilyl chloride[115] or tristrimethyl-silyl cyanurate[61], bistriethylsilylcarbodi-imide from bistrimethylsilylcarbodi-imide and triethylsilyl chloride[66]. Bistriphenylstannylcarbodi-imide is formed as a by-product in the reaction of triphenyltin hydroxide with bistrimethyl-silyl- or bistriethylgermyl-carbodi-imide[116]. In the dehydration of *NN'*-bistrimethylsilylurea with excess of phenyltri-chlorosilane bisphenyldichlorosilylcarbodi-imide is formed as a result of parallel transsilylation[66]. The interaction of equimolecular quantities of bistributylstannylcarbodi-imide and trimethylchlorosilane revealed intermediate formation of *N*-tributylstannyl-*N'*-trimethylsilylcarbodi-imide[115], which like *N*-trimethylsilyl-*N'*-triphenylsilylcarbodi-imide dis-proportionated when an attempt was made to distil it[15].

Nuclear magnetic resonance proved also the possibility of obtaining unsymmetrical germylsilylcarbodi-imides by exchange processes[117]:

$$Me_2RSiN=C=NSiRMe_2 + Me_3GeN=C=NGeMe_3 \rightleftarrows$$
$$\rightleftarrows 2Me_2RSiN=C=NGeMe_3$$
$$R = H,\ Me .$$

Heating bistrimethylsilylcarbodi-imide with di- and tri-halogenosilanes and with halogenated alkylsiloxanes, while the trimethylchlorosilane evolved is distilled off, yields polymeric carbodi-imides of silicon as viscous oils or rubberlike substances of high thermal stability[118–121]. Organosilicon cyanamides can also undergo transmetallation: for example, triethylchlorosilane acts on *N*-allyl-*N*-tri-methylsilylcyanamide to give an 89% yield of *N*-allyl-*N*-triethylsilylcyanamide[66].

Hetero-organic cyanamides and unsymmetrical carbodi-imides can be obtained by the interaction of $C(:NMR_3)_2$ ($M = Si$, Sn; $R = Alk$, Ar) or $R_3SnNR'C:N$ ($R = Alk$, Ar; $R' = H$, Alk, Ar) with alkyl and aryl halides[5,112,122,123], acyl halides[4,5,124–129], and other compounds containing an active halogen atom[4,6,129–137] or a pseudohalogen group[30,66,137–139]. Carbodi-imides $(CH_3)_3SiN:C:NSO_2R$ ($R = F$, CF_3) have been obtained from bistrimethylsilylcarbodi-imide and the sulphonic anhydrides $(RSO_2)_2O$.[140] These reactions will be discussed in detail below.

The reaction of *N*-t-butyl-*N'*-trimethylsilylcarbodi-imide with dimethyldichlorosilane gives bis-t-butylcarbodi-imido-dimethylsilane[28]:

$$t\text{-}BuN=C=NSiMe_3 + Me_2SiCl_2 \rightarrow$$
$$\rightarrow Me_2Si\begin{matrix} N=C=NBu\text{-}t \\ N=C=NBu\text{-}t \end{matrix} + Me_3SiCl .$$

Bistrimethylsilylcarbodi-imide is formed above 120 °C from its isomer of unknown structure obtained by reaction of lithium diazomethane with trimethylchlorosilane and the arbitrarily named[141] bistrimethylsilylisodiazomethane. The structure $[(CH_3)_3Si]_2C:N^+:N^-$ was later[142,143] attributed to this last compound. Pure bistrimethylsilyldiazomethane proved to be highly thermostable, and did not rearrange into the carbodi-imide even when heated to 150 °C (in nonane for 7 days).[143] However, such rearrangement is catalysed by copper(II) sulphate and by products of secondary reactions formed in the preparation of the silylated diazomethane. Since products of the silylation of lithium diazomethane obtained by different investiga-tors[141–143] differed in properties, it was considered[144] that either a substituted diazomethane or bistrimethylsilyl aminoisocyanide $[(CH_3)_3Si]_2\ddot{N}.N^+:C:^-$ could be formed in this reaction depending on the conditions, and that either product when heated or in the presence of a catalyst isomerised into

bistrimethylsilylcarbodi-imide[144,145]. The aminoisocyanide was also obtained by an independent method[144]:

$$(Me_3Si)_2N{-}N{:}\ CCl_2 + BuLi \xrightarrow[-78^\circ]{Et_2O} \rightarrow (Me_3Si)_2\ddot{N}{-}\overset{+}{\ddot{N}}{\equiv}\overline{C}{:} + LiCl + BuCl\ .$$

Heating the product to 100 °C for 20 h did indeed give a 97% yield of bistrimethylsilylcarbodi-imide. This last compound is formed in 10–30% yields also when bistrimethylsilyl aminoisocyanide is heated with sulphur dioxide, trimethylsilylimine sulphoxide $(CH_3)_3SiN:S:O$, or bistrimethylsilylthiodi-imide $S[:NSi(CH_3)_3]_2$. The corresponding reaction with phenyl isocyanate yielded a mixture of trimethylsilyl isocyanate, *N*-phenyl-*N'*-trimethylsilylcarbodi-imide, and bistrimethylsilylcarbodi-imide in the proportions 1 : 1 : 0.3.[145]

Bistrimethylsilylcarbodi-imide has been obtained by the ultraviolet irradiation of pentacarbonyltrimethylsilylmanganese and acetonitrile at room temperature[146].

III. PHYSICOCHEMICAL PROPERTIES AND STRUCTURE

Carbodi-imides and cyanamides containing silicon, germanium, tin, and lead are colourless liquids or solids having a characteristic odour, fairly readily soluble in organic solvents. Hetero-organic carbodi-imides are considerably more stable, but the cyanamides are less stable, than the organic analogues: the hetero-organic carbodi-imides can be stored for many months almost without change[15], without the increase in viscosity due to polymerisation that is so characteristic of organic carbodi-imides. The hetero-organic compounds can usually be vacuum-distilled at 250 to 260 °C without decomposition. Bistriphenylsilylcarbodi-imide undergoes appreciable decomposition only above 266 °C.[15] Certain hydride and unsymmetrical carbodi-imides constitute exceptions[6,15,115,134], either breaking down or symmetrising even on slight heating.

Hetero-organic cyanamides $R_3MNR'C:N$ (M = Si, Sn; R = Alk, Ar; R' = H, Alk, Ar) are extremely unstable thermally, rapidly passing into the corresponding carbodi-imides when heated. With organotin compounds this reaction is irreversible[25,50], but with organosilicon compounds a tautomeric equilibrium is observed[4,40,41,67,68].

Polymeric organosilicon carbodi-imides $[SiRR'N:C:N]_n$ (R, R' = CH_3, C_6H_5, $CH_2:CH$) are colourless or pale brown, and are converted into viscous oils when heated above 100 °C. Their thermal stability is apparently determined by the presence of a certain number of siloxane units in the macromolecular chain[20], since some loss in weight is observed even at 200 °C. The infrared spectra remain almost unchanged even when specimens are heated in a vacuum to 350 °C for 2 h, an indication of the great thermal stability of the poly(silicon–carbodi-imide) grouping.

Bistributylstannyl-, bistriphenylstannyl-, and bistriphenylplumbyl-carbodi-imides are completely decomposed when heated above 250 °C.[109–112].

Measurements of the Trouton constant showed that both disilyl- and bistrimethylsilyl-carbodi-imides are weakly associated in the liquid phase[6,11]. Organotin cyanamides and certain carbodi-imides are far more strongly associated and can form dimers, trimers, or tetramers even in solvents[29,31,128,147]. The fact that the coordination number of tin exceeds 4 explains the ability of these compounds to form oligomers[5,25,29,31,126,128,147].

The carbodi-imide structure of the disilyl[148], bistriphenylsilyl[149], digermyl[150,151], and bistrimethylstannyl[5,18,19] compounds has been confirmed by X-ray or gaseous electron diffraction.

The heteroatom–nitrogen bond energies in hetero-organic carbodi-imides and the increment in molecular refraction have been found only for bistriethylstannylcarbodi-imide (respectively 103 ± 6 kcal mole^{-1} and 3.44 cm^3) [152] and bistributylstannylcarbodi-imide (100 ± 5 and 3.42).[47,153]

Most workers have used infrared spectroscopy to establish the structure of the hetero-organic cyanamides and carbodi-imides they have prepared. Much information has been obtained also from study of the Raman[7,8,16,65,68,154], n.m.r.[6,15,16,20,25,30,40,41,54,68,69,71,73,76,93,102,114,123,128,130,132–135,140,141,147,155–159], and mass[16,73,136] spectra. In some cases spectral and physicochemical characteristics of other hetero-organic heterocumulenes are given for comparison with data on carbodi-imides[9,11,65,82,112–114,136,137,150–152,155,160]. Infrared spectra establish quite unambiguously the appearance of a product of carbodi-imide structure in any reaction, from the characteristic frequency $\nu_{as}(N:C:N)$—respectively 2260–2170, 2160–2130, 2090–2070, and 2060 cm^{-1} for carbodi-imides containing silicon, germanium, tin, and lead.

Relative to the infrared spectra of analogous organic carbodi-imides [$\nu_{as}(N:C:N)$ 2150–2130 cm^{-1}] the organosilicon compounds exhibit a displacement of this band to higher frequencies, close to the C:N vibrations in organic cyanamides R_2NCN (2260–2210 cm^{-1}).[11,53] Nevertheless, the carbodi-imide structure—not the cyanamide structure—was adopted for the compounds $(R_3Si)_2N_2C$, on the grounds that their spectra contain neither the bands due to symmetrical N.C:N-stretching vibrations characteristic of cyanamides (~1200 cm^{-1}) [114] nor the unsymmetrical Si.N.Si vibrations at 934 cm^{-1} usually observed with other disilyl derivatives containing an Si_2N group[11]. Nor has the $\nu_s(N.C:N)$ band been found in the spectrum of digermylcarbodi-imide[114].

For the most thoroughly studied compounds—the bistrimethylsilyl, bistriethylstannyl, and bistributylstannyl derivatives—the carbodi-imide structure was adopted also in view of the comparatively small dipole moment, respectively 1.48 [12] (1.84 [161]), 1.79 ± 0.02, and 2.74 ± 0.02 D,[152] which compare with 4.5–4.8 D,[4,152,161] in the case of disubstituted organic cyanamides.

The carbodi-imide structure of the bisdimethylsilyl compound is supported convincingly also by ^{14}N n.m.r. spectral data: the spectrum contains only one signal, at 325 ppm (relative to ammonium nitrate).[15] It may be noted for comparison that dicyclohexylcarbodi-imide also gives only one resonance signal, at 240 ppm, whereas diethylcyanamide exhibits two clearly separated signals, at 149 and 258 ppm due to nitrilo- and amino-nitrogen atoms respectively[15]. The greater positive chemical shift displayed by bistrimethylsilyl- than by dicyclohexyl-carbodi-imide can be explained by the purely inductive effect of the silicon atom, which is more electropositive than carbon.

It is noteworthy that the $\nu_{as}(N:C:N)$ frequencies of organosilicon carbodi-imides containing an organic function (2160–2130 cm^{-1}) [91,107] lie in the same region as those of their carbon analogues.

The structures of hetero-organic cyanamides and unsymmetrical carbodi-imides of silicon[28,38–41,54,66–69,71,101,102,104,115,117,130–136,140,145,158,159], germanium[35,71,117,138], tin[25,27,29–37,50,73,115,123,125–129,137,139,162], and lead[29,51] have also been determined from infrared, Raman, n.m.r., mass, and Mössbauer spectral data together with X-ray diffraction results. In some cases, however, complete certainty has not yet been achieved that the choice between cyanamide and carbodi-imide forms is correct for individual compounds, since the physicochemical data sometimes do not provide unambiguous answers to such questions. Thus, whereas there is no doubt about the structure of *N*-triphenylmethyl-*N'*-triphenylstannylcarbodi-imide[25,30,123] (the corresponding

cyanamide form is improbable also as a consequence of great steric hindrance), the structure of the arenesulphonyl derivatives

$$R_3SnN{=}C{=}N{-}SO_2R' \qquad R_3SnN(SO_2R')-C{\equiv}N$$
(A) (B)

is debatable. On the basis of the infrared spectra (2193 cm^{-1}) the cyanamide structure (B: R = CH_3, C_6H_5; R′ = C_6H_5, p-$CH_3C_6H_4$, p-BrC_6H_4) has been attributed[30,126,128] to such compounds, since the ν(C:N) frequencies of organotin cyanamides of type $R_3SnNHC{:}N$ (R = CH_3, C_4H_9, C_6H_5) lie in the range 2183–2174 cm^{-1}.[25,50] On the other hand, there are good reasons for regarding such compounds as hetero-organic carbodi-imides by analogy with organic sulphonylcarbodi-imides [ν_{as}(N:C:N) 2180–2175 cm^{-1}].[163,164] Definite evidence in support of structure (A) is also the comparatively low dipole moment found for *N*-phenylsulphonyl-*N*′-tributylstannylcarbodi-imide (μ_{exp} = 5.4 ± 0.3 D, μ_{calc} = 5.04 D; for the cyanamide form μ_{calc} = 6.87 D).[129] The preparation has also been reported of *N*-phenylsulphonyl-*N*′-triethylgermylcarbodi-imide[138] and of $(CH_3)_3SiN{:}C{:}NSO_2R$ [R = F, CF_3, $(CH_3)_3SiO$],[136,140] whose carbodi-imide structure is not open to doubt; their ν_{as}(N:C:N) frequencies are respectively 2190 and 2250–2240 cm^{-1}.

Several investigations have been made recently on the structure of organosilicon cyanamides and unsymmetrical carbodi-imides[4,40,41,54,67–69]. The infrared spectra and the ^1H, ^{29}Si, and ^{13}C n.m.r. spectra have shown that the freshly prepared products of the reaction of secondary organosilicon amines with cyanogen chloride are carbodi-imides, which in time undergo a silatropic rearrangement and are converted into the corresponding cyanamides (Eqn.6). Heating again yields the original organosilicon carbodi-imides[40]. Formation of the cyanamide form is prevented by the steric effect of the t-butyl and phenyl groups.

Study of the reaction of cyanogen chloride with silylamides of carboxylic acids led to the conclusion that the products could exist in three tautomeric forms (A) ⇌ (B) ⇌ (C) (Eqn.7). The infrared spectra suggest that form (C) predominates[67,68]. In the case of the organotin analogues opinions on the structure of the products were divided. On the basis of infrared spectral data preference has been given[125,126,128] to form (B):

$$R'C(=O)N{=}C{=}NSnR_3 \rightleftarrows R'C(=O)N(SnR_3)-C{\equiv}N \rightleftarrows R'-C(OSnR_3){=}N-C{\equiv}N$$
(A) (B) (C)

R = Me, Ph; R′ = Me, Et, CF_3, $PhCH_2$, p-$O_2NC_6H_4$, p-FC_6H_4, p-ClC_6H_4, MeO, EtO.

Other workers have shown[127,162] that tautomers can be formed with compounds of this type having R = C_4H_9 and R′ = C_6H_5, but structure (C) is thermodynamically the most stable. The position of equilibrium in such systems is displaced under the influence of heating and additions of tributyltin chloride. Other discussions of the structures of such products have appeared[31,73].

The nitrile band in the infrared absorption spectra of organosilicon cyanamides containing an organic function $CH_3SiRR'CH_2NR''C{:}N$ (R = CH_3, C_2H_5O; R′ = CH_3O, C_2H_5O; R″ = iso-C_3H_7, iso-C_4H_9, C_6H_5)[53] lies in the range 2228 to 2211 cm^{-1}. Polymeric carbodi-imides $[SiRR'NCN]_n$ [n = 6–8; RR′ = $(CH_3)_2$, $(C_6H_5)_2$, $CH_3.C_6H_5$, $CH_3.CH_2{:}CH$, $(C_2H_5O)_2$] contain a strong N:C:N band at 2200–2150 cm^{-1}. The position of ν_{as}(N:C:N) is little affected by different substituents attached to the silicon atom. In the spectrum of the organotin tetramer $[(C_4H_9)_2SnN{:}C{:}N]_4$ this band has its maximum at 2063 cm^{-1}.

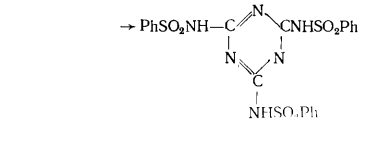
Study of n.m.r. spectra showed that the resonance signal of protons in organic groups attached to a silicon atom shifts upfield on passing from chlorosilanes to monomeric or polymeric organosilicon carbodi-imides. This indicates that the carbodi-imide group is less electronegative than the chlorine atom[15,20]. Thus for bistrimethylsilylcarbodi-imide and trimethylchlorosilane the difference is $\Delta\delta$ = 0.425 – 0.157 = 0.268 ppm.[20] This difference is increased when more than one chlorine atom is replaced by carbodi-imido-groups[20].

IV. CHEMICAL PROPERTIES

Hetero-organic carbodi-imides have very unusual chemical properties: in contrast to their organic analogues they can react not only at the carbodi-imide group but also at the heteroatom–nitrogen bonds. Furthermore, interaction between the N=C=N and M–N fragments results in a redistribution of electron density in the M–N=C=N system, with a consequent substantial change in reactivity of the compound as a whole. Thus the reactions of hetero-organic carbodi-imides can be divided into two main groups—(A) those accompanied by fission of heteroatom–nitrogen bonds and (B) additions at the cumulative double bonds.

The chemical properties of hetero-organic cyanamides will be considered at the same time and compared with those of the carbodi-imides.

A. Reactions with Fission of Heteroatom–Nitrogen Bonds



1. Interaction with compounds having a mobile hydrogen atom

Reactions of type (A) include primarily those of hetero-organic carbodi-imides with compounds containing a mobile hydrogen atom, e.g. water, alcohols, carboxylic acids. In contrast to organic carbodi-imides, which tend to undergo additions as a consequence of the unsaturation of the carbodi-imide group[1,3], their hetero-organic analogues are characterised by substitutions.

Hetero-organic carbodi-imides are usually quite stable towards atmospheric moisture under normal conditions. Thus bistriphenylsilylcarbodi-imide remains unchanged on contact with water for 10 days.[15] The enhanced hydrolytic stability of this class of compounds is explained by strengthening of heteroatom–nitrogen bonds due to delocalisation of electron density throughout the heterocumulene system under the influence of Group IVB elements[104,165,166]. However, prolonged heating of hetero-organic carbodi-imides with water results in fission of heteroatom–nitrogen bonds and separation of the coresponding hetero-organic oxides or hydroxides, together with cyanamide or a derivative thereof. Data have been published[11,25,28,44] on the hydrolysis of carbodi-imides containing silicon, germanium, and tin.

The hydrolysis of *N*-difluorophosphoryl-*N*′-trimethylsilylcarbodi-imide yields not only hexamethyldisiloxane and cyanamide but also phosphoric acid and hydrogen fluoride[132]. *N*-Phenylsulphonyl-*N*′-tributylstannylcarbodi-imide with water undergoes the reaction[129]

$$Bu_3SnN{=}C{=}NSO_2Ph \xrightarrow[-Bu_3SnOH]{H_2O} [PhSO_2NHCN] \rightarrow$$

Under similar conditions *N*-trimethylphenyl-*N'*-triphenylstannyl- and bistriphenylplumbyl-carbodi-imides do not react with water[25,49].

Hydrolysis of bistriethylgermyl- and bistriphenylgermylcarbodi-imides proceeds farther on the addition of 5–10% of sodium hydroxide to the reaction system. The final products are in the former case urea, cyanates, and hexaethyldigermoxane[45], and in the latter case urea, a mixture of cyanates, and sodium triphenylgermyl oxide[44].

Germanium-containing carbodi-imides react with water and hydrogen chalcogenides (sulphide, selenide, telluride) at room temperature[16,24]:

$$Me_nH_{3-n}GeN{=}C{=}NGeH_{3-n}Me_n + H_2El \rightarrow (Me_nH_{3-n}Ge)_2El + (H_2NCN)_2$$
$$El = O, S, Se;\ n = 0{-}3\ .$$

Similarly, bistriphenylplumbylcarbodi-imide is quantitatively converted by hydrogen sulphide at room temperature into bistriphenylplumbyl sulphide $S[Pb(C_6H_5)_3]_2$ and cyanamide[49]. Bistrimethylsilylcarbodi-imide, in contrast to the germanium and lead analogues, does not react with the hydrogen chalcogenides even when heated to 60–100 °C.[11-16]

Carbodi-imides containing silicon[16,116,117,168,169], germanium[114,116,117,168,169], and tin[25,55] react with alcohols and carboxylic acids to give the corresponding alkoxy- or acyloxy-derivatives together with cyanamide, dicyanodiamide, or melamine. Reaction takes place over a wide temperature range depending on the type and nature of the initial compounds. Thus digermylcarbodi-imide reacts rapidly and quantitatively with methanol at room temperature[114], whereas bistrimethylsilylcarbodi-imide requires heating to 100 °C.[116] The reaction of bistributylstannylcarbodi-imide with alcohols is reversible[55].

N-Triphenylmethyl-*N'*-triphenylstannylcarbodi-imide is decomposed by acetic acid under mild conditions to give triphenylstannyl acetate and triphenylmethylcyanamide[25].

In contrast to the above results, bistriphenylplumbylcarbodi-imide and trimethylplumbylcyanamide do not react with alcohols, and can be prepared in ethanol[49,51].

The reactions of bistrimethylsilyl- and bistriethylgermylcarbodi-imides[116] with hydroxylated compounds such as triethylsilanol and triphenyltin hydroxide also involve fission of heteroatom–nitrogen bonds, but they are complicated by simultaneous reaction between the initial carbodi-imides and water liberated on dehydration of the hydroxides:

$$R_3MN{=}C{=}NMR_3 + Ph_3SnOH \rightarrow Ph_3SnN{=}C{=}NSnPh_3 + R_3MOH$$
$$R_3MOH \xrightarrow{-H_2O} R_3MOMR_3\ .$$

The reaction of carbodi-imides containing Group IVB elements with thiols[16,117] and selenols[117,165,166,170] have a similar course to those with alcohols and lead to the separation of dicyanodiamide and the corresponding hetero-organic sulphur or selenium derivatives:

$$R_3MN{=}C{=}NMR_3 + REIH \rightarrow R_3MEIR' + (H_2NCN)_2$$
$$EL = S:\ M{=}Ge;\ R_3 = H_3,\ H_2Me,\ HMe_2,\ Me_3;$$
$$R'{=}Me,\ Et,\ Bu,\ Ph,\ Ac;\ El = Se:\ M = Si;$$
$$R{=}Me;\ R'{=}Bu;\ M{=}Ge;\ R{=}H,\ Et,\ Ph;$$
$$R'{=}Me,\ Bu,\ Ph;\ M{=}Sn;\ R{=}R'{=}Bu\ .$$

Bistrimethylsilylcarbodi-imide either does not react at all with thiols or gives insignificant [sic] 39–40% yields[16]. The SiN : C : NSi heterocumulene system is less liable to nucleophilic attack by heavy chalcogenols RSH, RSeH, and RTeH than is the corresponding GeN : C : NGe system. This is attributed to the enhanced stability of the silicon–nitrogen bond in carbodi-imides resulting from d_π–p_π interaction between the silicon and nitrogen atoms. The possibility of rupture of this bond by alcohols and acids is due to formation of the energetically more favourable silicon–oxygen bond[16]. The quantitative formation of products on treatment of germanium-containing carbodi-imides with these reagents results from the less double-bonded character of the germanium and nitrogen atoms.

The action of thioacetic acid on $C(:NSiR_3)_2$ ($R = H, CH_3$) and $C(:NGeR_3)_2$ [$R_3 = H_3, H_2CH_3, H(CH_3)_2, (CH_3)_3$] yields the corresponding thioacetates[168]. Spectral data show that in organosilicon thioacetates $R_3Si.O.CS.CH_3$ the R_3Si group is attached to the oxygen atom, whereas in the corresponding organogermanium derivatives $R_3Ge.S.CO.CH_3$ the R_3Ge group is attached to the sulphur atom.

Bistrimethylsilyl- and bistrimethylgermyl-carbodi-imides react vigorously with nitric acid at 0 °C to give the hetero-organic nitrates[171]:

$$Me_3MN{=}C{=}NMMe_3 + HNO_3 \rightarrow Me_3MONO_2 + (H_2NCN)_2\ .$$

Bistrimethylgermylcarbodi-imide reacts[117] with diphenylphosphine and phenylacetylene. The compounds $C[:NM.(CH_3)_3]_2$ (M = Si, Ge) do not react with phosphine, arsine, dimethylarsine, triphenylsilane, trimethylsilane, or pyrrole.

Bistrimethylsilylcarbodi-imide is reduced by lithium tetrahydroaluminate[15]:

$$Me_3SiN{=}C{=}NSiMe_3 + LiAlH_4 \rightarrow Me_3SiH + Li_2NCN + Al_2(NCN)_3\ .$$

Bistriphenylstannylcarbodi-imide is split by cyanamide[25]:

$$Ph_3SnN{=}C{=}NSnPh_3 + H_2NCN \rightarrow Ph_3SnNHCN\ .$$

Organosilicon carbodi-imides differ from their organic analogues in not reacting with ammonia or aniline, not adding hydrogen even in the presence of a palladium catalyst, and not causing amino-acids to condense to peptides[11].

2. Reactions with halogens and halogen-containing compounds

The action of halogens and their compounds on carbodi-imides containing silicon, germanium, and tin also involves fission of the heteroatom–nitrogen bond with formation of the corresponding hetero-organic halides and of cyanamide derivatives. Among halogen-containing compounds used have been hydrogen, alkyl, aryl, and acyl halides and Lewis acids. Only one publication[45] has described the reaction with an elementary halogen: bistriethylgermylcarbodi-imide reacts with bromine in benzene at 20 °C to give up to 70% yields of triethylgermyl bromide accompanied by dicyanodiamide and a polymer of undetermined structure. Disilylcarbodi-imide reacts with hydrogen chloride[6] to form chlorosilane and a compound to which the formula $H_2NCCl_2NH_2$ was assigned. A little later a similar reaction was accomplished with bistrimethylsilylcarbodi-imide, for which the scheme

$$R_3SiN{=}C{=}NSiR_3 + HCl \rightarrow R_3SiCl + Cl^- [H_2\overset{+}{N}{=}C{=}\overset{+}{N}H_2]\ Cl^-$$

was suggested[11].

Unsymmetrical *N*-trifluorosilyl-*N'*-trimethylsilylcarbodi-imide on treatment with excess of hydrogen chloride gives a quantitative yield of trimethylchlorosilane, chlorotrifluorosilane, and cyanamide dihydrochloride[130]:

$$Me_3SiN{=}C{=}NSiF_3 + HCl \rightarrow Me_3SiCl + F_3SiCl + H_2NCN{\cdot}2HCl\ .$$

When dry hydrogen chloride is passed through bistributylstannylcarbodi-imide at room temperature for 2 h the dihydrochloride is accompanied by tributyltin chloride (94%).[122]

Hetero-organic carbodi-imides react with metal salts of the Lewis acid type. Thus the reaction of disilylcarbodi-imide with silver chloride, bromide, and thiocyanate (at −78 °C for 18 h) gave low yields of chlorosilane, bromosilane, and isothiocyanatosilane respectively[6]. Treatment of bistriethylstannylcarbodi-imide with metal chlorides in boiling moist ether yields hydrates of the metal salts of cyanamide[5,167]:

$$Et_3SnN{=}C{=}NSnEt_3 + MCl_2 \rightarrow Et_3SnCl + MNCN\cdot nH_2O$$
$$M = Cu,\ Zn,\ Cd,\ Ca,\ Sn\ .$$

Products of the reaction with copper(II) sulphate are the monohydrate of copper(II) cyanamide $CuNCN.H_2O$ (91%) and bistriethylstannyl sulphate (98%).[167]

Hetero-organic carbodi-imides and cyanamides react very peculiarly with alkyl and aryl halides[5,112,122,123] and with arenesulphonyl chlorides[125,126,128,129,137,172]. Thus with ethyl and pentyl bromides bistributylstannylcarbodi-imide gives high yields of tributylstannyl bromide and the dialkylcyanamide[5,112,122]:

$$Bu_3SnN{=}C{=}NSnBu_3 + RBr \xrightarrow[84}{110-120^\circ} \rightarrow$$
$$\rightarrow Bu_3SnBr + \left[\begin{array}{c} Bu_3Sn \\ \diagdown \\ R \end{array}\!\!>\!N{-}C{\equiv}N\right] \xrightarrow{RBr} R_2NCN + Bu_3SnBr\ .$$

Bistriphenylstannylcarbodi-imide, in contrast to its butyl analogue, does not react with ethyl bromide (when boiled in acetonitrile), but with ethyl iodide triphenylstannyl iodide has been isolated[123]. With benzyl bromide it gives as final products triphenylstannyl bromide and the dibenzylcyanamide complex of the latter $(C_6H_5CH_2)_2NCN.(C_6H_5)_3SnBr$. An analogous reaction with *N*-triphenylmethyl-*N'*-triphenylstannylcarbodi-imide leads to isolation of the corresponding complex $(C_6H_5)_3C(C_6H_5CH_2)NCN.(C_6H_5)_3SnBr$.[123] Replacement of benzyl bromide by triphenylmethyl chloride yields either bistriphenylmethyl- or *N*-triphenylmethyl-*N'*-triphenylstannyl-carbodi-imide depending on the initial ratio of the reactants:

$$Ph_3SnN{=}C{=}NSnPh_3 \begin{cases} \xrightarrow[-Ph_3SnCl]{Ph_3CCl} Ph_3SnN{=}C{=}NCPh_3 \\ \xrightarrow[-2Ph_3SnCl]{2Ph_3CCl} Ph_3CN{=}C{=}NCPh_3 \end{cases}\ .$$

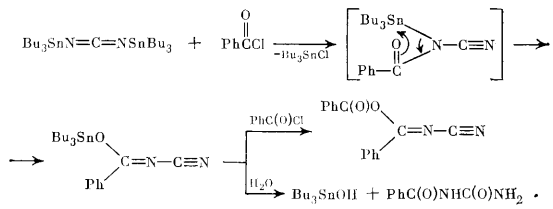
Here the usual exchange process is observed: the mechanism with migration of the reaction centre is not realised owing to the large bulk of the triphenylmethyl group[123].

Reaction of triphenylstannylcyanamide with triphenylmethyl chloride in the presence of triethylamine in the proportions 1 : 1 : 2 in benzene at 20 °C yields triethylamine hydrochloride (56%), bistriphenylmethylcarbodi-imide (38%), and *N*-triphenylmethyl-*N'*-triphenylstannylcarbodi-imide (5%).[123]

Organotin carbodi-imides and cyanamides react also with arenesulphonyl halides and pseudohalides. Thus the action of benzenesulphonyl chloride on bistributylstannylcarbodi-imide yields *N*-phenylsulphonyl-*N'*-tributylstannylcarbodi-imide and tributylstannyl chloride independently of the initial proportions of the reactants[129,137,172]; benzenesulphonyl azide reacts similarly[137,172]:

$$Bu_2SnN{=}C{=}NSnBu_3 + PhSO_2X \rightarrow Bu_3SnX + Bu_3SnN{=}C{=}NSO_2Ph$$
$$X = Cl,\ N_3\ .$$

Other publications have appeared[126,128] on the interaction of organotin carbodi-imides and arenesulphonyl chlorides, but a cyanamide structure was attributed to the products, as already mentioned:

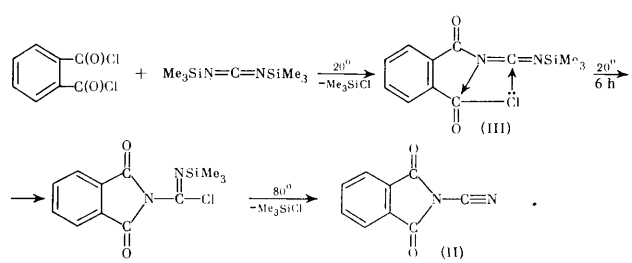


$$R_3SnN{=}C{=}NSnR_3 + R'Cl \rightarrow \underset{|}{\overset{C{\equiv}N}{R'NSnR_3}} + R_3SnCl \qquad (9)$$
$$R = Me,\ Ph;\ R' = PhSO_2,\ p\text{-}MeC_6H_4SO_2,\ p\text{-}BrC_6H_4SO_2\ .$$

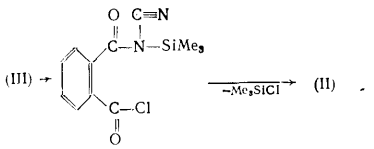
In contrast to carbodi-imides triphenylstannylcyanamide forms with benzenesulphonyl chloride in the presence of triethylamine an anionic complex[125]:

$$Ph_3SnNHC{\equiv}N + RCl + Et_3N \rightarrow [RN(CN)SnPh_3Cl]^-[Et_3NH]^+ \qquad (10)$$
$$R = Ph,\ SO_2\ .$$

Reactions with acyl halides[4,5,124-129] also correspond to Eqns.(9) and (10),[125,126,128] but yield more complicated product mixtures, owing to the possibility of heterotropic rearrangements of the cyanamides (or carbodi-imides) formed. Bistrimethyl-, bistributyl-, and bistriphenylstannylcarbodi-imides react with acid chlorides at room temperature in the absence of a solvent[127,129] or in oxolan[125,126,128] to give the corresponding stannyl chlorides and cyanamide derivatives [Eqn.(9): R = CH_3, C_4H_9, C_6H_5; R' = CH_3CO, C_6H_5CO, $C_6H_5CH_2CO$, *p*-$CH_3C_6H_4CO$, *p*-$NO_2.C_6H_4CO$, *p*-ClC_6H_4CO, *p*-BrC_6H_4CO, CH_3OCO, CF_3CO]. The structure of these and the products of the reaction of bistrimethylsilylcarbodi-imide with trifluoroacetyl chloride[124] and with benzoyl chloride[4,66-68] has been discussed already (Sections II, 2 and III).



It is noteworthy that benzoyl chloride is able to react with bistributylstannylcarbodi-imide also in the proportions 2 : 1,[129] a process that is shown by the infrared spectra to take place in stages. One of the tin-nitrogen bonds is broken at room temperature within a few minutes, with formation of a substituted cyanoimine; reaction with the second molecule of benzoyl chloride takes place at 100 °C:



Hydrolysis of the intermediate organotin cyanamide leads to formation of benzoylurea[129].

Triphenylstannylcyanamide reacts with acid chlorides in conformity with Eqn.[(10): R = CH_3CO, C_2H_5CO, C_6H_5CO, CH_3OCO, C_2H_5OCO, $C_6H_5CH_2OCO$]. The corresponding anionic complexes were isolated as final products[125,126]. One such complex (R = CH_3CO) was obtained by cross synthesis from *N*-cyano-*N*-triphenylstannylacetamide and triethylamine hydrochloride[125]. Anionic complexes of the type $[N{:}C.N{:}C(NHR).OSn(C_6H_5)_3Cl]^-[(C_2H_5)_3NH]^+$ (R = C_2H_5, C_6H_5) have been prepared similarly[173].

The reaction of bistrimethylsilylcarbodi-imide with phthaloyl dichloride led to the isolation only of the final acylation product (II), whose formation was assumed[174] to involve the processes:

Alternatively, the reaction might involve intermediate formation of a cyanamide derivative:

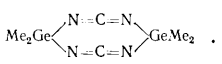
The action of terephthaloyl and *p*-nitrobenzoyl chlorides on triphenylstannylcyanamide and triethylamine yields not complexes but triethylammonium salts of the corresponding acylcyanamides[125].

Organosilicon carbodi-imides are often used as intermediates in the preparation of novel hetero-organic compounds. The reaction of disilylcarbodi-imide with boron trifluoride was described as early as 1962:[7] an addition product is formed at −78 °C, which at room temperature breaks down into fluorosilane and *N*-boryl-*N*-silylcyanamide. The action of boron trifluoride on bistrimethylsilylcarbodi-imide yields trimethylfluorosilane and an unidentified polymer[117].

This communication served to initiate a large number of studies on the preparation of unsymmetrical organosilicon carbodi-imides and hetero-organic cyanoimines. Thus treatment of bistrimethylsilylcarbodi-imide with silicon tetrafluoride[130,131], phosphoryl trifluoride[132,133], thiophosphoryl trifluoride[134], $S:PF_2.N:PF_3$,[135] and $(CH_3)_3SiO_3.SCl$ [136] has yielded the corresponding halogenosilanes and carbodi-imides:

$$Me_3SiN{=}C{=}NSiMe_3 + RX \rightarrow Me_3SiN{=}C{=}NR + Me_3SiX$$
$$R = SiF_3,\ POF_2,\ PSF_2,\ S{=}PF_2N{=}PF_2;\ X = F;$$
$$R = SO_3SiMe_3;\ X = Cl\ .$$

Treatment with sulphur tetrafluoride[175,176], thionyl tetrafluoride[177,178], R_2NSF_3,[179,180] R_2NSOF_3 ($R = CH_3$, C_2H_5, C_5H_{10}),[179,181] $C_6H_5OSOF_3$,[182] $(CF_3)_2CFSF_3$,[183] $C_6H_5PF_4$, $(C_6H_5)_2PF_3$,[133,184,185] and thionyl dichloride[74-76] involves detachment of both trimethylsilyl groups to give up to 65% yields of cyanoimines:



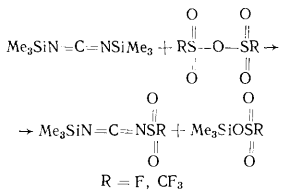
$$Me_3SiN{=}C{=}NSiMe_3 + YX_2 \rightarrow Y{=}N{-}C{=}N + Me_3SiX$$
$$Y = F_2S,\ F_2SO,\ Alk_2NS(O)F;\ (CF_3)_2CFSF,\ PhPF_2,$$
$$Ph_2PF;\ X = F;\ R = SO;\ X{=}Cl\ .$$

Depending on the conditions treatment with sulphur tetrafluoride may yield products differing in structure[176]:

$$F_2S{=}N{-}C{\equiv}N \xleftarrow[50°]{SF_4} Me_3SiN{=}C{=}NSiMe_3 \xrightarrow[200°]{SF_4} F_2S{=}NSF_2N{=}SF_2\ .$$

Exchange reactions between silylcarbodi-imides and inorganic halides were partly covered in a review[186].

The reported[117] reaction of bistrimethylsilylcarbodi-imide with germanium tetrafluoride and dimethylgermanium difluoride gave as final products not only trimethylfluorosilane but also a polymer containing fluorine, germanium, and nitrogen together with the compounds bisdimethylfluorogermylcarbodi-imide and



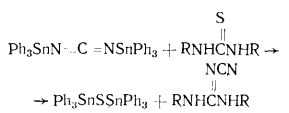
The transmetallation of hetero-organic carbodi-imides by means of organo-silicon, -germanium, and -tin halides has already been discussed in detail (Eqn.8).[1,4,14-16,66,114,115,117-121]

The reactions of unsymmetrical organosilicon carbodi-imides with hydrogen-containing compounds do not differ fundamentally from those of their symmetrical analogues. Thus the action of dimethyldichlorosilane and also of chlorine-containing sulphur compounds (sulphur dichloride and R_2NSCl) on *N*-t-butyl-*N'*-trimethylsilylcarbodi-imide has been described[158]. Elimination of trimethylchlorosilane led to isolation of the corresponding carbodi-imides:

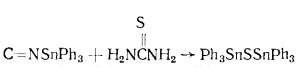
$$t\text{-}BuN{=}C{=}NSNR_2 (R = Me,\ Et),$$
$$t\text{-}BuN{=}C{=}NSiMe_2N{=}C{=}NBu\text{-}t,$$
$$t\text{-}BuN{=}C{=}NSN{=}C{=}NBu\text{-}t\ .$$

3. Reactions with compounds containing S–O–S and P–O–P links

Bistrimethylsilylcarbodi-imide undergoes exchange processes also with compounds containing labile S–O–S and P–O–P bonds. Thus with disulphuryl difluoride and bistrifluoromethide at room temperature the corresponding unsymmetrical organosilicon carbodi-imides are obtained[140]:



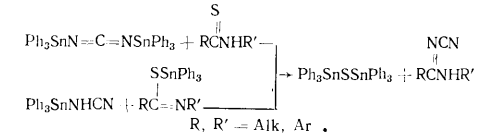
The reaction with pyrophosphoryl tetrafluoride $O(POF_2)_2$ apparently follows the same course[187], to give $(CH_3)_3.SiOPOF_2$ (85%) and an unidentified colourless solid.



4. Interaction with thiourea derivatives and thioamides

The action of substituted thioureas and thioamides on organotin carbodi-imides and cyanamides also involves reactions of type (A).

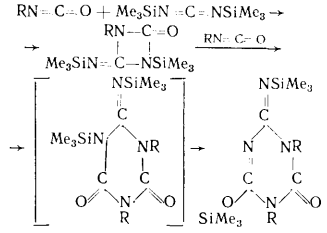
When disubstituted thioureas are heated with bistriphenylstannylcarbodi-imides in boiling acetonitrile for 20 h, 45–74% yields of the corresponding *NN'*-disubstituted *N''*-cyanoguanidines and bistriphenylstannyl sulphide are obtained[25]:



However, the use of thiourea results in the formation of triphenylstannylcyanamide, which can be explained by the scheme[25]:

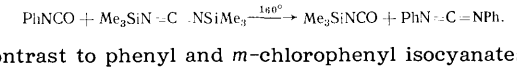
Reaction of trimethyl- and triphenyl-stannylcyanamides with various isothioureas makes it possible to obtain the corresponding *N*-cyano-*S*-trialkylstannylisothioureas of general formula $R'N:C(NHCN)SSnR_3$ ($R = CH_3$, C_6H_5; $R' = CH_3$, C_6H_5, $p\text{-}FC_6H_4$, $p\text{-}NO_2C_6H_4$, $C_6H_5CH_2$, cyclo-C_6H_{11}).[188]

The reactions of bistriphenylstannylcarbodi-imide and of triphenylstannylcyanamide with *N*-substituted thioamides at room temperature in acetonitrile (63 h) or in ethanol (15 h) resulted in the same products—the corresponding *N'*-substituted cyanamidines (yields 25–67%):[189]



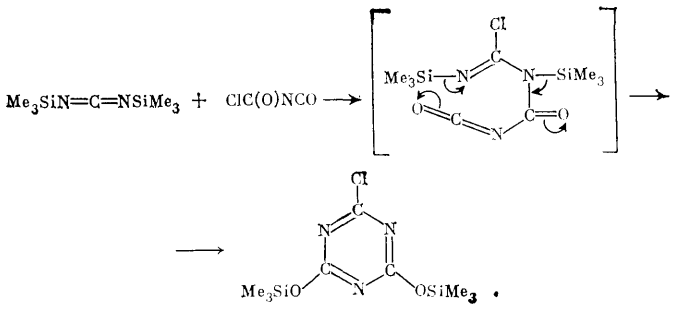
Treatment of the above carbodi-imides with thioamides in

ether or acetonitrile led to the isolation of acetonitrile or benzonitrile, bistriphenylstannyl sulphide, and dicyanodiamide. The sulphide and the organic nitrile could have been formed by decomposition of an intermediate compound of the type $(C_6H_5)_3Sn.S.CR:N.Sn(C_6H_5)_3$.[189]

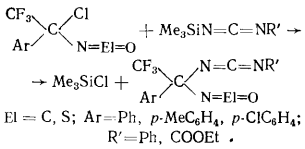


Several reactions of tin-containing carbodi-imides and cyanamides have been systematised in annual reviews on organotin compounds[190,191].

B. Additions at Cumulative Bonds of Carbodi-imides

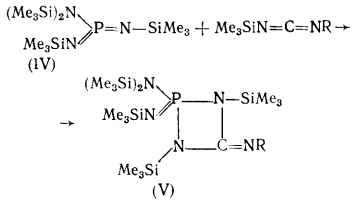


As mentioned above, addition reactions are far less characteristic of hetero-organic carbodi-imides than of the organic analogues. The first mention of reactions of this type related to that between bistrimethylsilylcarbodi-imide and fluorosulphuryl isocyanate $FSO_2N:C:O$.[192] An equimolecular adduct was formed, whose pyrolysis yielded trimethylfluorosilane. The carbodi-imide reacts with benzenesulphonyl isocyanate when heated to 100–150 °C,[138] with the formation of four- or six-membered heterocycles containing silicon depending on the initial proportions of the reactants:



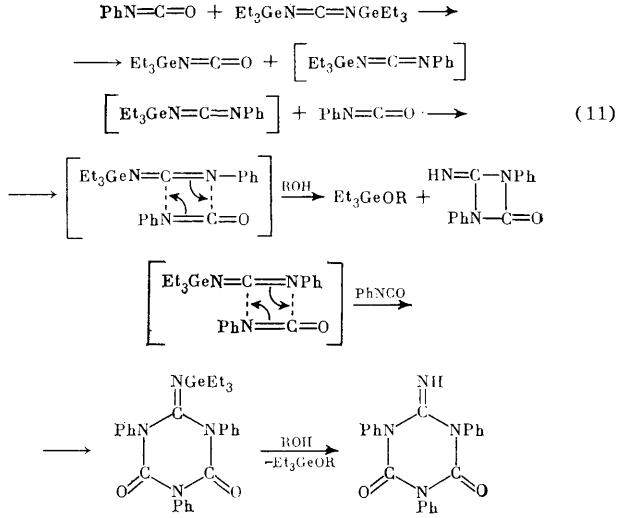
Such a scheme was suggested for the interaction of organic isocyanates with organic carbodi-imides[164,193]. In the case of phenyl isocyanate the only product of the reaction is the 1:2 adduct 2-oxo-1,3-diphenyl-4-trimethylsiloxy-6-trimethylsilylimino-1,2,3,6-tetrahydro-1,3,5-triazine (yield 82%).[194,195] A similar reaction occurs with *m*-chlorophenyl isocyanate[196]. If the low-boiling trimethylsilyl isocyanate formed is distilled off, an exchange reaction occurs with phenyl isocyanate[66]:

In contrast to phenyl and *m*-chlorophenyl isocyanates, chloroformyl isocyanate reacts with bistrimethylsilylcarbodi-imide in equimolecular proportions under mild conditions (in ether at 20 °C) to give a 64% yield of 2-chloro-4,6-bistrimethylsiloxy-1,3,5-triazine[197]:



The reaction is seen to begin with electrophilic addition of the isocyanate at the carbon–nitrogen double bonds of the carbodi-imide. The product cyclises with simultaneous migration of the trimethylsilyl groups from nitrogen to oxygen atoms. Unsymmetrical organosilicon carbodi-imides undergo exchange reactions with chlorinated isocyanates; as final products have been isolated for the first time compounds having two different heterocumulene groups attached to the same carbon atom[38,39,198]:

El = C, S; Ar = Ph, *p*-MeC_6H_4, *p*-ClC_6H_4; R′ = Ph, COOEt .



Interaction of bistrimethylsilyl- or *N*-t-butyl-*N*′-trimethylsilyl-carbodi-imide with the fully *N*-trimethylsilylated aminodiiminophosphorane (IV) at 0 °C for 2 h yielded cyclic adducts:

[R = $(CH_3)_2Si$, $(CH_3)_3C$].[159] When the reaction conditions were changed to 25 °C for 7 days, the product was not the compound [V: R = $(CH_3)_3Si$] but the carbodi-imidophosphinoimine:

The reaction of bistriethylgermylcarbodi-imide with phenyl isocyanate in the proportions 1:2 follows a rather different course[194]. Initial exchange of one of the triethylgermyl groups for phenyl is followed by cycloaddition of the resulting unsymmetrical carbodi-imide to a second phenyl isocyanate molecule; at the same time an organogermanium 1,3,5-triazine is formed to a slight extent:

(11)

R = H, Me, Et, iso-Pr .

Hydrolysis of the resulting organogermanium cycloadducts yields the corresponding organic isoammelide derivatives, as in the case of the organosilicon analogues. The action of benzenesulphonyl isocyanate involves mainly the first stage of reaction (11), which on heating is complicated by considerable resinification[138]. The final products isolated were triethylgermyl isocyanate (yield 34%) and *N*-phenylsulphonyl-*N*′-triethylgermylcarbodi-imide.

Benzenesulphonyl isocyanate reacts in just the same way when heated with bistributylstannylcarbodi-imide, giving an 83% yield of tributylstannyl isocyanate[138]. At 25 °C this carbodi-imide forms with benzenesulphonyl, phenyl, and 6-chlorohexyl isocyanates linear adducts of length depending on the initial proportions of the reactants[59,138,199,200]. Heating the adduct $C[:NSn(C_4H_9)_3]_2.3C_6H_5NCO$ and then hydrolysing the resulting mixture yielded several products indicating a reaction mechanism similar to (11). In particular 2-imino-4,6-dioxo-1,3,5-triphenylperhydro-1,3,5-triazine and triphenyl isocyanurate were isolated in yields of 61% and 30% respectively. Formation of the latter compound is apparently due to catalytic cyclotrimerisation of phenyl isocyanate under the influence of organotin compounds, which has been studied thoroughly[201,202]. Thermal decomposition of the adduct $C[:NSn(C_4H_9)_3]_2.ClC_6H_{12}NCO$ (at 200 °C for 4–5 h) gives tributyltin chloride, tributylstannyl isocyanate, bistributylstannylcarbodi-imide, and a polymer of 6-chlorohexyl isocyanate[200].

The structure of the equimolecular adducts of phenyl isocyanate with trimethyl- and triphenyl-stannylcyanamide has not been established with certainty. It is supposed[123,139] that the stannyl group can add both to nitrogen and to oxygen atoms. More definite conclusions have been reached[123,190] concerning the structure of the products of the action of phenyl isothiocyanate on bistriphenylstannylcarbodi-imide (in benzene at 26 °C):

$$Ph_3SnN{=}C{=}NSnPh_3 + PhN{=}C{=}S \rightarrow \rightarrow \begin{matrix} PhN{=}C{-}SSnPh_3 \\ | \\ Ph_3SnN{-}C{\equiv}N \end{matrix} \xrightarrow{H_2O} \begin{matrix} PhN{=}C{-}SSnPh_3 \\ | \\ HN{-}C{\equiv}N \end{matrix}.$$

An organotin derivative of cyanoisothiourea can be obtained also by the action of phenyl isothiocyanate on triphenylstannylcyanamide:

$$Ph_3SnNHCN + RN{=}C{=}S \rightarrow \begin{matrix} RN{=}C{-}SSnPh_3 \\ | \\ HN{-}C{\equiv}N \end{matrix}.$$

The rate of the reaction increases with the nature of the radical in the isothiocyanate in the sequence[123,190]

$$p\text{-}O_2NC_6H_4NCS > PhNCS > PhCH_2NCS \sim$$
$$\sim p\text{-}EtOC_6H_4NCS > EtNCS.$$

N-Triphenylmethyl-*N'*-triphenylstannylcarbodi-imides had not reacted with an isothiocyanate in ether at 28 °C after 23 h.[123]

Trialkylstannylcyanamides react with yet another hetero-cumulene system--carbon disulphide[50]:

$$R_3SnNHCN + CS_2 \rightarrow HN{=}\underset{\underset{NH_2}{|}}{C}{-}NHC{\equiv}N + R_3SnSSnR_3 + NCN{=}\underset{\underset{NC{-}NSnR_3}{|}}{C}SSnR_3$$

R=Me, Ph, $PhCH_2$.

It has been reported also[117] that organogermanium carbodi-imides do not react with carbon disulphide.

V. ASPECTS OF PRACTICAL APPLICATION

Hetero-organic carbodi-imides and cyanamides have recently begun to find practical application in the synthesis of various polymers and difficultly accessible organic compounds, as well as in certain industrial chemical processes. Thus bistrimethylsilylcarbodi-imide has been successfully tried as a moisture stabiliser for polyurethanes based on complicated polyesters employed for the production of artificial leather and other purposes[203]. It has been proposed as a substitute for the most widely used for these purposes, 2,2,6,6-tetraisopropyldiphenylcarbodi-imide (Stabaksol 1). Oligomers and polymers containing a carbodi-imide group in the macromolecular chain, obtained by the interaction of organosilicon diols and isocyanatocarbodi-imides, are used for the stabilisation of polyester–urethanes to moisture and heat. Additions of 0.1–3% to polyurethanes significantly enhance their resistance to high temperatures and moisture[204].

Polymeric organosilicon carbodi-imides, obtained by the action of polychlorosilanes or chlorosilanes on bisdimethylsilylcarbodi-imide, can be used as insulating coatings, components of high-temperature colorants, etc., in cases in which high heat resistance is required[118–121]. Furthermore, such polymers are stable to irradiation, which permits their use in various types of packing operating under conditions of intense irradiation. For example, polysilylcarbodi-imide $[(C_6H_5)_2SiNCN]_n$ of molecular mass 4285 undergoes no loss in weight when heated in nitrogen to 400 °C, and retains its elasticity when exposed to an [electron irradiation] dose of 2000 MR g^{-1}.[118–121]

Organotin carbodi-imides have been suggested as heat stabilisers for polyvinyl chloride compositions[205,206]. They are also effective catalysts for urethane formation[207–211]. Thus bistributylstannylcarbodi-imide has been used as catalyst for the preparation of film-forming polyurethane coatings based on organosilicon polyols and aliphatic polyisocyanates of biuret structure[209]. Bistrimethylsilylcarbodi-imide is also a heat stabiliser for polyvinyl chloride, but considerably less effective than organotin carbodi-imide[212].

Organotin cyanamide derivatives possess antibacterial activity[139,188]. Organolead cyanamides of type $(CH_3)_3.PbNHC{:}N$ are employed as extremely efficient antioxidants and additives in lubricating and engine oils[51,213].

Hetero-organic carbodi-imides can also be employed as intermediates in the synthesis of various difficultly accessible organic compounds, e.g. dialkylcyanamides[112,122] and 1,3,5-triazines[138,194,195,197,199].

There is no doubt that the fields of practical application of hetero-organic cyanamides and carbodi-imides of Group IVB elements have not been fully studied. Further, more thorough investigation of the chemical properties of these interesting compounds will make it possible to extend considerably the range of their practical application.

* * *

During preparation of this Review for the press additional publications have appeared on the synthesis[214–219] and properties[219–221] of organosilicon and organogermanium carbodi-imides.

Oxidation of Organometallic Compounds by Transition Metal Salts

A.N.Kashin and I.P.Beletskaya

The mechanisms of one- and two-electron oxidation of organometallic compounds by transition metal salts are considered. It is shown that organometallic compounds can be oxidised as a result of dielectric electron transfer but usually unstable transition metal compounds are formed as intermediates in the reactions. The mechanisms of the thermal and catalytic decomposition of certain types of organometallic compounds are discussed in this connection.
The bibliography includes 244 references.

I. INTRODUCTION

The reactions of organometallic compounds with transition metal salts have continuously attracted the attention of investigators because many of them are of preparative value. Recently interest in such reactions has increased still further in connection with their involvement in complex processes catalyses by transition metal complexes.

Various reactions occur when organometallic compounds interact with transition metals salts. These include in the first place the transmetallation reaction as a result of which a new organometallic compound is formed:

$$RMX_n + M'X_n \rightarrow RM'X_{m-1} + MX_{n+1} . \quad (1)$$

Since this review is devoted to reactions involving the oxidation of organometallic compounds, we shall consider only those in which unstable organometallic intermediates, decomposing with formation of the products R_2, RH, and R(-H), are formed.

According to modern ideas, organic compounds of transition metals can decompose via the free-radical mechanism (2) and via the so-called bimolecular mechanism (3) in which free radicals are not formed:

$$RM'X_{m-1} \rightarrow R^{\cdot} + M'X_{m-1} ,$$
$$2R^{\cdot} \rightarrow RH + R(-H) , \quad (2)$$
$$2R^{\cdot} \rightarrow R_2 ;$$

$$2RM'X_{m-1} \rightarrow RH + R(-H) + 2M'X_{m-1} ,$$
$$2RM'X_{m-1} \rightarrow R_2 + 2M'X_{m-1} . \quad (3)$$

Whereas the free-radical mechanism of the decomposition of organometallic compounds is understood in all its aspects, the question of the essential features of the bimolecular mechanism is not quite so clear and there is not even a unanimous view concerning the nature of the reactions occurring. For example, it is not clear how the organometallic compounds decompose in this instance, whether the process is homolytic and occurs within a radical cage or whether it is heterolytic

and involves, for example, the hydride elimination stage whose products are RH and R(−H). This uncertainty has resulted in the lack of a single terminology used to designate this mechanism. It is referred to as the bimolecular mechanism, the latent radical mechanism, and sometimes the latent ionic mechanism, but these terms merely confirm the absence of free radicals.

When organometallic compounds interact with metal salts, free radicals can be formed not only as a result of the homolytic decomposition of the product of the transmetallation reaction (2) but also in the one-electron oxidation of the organometallic compounds. The radicals formed in this instance, as in mechanism (2), dimerise, disproportionate, or react with the solvent:

$$RMX_n + M'X_m \rightarrow [(RMX_n)^+ (M'X_m)^-] \rightarrow R^\cdot + MX_{n+1} + M'X_{m-1} ,$$
$$2R^\cdot \rightarrow R_2 ,$$
$$2R^\cdot \rightarrow RH + R(-H) . \qquad (4)$$

This pathway, leading to the oxidation of organometallic compounds, is fundamentally different from mechanism (2) discussed above. On the other hand, they are difficult to distinguish because the reaction results in the formation of free radicals and the same products. Finally, when organometallic compounds interact with metal salts, there is a possibility of two-electron oxidation to carbonium ions R^+, which react with nucleophilic species via mechanism (5). Carbonium ions can be formed in these reactions in a wide variety of ways: in the intramolecular decomposition of $RM'X_{m-1}$ [mechanism (5), pathway *a*] produced as a result of transmetallation in accordance with Eqn.(1), in the oxidation of the radicals $R^\cdot$ [mechanism (5), pathway *b*] generated via pathways (2) and (4), or in the direct two-electron oxidation of the initial organometallic compound [mechanism (5), pathway *c*]:

$$RM'X_{m-1} \xrightarrow{a} R^+ + M'X_{m-2} + X^- ,$$
$$R^\cdot + M'X_m \xrightarrow{b} R^+ + M'X_{m-1} + X^- ,$$
$$RMX_n + M'X_m \xrightarrow{c} R^+ + MX_{n+1} + M'X_{m-2} + X^- ,$$
$$R^+ + Nu^-(X^-) \rightarrow RNu(RX) . \qquad (5)$$

We may note that free carbonium ions are not always formed in the two-electron oxidation of organometallic compounds—for example, when electron transfer takes place with the simultaneous transfer of a nucleophilic ligand:

$$RM'X_{m-1} \xrightarrow{a} RX + M'X_{m-2} ,$$
$$R^\cdot + M'X_m \xrightarrow{b} RX + M'X_{m-1} ,$$
$$RMX_n + M'X_m \xrightarrow{c} RX + MX_{n+1} + M'X_{m-2} . \qquad (6)$$

There is also a possibility of a rarely encountered activation of the intramolecular transfer of a second electron as a result of the attack by the nucleophile (Nu) on the radical-cation intermediate:

$$RMX_n + M'X_m \rightarrow (RMX_n)^+ + M'X_{m-1} + X^- ,$$
$$(RMX_n)^+ + Nu^- \rightarrow RNu + MX_n . \qquad (7)$$

This review deals with the above mechanisms of the oxidation of organometallic compounds by metal salts. To facilitate exposition, the data for reactions involving the oxidation of organometallic compounds by silver(I), copper(I), and copper(II) salts as well as Group VIII metal salts are considered as far as possible in separate sections. This is mainly because specific mechanisms have been proposed for each oxidant and numerous examples of their reactions have been studied. Analogous problems are dealt with also in recently published reviews[1,2].

In our view, the thermal decomposition reactions of organic derivatives of silver, copper(I), and other transition metals also merit attention. Interest in these processes is due to two causes. Firstly, they may constitute the stage in which the intrinsic oxidation of the organic group R occurs. This happens when the oxidation of an organometallic compound by the metal salt begins with the transmetallation reaction and an intermediate RM is formed. Secondly, these reactions are oxidation processes of a specific type for which independent mechanisms have been proposed. We shall adhere to these standpoints in considering the wide variety of decomposition reactions of organometallic compounds. Thus we shall regard the homolytic decomposition of organometallic compounds as a one-electron oxidation process. This is not a formal approach, since the carbanion bound to the metal cation is indeed oxidised in the course of the reaction, being converted into a radical. Similarly the decomposition of the compounds RM with formation of R^+ or intramolecular decomposition of R_2M with formation of R_2, RH, and R(−H) should be regarded as two-electron oxidation processes. These reactions are considered in detail in the last section of the present review.

II. ONE-ELECTRON OXIDATION OF ORGANOMETALLIC COMPOUNDS BY TRANSITION METAL SALTS

Particularly numerous reactions with transition metal salts are known for organomagnesium compounds RMgX. In many instances, especially for R = Ar, this reaction can serve as a preparative method for the synthesis of biaryls, since in the synthesis of a symmetrical product this reaction is simpler than the Wurtz–Fittig reaction.

The reaction (with a nearly quantitative yield of biaryl) was first carried out in 1914:[3]

$$p\text{-}MeC_6H_4MgBr \xrightarrow[80-85\%]{CrCl_3} (p\text{-}MeC_6H_4)_2 .$$

In subsequent years the number of examples of similar reactions increased and studies were mainly carried out in order to elucidate the influence of the nature of the metal salt on the yield of product. It was shown[4] that the yield of biphenyl (%) varies as follows as a function of the nature of the oxidant in the reactions of PhMgI with metal salts in ether:

$FeCl_2$	98	$PdCl_2$	98
$CoBr_2$	98	$OsCl_3$	53
$NiBr_2$	100	$IrCl_3$	28
$RuCl_3$	99	$PtCl_4$	5
$RhCl_3$	97	—	—

According to Tsutsui[5], the yield of the dimerisation product (%) in the reaction of ArMgX with various metal chlorides in tetrahydrofuran (THF) varies within a very wide range:

$FeCl_2$	47	$MnCl_2$	21
$CoCl_2$	86	$CrCl_3$	7
$NiCl_2$	72	$CuCl_2$	6

Biaryls are formed when arylmagnesium bromides are treated with thallium(I) bromide[6], uranyl nitrate[7], titanium tetrachloride and vanadium oxide trichloride[8], and chromium(IV) t-butoxide[9]. Depending on the nature of the aryl group, the yield of the dimerisation product varies for the majority of salts from 25 to 100%.[8]

When transition metal salts act on alkylmagnesium halides, the main products become olefins and alkanes and not coupling products[10]. The yields of the products of these reactions have been reported[11]. Cotton[12] proposed the following

classification of the reactions taking into account the preferential formation of particular products: mainly alkanes in group I reactions, disproportionation products in group II reactions, and alkanes and olefins together with coupling products in group III reactions, while group IV reactions include those whose products are the dimers Alk_2. According to this classification, transition metal salts are involved mainly in reactions to the following types:

group I: $TiCl_4$, $Ti(OR)_4$, $ZrCl_4$, $TaCl_5$;
group II: $CrCl_3$, $MnBr_2$, $FeCl_2$, TlCl, Cu_2Cl_2, $CuCl_2$;
group III: AgX, $AuCl_3$.

Group IV reactions are those of silver and copper salts with organomagnesium and organolithium compounds without a β-hydrogen atom.

The mechanisms of the reactions of transition metal salts with aryl- and alkylmagnesium halides are usually regarded as consecutive transmetallation and decomposition of the organometallic intermediate by a radical mechanism or without the involvement of free radicals. It is believed[11] that the decomposition of the organometallic intermediate can be unimolecular [radical mechanism (2)] or bimolecular [without the involvement of radicals—mechanism (3)]. The decomposition of aliphatic organometallic derivatives containing a β-hydrogen atom apparently takes place via a hydride abstraction stage. This case will be examined below.

A detailed study of the products of the reactions of organomagnesium compounds with transition metal salts was first undertaken by Smith[13] in order to elucidate the mechanism of the decomposition of organometallic intermediates. It was found that, when cobalt(II) bromide reacts with PhMgBr, benzene (42%) and biphenyl (45%) are formed, whereas in the case of p-MeC_6H_4MgBr the products are toluene (55%) and bitolyl (33%). On the other hand, when a mixture of these Grignard reagents (PhMgBr and p-MeC_6H_4.MgBr) is treated with $CoBr_2$, an asymmetric biaryl resulting from cross-coupling is formed together with the above products, the relative yields of the biaryls (%) differing from the statistical distribution: PhH (53)†, Ph_2 (30), PhMe (55), $(p\text{-}MeC_6H_4)_2$ (18), and PhC_6H_4Me (15). This result alone provides grounds for the hypothesis that the biaryls are not formed from free radicals.

When $CoBr_2$ reacts with a mixture of aryl and alkyl Grignard reagents (PhMgBr and EtMgBr), mainly benzene, ethane, and ethylene are formed, whereas the amount of cross-coupling products obtained is small[13]: PhH (81)†, Ph_2 (16), PhEt (5), EtH (52), C_2H_4 (47), and BuH (1).

In addition, the ratio of the alkanes and alkenes formed is smaller than in the reaction of individual alkylmagnesium bromides. In its turn the amount of benzene formed in this instance is greater than in the reaction of PhMgBr with $CoBr_2$ while that of biphenyl is actually smaller. According to Smith[13], this can be associated with the additional disproportionation reaction between the phenyl and alkyl derivatives of cobalt(II).

The results presented undoubtedly indicate a bimolecular mechanism of the decomposition of the intermediates or at least an appreciable contribution of this reaction pathway to the overall process. The data obtained by Wittig for the reactions of 2,2'-dilithiobiphenyl [14] or o-dilithiobenzene [15] with transition metal salts agree with this view. Thus o-dilithiobenzene gives rise to biphenyl and triphenylene (in an overall yield up to 25%), their relative yields depending on the nature of the salt employed. We may note that dehydrobenzene is not formed in this reaction and triphenylene could not therefore be produced as a result of its trimerisation.

The only product of the reaction of PhMgBr with cobalt(III) and manganese(III) acetylacetonates is biphenyl[16], whose yield is independent of the added α-methylstyrene. The operation of the bimolecular mechanism is apparently due to the fairly high stability of the aryl derivatives of cobalt(III) and manganese(III).[12,17]

In principle, a free-radical mechanism is also possible for the reactions of organomagnesium compounds RMgX with transition metal salts. Both the formation of the hydrocarbons RH in a series of reactions as well as the presence of deuterium in the products of the reaction of PhMgBr with various salts in a mixture of deuterated benzene and ether can serve as confirmation of this postulate[18]. The radicals can be formed in these reactions on homolytic decomposition of the transmetallation product or as a result of the one-electron oxidation of the organomagnesium compound. The available data are usually insufficient to make an unambiguous choice between the possible pathways leading to the formation of the reaction products. It has been shown convincingly in only one study[19] that radicals are formed in the reaction of alkyl-lithium with $TiCl_4$ as a result of electron transfer and not on decomposition of $RTiCl_3$, because the above compound is stable under the experimental conditions.

Like the aryl derivatives, aliphatic organomagnesium compounds react with transition metal salts apparently with formation of unstable organometallic compounds. It has been shown[20] that, when EtMgBr is treated in THF with palladium(II), copper(II), and copper(I) salts, the ratio of the products formed (ethane and ethylene) is close to unity. On treatment with iron(II), iron(III), cobalt(II), nickel(II), and manganese(II) salts, the ethane : ethylene ratio varies in the range 2–5,[20,21] but in the presence of styrene the yields of ethane and ethylene become identical and the yield of butane increases. According to the authors[20], styrene plays the role of a π-ligand and stabilises the organometallic intermediate; this reduces the probability of the homolytic decomposition, as a result of which the reaction proceeds via a bimolecular mechanism.

In the reaction involving the oxidation of two organomagnesium compounds (RmgX and R'MgX) containing a β-hydrogen atom the yield of the cross-coupling products is appreciable only for copper and silver salts, while in the remaining instances disproportionation products are formed. It is of interest to note that the ratio of alkanes and alkenes formed from RMgX depends on the nature of the R'MgX. Thus, in the interaction of ethyl- and n-propyl-magnesium bromides with palladium chloride, the ratio $C_2H_4/C_2H_6 = C_3H_6/C_3H_8 = 0.9$, while in the reaction of ethyl- and isopropyl-magnesium bromides $C_2H_4/C_2H_6 = 0.4$ and $C_3H_6/C_3H_8 = 2.6$, i.e. the alkane is formed mainly from the ethyl group, while the olefin is formed from the propyl group. An analogous behaviour has been observed for other transition metal salts, but the differences between the ratios of products are not so significant.

Two possible mechanisms of the formation of alkanes and alkenes in these reactions were considered[20]:

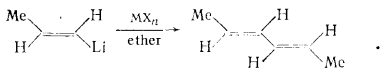
(1) the hydride mechanism[21]:

$$RCH_2CH_2M \rightarrow RCH{=}CH_2 + MH \quad ,$$
$$RCH_2CH_2M + MH \rightarrow RCH_2CH_3 + 2M \quad ;$$

(2) the bimolecular mechanism:

$$2RCH_2CH_2M \rightarrow RCH{=}CH_2 + RCH_2CH_3 + 2M \quad .$$

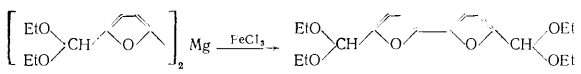
The authors[20] believe that organometallic intermediates formed in many reactions decompose with participation of the



† The yields of the reaction products are calculated taking into account the overall concentration of Grignard reagents.

metal hydride. Reactions of organometallic compounds with copper(I) and silver salts, particularly in the case of secondary and tertiary derivatives, are an exception[22].

One of the distinctive features of vinyl Grignard reagents or organolithium compounds in reactions with transition metal salts is their tendency to form dimerisation products. However, the yield of the latter depends greatly on the nature of the metal salt. Thus the yield of hexa-2,4-diene in the reaction of *trans*-propenyl-lithium in ether varies as follows as a function of the salt[23]:



MX_n	$ZrCl_4$	$CrCl_2$	VCl_3	$PdCl_2$	$FeCl_2$	$CrCl_3 \cdot 3THF$	$MnBr_2$	$CoCl_2$	$(Ph_3P)_2PtCl_2$	MoCl
Yield, %	2	9	24	24	25	47	49	73	115	176

The reaction is to a large extent stereospecific even in those cases when the yield of hexa-2,4-diene is low. The reaction mechanism apparently involves the bimolecular decomposition of vinyl derivatives of metals. According to the authors[23], the high stereospecificity of the reaction is due to the involvement of the π-bond in the stabilisation of the configuration of the transition state:

Biaryls are apparently formed in reactions of aryl Grignard reagents with transition metal salts also on bimolecular decomposition of the intermediates. For example, the fact that the yield of biphenyl reaches 70% in the interaction of PhMgBr with $FeCl_3$ in ether at −80 °C, while chlorobenzene and an appreciable amount of tarry products are formed at the usual temperatures is consistent with this view[24]. One cannot rule out the possibility that at room temperature the intermediate undergoes the usual homolytic decomposition and not bimolecular decomposition and the phenyl radicals formed are oxidised to chlorobenzene. Such a decrease of the relative yield of the dimer with increase of temperature was observed for the reaction of $CoBr_2$ with a neophyl Grignard reagent without a β-hydrogen atom[25].

Organomagnesium derivatives of the furyl series are oxidised by transition metal salts with formation of dimerisation products. Thus treatment of bis(2-diethoxymethyl-5-furyl)-magnesium with iron(III) chloride results in a quantitative yield of bis-2,2′-diethoxymethyl-5,5′-bifuryl[26]:

Organoaluminium compounds react fairly readily with transition metal salts. When triethylaluminium is treated with cobalt(II) chloride in ether, ethane and ethylene are formed in nearly unimolecular proportions (51.5 : 48).[27] At a higher temperature, for example on refluxing in methylcyclohexane, the yield of the alkane increases to 69%, which may be associated with the homolytic decomposition of the organocobalt intermediate. When trimethylaluminium interacts with cobalt(II) acetylacetonate in benzene, methane and ethane are mainly formed (in proportions of 3 : 1) together with a small amount of toluene[28]. The authors[28] believe that toluene is the product of heterolytic substitution in which the intermediate $CH_3Co(acac)_2$ participates, and it is most probably formed on radical methylation of benzene.

The reactions of triethylaluminium with cobalt(III), chromium(III), and iron(III) acetylacetonate complexes have been investigated in fair detail[29,30], because these systems are used to initiate the polymerisation of monomers. The formation of nickel(I) compounds has been detected by EPR in the reaction involving a nickel(II) complex.[31]

Organometallic compounds having a more covalent C–M bond than the compounds of alkali and alkaline earth metal metals also react fairly readily with transition metal salts. For example, Razuvaev and coworkers have shown that, when diphenylmercury is refluxed with iron(III), cobalt(II), manganese(II), and nickel(II) chlorides in dioxan, ethylcellosolve, or pyridine, the product is benzene. Biphenyl was not detected among the products[32,33]. The intermediates formed apparently decompose under the reaction conditions via a free-radical mechanism and the phenyl radicals react with the solvent. At a lower temperature the stability of the intermediates increases and, as already shown for reactions with active organometallic compounds, a bimolecular decomposition mechanism operates in this instance and a biphenyl is formed.

In the reaction of diphenylmercury with highest-valence vanadium compounds ($VOCl_3$ and VCl_4) in cyclohexane, biphenyl is formed[34], i.e. the intermediates decompose via a bimolecular mechanism. This is also indicated by the finding that, for the equimolar reactant ratio, these reactions do not induce the polymerisation of ethylene. However, in the presence of an excess of diphenylmercury relative to the oxidant, polyethylene with a low molecular weight is formed, which the authors[34] believe to be due to the homolytic decomposition of vanadium derivatives containing several phenyl groups.

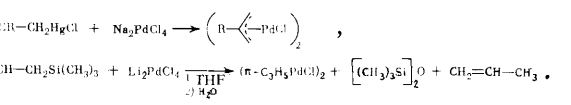
When dibenzylmercury or benzylmercury chloride is oxidised with iron(III), cobalt(II), and copper(II) chlorides, benzyl chloride is formed[35]:

$$PhCH_2HgCl + FeCl_3 \rightarrow PhCH_2Cl + HgCl_2 + FeCl_2 \quad .$$

The authors[35] believe that the reaction has a latent ionic mechanism (free radicals are not formed in the reaction). These two-electron oxidation reactions will be examined in greater detail below.

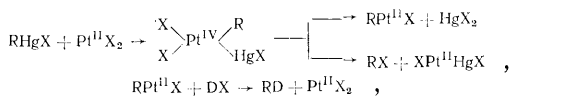
The reactions of di-isopropylmercury with titanium(IV), iron(III), cobalt(II), and tin(IV) chlorides result in the formation of isopropyl radicals, because the acrylonitrile added to the reaction mixture polymerises under these conditions[36]. However, it is difficult to agree with the authors[36] that this is evidence for the one-electron transfer mechanism because the radicals might have been formed as a result of the homolysis of the intermediate formed.

The main product of the reaction of di(*p*-tolyl)mercury with $Pd(OAc)_2$ or of *p*-tolylmercury acetate with $PdCl_2$ is bitolyl[37]. Heterocyclic organomercury compounds react similarly[38]. The formation of biaryls in the reaction of substituted arylmercury salts with palladium(II) chloride proceeds equally well in the presence of both electron-donating and electron-accepting substituents[39]. The reaction was patented as a method of synthesis of biaryls as a result of the oxidative coupling of organomercury salts and was modified in such a way that the palladium(II) salts functioned as the catalyst and the oxidant was $CuCl_2$:[39]



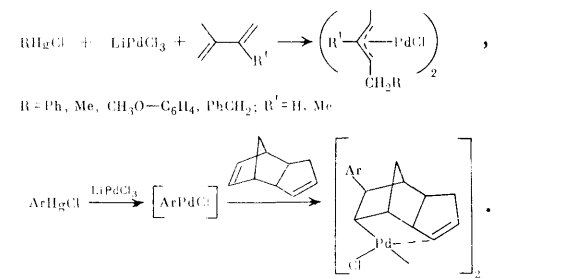
$$p\text{-}MeC_6H_4HgCl \xrightarrow[AcOH]{PdCl_2\text{-}CuCl_2} (p\text{-}MeC_6H_4)_2 \quad .$$

The interaction of arylboronic acids with palladium salts should be included among the oxidative coupling reactions of the type considered[40]. A common feature of all these reactions is that they apparently proceed via a transmetallation stage and subsequent bimolecular decomposition of organopalladium intermediates:

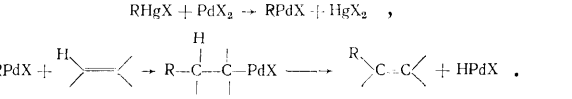


$$RHgX + PdX_2 \rightarrow RPdX + HgX_2 \quad ,$$
$$2RPdX \rightarrow R_2 + PdX_2 + Pd \quad .$$

When the organopalladium intermediate is relatively stable, the reaction stops at the transmetallation stage. For example, when allyl derivatives of metals are treated with palladium(II)



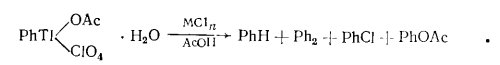
chloride, a stable dimer of π-allylpalladium dichloride is formed[41,42]:



On the other hand, if the palladium intermediate is unstable, its formation can be inferred from the products formed following the addition of special reagents or on reaction with the solvent. For example, it has been shown that[43] the protolysis of alkylsilanes is catalysed by palladium(II) and platinum(IV) salts. Transmetallation leads to the formation in the reaction of organometallic intermediates, which undergo protolysis. The formation of platinum intermediates in the reaction of RHgBr (R = Me, Et, or Bu) with K_2PtX_4 (X = Cl or Br) may be postulated analogously[44]. The reaction was carried out in a D_2O–MeCOOD mixture, in which organomercury compounds are stable, but, after the addition of platinum salts, deuterated hydrocarbons and alkyl halides were formed. It has been suggested that the reaction proceeds via an oxidative addition stage:

Olefins are specific agents trapping the unstable organopalladium intermediates. The reaction involving addition to a multiple bond results in the formation of a new organopalladium compound which can be isolated if it is sufficiently stable[45–47]:

The reaction continues in an interesting manner when the organopalladium intermediate is not stabilised by ligands and contains a β-hydrogen atom. The elimination of palladium hydride then results in the formation of a substituted olefin[46]:



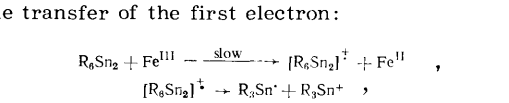
This reaction, discovered by Heck and given his name, is of preparative value as a method of arylating olefins[46,48–50].

Another compound whose reaction can serve as a test for the formation of palladium intermediates is carbon monoxide. For example, alkyl carboxylates and ketones are formed in alcohol in the presence of CO.[51] However, in the presence of a very large excess of the olefin or CO, the bimolecular decomposition of intermediates is not fully suppressed, although the yield of a dimeric product diminishes[51,52].

Apparently there exists also another pathway in the reaction of organometallic compounds with palladium(II) salts in which there is no transmetallation stage. Thus the composition and yield of the products of the reaction of bis(allylpalladiumchloride) with organic derivatives of Group IVB elements depend on the nature of the metal[53]. It has therefore been suggested that the oxidation proceeds in the complex of R_4M with $(\pi\text{-}C_3H_5PdCl)_2$.

In the reaction of the organothallium compound PhTl(OAc).$.ClO_4.H_2O$ with $PdCl_2$, benzene and biphenyl are formed on refluxing in acetic acid[54]. If the same reaction is carried out in the presence of catalytic amounts of other transition metal chlorides (117 °C, 5 h), then chlorobenzene and phenyl acetate are formed together with biphenyl[55]:

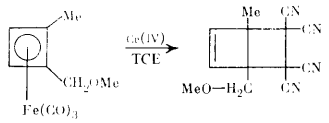
We may note that, with the exception of biphenyl, all these products might be formed in the presence of metal salts either as a result of acetolysis or as a result of the oxidative elimination of thallium. The mechanism of the formation of biphenyl, whose yield depends on the nature of the catalyst employed, is more complex. It is believed[55] that the poor reproducibility of the yield of biphenyl in the reactions involving iron(II), thallium(III), and copper(II) chlorides indicates a radical reaction mechanism. Presumably the intermediate $PhMCl_{n-1}$, formed as a result of transmetallation, undergoes homolytic decomposition and the catalyst is regenerated when MCl_{n-1} is oxidised with tervalent thallium. At the same time one cannot rule out the possibility of the formation of biphenyl also without the involvement of free radicals, as has been suggested, for example, for the reaction of organothallium compounds with $PdCl_2$:[55]



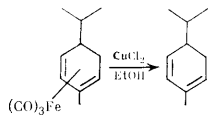
This reaction pathway resembles very closely the bimolecular decomposition of organometallic compounds discussed above and formally constitutes two-electron oxidation.

It is seen from the data presented above that the commonest mechanism of the oxidation of organometallic compounds by a transition metal salt involves consecutive transmetallation stages and thermal decomposition of the intermediates formed. However, there exist processes in which oxidation takes place as a result of intermolecular electron transfer. Such reactions are particularly characteristic of organobimetallic compounds and π-bonded transition metal compounds—for example the oxidation of distannanes R_3SnSnR_3 (R = Me, Bu, or Ph) by compounds of iron(III) perchlorate with phenanthroline[56] or other complex-forming agents[57] in acetonitrile:

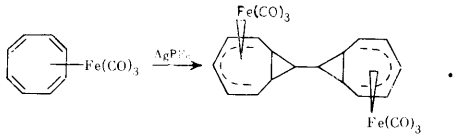
The reaction is of second order overall and of first order with respect to each reactant and the slow stage is apparently the transfer of the first electron:



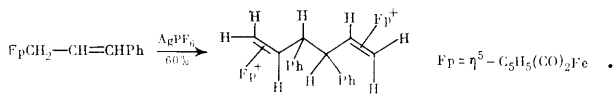
The observed sequence of reactivities



reflects the electron-donating capacity of these compounds relative to the oxidant. The satisfactory linear correlation between $\lg k_2$ and $E^0(Fe^{III}L_n/Fe^{II}L_n)$ with a slope $\alpha = 0.44$ suggests that electron transfer proceeds via an outer-sphere mechanism[56]. Processes such as the interaction of silver



salts with the distannanes R_6Sn_2 [58] and diplumbanes[59] or the oxidation of π-bonded transition metal compounds should apparently be considered within the framework of the oxidation-reduction mechanism. Thus the oxidation of substituted cyclobutadieneiron tricarbonyl by cerium(IV) leads to the formation of a substituted cyclobutadiene, which can be trapped by tetracyanoethylene (TCE):[60]



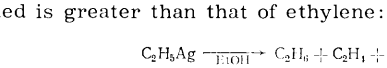
The dienyl complexes of $Fe(CO)_3$ are oxidised similarly by copper(II) chloride[61]:

Whereas the iron atom is oxidised in the above reactions of dienyl complexes of $Fe(CO)_3$, in the interaction of the η^4-cyclo-octatetraenyl complex with silver hexafluorophosphate only the organic ligand is oxidised and a new organometallic compound is formed[62]:

The oxidation of allyl σ-derivatives of cyclopentadienyliron dicarbonyl is the same type of reaction[63]:

We may note that in this case both the organic group and the organometallic fragment are oxidised. The intermediate formation of allyl radicals in this reaction has been confirmed by the finding that the π-olefin cation (Fp^+-π-CH_2=CR^1-CR^2R^3H), which is a product of the reaction of the radical with a solvent, is formed together with the dimer.

III. OXIDATION OF ORGANOMETALLIC COMPOUNDS BY SILVER AND COPPER SALTS



We shall consider the reactions involving the oxidation of organometallic compounds by salts of the copper subgroup metals: Cu, Ag, and Au. These reactions are of interest because many of them, particularly those involving copper(I) salts, are widely used in organic synthesis[63].

1. Reactions of Organometallic Compounds with Univalent Silver Salts

It is well known that the interaction of organometallic compounds with silver salts results in the formation of organosilver compounds which are usually unstable and yield on decomposition the radical coupling products[65]. Thus the reactions of Grignard reagents RMgX (for example, with R = Ar, $PhCH_2$, or Bu) with silver salts lead to the formation of the hydrocarbon R_2, whose yield is frequently quantitative[66,67]. Apart from the coupling product R_2, the reactions of isobutyl- and s-butyl-magnesium bromides results in the formation of a small amount of butene and butane[68]. It has been shown that the reaction of $RPbEt_3$ (R = p-$CF_3C_6H_4$, p-$Me_2NC_6H_4$, PhCH=CH, etc.) involves the cleavage of the bond and the formation of an organosilver compound which then decomposes to R_2.[69] The reactions of benzyl and allyl derivatives of lead result directly in the formation of R_2. The intermediate formation of organosilver compounds cannot be detected in this instance because they are extremely unstable. In the reaction of vinyl derivatives of lead, mono-olefins are obtained together with hydrocarbons[70,71].

Thus the reactions of organometallic compounds with silver salts as a rule begin with transmetallation. This view gives rise to no doubts at the present time and the problem therefore consists in establishing the mechanism of the thermal decomposition of the organosilver compounds. Numerous investigations in this field have shown that RAg can decompose via a bimolecular mechanism, i.e. without the involvement of free radicals[22,72,73], and via a free-radical mechanism[69,74–77]. The relative contributions of these reaction pathways are in general determined both by the nature of the group R and by the reaction conditions. We shall consider the problem in relation to the thermal decomposition reactions of alkyl, vinyl, and aryl derivatives of silver.

The radical mechanism of the thermal decomposition of organosilver compounds was first proposed for ethylsilver[78] and was subsequently confirmed as a result of a study of the kinetics of this reaction[74]. The main evidence in support of the formation of radicals is that the amount of ethane formed is greater than that of ethylene:

The ratios of the yields of C_2H_6, C_2H_4, and C_4H_{10} are 2.5 : 0.38 : 0.37.[74] There is no doubt that ethane is a product of the reaction of the ethyl radical with the solvent#. An analogous behaviour has been observed in the reaction of Et_4Pb with $AgNO_3$ in which ethylsilver is obtained as an intermediate, while ethane, ethylene, and butane are formed in ratios of 53.2 : 9.9 : 36.2.[72]

At the same time, there are data which do not agree with the free-radical mechanism of these reactions. For example, the reaction of tetramethyl-lead with $AgNO_3$ results in the formation of ethane; methane has not been detected among the reaction products[78]. Furthermore, styrene, methyl methacrylate, or acrylonitrile added to the reaction mixture do not polymerise under the reaction conditions[76].

A widely used procedure, with the aid of which investigators have frequently attempted to determine the mechanism of the decomposition of organosilver compounds, consists in carrying out simultaneously the reactions of the silver salt with two different Grignard reagents and subsequent analysis of the reaction products. Thus the interaction of silver bromide in THF with ethylmagnesium bromide mixed with other alkylmagnesium bromides results in the formation of the following coupling products[79]:

R	n-C_4H_{10}, %	EtR, %	R_2, %	Σ, %
Et	46	46	--	92
Pr	47	37	12	96
iso-Pr	41	28	10	79
t-Bu	36	5	19	60

The data presented show that in the case of normal alkylmagnesium bromides the overall yield of coupling products is also quantitative. The amount is somewhat smaller in the

It has been shown that the radical abstracts hydrogen from the hydroxy-group of the alcohol but in the decomposition of methylsilver more hydrogen is abstracted from the α-CH bond[77].

reaction with Grignard reagents having a branched group R, which is apparently associated with the formation of alkanes and alkenes in side reactions. It is also striking that, with increase of the degree of branching in the group R in the Grignard reagent, the yield of cross-coupling products diminishes from 46% to 5%, while the yield of homocoupling products R_2 not only does not diminish but actually increases. These data are difficult to account for from the standpoint of the free-radical mechanism.

The most convincing evidence for the possibility of a bimolecular mechanism of the decomposition of alkyl derivatives of silver has been obtained by Clinton and Kochi[80], who investigated the reaction of tetraethyl-lead with silver triflate in THF. It was found that the ratio of the ethane, ethylene, and butane formed in this instance depends on the concentration of the silver salt and that in the presence of oxygen the yield of ethane is significantly reduced, while that of butane remains almost unaltered. Evidently ethane is formed predominantly via a radical pathway, while butane results from the bimolecular reaction

$$2EtAg \rightarrow BuH + 2Ag \quad .$$

In contrast to free alkyl derivatives of silver, the tributylphosphine complex of n-butylsilver is more stable and decomposes in ether with formation of octane (93%) and insignificant amounts of butane (5%) and butene (2%).[22] According to the authors[22], the C–Ag bond dissociates in this instance with simultaneous formation of a new C–C bond, while the contribution of the radical reaction pathway is insignificant. Furthermore, silver(I) hydride is apparently not involved in the formation of the disproportionation product, because the yield of butane is higher than that of butene. However, one cannot rule out the possibility that the thermal decomposition of s-BuAg(PBu_3) does in fact proceed via a stage involving the formation of AgH, since all the products (butane, butene, and octane) are obtained in comparable amounts and, furthermore, the amount of butene is greater than that of butane:

$$\underset{29\%}{\text{s-BuAg}(PBu_3)} \rightarrow \underset{35\%}{BuH} + \underset{30\%}{C_4H_8} + C_8H_{18} + Ag + PBu_3 \quad ,$$

$$RAg(PBu_3) \rightarrow R(-H) + HAg(PBu_3) \quad ,$$

$$RAg(PBu_3) + HAg(PBu_3) \rightarrow RH + Ag + PBu_3 \quad ,$$

$$2RAg(PBu_3) \rightarrow R_2 + Ag + PBu_3 \quad ,$$

$$2HAg(PBu_3) \rightarrow H_2 + Ag + PBu_3 \quad .$$

It is seen from the data presented that the alkyl derivatives of silver can decompose via both radical and bimolecular mechanisms. Vinyl organosilver compounds decompose similarly. For example, the interaction of triethylisobutenyl-lead with silver nitrate at very low temperatures yields a relatively unstable isobutenyl derivative of silver. At temperatures above −20 °C isobutene is formed preferentially together with a small amount of 2,5-dimethylhexa-2,4-diene (10%).[70] The detection of the olefin among the reaction products undoubtedly demonstrates the formation of free radicals in the decomposition of the corresponding silver compound. The author[70] proposed the following chain mechanism of the process with participation of the ethoxy-radical:

$$Et_3PbCH{=}CMe_2 \xrightarrow{AgX} Me_2C{=}CHAg \quad ,$$

$$Me_2C{=}CHAg \rightarrow Me_2C{=}CH^{\cdot} + Ag \quad ,$$

$$2Me_2C{=}CH^{\cdot} \rightarrow Me_2C{=}CH{-}CH{=}CMe_2 \quad ,$$

$$Me_2C{=}CH^{\cdot} + EtOH \rightarrow Me_2C{=}CH_2 + EtO^{\cdot} \quad ,$$

$$Et_3PbCH{=}CMe_2 + EtO^{\cdot} \rightarrow Et_3PbOEt + Me_2C{=}CH^{\cdot} \quad .$$

An analogous mechanism has been proposed for the reaction of tetravinyl-lead with silver nitrate[71§]. The hypothesis of the radical chain mechanism is based on the finding that, with decrease of the concentration of $AgNO_3$, the yield of isobutene increases[70]. However, Tamura and Kochi[79] showed that the metallic silver formed in the decomposition process can be oxidised by the nitrate ion and the effect of the $AgNO_3$ concentration observed by Glockling[70] might be partly due to this reaction. Thus the decomposition of vinylsilver is a radical process.

On the other hand, the tributylphosphine complexes of 1-propenyl- and 2-butenyl-silver decompose via the bimolecular mechanism, judging from stereochemical data, since the only reaction product, resulting from the coupling of the radicals, is formed with retention of the configuration of the sp^2-hybridised carbon atom[82].

We shall consider the decomposition reactions of aromatic derivatives of silver primarily in order to demonstrate the possibility of the occurrence of the radical and bimolecular mechanisms for this class of compounds and to discuss certain problems concerning the nature of the bimolecular mechanism.

It has been shown that in the joint decomposition of phenyl- and tolyl-silver in pyridine at 50–80 °C, the cross-coupling product is formed in a statistical proportion and that the addition of quinone diminishes appreciably the yield of not only ArH but also Ar_2.[75] There is no doubt that the decomposition of ArHg results in the formation of free radicals in this instance, apparently owing to the high reaction temperature.

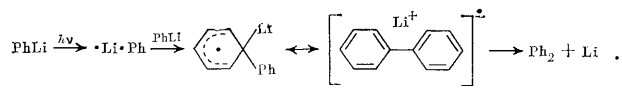
In contrast to this, the reaction of silver bromide with a mixture of phenyl- and anisyl-magnesium bromides in ether leads to proportions of products which differ from the statistical distribution[83]:

$$\underset{}{PhMgBr} + \underset{}{p\text{-}MeOC_6H_4MgBr} \xrightarrow{AgBr} \underset{22\%}{Ph_2} + \underset{18.2\%}{PhC_6H_4OMe} + \underset{4.7\%}{(MeOC_6H_4)_2} \quad .$$

Furthermore, the relative yields of products depend on the concentration of the Grignard reagent. The authors[83] believe that ArAg decomposes via a radical pathway, but we think that the data presented actually support the bimolecular reaction mechanism.

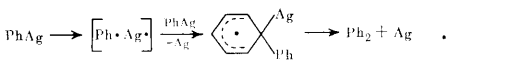
The reactions of silver nitrate with tetraphenyl derivatives of tin and lead merit special attention[73]. Whereas in the first reaction the main product is benzene (80.6%) with only 5.2% of biphenyl, in the second case the main product is biphenyl (70.2%) and only trace amounts of benzene are produced. The observed differences between the compositions of the reaction products are undoubtedly associated with the different conditions in the decomposition of phenylsilver. Presumably the steady-state concentration of phenylsilver in the reaction of Ph_4Pb, which is much faster than the reaction of Ph_4Sn,[73] is high and the bimolecular decomposition of PhAg is therefore more probable. On the other hand, in the reaction of Ph_4Sn with $AgNO_3$ phenylsilver decomposes mainly via a radical mechanism and benzene is formed¶.

We believe that benzene can be formed also as a result of the catalytic decomposition of PhAg by silver nitrate. This view is confirmed indirectly by the finding that the complex



---

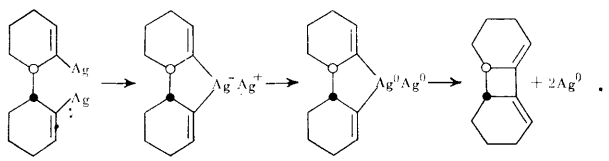
§ A radical chain mechanism has also been proposed for the decomposition of RMe_2SiCH_2Ag (R = Me or Ph).[81]



¶ The formation of benzene in this reaction can hardly be attributed to the radical chain mechanism considered above for vinyl derivatives of lead, because organotin compounds show a smaller tendency, compared with lead compounds, to enter into S_H2 reactions[84].

$5PhAg.2AgNO_3$ decomposes rapidly at room temperature, while pure phenylsilver is stable even in the course of a whole day[85]. Generally speaking, this is by no means a common phenomenon where the metal salt initiates the decomposition of an organic derivative of the same metal, particularly when the latter is in the same oxidation state. An attempt may be made to account for this finding by taking into account certain characteristics of silver compounds. The effect of silver nitrates in this reaction can be twofold: firstly, the Ag^+ cation is in principle capable of oxidising PhAg with formation of phenyl radicals, whereupon the reaction product is benzene, and, secondly, silver nitrate can prevent the formation of dimeric (polymeric) associated species, which are known for organosilver compounds[65]. We draw special attention to the possible role of the formation of associated species, because the latter can influence in a most unusual manner the pathway leading to the decomposition of organometallic compounds. On the other hand, the formation of associated species can increase the stability of the organosilver compound irrespective of decomposition. On the other hand, the decomposition of the associated species should lead to the formation of a dimer R_2, which is usually explained from the standpoint of the bimolecular mechanism.

Van Tamelen's mechanism, proposed for the photochemical decomposition of phenyl-lithium in ether[86], can involve an unusual mode of bimolecular decomposition of PhAg:



At first sight this photochemical reaction has little in common with the decomposition of PhAg, but these processes have the common feature that free radicals are not formed and the only product is biphenyl. By analogy with van Tamelen's mechanism, one can put forward the following mechanism for the decomposition of phenylsilver:

Evidently the formation of dimers can favour this course of reaction.

Another model for the decomposition of organosilver compounds without the involvement of free radicals has been considered by Moore et al.[87] These workers suggested that the intramolecular coupling products are formed in the decomposition of *d,l*-2,2′-disilver-3,3-bicyclohexenyl as a result of the following oxidation-reduction processes†:

In essence, this mechanism postulates the formation of intermediates whose structure is analogous to that of the organic cuprates R_2CuLi.

In conclusion of this section on the action of silver salts on organometallic compounds we may note that certain organic derivatives of non-metallic elements, for example, boron[88,89], react analogously. The reaction yields the corresponding silver compounds whose decomposition leads to the formation of coupling products.

Gold(I) salts have analogous chemical properties to those of silver salts; for example, their reaction with organoboron compounds results in the formation of the dimerisation products R_2 [89,90]

2. Reactions of Organometallic Compounds with Copper Salts

The reactions of organometallic compounds of the type RM with copper salts are undoubtedly more common and have been more thoroughly investigated than the reactions with silver salts. This is not surprising bearing in mind not only the wide variety of the products formed but also the definite synthetic value of these reactions. Depending on the oxidation state of copper, the hydrocarbon R_2 or RH and R(-H), as well as two-electron oxidation products, for example, organic halides in reactions with copper(II) halides, can be formed.

Leaving aside for the moment the details of the mechanisms of the interaction of organometallic compounds with copper salts, we may note that all these reactions usually proceed via a transmetallation stage. However, the intermediates formed are relatively stable only in the case of copper(I) compounds and they can be sometimes actually isolated at the usual temperature[85,91,92]. On the other hand, if the intermediates are very unstable, and this happens much more frequently, then their formation can sometimes be confirmed indirectly[93]. For example, Clinton and Kochi[94] established that the acetolysis of tetraethyl-lead is catalysed by copper(I) salts. The study of this phenomenon in a deuterated solvent showed that the kinetic isotope effect (KIE) in the reaction differs from that in the non-catalysed reaction (in the absence of copper salts, ethane-d_1 is formed six times more slowly than in the catalysed reaction). The results demonstrate convincingly the intermediate formation in the catalysed reaction of ethylcopper, which undergoes protolysis.

The oxidation of organometallic compounds by copper(II) salts proceeds similarly via a transmetallation stage. Although the corresponding intermediates have never been obtained, this view has now become firmly established. The mechanism of oxidation via a one-electron transfer stage appears unlikely in view of the low oxidising capacity of copper(II) salts[95] (admittedly the oxidation of carbanions may prove to be an exception to this rule). This can be illustrated fairly clearly by comparing the reactions involving the oxidation of tetraalkyl-lead by copper(II) chloride and the anion $IrCl_6^{2-}$, which is a one-electron oxidant:

$$R_4Pb + 2CuCl_2 \rightarrow RCl + R_3PbCl + 2CuCl \quad ,$$

$$R_4Pb + 2IrCl_6^{2-} \rightarrow RCl + R_3PbCl + 2IrCl_5^{2-} \quad .$$

The same product, namely alkyl chloride, is formed in both processes but there are significant differences between the reaction kinetics[96,97]. Whereas in the oxidation of tetraethyl-lead by $IrCl_6^{2-}$ the rate of reaction exceeds by a factor greater than 1000 the rate of oxidation of Me_4Pb, the opposite relation is observed in the reaction with $CuCl_2$—Me_4Pb proved to be 44 times more active than Et_4Pb. There is no doubt that these differences are due to the high steric hindrance by the bulky Et_3Pb group in the transmetallation reaction. Furthermore, in the oxidation of a mixed compound of the type $Et_{4-n}Me_nPb$ (n = 1–3) by $IrCl_6^{2-}$, the ethyl group shows a greater tendency to be split off, and not the methyl group as usually happens in electrophilic substitution.

† The open and filled circles denote carbon atoms having different configurations.

Combined analysis of the results of studies of the reactions of copper salts with organometallic compounds permits the differentiation of three main problems: (1) the mechanism of the formation and decomposition of organic derivatives of copper(I); (2) the mechanism of the reaction of organometallic compounds with copper(II) salts; (3) the possible pathways leads to the formation of the products of the two-electron oxidation of organometallic compounds by copper salts. All these problems are considered in subsequent sections.

3. Thermal Decomposition of Organocopper Compounds

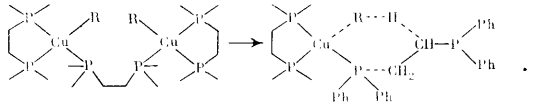
Numerous studies on the thermal decomposition of organocopper compounds have been published recently. In these reactions the organic derivatives of copper(I) partly resemble the organosilver compounds, although, depending on the nature of the organic group in the RCu or RAg molecules and the reaction conditions, certain differences are also observed. Thus, in the thermal decomposition of alkylcopper, alkanes and alkenes are formed in maximum amounts rather than the coupling products R_2 as was the case for the silver compound. Alkanes and alkenes are virtually the only decomposition products of alkylcopper stabilised by trialkylphosphines and their ratio may be the same[30]. For example, butane and but-1-ene in proportions of 49 : 51, hydrogen (10%), and less than 0.1% of octane are formed in the thermal decomposition of the tributylphosphine complexes of butylcopper in ether[21,82]. The decomposition of 5-hexenylcopper-(I) in a complex with tributylphosphine in ether gives rise to 44% of hex-1-ene, 52% of hexa-1,5-diene, and only 3.5% of cyclic hydrocarbons[81]. In this case the reaction does not have a radical mechanism, since it is known that the cyclisation of hexenyl radicals is faster than the abstraction of hydrogen from the solvent[98,99]. Furthermore, it has been shown that the rate of decomposition of alkylcopper is not influenced by the addition of "radical trapping agents" such as styrene[21,82,100,101]. To explain the results, a mechanism has been proposed for the thermal decomposition with participation of copper hydride[21,100]:

$$\text{a. } \mathrm{BuCu \cdot P(n\text{-}Bu)_3} + \mathrm{CH_2{=}CH{-}CH_2{-}CH_2{-}CH{=}CH_2} \rightarrow \mathrm{HCu \cdot P(n\text{-}Bu)_3} + \text{cyclic hydrocarbons},$$

$$\text{b. } \mathrm{BuCu \cdot P(n\text{-}Bu)_3} + \mathrm{HCu \cdot P(n\text{-}Bu)_3} \rightarrow \mathrm{BuH} + 2\mathrm{Cu} + 2\mathrm{P(n\text{-}Bu)_3}.$$

Analysis of the products formed in the decomposition of a mixture of RCu and R'Cu (R = Et, and R' = Pr or iso-Pr) showed that there are two independent decomposition pathways:

$$\mathrm{EtCu + PrCu \text{ or iso-PrCu} \rightarrow} \begin{cases} \xrightarrow{a} \mathrm{C_2H_6 + C_3H_6 + 2Cu}, \\ \xrightarrow{b} \mathrm{C_2H_4 + C_3H_8 + 2Cu}. \end{cases}$$



Pathway *a* proves to be dominant in the case of PrCu, while pathway *b* is dominant for iso-PrCu, which has been explained[78] by the easier reduction of secondary derivatives by copper hydride compared with the primary derivatives.

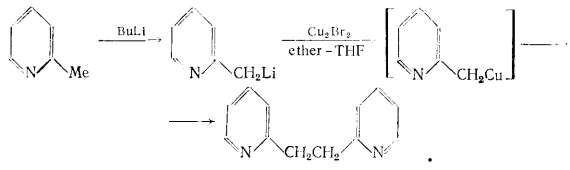
There exists the view that copper hydride is formed in the thermal decomposition of alkylcopper as a result of the β-elimination of the hydride ion[21], similarly to the formation of hydrides of other transition metals on decomposition of unstable organometallic compounds[102]. However, it is difficult to explain from this standpoint why the olefin is formed mainly from the ethyl fragment in the decomposition of a mixture of ethylcopper and isopropylcopper[78], since the hydride ion is usually abstracted from the carbon atom with the smallest number of hydrogen atoms. We believe that the thermal decomposition reactions are in reality of the radical type but occur within the complex. In fact, if the decomposition takes place within a binuclear complex formed in the solution, for example, on elimination of a phosphine ligand, then the heterolysis of the C–C bond will occur more readily in the case of isopropylcopper; in its turn the radical formed abstracts a β-hydrogen from another organic group#.

One may point to a certain analogy between the reaction mechanism discussed above and the mechanism proposed by Miyashita and Yamamoto[104], who investigated the thermal decomposition of the 1,2-bis(diphenylphosphino)ethane complex of RCu (R = Me, Et, Pr, or iso-Bu). It was found that this reaction does not proceed entirely in the usual manner—biphenylvinylphosphine is formed together with an alkane:

$$(\mathrm{RCu})_2(\mathrm{dppe})_3 \xrightarrow{\mathrm{THF}} \mathrm{Ph_2PCu(dppe)} + \mathrm{RH} + \mathrm{Ph_2PCH{=}CH_2} + \mathrm{RCu(dppe)};$$
$$\mathrm{dppe} = \mathrm{Ph_2PCH_2CH_2PPh_2}.$$

The authors[104] believe that an intramolecular reaction with a phosphine ligand in which there is a concerted transfer of hydrogen and the cleavage of a carbon–phosphorus bond, takes place in this instance:

An interesting feature of the decomposition reaction of alkylcopper and possibly of other copper(I) derivatives is that the process can be catalysed by metals and not only by copper and silver but also by palladium[100]. Thus the decomposition of alkylcopper is an autocatalytic process and the induction period observed in this reaction diminishes following the addition of metals which can be arranged in the following sequence in terms of their activities: Cu > Ag > Pd. The formation of the paramagnetic dinuclear organocopper intermediate $[\mathrm{EtCu^I.Cu^0}]$ was demonstrated by EPR in the decomposition of ethylcopper in THF. The authors[100] proposed the following mechanism of the catalytic process involving the species:

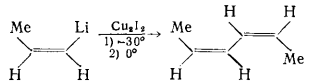


$$\mathrm{RCu^I + Cu^0} \rightarrow [\mathrm{RCu^ICu^0}],$$

$$[\mathrm{RCu^ICu^0}] \xrightarrow{\text{fast}} \mathrm{R(-H) + Cu^0 + CuH},$$

$$\mathrm{RCu^I + CuH} \rightarrow \mathrm{RH + 2Cu^0 \text{ etc.}}$$

However, we believe that the catalytic decomposition of alkylcopper can also occur on the surface of the metal. The copper atoms formed in the reaction are incorporated in the metal lattice and the resulting energy gain, equal to the heat of condensation, is the decisive factor in this catalytic reaction.



Benzyl derivatives of copper(I) are particularly unstable and readily decompose during preparation with formation of the dimer R_2. This reaction is used, for example, in the dehydrodimerisation of picolines[105,106]:

Since benzyl radicals usually dimerise and do not abstract hydrogen from the solvent, the formation of R_2 in the decomposition of benzyl derivatives of copper(I) is no longer a criterion of a bimolecular reaction mechanism. The homolytic dissociation of a carbon–metal bond can occur in this reaction with equal success.

The radical abstraction of a β-hydrogen atom is known to occur, for example, in the reaction of organomercury compounds with $CCl_3^{\cdot}$.[103]

Dienes are formed in the decomposition of vinyl derivatives of copper as in the case of silver compounds. The reaction is more stereospecific both in the presence and in the absence of tributylphosphine[23,82,107]. This is usually regarded as an argument against a radical reaction pathway:

Judging from the formation of the hydrocarbon ArH, the decomposition of the aryl derivatives of copper ArCu takes place in many instances via a radical mechanism[75]. The thermal decomposition of 2-dimethylaminophenylcopper in dimethylformamide (DMF) apparently takes place in this way, since *N*,*N*-dimethylaniline is formed in this reaction together with 2,2′-bis(dimethylamino)diphenyl (40%).[108] Even in the complex with 1,2-bis(diphenylphosphino)ethane this compound decomposes with participation of radicals and diphenylvinylphosphine is formed in addition to *N*,*N*-dimethylaniline [109] (see the analogous reaction for alkyl compounds of copper[104]).

At the same time there exist data showing that aryl derivatives of copper(I) can decompose without the participation of free radicals[111,112]. This applies particularly to the decomposition of various cluster compounds. Thus the decomposition of the octanuclear cluster $(m\text{-}CF_3C_6H_4)_8Cu_8$ yields biaryl and a cluster assumed to be of the type R_4Cu_8.[113,114] However, this cluster apparently decomposes via a radical mechanism, since trifluoromethylbenzene is then formed[114].

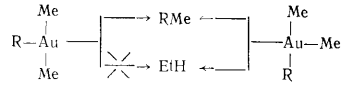
The dimer 2,2′-bis(dimethylamino)biphenyl is formed in a yield exceeding 90% on decomposition of $(2\text{-}Me_2NC_6H_4)_4Cu_6Cl_2$, while the decomposition of the corresponding non-cluster compound yields mainly *N*,*N*-dimethylaniline[108]. The steric proximity of the aryl group in this hexanuclear cluster promotes this reaction pathway[115]. The relative positions of the groups Ar and R (Ar = $2\text{-}Me_2NC_6H_4$, R = PhC≡C) determine similarly the decomposition of the cluster $Ar_4R_2Cu_6$. The only product of this reaction is ArR and there are not even traces of R_2 and Ar_2.[116,117]

The data presented show that the formation of cluster intermediates is important for the decomposition of organocopper compounds with formation of radical coupling products. The finding that the yield of 1-phenyl-1-propyne reaches 75% in the joint decomposition of methyl- and phenylethyl-copper in ether[118], i.e. greatly exceeds the yield expected for statistical coupling of the radicals, can be explained from this standpoint[1].

IV. THERMAL DECOMPOSITION OF ORGANIC COMPOUNDS OF OTHER METALS

To complete the overall picture of the state of research into the thermal decomposition of organic derivatives of metals, particularly those of the copper subgroup, we shall consider data for the decomposition of compounds of other transition metals. The decomposition of alkylgold(I) stabilised by triphenylphosphine, in both the solid phase and in solution in decalin at a temperature close to 100 °C, leads to the formation of products of the radical dimerisation and disproportionation reactions[119]. Thus ethane and a very small amount of methane are formed from methylgold, butane (90%), ethane (1.4%), and ethylene (0.7%) are formed from ethylgold, propane (28%), propene (34%), and only traces of 2,3-dimethylbutane are formed from isopropylgold, while t-butylgold gives rise to isobutane (13%), isobutene (48%), and a certain amount of unidentified products.

Thus it can be seen that the thermal decomposition reactions of primary derivatives of alkylgold resemble those of the silver derivatives, while the reactions of the secondary and tertiary derivatives take place analogously to the decomposition of the copper compounds. The study of the kinetics of the decomposition of the triphenylphosphine complex of methylgold in decalin showed that the reaction is of first order with respect to $MeAu.PPh_3$. This suggested that the rate-determining stage is the elimination of the triphenylphosphine ligand:



$$MeAu \cdot L \xrightarrow{k_1} MeAu + L \ ,$$
$$MeAu \cdot L + MeAu \rightarrow EtH + 2Au + L \ .$$

In contrast to alkyl derivatives of gold(I), the thermal decomposition of trialkylgold takes place as reductive elimination[120,121], for which various mechanisms have been proposed depending on the nature of the solvent:

$$Me_3AuL \rightarrow EtH + MeAuL \ .$$

The study of the products of the thermolysis of equimolar mixtures of Me_3AuPPh_3 and $(CD_3)_3AuPPh_3$ showed that at 80 °C in decalin and chlorobenzene the decomposition reaction is unimolecular, because a statistical average distribution of products is obtained ($C_2H_6 : CH_3CD_3 : C_2D_6 = 1 : 2 : 1$). On the other hand, in polar solvents [dimethyl sulphoxide (DMSO) and DMF] at a low concentration of trialkylgold the reaction proceeds almost exclusively via an intramolecular mechanism and the yield of the cross-coupling product reaches only 5% in this instance. The results of the study of the decomposition reaction of $CD_3Me_2AuPPh_3$ also agree with this conclusion; in chlorobenzene the yields of EtH, $MeCD_3$, and C_2D_6 are in the proportions 49 : 46 : 6, while in DMSO these ratios are 25 : 75 : 0.

It has been shown for *cis*- and *trans*-RMe_2AuPPh_3 (R = Et or Pr)[121] that the yield of ethane in the decomposition of the *cis*-isomer in decalin greatly exceeds that in the case of the *trans*-isomer, which agrees with an intramolecular process occurring as stereospecific *cis*-elimination:

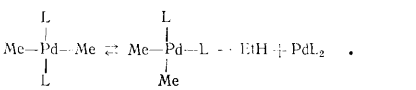
In contrast to this, in the decomposition of *cis*- and *trans*-$CD_3Me_2AuPPh_3$ in decalin, the composition of the products is independent of the isomer undergoing decomposition which indicates the intermolecular nature of the reaction. Thus the mechanism of the thermal decomposition of trialkylgold is largely determined by the nature of not only the solvent but also of the alkyl group.

The phosphine complexes of dialkylgold salts decompose similarly—via intermolecular reductive elimination[122]:

$$[R_2Au(PPh_3)_2]O_3SCF_3 \rightarrow R_2 + Au(PPh_3)_2O_3SCF_3 \ ,$$
$$R = Me, Et, Bu \ .$$

A characteristic feature of the majority of the thermal decomposition reactions of organometallic compounds of transition metals is inhibition of the process following the addition of complex-forming agents. For example, it is known that alkylcopper is absolutely unstable at room temperature, while some of its phosphine complexes are fairly stable under these conditions[104]. The rate of the decomposition reaction of phosphine complexes of trialkylgold[121] and salts of dialkylgold[122] examined above diminishes appreciably after the addition of substituted phosphines. An analogous effect of added phosphines is manifested in the reductive

elimination of triethylphosphine complexes of methylarylnickel:[123]



$$(Et_3P)_2NiArMe \rightarrow ArMe + (Et_3P)_2Ni \quad .$$

It is usually assumed that the addition of complex-forming agents prevents the formation of coordination-unsaturated intermediates, while the electronic structure favours the decomposition reaction. This has been confirmed, for example, in a thermographic study[124] of the decomposition of the complexes C_6F_5CoL (L = Schiff base) with various ligands Q (Q = H_2O, NH_3, Py, etc.). It was shown that the formation of perfluorobiphenyl in this reaction is always preceded by the ligand elimination stage, i.e. the process takes place in stages:

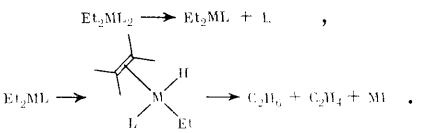
$$RCoLQ \rightarrow RCoL + Q \quad ,$$
$$RCoL \rightarrow CoL + 1/2R_2 \quad .$$

For some ligands, the elimination of Q takes place at temperatures lower than that required for further decomposition of RCoL. Other ligands are so strongly coordinated to the metal atom that their elimination requires a higher temperature at which both reactions—the elimination of Q and the formation of R_2—take place simultaneously.

Another explanation of the influence of added ligands on the decomposition of metal complexes has been given in a study[125] of the intramolecular decomposition of phosphine complexes of dimethylpalladium leading to the formation of ethane. It was found that this reaction occurs only for *cis*-complexes, while the decomposition of *trans*-complexes proceeds via the *trans–cis* isomerisation stage. The latter process is facilitated in the presence of polar solvents and added ligands:

Thus the influence of added ligands on the decomposition of metal complexes may be associated with the acceleration of the *trans–cis* isomerisation and also with the increase of the concentration of active species having the *cis*-configuration.

However, processes are known in which added complex-forming agents facilitate the thermal decomposition of complexes already having the *cis*-configuration. Thus the intramolecular reductive elimination reaction of *cis*-$PtAr_2L_2$ in toluene at 60 °C is accelerated in the presence of free triarylphosphine[126]:



$$PtAr_2L_2 \rightarrow Ar_2 + PtL_2 \quad ,$$
Ar = Ph, p-MeC_6H_4; L = PPh_3, (p-$MeC_6H_4)_3P$.

The kinetics of this reaction have been studied in very great detail, but the mechanism of the influence of triphenylphosphine on the rate of the process remains unelucidated.

We shall consider a further two types of thermal decomposition reactions of organic compounds of transition metals. One of these consists of reductive elimination reactions leading to the formation of alkanes and alkenes, an example of which is provided by the decomposition of dialkyl complexes of cobalt(III),[127] palladium(II),[128] platinum(II),[129] and iron(II):[130,131]

$$MR_2L_n \rightarrow RH + R(-H) + ML_n \quad .$$

Studies of the kinetics of the decomposition of $CoR_2(acac).(PR'_3)_2$,[127] $Et_2Pd(PR'_3)_2$,[128] and $Et_2Pt(PEt_3)_2$ [129] showed that the reactions are of first kinetic order, i.e. are intramolecular. On the basis of these results as well as data for the influence of the nature of the group R on the thermal stability of organometallic compounds, a reaction mechanism has been proposed, according to which the decomposition of the compounds is preceded by the ligand displacement stage and the formation of a metal hydride complex:

Judging from the values of the kinetic isotope effect in the reactions of R_2ML_n with R = Et and CD_3CH_2, any of these stages can be the rate-determining step[129].

Another reaction which has attracted the attention of investigators recently is the thermal decomposition of organometallic compounds involving the transfer of an α-hydrogen atom[132,133]. It was shown, for example, that the decomposition of pentabenzyltantalum proceeds precisely in this manner[134]:

$$(PhCH_2)_5Ta \rightarrow PhCH_3 + (PhCH{=})_5Ta_2 \quad .$$

This reaction is apparently intramolecular and takes place without the formation of free radicals, because α-deuterotoluene is not formed when the decomposition of $(PhCH_2)_5Ta$ is carried out in C_6D_6 and the reaction is not accelerated in the presence of radical initiators.

V. ONE-ELECTRON OXIDATION OF ORGANOMETALLIC COMPOUNDS BY COPPER(II) SALTS

The mechanism of the reactions of organometallic compounds with copper(II) salts differs significantly from the mechanism of the reactions with copper(I) salts. Bawn and Whitby[76] investigated the reaction of tetramethyl-lead with coppper(II) nitrate in ethanol and showed that it results in the formation of ethane and methane in proportions of 1 : 0.47. They put forward the hypothesis that the reaction proceeds in stages. The first stage is of the oxidation-reduction type and leads to the formation of radicals and a copper(I) salt:

$$Cu^{2+} + Me_4Pb \rightarrow Cu^+ + Me_3Pb^+ + Me^\cdot \quad ,$$
$$2Me^\cdot \rightarrow EtH \quad .$$

In the second stage the interaction of $(CH_3)_4Pb$ with Cu^+ leads to the formation of an organocopper compound which undergoes thermal decomposition:

$$Cu^+ + Me_4Pb \rightarrow MeCu + Me_3Pb^+ \quad ,$$
$$MeCu \xrightarrow{EtOH} MeH + Cu^0 \quad .$$

An analogous reaction mechanism was subsequently examined for the interaction of organolithium compounds with copper(II) chloride[135].

Despite the fact that subsequent studies showed that the mechanism of Bawn and Whitby is largely correct, in its initial version[76], proposed for the methyl system, there was a clear contradiction. In fact, in the first stage of this mechanism[76] methyl radicals dimerise, while in the second stage they abstract hydrogen from the solvent (although it would seem that this process should be the only one occurring if the reaction does indeed involve the formation of free methyl radicals). Furthermore, it is known that the decomposition of alkyl derivatives of copper(I), even those containing a β-hydrogen atom, results in the formation of a considerable amount of a radical coupling product (see Section III), whereas according to the mechanism of Bawn and Whitby only methane is obtained at this stage.

Studies[136,137] which established that the butane formed in the reaction of tetraethyl-lead with copper(II) nitrate is obtained on decomposition of ethylcopper are remarkable in

this connection. This conclusion is based on the finding that butane is not formed in the presence of *p*-dimethylaminobenzylidenerhodanine (A) [which forms complexes with copper(I) salts], while in the absence of the rhodanine its yield is 17%:

$$Et_4Pb \xrightarrow{Cu(NO_3)_2} EtH + C_2H_4 + BuH + Et_3PbNO_3 + Cu^0$$

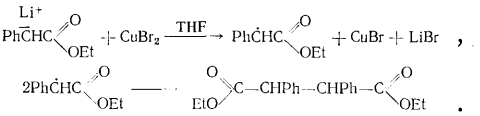
	EtH	C_2H_4	BuH
In the absence of A	77%	6%	17%
In the presence of A	86%	14%	0%

Furthermore, it has been shown in special experiments that[136,137] the decomposition of ethylcopper leads to the formation of butane:

$$\underset{74\%}{EtCu} \rightarrow \underset{74\%}{EtH} + \underset{0\%}{C_2H_4} + \underset{26\%}{BuH} + Cu^0 \quad .$$

The data presented are also of interest from the point of view that they demonstrate the formation of ethylcopper only as a result of the reaction of the initial organometallic compound with copper(I) nitrate. This makes it possible to reject the mechanism of Thiele and Kohler[138], who believe that the reactions of organometallic compounds with copper(II) salts proceed via a stage involving the total transmetallation and subsequent decomposition of the copper(II) derivative[138]:

$$Alk_2Zn + CuCl_2 \rightarrow ZnCl_2 + Alk_2Cu \quad ,$$
$$Alk_2Cu \rightarrow AlkCu + Alk^{\cdot} \quad .$$



This mechanism is unlikely also because it is difficult to imagine the formation of dialkylcopper by-passing the stage involving the formation of a mixed derivative RCuX. If the latter compound had in fact been obtained, then, by virtue of its instability, it would have decomposed before being able to react with another molecule of dialkylzinc. However, its decomposition should occur with the cleavage of the R–Cu bond, in contrast to dialkylcopper, and cannot lead to the formation of alkylcopper:

$$RCuX \rightarrow R^{\cdot} + CuX \quad .$$

Thus the main feature distinguishing the mechanism of the interaction of organometallic compounds with copper(II) salts is the formation of free radicals. Their generation in these reactions was demonstrated by introducing "radical trapping agents" such as diphenylpicrylhydrazyl[136] or by initiating the polymerisation of monomers added to the reaction mixture[76,136]. In all cases the yield of the products of the radical reactions, mainly alkanes, diminished under these conditions.

The formation of free radicals is also indicated by the nature of the products obtained. Thus, when triethylaluminium is refluxed with copper(I) and copper(II) chlorides in cyclohexane, ethane and ethylene are formed in proportions of ~2 : 1 together with a small amount of butane (2–9%).[27] The composition of the mixture of products depends little on the oxidation state of copper in the salt used. In the reaction of organolead compounds of the type of R_4Pb with copper(II) salts, several products are formed whose ratio depends on the nature of R and X. Thus the interaction of tetraphenyl-lead or tetraphenyltin with copper(II) nitrate in ethanol results in the quantitative formation of benzene[73], tetramethyl-lead gives rise to methane (21.2%) together with ethane (74.6%),[73,135] while the reaction of tetraethyl-lead leads to the formation of ethane, ethylene, and butane in the same proportions as in the reaction with silver nitrate (26.3% EtH, 16.7% C_2H_4, and 52.5% BuH).[73,76,136]

At the same time reactions of organometallic compounds are known in which the yield of radical coupling products is greater—for example, the oxidation of the lithium enolates of acetate esters, acetic acid derivatives[139], and ketones[140]. These reactions are usually regarded as electron transfer from the enolate to the copper(II) halide with subsequent dimerisation of the radicals:

The coupling of radicals in reactions of diphenylmethyl[141,142] and fluorenyl derivatives of lithium[142] with copper(II) halides apparently proceeds analogously. This pathway most probably operates when fairly stable radicals are formed in the reaction. For the usual reactions of organometallic compounds, a hypothetical mechanism postulating the involvement of organic copper(II) chlorocuprates of the type $[RCuCl_3]^{2-}$ in the coupling reaction has been proposed[20].

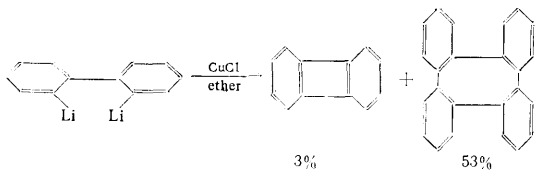
Organic compounds of copper(II) are known to be exceptionally unstable; any attempt to prepare them led to the formation of radicals. On the other hand, one cannot rule out the possibility of an increase of the stability of RCuCl as a result of coordination to ligands, for example, the chloride ion. The number of examples of such stabilisation of organometallic compounds is fairly large; it is sufficient to mention that the majority of σ-linked transition metal compounds are stable by virtue of such coordination. The existence of copper(I) cuprates of the type of R_2CuM, widely used in organic synthesis[64], has also played a considerable role in the development of ideas about the organic copper(II) chlorocuprates.

The mechanism of the coupling of organometallic compounds with participation of chlorocuprates has been invoked to account for the results of the study of the reaction of RMgBr with Li_2CuCl_4 in THF.[20] Its products are the dimers R_2 and organic chloro-derivatives RCl; the products do not contain the hydrocarbons RH. The ratio of R_2 and RCl depends on the reactant concentrations and the yield of the dimeric products increases with increasing RMgBr concentration.

[EtMgBr]/[Cu^{2+}]	BuH, %	EtCl, %
0.6	50.6	49.4
1.2	53.9	46.1
2.9	73.7	26.3

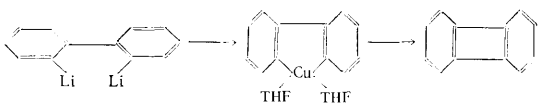
The yield and proportions of the products are not influenced by the addition of styrene, which rules out the possibility of the formation of free radicals in this reaction. The authors[20] proposed the following reaction scheme, in which organic chlorocuprates decompose via a bimolecular mechanism with formation of a dimeric product:

$$(Cu^{II}Cl_4)^{2-} + RMgBr \rightarrow [RCuCl_3]^{2-} + MgBrCl \quad ,$$
$$2\,[RCuCl_3]^{2-} \rightarrow R_2 + 2\,(Cu^{I}Cl_2)^{-} + 2Cl^{-} \quad .$$



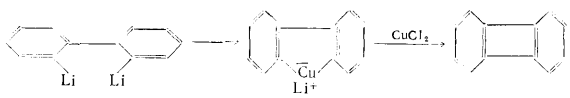
Yet another possibility of the formation of coupling products in these reactions should be noted. According to Whitesides et al.[143], treatment of the homocuprate Bu_2CuLi in THF with the copper(II) chloride complex of tetramethylethylenediamine (TMEDA) leads to the formation of octane:

$$Bu_2CuLi \xrightarrow[THF]{CuCl_2 \cdot TMEDA} Bu{-}Bu \quad .$$



One cannot therefore rule out the possibility that organic cuprates, whose subsequent oxidation leads to the formation of dimeric products, are formed in the reactions of organic compounds of lithium and possibly also magnesium with copper(II) salts.

The involvement of cuprates can be postulated in the reaction of 2,2′-dilithiobiphenyl with copper(II) chloride in ether[64], while diphenylene and tetraphenylene are formed



together with biphenyl and *o*-quaterphenyl:[14,144-146]

When a 1 : 1 mixture of ether and THF is used as the solvent, the yield of diphenylene increases to 36% and that of tetraphenylene falls to 24%. According to the authors[146], THF stabilises the intermediate R_2Cu, which increases the contribution of the decomposition via the intramolecular mechanism:

However, it is most likely that cuprates are formed, whose oxidation leads to intramolecular coupling:

The formation of the remaining products—tetraphenylene and *o*-quaterphenyl—can be account for analogously.

In our view, cuprates can also be involved in the reactions of vinyl derivatives of aluminium with copper(II) chlorides, because dienes are formed in this reaction with retention of the configuration at the carbon atom[147]. If free vinyl radicals participated in the reaction, the geometrical configuration might be distorted somewhat, but in the first place this would involve the abstraction of hydrogen from the solvent molecule with formation of an olefin.

There exists yet another possibility of the formation of coupling products in the oxidation of organometallic compounds by a copper(II) salt. It is known that organic copper(I) compounds, formed in these reactions as intermediates, give rise to associated species having the polymeric 3*c*–2*e* structure. This specific feature of the structure of the organometallic compounds can favour the formation of the dimers R_2 in the subsequent oxidation reaction[1]. This applies particularly to the oxidation of ethynyl derivatives of metals in which copper acetylides, existing only in a polymeric form, are formed. For example, in the interaction of copper(II) halides with ethynyl Grignard reagents[148] or with the corresponding derivatives of gold, silver, and copper[149,150], the yield of the dimeric product is as a rule quantitative:

$$RC{\equiv}CM + CuCl_2 \xrightarrow[M=Cu,\ Ag,\ Au]{THF} RC{\equiv}C{-}C{\equiv}CR + CuCl + MCl \ .$$

Another product of the reactions of organometallic compounds with copper(II) halides is an organic halide. It is evidently the product of the two-electron oxidation of the organometallic compound, since a carbonium ion linked to a halide ion is then formed from the carbanion R^- in RM. There exist various views on the mechanism and the formation of such halides; the next section is devoted to the consideration of this question and in general to the two-electron oxidation of organometallic compounds.

VI. TWO-ELECTRON OXIDATION OF ORGANOMETALLIC COMPOUNDS

A greater number of possible mechanisms have been considered for the two-electron oxidation of organometallic compounds than for the one-electron oxidation. In principle, such oxidation can occur in stages as a result of the successive transfer of two electrons from the organic group R:

$$RMX_n \xrightarrow{-e^-} R^\cdot + MX_n^+ \ ,$$
$$R^\cdot \xrightarrow{-e^-} R^+ \xrightarrow{Nu^-} RNu \ .$$

However, it has been suggested for certain reactions that the conversion of RM into RNu takes place in a single stage via a heterolytic mechanism, which can be formally regarded as nucleophilic substitution:

$$RMX_n + Nu^- \longrightarrow RNu + MX_{n-1} + X^- \ .$$

The role of the transition metal salt in these processes can be most varied: it can participate in the transmetallation reaction, can manifest the properties of an oxidant, and can even catalyse the single-stage two-electron oxidation.

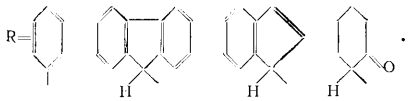
1. Oxidation by Bivalent Copper Salts

The two-electron oxidation takes place particularly frequently in the reactions of organometallic compounds with copper(II) salts, for example with copper(II) halides. It was shown in Section V that the primary product of these reactions may be free radicals and one can therefore suggest that these are in fact the species oxidised by the copper(II) salt with formation of the two-electron oxidation product RX:

$$RMX_n + CuX_2 \longrightarrow [RCuX] + MX_{n+1} \ ,$$
$$RCuX \longrightarrow R^\cdot + CuX \ ,$$
$$R^\cdot + CuX_2 \longrightarrow RX + CuX \ .$$

The studies by Kochi and coworkers[151-153], which established that the radicals are very effectively oxidised by copper(II) salts, greatly promoted the development of such ideas. It has been shown for alkyl radicals that their oxidation by copper(II) acetate leads to the formation of carbonium ions, which are stabilised either by eliminating a proton with formation of an olefin or by interacting with the solvent to form solvolytic products. The reaction with copper(II) chloride yields bromoalkanes, i.e. the radicals are oxidised with simultaneous "ligand transfer". It has been suggested that the oxidation of the radicals leads to the intermediate formation of an unstable copper(III) compound§, which is converted into RX by oxidative substitution[152]:

$$R^\cdot + CuX_2 \rightleftarrows [RCuX_2] \ ,$$
$$[RCuX_2] \rightleftarrows R^+CuX_2^- \rightarrow RX + CuX \ .$$

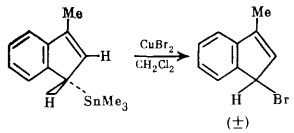


In agreement with these data, organic halides are formed in the reaction of organometallic compounds with copper(II) halides, while the reaction with copper acetate leads to acetates and olefins (in the case of alkyl derivatives of metals). For example, it has been frequently noted that the reaction of R_2Hg or RHgX (R = Ph, $PhCH_2$, ferrocenyl, etc.) with copper(II) halides results in the formation of halogenoderivatives RX or solvolytic products[33,35,156-165]. Using an excess of copper(II) bromide in dimethylformamide and most

§ The hypothesis of the intermediate formation of unstable copper(III) compounds has been recently confirmed in a study of the oxidation of radicals by a peptide complex of copper(II).[154]

varied radicals R [Bu, Ph, $PhCH_2$, C_6F_5, $C_6F_5CH_2$, $(CF_3)_2CH$, $PhCOCH_2$, CCl_3], it is possible to obtain organic bromides in nearly quantitative yields[160].

The interaction of organotin compounds $RSnMe_3$ with $CuBr_2$ in methylene chloride similarly results in the formation of the corresponding bromides RBr, whose yield is also quantitative [161]:

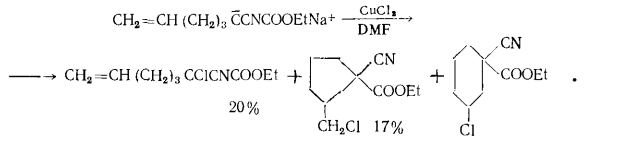


$$RSnMe_3 + 2CuBr_2 \rightarrow RBr + Me_3SnBr + 2CuBr ,$$

R=  .

This reaction is remarkable in the sense that with its aid organic bromides containing electron-accepting groups such as 9-fluorenyl, indenyl, and 2-cyclohexanonyl have been obtained. The point is that fairly stable free radicals are formed as intermediates in the oxidation of the corresponding organometallic compounds. In the case of more active derivatives of lithium or magnesium, radicals are not usually oxidised but dimerise, since the copper(II) halide reacts preferentially with the initial organometallic compound (see Section V). However, in the reactions of covalent derivatives of tin the radicals are oxidised to organic bromides.

It follows from the foregoing that both two-electron and one-electron oxidation is possible in the interaction of copper(II) salts with organic derivatives of metals RM and in general with organic derivatives of the elements, whose chemical properties are similar to those of organometallic compounds and the relative contributions of the two reaction pathways for derivatives of a single element depend on the nature of R and X in CuX_2. This can be seen in relation to the reactions of readily oxidised oxidisable organoboron compounds. Thus treatment of trialkylboranes[161] and phenylboronic[162], thienylboronic[163], ferrocenylboronic[164], and cymantrenylboronic acids[165] with copper(II) halides leads to the formation of organic halides only. In contrast to this, the interaction of organoboron compounds of copper(II) acetate usually results in the formation of one-electron oxidation products—the corresponding dimers[164-168]. The intermediate formation of an organic copper(I) compound, which decomposes in benzene with formation of R_2 and the product RH of the interaction of radicals with the solvent, was detected in the reaction of cymantrenylboronic acid[167]. The two-electron oxidation by copper(II) acetate is known for trialkylboranes, the products of the reactions of which are olefins[161], and for ferrocenylboronic acid, the oxidation of which gives a 59% yield of acetoxyferrocene[168].



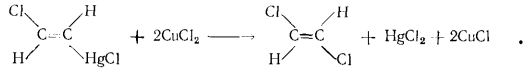
The involvement of free radicals in the reactions of organometallic compounds has not been confirmed solely by the formation of one-electron oxidation products, stereochemical evidence also being available. Thus the formation of free radicals in the reaction of $CuBr_2$ with alkyl derivatives of mercury has been demonstrated[169]. It was found that, regardless of which diastereoisomer of 3,3-dimethyl-1,2-dideuterobutylmercury chloride is introduced into the reaction, a mixture of deuterated neohexyl bromides with the same contents of the *threo*- and *erythro*-isomers is alway formed. The same stereochemical approach has been used to demonstrate the formation of radicals in the oxidation of organotin compounds—the racemic 1-bromo-3-methylindene was obtained in the reaction of the optically active *S*-(+)-3-methylindenyltrimethyltin with $CuBr_2$:[160]

(±)

There is no doubt that the loss of stereochemical configuration occurred in the indenyl radical formation stage.

The cyclisation of the hexenyl radical has been used as a test for its formation in reactions of the sodium enolate of the ethyl ester of 2-cyanohept-6-enoic acid with CuX_2 (X = Cl, SO_4, OAc, PhCOO, or p-$NO_2C_6H_4COO$) in DMF.[170] Derivatives of cyclopentane- and cyclohexane-carboxylic acids were detected in the reaction mixture:

The majority of investigators agree that the oxidation of organometallic compounds by copper(II) salts usually occurs with participation of free radicals, but it has been suggested that free radicals are not formed in some of the reactions. The reaction of Grignard reagents with the chlorocuprate Li_2CuCl_4 in THF, which has already been considered, apparently belongs to processes of this type[20]. Its products are the dimers R_2 and the chloro-derivatives RCl, which is obtained, according to the authors[20], in the oxidation of the intermediate organic chlorocuprate:

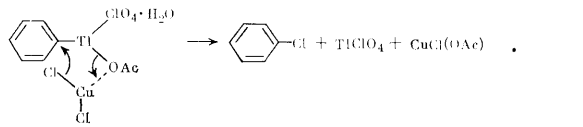


$$RMgBr + (CuCl_4)^{2-} \rightarrow [RCuCl_3]^{2-} + MgBrCl ,$$
$$[RCuCl_3]^{2-} + (CuCl_4)^{2-} \rightarrow RCl + 2(CuCl_2)^- + 2Cl^- .$$

The observed increase of the yield of RCl with increase of the Li_2CuCl_4 concentration agrees with this view. By analysing the overall kinetic reaction mechanism, it is possible to show that such dependence of the yield of RCl on the Li_2CuCl_4 concentration is possible only when RCl is obtained as a result of the oxidation of $[RCuCl_3]^{2-}$ and not of the radical R$^{\cdot}$ formed in the homolysis of this intermediate.

Kinetic analysis also leads to serious objections to the possibility of the formation of RCl as a result of the intramolecular decomposition of the intermediate RCuCl via the mechanism

$$RCu^{II}Cl \rightarrow RCl + Cu^0 .$$



This pathway to the formation of two-electron products of organometallic compounds has been considered in a study[155] of the reaction of *trans*-β-chlorovinylmercury chloride with copper(II) chloride:

According to the authors[155], free radicals are not formed in this reaction, since it takes place with retention of the geometrical configuration at the carbon atom—*trans*-dichloroethylene is obtained from *trans*-β-chlorovinylmercury chloride, while *cis*-dichloroethylene is obtained from the *cis*-isomer[171]. However, this test for the formation of radicals is not very reliable, because it postulates that the loss of configuration in the vinyl radical occurs faster than its oxidation by copper(II) chloride. This cannot be claimed *a priori*, particularly if account is taken of the fact that the vinyl radicals invert much more slowly than alkyl radicals.

Finally, we shall consider the heterolytic mechanism of the two-electron oxidation of organometallic compounds by copper(II) halides which has been proposed for the oxidation of organic derivatives of thallium(III). According to this mechanism, the formation of organic halides proceeds in a

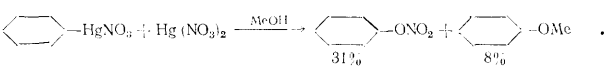
single step involving the elimination of thallium with reduction of thallium(III) to thallium(I), catalysed by the copper(II) salt[55,156,172]:

Formally this process can be regarded as substitution via the S_NC mechanism, but this is not the usual nucleophilic substitution because its driving force is the ability of thallium(III) to act as a two-electron oxidant. Furthermore, the role of the copper(II) salt in this mechanism is not clear.

One must note that the products of the one-electron oxidation ArH and Ar_2 are also formed in this reaction and the yields of all the products vary as a function of the nature of Ar and the anion X in the copper(II) salt. Thus, when $PhTl(OAc)ClO_4$ is treated with copper(II) chloride in acetic acid, the main product is chlorobenzene (yield 56–59%), but a small amount of benzene and biphenyl (2–4%) is also formed. On the other hand, mainly anisole (30–65%) and only 2% of chloroanisole are obtained from p-$MeOC_6H_4Tl(OAc)ClO_4$, while bianisyl is absent. The interaction of $PhTl(OAc)ClO_4$ with copper(II) acetate results in the formation of only benzene (13%) and biphenyl (2%).[156] The reaction with copper(I) or copper(II) cyanide leads to benzonitrile[53], while phenyl thiocyanate is formed in 42% yield in the reaction with copper(II) thiocyanate[171]. It is interesting that in the latter case the addition of potassium thiocyanate diminishes the yield of PhSCN and the yield of benzene then increases from 0 to 19%. However, the observed effect of the common ion has not been explained[173].

We may note that even copper(I) halides initiate the decomposition of organic compounds of thallium(III). Thus the interaction of CuBr with β-methoxyphenylethylthallium diacetate in acetonitrile yields the corresponding bromo-derivative[174] and it has been established with the aid of radical traps that free radicals are involved in its formation[175]. It is believed that the copper(I) halide behaves as the reductant in this reaction, converting the thallium(III) compound into an intermediate containing thallium(II).[176] The latter decomposes with formation of a radical which is oxidised further by the copper(II) halide:

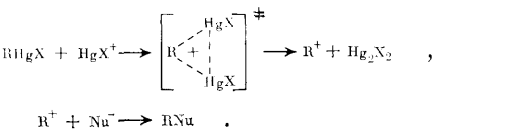
$$R{-}C(OMe)HCH_2{-}Tl^{III}(OAc)_2 \xrightarrow{CuX^-} [R{-}C(OMe)HCH_2{-}Tl^{II}(OAc)_2]^- \cdot \rightarrow R{-}C(OMe)HCH_2^{\bullet} + Tl^{I}(OAc)_2^- ,$$



$$R{-}C(OMe)HCH_2^{\bullet} + CuX_2 \longrightarrow R{-}C(OMe)HCH_2X + CuX .$$

However, the radical reaction pathway obtains at 80 °C. Under milder conditions, the reaction has a predominantly ionic mechanism. It has been shown in relation to *erythro*-n-$C_8H_{17}CH(OMe)CHDTl(OAc)_2$ that at 60 °C the reaction takes place with inversion of configuration[176].

The data presented show that the oxidation of phenyl compounds of thallium(III) by copper(II) salts differs from the oxidation of derivatives of other metals—particularly by the fact that one-electron oxidation products can be obtained in considerable amounts in reactions with copper(II) halides. The cause of these differences is associated with the fact that the thallium in these compounds exists in the highest valence state and is a powerful electron acceptor. However, the true mechanism of these reactions is so far not clear and the substitution mechanism put forward by Ichikawa and coworkers[55,156,172] is to a large extent hypothetical.



2. Oxidation of Mercury Salts

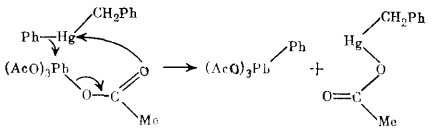
Certain electrophilic substitution reactions of organometallic compounds with bivalent mercury salts are accompanied by the formation of two-electron oxidation products. In a number of instances the process is dominant. For example, the interaction of benzylmercury nitrate with mercury(II) nitrate results in the formation of benzyl nitrate and benzyl ethyl ether in methanol and of benzyl alcohol, benzyl nitrate, and benzaldehyde in water[177,178]. The reaction with cyclohexylmercury nitrate in methanol takes place similarly, the corresponding nitrate and ether also being obtained:

According to Ichikawa and Ouchi[179], the reaction of organomercury acetates with mercury acetates likewise leads to the formation of organic acetates and a mercury(I) salt.

So far little is known about the mechanism of these reactions. It is most likely that it involves a special type of oxidative demetallation (see subsection 5 below), in which the organic group is oxidised with the simultaneous participation of the two mercury atoms. Since the rate of reaction increases following the addition of strong inorganic acids[179], presumably it involves the participation of the species HgX^+, which has a greater oxidising capacity than HgX_2:

It was noted that the interaction of propylboronic acid with mercury(II) chloride in water leads to the formation of propyl chloride and calomel together with propylmercury chloride[180]. The authors[180] believe that propyl chloride is obtained on oxidation of the transmetallation product—propylmercury chloride:

$$PrB(OH)_2 + HgCl_2 + H_2O \rightarrow PrHgCl + B(OH)_3 + HCl ,$$
$$PrHgCl + HgCl_2 \rightarrow PrCl + Hg_2Cl_2 .$$



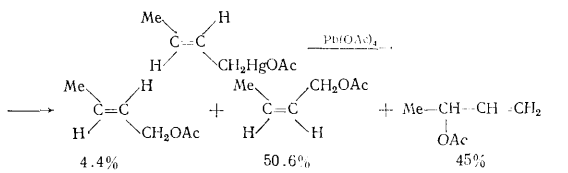
When organic derivatives of titanium(IV) ($MeTiCl_3$ [181] or Cp_2TiPh_2 [182]) react with mercury(II) chloride, calomel is formed as one of the products. According to the authors[182], the organotitanium compound decomposes and the new organic derivative of titanium(II) formed is oxidised by mercury(II) chloride:

$$Cp_2TiPh_2 + HgCl_2 \xrightarrow{CCl_4} Cp_2TiCl_2 + PhHgCl + PhCl + Ph_2 + Hg_2Cl_2 ,$$
$$Cp_2TiPh_2 \rightarrow Cp_2Ti + 2Ph^{\bullet},$$
$$n\,Ph^{\bullet} \xrightarrow{CCl_4} PhCl + Ph_2,$$
$$Cp_2Ti + HgCl_2 \rightarrow Cp_2TiCl_2 + Hg_2Cl_2 .$$

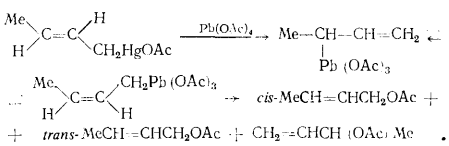
3. Oxidation by Lead-Tetra-acetate

The oxidation of organometallic compounds, particularly mercury derivatives, by lead tetra-acetate was first carried out by Criegee et al.[183] The reaction of alkyl derivatives of mercury leads to the formation of the corresponding alkyl acetates, both primary and secondary acetates being formed from primary alkylmercury acetates, which indicates the intermediate formation of carbonium ions. Thus the acetates derived from benzyldimethylmethanol and t-pentyl alcohol were isolated in the oxidation of dineophyl- and dineopentylmercury instead of the corresponding neophyl and neopentyl acetates[183]. The interaction of a fully asymmetric compound

(benzylphenylmercury) with lead tetra-acetate in benzene at room temperature results in electrophilic substitution and the elimination of the phenyl group, which is most nucleophilic[183]:



It has come to be believed that an organolead compound is always formed in the first stage of these reactions and then decomposes with formation of a two-electron oxidation product[183,184]:



$$(PhCH_2)_2Hg \xrightarrow{Pb(OAc)_4} PhCH_2Pb(OAc)_3 \xrightarrow{-Pb(OAc)_2} PhCH_2OAc .$$

In the case of alkyl derivatives of metals, it is usually impossible to isolate the corresponding lead(IV) compound under the reaction conditions. Only the quantitative formation of $Et_2Pb(OAc)_2$ in the reaction of Et_2Hg with $Pb(OAc)_4$ in chloroform at room temperature has been described[185], but in benzene the above compound is not obtained on interaction of Et_4Sn with $Pb(OAc)_4$, ethyl acetate being produced in 78% yield[186].

All three possible isomers of the organic acetate are formed on oxidation of *trans*-crotylmercury acetate[185]:

However, the fact that much more of *cis*-crotyl acetate is formed than of the *trans*-isomer suggests that free carbonium ions do not participate in the reaction. It is most difficult to account for the preferential formation of the thermodynamically less stable *cis*-crotyl acetate. According to Kitching et al.[187], this reaction includes the following stages: transmetallation via the S_E2' (or S_Ei') mechanism, intramolecular metallotropic rearrangement of the intermediate, and oxidative demetallation of the organolead compounds formed:

The capacity of organic compounds of lead(IV) for decomposition without the oxidative demetallation mechanism depends on the nature of not only the organic group but also the anions present in solution. Thus, when potassium iodide[188] or PhMgBr [189] is added to a solution of the stable $PhPb(OAc)_3$, acid anion exchange takes place and the resulting intermediate decomposes with formation of halogenobenzenes and lead(II) salts.

It is noteworthy that the formation of products of two-electron oxidation in these reactions can occur both on oxidative demetallation of $RPb(OAc)_3$ and as a result of homolytic decomposition with cleavage of the R–Pb bond and subsequent oxidation of the radical R$^{\cdot}$ by the excess lead tetra-acetate. Presumably the oxidation of organic compounds of thallium(III) by lead tetra-acetates proceeds via one of these pathways[190]:

$$ArTl(OOCCF_3)_2 \xrightarrow[Cl_3CCOOH]{Pb(OAc)_4} ArOOCF_3 + Tl^{I} + Pb^{II} .$$

Another view on the mechanism of the formation of radicals in these reactions has been expressed in a study[191] of the oxidation of alkyl derivatives of mercury and tin by lead tetra-acetate. The reaction proceeds fairly readily on refluxing in acetic acid but the yield of the acetates is high only in the case of benzyl derivatives¶:

$$\text{n-PrHgOAc} \xrightarrow[6.5\%]{Pb(OAc)_4} \text{n-PrOAc} + \textit{cis}\text{-PrOAc} ,$$

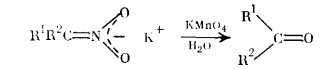
$$\text{iso-BuHgOAc} \xrightarrow[10\%]{Pb(OAc)_4} \text{iso-BuOAc} + \text{s-BuOAc} + \text{t-BuOAc} ,$$

$$PhCH_2HgOAc \xrightarrow[82\%]{Pb(OAc)_4} PhCH_2OAc ,$$

$$(PhCH_2)_3SnCl \xrightarrow[77\%]{Pb(OAc)_4} PhCH_2OAc + PhCH_2Cl .$$

The authors[191] proposed a mechanism involving the one-electron oxidation of the organometallic compound with subsequent oxidation of the radicals and the formation of organic acetates. However, this alternative transmetallation oxidation reaction is not supported by any evidence.

On the other hand, the oxidation of trialkylboranes by lead tetra-acetate in benzene apparently proceeds via an electron transfer stage[193]. The point is that secondary radicals and not primary radicals, as is usually the case in transmetallation reactions, are preferentially split off in this reaction. For example, the amount of n-hexyl acetate formed in the reaction of bicyclohexyl-n-hexylborane with $Pb(OAc)_4$ is 10 times smaller than that of cyclohexyl acetate. This is apparently due to the preferential decomposition of the radical-cation with formation of a more stable secondary radical:



$$[C_6H_{13}(C_6H_{11})_2B]^{\cdot+} \rightarrow C_6H_{11}^{\cdot} + C_6H_{13}C_6H_{11}B^{+} .$$

4. Oxidation by Compounds of Other Metals

The oxidation of organometallic compounds by chromium trioxide apparently also proceeds via an electron transfer stage since transmetallation is hardly possible in this instance. When PhHgI and $PhCH_2HgCl$ are treated with chromium trioxide in a 1 : 1 $AcOH/Ac_2O$ mixture or in the complex $CrO_3.2Py$ in dichloromethane, iodobenzene and benzyl chloride are formed. Benzaldehyde has also been detected in the case of $PhCH_2HgCl$.[194] Tetra-alkyl derivatives of tin react with chromium trioxide in acetic acid to form aldehydes and acids[195]. The reactions of organic boronic acids with chromic acid (with CrO_3 in water) lead to the formation of an alcohol[196]:

$$\text{t-BuB(OH)}_2 + CrO_3 \xrightarrow{H_2O} \text{t-BuOH} + Cr^{III} + H_3BO_3 .$$

The oxidation of potassium salts of nitroparaffins by potassium permanganate belongs to processes of the same type[196]:

This reaction has been suggested as a method of synthesis of aldehydes and ketones.

The oxidation of tetra-alkyltin by phenanthroline complexes of iron(III) [197] and the reactions of alkyl derivatives of lead[96], tin[198], mercury[199], and platinum[200] as well as benzylcobaloxime[201] with the $IrCl_6^{2-}$ anion, which is a one-electron

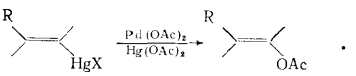
¶ A high yield of alkyl acetates is observed in the reaction of $Pb(OAc)_4$ with organoaluminium compounds obtained as a result of the addition of $LiAlH_4$ to olefins in the presence of $TiCl_4$.[192] Since the reaction is not accompanied by isomerisation, it is of interest from the synthetic standpoint.

oxidant, are examples of oxidation reactions of organometallic compounds which undoubtedly proceed via a one-electron transfer stage. The products of these reactions are chloroderivatives formed as a result of the multistage two-electron oxidation with the intermediate formation of radicals. A clear confirmation of the one-electron transfer mechanism of these reactions is finding that on oxidation of, for example, a mixed lead compound $Et_{4-n}Me_nPb$, the ethyl group is split off preferentially[96] and not the methyl group as is usually the case in electrophilic substitution. Furthermore, the partial [rate?] factor for this process is independent of the number of ethyl groups in the molecule of the organolead compound, which is apparently associated with the preferential decomposition of the radical-cation via the mechanism

$$[(Et_{4-n}Me_n)Pb]^{+\cdot} \rightarrow Et^{\cdot} + (Et_{3-n}Me_n)Pb^{+} \quad .$$

The intermediate formation of radicals in the reaction of R_4Pb with $IrCl_6^{2-}$ has been demonstrated with the aid of "radical trapping agents" of the type of nitrosoisobutane[96]. Since only alkyl chlorides are formed in the reaction, one must suppose that the radicals are oxidised very rapidly.

An additional confirmation of the one-electron transfer mechanism is provided by the satisfactory linear correlation between the logarithms of the rate constants for the oxidation of organometallic compounds and their ionisation potentials[96,202,203] as well as the [absorption] frequencies corresponding to charge transfer to the complex from tetracyanoethylene[203,204]. Analysis of these correlations from the standpoint of the Marcus theory demonstrated that these reactions have an electron transfer mechanism[196,201]. It has been shown, for example, that the reaction of R_4Sn with phenanthroline complexes of iron(III) takes place as an outer-sphere transfer, while the oxidation of R_4Sn by $IrCl_6^{2-}$ involves an inner-sphere electron transfer.

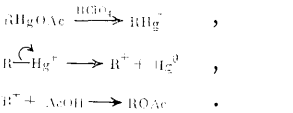


The reaction of benzylchromium $[PhCH_2Cr(H_2O)_5]^{2+}$ with iron(III), cobalt(III), and copper(II) salts, which leads to the formation of typical oxidation products of the benzyl fragment, namely benzaldehyde, benzyl alcohol, and bibenzyl, has an interesting mechanism[205]. However, kinetic study showed that the rate of this process is not determined by the electron transfer stage, since the reaction is of first order with respect to the benzylchromium cation and of zero order with respect to the oxidant. The authors[205] suggest that the rate-limiting stage of the process is the homolysis of the benzylchromium cation and that the radical fragments formed are oxidised in the rapid stage.

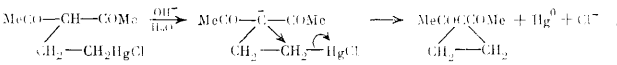
Using a combination of two oxidants [a palladium salt in a catalytic amount and one of the oxidants in the series comprising chromium(VI) salts, $Pb(OAc)_4$, $NaClO_3$, $KMnO_4$, $NaNO_3$, and $NaNO_2$], it was possible to achieve an interesting two-electron oxidation of phenylmercury salts. The reaction products in the presence of freshly added nucleophiles Nu^- are substituted benzenes PhNu, while in the absence of oxidants the main product of the stoichiometric reaction is biphenyl[206]:

$$PhHgOAc \xrightarrow[K_2Cr_2O_7]{Pd(OAc)_2} \underset{50\%}{PhOAc} + \underset{6\%}{Ph_2} \quad ,$$

$$PhHgOAc \xrightarrow[LiOAc]{Pd(OAc)_2} \underset{\sim 5\%}{PhOAc} + \underset{95\%}{Ph_2} \quad .$$



It has been suggested that transmetallation results in the formation of a phenylpalladium(II) salt which is subsequently oxidised by the main oxidant. The catalytic cycle terminates by the addition of the nucleophile Nu^- to the phenylcarbonium ion formed. The vinylmercury salts are similarly oxidised by mercury(II) acetate, the reaction being catalysed by palladium(II) acetate[207]. The reaction proved to be a convenient preparative method of synthesising substituted enol acetates:



Another possible reaction mechanism is the oxidation of C_6H_5HgX or C_6H_5PdX with a palladium(IV) salt[206], obtained by the reaction of the palladium(II) salt with the main oxidant. In his analysis of this possibility, Henry[206] drew attention to the fact that, in the oxidation of an oxidant weaker than palladium(IV) such as copper perchlorate, alkyl chlorides are formed from alkyl derivatives of palladium(II), while radical coupling products are obtained from aromatic derivatives of palladium(II). Since it is difficult to suppose that PhPdX is oxidised with greater difficulty than AlkPdX, it follows from the data presented that the PhPdX oxidation reaction competes with the coupling reaction only when sufficiently strong oxidants are employed.

5. Oxidative Demetallation Reactions

The decomposition of unstable organic compounds of metals with formation of two-electron oxidation products is of special interest. The reaction involving the elimination of mercury from organomercury cations in the presence of acids is an example of such a process[179,208–210]:

A mercury elimination reaction under the influence of bases is known[211]:

This reaction is unusual, since the carbanion formed in it formally substitutes the $HgCl^-$ group by an intramolecular nucleophilic mechanism.

The acetolysis of mercury benzylmercaptide is of a type similar to that of the processes considered[212]:

$$PhCH_2SHgOAc \xrightarrow[90-100^\circ]{AcOH} PhCH_2OAc + (PhCH_2)_2 + HgS \quad .$$

The intermediate formation of the benzyl cation in this reaction has been demonstrated by trapping it with mesitylene.

The decomposition of phenylthallium bromides and iodides is in essence an oxidative demetallation reaction[213,214]:

$$PhTlBr_2 \rightarrow PhBr + TlBr \quad ,$$

$$PhTlI_2 \rightarrow PhI + TlI \quad .$$

This reaction has been suggested as a method of synthesis of aryl iodides. It has been postulated that iodobenzene is formed in the interaction of $Ph_2TlOCOCF_3$ with I_2 not only on electrophilic substitution but also as a result of oxidative demetallation[215]:

$$Ph_2Tl(OCOCF_3) + I_2 \rightarrow PhTlIOCOCF_3 + PhI \quad ,$$

$$PhTlIOCOCF_3 \rightarrow PhI + TlOCOCF_3 \quad .$$

The same pathway apparently obtains in the reactions of bismuth(V) and bismuth(III) compounds[180]:

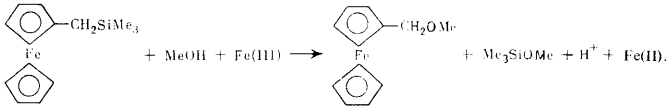
$$Ph_3Bi(OH)_2 \rightarrow Ph_2BiOH + PhOH \quad .$$

The intramolecular decomposition of unstable organopalladium intermediates, formed in the interaction of palladium(II) salts with organometallic compounds, also constitutes an oxidative demetallation reaction, because it yields metallic palladium. For example, when $PdCl_2$ interacts with β-chloromercuriethanol or β-chloromercuriethyl acetate, acetaldehyde and vinyl acetate are formed respectively[216]:

$$HO{-}CH_2CH_2HgCl \xrightarrow{PdCl_2} \left[ClPd{-}CH_2{-}\underset{H}{CH}{-}OH\right] \rightarrow MeCHO + Pd^0 ,$$

$$MeCO{-}CH_2CH_2HgCl \xrightarrow{PdCl_2} \left[ClPd{-}CH_2{-}\underset{H}{CH}{-}\underset{O}{OCMe}\right] \rightarrow CH_2{=}CH{-}OAc + Pd^0 .$$

The nature of the products formed suggests that the decomposition of the organopalladium intermediate entails the generation of carbonium ions, which are stabilised as a result of a hydride shift (on formation of acetaldehyde) or the elimination of a proton (on formation of vinyl acetate).



The decomposition of organometallic compounds accompanied by the intramolecular oxidation of the organic group is naturally possible only for compounds containing a metal capable of effecting two-electron oxidation. There is no doubt that this process depends both on the nature of the organic group and on the coordination environment of the metal atom. For example, the mode of the decomposition reaction of β-methoxyphenylethylthallium diacetate in aqueous methanol in the presence of perchloric acid depends on the concentration of the added chloride ions[217]. Whereas at low Cl^- concentrations oxidative demetallation, accompanied by the migration of the phenyl group, takes place and the rate of reaction increases with increasing Cl^- concentration, i.e.

$$PhCH(OMe)CH_2Tl(OAc)_2 \xrightarrow[MeOH]{Cl^-,H^+} PhCH_2{-}CH(OMe)_2 + Tl^I ,$$

at high Cl^- concentrations, where the acetate ions are fully substituted by chloride ions, the product is styrene and the rate of reaction is independent of the Cl^- concentration and is determined solely by the acidity of the medium:

$$PhCH(OMe)CH_2Tl(OAc)_2 \xrightarrow{Cl^-} PhCH(OMe)CH_2TlCl_2 \rightarrow$$
$$\xrightarrow{H^+} PhCH(\overset{+}{O}Me)CH_2TlCl_2 \rightarrow PhCH{=}CH_2 + Tl^{III} .$$

An interesting instance of oxidative demetallation has been observed by Kumada and coworkers[218,219] in studies of the solvolysis of ferrocenylmethyl derivatives of silicon and germanium in methanol, initiated by iron(II) salts:

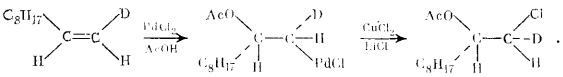
According to the authors, methoxymethylferrocene is formed as a result of consecutive intermolecular and intramolecular electron transfers:

$$FcCH_2MMe_3 + Fe^{III} \rightarrow Fc^+{-}CH_2MMe_3 + Fe^{II} ,$$
$$Fc^+CH_2MMe_3 + CH_3OH \xrightarrow{slow} Fc{-}\dot{C}H_2 + MeOMMe_3 + H^+ ,$$
$$FcCH_2^{\cdot} + Fe^{III} \rightarrow [Fc^+{-}CH_2^{\cdot}] + Fe^{II} ,$$
$$[Fc^+{-}CH_2^{\cdot}] + MeOH \rightarrow FcCH_2OMe + H^+ .$$

The absence of a correlation between the rate constants for the solvolytic reaction and the oxidation-reduction potentials of substituted ferrocene derivatives indicates, according to the authors[218], that the rate-determining stage of the process is nucleophilic attack by methanol on the metal atom in the ferrocenium ion.

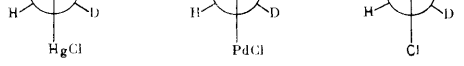
We shall consider yet another pathway leading to the formation of the two-electron oxidation products, which is possible for organic derivatives of transition metals, particularly for alkylcobaloximes. According to Anderson et al.[220], the one-electron oxidation of organocobalt compounds results in the formation of an intermediate containing a metal atom in a higher valence state. As a result of this, the electron density at the α-carbon atom is reduced so much that the carbon–cobalt bond is broken on nucleophilic substitution via the S_N2 mechanism:

$$RCo^{III}L_2 \xrightarrow{-e^-} [RCo^{IV}L_2] \xrightarrow[-Co^{II}L_2]{Nu^-} RNu .$$



The studies of the composition of products as a function of the nature of the nucleophilic species present in solution and competing for the intermediate formed[201] as well as stereochemical data in general confirm this view. Thus it has been shown that the oxidation of (+)-*S*-(1-methylheptyl)bis(dimethylglyoximato)pyridinecobalt(III) with a two-fold excess of $IrCl_6^{2-}$ in the presence of bromide ions results in the formation of (−)-*S*-1-methylheptyl bromide in 37% yield and with an optical purity in excess of 50%,[220] i.e. the configuration at the carbon atom is inverted. However, in this formulation of the experiment one cannot rule out the possibility that the active agent in the reaction might have been the bromine formed on oxidation of Br^-. This deficiency was taken into account in a study[221] where 1-methylheptylbis(dimethylglyoximato)cobalt was oxidised at a low temperature with a cerium(IV) salt and then chloride ions were added to the reaction mixture:

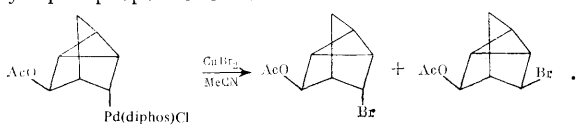
$$RCo^{III}(dmgH)_2 \xrightarrow[MeOH]{CAN,\ -60^\circ} RCo^{IV}(dmgH)_2 \xrightarrow{Cl^-} RCl ,$$



$dmgH_2 = CH_3C(=NOH)C(=NOH)CH_3$, CAN = cerium ammonium nitrate

The degree of inversion of the configuration was 90 ± 10%.

It is noteworthy that the mechanism of the oxidation of organometallic compounds examined above, which includes a nucleophilic substitution stage activated by electron transfer, has been widely used recently to account for the inversion of the stereochemical configuration in electrophilic substitution reactions involving transition metals[222]. Apparently the inversion of configuration on cleavage of the C–Pd bond with copper(II) chloride, which has been observed by Backvall[223], can be explained from the same standpoint.



Presumably the palladium intermediate formed, whose *threo*-configuration is determined by the stereochemistry of the oxypalladisation reaction[224,225], is oxidised by $CuCl_2$ and attack by Cl^- comes from the side opposite that of the metal. It is possible to explain similarly the inversion of configuration observed in the oxidation of *threo*-3,3-dimethylbutyl-1,2-d_2-mercury chloride with copper(II) chloride in the presence of $PdCl_4^{2-}$.[226] It is believed that this reaction involves the formation of *threo*-3,3-dimethylbutyl-1,2-d_2-palladium chloride as the palladium intermediate:

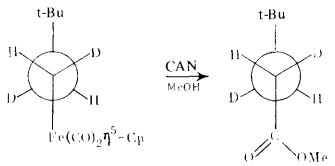
Thus it is seen from the above examples that the oxidation of organopalladium compounds by copper(II) halides can bypass the transmetallation stage. Henry, who investigated

the oxidation of but-2-ene by copper(II) chloride in the presence of $PdCl_2$, reaches the same conclusion[227].

On the other hand, judging from the stereochemical results of certain reactions of organopalladium compounds with copper(II) halides, the latter proceed like those involving non-transition metal compounds, i.e. via stages involving transmetallation and the intermediate formation of radicals. An example of such reactions is provided by the interaction of *endo*-norticyclenylpalladium(II) with $CuBr_2$, which leads to the formation of the *endo*- and *exo*-isomers in approximately equal proportions[169]:

Interesting reactions occur in the oxidation by copper(II) chloride of alkyl and aryl alkyl σ-derivatives of iron [η^5-Cp.$(CO)_2$FeR]. For example, the reaction of the benzyl derivatives with $CuCl_2$ in CH_2Cl_2 results in the formation of benzyl chloride only[228]:

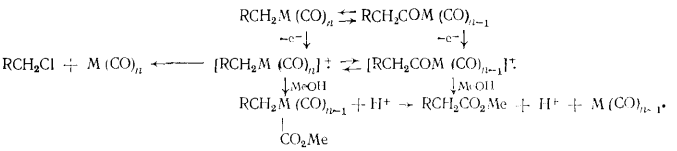
$$\eta^5\text{-CpFe(CO)}_2\text{CH}_2\text{Ph} + \text{CuCl}_2 \rightarrow \eta^5\text{-CpFe(CO)}_2\text{Cl} + \text{PhCH}_2\text{Cl} + 2\text{CuCl} \quad .$$



This reaction can be modelled by the electrochemical oxidation of $RFe(CO)_2\eta^5$-Cp (R = Me, $PhCH_2$, or $PhCH_2CH_2$) in the presence of chloride ions, whereupon the corresponding chloro-derivatives are also formed. It has been shown in relation to *threo*-PhCHDCHD-Fe$(CO)_2\eta^5$-Cp [228] that the electrochemical oxidation takes place with the preferential retention of configuration. Since the label is distributed between both carbon atoms of the ethyl fragment in the oxidation of the ^{13}C- labelled β-phenylethyl derivative, presumably a phenonium ion is formed in the reaction and the observed stereochemical result (retention of configuration) is due to attack by a chloride ion from the side of the iron atom.

When the same iron complexes are oxidised in alcohol and not in CH_2Cl_2, particularly in the presence of CO, carbonylation products (alkyl carboxylates) are formed[229]:

$$\text{RFe(CO)}_2\eta^5\text{-Cp} \xrightarrow[\text{R'OH,CO}]{\text{CuCl}} \text{RCOOR'} \quad ;$$



$$\text{R} = \text{PhCH}_2\text{CH}_2,\ \text{cyclo-C}_6\text{H}_{11}\text{CH}_2,\ \text{cyclo-C}_6\text{H}_{11} \quad .$$

A similar reaction takes place in the oxidation of *erythro*-3,3-dimethylbutyl-1,2-d_2-Fe(CO)η^5-Cp by cerium ammonium nitrate in methanol[230]:

The stereochemistry of this process and also the reaction with $CuCl_2$ considered above[229] shows that the oxidation of the complex causes the insertion of CO in the C—Fe bond, which takes place with retention of configuration, after which nucleophilic attack on the alcohol takes place.

The oxidation of *p*-fluorobenzyl (R) derivatives of molybdenum, chromium, iron, manganese, namely π-$Cp(CO)_3$MoR, π-$Cp(CO)_3$CrR, π-$Cp(CO)_2$FeR, and $RMn(CO)_5$, by cerium(IV) salts in methanol in the presence of LiCl was considered from the same standpoints[231]. Apart from *p*-fluorobenzyl chloride, methyl *p*-fluorophenylacetate is formed in the reaction, the ratio of the yields of the products depending on the nature of the metal atom. The following mechanism accounts for the possible pathways leading to their formation:

Finally we shall turn to the coupling reactions which occur in the oxidation of transition metal compounds $R^1R^2ML_n$ and lead to the formation of the dimer R^1R^2. We have already encountered one example of such reactions when the oxidation of the cuprates R_2CuLi by copper(II) halides was considered[143]. The $Ar_4Cu_6X_2$ clusters are oxidised similarly[232]. Here we should like to examine these reactions in greater detail and note the role which they can play in complex processes involving transition metal complexes, particularly in the cross-coupling reaction.

Morell and Kochi were some of the first investigators who drew attention to the intramolecular coupling reactions occurring in the oxidation of organometallic compounds. They observed that the intramolecular decomposition of the complexes $[Et_3P]_2[MeArNi]$ is accelerated in the presence of ArBr or O_2.[123,233]

On the basis of these data, it was suggested that the reductive elimination can be activated by electron transfer from the complex to ArX and that ArX yields an oxidative addition product in the mechanism proposed for the decomposition:

$$L_2NiArCH_3 + ArX \rightleftarrows [L_2NiArCH_3]^{\pm} + Ar^{\cdot}X^{\cdot-} \quad ,$$

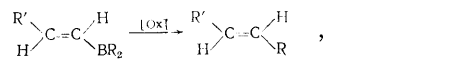
$$[L_2NiArCH_3]^{\pm} \rightarrow ArCH_3 + L_2Ni \quad ,$$

$$L_2Ni^{\pm} + ArX^{\cdot-} \rightarrow L_2NiArX \quad .$$

Generally speaking, this hypothesis was not confirmed, but data exist showing that intermediates capable of reductive elimination can be formed in the oxidation of transition metal complexes. Thus only coupling products are formed in the oxidation of dialkyl derivatives of iron(II) by a wide variety of reagents, such as Na_2IrCl_6 or thallium(III), cerium(IV), and cobalt(III) triflates[234]:

$$R_2Fe(bipy)_2 + 2IrCl_6^{2-} \rightarrow R_2 + FeCl_2(bipy)_2 + 2IrCl_6^{3-} \quad .$$

This reaction is not intermolecular and proceeds without the involvement of free radicals, because the decomposition of a mixture of the diethyl and dimethyl complexes does not result in the formation of propane. Halogens behave in a very unusual manner in the reaction considered—they exhibit exclusively oxidising properties and alkanes are formed in this instance instead of alkyl halides[130,234]:



The above oxidative coupling reactions involving transition metal complexes can be modelled by electrochemical oxidation on platinum. Thus the electrolysis of triethylphosphine complexes of diarylnickel in acetonitrile leads to the formation of biaryl, whose yield reaches 94% in the case of $(PEt_3)_2Ni(o\text{-}MeC_6H_4)_2$. Some of the intermediates formed in the one-electron oxidation of the complexes have been detected with the aid of cyclic voltamperometry at −50 °C.[235]

An interesting coupling reaction occurs in the oxidation of the phosphine complexes of arylnickel bromide by Na_2IrCl_6, $Ce(CF_3COO)_4$, and $CuBr_2$:[234]

It has been shown for o-$MeC_6H_4NiBr(PEt_3)_2$ that a phosphonium cation is formed from the $[o\text{-}MeC_6H_4NiBr(PEt_3)_2]^{\ddagger}$ species, for which the corresponding EPR spectrum has been obtained at −50 °C. The same species was detected with the aid of CO and the formation of the cation $[ArCONiBr.(PEt_3)_2]^+$ was detected by EPR.

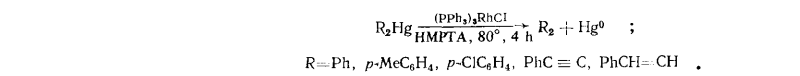
The stereospecific oxidation of alkenyldialkylboranes by $Pb(OAc)_4$, $PhI(OAc)_2$,[236] and $Pd(OAc)_2$,[237] leading to the formation of substituted olefins

constitutes an interesting case of oxidative coupling of radicals. The Zweifel reaction, in which iodine is used as the oxidant, is a prototype of these processes[238].

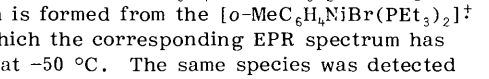
The above coupling reactions, promoted by electron transfer, in essence do not differ in any way from the intramolecular thermal decomposition of organometallic compounds (reductive elimination reactions) examined in Section IV. The role of the oxidant in these reactions reduces to effecting a transition of the complex to an oxidation state which favours the occurrence of the reductive elimination reaction. However, there exist a multiplicity of reactions in which coupling takes place under the influence of compounds which function exclusively as catalysts. For example, the decomposition of the cluster compound arylcopper(I) (Ar_4Cu_4) is catalysed by copper(I) triflate. According to van Koten et al.[239], the coupling in such clusters takes place as a result of the intramolecular electron transfer in the complex formed by the reactants:

The decomposition of the clusters $R_4Cu_6X_2$ (X = Br, I, or CF_3SO_3) is promoted similarly by the addition of copper(II) salts[108,232] or copper(I) triflate[239].

Another example of such reactions is the decomposition of R_2Hg in the presence of palladium and platinum complexes in which the metal is in a low valence state[240,241]:



dba — dibenzylideneacetone ;



It has now been established that $Pd(PPh_3)_4$ or $Pt(PPh_3)_3$ are initially inserted in the C–Hg bond in these reactions, exhibiting the properties of a nucleophilic carbenoid. In a number of instances, when R_2Hg contains the powerful electron-accepting groups R = CF_3 and C_6H_5,[242] the insertion products can be isolated and characterised by physicochemical methods. However, the intermediates are usually unstable and undergo the elimination of mercury and reductive elimination with formation of a coupling product.

The decomposition reactions of the compounds R_2Hg catalysed by rhodium(I) complexes apparently have an analogous mechanism[243]:

We may note that similar reactions are known for organomercury salts. Thus biaryls are formed from ArHgCl on treatment with rhodium(I) complexes in the presence of LiCl.[244] The carbenoid insertion of the rhodium(I) atom in the C–Hg bond apparently takes place in this instance and Ar_2 is formed as a result of reductive elimination:

As in the instances considered above, mercury is the oxidant in this catalytic process, its oxidation state changing from +2 to 0 in the course of the reaction.

The Mechanism of the Photolysis of Certain Hydrocarbons by Vacuum Ultraviolet Radiation

Yu.I.Dorofeev and V.E.Skurat

The results of studies of the photolysis by vacuum ultraviolet radiation of saturated hydrocarbons and hydrocarbons containing individual double bonds are examined and characteristics of the photolysis of these classes of substances are discussed as a function of the molecular structure, the phase state of the given substance, and the wavelength of the radiation.
The bibliography includes 104 references.

CONTENTS

I. Introduction 527

VI. Conclusion 539

I. INTRODUCTION

The study of the photochemical reactions of hydrocarbons under the influence of vacuum ultraviolet radiation constitutes a branch of chemistry which has been vigorously developing in the last 15–20 years. The interest in this field is due to a number of causes.

Firstly, vacuum ultraviolet radiation constitutes an appreciable proportion of the solar radiation spectrum in the upper layers of the Earth's atmosphere and outside its limits. In particular, it is responsible for the ionisation and dissociation of atmospheric gases and for photochemical reactions involving the molecules of atmospheric contaminants. Changes in the composition of the atmospheres of other planets of the solar system also occur under the influence of vacuum ultraviolet radiation, since molecules of greatest geochemical interest absorb only this light (for example, methane, an important component of the atmosphere of Jupiter, absorbs light with $\lambda < 143$ nm [1]). Evidently, this radiation can influence significantly the physicochemical surface characteristics of the materials of flying machines in the upper layer of the atmosphere and in space; therefore the determination of the general characteristics of the effect of vacuum ultraviolet radiation on polymers is of considerable interest from the standpoint of the development of the scientific foundations of materials science.

Secondly, vacuum ultraviolet radiation is one of the significant factors acting on matter when materials, including polymers, are treated in a plasma[2].

Thirdly and finally, the study of the chemical consequences of the action of vacuum ultraviolet radiation is important for high-energy chemistry in general. Depending on the wavelength of the active light, various electronic states of molecules are excited and at shorter wavelengths (with photon energy in excess of 10–15 eV) the substance is photoionised; studies of the reactions occurring under these conditions permit inferences about the properties of the photochemical reactions of various neutral electronically excited states and ionised states of molecules. Such information is of interest for many branches of high-energy chemistry, for example, for plasma chemistry and radiation chemistry.

The aim of the present review is to examine the fundamental features of the photolysis of paraffinic and olefinic hydrocarbons in the vacuum ultraviolet region i.e. in the spectral region corresponding to intrinsic absorption by these substances. Particular attention has been concentrated on the comparative study of the photolysis of gaseous, liquid, and solid hydrocarbons.

II. CHARACTERISTIC FEATURES OF THE EXPERIMENT

Active research in the vacuum ultraviolet region has been prosecuted only during the last two decades because only comparatively recently the necessary optical materials, transparent in the wavelength range 105–160 nm, sufficiently powerful light sources in this region, and the corresponding spectroscopic apparatus have become available for experiments[3].

Optical Materials

The optical components of apparatus designed for research in the vacuum ultraviolet region must be made of substances transparent to this type of radiation. Such substances are LiF, CaF_2, MgF_2, BaF_2, SrF_2, LiO, BeO, and sapphire[3,4]. However, these substances are opaque to light with $\lambda < 105$ nm so that studies in the above spectral region are still more difficult. However, the use of various substances in the form of thin film permits experiments also at $\lambda < 105$ nm. The choice of substances suitable for the preparation of thin transparent films which can be used to make windows in photochemical cuvettes or filters depends on their absorption coefficients in the experimental region and also on their mechanical properties. The films are obtained from organic substances or metals[4].

Light Sources

The main requirement which must be met by photochemical light sources is high radiation intensity (not less than 10^{13} to 10^{14} quanta s^{-1}), which is dictated by the sensitivity of modern analytical methods and the limited amount of time available. It is desirable to have a monochromatic light source, which permits the generation in the test specimen of quite definite excited electronic or ionic states. Various monochromatic radiation sources in the vacuum ultraviolet region, operating on the basis of various types of electric

discharge (ultrahigh frequency, high frequency, arc, spark, and glow discharges) in the inert gases (Xe, Kr, Ar, Ne, and He) and in molecular gases (Br_2, I_2, N_2, etc.) have now been developed and used.

Electrodeless resonance lamps, in which the discharge is maintained with the aid of a decimetre wave generator, have been most widely used in the last decade[1,5,6]. Xenon and krypton arc discharge resonance lamps (of types of KSR-1, KSR-2A, KRR-2A) are manufactured in the USSR.[7,8] In addition, synchrotron radiation, i.e. the electromagnetic radiation of electrons moving in a circular orbit with a velocity close to that of light, can be employed as the source of vacuum ultraviolet radiation[4,9]. The continuous spectrum of synchrotron radiation extends from the near infrared to hard X-rays. The intensity of the radiation is stable and is calculated in absolute units, which permits its employment as a standard light source. The radiation is polarised (degree of polarisation approximately 85%; the electric vector lies in the plane of the electron orbit). In order to isolate monochromatic light, monochromators are used; the intensity of the vacuum ultraviolet radiation, for example, that of the DEZI synchrotron (Hamburg, Federal Republic of Germany) at the outlet slit of the monochromator then reaches ~10^{12} quanta s^{-1} nm^{-1}.[9]

Detectors of Vacuum Ultraviolet Radiation

A whole series of detectors are used to detect vacuum ultraviolet radiation: photoelectric detectors, thermophosphors, photographic plates, and ionisation chambers[4]. Photochemical actinometry is also widely used. One of the easiest and commonest methods of measuring the absolute radiation intensities is photochemical gas actinometry, i.e. the determination of the intensity of the light generated by the source from the known yield of gaseous products of photochemical reactions. The following actinometric systems may be noted: the decomposition of carbon dioxide[4,10] or hexafluoroacetone[11] with formation of CO; the formation of O_3 in the photolysis of O_2,[12] the formation of H_2 and C_2H_2 in the photolysis of C_2H_4,[13] the formation of NO in the photolysis of N_2O,[14] the formation of H_2 on irradiation of HBr,[15] etc.[1,4,15].

Analytical Methods for the Products of Photochemical Reactions

The analysis of the products of the photolysis of hydrocarbons by vacuum ultraviolet radiation requires the application of extremely sensitive analytical methods, particularly in the photolysis of solids. On the one hand, this can be accounted for by the low intensity of the radiation from the existing light sources (~10^{14}–10^{15} quanta s^{-1}). On the other hand, the changes in polymeric materials lead to the accumulation of products in a very thin layer (~100 to 200 nm [16,17]) even after long photolysis times, and even high concentrations of these products can be detected only with the aid of sensitive methods. Gas and liquid chromatography, mass spectrometry, optical absorption spectroscopy in the vacuum ultraviolet region, multiple diffuse total internal reflection infrared spectroscopy, and EPR are used nowadays for the qualitative and quantitative detection of the products of the vacuum ultraviolet photolysis of hydrocarbons[5,16–21].

III. PHOTOLYSIS OF SATURATED HYDROCARBONS

1. Optical Spectroscopy

The threshold in the absorption of light by saturated hydrocarbons is near 7–8 eV. With increase of the number of carbon atoms in linear alkanes, the light absorption threshold shifts from ~143 nm for methane[1,22] towards longer wavelengths (Fig.1). The absorption threshold for polyethylene (Fig.2) is observed at 160–165 nm [23,24] (at longer wavelengths the optical density is mainly due to light scattering[23]). It is believed[22] that the first absorption band of alkanes is due to the $\sigma \rightarrow \sigma^*$ excitation of the electrons of the C–C bond, while the C–H bond begins to absorb light with $\lambda \lesssim 143$ nm. However, it has been suggested[26,27] that the first absorption band is due to Rydberg transitions to 3*s* and 3*p* orbitals. The transition takes place from two close molecular orbitals: $1e_g$ and $3a_g$ (Sandorfy[27]); the $1e_g$ molecular orbital is strongly bonding for the C–H bond and is antibonding for the C–C bond, while the $3a_{1g}$ orbital is weakly C–H bonding and is strongly C–C bonding. Mulliken[26] believes that the difference between the Rydberg transitions and the transitions of the valence shell electrons is in this case merely semantic and in reality these two types of transitions are coupled.

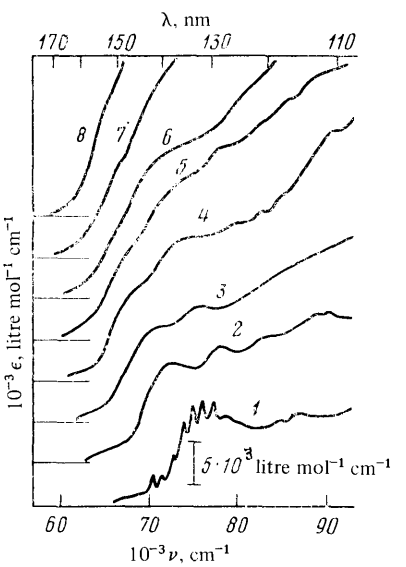

Figure 1. Absorption spectra of linear alkanes in the gas phase[22]: *1)* C_2H_6; *2)* C_3H_8; *3)* C_4H_{10}; *4)* C_5H_{12}; *5)* C_6H_{14}; *6)* C_7H_{16}; *7)* C_8H_{18}; *8)* C_9H_{20}.

The study[25] (Fig.2) of the absorption spectra of polyethylene (PE) and the normal paraffins $C_{28}H_{58}$ and $C_{42}H_{86}$ at 4.2 K led to the discovery of a peak with $\lambda_{max} \cong 148$ nm, which is not observed at room temperature. The authors[25] assigned it to a transition due to a Vanier exciton. Partridge[23,28–31] believes that the entire PE absorption band is due to the exciton interaction. On irradiation with $\lambda \cong 125$–100 nm light, the C_1–C_8 alkanes begin to ionise in

the gas phase. For photon energies near the ionisation threshold, the ionisation quantum yield is low, but, with increase of the photon energy, it rises and, for low-molecular-weight alkanes and light with $\lambda \cong 83-78$ nm, it is unity[32]. In the absorption spectra this region has the form of a broad maximum at the above wavelengths (~80 nm). The absorption intensity then falls monotonically to ~28 nm.[26]

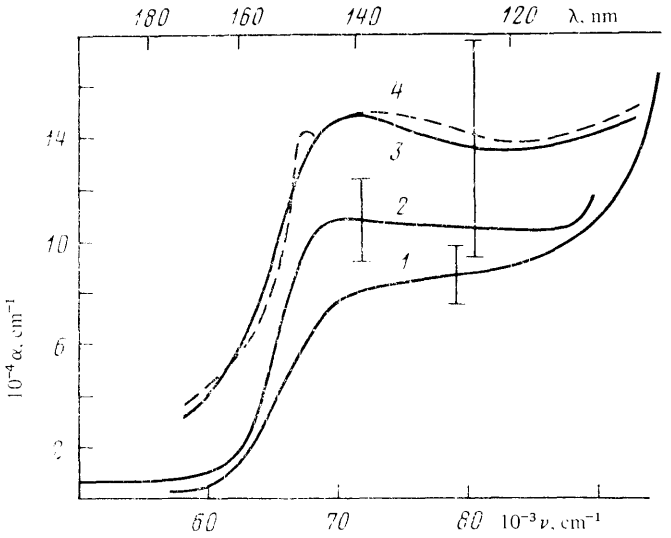

Figure 2. Absorption spectra of polyethylene: *1*)–*3*) at room temperature (data from Refs. 23–25 respectively); *4*) at 4.2 K;[25] α = decadic absorption coefficient.

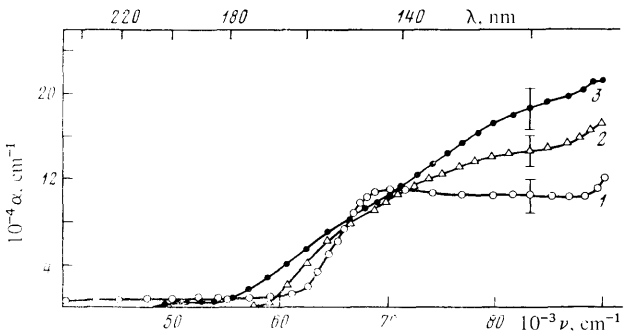

Figure 3. Absorption spectra: *1*) polyethylene; *2*) polypropylene; *3*) polyisobutylene[24]; α = decadic absorption coefficient.

The spectra of highly branched saturated hydrocarbons exhibit a bathochromic shift of the edge of the absorption band relative to the spectra of linear hydrocarbons owing to the decreased energy of the first excited state[33].

In the theory of the absorption spectra of branched alkanes in the gas phase it is assumed that the excited states are degenerate[22], but in reality this degeneracy is removed. For example, for isobutane two transitions are observed instead of one transition (as for propane), the two transitions being symmetrically displaced relative to the transition frequency in propane; for neopentane, three transitions are observed instead of one[22].

Analogous changes have been observed also on comparing the absorption spectra of polymers: PE, polypropylene (PP), and polyisobutylene (PIB) [24] (Fig. 3). To account for this, Raymonda and Simpson[22] and Dorofeev and Skurat[24] resorted to the Jahn–Teller theorem, according to which the degeneracy of the excited state is removed when the molecular symmetry is disturbed. As a result, one observes states with higher and lower energies than those observed for linear saturated hydrocarbons.

Cycloalkanes and highly branched alkanes absorb at longer wavelengths than the corresponding linear alkanes. Thus it has been established[22] that the C_3–C_8 cycloalkanes begin to absorb light at a wavelength of ~175 nm.

The fluorescence of saturated hydrocarbons on excitation with light corresponding to the intrinsic absorption band has been investigated in a number of studies[29–32]. The observed luminescence is monomeric and not excimeric, as suggested by Antonova et al.[21], because the luminescence spectra of hydrocarbons in the vapour phase and the pure liquid hardly differ[34,36]. Furthermore, the emission does not change even in dilute solutions of hydrocarbons in various solvents frozen at 77 K.[36]

The fluorescence of hydrocarbons is characterised by the following features. The spectral distribution of the fluorescence exhibits a Gaussian dependence of the intensity on the wavenumber[37]. On excitation of the fluorescence with light at different wavelengths, its spectrum remains unaltered but the quantum yield decreases with decrease of the wavelength of the exciting light. The fluorescence spectra of saturated hydrocarbons are displaced relative to their absorption spectra by approximately 0.7–1.8 eV;[37] such a large Stokes shift indicates appreciable nuclear perturbations in the excited emitting state[36,37]; under these conditions, the position of the maximum remains unaltered as the number of carbon atoms (N_C) increases, but the fluorescence quantum yield increases (Table 1). The increase of the fluorescence quantum yield is believed[35–37] to be due to a significant decrease in the rates of certain non-radiative processes.

Table 1. The lifetimes of the excited states and the fluorescence quantum yields (liquid phase, 147 nm).[34–37]

Compound	$10^9 t$, s	$10^4 \cdot \Phi_f$	Compound	$10^4 \cdot \Phi_f$
n-Pentane	0.3	0.6	2-Methylpentane	0.001
n-Heptane	6	7	3-Methylhexane	0.007
n-Nonane	15	15	4-Methylnonane	0.028
n-Undecane		28	2-Methylundecane	0.036
n-Hexadecane	50	44		

This influence of N_C can be explained by the fact that its increase entails an increase of the lifetime of the excited states as a consequence of the delocalisation of the electronic excitation over a long chain. The potential surfaces of the ground and excited states approach one another with increase of N_C, diminishing the excitation amplitude, which reduces the probability of non-radiative transitions (including chemical processes). This explanation is consistent with the

fact that the first absorption transition of n-alkanes undergoes a bathochromic shift with increase of N_C, while the energy of the fluorescence transition remains unaltered[35-37]. After the introduction of branches into n-alkanes, the emission spectrum undergoes a bathochromic shift. Thus all the n-alkanes investigated emit light at ~207 nm, 2-methylbutane emits at 233 nm, 2-methylhexane emits at 223 nm, 2-methyloctane emits at 217 nm, etc.[37]. As mentioned above, the wavelength of the first absorption transition also increases under these conditions, but the wavelengths of the emitted light increases to a greater extent, implying that branching increases the changes in the internuclear distances in the excited state, which leads to an increase of the rate of nonradiative transitions and to a corresponding decrease of the fluorescence quantum yield (Table 1).[35,36] The fluorescence of unsubstituted cycloalkanes is observed only for cyclohexane[35,37] (at 201 nm with quantum yields of 8.8×10^{-3} and 3.5×10^{-3} on excitation with light at 165 and 147 nm respectively).

Table 2. The quantum yields of the products of primary processes in the photolysis of fully deuterated n-butane (n-C_4D_{10}).[38]

Product	147 nm	123.6 nm
$CD_4 + C_3D_6$	0.009	0.04
$\dot{C}D_2 + C_3D_8$	0.005	0.018
$C_2D_4 + C_2D_6$	0.21	0.28
$\dot{C}_2D_5 + \dot{C}_2D_5$	0.15±0.01	0.17±0.02
$\dot{C}_2D_7 + \dot{C}D_3$	0.04	0.07
$\dot{C}_4D_9 + \dot{D}$	0.05	0.06
$C_4D_8 + D_2$	0.55±0.05	0.40±0.05

2. Photolysis of Low-Molecular-Weight Hydrocarbons

The gas phase. The photolysis of alkanes in the gas phase has been studied in greatest detail for photon energies below the ionisation threshold: the yields of the products of photochemical reactions have been determined and the mechanisms of the formation of a number of substances have been deduced. Table 2 lists the products of the primary photolytic reactions of n-butane under the influence of light at 147 and 123.6 nm in the gas phase with an indication of their quantum yield. The processes and yields presented in Table 2 are typical for the photolysis of linear alkanes in the gas phase[1,32,38]. The main process in the photolysis of linear alkanes by light below the ionisation threshold involves the removal of a hydrogen molecule on decomposition of an electronically excited molecule. In addition to the elimination of a hydrogen molecule, for ethane the elimination of two hydrogen atoms has been noted:

$$CH_3CH_3 + h\nu \begin{cases} \longrightarrow H_2 + CH_3\ddot{C}H^{\neq} \\ \longrightarrow 2\dot{H} + CH_2{=}CH_2^{\neq} \end{cases}.$$

Acetylene is formed in the decomposition of excited $C_2H_4^{\neq}$:

$$C_2H_4^{\neq} \rightsquigarrow H_2 + CH \equiv CH \quad .$$

Decomposition side reactions have been noted[1] also for propane and butane.

The study of the isotopic composition of hydrogen in the photolysis of mixtures of the normal and deuterated alkanes and also of partly deuterated alkanes has shown (Table 3) that H_2 can be eliminated from both two neighbouring carbon atoms and from the same carbon atom, for example[1]:

$$CH_3CD_2CH_3 + h\nu \begin{cases} \longrightarrow H_2 + CH_3CD_2\ddot{C}H^{\neq} \\ \longrightarrow D_2 + CH_3\ddot{C}CH_3^{\neq} \\ \longrightarrow HD + CH_3\dot{C}D\dot{C}H_2^{\neq} \end{cases}.$$

In the photolysis with light at 147 nm a hydrogen atom is eliminated with a probability smaller by a factor of ~10; in the photolysis by light at shorter wavelengths the process probability increases. Overall, a decrease of the wavelength of the photolysing light entails a decrease of the overall yield of hydrogen: for example, the quantum yield of hydrogen from ethane[46] changes from 0.85 (147 nm) to 0.4 (123.6 nm). The decrease is compensated by an increase of the yields of other primary processes, for example, the dissociation of the C–C bond.

Table 3. The isotope composition (mole %) of the hydrogen formed on irradiation of partly deuterated hydrocarbons and 1 : 1 mixtures of the usual and fully deuterated hydrocarbons.

Hydrocarbon	λ, nm	H_2	HD	D_2	Refs.

*Irradiation with fast electrons. **Irradiation with ^{60}Co γ-rays.

The dissociation of the C–C bond can occur with formation of both molecular and radical hydrocarbon products, for example[1]:

$$CH_3CH_2CH_3 + h\nu \begin{cases} \longrightarrow CH_4 + C_2H_4 \\ \longrightarrow \dot{C}H_3 + \dot{C}H_2CH_3 \end{cases}.$$

However, the probability of the dissociation of the C–C bond with formation of molecular hydrocarbons is greater than for the process involving the formation of radical products[1,32,38]. It is noteworthy that the dissociation of the C–C bond with formation of molecular products involves the transfer of a hydrogen atom. Experiments with partly deuterated hydrocarbons permit a determination of the relative probability of the transfer of primary, secondary, and tertiary hydrogen atoms (Table 4).

With increase of the branching of the alkanes, the yields of processes involving the dissociation of the C–C bond increase, while the yield of hydrogen falls (Tables 5–7); the fraction of HD in the hydrogen produced increases (Table 3). For cyclopropane and cyclobutane, hydrogen is formed with a low quantum yield (Table 5), as for branched alkanes, while the fraction of atomic hydrogen eliminated increases (Table 3); on the other hand, the main process is one involving the dissociation of the C–C bond:[1,38]

$$\text{cyclo-}C_3H_6 + h\nu \rightarrow C_2H_4 + \ddot{C}H_2 \ .$$

However, in the case of cyclopentane and cyclohexane the main processes involve (as for linear alkanes) the elimination of molecular hydrogen (Table 5).[38]

Table 4. The form in which alkanes are formed in the photolysis of branched alkanes $CH_3CX_2CYCZ_3$ by 147 nm light[38].

Product	Relative probabilities of formation	
	R=CH_3	R-CH_2CH_3
RY	1.0	1.0
RX	1.3	1.0
RZ	0.15	0.17

Note. X, Y, and Z denote hydrogen and/or deuterium atoms in various partly deuterated compounds. No correction was applied for the isotope effect.

Table 5. The quantum yields of hydrogen in the gas-phase photolysis of alkanes by 147 nm light[38].

Compound	Φ	Compound	Φ
CH_3CH_3	0.85	$(CH_3)_4C$	<0.05
$CH_3CH_2CH_3$	0.70	cyclo-C_3H_6	<0.02
$CH_3CH_2CH_2CH_3$	0.59	cyclo-C_4H_8	<0.02
$CH_3CH_2CH_2CH_2CH_3$	0.65	cyclo-C_5H_{10}	0.7±0.1
$(CH_3)_2CHCH_3$	~0.22	cyclo-C_6H_{12}	0.7±0.1
$(CH_3)_2CHCH_2CH_3$	~0.24		

Overall the molecular decomposition reactions of electronically excited alkanes (linear, branched, and cyclic) predominate. The decomposition quantum yields are then close to unity.

The liquid phase. A number of studies have been made on the photolysis of linear and branched alkanes in the liquid phase[5,20,21,47–49]. It has been established that the primary processes are similar to those observed in the gas phase (Tables 6 and 7). However, the secondary fragmentation of the excited molecules formed in the primary process is less important than in the gas phase. For example, in the photolysis of ethane at the temperature of liquid nitrogen, excited ethylene molecules are formed. The decomposition of these excited molecules with formation of acetylene, which plays an important role in the gas-phase photolysis, is in this case inhibited by deactivating collisions in solution[50]. As in the gas phase, the formation of hydrogen is unimportant for branched alkanes in the liquid phase (Table 7); the yields of processes involving the dissociation of the C–C bond and the formation of molecular hydrocarbon products are higher in the liquid phase than in the gas phase but the relative probabilities of these processes are approximately the same in the two cases (Table 7).

Table 6. The quantum yields of the primary products in the photolysis of n-pentane (n-C_5H_{12}) on irradiation with 147 nm light in the gas and liquid phases[20,38].

Product	Gas	Liquid
CH_4	0.01	0.01
C_2H_6	0.048	0.05
C_3H_8	0.053	0.06
H_2	0.65±0.1	0.70

Table 7. The quantum yields of the primary molecular hydrocarbon products in the photolysis of 2,2,4-trimethylpentane (iso-C_8H_{18}) in the gas and liquid phases[20,32,38].

Product	Gas		Liquid
	147 nm	123.6 nm	147 nm
CH_4	0.063	0.066	0.17
iso-C_4H_{10}	0.190	0.225	0.36
neo-C_5H_{12}	0.029	0.34	0.05
H_2	~0.1		

Overall, the different primary decomposition reactions of excited alkane molecules persist and their quantum efficiency remains high also in the liquid phase. For example, in the photolysis of liquid cyclohexane, on irradiation with light at 147 nm, the quantum yield of hydrogen is close to unity, as in the gas phase[51,52]. In the study of the photolysis of isooctane by light at 147 and 160–180 nm in the condensed phase over the temperature range 173–373 K, it was established[49] that the ratio of the yields of the photolysis products hardly changes with increase of temperature but the overall quantum yield becomes greater than unity.

3. The Photolysis of Polyolefins

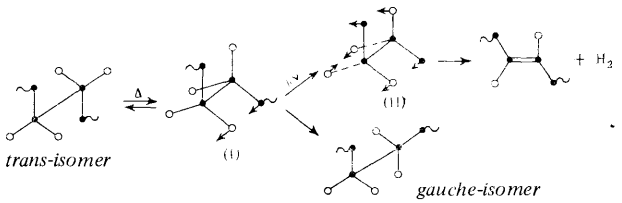
Polyethylene. The photolysis of PE by light at the wavelengths corresponding to the intrinsic absorption band has been investigated in a series of studies[16,17,43,45,53–57]. It was established that the main gaseous product (and virtually the only product) of the photolysis of PE on irradiation with light at 147 nm is hydrogen[43,57]. Its initial quantum yield is 0.4 ± 0.1.[43] Hydrogen can be eliminated in the form of a molecule accompanied by the formation of a *trans*-vinylene double bond[16] (hydrogen can then be eliminated from one carbon atom or two neighbouring atoms[45]):

$$M + h\nu \xrightarrow{\Phi\simeq 0.31} H_2 + \sim CH{=}CH \sim \ ,$$

and also on elimination of the $\dot{H}$ atom[17,43,56]:

$$M + h\nu \xrightarrow{\Phi\simeq 0.06} \dot{H} + \sim \dot{C}H{-}CH_2 \sim \ .$$

The relative probability of the elimination of atomic hydrogen



is approximately the same for solid PE as for low-molecular-weight alkanes in the gas phase. This is also indicated by a comparison of the isotopic compositions of the hydrogen formed in the photolysis of mixtures of the usual and deuterated hydrocarbons (Table 3). However, in contrast to the photolysis of simple alkanes in the gaseous and liquid phases, where $\Phi(H_2) \cong 1$, in the photolysis of solid PE pathways leading to the deactivation of the excited state of molecules without the formation of hydrogen predominate[43]. According to the authors[43], the factors responsible for the decrease of the quantum yield of hydrogen must be both transition to the solid phase, facilitating the deactivation of the electronically excited states, and the large size of the polymeric molecules, promoting the delocalisation of the excitation.

Table 8. Temperature dependence of the quantum yields of hydrogen in the photolysis of deuteropolyethylene[43,54].

t, °C	23	100	120	150	175	200	220	250
$\Phi(D_2+HD)$	0.2—0.25	0.4	0.5	0.65	0.75	0.8	0.9	0.9

The influence of temperature above room temperature on the quantum yield of hydrogen (Table 8) has also been observed[43,54], the greatest increase of the yield being noted at high temperatures even in a polymer melt. It is believed[54] that this temperature dependence indicates the elimination of molecular hydrogen from the vibrationally excited states. Presumably, the fraction of polymeric molecules having a conformation favourable for the elimination of molecular hydrogen increases with increase of temperature.

The relation between the effect of temperature in the photolysis of PE and the conformational kinetics has been explained[58] on the assumption that the transient configurations in the rotational-isomeric transition (I) and in the elimination of molecular hydrogen (II) in the $\sim CH_2-CH_2\sim$ unit in the electronically excited state are similar. In this case, the hydrogen atoms approach one another most closely and the steric conditions are most favourable for the elimination of an H_2 molecule:

According to selection rules, the probability of the absorption of a photon is a maximum for excitation of symmetrical vibrations of the unit (in the scheme above the directions of the vibrations are indicated by arrows). The planar disposition of the H–C–C–H bonds occurring in the *trans–gauche* transitions is therefore most favourable for the elimination of H_2, the transhybridisation $sp^3 \rightarrow sp^2 + p$ of carbon atoms, and the formation of a double bond. As a consequence of this stereospecificity of the process, the kinetics of slow conformational transitions partly determine (since the hydrogen molecule is also eliminated with a high probability from the same carbon atom and not only from two neighbouring carbon atoms[45]) the unusual temperature dependence of the quantum yield of hydrogen in the rapid photolysis of PE.

In the photolysis of PE by light at 147 nm, a C–C bond is also ruptured with formation of a vinyl double bond[16,17]:

$$M + h\nu \xrightarrow{\Phi \cong 0.0} \sim CH_2-CH_3 + CH_2=CH-CH_2\sim \quad .$$

It has been observed[43,45] that the hydrogen formed in the photolysis of mixtures of PE and deuterated polyethylene (DPE) is characterised by a higher [H]/[D] ratio than the mixture of polymers. This effect is due to the intermolecular transfer of excitation energy from the deuterated PE molecules to the normal molecules. Judging from the isotopic composition of the hydrogen formed, in the 1 : 1 copolymer of C_2H_4 and C_2D_4 the energy transfer from the C_2D_4 units to C_2H_4 units via the polymer chain takes place with a greater efficiency than the intermolecular transfer in the mixture of PE and DPE.

The radius of energy transfer from methylene units to *trans*-vinylene double bonds, amounting to 0.3–0.7 nm, has been calculated[57]. In the course of photolysis the quantum yields of the main products diminish: the double bonds attain a limiting concentration (4×10^{-3} mol g^{-1}), while hydrogen continuously evolves with a low (~0.02), slowly decreasing quantum yield. The observed sharp diminution of the quantum yield of hydrogen at the beginning of the photolysis is due to the transfer of excitation energy to double bonds.

The photolysis of PE is also accompanied by a cross-linking process[56,57] as a result of the recombination of the radicals formed in the course of the elimination of a hydrogen atom H and

$$\dot{H} + \sim CH_2-\dot{C}H_2 \sim \rightarrow H_2 + \sim \dot{C}H-CH_2\sim \quad .$$

As double bonds accumulate, they are also hydrogenated by atomic hydrogen:

$$\dot{H} + \sim CH=CH\sim \rightarrow \sim \dot{C}H-CH_2\sim \quad .$$

Furthermore, double bonds are consumed in the intramolecular cross-linking reaction, which leads to the attainment of their limiting concentration[17,56,59].

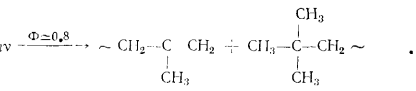
Polypropylene (PP). It has been established[17,60] that the photolysis of PP by light at 147 nm results in the formation of individual bonds and hydrogen in the main primary processes. The double bonds are produced on elimination of a hydrogen molecule and on degradation of the main polymer chain into molecular products:

$$M + h\nu \xrightarrow{\Phi \lesssim 0.25} H_2 + \sim \underset{\displaystyle CH_3}{\overset{\displaystyle |}{C}}-CH\sim \quad ,$$

$$M + h\nu \xrightarrow{\Phi \cong 0.25} \begin{cases} \sim CH_2CH_2CH_3 + CH_2=\underset{\displaystyle CH_3}{\overset{\displaystyle |}{C}}\sim \\ \sim CH_2CH=CH_2 + CH_3-\underset{\displaystyle CH_3}{\overset{\displaystyle |}{C}}\sim \end{cases} \quad .$$

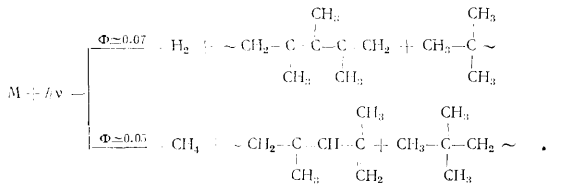
Processes involving the elimination of a hydrogen atom,

$$M + h\nu \rightarrow \dot{H} + R$$



and the formation of methane,

$$M + h\nu \xrightarrow{\Phi \cong 0.025} CH_4 \quad ,$$



also occur. 2-Methylpropane and propene are formed in still lower yields.

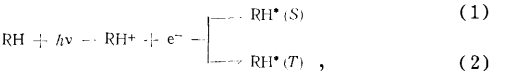
In the course of its photolysis, PP undergoes cross-linking, apparently by the recombination of radicals in reactions similar to those in the photolysis of PE. However, in contrast to PE, in PP the cross-linking process is accompanied by a highly efficient degradation process, which is indicated by the decrease of the thickness of PP films during photolysis.

Polyisobutylene (PIB). In the photolysis of PIB by light at 147 nm, mainly individual double bonds and conjugated diene double bonds are formed in the primary stage[17,24]. Individual double bonds are produced on degradation of the main polymer chain:

The conjugated diene double bonds are formed in the primary process with elimination of H_2 or CH_4 and the degradation of the main polymer chain:

In the secondary stages of photolysis, gaseous hydrocarbon products are formed (2,4,4-trimethylenepentane, 2,4,4-trimethylpent-1-ene, and isobutene) with increasing quantum yields, which leads to the conversion of the surface layer of the polymer into a viscous liquid and to a decrease of the thickness of the specimen.

4. Excited States of Saturated Hydrocarbons and Their Decomposition Products



According to optical selection rules[61], in the photolysis of hydrocarbons virtually only singlet states are excited (the probability of the excitation by light of the triplet states of organic molecules without heavy atoms is $\sim 10^{-5}$).[61] However, on the basis of theoretical calculations, it has been claimed[62,63] that the rate of the intersystem crossing for alkanes, particularly in a condensed phase, is high ($\sim 10^{10}$ to 10^{11} s^{-1}). It follows from studies on the fluorescence of alkanes[34-37], examined above, that the radiative deactivation of the excited singlet state is accompanied by non-radiative deactivation processes (including chemical processes), the overall rate constant for which decreases almost linearly with increasing chain length. This suggests that the intersystem crossing cannot be very significant in long-chain alkanes.

Liquid iso-octane has been photolysed[48] by 147 nm light in the presence of 1,3-cyclohexadiene (it is known[64] that 1,3-cyclohexadiene, which is an acceptor of the donor triplet state, undergoes photochemical dimerisation in the triplet state). The 1,3-cyclohexadiene dimer was then detected and identified, but its quantum yield did not exceed 0.005, indicating that the probability of the intersystem crossing in hydrocarbons (linear and branched) is low.

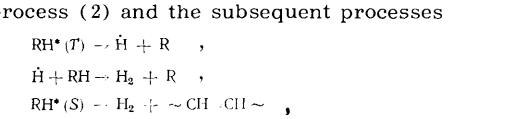
The effects involving a decrease of the quantum yields of the iso-octane photolysis products as a result of combination with radicals and transfer of excitation energy to the molecules of additives (CCl_4, $C_6H_{13}Cl$, C_6F_{16}, O_2, cyclo-C_6H_8) suggest[21,48] the presence of two excited states of iso-octane, leading to the same products via mechanisms involving the molecular and radical decomposition of iso-octane molecules.

The presence of at least two electronically excited states of n-hexane, from which hydrogen is formed, is also indicated by a decrease of the quantum yield of hydrogen to a constant value of 0.65 following the addition of SF_6, compared with that observed in the photolysis of pure n-hexane[47]. It has been established that in the photolysis of hydrocarbons hydrogen is split off in the form of a molecule or atom.

Theoretical studies[62,63] have led to the conclusion that excited singlet states of alkanes are capable of decomposing with elimination of molecular hydrogen directly in the primary step, while triplet states give rise to atomic hydrogen and a free radical via a predissociation mechanism. To test this hypothesis (the elimination of atomic hydrogen from the triplet state), a study was made[55] of the isotope composition of the hydrogen formed in the photolysis of the 1:1 copolymer of C_2H_4 and C_2D_4 at 77 K by 147 and 123.6 nm light. It was established that, in the photolysis at 77 K, ~30 and 37% of the hydrogen formed is evolved directly in the course of elimination (for 147 and 123.6 nm light respectively). The residual hydrogen is evolved only in the course of heating the specimen to room temperature. It has been observed (Table 9) that the fraction of HD in the hydrogen evolved on warming the copolymer irradiated at 77 K is greater than in the hydrogen evolved directly during photolysis. Since the photoionisation of PE takes place preferentially with formation of charged pairs, like that of any other solid organic compound with a low dielectric constant, i.e.

(1)

(2)



the above processes proceed via a mechanism involving the recombination of charged pairs. In this case, the ratio of the yields of reactions (1) and (2) depends on the average lifetime τ of the ion pairs relative to the recombination process[65]. For low values of τ (less than the spin relaxation time of the electron, which is $\sim 10^{-6}$ s), the charged pair recombines only via mechanism (1), while for large τ ($>10^{-6}$ s), the statistical ratio of the yields of reactions (1) and (2), amounting to 1:3, is attained[55,65].

Table 9. The isotope composition of the hydrogen (H_2:HD:D_2) evolved in the photolysis of specimens I–IV at 77 K and after photolysis on heating the specimens to room temperature[55].

Specimen	Photolysis			Heating		
	H_2:HD:D_2	HD/H_2	HD/D_2	H_2:HD:D_2	HD/H_2	HD/D_2
I	72:16:12	0.22	1.3	69:19:12	0.28	1.6
II	82:9.6:8.4	0.12	1.1	64:22:14	0.34	1.6
III	73:7:20	0.096	0.35	74:9:14	0.12	0.53
IV	0:19:81	—	0.23	0:18:82	—	0.22

Notation: I—1:1 C_2H_4–C_2D_4 copolymer (irradiation with 147 nm light); II—1:1 C_2H_4–C_2D_4 copolymer (123.6 nm); III—1:1 polyethylene–deuteropolyethylene mixture (147 nm); IV—deuteropolyethylene (147 nm).

Thus at 77 K process (2) and the subsequent processes

take place on heating PE containing captured charges with $\tau \gg 10^{-6}$ s (with a probability of 0.75). The hydrogen evolved in the course of photolysis is formed via a non-ionic mechanism or via rapid ($\tau < 10^{-6}$ s) recombination of "close" charged pairs in process (1), which does not give rise to HD. The fraction of HD in this hydrogen is therefore reduced. This explanation is supported also by the finding that the increase of the HD content in the retained hydrogen is particularly high on photolysis by light at $\lambda = 123.6$ nm (10 eV), compared with photolysis at 147 nm (8.4 eV).

However, the authors of a later review[66] believe that the triplet states of alkanes can decompose also with elimination of molecular hydrogen. Indeed, it has been shown[67] that the formation of fairly excited triplet states of 1,2-diphenylethane entails, together with the elimination of atomic hydrogen, also the elimination of molecular hydrogen with a quantum yield of 10^{-2}. Unfortunately, the yield in the elimination of atomic hydrogen was not determined in the above studies, which precludes the determination of the relative probabilities of these two processes involving the formation of hydrogen from the triplet state. However, comparison of the yields of double bonds and radicals and also of the isotope composition of hydrogen (Table 3) in the photolysis of linear hydrocarbons and in their radiolysis shows that, whereas the yields of atomic and molecular hydrogen elimination reactions in radiolysis are approximately identical[17,57,68], the elimination of molecular hydrogen predominates in photolysis[17,43,56,57].

This difference is due to the fact that, as a consequence of prohibition rules, virtually only the singlet state is excited in photolysis, whereas in radiolysis, where the main active factor is secondary radicals with an energy below 100 eV, such prohibition rules are missing (particularly for resonance energies of the electrons) and triplet states should be formed with a high probability already in the primary process and also in the ion recombination process. On the basis of this comparison, one may claim that the dominant process in the decomposition of the electronically excited triplet state is the elimination of atomic hydrogen with formation of a free radical.

According to Raymonda and Simpson[22], the 147 nm light excites only C–C bond electrons in hydrocarbons. On this basis, Holroyd[20] suggests that the elimination of molecular hydrogen should be attributed to the excitation of the electrons of the above bonds. However, it has been assumed[32] that the ^1E_u state, produced by the excitation of the C–H bonding electron, is responsible for the elimination of molecular hydrogen.

The decrease of the yield of hydrogen with increasing branching of hydrocarbons (Tables 4 and 8) has been explained[17,24], on the one hand, by the decrease of the number of CH_2 and CH–CH groups (molecular hydrogen is eliminated from these groups[45]) and, on the other hand, by the more effective consumption of the absorbed energy in processes involving the dissociation of the C–C bond.

The observed increase of the yield of processes involving the dissociation of the C–C bond with increasing branching of compounds is due to the weakening of the C–C bond near the branching point (for example, in the case of polymers, which is indicated by the decrease of the heat of polymerisation of the corresponding monomers, which amounts to 92, 69, and 54.5 kJ mol^{-1} for PE, PP, and PIB respectively[69]). It is noteworthy that the high yield in the dissociation of the C–C bonds of polymers is believed[70] to be caused (according to theoretical calculations of adiabatic potential curves) by the low activation energy for this process in the excited state and the correlation between the yields of C–C bond dissociation processes involving polymers and the corresponding heats of polymerisation is justified if the adiabatic potential curve in the ground state for a given bond characterises the potential curve in the excited state.

According to calculations[70], such a correspondence obtains for PE and PIB. However, in the case of polytetrafluoroethylene (which undergoes degradation on radiolysis) a high heat of polymerisation (165 kJ mol^{-1}) corresponds to a low activation energy in the excited state[70]. Such weakening of the C–C bond is caused by steric strain in the ground and excited states as a consequence of the presence of side groups; it leads to a decrease of the dissociative lifetime for the C–C bond dissociation reaction (this is indicated by the decrease of the fluorescence quantum yield of alkanes with increase of the degree of branching—see Table 1 and Refs. 34 and 37) and hence to an increase of the yield of processes involving the dissociation of this bond.

It is noteworthy that the dissociation of the C–C bond is observed mainly near the branching point and in hydrocarbons containing methyl side groups the C–C bonds of the main chain are largely dissociated (in the PP and PIB polymers the yield of the bond branching reactions involving the main polymer chain is approximately ten times higher than the yield corresponding to the methyl side groups[17,24,57,60]). Apart from the features examined above, in PE, PI, and PIB there is an increase of the overall quantum yield of the photodecomposition of the polymers (Table 10). It has been noted[17,24] that, with increased degree of branching in the above series of compounds, the efficiency of the deactivation of the electronically excited states diminishes with a simultaneous increase of the contribution of processes involving the dissociation of the C–C bonds in the main polymer chain. On the basis of the results of studies[34–37] of the fluorescence of saturated hydrocarbons, this effect has been explained by the increase of the lifetime of the excited states with increase of the number of carbon atoms in linear alkanes (Table 1) accompanied by an increase of the fluorescence quantum yield. Therefore, on the basis of the data in Table 1 for PE, one may expect still higher lifetimes of the excited singlet states, which would promote their effective deactivation, particularly in the solid phase. Such increase of the lifetime of excited states has been explained[34–37] by the diminution of the changes in the internuclear distances in the excited state (as a consequence of the delocalisation of the electronic excitation over a long chain), which diminishes the probability of non-radiative transitions (for example, chemical processes). This explanation is confirmed by the finding that the first absorption transition of normal alkanes undergoes a bathochromic shift with increasing number of carbon atoms, while the energy of the fluorescence transition remains unaltered[34–37]. This is one of the possible causes[43] of the low quantum yield of the photodecomposition of PE compared with that observed in the photolysis of the lower linear alkanes, where the photodecomposition quantum yield is close to unity[1,32,38].

It has been established (see Table 1 and Refs. 35–37) that the luminescence quantum yield or branched alkanes is appreciably lower than for normal alkanes (by a factor of approximately 10). It is suggested that the emitting state is characterised by a high degree of localisation of the electronic excitation near the branching point. The localisation of the electronic excitation is accompanied by a large change in internuclear distances and this induces an increase of the rates of certain non-radiative processes, i.e. polymer chain degradation processes. Another possible explanation

involves a diminution of matrix effects hindering the photodecomposition of polymer molecules on transition to the amorphous PIB polymer[24].

Table 10. The quantum yields of the primary photolytic processes involving PE, PP, and PIB on irradiation with 147 nm light[17,24].

Process	PE	PP	PIB
Elimination of hydrogen molecule	~0.3	⩽0.25	⩽0.07
Degradation with formation of terminal double bonds	0.03	~0.25	0.8

It is interesting to compare certain predictions of the molecular exciton theory for σ-bonds of alkanes, examined in a number of studies[23,28–31], with the results of experiments on the photolysis of PE by 147 nm light. In the first place one should note that the light quantum with $\lambda = 147$ nm has an energy of 8.4 eV, which is apparently sufficient for the formation of an exciton (according to some data[23,28–31], the formation of an exciton requires an energy of ~7.5–9.5 eV). According to the above investigations[23,28–31], the excitation energy of linear alkanes can be divided into two parts, one of which is localised at the C–H bonds of the $\sim CH_2\sim$ group and the other migrates from one C–C bond to another. Only localised excitation of carbon–hydrogen bonds can lead to the formation of a hydrogen atom or an H_2 molecule as a result of their separation from the $\sim CH_2\sim$ group.

However, the results of experiments on the photolysis of PE conflict with this postulate of the theory of singlet σ-bond excitons. The results are as follows. An H_2 molecule is eliminated not only from a single carbon atom but also from two neighbouring atoms[45] and there is excitation energy transfer from deuterated units to the usual units on photolysis of the C_2D_4–C_2H_4 copolymer[45]; the double bonds formed on photolysis hinder the formation of hydrogen[17,57], the quantum yield of hydrogen increasing with temperature and approaching unity (see Table 8 and Refs. 43 and 44).

IV. PHOTOLYSIS OF HYDROCARBONS CONTAINING INDIVIDUAL DOUBLE BONDS

1. Optical Spectroscopy

Absorption by ethylene is observed at $\lambda \cong 200$ nm [71,72] (Fig. 4). At $\lambda \cong 175$ nm, a series of sharp intense peaks are observed and are superimposed on the absorption continuum with a maximum at ~164 nm. A new series of sharp bands are observed at ~142 nm and are superimposed on another continuum with maximum absorption at ~130 nm. It is believed to be established[71] that the long-wavelength absorption and the first continuum are due to the singlet excitation of the electron from the bonding molecular π orbital $1b_{2u}$ with transition to the antibonding π orbital $1b_{3g}$. The sharp absorption bands at 175 nm are due to Rydberg transitions; the lowest Rydberg transition $N \rightarrow 3s$ is observed at 174.4 nm. Rydberg transitions ($\pi \rightarrow 3p$, $\pi \rightarrow 3d$) [71] have also been noted in the range 154–118 nm. It is believed that the second absorption continuum of ethylene at 125 nm is due to the $\sigma \rightarrow \sigma^*$ transition. The ionisation of ethylene begins at 128 nm.[71] It has been suggested[71,73] that the ethylene molecule in the lowest Rydberg state has been "twisted" by an angle of 30° relative to the geometrical plane in the ground state. The geometry of the ethylene molecule in the singlet π^* state has not been established, while in the triplet state the molecule has been "twisted" by an angle of 90°.

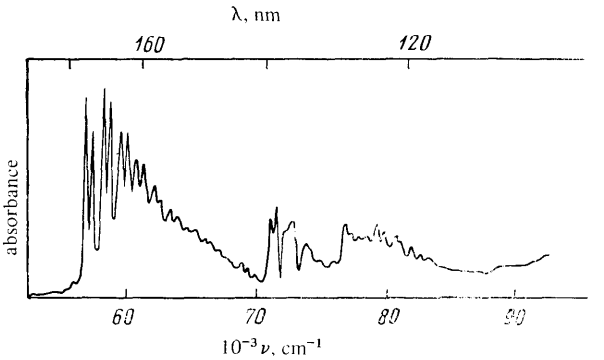


Figure 4. Absorption spectrum of gaseous ethylene in the vacuum ultraviolet region[72].

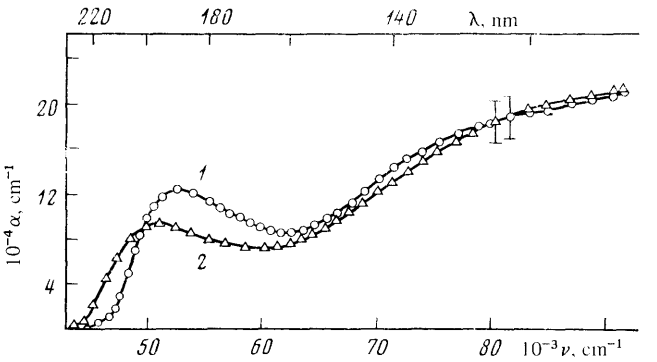

Figure 5. Absorption spectra: *1*) polybutadiene; *2*) polyisoprene[59]; α = decadic absorption coefficient.

As for ethylene, the first intense band in the absorption spectra of alkylolefins is due to the $\pi \rightarrow \pi^*$ transition and the fine structure superimposed on this band is less well resolved than for ethylene. It has been noted[71] that, with increase of the number of alkyl groups at the double bond, the absorption band undergoes a bathochromic shift (Fig. 5). The literature data on the oscillator strengths of various substances at the wavelength of the absorption band of carbon–carbon double bond ($\pi \rightarrow \pi^*$ transition) have been compiled in a monograph[71]. These data show that the oscillator strengths of compounds of different types are in the range from 0.26 to 0.59.

The fluorescence of mono-olefins irradiated with light corresponding to the absorption band of the double bonds has been studied[37,73]. On excitation by 184.9 nm light, a weak emission by gases at a pressure of 1 atm is observed (propene has a fluorescence band maximum at $\lambda_f \cong 223$ nm and *cis*- and *trans*-but-2-enes have $\lambda_f \cong 223$–227 nm). The fluorescence quantum yields for these substances are $\sim(1-2) \times 10^{-6}$. A similar luminescence has been observed also for pure liquids: hex-1-ene ($\lambda_f \cong 236$ nm), *cis*-hex-2-ene ($\lambda_f \cong 238$ nm), and *trans*-hex-2-ene ($\lambda_f \cong 235$ nm). The luminescence quantum yields for these substances are $(5-7) \times 10^{-6}$. With increase of the degree of branching, the fluorescence undergoes a bathochromic shift and its quantum yield increases[37,73]. Thus the fluorescence of liquid tetramethylethylene is observed at $\lambda_f \cong 258$ nm with a quantum yield of 1.5×10^{-4}.

2. Photolysis of Mono-olefins

The photolysis of ethylene has been studied in greatest detail. For photons with energies ranging from 6.1 to 11.8 eV, the elimination of H_2 is the main process[38,74,75] [$\Phi(H_2) \cong 0.45 \pm 0.05$ in the range of photon energies 8.4–6.4 eV [38,74]]. Experiments on the photolysis of CH_2CD_2 by 147 and 123.6 nm light have shown[38] that the elimination of H_2 and D_2 from a single carbon atom is more probable than the elimination of HD from two carbon atoms. Furthermore, it has been established that the relative probabilities of the formation of H_2, D_2, and HD are independent, within the limits of experimental error, of the wavelength and the phase state of ethylene[76]. However, it has been stated that the probability of the competing process

$$C_2H_4 + h\nu \rightarrow \overset{*}{C}_2H_3\,(C_2H_2 + \dot{H}) + \dot{H}$$

increases with increase of the photon energy from 8.4 to 11.6–11.8 eV. In addition the following process has also been observed:

$$C_2H_4 + h\nu \rightarrow 2\ddot{C}H_2 \quad .$$

It has been suggested that there should be at least three different electronic states of ethylene in order to account for the photodecomposition processes in the range of photon energies from 6.4 to 8.4 eV.

The photolysis of ethylene by 104.8–106.7 nm light[38,77] entails ionisation and the formation of superexcited states:

$$C_2H_4 + h\nu \begin{cases} \rightarrow (C_2H_4^{\neq})^+ + e^- \\ \rightarrow C_2H_4^{**} \rightarrow (C_2H_4^{\neq})^+ + e^- \end{cases} .$$

The superexcited ethylene molecule ($C_2H_4^{**}$) can also decompose in the following processes:

$$C_2H_4^{**} \begin{cases} \rightarrow C_2H_2 + H_2 \\ \rightarrow C_2H_2 + 2\dot{H} \end{cases} .$$

It is believed[77] that, on collision with an ethylene molecule, $C_2H_4^+$ gives rise to a vibrationally excited ion:

$$C_2H_4^+ + C_2H_4 \rightarrow (C_4H_8^{\neq})^+ \quad .$$

In the absence of deactivating collisions, the $(C_4H_8^{\neq})^+$ ion decomposes:

$$(C_4H_8^{\neq})^+ \begin{cases} \rightarrow C_3H_5^+ + \dot{C}H_3 \\ \rightarrow C_4H_7^+ + \dot{H} \end{cases} .$$

Ethylene has been photolysed[76] in the condensed phase at 20 K by photons with energies from 8.4 to 21.2 eV. It has been established that, for higher photon energies, the relative yields of the products are comparable to the yields in the decomposition of solid ethylene. The relative yields of acetylene and cyclobutane (these are not the main products in the photolysis by photons with an energy of 8.4 eV) increase by an order of magnitude for higher photon energies, where the ions play a significant role.

Table 11. The composition of the products of the gas-phase photolysis of propene[78].

Product	147 nm	123.6 nm	Product	147 nm	123.6 nm
Hydrogen	7.6	14.7	Allene	7.4	6.8
Methane	3.4	3.8	Isobutane	11.4	8.6
Acetylene	38.0	34.9	Isobutene + but-1-ene	3.5	4.8
Ethylene	12.2	18.2	*trans*-But-2-ene	7.2	4.8
Ethane	7.4	4.1	*cis*-But-2-ene	1.9	0.0

The products of the photolysis of propene by 147 and 123.6 nm light are presented in Table 11.[78,79] The hydrogen formed in the photolysis is split off mainly in molecular processes:

$$CH_3CH{=}CD_2^{\neq} \begin{cases} \rightarrow H_2 + \ddot{C}HCH{=}CD_2 \\ \rightarrow H_2 + CH_2{=}C{=}CD_2 \end{cases} .$$

Acetylene is formed as a result of the rapid consecutive dissociation of two bonds:

$$CH_3CH{=}CH_2 \rightarrow \dot{C}H_3 + \dot{C}H{=}CH_2^{\neq} \quad ,$$

$$\dot{C}H{=}CH_2^{\neq} \rightarrow CH{\equiv}CH + \dot{H} \quad .$$

In the photolysis of the $C_3H_6 + C_3D_6$ mixture the yield of C_2H_4 is higher than that of C_2D_3H. Hence it follows that ethylene is partly formed via a molecular pathway:

$$CH_3CH{=}CH_2 + h\nu \rightarrow \ddot{C}H_2 + CH_2{=}CH_2 \quad .$$

Another process is also possible:

$$\dot{H} + C_3H_6 \rightarrow \dot{C}_3H_7 \rightarrow \dot{C}H_3 + C_2H_4 \quad .$$

The photolysis of propene by 123.6 nm light entails ionisation with a quantum yield of 0.197. Direct ionisation and self-ionisation in the superexcited state are observed. The $C_3H_6^+$ ions formed are involved in ion–molecule reactions:

$$C_3H_6^+ + C_3H_6 \rightarrow C_6H_{12}^+ \quad ,$$

$$C_6H_{12}^+ + C_3H_6 \rightarrow C_6H_{10}^+ + C_3H_8 \quad .$$

The process

$$C_6H_{12}^+ + C_6H_6 \rightarrow C_9H_{18}^+ ,$$

is possible but with a much lower probability.

In the photolysis of but-1-ene by 184.9, 147, 123.6, and 104.8–106.7 nm light, the main products are formed on fragmentation of the excited molecule[80]. Allene, buta-1,3- and buta-1,2-dienes, ethylene, and acetylene are formed (Table 12). When a hydrogen atom interacts with a double bond, the butyl radical is formed. On photolysis of trimethylethylene by 147 and 123.6 nm light, the following main products are formed: isopropene, buta-1,3-diene, propyne, allene, and ethylene[81] (Table 13).

It follows from Tables 12 and 13 and the results of a series of investigations[80–97] that, in the photolysis of linear olefins by light corresponding to the absorption band of double

bonds, the main process is the dissociation of the C–C β-bond if such is present and a C–H bond if there is no C–C bond in the β-position:

$$C_4H_8\text{-}1 + h\nu \xrightarrow{\Phi=0.71} \dot{C}H_3 + \dot{C}H_2{-}CH{=}CH_2 \ ,$$

$$C_4H_8\text{-}2 + h\nu \xrightarrow{\Phi=0.6} \dot{H} + \dot{C}H_2{-}CH{=}CH{-}CH_3 \ .$$

Analogous processes occur also in the photolysis of hex-2-ene and but-2-ene by 202.6 and 206.2 nm light:

$$C_6H_{12}\text{-}2 + h\nu \rightarrow CH_3CH{=}CH\dot{C}H_2 + \dot{C}H_2CH_3 \ ,$$

$$C_4H_8\text{-}2 + h\nu \rightarrow CH_3CH{=}CH{-}\dot{C}H_2 + \dot{H} \ .$$

In branched olefins the methyl side groups promote the dissociation of the C–C bonds in the α-position:

$$iso\text{-}C_4H_8 + h\nu \rightarrow \begin{cases} \xrightarrow{\Phi\geq 0.78} CH_3{-}\dot{C}{=}CH_2 + \dot{C}H_3 \\ \xrightarrow{\Phi\geq 0.25} \dot{C}H_2{-}C{=}CH_2 + \dot{H} \\ \qquad\quad | \\ \qquad\quad CH_3 \end{cases} .$$

Table 12. The quantum yields of the primary processes in the decomposition of the excited state of but-1-ene (C_4H_8-1) in photolysis by light corresponding to the intrinsic absorption band[80].

Product	184.9 nm	147 nm	123.6 nm	104.8–106.7 nm
$C_3H_4+\dot{C}H_3+\dot{H}(CH_4)$	0.04	0.38	0.23	0.16
$C_4H_6+2\dot{H}(H_2)$	—	0.32	0.36	0.17

$\dot{C}_3H_5+\dot{C}H_3$	0.71	0.0	0.0	0.0

Table 13. The quantum yields of the decomposition processes involving the excited state of the trimethylethylene (C_5H_{10}) molecule[81].

Product	147 nm	123.6 nm	Product	147 nm	123.6 nm
$\dot{C}_5H_8+2\dot{H}(H_2)$	0.33	0.28	$[C_5H_{10}^+]^* + e^-$	0.00	0.22
$C_3H_4+2\dot{C}H_3$	0.27	0.2	$\dot{C}_5H_9+\dot{H}$	0.15	0.12
$C_4H_6+\dot{C}H_3+\dot{H}(CH_4)$	0.15	0.1	Other products	0.09	0.08

In the photolysis by light at $\lambda \leq 145$–150 nm decomposition processes involving the formation of three species, namely a hydrogen molecule and two radical species ($\dot{H}$ and the hydrocarbon radical or $2\dot{H}$), begin to predominate. A decrease of the yields of certain products with increase of pressure has been noted in the photolysis of olefins by light corresponding to the absorption band of double bonds[81,84,85,89,90,93,96]. The influence of pressure is due to the following sequence of processes:

$$M + h\nu \rightarrow M^{**} \ ,$$

$$M^{**} \rightarrow R^* + R_1 \ ,$$

$$R^* \rightarrow m + \dot{H} \text{ (or } \dot{C}H_3) \ ,$$

where m is a molecule containing an acetylenic or cumulated bond[84,93,94]. The influence of pressure is due to the stabilisation of the excited radical R* in the process

$$R^* + M \rightarrow R + M \ .$$

A similar mechanism of the effect of pressure has been considered also in the photolysis of hex-2-ene and but-2-ene by 202.6 and 206.2 nm light[92]:

$$C_6H_{12}\text{-}2 + h\nu \rightarrow C_6H_{12}\text{-}2^{**} \ ,$$

$$C_6H_{12}\text{-}2^{**} \rightarrow C_6H_{12}\text{-}1^{**} \ ,$$

$$C_6H_{12}\text{-}2^{**} \rightarrow C_6H_{12}\text{-}2^* \ ,$$

$$C_6H_{12}\text{-}2^{**} \rightarrow CH_3CH{=}CH\dot{C}H_2 + \dot{C}H_2CH_3 \ ,$$

$$C_6H_{12}\text{-}2^* + M \rightarrow C_6H_{12}\text{-}2 + M \ .$$

The absence of an influence of pressure on the yields of various products in photolysis by short-wavelength light has been explained[88] by the faster decomposition of excited radicals and molecules owing to their higher excess energy. The photolysis of olefins by 123.6 and 104.8–106.7 nm light involves the ionisation of double bonds with a quantum yield of ~0.2–0.3.[81,87,88,97]. The ions formed participate in ion-molecule reactions leading to the formation of saturated hydrocarbons as well as hydrocarbons containing a larger number of carbon atoms than the initial olefin.

3. Photolysis of Diene Polymers

Polybutadiene (PB) and polyisoprene (PI). The photolysis of polymers containing individual double bonds (PB and PI) on irradiation with 147 and 123.6 nm light has been investigated[17,56,59,98]. It has been established that the main processes involve the consumption of double bonds and their *cis–trans* isomerisation. In addition, hydrogen and intermolecular cross-links are produced (Table 14) as well as unidentified hydrocarbon products. The formation of these hydrocarbons entails a decrease of the thickness of PB and PI film by 30–50 nm on photolysis by 147 and 123.6 nm light with a dose of $(1–2) \times 10^{18}$ quanta cm^{-2}. It is believed that mainly electronically excited states of the polymer molecules arise in this instance as in the photolysis of olefins in the gas phase:

$$M + h\nu \rightarrow M^* \ .$$

The decomposition of M* involves the elimination of atomic hydrogen:

$$M^* \rightarrow R + \dot{H} \ .$$

However, the photolysis of PB and PI differs significantly from the photolysis of olefins in the gas phase by the fact that the overall yield of diene, cumulated, and acetylenic bonds (~0.06) is approximately ten times lower than in the gas-phase photolysis of butenes and pentenes, where the yield of the above bonds is ~0.5.[80,81,87,94]. The difference is believed[17,59] to be caused by the transition to the condensed phase, which suppresses the secondary decomposition reactions of the excited radicals leading to the formation of these bonds:

$$M^* \rightarrow \begin{cases} R^* + \dot{C}H_2{-}CH{=}CH{\sim} \\ m + \dot{H} \end{cases} .$$

The hydrogen detected is formed in the molecular elimination reaction

$$M^* \begin{cases} \rightarrow H_2 + \sim CH{=}CH{-}CH{=}CH{-}CH{=}CH \sim \\ \rightarrow H_2 + \sim CH{=}C{=}CH{-}CH_2 \sim \end{cases} .$$

C–C bond dissociation reactions involving the main polymer chain take place:

$$M^* \begin{cases} \rightarrow \sim CH{=}CH{-}\dot{C}H_2 + \dot{C}H_2{-}CH{=}CH \sim & (3) \\ \rightarrow \sim CH{=}\dot{C}H + \dot{C}H_2{-}CH_2{-}CH{=}CH \sim . & (4) \end{cases}$$

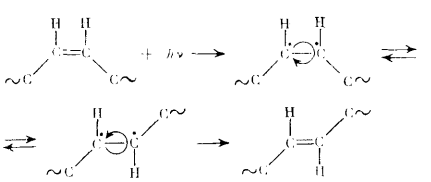
It is believed[17,59] that the probability of process (3) is higher than that of process (4) owing to the fact that the C–C bond in the β-position is weaker (~231 kJ mol^{-1}). The strength of this bond is appreciably lower than that of the usual C–C bond (~374 kJ mol^{-1}) owing to the resonance stabilisation of the two allyl radicals formed on dissociation of the main polymer chain[99].

It is thought possible that the double bond migrates with formation of a conjugated diene double bond[59]:

$$M + h\nu \rightarrow \sim CH{=}CH{-}CH_2{-}CH{=}CH \sim + h\nu \rightarrow \sim CH{=}CH{-}CH{=}CH \sim .$$

The primary process can also be the formation of cyclopropane groups:

$$M + h\nu \rightarrow \sim CH_2{-}\dot{C}H{-}\dot{C}H{-}CH_2 \sim \rightarrow \sim CH_2{-}\dot{C}H{-}CH_2{-}\dot{C}H_2 \sim \rightarrow \quad (5)$$
$$\rightarrow \sim CH_2{-}CH(\diagup\diagdown CH_2){-}CH \sim .$$



This process occurs in the photolysis of PB and PI by 253.7 nm light, assumed to proceed via the triplet state[98,100], and in the triplet sensitisation of but-1-ene in the gas phase by mercury atoms[15]. Cyclopropane groups can also be formed in the isomerisation of the allyl radical:

$$\sim CH_2{-}CH{=}CH{-}\dot{C}H_2 \rightarrow \sim CH_2{-}CH(\diagup\diagdown CH_2){-}\dot{C}H \quad . \quad (6)$$

Cross-links are formed mainly in radical recombination processes and possibly also in the interaction of radicals with double bonds:

$$R + \sim CH{=}CH \sim \rightarrow \text{cross-link} + R'.$$

It has been established[98] that *cis–trans* isomerisation takes place in the photolysis of PB by 123.6 nm light. It has been suggested that this process proceeds as follows: when a light quantum is absorbed, the π-electrons are transferred to the antibonding orbital, whereupon there is a possibility of free rotation leading to a change in the steric configuration[99]:

A similar process should apparently be observed also in photolysis by light at 147 nm, since it has been noted[100] that *cis–trans* isomerisation proceeds also in the photolysis of PB and PI by light at λ = 253.7 nm with a quantum yield of ~0.04.

The difference between the yields of reactions involving the consumption of double bonds in photolysis by 147 and 123.6 nm light is striking (Table 14). It is believed to be caused by the ionisation of double bonds by 123.6 nm light, in contrast to 147 nm irradiation. The ion–molecule mechanism of the cross-linking of PB and PI in photolysis by light at λ = 123.6 nm has been considered:

$$M + h\nu \rightarrow \sim CH_2{-}\dot{C}H{-}\overset{+}{C}H \sim + e^-,$$
$$\sim \dot{C}H{-}\overset{+}{C}H \sim + M \rightarrow \sim CH_2{-}\overset{+}{C}H \sim + R ,$$
$$\sim CH_2{-}\overset{+}{C}H \sim + \sim CH{=}CH \sim \rightarrow \sim CH_2{-}CH(\overset{+}{C}H){-}CH \sim .$$

This is followed by further chain propagation.

Table 14. The quantum yields of the main processes in the photolysis of polybutadiene and polyisoprene on irradiation with 147 and 123.6 nm light.

Process	Polybutadiene		Polyisoprene	
	147 nm	123.6 nm	147 nm	123.6 nm
Consumption of individual double bonds	0.28 [59]	1.3 [59]; 1.53 [98]	0.24 [59]	1.3 [59]
cis–trans-Isomerisation	—	0.25 [98]	—	—
Formation of H_2	0.019 [59]	0.023 [59]	0.015 [59]	0.022 [59]
Formation of intermolecular cross-links	0.012–0.024 [56]	0.027–0.056 [56]	0.008–0.03 [56]	0.048–0.063 [56]

Note. The numbers in square brackets denote references (Ed.of Translation).

It has been postulated[56] that the free-radical mechanism of cross-linking determines the formation of a gel in photolysis by 147 nm light, while in photolysis by 123.6 nm light the ion–molecule cross-linking mechanism should play a decisive role. The large difference between the yields of the cross-linking and double bond consumption reactions is striking, although, according to both the free-radical and ion–molecule mechanisms, these quantities should be similar. The higher overall quantum yield (>1)† (Table 13) in photolysis by 123.6 nm light indicates a chain mechanism of the destruction of double bonds.

The yields of the cross-linking reaction are much lower than these values, which makes it necessary to seek additional double bond destruction processes apart from intermolecular cross-linking. It has been suggested[17,56,59] that there exist two types of such processes: intermolecular cross-linking with formation of cyclopropane groups [processes (5) and (6)] and the formation of multiple intermolecular cross-links in the same pair of macromolecules, which should be promoted by chain processes due to the migration of a charge or a radical. The ratio of the rates of these processes and the number of cross-links in the pair of macromolecules probably depend on the type of active radiation: on passing from photolysis by 147 nm light to photolysis by 123.6 nm light, the yield of the double bond consumption reaction increases by a factor of 5–6 and the yields of the cross-linking reactions increase only by a factor of two.

V. PHOTOCHEMICAL REACTIONS OF CERTAIN POLYMERS INVOLVING OXYGEN

The influence of vacuum ultraviolet light in the wavelength range ~110–220 nm on polymers in the presence of oxygen has been investigated in several studies[101–104].

†Probably >0.1 (Ed.of Translation).

Thus a silicone rubber, poly(vinyl chloride) (PVC), and poly(methyl methacrylate) (PMMA) have been irradiated with the light of a hydrogen discharge[102]. During photolysis by radiation *in vacuo* in the course of approximately 100 h, no changes in the irradiated films were detected by infrared spectroscopy. However, during photolysis the films changed colour, particularly the PVC films, and ceased to dissolve in solvents, which indicates the formation of intermolecular cross-links. After the addition of small amounts of oxygen to the photochemical cuvette, the absorption band due to carbonyl groups appeared in the infrared spectra.

PVC, PMMA, polystyrene (PS), and polycarbonate (PC) films 100–150 nm thick have been irradiated with light at λ = 110–200 nm in an atmosphere of nitrogen[101]. It was established that, on irradiation, the optical densities of the PVC and PMMA specimens decrease fairly appreciably in the first 15 min and then, having attained ~50% of the initial value, no longer change. The optical densities of PS and PC change very insignificantly during irradiation for 1.5 h. The irradiated sections of all four polymers become insoluble in solvents which are effective for the initial non-cross-linked polymers.

Table 15. Some parameters of the decomposition of polymers [rate of decomposition v (nm min^{-1}), quantum yield Φ, and consumption of O_2 molecules in the decomposition of one unit n] on irradiation with light at $\lambda \cong$ 100–200 nm in an atmosphere of oxygen[103].

Polymer	v, nm min^{-1}	Φ	n
PVC	16	0.32	1
PMMA	10	0.24	1
PS	1.6	0.01	10
PC	1.5	0.005	20
PTFE	2.5	0.1	2

The kinetics of the decomposition of polymer films by light at 110–200 nm have been investigated[101,103] in an oxygen-containing medium. Table 15 presents the results of measurements of the rates of decomposition of PVC, PMMA, PS, PC, and polytetrafluoroethylene (PTFE). The following stable decomposition products of PVC, PMMA, PS, and PC were detected: CO_2, CO, and H_2O. A more involved mass spectrum containing the following ions was obtained for PTFE: F^+, CO^+, CO_2^+, COF^+, COF_2^+, CF_3^+, $C_2F_4^+$, $C_2F_5^+$, and $C_2F_4O_2^+$; other ions with a mass number m/e > 180 were also detected. The absence of a signal due to fragments resulting from the decomposition of the polymer chain in the mass spectra of polymers without fluorine and the low consumption of oxygen are apparently due to the activity of the decomposition products of these polymers: they settle on the walls of the reactor in the form of solid deposits. It has been suggested that the stable radicals $\sim CF_2CF(\dot{O}_2)CF_2\sim$ and $\sim CF_2CF_2\dot{O}_2$ participate in the PTFE decomposition reactions. The formation of such radicals on irradiation of PTFE with vacuum ultraviolet light (~120–160 nm) with subsequent exposure of the specimen to air has been detected by EPR.[104] The authors[104] believe that the peroxy-radicals detected are formed from central ($\sim CF_2\dot{C}FCF_2\sim$) and terminal ($\sim CF_2-\dot{C}F_2$) radicals under the influence of vacuum ultraviolet light.

VI. CONCLUSION

Thus the photolysis of two classes of hydrocarbons (including polymers) by vacuum ultraviolet radiation, mainly in the wavelength range 105–200 nm, results in the formation of electronically excited states due to the transitions $\sigma \rightarrow \sigma^*$, $n \rightarrow \sigma^*$, $\pi \rightarrow \pi^*$, and $n \rightarrow \pi^*$, Rydberg states are excited, and ionisation takes place.

In the photolysis of the compounds examined, both molecular and free-radical products can be formed in the photochemical process. The formation of primary products in an excited state is characteristic of olefins, which can lead to their subsequent dissociation in secondary processes. It has been noted for a number of substances that secondary fragmentation can be suppressed by increasing the pressure in the gas phase, by conversion into the liquid phase, and particularly by conversion into the condensed phase (polymers). A decrease of the yield of primary processes has also been noted for PE owing to the transition to the condensed phase and the formation of long-chain molecules.

Comparison of primary processes involving low-molecular-weight substances in the gas phase and polymers with a similar structure in the condensed phase shows that the primary processes are as a rule the same in both cases. This makes it possible to predict the photochemical processes in polymers on the basis of the results of the photolysis of low-molecular-weight substances in the gas phase. However, the analogy is not complete. Thus PIB gives rise to the formation of conjugated diene double bonds, which has not been noted for low-molecular-weight branched alkanes. This feature is apparently due to the regularity of the structure of the PIB macromolecules.

It is of interest to compare certain characteristics of the photolysis of polymers by vacuum ultraviolet light, i.e. by light corresponding to the intrinsic absorption band, and light at $\lambda \gtrsim 200$ nm, when absorption is due to impurities or anomalies in the structure of the real macromolecule. In photolysis by light at $\lambda \lesssim 200$ nm the quantum yields of products derived from the polymers investigated are in the range ~0.1–1, while in the photolysis of the same polymers by light at $\lambda \gtrsim 200$ nm the quantum yields are lower by a factor greater than ten[99]. Whereas the photolysis of PE, PP, and PBI by vacuum ultraviolet radiation involves the occurrence of molecular processes, in photolysis by light at $\lambda \gtrsim 200$ nm free-radical processes take place. Since the absorption coefficients of polymers in the vacuum ultraviolet region are high (~10^3–10^6 cm^{-1}), the photochemical reactions take place under the influence of this light in a thin surface layer (~0.1–100 μm) and the energy absorbed in this layer is high, which leads to high degrees of conversion. As a result of this, a non-trivial phenomenon has been observed for a series of polymers (PP, PIB, PB, and PI): photo-etching of the surface layer, particularly in the presence of oxygen.

Catalytic Oxidation of Propene

T.G.Alkhazov, K.Yu.Adzhamov, and A.K.Khanmamedova

The oxidation of propene on simple and mixed oxide catalysts to form various oxygen-containing products—acrylaldehyde, acrylic acid, acetone, and acetic acid—is surveyed, and the role of individual components of the active catalysts discussed. A list of 110 references is included.

CONTENTS

I. Introduction 542
II. Oxidation of propene to acrylaldehyde and acrylic acid 542
III. Oxidation of propene to acetone and acetic acid 546

I. INTRODUCTION

Catalytic oxidation of propene is one of the chief methods for obtaining monomers and intermediates in organic synthesis. The increasing demands made by the national economy for such important compounds as aldehydes, ketones, and carboxylic acids require the development of new, more economic methods for their production. A problem of primary importance is to choose active and highly selective catalysts. Those containing molybdenum have become the most widely used mixed oxide catalysts for the selective oxidation of propene.

A vast literature has now accumulated on the catalytic oxidation of propene to acrylaldehyde. The kinetics has been studied in detail, reliable data are available on the mechanism of the formation of acrylaldehyde on several catalysts, and highly effective industrial catalysts have been developed.

Studies of the oxidation of propene to acrylic and acetic acids, acetone, and methyloxiran have increased during recent years. The production of acrylic acid has now reached the stage of semi-industrial trials, that of acetone and acetic acid is at the level of laboratory investigation, and an active catalyst is being sought to obtain methyloxiran.

There have been hardly any reports of processes in which such oxygen-containing compounds as propionaldehyde, propionic acid, formaldehyde, formic acid, and acetaldehyde are formed as main products. These compounds are usually obtained as by-products in various processes involving the oxidation of propene.

II. OXIDATION OF PROPENE TO ACRYLALDEHYDE AND ACRYLIC ACID

Among individual oxides copper(I) oxide is the most active catalyst for the oxidation of propene to acrylaldehyde[1]. This process has been developed to an industrial level, but the use of bismuth molybdate has enabled higher indices to be achieved and also research on the preparation of mixed oxide systems containing molybdenum to be started.

In 1978 Keulks published a review[2] which touched only part of the problem, with the oxidation of propene mainly on bismuth molybdates as example. Reference 3 also reviews the physicochemical and catalytic properties of the latter products, and includes structural features and data on the kinetics and the mechanism of the oxidation of propene. The present Review attempts to summarise the disconnected data published during recent years on the oxidation of propene.

It can be accepted as established that bismuth molybdate Bi_2MoO_6 is almost inactive[4]. It comprises octahedra of oxygen atoms surrounding a molybdenum ion and alternating with layers of bismuth ions. The structures of the molybdates $Bi_2Mo_2O_9$ and $Bi_2Mo_3O_{12}$ have been less thoroughly studied, but they definitely contain more oxygen vacancies than in Bi_2MoO_6. Among the bismuth molybdates $Bi_2Mo_3O_{12}$ possesses moderate activity, while $Bi_2Mo_2O_9$ and the two-phase catalysts (mixtures of Bi_2MoO_6 and $Bi_2Mo_3O_{12}$) have about the same high activity. X-Ray electron spectroscopy has shown that in the catalysts Bi_2MoO_6, $Bi_2Mo_2O_9$, and $Bi_2Mo_3O_{12}$ the ratios of bismuth to molybdenum are about the same on the surface and in the mass[4]. In two-phase specimens in which the mass ratio is 1–2 : 1 the surface ratio is unity; it gradually decreases with increase in the molybdenum content, and very slowly increases with increase in the bismuth content. The catalytic activity is assumed to be determined by a surface phase having the ratio Bi : Mo $\approx$ 1. One factor determining the activity and the selectivity of bismuth molybdates is the high rate of diffusion of oxygen in the crystal lattice.

Using ^{18}O and $CD_3.CD{:}CH_2$ as labelled reagents Keulks et al. have established[5] that on the bismuth molybdates $Bi_2Mo_3O_{12}$ and Bi_2MoO_6 acrylaldehyde is formed solely by a redox mechanism, and that the reaction involves oxygen from several surface layers of the lattice (respectively 13–47 and 79–280 monolayers). Oxidation of acrylaldehyde to carbon dioxide is effected also by oxygen of the crystal lattice.

The activation energy of removal of oxygen ions O^{2-} located between layers of molybdenum and bismuth atoms is much lower for those attached to molybdenum[6,7]. Hence experimental results are regarded[6,7] as indicating that on selective oxidation the adsorbed hydrocarbon interacts with an oxygen ion attached to bismuth, and are explained by the formation of oxygen vacancies in the molybdenum layer during preliminary reduction of the bismuth–molybdenum oxide catalyst; vacancies formed at bismuth(III) ions are filled by oxygen ions attached to molybdenum(VI), while oxygen from the gas phase fills vacancies at the molybdenum ions. Such a mechanism of migration of oxygen ions ensures a steady state of oxidation of the catalyst and explains the enhanced activity and the selectivity of bismuth molybdates in comparison with the individual oxides.

The structure of bismuth molybdate and the energy of bonding of oxygen in the lattice are influenced by the introduction of various additives. Heavy oxygen $^{18}O_2$ has been used as tracer to study the selectivity of the oxidation of propene to acrylaldehyde on bismuth molybdate modified with cobalt, nickel, manganese, magnesium, strontium, barium, and lead[8]. Since the acrylaldehyde and carbon

dioxide had the same oxygen-18 content, but the water a diminished content, it was supposed that two types of oxygen atoms—active towards addition to propene and active towards removal of hydrogen atoms—were present in the catalyst. After addition of cobalt, nickel, manganese, or magnesium the catalyst has the α-$MnMoO_4$ structure and the selectivity of oxidation of propene to acrylaldehyde reaches 93–97%, whereas a catalyst containing strontium, lead, or barium gives a lower selectivity (71–87%) and has the scheelite structure. The varying reactivity of oxygen in the lattice is governed by the modifying effect of the additives.

Introduction of small quantities (0.2 mass %) of phosphorus into bismuth molybdate $Bi_2Mo_3O_{12}$ transforms it into $Bi_2Mo_2O_9$. When the phosphorus content exceeds 1.3 mass %, a ternary chemical compound $2Bi_2O_3.MoO_3.P_2O_5$ is formed[1]. A ternary compound has been observed also in the bismuth–molybdenum–iron system[9–11]. Addition of iron(III) is assumed to result in filling of cationic vacancies in $Bi_2Mo_3O_{12}$ and in formation of at least two ternary compounds having the proportions Pi : Fe : Mo = 1 : 1 : 1 and 3 : 1 : 2. It appears that Bi^{3+} and Fe^{3+} ions can be interchanged in these compounds without significant structural changes. The catalytic activity of bismuth–molybdenum–phosphorus and bismuth–molybdenum–iron oxide systems is attributed to the presence of ternary compounds.

Tracer and spectroscopic methods have been widely used[12–16] to investigate the mechanism of the partial oxidation of propene on bismuth–molybdenum and copper oxide catalysts. Experiments with deuterated propene have proved that the rate-determining stage in the formation of acrylaldehyde is detachment of a hydrogen atom from the methyl group.

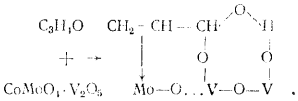
Considerably more by-products (e.g. carbon dioxide, acetaldehyde are formed on the interaction of allyl radicals (obtained by the thermal decomposition of azo-3,3′-propene) on the surfaces of molybdenum(VI) and bismuth(III) oxides and on bismuth molybdates than in the conversion of propene or allyl iodide under corresponding conditions[17]. The hypothesis was therefore put forward that the oxidation of propene does not involve formation of a free allyl radical. These results together with experiments on the oxidation of allyl alcohol suggested[18] a mechanism of selective oxidation of propene with transition from π-allyl to σ-allyl molybdate before detachment of the second hydrogen atom with formation of acrylaldehyde and a reduced form of the catalyst.

Comparison of the products formed in the oxidation of propene on bismuth oxide and on bismuth molybdates indicates[19–21] that dissociative adsorption of propene with detachment of the first hydrogen atom takes place on a bismuth cation, while the role of molybdenum is merely to change the energy of bonding of oxygen with the catalyst.

The opposite view is also widely represented in the literature, that an allyl complex is formed on a multivalent molybdenum ion[22–30]. The alkene interacts with an oxygen vacancy in the vicinity of a molybdenum ion and forms a π-allyl complex of molybdenum, which is then oxidised by oxygen of the catalyst to the reaction products. The role of bismuth is merely to facilitate dehydration of and to reduce the catalyst surface.

The oxidation of propene and of acrylaldehyde to acrylic acid has been studied on the tellurium–molybdenum oxide system containing various additives[31]. The sequence of the latter with respect to selectivity of such oxidation is respectively

V>Mn>Sn>Ti>W>Ni>Cr>Bi>Co>Fe>Cu,



and the somewhat modified

V>Sn>Ti>Co>W>Cr>Bi>Ni>Fe>Cu>Mn.

The optimum catalyst for the oxidation of both compounds to acrylic acid is a tellurium–molybdenum oxide system containing 25 mass % of vanadium. The parallelism in the variation of catalytic properties with the vanadium content suggests that the oxidation of propene to acrylaldehyde and to acrylic acid takes place on the same active centres of the catalyst. The yield of acrylaldehyde and acrylic acid is increased significantly by the introduction of tellurium into the chromium–molybdenum oxide system[32]. Study of the acidity of the surface and of the surface complexes formed on adsorption of alkenes indicates that both carbon dioxide and acrylic acid result from the breakdown of carboxylate complexes formed on aprotic acid centres. The presence on the surface of proton-donor centres and the absence of active, weakly bound oxygen favour the formation of acids.

The catalytic properties of the cobalt–molybdenum oxide system, which is active in the oxidation of propene to acrylic acid, are significantly determined by the phase constitution. Maximum yield of the acid corresponds to the highest content of the acitve phase b-$CoMoO_4$.† Formation of the active phase is largely determined by the conditions of preparation of the specimens (pH, temperature of precipitation, concentrations of initial salt solutions, temperature of ignition).[33,34] Introduction of bismuth, chromium, and iron oxides into cobalt molybdate changes the content of the active phase and influences the selectivity of oxidation of propene to acrylaldehyde[34].

The introduction of vanadium and copper ions into cobalt molybdate increases the rate of formation of acrylic acid from acrylaldehyde by factors of 40 and 28 respectively. Nickel has the least effect[29]. It is significant that these additives lower the rate of conversion of propene into acrylaldehyde. It was suggested that they block the molybdate anions responsible for the formation of π-allyl complexes in molybdates. Electron spin resonance spectroscopy has shown that interaction of the catalyst with propene and with acrylaldehyde changes the oxidation states of the molybdenum ions and also of the additives; in particular, when the surface is modified with vanadium ions, reduced centres V^{4+} and V^{3+} are readily formed, and govern the oxidation-state transitions. Complex formation between acrylaldehyde and surface ions of the catalyst may involve interaction with both ethylenic and carbonyl bonds. Since the rate of conversion of acrylaldehyde into acrylic acid far exceeds the rate of oxidation of propene in the same direction, it was supposed[29] that in the case of acrylaldehyde interaction is effected at the carbonyl bond, with oxidation on cobalt molybdate containing added vanadium following the scheme

Catalytic activity is enhanced by the addition of tellurium and phosphorus to the cobalt–molybdenum oxide system: the conversion of propene reaches 80%, and selectivity with respect to acrylic acid and acrylaldehyde respectively 50% and 20%.[35] Investigation of the phase constitution of the cobalt–molybdenum–tellurium–phosphorus oxide catalyst has shown that it consists of a-$CoMoO_4$#, MoO_3, P_2O_5, TeO_2, and

†Here b-$CoMoO_4$ is a modification of cobalt molybdate characterised by an octahedral oxygen environment of the molybdenum.

#Here a-$CoMoO_4$ is a low-temperature modification of cobalt molybdate with four-coordinated molybdenum and six-coordinated cobalt.

a chemical compound (the x-phase§). The active component of the catalyst is molybdenum trioxide promoted with tellurium dioxide in the oxidation of propene to acrylaldehyde, but α-$CoMoO_4$ in the oxidation of acrylaldehyde to acrylic acid[35].

Several general ideas have now been formulated on the selective oxidation of alkenes and in particular of propene[36,37]. In selective oxidation activation of the propene molecule requires that the catalyst should possess certain acid–base properties in order to abstract α-hydrogen and form an allyl group. Furthermore, the catalyst should possess appropriate redox parameters in order to bind this group by electron transfer from an allyl π-orbital to a d-orbital of the cation and produce a definite charge on it, since the subsequent reaction depends on the sign of this charge.

A molecule of an oxygen-containing product is formed by nucleophilic addition of oxygen ions from the crystal lattice to the activated hydrocarbon complex. Thus oxygen ions implanted in the catalyst lattice are nucleophilic reagents devoid of oxidising properties, while lattice cations act as oxidant in selective oxidation, activating hydrocarbons and forming a hydrocarbon residue having electrophilic properties. However, what properties of a surface cation on the catalyst influence activation of the alkene remains an open question.

It has been suggested[38,39] that catalysts of partial oxidation are characterised by metal–oxygen double bonds. It has been shown for molybdates of various elements that on those containing Mo=O bonds oxidation takes place via an allyl group. Such bonds are not present in catalysts of complete oxidation, such as molybdates of Groups I and II elements having the scheelite structure. The direction of oxidation of an alkene is assumed[30] to be independent of the nature of the metal M and determined solely by the electronic structure of the bond: low polarity of the M=O bond favours selective oxidation; with a strongly polar bond electrophilic attack of π-electrons of the alkene is probable with rupture of the ethylenic bond.

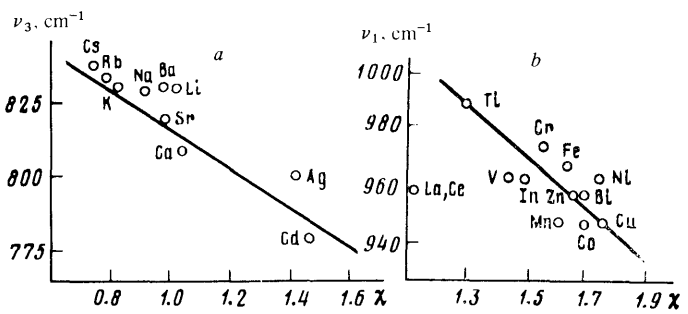


Figure 1. Comparison with the cation electronegativities χ of the wavenumbers ν of the characteristic bands in the infrared spectra of molybdates for the bonds: *a*) Mo=O, ν_3; *b*) Mo–O, ν_1.

The frequency of vibration of single and double-molybdenum–oxygen bonds depends on the nature of the cations present in molybdates[39]: the absorption bands move to lower frequencies with increase in electronegativity of the elements involved, which indicates increasing lability of these bonds (Fig.1), while the rate of allylic oxidation of propene increases (Fig.2). The formation of metal–oxygen double bonds may be promoted by oxygen vacancies appearing on the surface during the reaction, as is assumed in the mechanism of the oxidation of propene to acrylaldehyde on a uranium–antimony catalyst[40], and also by the introduction of additives, e.g. of tellurium into cadmium molybdate[41].

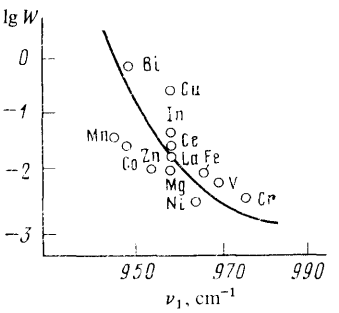

Figure 2. Specific rate of formation W of products of allylic oxidation on molybdates as function of wavenumbers of infrared absorption bands due to the Mo=O bond.

Several studies[42–50] have revealed the activating effect of excess of molybdenum trioxide on the catalytic properties of molybdates in various types of oxidation of alkenes. Such excess was assumed to be necessary to maintain the stoichiometric composition of the surface layer with loss of molybdenum during catalysis[46], to promote complete interaction of the initial salts during preparation of the normal molybdate[48], and also apparently to produce structural defects[42,43,49,50].

X-Ray diffraction, infrared spectroscopy, conductivity measurements, and density measurements on cobalt, iron, and chromium molybdates containing excess of molybdenum trioxide indicate that such excess within certain limits leads to formation of an imperfect structure, a solid solution. The defect structure produces a considerable increase in catalytic activity of the system towards the oxidation of propene[50–52] (Fig.3).

The probability of the dissolution of molybdenum trioxide in a molybdate is determined by the similarity of their structural fragments, comprising alternating oxygen octahedra and tetrahedra populated by the corresponding metal cations[53]. The degree of substitution of cations in the molybdate structure by the molybdenum ion is largely determined by the closeness of their ionic radii and also by the configuration of the electron shells. Absence of such correspondence, e.g. in indium and bismuth molybdates, leads to formation of a mechanical mixture of the molybdate with molybdenum trioxide[50].

It has been shown for isostructural cobalt and magnesium molybdates that introduction of excess of molybdenum trioxide not only increases substantially the rates of oxidation of propene to acrylaldehyde but also results in almost the same rates, evidence that active centres of closely similar composition have been formed[54].

A favourable influence of excess of one of the components on the activity and selectivity of a catalyst has been established also in other cases. Thus in the iron–antimony oxide system the selectivity of the chemical compound $FeSbO_4$

§Here the x-phase is a chemical compound formed in the tellurium–molybdenum oxide system at 425–450 °C.[35]

in allylic oxidation is considerably increased in the presence of excess of Sb_2O_4.[55] It was suggested that the latter suppresses the presence of free iron oxide, which is active in further oxidation[56,57]; formation of new chemical compounds—$FeSb_2O_4$ and $Fe_2Sb_2O_7$—may well be probable[58]. The high selectivity of the $FeSbO_4$–Sb_2O_4 system has been attributed[59] to interaction at the phase boundaries.

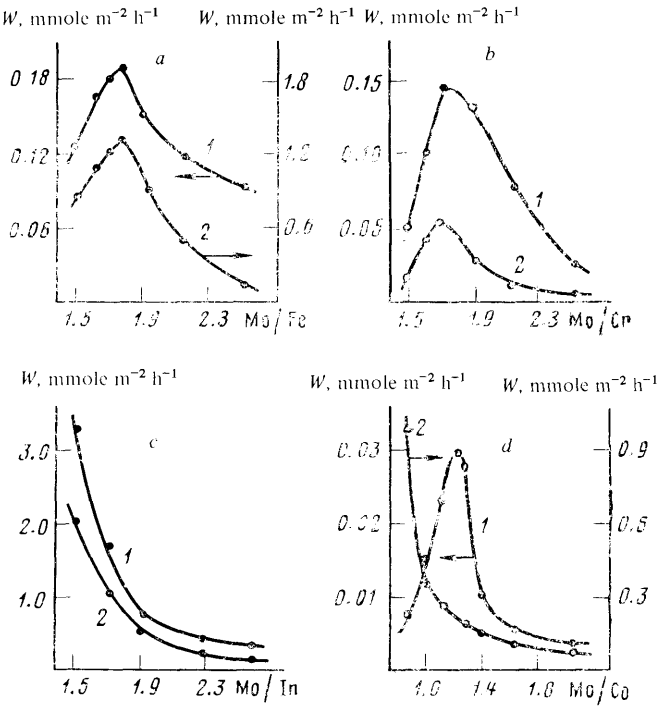

Figure 3. Variation[50] in specific rate of formation of *1*) acrylaldehyde; *2*) carbon dioxide with Mo/M ratio for M: *a*) Fe; *b*) Cr; *c*) In; *d*) Co.

Comparison of the activities of catalysts having antimony–iron ratios of 1 and 2 towards the oxidation of propene to acrylaldehyde in oxidising and reducing media indicates[55] that the decrease in the yield of carbon dioxide with simultaneous increased formation of acrylaldehyde is due to modification of the properties of oxygen on the catalyst surface: with excess of Sb_2O_4 on the surface of $FeSbO_4$ a thin (<20 Å) antimony-enriched layer is formed, responsible for the selective oxidation of propene to acrylaldehyde. Considerable enhancement of selectivity of oxidation to acrylaldehyde is possible[60] on an $FeSbO_4$ catalyst on which a small quantity (1–2 atomic layers) of Sb^{5+} ions have been deposited.

Excess of an oxide held in solid solution also enhances activity[61]. In the antimony–tin oxide system containing 5 mass % of antimony the latter is present in the SnO_2 lattice as Sb^{5+} ions, but at higher contents as a mixture of Sb^{5+} and Sb^{3+}. Calcination leads to separation of an oxide phase, identified as a two-dimensional layer of Sb_2O_4. A two-phase catalyst containing 18.7 mass % of antimony is the most selective with respect to acrylaldehyde. The effective catalyst comprises an oriented film of Sb_2O_4 deposited on an Sb^{5+}–SnO_2 solid solution[61].

The matching of activating components to simple and binary oxides with the aim of improving the effectiveness of catalysts has led to considerable complication of their composition. At the present time multicomponent systems are used in industrial production, and the majority of patents propose catalysts containing at least four different elements (Table 1). The phase composition of most mixed catalysts and the function served by their individual components have not yet been elucidated.

It is noteworthy that molybdenum predominates in almost all the catalysts listed in Table 1. Molybdenum trioxide is known as a relatively inactive but highly selective catalyst for the oxidation of propene to acrylaldehyde, and is usually employed in admixture with other oxides. Preparation of a mixed catalyst may involve various types of interaction of the trioxide with the other oxide components—formation of chemical compounds such as molybdates, solid solutions, and mechanical mixtures.

Table 1. Catalysts for the oxidation of propene to acrylaldehyde and acrylic acid.

Catalyst	Ref.
$K_{0.1}Ni_{2.5}Co_{4.5}Cr_3BiP_{0.5}Mo_{12}O_x$	[62]
$Cr_{0.5}K_{0.1}Ni_{2.5}Co_{4.5}Fe_3BiMo_{12}O_x$	[63]
$Mo_{12}Cu_{0.1-9}Te_{0.2-0.8}Sb_{0.2-15}O_{36.8-85.5}$	[64]
$W_{0.5}Cs_{0.2}Ni_{2.5}Co_{4.5}Cr_2BiMo_{12}O_x$	[65]
$K_{0.07}Mg_{4.5}Fe_4Bi_2P_{0.5}Mo_{12}O_{51}$	[66]
$Mo_{12}BiFe_{12}Co_1NiBe_2P_{0.5}KO_x$	[67]
$Mo_{12}V_{2-11}Cu_{1-6}Cr_{0-1}W_{0-12}O_x$	[68]
$Ce_3W_{1.2}V_3Mo_{12}O_x$	[69]
$Mo_{12}Cu_{0.05-3}B_{0.001-0.1}P_{0.1-5}Sb_{0.001-1}V_{0.5}K_{0.05-5}O_x$	[70]
$Mo_{8-18}V_{0.1-6}Cu_{0.1-6}Ge_{0.1-6}O_x$	[71]
$Mo_{12}P_2Cr_{0.5}Zr_{0.5}Sn_{0.5}K_2O_x$	[72]

The high activity and the selectivity of multicomponent oxide systems has been explained[54] on the assumption that most of the active centres are grouped at the boundaries between individual crystallites, where different kinds of ions differing in charge and coordination coexist, and where the diffusion of oxygen, the adsorption of reactants, and the transfer of charge are accomplished with the least consumption of energy. Examination of a catalyst of general composition $M_n^{2+}Mo_{12}Bi_{0.75}O_x$ revealed the phases $M^{2+}MoO_4$, $Bi_2(MoO_4)_3$, MoO_3, and also strongly disintegrated iron molybdate; some of the ferric ions can partly penetrate molybdenum oxide and bismuth molybdate, while some of the ferrous ions are dissolved in M^2MoO_4.[73]

Numerous examples have been published of the interpenetration of ions when molybdenum trioxide is deposited on an "inert" carrier[74–80]. Thus on silicon dioxide a limiting concentration exists (~8 mass %) above which polymolybdate particles are formed and then crystallites of molybdenum trioxide. Below this concentration the catalyst contains particles of molybdosilicic acid and dimolybdates, while Mo–O fragments appear implanted in the silica structure[74,75]. It has also been shown[76] that silicon ions incorporated into molybdenum trioxide stabilise the hexagonal structure of the latter.

Calcination of a molybdenum oxide catalyst deposited on alumina and containing <9 mass % of molybdenum results in dispersion of the molybdenum as a monolayer, but with higher contents some bulk phase is observed[77]. Ignition causes molybdenum atoms to migrate into the interior of the

γ-alumina. According to X-ray electronic spectroscopy this is accompanied by displacement of the 3*d* line in the molybdenum spectrum to higher bond energies, as a consequence of transition of molybdenum from a covalent state in surface oxy-anions to a more ionic state in cavities of the crystal lattice[78]. A low molybdenum content (1.5 mass %) is almost entirely located in tetrahedral cavities of the alumina lattice and cannot be reduced. Increase in the content is accompanied by increase in the proportion of surface molybdenum in octahedral coordination and enhancement of the reducibility of the catalyst[79].

Unlike ions deposited together interact with the substrate. In the cobalt(II)–molybdenum(VI) oxide system on alumina the molybdenum ions prevent penetration of cobalt ions into the lattice with formation of the spinel $CoAl_2O_4$ and facilitate reduction of cobalt to the metal. The appearance of metallic cobalt in turn initiates reduction of molybdenum by atomisation of hydrogen molecules and diffusion of hydrogen atoms towards the molybdenum ions, i.e. by a "spillover" effect. It is significant that surfaces differing in composition can be formed in different media: heat-treatment of the cobalt–molybdenum–aluminium oxide system in air tends to enrich its surface with molybdenum ions, but reduction of the catalyst enriches it with cobalt ions[73]. Migration of molybdenum ions takes place during heating. After γ-alumina has been impregnated successively with solutions of ammonium paramolybdate and cobalt nitrate, subsequent heating at 500 °C produces a redistribution of cobalt and molybdenum ions. As a result, a layer of molybdenum oxide is formed on the surface of the catalyst, and a layer of cobalt oxide directly covers the surface of the carrier[80].

It is now suggested that the catalytic activity and selectivity of several oxide systems based on molybdenum (the trioxide on silica and on alumina) are determined by stabilised salts of heteropoly-acids attached to the surface[81–84]. Molybdenum(VI), tungsten(VI), and vanadium(V) are known to form heteropoly-acids with heteroatoms—phosphorus, silicon, arsenic, etc.—that are strong many-electron oxidants and at the same time inorganic acids possessing high Brønsted acidity[85–87]. Heteropoly-acids are used as homogeneous catalysts for the partial oxidation of organic compounds[88], including alkenes[89]. In the Reviewer's opinion, however, further evidence is required to support the view that heteropoly-acids have a decisive role in the activity of oxide systems in heterogeneous catalysis.

Supported molybdenum catalysts containing definitely coordinated molybdenum ions have proved several times more active and more selective than corresponding catalysts prepared by impregnation[90]. The active centres are coordinatively unsaturated molybdenum ions combined with Brønsted acid centres of the carrier. Thus the construction of an active surface by attaching complexes of definite composition to a catalyst and the formation of clusters of several identical or different metal atoms may prove an effective method for enhancing the activity and the selectivity of a catalyst.

III. OXIDATION OF PROPENE TO ACETONE AND ACETIC ACID

The production of acetone and its analogues by the gas-phase catalytic oxidation of alkenes has many advantages over other methods (cheap starting materials, absence of corrosive agents, simple apparatus, etc.). Various catalysts have been proposed, including binary molybdenum-containing systems, for the single-stage oxidation of propene to acetone[91–95].

It had been shown earlier[91] that selective formation of acetone takes place on the Co_3O_4–MoO_3 system over the range of cobalt–molybdenum ratios 9–4 : 1.

This work was continued by investigating the oxidation of propene to acetone on various oxides containing 10% of molybdenum trioxide[92]. The most effective in this series was a tin–molybdenum oxide catalyst: acetone begins to be formed even at 110–120 °C, and at 170 °C the selectivity with respect to acetone is 80–85%.

The titanium–molybdenum oxide system is somewhat less effective than a tin–molybdenum oxide catalyst. It is catalytically active at 110 °C, but the rate of formation of acetone is lower than on the latter system. Isopropyl alcohol is formed on both systems at low temperatures.

The ion–molybdenum oxide system catalyses the formation of acetone above 150 °C, with a maximum rate at 200 °C (selectivity 80%). A chromium–molybdenum oxide catalyst is active above 200 °C, and approaches the cobalt–molybdenum oxide system in activity. Acetone is formed also on oxide systems of molybdenum with vanadium, nickel, copper, and zinc, but the selectivity is low.

Study of the aluminium–molybdenum oxide system[93–95] containing up to 30 mass % of molybdenum has established that water vapour increases considerably its catalytic activity and selectivity in the oxidation of propene to acetone. The active centres presumably represent a combination of reduced and oxidised forms of molybdenum(V) and (VI). Catalytic activity is determined in considerable measure by the acidity of the surface, which is governed by the presence of molybdenum(V) ions formed by reduction of the catalyst. Molybdenum(VI) ions are involved in oxidising intermediate products. The surface acidity in turn influences the mobility and the reactivity of hydroxy-groups[94].

The investigations suggested, for the oxidation of propene to acetone, the scheme

$$CH_3{-}CH{=}CH_2 \xrightarrow{+H^+} CH_3{-}{}^+CH{-}CH_3 \xrightarrow{+OH^-} \rightarrow [CH_3{-}CHOH{-}CH_3]_{ads} \xrightarrow{O} (CH_3)_2CO + H_2O \ .$$

The intermediate complex was assumed[94] to be an isopropoxy-group.

Kinetic study of the formation of acetone by the oxidation of propene on an iron–molybdenum oxide catalyst (Mo/Fe = 1.5) showed that the quantity of acetone formed varies linearly with the partial pressures of water vapour and propene, whereas the order with respect to oxygen is zero. The reaction velocity is given by the equation

$$V = k \cdot P_{H_2O} \cdot P_{C_3H_6} \ .$$

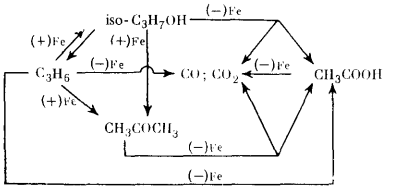
Either acetone or acrylaldehyde can be obtained depending on the temperature and also on the presence or absence of water in the reaction zone on iron molybdate. Hence an iron–molybdenum oxide catalyst can be regarded as bifunctional. Hydroxy-groups present on the surface in the presence of water vapour are assumed to take part in the hydration of propene, whereas oxygen ions attached to molybdenum effect the formation of acetone[96]. The mechanism of the oxidation of propene to acetone on an iron–molybdenum oxide catalyst has been assumed[97] to involve a stage of hydration of propene to isopropyl alcohol followed by oxidation of the secondary alcohol to acetone.

According to some workers[98] the oxidation of propene on a tin–molybdenum oxide system yields mainly acrylaldehyde and acrylic acid, but according to others[99,100] acetone and acetic acid. Information on the phase composition of this catalytic system is also contradictory: formation of a mechanical mixture of oxides, a chemical compound, or a solid solution based on tin dioxide have been suggested[99],

but evidence has been provided[101] for the formation of a solid solution based on molybdenum trioxide. It has been established that the phase composition and the direction of the partial oxidation of propene depend significantly on the method of preparation of the catalyst—the starting materials, the temperatures of coprecipitation and ignition, etc.

Pure tin dioxide is almost completely devoid of surface acid centres[102]. As molybdenum trioxide is added, the concentration of active centres increases significantly. This is to some extent supported by experiments undertaken by Buiten[103], in which the trioxide was deposited on the dioxide at high temperatures by means of water vapour, which interacts with the former to give the volatile species $MoO_2(OH)_2$, and this migrates through the gas phase to settle on the surface of the dioxide. The activity of the specimen in the oxidation of propene to acetone and acetic acid is thus greatly enhanced.

A parallelism has been established[104] between the activity of a tin–molybdenum oxide catalyst in the isomerisation of but-1-ene and the rate of oxidation of propene to acetone. The rate of isomerisation of an oxide catalyst depends on the surface acidity[105], so that active centres formed by the combination of tin dioxide and molybdenum trioxide are probably acidic in character. The acid–base properties of specimens are in turn determined by the method of preparation. Thus at high ignition temperatures irreversible desorption of hydroxy-groups—acid centres promoting the formation of acetone—may occur on the catalyst surface, with simultaneous increase in the relative number of metal ions, which are centres for the oxidation of propene to acrylaldehyde.



The effect of adding oxides of fourth-period transition metals to the tin–molybdenum oxide system has been investigated[106] on specimens of composition Mo : Sn : M = 3 : 1 : 0.15 (M = Ti, V, Cr, Mn, Fe, Ni, Co, Cu, Zn). The catalysts were in all cases solid solutions based on molybdenum trioxide. The additives produced appreciable changes in activity and selectivity of the tin–molybdenum oxide catalyst. With the exception of cobalt and titanium they all enhanced the selectivity of formation of acetone, but the maximum yields achieved on the ternary catalysts varied: introduction of copper, zinc, manganese, and vanadium produced lower maximum yields of acetone than on the tin–molybdenum catalyst; chromium, nickel, and iron increased the maximum yield. Addition of 2 mass % of iron oxide was the most effective for the production of acetic acid (Table 2).

Table 2. Oxidation of propene on Sn–Mo and Sn–Mo–Fe oxide catalysts[106].

Catalyst	t, °C	Yields of reaction products, mass %			
		C_3H_7OH	$(CH_3)_2CO$	CH_3COOH	CO_2
Sn–Mo	175	0.1	8.2	1.9	3.7
Sn–Mo–Fe	175	3.1	11.3	0.5	0.3
Sn–Mo	200	0	9.3	5.3	9.0
Sn–Mo–Fe	200	2.1	18.5	2.0	1.9

Experimental results obtained on a tin–molybdenum oxide catalyst have shown[107] that propene is oxidised to acetone mainly via isopropyl alcohol, but acetic acid is formed both from acetone and from this alcohol.

A similar investigation has been made on a tin–molybdenum–iron oxide catalyst, with comparison of the rates of oxidation of conversion products of propene. Oxidation of isopropyl alcohol on a catalyst containing added iron ions gives a rather higher yield of acetone than on a tin–molybdenum oxide catalyst, whereas the yields of acetic acid and carbon dioxide are diminished by factors of 2 and 3.6. It is significant that the acidity of a tin–molybdenum oxide specimen is diminished by the introduction of iron. The results suggest the scheme

for the oxidation of propene on a tin–molybdenum–iron catalyst[107]. It shows the influence of positive and negative iron ions on the activity of a tin–molybdenum catalyst in various intermediate reactions in the oxidation of propene.

Table 3. Effect of potassium ions on specific rate of formation of oxidation products of propene on an Sn–Mo–Fe oxide catalyst[108].

Catalyst	t, °C	W, mmole m^{-2} h^{-1}			S*, %	K**, %
		CO_2	CH_3COCH_3	CH_3COOH		
Sn–Mo–Fe	190	0.03	0.12	0.03	83	17
Sn–Mo–Fe	230	0.15	0.15	0.08	62	29
Sn–Mo–Fe+K***	190	0.02	0.30	0.02	94	21
Sn–Mo–Fe+K	230	0.15	0.50	0.04	87	39

*S = selectivity of oxidation of propene to acetone.
**K = conversion of propene.
***Quantity of potassium introduced 0.7 mass %.

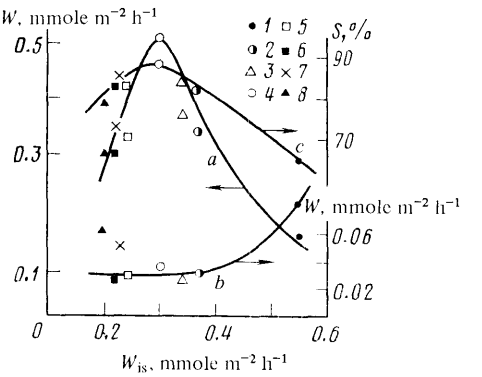


Figure 4. Variation[108] of: *a*) specific rate of formation of acetone; *b*) specific rate of formation of acetic acid; *c*) selectivity S of oxidation of propene to acetone with rate of isomerisation W_{is} of but-1-ene into but-2-ene on an Sn–Mo–Fe oxide catalyst containing added Group I elements: *1*) none; *2*) Li; *3*) Na; *4*) K; *5*) Rb; *6*) Cs; *7*) Cu; *8*) Ag.

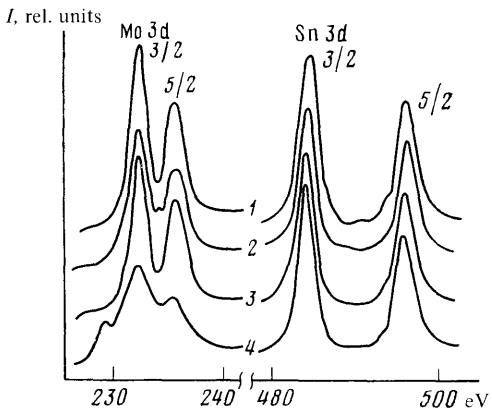
The activity of a tin–molybdenum–iron catalyst and its selectivity of oxidation of propene to acetone are increased by the introduction of Group I elements[108]. The activity

depends on the quantity of additive, and reaches a maximum in the presence of 0.7 mass % of potassium. The yield of acetone is greatest at relatively high temperatures (Table 3).

Addition of alkali metals to a tin–molybdenum–iron oxide catalyst diminishes the surface acidity, the effect being greater the more basic the additive. Fig.4 shows the dependence of the specific rate of formation of oxidation products of propene on the acidity assessed from the rate of isomerisation W_{is} of but-1-ene into but-2-enes. With decrease in acidity the rate of formation of acetone passes through a maximum, and those of acetic acid and carbon dioxide decrease. The specific rate of formation of acetone increases more than the latter rate decreases, from which it may be concluded that the observed increase in activity is due mainly to the formation of new active centres.

The maximum specific rate of formation of acetone is achieved on catalysts containing added sodium and potassium ions[108]. The more basic the ions the higher the rate of formation of acetone and the lower the degradative oxidation of propene[108]. It can be concluded that high activity and selectivity of a catalyst in the oxidation of propene to acetone require an optimum acidity, which can be produced by introducing into a tin–molybdenum–iron oxide catalyst a definite quantity of alkali-metal ions depending on their basicity.



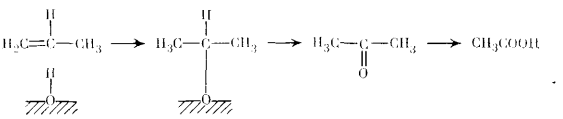


Figure 5. X-Ray electronic spectra of Sn–Mo–Fe oxide catalysts:
1) after roasting in oxygen at 250 °C;
2) after vacuum treatment at 425 °C;
3) catalyst with added potassium after roasting in oxygen at 250 °C;
4) catalyst with added potassium after vacuum treatment at 425 °C.

The incorporation of alkali metals into tin–molybdenum–iron oxide catalysts affects their X-ray electronic spectra[108]. Only tin, molybdenum, and oxygen ions are found on the surface, while iron and potassium ions are absent, which indicates that they have entered into the molybdenum trioxide structure. It is significant that reduction of a promoted catalyst affects mainly the oxidation state of the molybdenum ions, while tin ions remain almost unchanged (Fig.5). The spectrum of a reduced tin–molybdenum–iron oxide catalyst contains a weak signal due to Mo^{5+}, but in those of a promoted catalyst the signals due to reduced forms of molybdenum are considerably strengthened. The Mo^{5+}–O bond is less stable than Mo^{6+}–O, so that the introduction of potassium ions is responsible for the lability of the molybdenum–oxygen bond. The activating effect of alkali-metal ions in a tin–molybdenum–iron oxide catalyst apparently consists in changing the valency of the molybdenum, with the consequent appearance of new centres, on which alkenes undergo partial oxidation to ketones.

A mechanism of oxidation of propene to acetone on a tin–molybdenum oxide catalyst, involving formation of an alkoxy-group, was suggested by Buiten[103]. In the presence of deuterium oxide it proved difficult to exchange the hydrogen atom attached to the middle carbon atom in propene and also in isopropyl alcohol[109]. This was explained by interaction of propene with a surface hydroxyl to form an isopropyl group attached to a surface oxygen atom, and this group is an intermediate in the oxidation of propene to acetone and acetic acid:

Several results led Buiten[103] to deny intermediate formation of isopropyl alcohol in the oxidation of propene to acetone. Indeed, oxidation of the alcohol produces less acetone than expected, and furthermore the relative rates of formation of acetone and propene do not correspond to the rates of oxidation of propene to acetone and acetic acid according to the above scheme. Buiten's suggested mechanism involving detachment of the hydrogen atom from the middle carbon atom of the isopropyl group was supported by an investigation of the kinetic isotope effect of hydrogen involving comparison of the rates of oxidation of 2-deuteropropene $CH_2{:}CD.CH_3$ and non-deuterated propene[109].

Moro-Oka et al.[91,92] used a tracer method to determine the source of oxygen in the formation of acetone. In experiments on a tin–molybdenum oxide catalyst oxygen-18 was detected only in the acetone, whose content of the isotope was the same as that in the water present in the reaction system. Hence rapid exchange between adsorbed oxygen and the oxygen of the water does not take place, and oxygen-18 apparently passes into acetone by direct interaction between propene and adsorbed water[104]. Two mechanisms for the formation of acetone were suggested on the basis of these results:

$$CH_2{=}CH{-}CH_3 \xrightarrow{+OH^-} CH_2{-}CHOH{-}CH_3 \xrightarrow{\text{migration of H atom}}$$
$$\rightarrow {}^{+}CH_3{-}CHO{-}CH_3 \xrightarrow{-H^+} CH_3{-}CO{-}CH_3 \qquad (1)$$

$$CH_2{=}CH{-}CH_3 \xrightarrow{+H^+} CH_3{-}{}^{+}CH{-}CH_3 \xrightarrow{+OH^-}$$
$$\rightarrow CH_3{-}CHOH{-}CH_3 \xrightarrow{-2H^+} CH_3{-}CO{-}CH_3 + H_2O \qquad (2)$$

The first mechanism involves addition of a hydroxy-group to the π-bond of the alkene with formation of a σ-complex, which is converted into the carbonyl compound with liberation of a hydrogen atom. In the second mechanism addition of a proton produces a carbonium ion, subsequent attack on which by a hydroxy-group gives the secondary alcohol, which is oxidised to acetone. Since isopropyl alcohol was detected among the reaction products, the latter mechanism was regarded[104] as the more probable.

A scheme has been suggested for the oxidation of propene on a tin–molybdenum–iron catalyst[107,110] according to which acetone is formed below 150 °C mainly from isopropyl alcohol, but above 200 °C directly from propene.

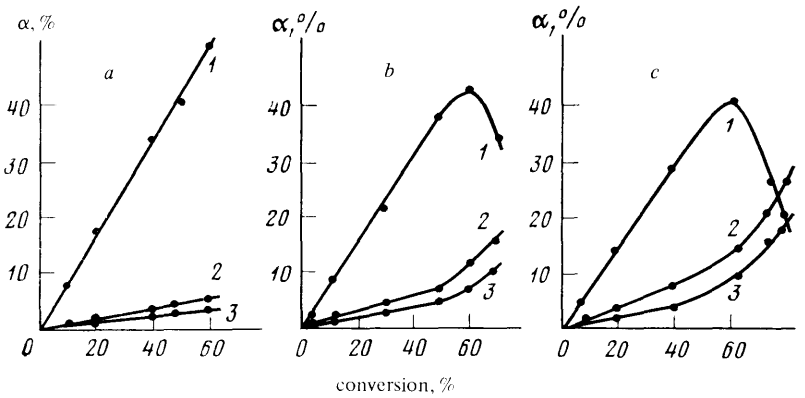

Figure 6. Degree of conversion α of propene into: *1*) acetone; *2*) carbon dioxide; *3*) acetic acid as function of total conversion[110] at various temperatures (°C): a) 190; *b*) 210; c) 230.

Formation of isopropyl alcohol was not observed[108] in the oxidation of propene on a promoted tin–molybdenum–iron catalyst at 170–210 °C. Comparison of the rates of accumulation of acetone in the oxidation of propene and of the alcohol showed that the latter is converted mainly into propene, only a small proportion being oxidised to acetone. This suggested that in the oxidation of propene the formation of acetone does not involve isopropyl alcohol:

$$CH_3{-}CH{=}CH_2 \xrightarrow{+H_2O_{ads}} [CH_3CHOHCH_3]_{ads} \xrightarrow{+O_{ads}}$$

$$\begin{array}{ccc} CH_3COCH_3{}_{ads} & & H_2O_{ads} \\ \downarrow\uparrow & & \downarrow\uparrow \\ CH_3COCH_3 & & H_2O \end{array}$$

Propene reacts with molecularly absorbed water to form a complex of alcoholate type, whose interaction with adsorbed oxygen releases a molecule of water with the formation of acetone. The zero order with respect to oxygen indicates that the latter is not involved in the rate-determining stage of acetone formation. In the absence of oxygen, however, acetone is not formed, and adsorbed oxygen is apparently involved in oxidation of the alcoholate complex.

Mechanisms of the formation of acetic acid in the oxidation of propene on catalysts containing molybdenum have been discussed[103,104,110]. It may be formed as a result of degradation of the activated complex of propene at the double bond[104] or by the oxidation of acetone[103]. Study of the oxidation of acetone in admixture with propene[108,110] has shown that at low temperatures acetone is hardly oxidised at all, acetic acid being formed from propene, whereas at high temperatures it is formed from propene and from acetone. Discrepancies in the literature concerning the mode of formation of acetic acid are apparently due to the temperature ranges over which this reaction has been studied.

Fig.6 illustrates the dependence of the yields of acetone, acetic acid, and carbon dioxide on the conversion of propene. At 190 °C they increase linearly with the conversion: i.e. acetic acid is formed by the degradative oxidation of propene at the double bond. At 210 and 230 °C the yield of acetone passes through a maximum, while those of acetic acid and carbon dioxide increase rapidly as a consequence of subsequent oxidation of acetone.

* * *

Thus in both molybdates and solid solutions based on molybdenum trioxide partial catalytic oxidation of propene takes place on active centres containing molybdenum, but the direction of oxidation and the oxidation state of the molybdenum cation are determined also by the nature of the functional groups present in the centres.

From the totality of results obtained on the physicochemical properties of molybdenum-containing oxide systems it can be concluded that the production of practically effective catalysts requires the presence of activating additives, which dissolve in the catalyst structure, promote the appearance of additional defects, and participate in the formation of an active surface.

Catalytic Polarographic Currents of Oxidants

P.M.Zaitsev, S.I.Zhdanov, and T.D.Nikolaeva

The state of the theory and practice in an important field of polarography—the catalytic currents of oxidant-substrates—is examined. It has found extensive applications in the last ten years in the development of highly sensitive methods for the determination of a large number of substrates, catalysts, and polarographically inactive ligands. Attention has been given to the problem of the electrocatalytic reduction of molecular nitrogen for its fixation under mild conditions.
A systematic account is given of data for a series of inorganic and organic substrates and catalysts which transfer an electron to the substrate.
The bibliography includes 242 references.

I. Introduction 552
II. Catalytic currents of oxidants 556
III. The fixation of atmospheric nitrogen—a possible application of the catalytic currents of substrates 560

I. INTRODUCTION

Catalytic currents in polarography, due to the regeneration of the depolariser via a chemical reaction, still attract much attention, mainly because they make it possible to increase appreciably the sensitivity of the analytical method and permit the determination of electrochemically inactive substances. However, the importance of catalytic currents goes beyond the analytical applications of polarography. In essence, these phenomena constitute the basis of the coulometric titration method and electrochemical synthetic processes with participation of electron transferring agents[1].

It is very likely that the fixation of atmospheric nitrogen, occurring in plant cells with participation of specific metal-containing enzymes[2,3], as well as many oxidation-reduction reactions constituting the basis of respiration, oxidative phosphorylation, and other processes important to life also occur under the conditions of the catalytic action of micro-elements. For this reason, examination of the available data on the mechanism of the occurrence of catalytic phenomena in polarography, to which this review is devoted, may be of general interest.

The review deals mainly with the reduction of a substrate by variable oxidation state metals; catalytic systems involving the oxidation of the substrate as well as catalysis by ligands (the complex is reduced or oxidised more readily than the aquo-ions) and the catalytic evolution of hydrogen are not discussed, because these two cases have been described quite adequately in other reviews[4,5] and monographs[6,7].

Catalytic currents of the type considered are manifested on polarograms as a rule by an increase of one of the diffusion waves of the catalyst metal and only in systems with hydrogen peroxide as the substrate does a separate reduction wave of the metal peroxide appear.

In the simplest case the mechanism of generation of the catalytic current can be represented schematically as follows:

$$\begin{array}{l} A + ne \rightarrow B \\ \uparrow\!\!_____| \\ B + S \xrightarrow{k} A \end{array} \quad , \qquad (1) \quad (2)$$

where A is the depolariser (the oxidised form of the catalyst), B the reduced form of the catalyst, and S the reagent (substrate or oxidant-substrate) participating in the chemical depolariser regeneration reaction. The catalytic current is determined by the rate of chemical reaction (2).

For a quantitative description of the catalytic currents arising via this scheme, an approximate solution was proposed initially[8,9] and then an exact solution[10], both based on the concept that the chemical depolariser regeneration reaction occurs in a thin layer of solution adjoining the electrode in the presence of an excess of the substrate.

When the reverse reaction (2) is neglected and when $k[S]_0\tau > 10$, the exact solution leads to the asymptotic equation

$$\bar{i}_c/\bar{i}_d = 0.81(k[S]_0\tau)^{1/2} , \qquad (3)$$

in which $\bar{i}_c$ is the average limiting catalytic current, $\bar{i}_d$ the average limiting diffusion current of the catalyst metal, k the rate constant for the forward reaction (2), $[S]_0$ the substrate concentration, and τ the drop period. The expression in square brackets in Eqn.(3) includes the stoichiometric coefficients, which depend on the nature of reaction (2).

A number of reviews have been devoted to the state of the theory and applications of catalytic polarographic currents[4,11-19], but examination of the literature shows that many important factors are still not clear. In particular, the causes of the differences between the rates of reduction of the substrate directly at the electrode and by reaction (2) have not been altogether elucidated. Andrieux et al.[20] considered the quantum-mechanical approach of Hush and Marcus to the relation between the rates of electronic transitions in the heterogeneous and homogeneous reactions. Attention has also been drawn[21] to the electrostatic factor, which increases the rate of interaction of the substrate and catalyst bearing different charges.

Studies have appeared in recent years in which the generation of the catalytic currents of the substrates is attributed to the formation of a complex BS and to electron transfer within the complex from the reduced form of the catalyst to the substrate. Such a mechanism has been proposed for both inorganic catalysts [W(VI)–ClO_3^- [22] and Mo(VI)–ClO_3^-–mandelic acid[23] systems] and for organic catalysts (dithiocarbamate–IO_3^-,[24] haemoglobin–H_2O_2, and iron(III) phthalocyaninetetrasulphonate–O_2 [25] systems), as well as for organic substrates in the Y(III)–L–dimethylformamide (DMF) system[26], which consist of carbonyl compounds: benzophenone, benzaldehyde, and crotonaldehyde.

The so-called coordination mechanism of the generation of catalytic currents has been proposed[16,17,27-30] and developed:

$$\begin{array}{l} A + n_1e \rightarrow B \ , \\ B + S \xrightarrow{k} BS \ , \\ \uparrow\!\!_____| \\ BS + n_2e \rightarrow B + P \ . \end{array} \qquad (4)$$

According to this mechanism the catalyst does not transfer electrons from the electrode to the substrate but merely activates the latter, increasing its reactivity in relation to reduction at the cathode. An equation has been derived for the description of the proposed mechanism[16,27-30]; despite the fundamental difference between the mechanisms, its form is close to that of Eqn.(3).

In order to account for the appreciable change in the catalytic current after the introduction of complex-forming substances into the solution, the formation of a ternary complex of the type BLS has been assumed in the last two concepts. One cannot rule out also another interpretation of this effect. Complex formation frequently accelerates electrochemical reaction (1) in both directions, so that irreversible reactions can actually become reversible. This should lead, in principle, to the acceleration of the homogeneous reaction (2) also.

Electron exchange within the complex is a reasonable alternative to the simple mechanism based on reactions (1) and (2), but we believe that the arguments adduced in its support in relation to the coordination mechanism are weak. Firstly, there is no direct evidence for the reduction of the substrate within the complex at the electrode. Secondly, the majority of substrates interact too weakly with the complex-forming metal to undergo an appreciable alteration in their reactivity. Nor is it clear why the interaction precisely with the reduced form of the catalyst are not with the initial, oxidised form is important for the generation of catalytic currents. Nevertheless, the coordination mechanism does not lack internal logic. Formally, systems with hydrogen peroxide behave seemingly in conformity with the coordination scheme: the metal peroxide compounds are reduced at the electrode.

An invariable condition for the appearance of the catalytic current of the substrate is its high electrochemical overvoltage. Many organic compounds do not exhibit a catalytic effect[21], because the electron transfer stage is in the vast majority of cases rapid (without overvoltage); on the other hand, the reason for the general irreversibility of the reduction of organic compounds is the occurrence of consecutive chemical reactions leading to the formation of covalent, inert C–H, C–C, etc. bonds. In such cases a significant increase of electron transfer to the substrate, with participation of the catalyst acting as an electron transferring agent, is impossible. The catalytic effect in polarography can be produced only by compounds in the electrochemical reduction of which the electron transfer stage is in fact slow. The reduction of the substrate can be accelerated by catalysts with a fairly high reduction potential and the necessary structure. The catalysts (among inorganic substances, these are usually transition metals) exist in aqueous solution in the form of monomeric or polymeric forms with different degrees of hydrolysis, depending on the conditions[31-35]. The activity of the catalyst depends on its state[36-39].

The wide variety of forms of the catalysts and the relatively few substrates make it possible to arrange the available literature data in terms of the nature of the oxidant-substrate.

II. CATALYTIC CURRENTS OF OXIDANTS

1. Catalytic Currents of Hydrogen Peroxide

The catalytic currents of H_2O_2 for the first row of transition metals are represented by the following systems: Ti(IV)–H_2O_2 and Ti(IV)–H_2O_2–L, where L = EDTA, nitrilo- triacetate (NTA), sulphosalicylate (SAL), and 4-(2-pyridylazo)-resorcinol (PAR);[40,41] V(V)–H_2O_2–H_2SO_4,[42] Fe(III)– H_2O_2–H_2SO_4,[43-52] and Fe(III)–H_2O_2–L, where L = bis-salicylidene-ethylenediamine and triethanolamine[53]; Cu(II)–H_2O_2–L, where L = Cl^- and α,α'-bipyridyl[54,55]. The second row of transition metals is represented by the first three numbers: Zr(IV)–H_2O_2,[56] Nb(V)–H_2O_2,[57] Nb(V)–H_2O_2–$H_2C_2O_4$,[58] and Mo(VI)–H_2O_2–L, where L = H_2SO_4 or acetate, phosphate, and hydrogen phthalate buffer mixtures[42,59,60]. The third row of transition metals is represented by the systems Hf(IV)–H_2O_2,[61] Ta(V)–H_2O_2–$H_2C_2O_4$,[62,63] and W(VI)–H_2O_2–L, where L = H_2SO_4, $H_2C_2O_4$, H_3PO_4, and H_3AsO_4,[42,64] and the Os(VIII)–H_2O_2 system[65]. The H_2O_2 catalytic reduction wave has also been observed for La(III).[66]

When the above transition metals are introduced into an aqueous solution of hydrogen peroxide, a catalytic wave appears on the polarogram whose height greatly exceeds the diffusion current of the metal and which is located at more negative potentials than the non-catalytic reduction wave of hydrogen peroxide and the transition metal. Os(VIII), for which the H_2O_2 catalytic wave coincides with its first two-electron reduction wave, is an exception[65]. The H_2O_2 catalytic wave has the form of a sharp or smooth peak, which is not due to adsorption effects, since the introduction of surfactants into the system does not cause the disappearance of the maximum in the polarographic wave[42,61]. The catalytic wave has the normal form without a maximum only for the Fe–H_2O_2 system[45-50]. Therefore the assignment of the M–H_2O_2 systems[67] to the group with a normal form of the limiting catalytic current plateau is incorrect.

A test of Koutecky's theory[10] in relation to the catalytic currents of the Fe(III)–H_2O_2 system demonstrated its validity[46]. The catalytic process in this system is described by the Haber–Weiss scheme[68] in which the rate-limiting stage involves the oxidation of Fe(II) to Fe(III) by hydrogen peroxide with formation of OH· radicals, which also oxidise Fe(II). Subsequently, this mechanism was confirmed also in relation to sulphuric and nitric acid solutions[69]. The presence of OH· radicals in the system was demonstrated by numerous instances of the decrease of the catalytic current in the presence of various organic substances[45,52] and monomers[70-72] which react with OH·.

In order to explain the catalytic H_2O_2 reduction currents in sulphuric acid solutions of the Fe(III)–H_2O_2–L system, investigators[48-50,53] proposed a coordination mechanism of their generation consisting in the fact that the iron(II) obtained at the electrode forms with H_2O_2 or HO_2^- the intermediate complex $[Fe(H_2O)_5(HO_2^-)]^+$, which is rapidly converted into $[Fe(H_2O)_5O]^{2+}$ and the latter is reduced at the electrode with regeneration of the Fe(II) aquo-ion. The slow stage of the process is the formation of the intermediate complex $[Fe(H_2O)_5O]^{2+}$, which is identical with the ferryl ion FeO^{2+}; this complex has properties analogous to those of the OH· radical. As already mentioned, the authors do not present direct evidence for the reduction of the oxygen atom (hydrogen peroxide) in $[Fe(H_2O)_5O]^{2+}$.

Titanium(IV) catalyses the reduction of H_2O_2 but at higher pH values than many other multicharged ions, even when a graphite rotating electrode is used[40]. The catalytic current in the Ti(IV)–H_2O_2 system is described by Koutecky's theory and is limited by the formation of $TiO(H_2O_2)^{2+}$ and the two-electron reduction at the electrode at pH 2–4 of the complex $[TiO(HO_2)]^+$, whose yield increases with pH as a consequence of the increase of the degree of acid dissociation of $TiO(H_2O_2)^{2+}$. The current i_c depends on the nature of the ligand: the presence of EDTA, SAL, and NTA increases i_c, while the addition of PAR decreases it.

The activating effect of ligands is due to the formation of Ti(IV) complexes, which react with hydrogen peroxide faster than the TiO^{2+} aquo-ions[40]. The catalytic activities of ligands increase in the sequence SAL < NTA < EDTA, which can be accounted for by the increasing stability of the complexes formed. Other metals of the titanium subgroup (zirconium[56] and hafnium[61]) catalyse the reduction of H_2O_2; the ease of reduction increases in the sequence Ti < Hf < Zr. As for titanium[40], the catalytic current is limited by the rate of formation of the intermediate complex between zirconyl[56] or hafnyl[61] and hydrogen peroxide. The current i_c in Zr(IV) and Hf(IV) solutions has a maximum (at pH 2.0 and 2.6) under the conditions of the maximum yield of the most active zirconyl or hafnyl ions[73].

Vanadium subgroup metals (vanadium, niobium, and tantalum) are readily hydrolysed[34] and tend to form many peroxide complexes[74] with different catalytic activities. The catalytic currents of the above elements are limited by the rate of formation of the peroxide compound. The vandium(V) peroxide compounds contain between one and four $H_2O_2(O_2^{2-})$ molecules[75]. The catalytic waves of vanadium, niobium, and tantalum have the form of a peak and are observed at less negative potentials than the waves due to metals and the non-catalytic reduction of H_2O_2; $E_{1/2}$ depends on the pH. As was to be expected, there is a complex dependence of i_c on the pH; the catalytic current has a maximum at the following pH:

Element	V(V)	Nb(V)	Ta(V)
pH	5.0	5.2	6.2

This behaviour of i_c for V(V) has been attributed[42] to the presence of its polymeric forms, which manifest different activities, and for Nb(V) and Ta(V) by the change in the composition of their peroxide compounds[56]. Since the vanadium(V) concentration in the above study[42] was very low (8×10^{-8} M), the maximum on the i_c–pH curve is most probably due to the presence in solution of various hydrolysed monomeric forms of vanadium(V) and not polymeric forms. In the presence of oxalic acid, the Nb(V) [58] and Ta(V) [62,63] electrode processes are limited by the formation of the peroxide compound $HMO_3.C_2O_4$, which is reduced to $HMO_2.C_2O_4$ (where M = Nb or Ca) with participation of two electrons.

The Cr(III)/Cr(II), Mo(VI)/Mo(V), Mo(V)/Mo(III), W(VI)/W(V), and U(IV)/U(III) systems, which possess reducing properties, are of greatest interest for the investigation of the catalytic currents of substrates in the presence of chromium subgroup elements (Cr, Mo, W and U). The H_2O_2 catalytic currents are known only for the Mo(VI)–H_2O [45,59] and W(VI)–H_2O_2 [45] systems. The formation of monomeric and polymeric forms of Mo(VI) [31,33,76,77] and W(VI) [31,33,78] in solution as well as a number of peroxides[76, 78,79] and complex compounds having different compositions are responsible for the complex form of the dependence of i_c on the pH and the catalyst concentration. The presence of a maximum on the i_c–pH curve[45], the dependence of its position and intensity on the nature of the buffer solution[45], the presence of a maximum on the i_c–c_{buff} curve for the phosphate buffer solution at pH 4.0,[59] and the decrease of i_c on passing from $HClO_4$ to H_3PO_4 solutions[45] have been explained on the basis of these ideas. The decrease of i_c in the phosphate buffer solution at pH 4.9 [45] on passing from vanadium to tungsten has likewise been accounted for from this standpoint.

The rate-limiting stage is the formation of the peroxide compound, which is reduced with participation of two electrons. The attempt[45] to explain the dependence of i_c on the pH by the presence of different polymeric forms reacting with H_2O_2 at different rates is in our view incorrect, since the Mo(VI) concentration was so low (3.2×10^{-6} M) that Mo(VI) was present only in the monomeric form[33,76]. The dependence of i_c on the pH is therefore associated with the presence of its different hydrolysed forms interacting with H_2O_2 at different rates.

In the manganese subgroup (Mn, Te, and Re) a catalytic H_2O_2 polarographic reduction wave is observed only for Te.[80] It is believed that in the homogeneous catalytic reaction the H_2O_2 oxidises the Te(V) formed to Te(VII).

The metals of the platinum subgroup (Ru, Rh, Pd, Os, Ir, and Pt) are characterised by a high oxidation potential and and extremely high capacity for hydrolysis and complex formation[31,79,81–84], which complicates the observation of the H_2O_2 catalytic currents. Ruthenium(VIII) is a stronger oxidant than osmium(VIII),[85] so that, in contrast to OsO_4, RuO_4 cannot give rise to H_2O_2 catalytic waves. The aquo- and hydroxo-complexes of certain platinum subgroup metals, for example Rh(III) and Ru(IV) (Ginzburg et al.[84] p.99) are extremely inert in processes involving the substitution of water molecules in the inner sphere of the ion by other ligands, which is probably the reason for the small number of examples of catalytic currents in platinum metal–oxidant systems; only two such examples are known: Os(VIII)–H_2O_2 [65,86] and Ru(III)–NH_2OH.[87]

The H_2O_2 catalytic wave in osmium(VIII) solutions[65,86] is observed in the positive range of potentials; with increase of $c_{H_2O_2}$, the current i_c passes through a maximum. The electrode process is determined by the rate of oxidation of Os(VI) to Os(VIII).[65] In unbuffered solutions this process may be limited by the formation of the peroxide compound $OsO_4.H_2O_2$.[86]

The metals of the copper subgroup (Cu, Ag, and Au) exhibit a considerable tendency towards complex formation. Ag(II), Ag(III), and Au(III) compounds show no catalytic activity with respect to the electrochemical reduction of H_2O_2, which can be explained by their high oxidising capacity. The high rate of exchange of water molecules in the first coordination sphere ($k = 8 \times 10^9$ s^{-1}) of copper(II) aquo-complexes (Basolo and Pearson[35], p.138) favours the generation of the catalytic currents of the substrate. The catalytic wave in the Cu(II)–H_2O_2 system[54] at pH < 7 is located in the range of potentials of the first one-electron copper(II) reduction wave and is described by the Koutecky equation[10]. The rate-limiting stage is the oxidation of Cu(I) by hydrogen peroxide with formation of the initial depolariser and the OH· radical, the latter being consumed in the oxidation of Cu(I) and Cl^-.

In neutral unbuffered chloride media the catalytic wave incorporates both Cu(II) reduction waves[54], which is probably associated with a change in the composition of the layer near the electrode as a consequence of the oxidation of Cu(I). The possibility of the oxidation of the metallic copper formed under these conditions cannot be ruled out either.

In an acetate medium[55] the catalytic wave, having the form of a maximum, arises at potentials more positive (by 0.1 V) than the copper reduction wave (pH 4.6), while in the presence of α,α′-bipyridyl the catalytic wave coincides with the copper reduction wave. A coordination mechanism has been proposed (but not justified experimentally) for the catalytic currents in the systems investigated[55].

The catalytic H_2O_2 reduction current is observed in solutions of copper salts also in anodic processes. It has been found[87] that, at the potential of the anodic peak associated with the dissolution of the copper amalgam (at $E = -0.18$ V), a cathodic current maximum is observed in the presence of H_2O_2 or O_2, which is due to the fact that the catalytic H_2O_2 reduction current is much greater (by a factor of 10–15) than the anodic copper dissolution current. The catalytic reduction current is due to the oxidation of the Cu(I) formed

to Cu(II), which is reduced to Cu(I) at the amalgam dissolution potential. An analogous behaviour has been observed also for lead[87–89], the only representative of non-transition elements catalysing the reduction of H_2O_2. The electrode process generating the catalytic current includes the reaction where the pH(II) at the electrode is oxidised by hydrogen peroxide to Pb(IV), which is reduced electrochemically to Pb(II).[87] The catalytic H_2O_2 current is also observed in the reduction of oxygen at platinum[90] and gold[91] microelectrodes. The exaltation of the limiting current can be explained by the generation of oxygen as a result of the oxidation of the superoxide ion by hydrogen peroxide.

Thus the appearance of i_c in many systems is due to the formation of peroxo compounds (of Ti, V, Mo, W, Nb, Hf, Zr, and Ta) which are reduced at less negative potentials than the metal in the highest oxidation state. The rate-limiting stage is the formation of the peroxo-compound (complex). In many systems incorporating Cu and Pb hydrogen peroxide is reduced by the ion of the catalyst metal.

The catalytic H_2O_2 currents make it possible to detect very low concentrations of catalysts (from 1×10^{-5} to 1×10^{-9} M) and have found extensive applications in the determination of vanadium[42], iron[45,47,50], copper[55,87], zirconium[56], niobium[57,58], molybdenum in soils[59] and granits[60], hafnium[61], tantalum[57,62], tungsten[42], osmium[65,86], and technetium[79]. Molybdenum[92] and titanium[41] (using a graphite electrode), copper[87], lead[87, 89] (in combination with amalgam polarography), and oxygen (using a rotating platinum[90] or gold[91] microelectrode) can be determined with a high sensitivity (to within 1×10^{-6} M). The catalytic H_2O_2 currents have been used successfully also for the investigation of the complex formation reaction between tantalum and oxalic acid[62] and between tungsten(VI) and oxalic, phosphoric, and arsenic acids[64].

2. Catalytic Currents of Hydroxylamine

The oxidising properties of hydroxylamine[93,94] have also been used to obtain its catalytic reduction currents. The first row of transition elements is represented by the systems Ti(IV)–NH_2OH–$H_2C_2O_4$,[95] Ti(IV)–NX_2OH (where X = H or D),[96,97] V(V)–NH_2OH,[98] Fe(III)–NH_2OH–$N(CH_2CH_2OH)_3$,[99] Ni(II)–NH_2OH–CN,[100] and Ni(II)–$NH_2(CH_2)_2NH_2$–CN,[100] the second row is represented by the system Nb(V)–NH_2OH [101, 102] and Ru(III)–NH_2OH,[103] while among the third row elements there are literature data only for tungsten: W(VI)–NH_2OH [104] and W(VI)–NH_2OH–L, where L = ascorbic acid, salicylic acid, catechol[105–107], etc. In the case of titanium-containing systems the catalytic current is limited by the rate of oxidation of titanium(III) ions by hydroxylamine with formation of titanium(IV) and the $NH_2^{\cdot}$ radical and is described by Koutecky's theory[10]. This is proved by the agreement between the rate constants for the oxidation reaction obtained by chemical and polarographic methods. The oxidation rate constants have the following values: 42.0,[95] 41.3,[96] 42,[108] 32.0,[109] and 43.4 litre mol^{-1} s^{-1}.[110] The mechanism adopted is also supported by data for the synthesis of α-aminosuccinic acid from maleic acid under the conditions of electrochemical generation of $NH_2^{\cdot}$ radicals[111].

The catalytic reduction of hydroxylamine in the presence of vanadium(V) in solutions at pH 1–5 is represented by a wave at a potential ~0.3 V more negative than $E_{1/2}$ for the V(V) → V(IV) waves[98]. According to the authors[98], the slow stage of the process is the formation of a complex between polymeric vanadium(V) and NH_3^+OH; the complex $V(V)_n$.NH_2^+OH is then reduced to $V(V)_n$ and $NH_2^{\cdot}$. It is difficult to agree with this, since the concentration at the electrode of the V(V) not bound in the complex at the potentials of the catalytic wave is zero and the mechanism involving vanadium(V) is therefore altogether impossible. We believe that the regeneration of the depolariser is due to the oxidation by hydroxylamine of the V(IV) formed. The introduction of EDTA and *trans*-1,2-cyclohexylenediaminetetra-acetate into the solution reduces i_c as a consequence of the formation of catalytically inactive complexes.

In the presence of the second representative of the vanadium subgroup, namely niobium, the catalytic hydroxylamine waves are observed in hydrochloric acid solutions with high HCl concentrations[101,102], where the catalyst exists predominantly in the monomeric form, which exhibits a higher catalytic activity than the polymeric and colloidal species. The authors[101] explained the generation of the catalytic current in terms of a coordination mechanism in which the rate-limiting stage is the formation of the intermediate complex Nb(IV).NH_3^+OH, which is reduced to Nb(IV) and NH_4^+; proof that the complex Nb(IV).NH_3^+OH is reduced is not presented.

The catalytic hydroxylamine current in the Fe(III)–NH_2OH–$N(CH_3CH_2OH)$ system at the Fe(II) oxidation potential (–1.05 V relative to the saturated calomel electrode) has been studied in 0.01–4.0 M NaOH.[99] The rate-limiting stage is the oxidation-reduction reaction of Fe(II) with NH_2OH. The validity of the mechanism adopted is demonstrated by the agreement between the rate constants for the reaction obtained by the chemical and polarographic methods. At 25 °C in 1 M NaOH they are respectively 205 ± 25 [97] and 198 ± 8 litre mol^{-1} s^{-1}.[99]

The catalytic hydroxylamine current in the Ni–CN–NH_2OH system[100] in neutral and alkaline media can be accounted for by the involvement of Ni(I) and Ni(0). The current i_c is a maximum at pH 8.5–9.5. Under these conditions, the system contains an appreciable amount of the hydrolysed form $NiOH^+$ (pK_1 = 9–9.5).[33] We therefore believe that one cannot rule out the involvement of the above form also in the reactions determining the catalytic current. When hydroxylamine is replaced by ethylenediamine, a catalytic current is also observed, but is smaller[100]. Thus the complexes incorporating elements with the d^8 configuration, which are fairly inert in the ligand exchange reaction in conformity with the crystal field theory[35], exhibit a fairly high reactivity after the introduction of one or even two electrons. Among the elements of the platinum group, the catalytic hydroxylamine current is observed only in the presence of ruthenium(III) [103] and is due to the oxidation by hydroxylamine of the Ru(II) formed and is described by the Koutecky theory; the rate constant for the rate-limiting stage in this process is 3×10^3 litre mol^{-1} s^{-1}. Since the ruthenium(II) aquo-complexes are inert (Cotton and Wilkinson[31], p.42), their observed reactivity is probably associated with the formation of a mixed complex.

A distinctive feature of tungsten, the only representative of the third row of transition elements, is the presence on the polarograms of the test systems of two catalytic hydroxylamine waves and of the catalytic wave of hydrogen ions[104–107]; the authors explained the appearance of the catalytic hydroxylamine waves in terms of a coordination mechanism. The rate-limiting stage for the first catalytic wave is the conversion of the intermediate tungsten(V) complex H_2WO_4.NH_2OH into the activated complex H_2WO_4.NH_3O^-, while for the second catalytic wave the rate-limiting stage involves the conversion of the intermediate tungsten(III) complex HWO.L.NH_3OH^- into the activated complex HWOL.NH_3O.[105,106] The charge of the species involved in the rate-limiting stage was determined using the dependence of the rate of reaction (the current i_c) on the ionic strengths[112]. The authors[105,106] do not present direct evidence for the reduction of the above species. One cannot rule out the possibility that the observed complex pattern may be associated with the presence of polymeric

forms of tungsten in solution, since at the concentrations investigated (5×10^{-4} M) a considerable proportion of the tungsten exists in the polymeric form[78]. This is indicated indirectly also by the decrease of the number of catalytic waves with decrease of the W(VI) concentration[105,106].

The rate constants for oxidation reactions with participation of substrates calculated from their catalytic polarographic currents in the presence of various catalysts and ligands at 20–25 °C.

*The rate constants for reactions involving oxidation by hydrogen peroxide were determined by a chemical method.

**The stoichiometric coefficient of the oxidation reaction was 5.5.

***The stoichiometric coefficient of the oxidation reaction was 6.

****The stoichiometric coefficient of the oxidation reaction was 3.

*****The stoichiometric coefficient of the oxidation reaction was 8. For the calculation of the oxidation reaction rate constant, it was necessary to divide k_{tot} by the corresponding stoichiometric coefficient of the oxidation reaction.

Notation: H_3Citr = citric acid; EDTA = ethylenediamine-tetra-acetic acid; PG = pyrogallol; CA = catechol; AA = ascorbic acid; BSED = bis-salicylidene-ethylenediamine; TEA = triethanolamine; NTA = nitrilotriacetate; SAL = sulphosalicylic acid; bipy = α,α′-bipyridyl; HA = hydroxylamine; SA = salicylic acid; H_2Trihydrox = trihydroxyglutaric acid; H_2Malic = malic acid; H_2Tartr = tartaric acid; H_2Malonic = malonic acid; H_2Glucar = saccharic acid; HGl = glycolic acid; H_2Tartron = tartronic acid; HMandelic = mandelic acid; HDPPA = α-hydroxy-α-dibutylphosphinoylpropionic acid.

Complex formation greatly influences the activity of the catalyst in the reduction processes, which also depends on the nature of the oxidant. Thus the activities of the Fe(II) and Ti(III) aquo-complexes in the reduction of H_2O_2 and NH_2OH are comparable, while the triethanolamine complexes of Fe(II) are more active by three–four orders of magnitude than the Ti(III) complexes (see Table).

The catalytic hydroxylamine waves are used in analytical practice mainly for the analysis of model solutions of niobium[101,102], ruthenium[103], tungsten[104,106], and the polarographically inactive CN^- ions[100].

3. The Catalytic Currents of Chlorate and Bromate Ions

Reactions involving oxidation by chlorates, bromates, iodates, perchlorates, and periodates are catalysed by variable oxidation state elements (molybdenum, osmium, etc.) (Kolthoff et al.[113], pp.97, 607), which can lead to the appearance of the catalytic currents of the above oxidants in the presence of transition elements. The ClO_3^- and BrO_3^- catalytic currents with participation of the transition elements of the first row, i.e. in the systems Ti(IV)–ClO_3^-–L,[114–132] Ti(IV)–BrO_3^-–L,[133–135] V(V)–BrO_3^-–L,[136] Fe(III)–ClO_3^-–L,[137] and Fe(III)–BrO_3^-,[138] with participation of transition elements of the second row, i.e. in the systems Mo(VI)–ClO_3^-–L [23,139–164] and Mo(VI)–BrO_3^-–L,[165,166] and with participation of the elements of the third row, i.e. in the system W(VI)–ClO_3^-–L [167] have been described in the literature. In addition a system involving a non-transition element, namely H_2SeO_3–ClO_3^-–L,[168,169] has also been described.

The catalytic ClO_3^- currents in the Ti(IV)–ClO_3^-–$H_2C_2O_4$–H_2SO_4 system were first investigated by Koryta and Tenygl[114], who established that 5.5 molecules of the titanium(III) complex participate in the reduction of ClO_3^- ions. The oxidation rate constant proved to be 1×10^4 litre mol^{-1} s^{-1}; this value was confirmed by many investigators[115–124].

Since the rate constants for the oxidation with chlorates of Ti(III) in $HClO_4$ and of the Ti(III) oxalate complex in H_2SO_4 are virtually equal (see Table), the Ti(III) aquo-ions are involved in the oxidation reaction responsible for the catalytic polarographic ClO_3^- current[126].

In the presence of an excess of oxalic (H_2Ox), citric (H_3Citr), and tartaric (H_2Tart) acids, EDTA, and CNS^- ions, titanium(IV) is reduced with a single reversible one-electron wave at less negative potentials than in the absence of the above ligands[39]. At low ligand concentrations a Ti(IV) reduction prewave is observed (catalysis by the ligand). In the presence of $KClO_3$ the height of both the aquo-ion wave and the prewave increases[124–126]. Among other acids, dicarboxylic acids comprising malonic acid (H_2Malonic) and carboxylic hydroxyacids comprising malic, trihydroxyglutaric (H_2Trihydrox), and glucaric (*d*-saccharic) acids also exhibit a catalytic activity (ligand catalysis). In the Ti(IV)–$KClO_3$–L systems the catalytic ClO_3^- current is superimposed on the Ti(IV) → Ti(III) reduction wave[127–132]. The current i_c is a maximum at pH 1–1.1, which can be explained by the involvement of the $Ti(OH)^{3+}$ species[127]. With increase of the $KClO_3$ concentration, the current i_c also increases and reaches a constant value, while with increase of the ligand content it passes through a maximum[124,125,127,128]. The catalytic waves in Ti(IV) solutions have the usual form with a distinct limiting current plateau and are described by the Koutecky theory[10].

The rate-limiting stages in the processes are the oxidation of $Ti(OH)^{3+}$ [125–127,130,132] or of its complex[128] by chlorate ions. At low ligand concentrations, where a prewave is observed, the mechanism of the generation of the catalytic current involves the oxidation of both the titanium aquo-ion and its complex ion[124,126], in which the organic ligands investigated exist in the form of uncharged species[125,132]. The ligands (see Table) can be arranged in the following sequence in terms of their increasing influence on the catalytic ClO_3^- current in the Ti(IV)–ClO_3^-–L system: H_2Malonic < H_2Malic < H_2Tart < H_2Citr < HDPPA < H_2Ox < Ph < H_2O < H_2Trihydrox < HMandelic ≪ CNS^-. The appreciable increase (by approximately four orders of magnitude) of the rate of oxidation of Ti(III)L on passing from an organic to an inorganic ligand (CNS^-) is probably associated with the faster formation of the complex $Ti(CNS)^{2+}$.[126]

The current i_c in the Ti(IV)–$KBrO_3$–EDTA system diminishes with increase of pH and at pH ≥ 3 reaches a constant value which is independent of the acidity of the solution[133].

As a representative of the titanium subgroup, zirconium does not give rise to a catalytic BrO_3^- wave in the presence of EDTA.[133]

In an acetate buffer solution at pH 5.0 the polarogram of vanadium(V) shows the catalytic BrO_3^- wave with a sharp maximum at $E = 0$ V,[136] which hardly changes after the introduction into the solution of 0.05 M resacetophenone oxime (2,4-dihydroacetophenone oxime), which forms a complex with V(V). The appearance of this wave is probably associated with the oxidation of the V(IV) formed by BrO_3^- ions to V(V), since it is located at the potentials of the V(V) → V(IV) reduction wave. The catalytic ClO_3^- and BrO_3^- currents in the Fe(III)–KCl system[137,138] are due to the interaction of ClO_3^- and BrO_3^- with the colloidal hydroxide $Fe(OH)_2$.

A large series of studies on the catalytic ClO_3^- currents in the presence of Mo(VI) have been carried out[23,139–164]. The first catalytic chlorate currents in the presence of Mo(VI) were investigated by Kolthoff and Hodara[139] at various sulphuric acid (0.01–2 M), sodium chlorate (0.2–1.2 M), and molybdenum(VI) concentrations. In weakly acidic H_2SO_4 solutions (up to 0.1 M) in the absence of chlorate, a single wave corresponds to the reduction of Mo(VI) to Mo(V) and two waves correspond to the reduction of Mo(V) to Mo(III). On the other hand, in strongly acid solutions ($c_{H_2SO_4} > 1$ M) the reduction of Mo(VI) to Mo(V) is characterised by two waves, while the reduction of Mo(V) to Mo(III) is characterised by a single wave, which can be explained by the reduction of various hydrolysed Mo(VI) and Mo(V) forms[140]. Two catalytic waves, due to the reduction by the Mo(V) and Mo(III) species of the chlorate ions formed at the electrode, are observed in the presence of chlorate. The rate of oxidation of Mo(III) to Mo(V) by chlorate, calculated from the data of Delahey and Stiehl[141], is independent of $c_{H_2SO_4}$.

In the presence of organic compounds (malic, tartaric, trihydroxyglutaric, mandelic[130], citric[144], glucaric[147], glycolic[148], tartronic[153], oxalic[145], and malonic[143] acids and catechol[149]), the Mo(VI) polarogram at pH 1.7 in the 0.1 M H_2SO_4 + 0.2 M Na_2SO_4 system consists of two or three waves. The catalytic wave in the form of a peak is located at the potentials of the first[143,144,147,149,153] or second[148] reduction wave of Mo(VI) and in oxalic acid solutions two peak-shaped catalytic waves, corresponding to the Mo(VI) and Mo(V) regeneration processes, are observed. In all cases the current i_c passes through a maximum with increase of the ligand concentration and the pH of the solution (pH_{max} 0.9–1.0). In the case of oxalic acid the heights of the first and second catalytic waves are maximum in 0.1 and 0.5 M H_2SO_4. With increase of c_{KClO_3} the current i_c increases in all cases and reaches a limiting value. The dependence of i_c on the acidity of the medium and other parameters can be explained by the different catalytic activities of the hydrolysed forms of molybdenum[23,145,161]. Many investigators[143–145,147–149,151–153] believe that the rate-limiting stage in the generation of catalytic currents is the oxidation of the molybdenum(V) complex by the chlorate ion. However, in some investigations[130,155] a coordination mechanism has been proposed, according to which the complex $Mo(V)L.ClO_3$ formed is reduced at the electrode.

The organic ligands investigated can be arranged in the following sequence in terms of increasing catalytic activity (see Table): $H_2O \ll H_3Citr < HGl < H_2Tart < H_2Malic < H_2Tartron < H_2Trihydrox < H_2Glucar < Ph \ll HMandelic$. A detailed study[23,161] of the catalytic currents in the presence of mandelic acid (the most active and the most readily sorbed ligand on the surface of mercury) showed that the catalytic currents are described by a mechanism in which the slow oxidation of various molybdenum(V) complexes incorporating the chlorate ion takes place on the surface of the electrode and not in the layer near it, as follows from Koutecky's theory[10].

In a study of the W(VI)–ClO_3^- system, where two catalytic peaks, observed in the presence of pseudotungstate, are due to the oxidation of $HW_6O_{20}^{3-}$ and $H_2W_6O_{20}^{2-}$, Hodara and Glasner[167] also concluded that the reaction responsible for the catalytic chlorate current occurs on the surface of the electrode; metatungstate does not exhibit a catalytic activity.

The joint influence of molybdenum(VI) and tungsten(VI) salts on catalytic ClO_3^- currents is of interest. The first catalytic ClO_3^- peak, due to the involvement of molybdenum(V), appreciably increases after the introduction of tungstate(VI) into the solution, which can be explained by the appreciable contribution of tungsten(V) to the catalytic activity of the heteropolyacid formed, which comprises tungsten(VI) and molybdenum(VI).[162]

On passing from titanium to molybdenum, the catalytic activity increases appreciably (see Table). The electrochemical reduction of BrO_3^- is catalysed by molybdenum(VI) in acetate buffer solution at pH 5.0. In the presence of resacetophenone isoniazid hydrazone the catalytic wave shifts towards more positive potentials and has the form of a peak with $E_p = -0.7$ V.[165] The authors[165] do not explain the generation of the catalytic BrO_3^- current.

The catalytic BrO_3^- current for selenium (a non-transition element) in solution at pH 2.5–4.0 is observed at the potentials of the second wave of selenium. It corresponds to the oxidation of H_2Se to zerovalent selenium[168,169] and obeys the Koutecky theory.

The catalytic chlorate currents have been used to determine ClO_3^- ions[114,129] and admixtures of titanium in trichlorosilane[121], in metallic aluminium of type Al 74[a], in steels[127,131,160], in natural waters and soil solutions[133,163], in rocks[158], in soils[159], in pure solutions[147,148,153], in technical sulphuric acid[164], and in tungsten[162]. Furthermore, the catalytic ClO_3^- currents are widely used in the determination of the polarographically inactive pyrogallol, salicylic and sulphosalicylic acids and catechol[123,125,149], and citric[124], glucaric[147], glycolic[148], tartronic[153], and mandelic[156] acids. Isopentyl alcohol, agar-agar[148], Tween 80,[153] and phenol[157] can be determined from the decrease of the catalytic current. Mandelic acid has come to be most widely used as the ligand for analytical purposes[158–160,163,164].

The catalytic bromate currents are used for highly sensitive determinations of titanium[133,134,135], vanadium[136], and molybdenum[165] (in solutions, and biological objects[166]) and of selenium[168,169].

4. Catalytic Currents of the Perchlorate Ion

In an acid medium perchlorates have a lower standard oxidation-reduction potential than chlorates, which is one of the causes of their low reactivity at room temperature. The catalytic perchlorate currents are therefore observed only for highly active catalysts such as molybdenum and tungsten. The catalytic ClO_4^- currents are not observed in the presence of titanium(IV) in view of the low rate of oxidation of titanium(III) by ClO_4^- ions; $k = 8.9 \times 10^{-2}$ litre mole^{-1} s^{-1} at 40 °C.[170]

The catalytic current in the Mo(VI)–ClO_4^- system has been observed by many investigators[139,171–180]. This phenomenon was first noted[171] in the polarography of Mo(VI) in $HClO_4$ solutions.

The formation of molybdenum(VI) and tungsten(VI) complexes with chloride ions[176,181] and carboxylic acids (tartaric, citric, and oxalic)[180] decreases i_c. Numerous mechanisms have been proposed for the catalytic current, according to which the current is due to the oxidation of Mo(IV) [174,175] or the reduction at the electrode of the complex Mo(V).ClO_4;[176] these mechanisms have been inadequately justified. We believe that the mechanism according to which the current is due to the oxidation of Mo(III) by perchlorate ions, proposed by Kolthoff and Hodara[139], is most correct. The catalytic current in the W(VI)–ClO_4^- system corresponds to the oxidation by perchlorate of the W(V) formed on the electrode[181].

The Table shows that the activities of molybdenum and tungsten in the catalytic reduction of ClO_4^- ions are approximately the same. The catalytic perchlorate currents make it possible to determine Mo(VI) at concentrations down to 1×10^{-6} M;[172–175] to increase the sensitivity of the methods, the solutions are polarographed at 40 °C [177] or time–current polarography is used[182].

The catalytic perchlorate currents have been used for analytical purposes in the determination of admixtures of molybdenum in iron and steels[182], in $HClO_4$,[170] in plants[173], in rocks[174,175], in various industrial and biological objects[177], and in soils[183].

5. Catalytic Currents of Iodate and Periodate Ions

Catalytic currents of iodate and periodate ions are observed in systems with sulphur-containing organic substances such as cystine[184], dithiocarbamate, and xanthate[24]. The ClO_3^-, BrO_3^-, NO_2^-, and H_2O_2 species do not exhibit catalytic effects in these organic systems. In the cystine–IO_3^-(IO_4^-) system the catalytic wave is combined with the first cystine reduction wave and has the form of a peak whose height is a maximum at pH 8.6–9.2. The current i_c can be greatly increased by the preliminary concentration of cystine at a stationary mercury microelectrode or by introducing ammonium or magnesium ions, which behave as activators[37].

The electrode process is described by the Koutecky theory and includes the oxidation of cysteine to the initial depolariser as the rate-limiting stage[185]. The introduction of IO_3^- at pH 7–11 into diethyldithiocarbamate (DTC) and ethyl xanthate (EX) solutions, which give rise to anodic polarographic waves, results in the appearance of a cathodic catalytic wave at potentials in the range between −0.5 and −0.6 V, which is much larger than the anodic wave and has the properties of surface waves[24]. The catalytic IO_3^- and IO_4^- currents make it possible to determine very low concentrations of sulphur-containing compounds: when cystine is initially concentrated at a stationary mercury microelectrode, its concentrations down to 10^{-8}–10^{-6} M can be determined[184].

The catalytic halogenate and perhalogenate currents tend to increase with increase of the number of the *d* orbital of the transition element (see Table). In catalysis by non-transition elements and organic substances, the catalytic current is observed only for bromate, iodate, and periodate. The rates of reduction of the substrates are then high and comparable to the rates characteristic of the Ti(IV)–ClO_3^-.(BrO_3^-)–organic ligand systems.

6. Catalytic Currents of Nitrate and Nitrite Ions

The catalytic currents of nitrate and nitrite ions are observed in the V(V)–NH_4Cl,[186] V(V)–EDTA,[187] Cr(III)–glycine[188], Cr(III)–EDTA,[189] molybdenum(VI),[139,177,180,190–195], and uranium(VI) [21,196–202] systems in various media. The catalytic currents for all the systems investigated are described by the Koutecky theory[10] and the reaction involving the oxidation of the depolariser reduction product by the nitrate or nitrite ion is rate-limiting. When the elements of the first transition series (vanadium and chromium) are used, V(II) or Cr(II) is oxidised to vanadium(IV) or chromium(III). The mechanism adopted is shown to be valid by the agreement between the rate constants for the Cr(II) oxidation reaction obtained by the chemical and polarographic methods[189].

The product of the reduction of NO_3^- by Cr(II) ions is NH_4^+.[189] The catalytic wave for the Mo(VI)–NO_3^- systems in acid sulphate[139,186,192], perchlorate[177], and chloride[192] solutions is located at the potentials of the Mo(V) → Mo(III) second wave and is due to the oxidation of Mo(III) to Mo(V). In contrast to nitrate ions, nitrite ions are involved in the oxidation of the Mo(V) formed to Mo(VI).[192]

The catalytic current in the U(VI)–NO_3^-(NO_2^-) systems is due to the oxidation of the U(III) formed to U(IV) [21,196–202] and the NO_3^- reduction product is hydroxylamine[203]. It has been established for the U(VI)–NO_3^- system[21] that the different signs of the charges of the reacting species exert an appreciable influence on the rates of the reactions responsible for the catalytic currents: the substrate has a negative charge and the catalyst has a positive charge. The rates of the NO_3^- or NO_2^- reduction reactions in the systems investigated (see Table) increase with increase of the number of the *d* or *f* orbital [sic], which is probably caused by the formation of labile systems capable of giving up electrons more readily on interaction with the oxidant.

The catalytic currents of nitrates are used for analytical purposes in order to determine the admixtures of molybdenum in technical and biological objects[177], in steels and reagents[193], in high-purity indium[194], in propene epoxidation products[195] and for the determination of uranium at very low concentrations, down to 1×10^{-8} M,[195–197,202] traces of uranium in rocks and untreated phosphates[201], NO_3^- and NO_2^-.[198]

7. Catalytic Currents of Persulphate Ions

The persulphate ion $S_2O_8^{2-}$ is reduced to SO_4^{2-} at positive potentials with participation of two electrons[39]. The specific adsorption of Br^- and I^- anions[204] or the formation of a sparingly soluble film of mercury iodide[205] have an inhibiting effect on its reduction. Chloride ions produce the same effect[206]. A catalytic wave, coinciding with the first copper(II) reduction wave, is observed in the Cu(II)–$S_2O_8^{2-}$–KCl system[206]. It is described by the Koutecky theory and is determined by the rate of oxidation of Cu(I) by persulphate ions with formation of Cu(II) and the SO_4^- radical-ion, which is consumed in the oxidation of Cu(I) or is reduced at the electrode. Interesting phenomena have been observed[207,208] in the study of the catalytic currents in the Cu(II)–$S_2O_8^{2-}$ system in 0.1 M $NaClO_4$ + 0.01 M $HClO_4$. A minimum arises on the polarogram in the presence of As(III) at $E = 0.1$ V, whose depth increases with increasing As(III), Cu(II), $S_2O_8^{2-}$, methanol, ethanol, and propanol concentrations and diminishes in the presence of acetonitrile, allylacetone, and Fe(III).[207] A minimum is also observed in the region of the reduction potential of the copper complex of EDTA (at $E \cong -0.5$ V) in $NaNO_3$ solutions containing 1 M ethylenediamine in the presence of As(III). To account for the results, a mechanism has been proposed in which the sulphate radical-anions formed are consumed in the oxidation of not only Cu(I) but also of As(III) and the other species investigated[207,208].

Catalytic Currents of Vanadium(IV)

In the generation of the catalytic oxygen currents described the oxidant-substrate is reduced at the electrode at much more negative potentials than the catalyst. However, there are systems in which part of the oxidant is reduced at the limiting current potentials of the catalyst wave and the oxidant reduction product is the catalyst itself, as, for example, in the V(IV)–V(III)–V(II)–H_2SO_4 system[209]. The polarogram of V(III) has a distinct diffusion wave with $E_{1/2} \cong -0.5$ V. When V(IV) is introduced, the V(III) reduction wave becomes indistinct and I_{lim} at the potentials corresponding to the V(III) diffusion current plateau exceeds the sum of i_d for V(III) and the V(IV) reduction current at this potential. The catalytic current is due to the oxidation of V(II) to V(III) by V(IV) ions. This process is accelerated by increase of pH in the range 0–1.3, which is due to the different oxidising capacities of the VO_2^{2+} and $V(OH).HSO_4^{2-}$ cations, which predominate under the given conditions. The catalytic currents, complicated by the reduction of the oxidant itself, are observed also in the Mo(VI)–V(V)–EDTA system at pH 4–6.[210].

In the Mo(VI)–V(V) mixture in the presence of EDTA, the three-electron molybdenum(VI) wave increases and the second vanadium(V) reduction wave, corresponding to the process V(IV) → V(III), disappears, which can be explained by the involvement of V(V) ions in the catalytic Mo(III) oxidation reaction[210]. However, it is difficult to agree with this, since the potential corresponding to the reduction of the complex V(V).EDTA to V(IV).EDTA is more positive by ~0.7–0.8 V than the reduction potential of molybdenum(VI). The involvement of V(IV) complexes as the oxidants is most probable. The V(IV) catalytic currents, observed in the U(VI)–V(IV) system[211], are used to determine low uranium concentrations.

9. Catalytic Currents of Sulphuric and Certain Carboxylic Acids

The limiting reduction currents of sulphur dioxide, bromine, and iodine against the background of concentrated sulphuric acid are catalytic in nature[212] owing to the oxidation of the electrochemical reduction products of these depolarisers to their initial state by sulphuric acid.

Among carboxylic acids, oxalic and glyoxylic acids are known as oxidant-substrates[213]. Oxalic acid is reduced to glyoxylic acid at the mercury dropping electrode[214]. In the presence of uranium(VI) the reaction takes place at more positive potentials with formation of glycolic acid[213]. Under these conditions, the catalytic wave of oxalic acid coincides with the second uranium(VI) reduction wave: $UO_2^+ + 2e \rightarrow U(III)$. The same catalytic wave is observed also in the presence of glyoxylic acid. The catalytic reduction currents of the above acids are due to their reaction with U(III) to form glycolic acid and U(IV). The latter is reduced electrochemically to U(III) and the reactions described are then repeated[213].

The catalytic currents in the U(VI)–glyoxylic acid system can be used to determine U(VI) and glyoxylic acid[215].

III. THE FIXATION OF ATMOSPHERIC NITROGEN—A POSSIBLE APPLICATION OF THE CATALYTIC CURRENTS OF SUBSTRATES

The intensive development of agriculture requires the use of considerable amounts of inorganic fertilisers. Thus, from 1st July, 1938 to 30th June, 1939, 9.2×10^6 tonnes of nutrient elements were produced in the world in terms of N_2, P_2O_5, and K_2O,[216] while in the period 1977–1978 the corresponding figure was 106.1×10^6 tonnes, including 40.9×10^6 tonnes of N_2.[217] The present capacity of the world nitrogen industry meets less than 10% of the requirements of agriculture for nitrogen fertilisers[218].

The industrial methods of producing bound nitrogen are energy consuming and are carried out at high temperatures and pressures, while the enzymic fixation of nitrogen† takes place in nature under very mild conditions. Consequently, the fixation of atmospheric nitrogen under mild conditions is possible in principle and the development of industrial fixation methods is an urgent problem in modern chemical science.

The fixation of atmospheric nitrogen under mild conditions is a reaction catalysed by electron-transfer reagents[219]. It is therefore interesting to consider them under the conditions of the electrochemical regeneration of mediators, together with the catalytic currents of molecular nitrogen as the substrate. The non-enzymatic fixation of nitrogen under mild conditions was first described by Vol'pin and Shur[220]. Numerous studies (surveyed in reviews[221–224]) on this question were published over a short period.

Thermodynamically feasible nitrogen fixation reduction processes are difficult because in the dissociation of the triple bond in the N_2 molecule most of the energy (131 kcal [225] out of 225 kcal [226]) is consumed in the rupture of the first bond. In the direct reduction one must therefore use particularly powerful reductants. The formation of complexes of nitrogen molecules with transition elements[227,228] makes it possible to distribute more uniformly the dissociation energy of the π-bonds in the N_2 molecule among separate stages.

Nitrogen can be reduced stepwise with participation of two, four, and six electrons, leading to the formation of N_2H_2, N_2H_4, and NH_3. The four-electron process, involving the reduction of nitrogen to hydrazine, is energetically most favourable[222]. The N_2–reductant (transition element and others) system under the conditions of the electrochemical generation of the reductant resembles the systems already considered, in which the catalytic currents of oxidant substrates are observed. One cannot therefore rule out the possibility that the study of the oxidant catalytic currents, including the molecular nitrogen current, may lead to the refinement of the mechanism of the nitrogen fixation process or may lead to the discovery of new principles for the selection of nitrogen-fixing systems "working" under mild conditions.

Vol'pin and Shur[220], who observed the fixation of nitrogen at room temperature also in aprotic (etheral and hydrocarbon) media, used powerful reductants such as $LiAlH_4$, C_2H_5MgBr, and (iso-C_4H_9)Al. Nitrogen fixation was observed in the presence of transition metal salts ($CrCl_3$, $MoCl_5$, WCl_5, $FeCl_3$, and $TiCl_4$). Ammonia was evolved in the hydrolysis of the products formed. Many investigators whose studies have been surveyed[221–224] used transition elements (V, Mn, Co, Zr, Ru, Os, and Nb), apart from the elements in the above salts, as catalysts and the reductants were alkali, alkaline earth (Mg) and lanthanide (La and Ce) metals, alkali metal naphthalides and hydrides[219,222–224], and sodium amalgam[229]; electrochemical reduction has also been employed[230–234]. As expected, hydrazine and ammonia were obtained in the hydrolysis of the products of the nitrogen-fixing systems. In the systems investigated the transition elements played the role of catalysts or, in rare instances, the role of both catalysts and reductants [for example, in the V(II)–Mg(II)–N_2 system[235,236]]. The catalytic effect of the transition element is manifested under a rigorously specific combination of conditions: the standard potential of the reductant must be greater or equal to the potential of the catalyst and greater than the potential of hydrazine; the reductant must exhibit a specific activity in relation to nitrogen[222].

Under the conditions investigated, the nitrogen activation stage consists of the formation of the dinuclear complex MN_2M,[237] in which the transition element M is in the d^1 or d^3 state. In subsequent steps electrons are transferred from the reductant to the activated nitrogen. This mechanism is identical with that of the catalytic reduction of nitrogen in biological processes catalysed by nitrogenase[219,222] and other enzymes[238,239]. In electrochemical systems the cathode is a universal reductant, at which one can establish any potentials for the reduction of substances, including molecular nitrogen. It is not therefore fortuitous that investigators have resorted to electrochemical methods[230–234], including polarography, to study the fixation of nitrogen.

The fixation of molecular nitrogen has also been studied by the molecular orbital (MO) method in relation to reactions in the $[N_2 + H]^{\cdot}$, $[N_2 + H^{\cdot}]^+$, and $[N_2^- + H^{\cdot}]^-$ model systems[240].

The nitrogen fixation mechanism presented above can ensure the appearance of the catalytic polarographic current of nitrogen. The behaviour of the nitrogen-fixing systems V(II)–catechol[241] and Mo(III)–Mg(II)–Na(Hg) [242] has been studied. The lack of literature data for the catalytic polarographic currents of molecular nitrogen as the oxidant-substrate in nitrogen-fixing systems is probably associated with the fact that the rate of oxidation of the intermediate transition metal complex by molecular nitrogen is not high enough to be appreciable under polarographic conditions. However, in principle, it will be possible to observe the catalytic polarographic current of molecular nitrogen under certain conditions and to use it as an indicator for the selection of nitrogen fixation conditions.

Thus transition and certain non-transition elements are used as catalysts of the reactions responsible for the catalytic polarographic currents of substrates. The catalytic activity of an inorganic catalyst increases with the number of its *d* orbital. Complex formation in most cases leads to an increase in activity of the catalyst, but sometimes the opposite phenomenon takes place.

The maximum activities of many catalysts are observed at pH values close to the p*K* for their hydrolysis, which can be used to estimate the activities and the degrees of involvement of various hydrolysed forms of catalysts in the catalytic process.

The properties of oxidant-substrates are shown by H_2O_2, ClO_3^-, BrO_3^-, IO_3^-, ClO_4^-, IO_4^-, NO_2^-, NO_3^-, NH_2OH, V(V), V(IV), $S_2O_8^{2-}$, H_2SO_4, $H_2C_2O_4$, COHCOOH, and saturated compounds, organic halogeno-compounds, sulphur-containing compounds, and amino-compounds. The strongest oxidants can be arranged in the following sequence in order of increase of their reactivity. $ClO_4^- < NH_2OH < NO_2^- < NO_3^- < H_2O_2 < S_2O_8^{2-} < IO_4^- < IO_3^- < BrO_3^- < ClO_3^-$ (see Table).

The generation of catalytic currents is in most of the cases examined due to the oxidation of the reduced form of the catalyst by the substrate in the layer near the electrode or

†By the fixation of nitrogen, we understand a process involving the complete or partial rupture of the N≡N bond.

on the electrode surface. In systems with hydrogen peroxide one cannot rule out the possibility of the reduction at the electrode of the substrate bound in a complex with one of the forms of the catalyst.

The catalytic currents have found extensive applications in analytical practice for the analysis of admixtures of the catalyst, substrates, and polarographically inactive substances forming complexes with the catalyst, and also in the study of complex formation. One cannot rule out the possibility of using the catalytic currents also in the study of the molecular nitrogen fixation processes under mild conditions.

Electrochemistry of Iodine

Ya.A.Yaraliev

The results of studies of redox processes in systems which include iodine are generalised. The adsorption of iodine on metals is discussed, and the relationship between the type of adsorption and the electrode reactions of the iodine is examined. 190 references.

I. SPECIFIC ADSORPTION OF IODIDE IONS

The adsorption of iodide ions on different electrodes from different media has been fully investigated[1-72]. The main aim of that work was to determine the structure of the electrical double layer (EDL) and, in particular, the effect of the specific adsorption of the ions on various electrode processes (metal dissolution, hydrogen evolution, etc.). In this Section we shall attempt to generalise (qualitatively) data on the adsorption of iodide ions on metals in order to explain the general features of the adsorption: this is an essential preliminary to any discussion of the kinetics and mechanism of the redox reactions of iodine.

The rate of an electrochemical process is strongly dependent on the structure of the EDL, which is determined by the nature of the adsorption of the reacting ions on the electrode surface. The adsorption type (especially in the case of specific adsorption) depends on the one hand on the stability of the complexes (or chemical compounds) formed by the adatoms (or ions) with the surface atoms of the metal electrode at the ψ' potential[1], and on the other hand it depends on the primary hydration (or solvation) number[2] of the ion in the bulk of the solution. The adsorption of iodide ions from different media and on different electrodes is determined by these factors.

On mercury electrodes[3-7] the adsorption of iodide ions causes an increase in the capacity of the EDL,[3] an anomalous change in zero-charge potential with the logarithm of the concentration of I^- (the Esin–Markov effect),[5] a lowering of the electrocapillarity maximum (accompanied by a negative shift)[1,3], a decrease in hydrogen evolution overvoltage (η_{H_2}) in acid solutions[4,7] a linear decrease in heat of adsorption with increase in surface coverage[6], and a shift of the ψ' potential towards more negative values[4,7]. If the formation of the surface compound results in a full (or partial) loss of charge by the iodide ions the EDL capacity should decrease, and conversely if as a result of the low stability of the surface complex the iodide ions accumulate in the fixed part of the EDL the capacity should increase.

The negative shift of ψ' (which lowers η_{H_2}) and the increase in capacity suggest a weak chemical interaction between Hg and I^-. In this case the I^- anions are adsorbed in the ionic "condenser plate" of the EDL, where they generate a negative ψ' potential and (according to the slow discharge theory) they increase the rate of evolution of hydrogen. However, it has been shown experimentally[8] that the negative shift of ψ' is not accompanied by an accumulation of H^+ ions on the mercury surface: this suggests[8] that the influence of I^- and other anions on this electrode is not primarily the ψ' effect but a substantial lowering of the activity coefficient of the activated complex. Another important factor on the mercury electrode is the mutual repulsion of the I^- ions chemisorbed on the surface, i.e. the high mobility of these ions on the uniform mercury surface[6].

There can be no doubt that the number of ions in the EDL depends on their degree of solvation (hydration) in the solution. Hence the observed sequence of specific adsorbability ($Cl^- < Br^- < I^-$) from water solutions, which applies to almost all metals, is invariably ascribed to decreasing hydration. In contrast to their behaviour in protonic solvents (water, methanol, acetic acid, etc.), iodide ions are easily solvated in dipolar aprotic solvents such as dimethylformamide (DMF), dimethylsulphoxide (DMSO), acetone, and acetonitrile[9]. This difference is sharply reflected in the specific adsorption of I^- at the mercury–electrolyte interface with non-aqueous solvents. For example, the surface activity of iodide anions at the mercury–DMF interface is lower than at the mercury–water interface[10,11,14], and the lowering of surface tension caused by the adsorption of I^- on an uncharged mercury surface in water is greater than in DMF.[10] The difference is even more marked if we compare water with formamide[10].

Damaskin and coworkers[10,11] ascribe this effect to competition between the adsorption of I^- anions and the adsorption of solvent molecules. Obviously, we must again allow for the strong solvation of I^- in aprotic solvents, since the difference in solvation energy of the anions decreases in the series from Cl^- to I^- in water, but increases in DMF.[11] The free energy of adsorption of I^- on an uncharged mercury surface from aqueous solutions is 37.1 kcal mole^{-1}, as compared with 29 kcal mole^{-1} for solutions in DMF under the same conditions. In comparison with the mercury–water interface, the mutual repulsion of specifically adsorbed anions is stronger at the mercury/DMF,[11] mercury–*N*-methylformamide (MFA),[12] mercury/formamide[15], and mercury/DMSO interface[13,16]: this is shown by the decrease in the second virial coefficient (B) when DMF is replaced by water.

Under certain conditions even organic surface-active ions have very little effect on the adsorption of I^- on mercury[7,17].

On iron, cobalt, and nickel. In contrast to its adsorption on mercury, the adsorption of I^- on solid metals (especially Fe,[18-24] Co,[25,26] and Ni [27-29]) is due to the formation of a strong M–I^- chemical bond. Iodide ions chemisorbed on an iron surface[18,19,21] have a passivating effect on the metal: η_{H_2} is increased[19,22], and the ionisation reaction is suppressed[20]. The capacity of the iron electrode decreases more

than two-fold in the presence of even very small amounts of KI (0.002 *N*), the additional decrease caused by increasing the KI concentration to 0.2 *N* being almost negligible[21]. The decrease in capacity increases with the concentration of H_2SO_4 (from 1 to 8 *N*).[21]

The maximum number of iodide ions adsorbed on Fe has been shown by a radioactive tracer method to be 4×10^{-10} g-atom cm^{-2}, corresponding to 50% coverage of the iron surface. Therefore it is generally thought that the passivating effect of I^- on Fe cannot be due to the formation of a surface compound. However, the lowering of the double layer capacitance of Fe from 33–35 μF cm^{-2} (in 1 *N* H_2SO_4) to 10–15 μF cm^{-2} by the addition of 0.001 mole $litre^{-1}$ of KI conclusively proves that iodide ions are chemisorbed[21]. It is interesting to note that the capacity of iron in sulphuric acid is unaffected by the presence in solution of an organic surface-active ion (the tetrabutylammonium cation), whereas addition of iodide ions to the same solution causes a marked decrease (to 7–10 μF cm^{-2}) in the capacity of the electrode[19]. This is explained by the formation of dipolar Fe–I^- molecules with their negative end pointing towards the solution, which assists the adsorption of positively charged species. The Fe–I^- surface complex is stable only in acid solutions[24].

It has also been shown that halogens adsorbed on Fe retain some excess negative charge, though not to the same extent as in the adsorption on mercury[22]. Oshe even suggests[23] that the halide ions can penetrate into the surface layer of the the iron and perturb the crystal structure.

Halide ions adsorbed on cobalt[25,26], as on iron, increase the overvoltage of both the cathodic process (discharge of hydrogen ions) and the anodic process (cobalt ionisation reaction). Increasing i_a and ϕ_a accelerates the removal of the adsorbed ions (together with the ionised surface atoms of the cobalt electrode[26]).

Iodide ions weaken the Ni–H bond: they displace adsorbed hydrogen atoms from the surface and they raise η_{H_2}, the magnitude of the effect increasing with the concentration of I^- in solution[27,28]. At low concentrations of I^- ($\lg c_{I^-} < -4$) the differential capacity of nickel decreases as the concentration of I^- increases due to increasing chemisorption of I^-. Further increase in the concentration of I^- brings less strongly bound I^- ions into the surface layer, and the capacity begins to rise[29].

On lead and tin. The adsorption of iodide ions on lead[30–34] takes place in two steps. Kolotyrkin and coworkers[30] have shown that the first step consist in the (fast) penetration of the anions into the EDL, accompanied by an increase in capacity. In the second (slow) step a strengthening of the bond between the anions and the surface metal atoms takes place, and the capacity decreases. In acid solutions an increase in the concentration of KI from 1×10^{-5} to 1×10^{-3} *N* increases the coverage of the lead electrode surface with iodide ions from 0.37 to 38.5% of a monolayer. At low coverages (0–15%) and increase in the number of adsorbed iodide ions lowers η_{H_2}, whereas at coverages greater than 15% the effect is the opposite: in this case an increase in adsorption produces a marked increase in η_{H_2}, to a level higher than the overvoltage in pure acid solutions when the coverage exceeds 30% of a monolayer.

The surface excess of specifically adsorbed I^- for the same total density of charge is lower on lead than on mercury[32]; the shift in the zero-charge potential caused by iodide anions is greater on mercury than on lead[31,33]; the minimum on the $c-\phi$ curve occurs at 10^{-5} *N* KI concentration on mercury[3], whereas on lead[31] (and on tin[37]) it occurs at 10^{-3} *N* KI. Thus it appears that the specific adsorption of I^- is weaker on lead than on mercury. A generalised model of the EDL [34] can be used to calculate the change in η_{H_2} on lead caused by the adsorption of I^-.

On cadmium and thallium. On a cadmium and a thallium electrode[30,35], as on a lead electrode, the positive swing in potential caused by I^- ions produces first a lowering and then a rise in η_{H_2}. The adsorption of water dipoles with their negative end towards the electrode surface is more marked on a cadmium than on a lead electrode[36]. The relative values of the energy of adsorption of the iodide ion on cadmium ($\Delta G^0_{I^-} = -22.0$ kcal $mole^{-1}$) and on mercury (−37.1 kcal $mole^{-1}$) are consistent with the surface excesses of iodide ions on the two metals, and show that the iodide ion is adsorbed less strongly on cadmium than on mercury[36].

On silver. The adsorption of I^- anions on the (100) face of silver single crystals is stronger than on any other solid electrode[38]. This is explained by the extremely low solubility in water of the silver halides[39,40], which causes a substantial (2–3-fold) decrease in the differential capacity of the EDL,[40] as in the case of iron. Unlike the adsorption on Pb, the adsorption of I^- on Ag causes only an increase in η_{H_2} over a wide range of KI concentrations (from 10^{-9} to 10^{-3} g-equiv $litre^{-1}$).[40]

The potential corresponding to full adsorption varies substantially with the pH of the solution. An increase in pH at constant potential always produces a marked decrease in adsorption: the effect is strongest in acid solutions (pH < 6), whereas in strongly alkaline solutions the effect of pH on the adsorption is much weaker[40].†

Because of the very low coverage of the silver surface by adsorbed ions (~10% of a monolayer[39]) the penetration of I^- into the metal lattice is thought[40] to be unlikely. However it has been shown[42,43] that the adsorption of I^- on Ag is accompanied by penetration into the metal lattice as a result of the relatively fast exchange with surface atoms of silver.

On bismuth. The adsorption of I^- on bismuth[44–47,50] is lower than on mercury, but somewhat higher than on Pb [31] and Cd.[35] However, the surface activity of the iodide ions, i.e. the magnitude of the negative shift of the minimum in the ε,ϕ curve, is lower for Bi and In than for Pb and Tl.[51]

At low concentrations of KI (<10^{-2} M) the shift in the zero-charge potential for the (111) face of a bismuth single crystal is smaller than for the surface of a cast bismuth ingot, but at higher concentrations of KI (>10^{-2} M) the shift becomes greater for the monocrystalline than for the polycrystalline surface. The repulsion between specifically adsorbed I^- anions on a (111) face with $\varepsilon < 0$ is substantially higher than on the polycrystalline face, but with $\varepsilon > 0$ the opposite is true. On a cast bismuth electrode the enhanced specific adsorption is accompanied by closer approach of the inner Helmholtz plane to the electrode surface[44].

The adsorption of I^- on Bi is stronger from aqueous than from methanolic solutions[48,49], increasing more rapidly with the concentration of I^- in water than in methanol solutions. Changing from water to methanol solutions of I^- causes the planes of the EDL on Bi to move apart[48]. The increase in the distance from the outer Helmholtz plane to the surface (x_2) in methanol is accompanied by a strong (2–3-fold) enhancement of the repulsion between adsorbed ions, caused by the closer approach of the inner Helmholtz plane (x_1) to

†A similar pH effect is observed in the adsorption of I^- on Cu, Au, Pt, Ni, and stainless steel. On the other hand on glass the adsorption of I^- increases significantly with pH.[41]

the electrode surface with increasing adsorption of the iodide ion[49]. The standard free energy of adsorption $\Delta G^0_{I^-}$ on Bi is -23.9 kcal mole^{-1} from aqueous solutions and -25.6 kcal mole^{-1} from methanolic solutions[48]. The increase in $\Delta G^0_{I^-}$ on changing the solvent from water to methanol is due essentially to the lower solvation of the anions in the latter medium, but there is also an effect from the change in interaction energy of the solvent molecules adsorbed on the Bi.[48,49]

The adsorption of I^- is weaker on Bi than on Hg even when ethylene glycol is used as the solvent[52]. However, and in contrast to aqueous, methanolic, and ethylene glycol solutions, in DMF [53] and DMSO [54] solutions the surface concentrations of specifically adsorbed anions are almost identical on Bi and Hg. The orientation polarisation of the DMF dipoles increases in the series $Cl^- < Br^- < I^-$, as does also the solvation energy of the halide ions in DMF.[53] The specific interaction of the solvents with the uncharged bismuth surface decreases in the sequence DMF > DMSO > $H_2O \geq CH_3OH \geq$ acetonitrile, and the ratio $(x_2 - x_1)/x_2$ which characterises the approach of the inner Helmholtz plane to the electrode surface increases as follows when I^- is adsorbed on Bi from different solvents: $H_2O <$ acetonitrile < DMSO = ethanol < methanol < DMF.[53]

On gallium the adsorption of I^- is also less than on mercury, but the M–I^- bond is stronger on gallium than on mercury[55]. The increase in η_{H_2} due to the presence of I^- is more marked on a solid than on a liquid gallium electrode[56]. When gallium is melted in solutions of sulphuric or perchloric acid containing iodides the overvoltage η_{H_2} immediately falls to the level for a liquid electrode in the same solution. If the gallium is re-frozen in the same solution η_{H_2} increases (more slowly) to the limiting value η_{lim}. Solidification of the gallium strengthens the bond between the halide ions and the metal, and the effect increases with time, suggesting a continuing expansion of the crystal lattice in solid gallium[56].

The increase in EDL capacity accompanied by a shift of ϕ towards less negative values was explained by Frumkin[55] not in terms of anion adsorption, though it must play a part (even if only minor), especially in the case of I^- ion, but in terms of the adsorption of water molecules on the gallium. It is interesting to note that on high-purity gallium (99.9998–99.9999%) the addition of halide anions raises η_{H_2},[57] whereas on gallium of 99.996% purity halide ions lower η_{H_2}.[58]

On platinum. On smooth platinum the adsorption of I^- from a 1 *N* H_2SO_4 + 0.01 *N* KI solution is 1.5×10^{-9} g-ion cm^{-2} of apparent surface, i.e. close to the number needed to form a complete monolayer[59]. Incomplete coverage of the platinum surface has been reported[60,61]. The maximum adsorption of iodide ions on platinised platinum (at $\phi = 0.4$ V) is 3.7×10^{-9} g-equiv cm^{-2}; for smooth platinum under the same conditions an adsorption of 6.5×10^{-8} g-equiv cm^{-2} was obtained (i.e. ~20 times greater than on platinised platinum when calculated for a uniform surface)[61]. However, 2–2.5 times more hydrogen is desorbed from smooth than from platinised platinum.

The difference in adsorption capacity between smooth and platinised platinum is ascribed[61] to faults in the lattice of smooth platinum resulting from its technological surface treatment. The increased irreversibility of the adsorption of iodide on platinum, and the decreased adsorption and increased desorption at higher temperatures, are ascribed[61] to the penetration of the adsorbed particles into the underlying layers of the metal. Hydroxyl ions suppress the adsorption of iodide on platinum at all potentials more negative than 1.0 V with respect to the NHE.[59] At high anodic potentials (the oxygen evolution potential) in alkaline solutions, however, the adsorption of iodine is substantial and well in excess of several monolayers of I^-. This is explained by the formation of a stable chemical compound between iodine and the platinum oxides produced under those conditions. The surface compounds are easily soluble in acids, but they are stable in alkaline solutions even under cathodic polarisation[59]. However, it is pointed out[62–64] that I^- (unlike I_2 [62]) is not adsorbed on an oxide-covered platinum surface.

It has been reported[65,66] that in the iodide–iodine–iodide/iodine complex system the species adsorbed on platinum is not I_3^- but I_2 (or iodine atoms), and that the adsorption of I_2 is far greater than that of I^-. The double mechanism (reversible, or irreversible) of the adsorption of I_2 and I^- on platinum[65,66] should also be noted: I_2 is adsorbed irreversibly on the part of the platinum surface which is free from adsorbed iodide, whereas on the regions covered with I^- or with irreversibly adsorbed I_2 the further adsorption of I_2 is reversible. Thus the irreversibly adsorbed state includes I_2 as well as I^-.[63,65] Of the various oxidised forms of iodine the most strongly adsorbed is I^-, even to the extent of displacing other adsorbed ions or molecules[63,64]. This explains the steep drop in the EDL capacity of platinum and in the electrical conductance of the platinum–solution interface, the decrease in the amount of adsorbed hydrogen, and the decrease in the energy of its bond to the platinum surface in the presence of I^-.[59,60,67,68]

On palladium, rhodium, and iridium. The main features of the adsorption of I^- on Pd,[69,70] Rh,[71] and Ir [72] are described by the logarithmic Temkin isotherm and Roginskii–Zel'dovich equation. The adsorption of I^- on palladium[69] produces a new phase of the compound PdI_2. In the ϕ region where the formation of compounds between I^- and the metal is inhibited the I^- ion exists at Pd–I^- dipoles. Pd and Rh surfaces, like Pt surfaces, acquire a greater positive charge in NaI solutions than in NaBr. On Rh, as on Pt, the coverage of the surface by iodide increases rapidly at first and then more slowly[71]. On rhodium the I^- cannot compete with oxygen for surface sites[71]. As on Pt,[61] and on Pd,[69] partial charge transfer from I^- to the electrode takes place on Ir.[72]

The metals of the platinum group can be arranged in the following order of decreasing displacement of adsorbed hydrogen by iodide ions: Rh > Ir > Pt > Pd. The slope of the I^- adsorption isotherms for metals of the platnium group is thought[71] to be determined by the simultaneous effect of two distinct factors: the nature of the surface non-uniformity and the mutual repulsion forces between anions.

Thus the adsorption of iodide ions on different electrodes is essentially chemical in nature. However, a number of features are inconsistent with this statement: a) full coverage of the metal surface by adsorbed ions is only exceptionally observed; b) the adsorption of I^- on Cd, Pb, Ga, and Bi is smaller than on Hg, and the adsorption on Ag and Pt is greater than on Hg, in spite of the fact that the energy of formation (in kcal mole^{-1}) of the compounds PbI_2 (41.85), CdI_2 (48), and GaI_3 (51.2) is much higher, and that of AgI (14.91) and PtI_4 (21.6) is much lower, than the energy of formation of HgI_2 (25) or Hg_2I_2 (29);[73,74] c) the radius of the Pt atom (1.38 Å) or of the Pt^{2+} ion (0.93 Å) is almost one-half the radius of the I^- ion (2.2 Å),[75] and therefore the formation of compounds of the PtI_2 (and especially the PtI_4) type on the surface of Pt seems unlikely.

The metals can be arranged in the following sequence of increasing adsorption of I^-: Cd (−0.402) ≅ Tl (−0.336) < Sn (−0.140) ≅ Pb (−0.126) < Ga (−0.520) < Bi (+0.200) < Hg (+0.788) < Co(−0.277) ≅ Ni (−0.25) < Fe (−0.036) < Ag (+0.799) ≅ Rh (~+0.8) ≅ Pd (+0.987) ≅ Ir (+1.00) < Pt (~+1.200). The numbers in brackets are the standard redox potentials (in volts) of the metals in aqueous solutions[75]. The adsorption of I^- increases as the standard potential becomes more positive, with gallium and the elements of the iron family as the only exceptions. Hence we may assume that the adsorption of I^- on metals is not purely chemical, but physicochemical in nature, i.e. dependent on the charge of the metal surface. This hypothesis is consistent with the finding[76] that the standard free energy of adsorption of I^- on mercury is linearly related to the positive charge on the electrode.

The sharp drop in EDL capacity caused by the adsorption of I^- on solid metals and the associated (partial, or full) charge transfer from the I^- to the metal[77] (especially on metals with a strongly positive surface charge) can be explained by the distortion of the outer electron clouds of the adsorbed ions, resulting in a deviation from a discrete distribution in the case of a solid electrode (in contrast to the mercury electrode).

II. STANDARD AND EQUILIBRIUM POTENTIALS IN SYSTEMS WHICH INCLUDE IODINE

The equilibrium potentials of the I_2/I^- system, for the overall electrode reaction

$$2I^- - 2e \rightleftarrows I_2 , \qquad (1)$$

and of the I_3^-/I^- system, for the overall electrode reaction

$$3I^- - 2e \rightleftarrows I_3^- , \qquad (2)$$

are given by the Nernst equation[78-80]

$$\varphi_{(1)} = \varphi^0_{(1)} + (RT/nF)\ln([I_2]/[I^-]^2) , \qquad (3)$$

$$\varphi_{(2)} = \varphi^0_{(2)} + (RT/nF)\ln([I_3^-]/[I^-]^3) . \qquad (4)$$

In these expressions n is the number of electrons in the overall electrode reaction, and F is the Faraday. The standard electrode potentials (in V) of the I_2/I^- system in aqueous solutions are 0.621 [81-83] or 0.628 [82,84] with I_2(aq), and 0.535 [83,85] or 0.536 [82] with I_2(s), whereas those for the I_3^-/I^- system are 0.536 [81-83,85] or 0.545.[82,84]

In Eqns.(3) and (4) the pre-logarithmic factor is the same for reactions (1) and (2), since $n = 2$ in both cases, and is a function of temperature only: $\partial\phi_p/\partial \ln([I_2]/[I^-]^2) = \partial\phi_p/\partial \ln([I_3^-]/[I^-]^3) = 0.02958$ at 25 °C.[79]

Increasing the concentration of I^- in solution converts the iodine into the iodine–iodide complex (I_3^-), and the equilibrium potential depends not only on the activity of I^- but also on the activity of I_3^-. At constant concentration of I_3^- the equilibrium potential of the I_3^-/I^- system decreases exponentially with the concentration of I^-:

$$\varphi_p = \varphi_0' - (RT/nF)\ln[I^-]^3 = \varphi_0' - (3RT/2F)\ln[I^-] . \qquad (5)$$

Assuming that the electrode reaction is described by Eqn.(1), at constant I_2 concentration the rate of decrease of the electrode potential with increasing I^- concentration is described by the equation

$$\partial\varphi_p/\partial \ln[I^-] = -(RT/F) .$$

At low and constant concentration of iodine[78], or when no iodine is present in the initial solution[80], the experimentally observed decrease in ϕ_p with increase in I^- concentration corresponds to Eqn.(5), i.e. the equilibrium in the system is described by Eqn.(2). This assumption is confirmed by the temperature dependence of the equilibrium potential, i.e.[80]

$$\partial\varphi_p/\partial T = -3R(\ln[I^-])/2F .$$

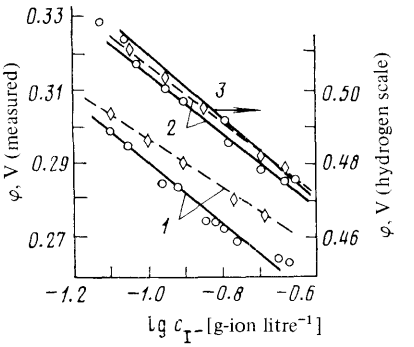

Figure 1. Equilibrium potential ϕ_p against logarithm of the concentration of iodide ions on platinum (*1*, *2*) and on graphite (*3*) in the presence (broken lines) and in the absence (full lines) of naphthenic acids[80]: *1*) and *3*) without supporting electrolyte, *2*) in the presence of 1 *N* Na_2SO_4.

At all concentrations of I^- the platinum[78,80] and the graphite[80] electrode have a positive potential (Fig.1), due to the dipole in the Pt–I^- bond[59], and the potential changes are caused not only by changes in surface coverage but also by changes in the electrode–adsorbate interaction energy[51] and changes in the dipole moment of the platinum–iodide bond brought about by the increased strength of the bond[59].

The equilibrium potential of platinum becomes more positive in the presence of 1 *N* Na_2SO_4 (Fig.1), evidently as a result of a change in state of the I^- in the outer Helmholtz plane (i.e. of a change in the ψ' potential)[80]. Naphthenic acids also cause a positive shift in the potential of platinum in iodide solutions (Fig.1).

On a tellurium[86] and a zinc[87] electrode in aqueous solutions the equilibrium potential corresponding to the following reactions is rapidly established:

$$TeI_6^{2-} + 4e \rightleftarrows Te + 6I^-$$

$$ZnI_3^- + 2e \rightleftarrows Zn + 3I^- .$$

The standard I_2/I^- potentials decrease as the concentration of acetic acid increases in $CH_3COOH + H_2O$ mixtures: the effect amounts to 200 mV for a change in concentration from 0 to 80% CH_3COOH.[88] This dependence of the standard potential of the I_2/I^- system on the concentration of acetic acid cannot be explained by an increase in the stability of I_3^-, since this complex raises the potential of the system [see Eqn.(4)].

The standard redox potentials (in V) are:

Solvent	Nitromethane	Acetone	Acetonitrile	DMF	CH_3COOH
I_3^-/I^-	0.11 [82,90]	0.11 [82,90]	0.06 [82,90]	−0.37 [82]	−0.112 [82]
I_2/I_3^-	0.36 [82] 0.71 [90]	0.86 [82,90]	0.396 [82] 0.65 [90]	0.27 [82]	0.344 [82]
I_2/I^-	0.31 [82,90]	0.36 [82,90]	0.26 [82,90]	—	0.273 [82,89]

The normal potentials (in V) are:

Medium	Neutral	Alkaline
I^-/IO^-	0.99 [82,85]; 1.313 [81]	0.49 [82,85]; 0485 [83]
I^-/IO_3^-	1.195 [84,85]; 1.085 [81,82]	0.26 [82—85]

In solutions containing chlorides $\phi^0_{I_2/ICl} = 1.19$ V [82,83,85] and $\phi^0_{I_2/ICl_2^-} = 1.06$ V [82,85] or 1.056 V.[83]

For the I_3^-/IO_3^- system $\phi^0 = 1.154$,[81] and for I_2/IO_3^- the following values of ϕ^0 have been reported:

t, °C	25	37.5	50
φ^0, V	1.1942 [91]; 1.195 [82,83]; 1.178 [81]	1.1903 [91]	1.1863 [91]

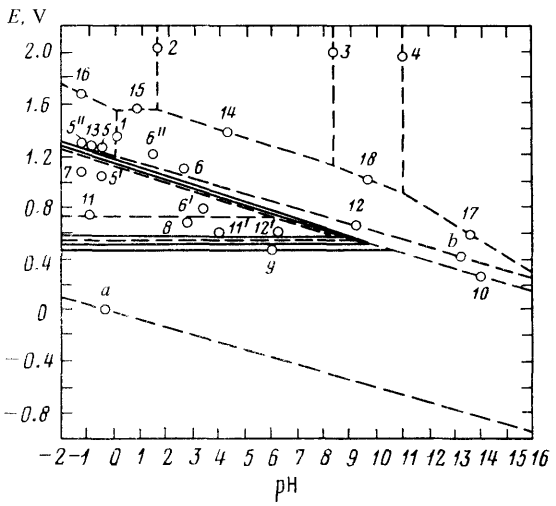

Figure 2. Potential–pH diagram for iodine[81] in the following systems: *a*) H_2/H^+, *b*) O_2/O_2^-, *1*) HIO_3/IO_3^-, *2*) HIO_4/IO_4^-, *3*) IO_4^-/HIO_5^{2-}, *4*) HIO_5^{2-}/IO_5^{3-}, *5*) I_2/HIO_3, *5'*) I_2/HIO_3 and I_2(s), *5''*) I_2(s)/HIO_3, *6*) I_2/IO_3^-, *6'*) I_2/IO_3^- and I_2(s), *6''*) I_2(s)/IO_3^-, *7*) I_2/I^+ and I_2(s), *8*) I^-/I_3^-, *9*) I^-/I_2, *10*) I^-/IO_3^-, *11*) I_3^-/I_2 and I_2(s), *11'*) I_3^-/I_2(s), *12*) I_3^-/IO_3^-, *12'*) I_3^-/IO_3^- and I_2(s), *13*) I^+/HIO_3 and I_2(s), *14*) IO_3^-/IO_4^-, *15*) IO_3^-/HIO_4, *16*) HIO_3/HIO_4, *17*) IO_3^-/IO_5^{3-}, *18*) IO_3^-/HIO_5^{2-}.

The pH dependence of the redox potential for various iodine compounds is shown in Fig.2.

III. REDOX PROCESSES IN I^-/I_2 AND I^-/I_3^- SYSTEMS

1. Electrolytic Oxidation of Iodide Ions

a) Studies by Faradaic impedance and rectification methods. The study of anodic and cathodic reaction kinetics in I_2/I^- and I_3^-/I^- systems is complicated by the strong diffusion control of the reactions[92]. Further difficulties arise from the adsorption of reactants and products in both anodic and cathodic reactions, and from the large number of independent paths available to the reactions.

Vetter[92] showed that the overall electrode reaction (2) takes place though the following steps:

$$I^- \rightarrow I\,(ads) + e \qquad (6)$$

$$2I\,(ads) \rightleftarrows I_2 \qquad (7)$$

$$I_2 + I^- \rightleftarrows I_3^-, \qquad (8)$$

reaction (6) being rate-determining. The kinetic order of the anodic reaction (p_a) with respect to I^- is 1, that of the cathodic reaction (p_c) with respect to I_2 is 1/2. This mechanism has been used[93,94] with a transfer coefficient $\alpha = 0.6$, but it was shown that at low concentrations of I^- the adsorption of I^- becomes rate-determining, and that electron transfer through a very thin adsorbed layer is slow.

Dane and coworkers[95] believe that Vetter's equations[92] are not generally applicable because they do not allow for changes in the coverage of the surface by I_2 and I^-, and they conclude that the impedance of the I_2/I^- system on a Pt electrode is unaffected by the adsorption of I^- and I_3^-, the rate-determining step being the Heyrovsky (electrochemical desorption) reaction

$$I^- + I\,(ads) \rightarrow I_2 + e\,. \qquad (9)$$

However, Tyagai's calculations[96] from Faradaic rectification data of the kinetic equations of the elementary steps [discharge–recombination, reactions (6) and (7), discharge–electrochemical desorption, reactions (6) and (9), and recombination–electrochemical desorption, reactions (7) and (9)], using the Langmuir, Temkin, and Frumkin adsorption isotherms, have clearly established that the electrode reaction mechanism for the Pt–I_3^-/I^- system consists of a series of discharge–recombination reactions with a slow discharge step, corresponding to the Langmuir isotherm.

The effect of surface non-uniformity on the kinetics of the electrode processes was studied by measuring the Faradaic impedance of an iridium electrode in the iodine–iodide system[97]. The electrode reaction on iridium was shown to take place only on active surface sites, whose size is smaller than the thickness of the diffusion layer. The extent of blocking of the Ir electrode increases with temperature.

b) Studies by voltammetry and oscillographic polarography. The anodic current–voltage curves for the oxidation of I^- in 3 and 6 M solutions of H_2SO_4 show one wave corresponding to the reversible oxidation [reaction (1)] of iodide to iodine[98]. In every case, irrespective of the composition and pH of the supporting electrolyte, this process begins at a potential of 0.55 V. A decrease in the anodic oxidation current of I^- has been observed[99] at 0.68–0.70 V (against the NHE). Changes in pH from approximately 0 to 12 have no effect on the potential at which the fall in current begins. This effect must be due to a retardation of reaction (2) [99] or (especially at the higher potentials, 1.6–1.7 V) to an oxide covering of the platinum surface[98].

The oscillographic polarograms for the oxidation of I^- obtained at 51 °C with a potential sweep rate of $\nu = 0.09$ V s^{-1} show a steep current rise followed by a fall[100], preceded by another clearly visible portion which becomes longer at high temperatures and disappears at low temperatures (20 °C). This additional feature of the polarogram is explained[100] by the evolution of liquid iodine on the electrode: the subsequent freezing of the iodine is responsible for the fall in current. The surface layer of iodine consists[101] of a dense part (next to the electrode) and a porous outer layer, and partial dissolution of the outer layer occurs while the dense inner layer becomes thicker. The decrease in current is due simply to the high resistance of the anodic film of iodine (0.18×10^5–7.0×10^5 Ohm cm).

A combination of oscillographic polarography and measurements of light intensity against time (ρ–τ) led to the conclusion[102] that the deposition of liquid iodine on the anode causes ρ to decrease, and the subsequent freezing of the layer results in a further increase in ρ. The maximum, and the final decrease in ρ, are ascribed to the consolidation of the iodine film.

In aqueous solutions reaction (1) is reversible on a Pt electrode[63,103], and in $HClO_4$ reaction (2) also takes place[103], the potential of reaction (1) being more positive than that of reaction (2). The second wave could correspond to the formation of I^+ [103,104] or of an oxide film[105,106].

The I^- ion has been studied by voltammetry also in other solvents; acetic acid[107–110], acetonitrile[90,111–117], DMF,[117–119], DMSO,[120] fluorosulphuric acid[121], nitromethane[90,122], pyridine[104,123,124], methanol[119,125], propanol[126], ethylene carbonate[127], propene carbonate[128], sulpholane[129], and acetone[90,113].

Changing from water to an organic solvent does not significantly alter the mechanism of the reactions in the I_2/I^- system: the oxidation of I^- in different solvents may involve either one or two steps. As Krishtalik points out[130], a change in the solvation energy of the electrically active ion is not directly reflected by the overvoltage of the electrode reaction. The indirect effect may be quite large, and lead to an increase in the concentration of non-solvated ions and in the stability of the I_3^- complex ion in different (protonic, or aprotic) solvents. The following values have been reported for the constant of the equilibrium (8): in water 10^3,[92,113] in t-butanol $10^{3.73}$,[131] in methanol $10^{4.2}$ (or $10^{4.94}$),[125,129,131] in isopropanol $10^{4.36}$,[131] in DMSO $10^{4.9}$,[131] in acetic acid $10^{5.0}$ (or $10^{5.24}$),[107,132] in acetonitrile $10^{6.6}$ (or $10^{6.75}$, $10^{4.0}$),[90,111,113,131] in nitromethane $10^{6.7}$,[90] in DMF $10^{7.35}$,[133] in sulpholane $10^{7.4}$,[129] and in acetone $10^{8.3}$.[90]

One-step oxidation of I^- is observed mainly in protonic solvents (water, methanol, acetic acid, etc.), the rate of the anodic reaction decreasing steeply (almost two-fold) from water to methanol and only slightly from methanol to CH_3COOH while the activation energy remains almost unaffected[119]. In aprotic solvents (acetonitrile, DMF, DMSO, nitromethane, etc.) the oxidation takes place in two steps: in the first the I_3^- complex is formed by reaction (2), and in the second it is discharged by the reaction

$$2I_3^- - 2e \rightarrow 3I_2 , \qquad (10)$$

because of the greater stability of I_3^- in these solvents.

In dilute (up to 10^{-3} M) methanolic solutions the I^- ion shows only one oxidation wave[125] to I_2 by Eqn.(1), whereas in more concentrated solutions the oxidation occurs in two steps through the formation of I_3^-. In acid methanolic solutions (pH 4.0) only one wave is observed [Eqn.(1)]. In weakly alkaline solutions (pH 8.5) two waves of approximately equal height are observed:

$$I_2 - 2e \rightarrow 2I^+ .$$

The I_2/I^- system in acetonitrile has been studied on pyrolytic graphite[112] by non-stationary and cyclic voltammetry, and three oxidation waves of I^- have been detected. The first has been assigned[113,114] to the irreversible reaction (2). The second wave is assigned to reaction (10), which is reversible according to the cyclic voltammetry method[112,127]. When an excess of iodine is added to a solution of KI in acetonitrile the I^- is converted into I_3^-, and the polarisation curve shows only the second wave with a height equal to the sum of the heights of the two I^- oxidation waves obtained in the absence of I_2.[114] Cyclic voltammetry has shown that the height of the cathodic peak is double the height of the anodic peak: this is explained[112] by the substantial adsorption of the electrically active I_2 species on the surface, as pointed out in Refs.63 and 65. The second wave shows a well developed anodic peak and a relatively small cathodic peak at low sweep rates (v) of the potential. This is explained by the instability of the product corresponding to the second peak. The cyclic voltammetry plots for the third wave do not show a cathodic wave in neutral or acid media[112]. Oxidation of I^- by reactions (2) and (10) is reported also in Ref.129.

In acidified pyridine four stable forms have been identified[124]: I^-, I_2, I_2^-, and I^+. The concentration of pyridine (even above 3 M) has no effect on the height of the first or the second wave in aqueous solutions, though the half-wave potential of the second wave is shifted towards more negative values[113]. The current decreases in the sequence pyridine > 2-picoline ≫ 2,6-lutidine (dimethylpyridine), which is the same as the order of decreasing basicity of these molecules.

At low concentrations of I^- (0.06 g-ion litre^{-1}) and especially in the presence of H_2SO_4 the potentiodynamic current–voltage curves[134] show two Tefel regions, corresponding to reactions (2) and (1), with the limiting current associated with the first step and the current peak with the second. The linear portions of the ϕ,lg i curves for the first step are parallel for different concentrations of KI, giving the order of the anodic reaction as $p_a = 2$.

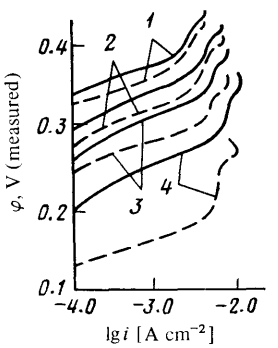

Figure 3. Anodic potentiodynamic curves in a solution (c_{KI} = 0.09 mole litre^{-1}) containing sulphuric acid (pH 0.62) in the presence (broken lines) and in the absence (full lines) of naphthenic acids for different potential sweep rates[136]: *1*) 0.04, *2*) 0.2, *3*) 0.4, *4*) 1.0 V min^{-1}.

The slope of the ϕ,lg i straight lines for the first step varies with the supporting electrolyte: in a solution without supporting electrolyte the slope is 0.042 V (α = 0.7), whereas in 1 *N* Na_2SO_4 it is 0.034 V (α = 0.87).[135,136] In the presence of an excess of supporting electrolyte the hydration of the I^- ions is suppressed, and this facilitates the discharge. Thus, in the presence of 1 *N* Na_2SO_4 the temperature coefficient of the overvoltage $(d\eta/dT)_i$ decreases from 3.5×10^{-3} to 0.85×10^{-3} V K^{-1}. Also, the activation energy of the process in 1 *N* Na_2SO_4 is much lower than in the absence of supporting electrolyte[135]. Even naphthenic acids (usually thought to be surface-active) lower the overvoltage for the oxidation of I^- (Fig.3), and when both the naphthenic acids and 1 *N* Na_2SO_4 are present together in solution the oxidation of iodide on platinum becomes almost barrierless (α = 0.97).[136] However, on a graphite electrode[137], and especially on a lead dioxide anode[138], the oxidation of I^- is strongly suppressed by naphthenic acids (Fig.4).

c) Studies by the rotating disk electrode method. The rates of the anodic and of the cathodic process are differently affected by the speed of rotation of a disk electrode ω:[139] a) the i,ϕ curves for the anodic and the cathodic process are asymmetric for different values of ω: b) the anodic reaction is ~10 times faster than the cathodic reaction; c) the rates of both processes are strongly influenced by stirring, but the effect is even more marked on the cathodic than on the anodic process.

At polarisation potentials <30 mV the rate of the anodic process is almost independent of ω, but for $\phi > 30$ mV the rate initially increases very rapidly with $\omega^{1/2}$ and reaches a constant level[140] for $\omega^{1/2} = 115-130$ min$^{-1/2}$. For fixed values of the potential and of ν the current increases with ω: the fall in current becomes sharp, and a large number of crystallisation centres appears on the electrode[141]. In a more concentrated solution (0.5 *N* KI + 0.01 *N* I_2) with $\omega = 580$ min^{-1} the fall in current no longer occurs, suggesting[141] a passivating role for the iodine film in the electrode process.

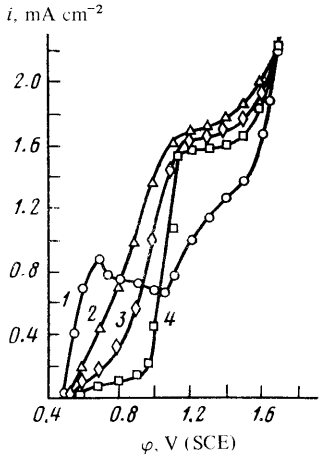

Figure 4. Anodic polarisation curves for the oxidation of iodide ions in an artificial concentrate on a lead dioxide electrode for different concentrations of naphthenic acids[138]: *1*) 0, *2*) 0.65, *3*) 1.02, *4*) 1.30 g litre^{-1}.

At low speeds of rotation of the electrode the overvoltage in the initial portion of the i, ϕ curve is close to that calculated by the Nernst equation (3).[97,142] However, as ω increases, the contribution to the polarisation from the slow electrochemical reaction also increases. Therefore in order to determine the kinetic currents (i_{kin}) for the oxidation of I^- we must extrapolate[142] the current at a given potential to an infinitely large value of ω by Frumkin and Tedoradze's method[143], since under these conditions linear (Tafel) regions are not found in the $\lg i-\phi$ curves. Extrapolation of the linear portions of the $\lg i_{kin}, \eta$ curves to $\eta = 0$ gave the exchange currents (i^0), which were shown[142] not to be equal for corresponding anodic and cathodic processes ($i_a^0 > i_c^0$, always).

The α_a and α_c values calculated from the slopes of the linear portions of the $\lg i_{kin}, \eta$ curves (i.e. the transfer coefficients for the anodic and the cathodic reaction) do not add up to 1. In solutions with $c_{I^-} \gg c_{I_2}$ we always find $\alpha_a + \alpha_c > 1$ (as high as 2 in some cases), whereas in solutions with similar concentrations of I^- and I_2 the sum is $\alpha_a + \alpha_c \leqslant 1$.[142] The order p_a is 1 with respect to I^- and 0 with respect to I_3^-. From these results it is concluded[142] that in the I^-/I_3^- system the overall electrode reaction (2) involves the two consecutive reactions (6) and (9), and the exchange current of the former reaction is greater than that of the latter.

The anodic oxidation of I^- becomes to a large extent irreversible when the solution pH is increased (pH > 1),[104] and it becomes reversible when the ratio $c_{I_3^-}/c_{I^-}$ decreases (with $c_{I^-} \leqslant 2.5 \times 10^{-4}$).[144] In very dilute solutions adequate kinetic currents are not obtained[145].

The order of the anodic reaction (1) with respect to I^- depends (though only slightly) on the supporting electrolyte present in solution[142]: without a supporting electrolyte $(\partial \lg i_{kin}/\partial \lg c_{I^-})_\phi = 1.3$, and in 1 *N* Na_2SO_4 $(\partial \lg i_{kin}/\partial \lg c_{I^-})_\phi = 1.0$. This effect is explained, according to Frumkin's theory[146], by the existence of a ψ' effect in the I_2/I^- system. Since in the presence of iodide ions the SO_4^{2-} ions are not specifically adsorbed, and the I^- ions irreversibly chemisorbed on Pt are not electrically active[63], we may assume[142] that the reacting species are mostly found on the outer Helmholtz plane of the diffusion layer, whose potential (ψ') varies with the concentration of the supporting electrolyte. Also, an increase in i^0 with concentration of the supporting electrolyte is possible only if ψ' is negative.

According to the present writer it is incorrect to ignore the decrease in hydration of I^- with increase in concentration of the supporting electrolyte. In the presence of electrolyte the concentration of non-hydrated I^- near the electrode surface increases, and this assists the discharge act. Hence in the presence of supporting electrolyte not only i^0 but also α should increase. In the absence of molecular iodine and under equilibrium conditions the inner Helmholtz plane consists of irreversibly adsorbed I^-(ads) species, and the outer plane of non-hydrated (or partially hydrated) I^- ions which are in equilibrium with the fully hydrated I' ions:

$$I^-(ads) \leftarrow I^- \rightleftarrows I' . \qquad (11)$$

When the oxidised form I_2 is also present in the solution (and adsorbed on the surface) the system becomes more complex:

$$\begin{array}{l} I^-(ads) \leftarrow \\ I_2(ads) \rightleftarrows I^- + I_2 \rightleftarrows I_3^- \rightleftarrows I' + I_2(aq) \rightleftarrows I_3' \end{array} \qquad (12)$$

Obviously the exchange current will increase with the concentration of I^- in both cases, but the dependence of the rate of the anodic process on $[I^-]$ will be more marked for (11) than for (12) because of the absence of I_3^- ions. Increasing the concentration of I_2 shifts the equilibria (12) towards the formation of I_3^-, which lowers the concentration of I_3^-, and should lower the limiting current of the anodic curve (as is found experimentally[139]). In the absence of the oxidsed form or with an excess of supporting electrolyte the equilibrium (11) is strongly displaced towards the left and the rate of the anodic process increases and becomes almost proportional to the square of the concentration of iodide ions[134,137].

It is interesting to consider whether adsorbed iodide can be oxidised. If a chemical compound of the MI_2 type is formed on the surface of the metal electrode this question cannot be answered meaningfully, but if physico-chemical adsorption (depending on the charge on the surface) is assumed, easy discharge of the adsorbed iodide can be expected.

After being immersed in a solution of KI for some time a platinum electrode gave a sharp current rise (at $\phi = 0.53$ V) followed by a slight fall. Even a second oxidation wave (iodine to iodate) has been observed at $\phi = 1.19$ V, and ascribed[148] to oxidation of adsorbed iodide. However, it is strongly argued[65] that oxidation of iodide does not take place on a Pt electrode previously immersed in an I^- solution: the adsorbed iodide is stated to be electrically inactive since the adsorption is irreversible and the exchange reaction $I^-(ads) \rightleftharpoons I^-(sol)$ is slow. These views are inconsistent with many published results[92,94,144,147]. It has been suggested[149] that the absence of an anodic oxidation wave for I^- on an electrode previously immersed in a solution of KI [65] could

be due to the influence of oxygen atoms resulting from the treatment of the platinum surface. Lukovtsev and coworkers[142,150,151] stress the lack of electrical activity of adsorbed iodine.

Various additives (ClO_4^-, CH_3COO^-, SO_4^{2-}, PO_4^{3-}, citrate ion) in I^- solutions lower the effective activation energy E_{eff} of the anodic process, the magnitude of the effect increasing with the concentration of the additive[152]. The dehydrating action of the added ions was suggested[152] as an explanation. At the higher additive concentrations the rate of the anodic process falls due to the adsorption of the added ions on the platinum surface[153]. Cationic additives (Hg_2^{2+}, Zn^{2+}, Cu^{2+}, Cd^{2+}) lower the limiting current of both the anodic and the cathodic process[151] by being adsorbed on the electrode or by forming stable compounds with the iodide.

In DMF solutions the order of reaction (2) with respect to I^- is 1, and the adsorption of I^- on the electrode has been suggested[117] as the slow step of reaction (2), since DMF is adsorbed on platinum more strongly than water and thus inhibits the adsorption of I^-. The fall of the current in the i,η curves is also explained[117] by the slow desorption of iodine from the electrode surface rather than by the formation of a new phase (iodine film) postulated for water solutions.

As the concentration of DMF in a water + DMF mixture increases, the overvoltage of the anodic reaction increases gradually, reaching its highest value in pure DMF.[118] On the anodic curves for the oxidation of I^- in a medium containing relatively small additions of water to DMF (2.2 and 11 M H_2O in DMF) two I^- oxidation waves are observed, as in pure DMF.[117] As the water content of the mixed solvent is increased, the first wave becomes indistinct, and at the potentials of the second wave we observe a sharp rise in current with an associated fall, as in the case (water solution) of the formation of a surface film on the electrode[101,114]. When the concentration of DMF in the mixture is increased, i^0 decreases and the sum of α_a and α_c changes from 2 (in pure water) to 1 (in pure DMF). It has been suggested[118] that in DMF and its mixtures with water (as in pure water) the overall electrode reaction involves two consecutive steps: discharge and electrochemical desorption [reactions (6) and (9)], with comparable exchange currents. The same mechanism# is proposed for DMSO [120] and acetonitrile[111].

d) Studies by chronopotentiometry. The kinetics of electrode reactions in the I^-/I_2 system have been studied[64] by the application of very short galvanostatic pulses, assuming the mechanism of the anodic and the cathodic reaction proposed by Vetter[92].

The chronopotentiograms for the electrolytic oxidation of I^- in water, methanol, 1-butanol, 2-propanol, and acetic acid indicate the formation of I_2 by a single one-electron step[104,110]. Two-step oxidation of I^- to I_2 was observed[110] in ethylene glycol, acetonitrile, acetone, 1,2-dimethyloxyethane, nitromethane[154], DMSO, and acetic anhydride. In pyridine (Py) the anodic reactions $I^- \to I$ and $I \to I^+$ take place[110,113] in spite of the fact that I_3^- is more stable than PyI_2.[155] The addition of NaI to a solution of I_2 in pyridine produces three steps on the chronopotentiogram, with $E_{1/4}$ values of 0.35, 0.5, and 0.9 V respectively, corresponding to reactions (2) and (10), followed by the oxidation of I_2 to I^+ [110] as a result of the dissociation of the iodine molecule in pyridine[123]:

$$2I_2 + Py = PyI^+ + I_3^- .$$

In the presence of chloride ions the oxidation of I^- in nitromethane[154] takes place by the reaction

$$I^- + Cl^- - 2e \to ICl . \qquad (13)$$

2. Electrolytic Reduction of Iodine and of the Iodine–Iodide Complex

a) Studies by Faradaic impedance and rectification methods. Vetter's Faradaic impedance method[92] has established the value of p_c for the electrochemical reduction of iodine on platinum by the overall reaction

$$I_3^- + 2e \to 3I^- \qquad (14)$$

and has led to the following mechanism for the process:

$$I_3^- \to I_2 + I^- \qquad (15)$$

$$I_2 \to 2I \qquad (16)$$

$$I + e \to I^- , \qquad (17)$$

in which the discharge is the slow step. The same mechanism has been proposed[156] for the electrolytic reduction of I_3^- on a porous graphite electrode in acid or neutral protonic solvents, with the following kinetic parameters:

α_c	α_a	p_c (for I_3^-)	p_a	p_c (for I^-)	p_a
0.5	0.5	0.5	0	−0.5	1

Simultaneous measurements of the Faradaic impedance and of rectification[157] have confirmed the scheme involving reactions (16) and (17). The transfer coefficient of the discharge step is given[157] as 0.47 (±0.04), but other workers[144, 150,151] report an α value varying regularly with the concentration of iodine in solution. The rate constant of the cathodic reduction of I_3^- is $(1–5) \times 10^{-2}$ cm s^{-1},[157] and it is assumed that at low coverages by adsorbed iodine ($\theta \to 0$) $p_c(I_2) = p_c(I_3^-) = \alpha = 1$, and the cathodic reduction of iodine on CdS and CdSe electrodes takes place by the discharge–electrochemical adsorption mechanism[157]

$$I_2 + e = I^- + I\,(ads) , \qquad (18)$$

with simultaneous rate limitation by the two electrochemical steps.

b) Studies by voltammetry and oscillographic polarography. The shape of the cathodic wave on the voltammetric curves measured on a platinum electrode is independent of the direction of the potential sweep[104]. The diffusion current is proportional to the concentration of I_2, and the ratio i_d/c_{I_2} is 190 μA mM^{-1}. In the absence of Cl^- ions the iodine is reduced by the reaction

$$I_2(aq) + 2e \rightleftarrows 2I^- , \qquad (19)$$

but in 4 M HCl the iodine exists mainly as the iodine–chloride complex (I_2Cl^-), and the electrode process corresponds to the reaction

$$I_2Cl^- + 2e \to 2I^- + Cl^- . \qquad (20)$$

In 0.1 M perchloric acid and in the presence of 0.05 M sodium cyanide the cathodic iodine reduction wave is not observed. Iodine cyanide, formed by the reaction

$$HCN + I_2 \rightleftarrows H^+ + I^- + ICN , \qquad (21)$$

is not reduced on platinum, and no free iodine is present[104].

On a Pd electrode the reduction of iodine is irreversible up to an overvoltage of ~500 mV, beyond which a steep current rise is observed, associated[158] with the reduction of the

At high positive potentials and low surface coverages the rate-determining step of the second wave in DMSO is thought to be the reaction[120] $I_3^- + M \rightleftarrows M(I_3) + e$.

film of iodine on the electrode surface. When this film has been removed the electrolytic reduction of iodine becomes much faster, reaching the limit set by the diffusion current. The existence of a "pre-wave" on the polarisation curve for the electrolytic reduction of iodine on Pd is explained by the partial blocking of the electrode at η values up to 0.5 V, so that the observed limiting currents are lower than those for an electrode with a uniform surface.

Since I_3^- is much more stable in DMF than in aqueous solutions, the species which is reduced in DMF is not I_2 but I_3^-.[118] The potentiodynamic curve for the reduction of I_3^- in DMF includes a limiting current plateau followed (beginning at $\eta = 0.8$ V) by a decrease in current arising from the negative charge of the reacting species[159]. This explanation implies that in the presence of an excess of I_2 (and in contrast to the case of high concentrations of I^-) no current fall should occur at potentials up to −2.0 V. During the reduction of I_3^- the curves plotted in the reverse direction always lie below the forward plots. Furthermore, the depth of the current minimum (beyond the current fall) decreases as the potential sweep rate increases, and disappears completely at the highest rates ($v \geq 40$ mV s^{-1}). According to Povarov and coworkers[159], at potentials close to the equilibrium value I_2 is reduced to I_3^-:

$$3I_2 + 2e \rightarrow 2I_3^- , \qquad (22)$$

and in the presence of high concentrations of KI the iodine–iodide ion is further reduced to I^- by reaction (14). These processes take place through the adsorption of I_2 and I_3^- on the electrode. At sufficiently high negative potentials the iodine is desorbed from the surface, and subsequent reduction takes place without adsorption. "Stretched" irreversible waves are observed in the reduction of iodine, and inhibition of the reaction in the case of I_3^- reduction: thus the process appears to be determined by the rate of penetration of I_3^- into the EDL.

Two-step reduction of iodine by reactions (22) and (14) has been observed also in acetic anhydride[107].

c) Studies by the rotating disk electrode method. A diffusion-limited current is observed[104,144,151,160] in the reduction of I_3^- on a Pt electrode. Under both turbulent and laminar stirring regimes a well defined plateau is observed on the cathodic i,ϕ curves for a 0.1 M I_2 + 1 M KI solution at different values of ω, and the limiting diffusion current varies linearly[160] with $\omega^{1/2}$, the activation energy of the cathodic process under laminar stirring being almost one-half the value for turbulent stirring. The activation energy of the process (E_{eff}) is also a function of the rate of rotation of the electrode: at first E_{eff} increases with $\omega^{1/2}$, but at the higher values of ω (beyond $\omega^{1/2} = 110$ $s^{-1/2}$) E_{eff} becomes constant[139]. The rate of the cathodic process also increases in proportion to the concentration of I_2.[139]

These results confirm that the rate-limiting process (as in the anodic process) is the diffusion of the reacting ion towards the electrode. But since the products of the anodic and the cathodic process are removed from the electrode at different rates, i.e. fairly slowly in the case of the anodic process (iodine–iodide complex) and rapidly in the case of the cathodic process (iodide ion), the oxidation and the reduction processes in the I_2/I^- system are affected by ω to different extents. For $\omega = 3000$ min^{-1} the rate of the cathodic process increases by a factor of 22.4 (as compared to the rate for $\omega = 0$), whereas the rate of the anodic process increases only by 9.6.[139] However, in a solution containing ~10 times more I_2 than I^- the rate of the cathodic process is ~10 times higher than the rate of the anodic process[140]. At high speeds of rotation the parameter ω no longer affects the rate of cathodic reaction[139,140], indicating electrochemical rate control.

Because iodine is reduced with a high overvoltage on a rotating Pd electrode[158] the order p_c with respect to I_2 can be determined from the kinetic currents obtained by extrapolation of the $i^{-1}, \omega^{-1/2}$ curves to $\omega \rightarrow \infty$: for $\eta = 100$–150 mV, $p_c = 1$.[158] On a Pt electrode the p_c value for I^- and I_2 could not be determined accurately[142,158], because the slope of the linear portions of the $\lg i_{kin} - \phi$ curves varies with the concentration of I^- and I_2. By using curves with similar slopes the parameter p_c was determined approximately for I^- and I_2: $p_c(I_2) = 1$ and $p_c(I^-) = -1$.[142] The negative order of p_c with respect to iodide suggests[142] that the kinetic unit in the cathodic process is I_2 rather than I_3^-. Thus, as the potential of the electrode is made more negative the bond between I^- and I_2 in the I_3^- complex should be weakened by the repulsion forces acting on the iodide, which favour the formation of adsorbed atoms or molecules of iodine on the electrode surface[64].

From the initial portions of the i,ϕ curves obtained in a study[144] of the electrolytic reduction of iodine on a rotating Pt electrode, which gave the kinetic parameters of the cathodic reaction, the order p_c was found to depend both on the concentrations of I_2 and I^- and on ω. This result was explained[144] in terms of the non-uniformity of the electrode surface. It was shown that electron transfer from the platinum to an adsorbed iodine atom is the slow step in this case. The height of the cathodic I_2 reduction waves on Pt is unaffected (within experimental error) by changes in the acidity of the solution[98], but the limiting current decreases if the time of immersion of the electrode in the solution is increased[151]. These changes in current on an activated electrode can be as high as 20–30% of the i_d value for the first wave in a solution containing an excess of supporting electrolyte (Na_2SO_4). In solutions containing only I_2 and I^- the time dependence of i_d is slighter, and decreases with the concentration of iodine. The changes in limiting current are ascribed[151] to non-uniformity of the platinum surface, produced by the irreversible adsorption of iodine on Pt.

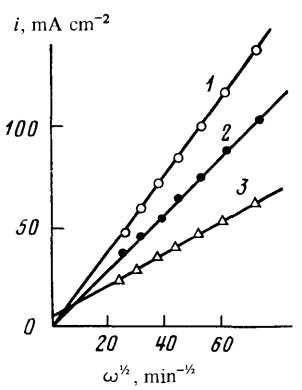

Figure 5. Cathodic limiting current against speed of rotation of the platinum electrode for a 0.2 M KI + 2×10^{-2} M I_2 solution at different temperatures[150]: *1*) 50, *2*) 25, *3*) 1 °C.

The surface non-uniformity of the platinum[139] and of the iridium electrode[97] causes anomalous variations of i_d with $\omega^{1/2}$: at low temperatures (1 °C) the extrapolation of the linear $i_d, \omega^{1/2}$ plots for the reduction of iodine does not pass

through the origin[150] (see Fig.5). A quantitative interpretation of this observation was proposed[150] by introducing into the Levich equation an additional term as required by Landsberg's theory[161], independent of ω and determined by the number of active sites on the electrode surface and on the distance between these sites:

$$1/i_d = 1.61\nu^{1/6}/nFD^{2/3}c\omega^{1/2} + \left|\sum A_n\right|/nFDc\,, \qquad (23)$$

where $|\Sigma A_n|$ is the non-uniformity function of the electrode surface, which increases with the non-uniformity, i.e. as the ratio of the radius (r_1) to the spacing (r_2) of the active sites decreases.

According to Landsberg[161] if $r_2 > \delta$ (where δ is the thickness of the diffusion layer) the current i_d is given by the equation

$$i_d = nFD^{2/3}\omega^{1/2}/1.61\nu^{1/6}\left(1 + \left|\sum A_n\right| r_n/r_2\right)\,, \qquad (24)$$

and if $r_2 \ll \delta$, i_d is given by Eqn.(23). It is pointed out[151] that at ordinary temperatures $r_2 > \delta$ on a platinum surface, and therefore i_d is given by Eqn.(24). At lower temperatures the size of the active sites decreases and we have $r_2 < \delta$, leading to a non-linear dependence of i_d on $\omega^{1/2}$ [Eqn.(23)]: a possible explanation of the decrease in radius of the active sites at low temperatures is the chemisorption of ions on the electrode surface[150]. The surface of the iridium electrode in the I_2/I^- system is partially blocked, and the active sites are small. Therefore the variation of i_d with $\omega^{1/2}$ is as predicted by Eqn.(23).[97] The surface of the palladium electrode is fairly uniform: a large number of small active sites is present on an active palladium surface. However, the number of active sites decreases with time, and the Pd electrode becomes similar to the iridium electrode, with relatively few, small active sites, so that for a partially poisoned Pd electrode we can write $r_2 \ll \delta$. When the electrode surface is uniform the E_{eff} value for the limiting diffusion current is determined by the activation energy for viscous flow, as in the case of the Pt electrode§. However, for the Ir electrode[97] the activation energy is lower, and it is a function of ω. The activity of the iridium surface decreases as the temperature rises: this effect is partially compensated by the increased rate of diffusion.

When zinc and mercury ions are present in solution the time dependence of i_d is even more marked[151]. At sufficiently negative potentials the surface is blocked by a film of zinc iodide, which causes a sharp fall in current, and the electrolytic reduction of I_2 and electrodeposition of zinc are suppressed. Mercury ions are adsorbed with the iodine, lowering the rate of both the anodic and the cathodic reaction. Zinc ions also increase the amount of iodine irreversibly adsorbed on the electrode surface, but the effect is less marked than with mercury. Cadmium ions have a smaller effect than Zn^{2+} ions on the cathodic reduction of iodine. They are adsorbed on Pt over a wide range of potential[162], and their effect on the cathodic process is negligibly small, but they lower the rate of the anodic process. A possible explanation[162] is the suppression of iodine adsorption, and hence of the rate of the electrochemical desorption (9), by the adsorbed Cd^{2+} ions. The adsorption of Cu^{2+} on Pt prevents the formation of Pt–I^- bonds but it has almost no effect on the amount of iodine reversibly adsorbed on the electrode surface[151]. Unlike mercury ions, which block the surface by forming iodine compounds, metallic mercury deposited on a Pt surface has very little effect on the current[151]. The presence of Cl^- ions does not affect the half-wave potential for the reduction of I_2 to I^-, or the reversibility of the process[164].

The fluctuation of the limiting reduction current of I_2 is also ascribed to surface non-uniformity[165]. On a platinised platinum electrode the mean amplitude of the oscillations of the limiting current is lower by almost a factor of two than on smooth platinum, and decreases faster than on smooth platinum with increase of ω.[165] Potential and current oscillations have been observed[84] in the I_2/I^- system, and ascribed to turbulence in the flow of electrolyte. The adsorption of Hg^{2+} on the electrode surface minimises the fluctuations in the limiting current[165], and the adsorption of DMF suppresses them completely. DMF solutions (unlike water solutions) show a fall in current (after the limiting current) accompanied by much stronger fluctuations[159].

In DMF two limiting currents for the cathodic reduction of iodine are observed, and both are free from oscillations. These waves correspond to reactions (22) and (19).[117]

Since the slopes of the $\Delta\phi$, $\lg(1 - i/i_d)$ plots for both these waves are substantially higher than their theoretical values the authors[159] conclude that the processes are irreversible, especially in the case of reaction (19), due to the absence of adsorbed iodine. When an excess of I^- is present in solution the cathodic curve consists of one wave, and the reaction is

$$I_2\ (ads) + I^- \rightleftarrows I_3^-. \qquad (25)$$

In solutions containing more I_2 than I^- the reduction of I_2 is kinetically of the first order, and the most likely slow step is the adsorption of iodine on the electrode surface[159]. In ethylene glycol[166] and acetonitrile[111] with $[I_2] > [I^-]$, I_2 and I_3^- are reduced successively by reactions (22) and (14). In acetonitrile both the first and the second cathodic process go through the rate-determining step (18).[111] In DMSO [120] the rate-determining step is the reaction

$$I_3^- + e \rightarrow I\ (ads) + 2I^-. \qquad (26)$$

In methanolic solutions[119] the iodine is reduced as in aqueous solutions, with more marked stirring effects on the cathodic than on the anodic process.

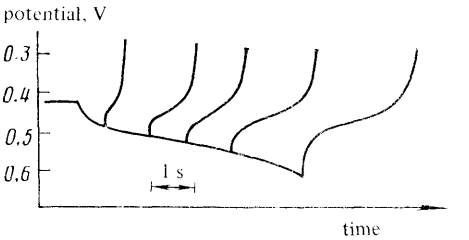

Figure 6. Effect of applying reverse current at various points of the chronopotentiogram for the oxidation of iodide ions[65].

d) Chronopotentiometric studies of the reduction of iodine in DMSO have given results consistent with those of the rotating disk electrode method: in particular, reaction (14) was shown to be irreversible. However, its rate constant determined chronopotentiometrically [$(1.12–2.86) \times 10^{-4}$ cm

§ An activation energy of 2.2 ± 0.1 kcal mole^{-1}, independent of ω, was obtained[97] from the slope of the $\lg i_d, T^{-1}$ straight lines. This is consistent with the published values[160,163] 2.08 and 1.88 kcal mole^{-1} respectively.

s^{-1}] is lower than the value obtained on a rotating disk electrode (6.8×10^{-4} cm s^{-1}).[120]

Contradictory conclusions as to the lack of electrical activity of adsorbed iodine have been drawn from chronopotentiograms. According to Hubbard and coworkers[63] only reversibly adsorbed iodine can be reduced cathodically, and the amount of electrically active iodine on the Pt surface is much less than the strongly bound iodine. However, Osteryoung and Anson[65] find that the reverse (cathodic) chronopotentiograms taken at different points of the anodic chronopotentiogram give transition times proportional to the amount of iodine evolved anodically and adsorbed on the electrode surface (Fig.6). According to Schuldiner and Presbrey[64] even α_c depends on the number of iodine atoms adsorbed on the Pt. The high rate of oxidation of I_2 chemisorbed on PbO_2 has been pointed out[62].

IV. REDOX REACTIONS IN I^-/IO_3^-, I_2/IO_3^-, AND I_2/I^+ SYSTEMS

1. Anodic Processes

Unlike the electrolytic oxidation of iodide to iodine, the deep oxidation of I^- to oxygenated compounds, in particular by the reaction

$$I^- + 3H_2O - 6e = IO_3^- + 6H^+, \quad (27)$$

depends on the pH of the electrolyte, as has been confirmed experimentally. Changing the pH between 5.85 and 1.72 produced a linear shift in potential towards more positive values[98] by 0.06 V for each pH unit, as required by Eqn.(27). Further increase in acidity did not affect the potential.

Since the "reverse" voltammetry curves (i.e. those plotted by decreasing the positive potential after the anodic wave corresponding to the formation of IO_3^-) do not reproduce the wave given by the oxidation of iodide to iodate[98,104], a mechanism involving the participation of oxygen from surface oxide layers of the platinum has been suggested[98]:

$$PtO[O]_n + I^- \rightarrow IO_3^- + PtO[O]_{n-3}. \quad (28)$$

The current fall observed on the polarisation curves is also ascribed to the formation of surface oxide layers on the platinum. It is suggested that reaction (27) takes place at 0.9–1.2 V, whereas at more positive potentials the oxidation of I^- involves the scheme (28). It has been established[148] that the second anodic oxidation wave of I^- corresponds to the deep oxidation of iodine:

$$I_2 + 6H_2O - 10e \rightarrow 2IO_3^- + 12H^+. \quad (29)$$

On an electrode consisting of a mixture of graphite and azobenzene[167] and on a pyrolytic graphite electrode[112,168] two iodide oxidation waves have been observed: to hypoiodite and to iodate. The height of these waves is proportional to the concentrations of I^- and I_2, and depends on ω. The total height of the waves is determined by the diffusion of OH^- to the electrode (for intermediate concentrations of OH^-). The electron transfer reaction for the iodate formation step is of the first order with respect to I^-; with respect to OH^- the order is 0.23 at pH 6–10.6 and zero at higher pH values. hence we may conclude that in alkaline solutions I^- is discharged on the surface sites where OH^- ions are adsorbed[167]:

$$I^- + OH^- \rightarrow HIO + 2e \quad (30)$$

$$I^- + 6OH^- \rightarrow IO_3^- + 3H_2O + 6e \quad (31)$$

or

$$M + OH^- \rightarrow M{-}OH + e \quad (31a)$$

$$x(M{-}OH) \rightarrow M{-}(O)_x + xH_2O \quad (31b)$$

$$M{-}(O)_x + I^- \rightarrow M{-}(O)_{x-3} + IO_3^-. \quad (31c)$$

In solutions of pH > 6.5–7 free iodine cannot take part in the anodic reaction because of its disproportionation

$$I_2 + OH^- \rightleftarrows IO^- + I^- + H^+ \quad (32)$$

$$3I_2 + 3OH^- \rightleftarrows IO_3^- + 5I^- + 3H^+. \quad (33)$$

In iodic acid solutions the $\lg i, \phi$ curve for Pt, Pb, and PbO_2 electrodes[169] has two linear portions, corresponding to two controlling steps for the oxidation of iodine to highly oxygenated compounds by the reactions (29) and (34):

$$HIO_3 + H_2O - 2e = HIO_4 + 2H^+, \quad (34)$$

the rate of the latter reaction determining the rate of the overall process. On a PbO_2 electrode (or on anodically oxidised lead) the iodine is oxidised by the oxidation products of water, and in particular by $OH^\cdot$ radicals according to the mechanism (31a)–(31c).

It has been shown[104] that in acid aqueous solutions of I^- two anodic waves [corresponding to reactions (1) and (35)] are obtained:

$$I_2 - 2e \rightarrow 2I^+. \quad (35)$$

The maximum current of the second wave is equal to twice the diffusion current of the first wave. At pH 8 the two waves merge, but the limiting current still corresponds to the quantitative oxidation of I^- to I^+. In a medium containing 0.05 M NaCN and 0.1 M $HClO_4$ the I^- ion gives an anodic wave with a height double that for an iodine solution of the same normality:

$$I^- + HCN \rightarrow ICN + H^+ + 2e. \quad (36)$$

These results[104] are not confirmed by chronopotentiometric data[170–172], which suggest that the second anodic wave in the oxidation of I^- is associated with reaction (29) rather than with the formation of I^+ by reaction (35), since this wave is completely suppressed when the electrode is polarised from an oxidation towards a reduction potential.

Measurements by the rotating disk electrode method with a guard ring have shown[164] that positively charged iodine ions (I^{n+}) are formed by the deep oxidation of I^- on a disk electrode and are transferred by convective diffusion to the ring electrode where they react with the I^- in solution as follows:

$$I^{n+} + nI^- = 1/2(n+1)I_2. \quad (37)$$

This explains the failure of positively charged forms of iodine to give a reverse electrolytic reduction wave. A mechanism involving reaction (27) was assumed[164], as in Ref.170, on the grounds that the ratio of the limiting currents for the first and the second I^- oxidation wave is six. However, it should be noted that the participation of the Cl^- ions in the electrode process was ignored in that work[170], though these ions are known to affect the mechanism of the deep oxidation of I^-. In the presence of a high enough concentration of Cl^- the first anodic wave corresponds to the oxidation of iodide to iodine [reaction (1)] followed by the formation of the iodine–chloride complex, and the second wave to the conversion of I_2Cl^- into iodine chloride[104,164,173–176]:

$$I_2Cl^- + 3Cl^- \rightarrow 2ICl_2^- + 2e. \quad (38)$$

The charge transfer processes in reactions (13) and (38) are polarographically reversible on smooth platinum[177].

In chloride solutions the I_2Cl^-, ICl, ICl_2^-, and I_3^- complexes are stable, with $[I_2Cl^-]/[ICl]\cdot[I^-] > [I_2Cl^-]/[I_2]\cdot[Cl^-] > [I_3^-]/[I_2]\cdot[I^-] > [ICl_2^-]/[ICl]\cdot[Cl^-]$.[177,178]

In methanolic solutions[125] and in acetic anhydride[107] iodine is oxidised to I^+, but the half-wave potentials for the oxidation of I_2 to I^+ and for the reduction of I^+ to I_2 are not the same at a given pH. In methanolic solutions the redox couple is thought[125] to be not I_2/I^+ but the iodine–iodonium methoxide couple:

$$I_2+2CH_3OH\rightarrow 2CH_3OI+2H^++2e\ . \qquad (39)$$

Iodonium methoxide is unstable and decomposes into iodates. The insolubility of iodates in methanol and the growth of an iodate layer cause passivation of the electrode.

In acetic anhydride[107] the iodine is initially oxidised to I^+, and then the I^+ reacts further with the acetic acid

$$I_2+2CH_3COOH-2e\rightarrow 2CH_2ICOOH+2H^+ \qquad (40)$$

to give monoiodoacetic acid which is decomposed in the next step by the Kolbe reaction

$$CH_2ICOOH-e\rightarrow (CH_2I)^\cdot+CO_2+H^+ \qquad (41a)$$

$$(CH_2I)^\cdot+H^+\rightarrow (CH_3)^\cdot+I^+\ . \qquad (41b)$$

2. Cathodic Processes

Iodine monochloride gives two scarcely distinguishable electrolytic reduction waves[104,179]:

$$2ICl_2^-+2e\rightarrow I_2Cl^-+3Cl^- \qquad (42)$$

$$I_2Cl^-+2e\rightarrow 2I^-+Cl^-\ . \qquad (43)$$

The reduction of ICl to I_2 is reversible, whereas the reduction to I^- is reversible only for $c_{H^+} < 0.3$ M.[164] The reversibility of the reduction of ICl_2^- to I_2 is influenced both by the concentration of HCl and by the state of the electrode surface. On smooth platinum the reduction of ICl_2^- to I_2Cl^- is quasi-reversible for $c_{HCl} \leq 1$ M, and becomes fully reversible for $c_{HCl} = 4$ M.[82]

On the dropping mercury electrode the reduction potential of IO_3^- in alkaline solutions is independent of pH, but in acid solutions it becomes less negative as the pH decreases[82].

The electrolytic reduction of iodates in aqueous, ethylene glycol, and propylene glycol solutions is essentially a catalytic reaction, different organic or inorganic additives affecting its rate in different ways[180]. Increasing the concentration of $NaClO_4$ lowers the reduction potential of IO_3^-; additions of $N(C_4H_9)_4^+$ in small amounts increase the rate of reduction, but in large amounts they inhibit the reduction by being adsorbed on the electrode. It is clear from the polarograms for the electrolytic reduction of IO_3^- [181] that gelatin, tylose, X-100 Triton, cetylpyridinium bromide, and cetyltrimethylammonium bromide behave as inhibitors towards this process, whereas *N,N*-dimethyl-*p*-phenylenediamine, hexamine, hydrazine, and polyethyleneimine catalyse it. It is suggested[181] that in acid and in neutral solutions the rate-determining step is a one-electron process, and in alkaline solutions a two-electron process, the slow step being the transfer of the second electron (involving breaking of the first bond between iodine and oxygen atoms).

Chronopotentiometric curves have been used[182] to determine the kinetic parameters of the reduction of IO_3^-. From the slope of the plot of ϕ against $\lg[1-(t/\tau)^{1/2}]$, where τ is the transition time, the authors[182] calculated the change in valency of the I during the slow step (unity), the coefficient $\alpha = 0.5$, and the order $p_C = 0.5$ with respect to iodates. However, according to Vetter[84] $\alpha = 0.6$ and is independent of the concentrations of IO_3^- and I^-, and the rate of the transition is proportional to the square root of the concentration of H^+ ions.

The reduction of iodate ions on platinum is strongly influenced by the state of the platinum surface. The reduction of IO_3^- is found[183] to be more reversible on the oxidised than on a reduced platinum electrode. The positive shift (by ~0.4 V) of the IO_3^- reduction potential caused by oxidising the electrode is explained[183] by postulating a catalytic interaction between the oxide films on the platinum surface and the iodate reduction process. However, the mechanism of the catalytic effect of the oxide films is not stated, though it is pointed out that the reduction of the oxide films begins before the reduction of IO_3^-.[183] The suggestion (from chronopotentiometric data) that oxide films may play a catalytic role is confirmed by voltammetry results: an additional peak at ~0.3 V in the i,ϕ curves for an oxidised platinum electrode, not observed for any other state of the electrode[183].

A mechanism for the electrolytic reduction of IO_3^- which allows for the postulated catalytic effect of oxide films has been proposed[184]. The role of the platinum oxides is interpreted as an increase in the rate constants of the dissociative chemisorption equilibria:

$$IO_2OH\rightleftarrows IO_2^+(\text{chem})+OH^-(\text{chem}) \qquad (44)$$

$$IO_2^+(\text{chem})+H_2O\rightleftarrows IO_2^++H^++OH^-\ . \qquad (45)$$

These catalytic changes produce substances which can be reduced at a lower overvoltage than the starting material.

The cathodic process in an IO_3^- solution in 0.1 M H_2SO_4 is catalysed also by sulphur atoms electrochemically adsorbed on the platinum surface from a solution of H_2S in 0.1 M H_2SO_4 or of 0.1 M Na_2S.[185] By comparing the polarisation curves for electrodes with and without a sulphur coating, and also for electrodes covered with oxygen, we can show that in the first case the half-wave potential ($E_{1/2}$) for IO_3^- is more positive than in the second case, but more negative than in the third. Hence the activating influence of sulphur is less effective than that of oxygen. The activation of the cathodic process by sulphur atoms has been explained[185] by an increased coverage of the electrode surface by IO_3^- ions in the sulphur-covered areas, due to the formation of stable compounds between IO_3^- and the adsorbed sulphur.

Vetter[84] noted a strong increase in the limiting current for the reduction of iodates at high concentrations of I_2. He ascribed the acceleration of the cathodic process by the addition of I_2 or by a decrease in pH to a fast ($E_{eff} = 5$–10 kcal mole^{-1} [186,187]) chemical reaction between IO_3^-, H^+, and I^- (the latter being formed by the direct reduction of IO_3^- or I_2):

$$IO_3^-+6H^++6e\rightarrow I^-+3H_2O\ (\text{slow}) \qquad (46)$$

$$5I^-+IO_3^-+6H^+\rightarrow 3I_2+3H_2O\ (\text{fast}). \qquad (47)$$

Anson[183] rejected Vetter's conclusion[84] and showed that the reduction of IO_3^- is independent of pH in the pH range 1–6, even with allowance for the formation[188] of iodine as an intermediate in the reduction of IO_3^- by a mechanism which includes reactions (46) and (47).

In the polarisation curves measured on a rotating disk electrode the autocatalytic mechanism including reactions (46) and (47) is more important at low rotation speeds ($\omega < 1600$ min^{-1}) than at high speeds[179]. The catalytic reduction is accelerated by increasing the concentration of IO_3^-.[164] The more positive half-wave potential for the reverse plot (i.e. for a potential sweep from the negative towards the positive values) than for the normal plot (Fig. 7) is also explained by the autocatalytic reduction of IO_3^-.[164] The observation that the direct reduction of iodate [reaction (46)] on a smooth platinum electrode in a 1–5 M H_2SO_4 supporting electrolyte requires a high overvoltage has led to the same conclusion[189].

In a hydrochloric acid medium at concentrations up to 3 M the cathodic processes include reaction (46) as the rate-determining step and the following fast reactions:

$$2I^- + IO^-_3 + 3Cl^- + 6H^+ \rightarrow 3ICl + 3H_2O \quad (48)$$

$$ICl + 2e \rightarrow I^- + Cl^- . \quad (49)$$

The electrochemical product I^+ is formed in substantial amounts when the concentration of I_2 is much greater than that of I^-.[164]

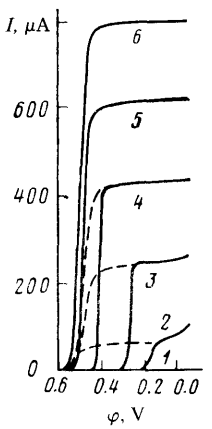

Figure 7. Reduction of IO_3^- in an HCl solution (rotating platinum disk electrode, $A = 0.36$ cm^2, $\omega = 400$ min^{-1}, $\nu = 0.4$ min^{-1}). Full lines denote potential sweep from (+) to (−), broken lines from (−) to (+):[164] *1*) 0.2 M HCl + 0.3 M NaCl, *2*)–*6*) with added KIO [10^4 c_{KIO}, mole litre^{-1}: *2*) 2 *3*) 4, *4*) 6, *5*) 8, *6*) 10].

In an acid 0.1 M phthalate buffer (0.01 M IO_3^- + 0.1 M KCl at pH 3.2) the catalytic effect is observed, and the current density and the kinetic parameters of the process vary with time[188]. Moderately fast stirring lowers the current at a given potential by the partial removal of iodine. In an alkaline 0.05 M borate buffer (0.01 M IO_3^- + 0.1 M KCl at pH 9.2) the current density is effectively independent of time. However, in the presence of camphor changes with time are observed. If KI is added to the borate buffer to a concentration of 0.1 M the current density changes with time both in the absence and in the presence of camphor. According to Vetter[84] a different mechanism should apply in an alkaline solution in which the iodine disproportionates according to reaction (33).

Thus we can infer from the inconsistency of published results on the mechanism and kinetics of the oxidation of I^- that the electrode processes in the I^-/I_2 system are so dominated by diffusion-limited kinetics that $i_0(6)$ and $i_0(9)$ are almost impossible to measure by any of the standard methods. Depending on the state of the I^- in the outer Helmholtz plane, and on the appearance of a ψ^- potential (which is often observed, especially in the presence of a supporting electrolyte, since I^- has "negative hydration"[190]), the rates of transfer of the first and the second electron in the overall reactions (1) and (2) can be very similar. The oxidation of I^- to I^{n+} is also very important; the reduction of IO_3^- to I^- is autocatalytic, but this mechanism has not been observed in the oxidation of I^- to IO_3^- (though it has been observed, at least in part[175], during the formation of ICl in the presence of Cl^-).

Mechanism of the Epoxidation of Alkenes by Molecular Oxygen

T.V.Filippova and E.A.Blyumberg

Radical and molecular mechanisms of the formation of oxirans are examined in the oxidation of alkenes by molecular oxygen. The reactivities of various epoxidising agents are discussed. A list of 87 references is included.

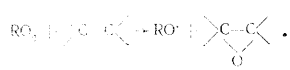
I. INTRODUCTION



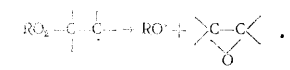
Direct oxidation of unsaturated compounds with molecular oxygen[1] is most promising for obtaining oxirans, which are used as monomers for the production of polyurethanes, stereospecific polymers, various additives, surface-active agents, and other important chemical products. The problem of establishing the mechanism of the epoxidation of alkenes by molecular oxygen therefore acquires great importance. It is now generally accepted that during direct oxidation alkene oxides are formed predominantly in the course of chain propagation by interaction between alkenes and various peroxy-radicals.

The present Review examines the structure of radical epoxidising agents, their reactivity, and the dependence of the selectivity of epoxidation on the structure of the initial alkene. Possible routes for epoxidation by molecular intermediate products are suggested. Catalytic epoxidation of alkenes by molecular oxygen and by hydroperoxides is not discussed here, since it has already been reviewed[2].

II. EPOXIDATION OF ALKENES BY ALKYLPEROXY-RADICALS

Most investigators accept that the main route to the formation of oxirans in the direct oxidation of alkenes is epoxidation of the latter by alkylperoxy-radicals[3-29].

The simplest reaction of this type occurs between a monomeric peroxy-radical and an alkene:



(1)

This takes place in two stages—addition of the peroxy-radical to the alkene to form a β-peroxyalkyl radical

(1′)

and breakdown of this radical into an oxiran and an alkoxy-radical

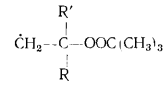
(1″)

The absence of stereospecificity in the epoxidation of alkenes by alkylperoxy-radicals[4,5,11,25] has been interpreted as evidence of intermediate formation of a β-peroxyalkyl radical. The probability of *cis–trans* isomerisation in this radical is determined by the relative rates of rotation about the C–C bond and of breakdown of the radical to form the oxiran.

The relative concentrations of *cis*- and *trans*-oxides of oct-4-ene among the reaction products depend[25] on the configuration of the alkene: more of the *cis*-oxide is obtained from *cis*-oct-4-ene, and more of the *trans*-oxide from the *trans*-alkene. This apparently indicates that the life of the β-peroxyalkyl radical is too short for the attainment of conformational equilibrium[25].

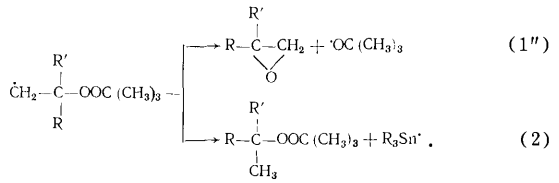
Effective activation energies for the overall reaction (1) have been determined for interaction of the methylperoxy-radical with substituted butenes in the gas phase at 100–130 °C[26] (Table 1). A similar value was obtained[87] for the gas-phase oxidation of ethylene: E_{eff} = 10 kcal mole^{-1}.

Table 1.



Alkene	2-Methylbut-1-ene	2-Methylbut-2-ene	2,3-Dimethylbut-2-ene
E_{eff}, kcal mole^{-1}	12.7±1.3	10.2±0.8	8.7±0.6

The addition of alkylperoxy-radicals to alkenes is reversible[28]. From the rate constants estimated from thermochemical data for the breakdown of β-peroxyalkyl radicals

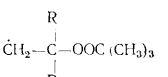


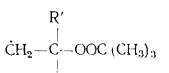
$$k_{1'} = 10^{11.5} \exp(-14\,000/RT);\quad k_{-1'} = 10^{13} \cdot \exp(-18\,000/RT)\quad (c^{-1}),$$

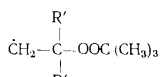
it can be concluded that the reverse reaction to (1′) begins to be significant only at high temperatures (above 300 °C)[28].

Rate constants for the decomposition of various β-peroxyalkyl radicals were determined experimentally[27]. The radicals were prepared independently by reaction between the corresponding brominated peroxides and hexamethyldistannane $(CH_3)_3Sn.Sn(CH_3)_3$ or a trialkylstannane R_3SnH in the presence of an initiator. Formation of the radicals was recorded by electron spin resonance at −70 °C. Further conversion of the β-peroxyalkyl radicals

was due to competition between two reactions—decomposition with formation of an oxiran (1″) and reduction in the presence of the trialkylstannane with formation of a dialkyl peroxide (2):







(1″)

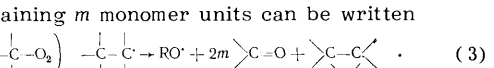
(2)

The relative concentrations of the products—oxiran and dialkyl peroxide—gave the ratio of the rate constants of the two competing reactions k_1''/k_2. From the known value of k_2, rate constants were found[27] for the formation of oxirans in the decomposition at 25 °C of the β-peroxyalkyl radicals in Table 2.

Table 2.

Radical*			
10^3k, s^{-1}	700	40	2

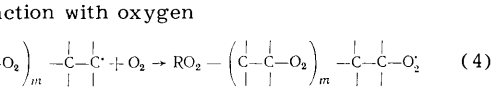
* R = CH_3 and R′ = H.



Thus the rate constant of reaction (1″) increases sharply with the number of substituent groups in the β-peroxyalkyl radical. The decomposition rate constants of such radicals are surprisingly large in absolute magnitude: the values obtained[27] exceed by many orders of magnitude those for the corresponding dialkyl peroxides (e.g. 10^{-6} s^{-1} for di-t-butyl peroxide in benzene at 80 °C[31]).

Indirect confirmation of the possibility that β-peroxyalkyl radicals decompose with the formation of oxirans was obtained as early as 1950[30]. Isobutene oxide (30 mole % based on the peroxide that had reacted) was detected in the thermal (100 °C) and photochemical decomposition of di-t-butyl peroxide, as a result of breakdown of the radical $(CH_3)_3COOC.(CH_3)_2CH_2$, formed in chain propagation[30].

Peroxy-radicals involved in epoxidation can react in either monomeric (RO_2) or polymeric



form[6,7,13-16,29]. Breakdown of the latter results in formation of an oxiran and a carbonyl compound in a single step, which for a radical containing m monomer units can be written

(3)

The length m of the carbon chain is determined by the relative rates of decomposition of the β-peroxyalkyl radicals (1″) or (3) and of reaction with oxygen

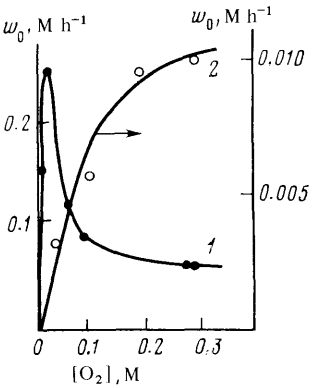
(4)

and depends on the structure of the initial alkene and the reaction conditions (Section IV).

Competition between reactions (1″) or (3) and (4) should lead to an inversely proportional dependence of the yield of oxiran on the concentration of molecular oxygen[10]:

$$\frac{w_{Ox}}{w_{Eth}} = \frac{1}{(A + B[O_2])} \qquad (4a)$$

where w_{Ox} is the rate of formation of the oxiran, w_{Eth} is the rate of consumption of the initial ethylenic compound, and A and B are constants containing the ratios of the rate constants of the primary stages. Decrease in yield (and rate of formation) of alkene oxides with increase in oxygen concentration over a certain range has been observed experimentally in the oxidation of a substituted norbornene (Fig. 1, curve *1*),[46] propene[59], and other alkenes[10,22,23], and is regarded as kinetic evidence of the formation of oxirans in the decomposition of β-peroxyalkyl radicals.



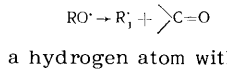


Figure 1. Dependence of initial rate of accumulation of alkene oxide on concentration of oxygen in the oxidation of methyl *exo*-2-methylbicyclo[2,2,1]hept-5-*endo*-carboxylate (a substituted norbornene) by molecular oxygen (50 atm) in benzene at 70 °C[46] in the presence of: 1) 0.01 M azoisobutyronitrile; 2) acetaldehyde (concerted oxidation).

Epoxidation (1″) should lead to the formation of equimolecular quantities of oxirans and monomeric or polymeric conversion products of alkoxy-radicals. Therefore some information on the course of such reactions in the complicated multistage oxidation of alkenes can be obtained by tracing the fate of such radicals formed in the epoxidation step. Three possible types of conversion are considered—(i) unimolecular decomposition with formation of an aldehyde and an alkyl radical[2,4,8,67]

(5)

(ii) detachment of a hydrogen atom with formation of an unsaturated alcohol (in the case of an allylic alkoxy-radical) or a polymer containing a terminal hydroxy-group[4,8-10,20,32,67]

(6)

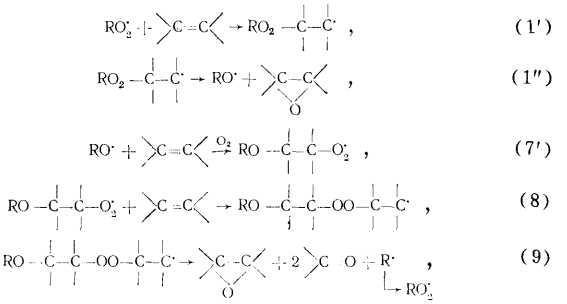
and (iii) addition at the double bond of the initial alkene[8-10,32]

(7)

In some cases (when epoxidation of alkenes is the main source of alkoxy-radicals) equivalence has been established

between the quantities of oxirans and conversion products of the radicals[3,8,9]. However, attempts to draw up such a balance have not always been successful. Thus decomposition should not be the only conversion undergone by alkoxy-radicals: in the presence of hydrocarbons containing reactive carbon–hydrogen or ethylenic bonds reaction (6) or (7) can compete successfully with unimolecular decomposition (5)[6,7] (especially in the case of primary and secondary alkoxy-radicals). In most work on the oxidation of alkenes however, unsaturated alcohols have been either detected in insignificant quantities or completely absent from the reaction products (Table 3).

Table 3. Oxidation of alkenes at 60–70 °C[8,9]*.

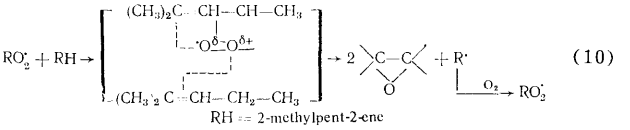


Alkene	β, %	10^3[Ox], moles	10^3[Alc], mole	10^3[Ke], moles	j	k	l
But-2-ene	4.5	2.31	0	3.27	4.00	7.78	2.18
2-Methylbut-2-ene	4.2	1.94	0.53	3.36	5.00	9.72	2.18
2,3-Dimethylbut-2-ene	4.7	3.06	0.58	4.31	6.00	11.66	2.26
Isobutene	4.5	3.39	0	2.82	4.00	6.98	1.60
Hex-1-ene	3.7	0.86	0.59		6.00	11.76	2.37
Cycloheptene (Ref.73)	5.5	2.04	1.55	0	7.00	13.81	2.00

* Here β represents the degree of conversion, Ox the alkene oxide, Alc an unsaturated alcohol, and Ke carbonyl compounds containing fewer carbon atoms than in the initial alkene. The composition of the macromolecular products $(C_jH_kO_l)_{m_i}$ was determined from elementary analysis; m_i is the number of monomer units in the polymer molecule.

The hypothesis that alkoxy-radicals are consumed mainly by addition to the double bond of the alkene is contradicted by the experimental observation that the rate of abstraction of a hydrogen atom from propene, determined for the t-butoxy-radical, exceeds about thirtyfold the rate of addition of this radical to propene[32] and other alkenes[31]. Furthermore, elementary analysis[8,9] indicates that the composition of the macromolecular products from several alkenes approximates to the empirical formula $C_nH_{2n}O_2$ (Table 3), which indicates that monomeric groups of peroxide character predominate in the polymer.

From the stoichiometry of the epoxidations (1) and (3) it may be expected that equimolecular quantities of alkene oxide and total conversion products of the epoxidising agent will be formed. This imposes a limit on the yield of oxiran, which theoretically should not exceed 50% based on the alkene consumed. In several cases, however, e.g. in the oxidation of cyclo-octene[34], norbornene derivatives[35–37,24], hexafluoropropene[38], "di-isobutene" (2,4,4-trimethylpent-1-ene)[39], and 2-methylpent-1-ene[33], the yield of alkene oxide exceeds the total yield of products formed from alkoxy-radicals, and reaches 70–80% based on the alkene that has reacted.



Except in the early work, in which direct incorporation of an oxygen molecule at the double bond of the alkene was assumed, as e.g. for di-isobutene[39], the observed regularities are mostly explained in terms of various radical epoxidation reactions having one fundamental common feature: regeneration of the $R\dot{O}$ (or $RO_2\dot{}$) radical carrying the chain oxidation is postulated in the epoxidation step. Thus the sequence of reactions

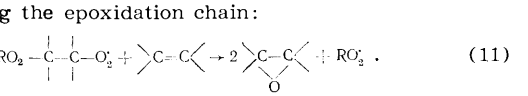
(1′) (1″) (7′) (8) (9)

provides a description of the kinetics of the oxidation of styrene derivatives[6,13], and gives theoretical maximum yields of alkene oxides up to 66%. This scheme of oxidation is applicable only to alkenes containing no reactive hydrogen atoms, for which chain propagation involves mainly addition of radicals at the double bond of the alkene and breakdown of the resulting polymeric radicals.

The composition of the oxidation products of 2-methylpent-2-ene, which is characterised by reactions involving abstraction of a hydrogen atom[33], can be explained by introducing into the scheme another epoxidation reaction

RH = 2-methylpent-2-ene (10)

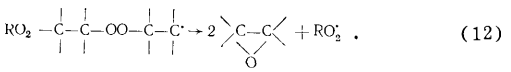
which like reaction (9) leads to regeneration of the peroxy-radical. Scheme (10) involves polarisation of the dioxy-bond in an allylic peroxy-radical by interaction of the electron of the latter with the π-electrons of the double bond. This facilitates migration of the oxygen atom to the double bond and detachment of the second oxygen atom by an adjacent alkene molecule.



The high yield of oxides of norbornene derivatives, in particular of cyanonorbornene (~ 70% based on the alkene consumed)[35–37], cannot be explained by the above reactions (9) and (10), since structural features of norbornene make formation of allylic peroxy-radicals improbable[24,35,41] (the usual delocalisation of electron density in the radical formed by detachment of an α-hydrogen atom is difficult). Furthermore, the carbonyl compounds whose formation is implied by reaction (9) do not exceed 10% of the alkene that has reacted in the oxidation of norbornene derivatives.

We have suggested a mechanism[35,42] in which the epoxidising agent is a peroxy-radical formed by addition of a chain-carrying radical to one of the carbon atoms forming the double bond, while oxygen adds to the other carbon atom:

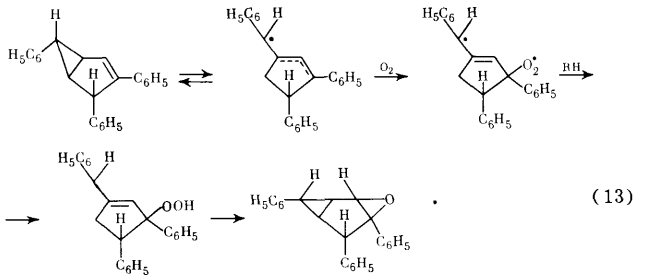
(1‴)



Such a radical reacts with the initial cyanobornene to form two molecules of the alkene oxide and regenerate the peroxy-radical carrying the epoxidation chain:

(11)

Overall, reaction (11) is energetically advantageous[42]. It

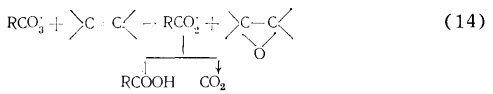


may take place not in a single stage but by formation and subsequent breakdown of a β-peroxyalkyl radical:

(12)

The mechanism of epoxidation suggested for derivatives of norbornene is also the most probable mode of formation of hexafluoropropene oxide[38], the yield of which reaches 80% based on the alkene that has reacted.

Yet another scheme of epoxidation was suggested in work[40] on the thermal oxidation of a bicyclo[3,1,0]hex-2-ene:

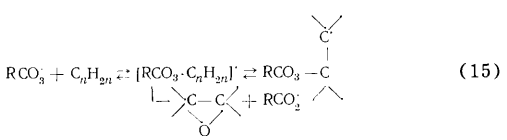


(13)

In this case the alkene oxide is formed by the breakdown and rearrangement of a hydroperoxyalkyl radical. The reaction sequence (13) was assumed by analogy with the published mechanism of thermal *exo–endo* isomerisation of bicyclo-compounds. However, oxidation of this bicyclo[3,1,0]hex-2-ene was conducted in xylene at temperatures above 100 °C, so that peroxy-radicals of xylene could have been the epoxidising agents, a possibility that was not considered[40]. Later other workers[19] published a study of the oxidation of conjugated dienones in cumene and in xylene at 120–130 °C, in which results were obtained indicating that under these conditions epoxidation involved peroxy-radicals of these solvents.

It must be noted that decomposition of hydroperoxyalkyl radicals has been assumed as the mode of formation of alkene oxides in the high-temperature (~ 400 °C) oxidation of alkenes in the gas phase[70–72].

III. EPOXIDATION OF ALKENES BY ACYLPEROXY-RADICALS



The epoxidation of alkenes by acylperoxy-radicals

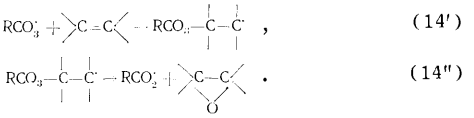
(14)

has an important role in systems in which aldehydes are formed as reactive intermediates. Reaction (14) has been studied in detail on the concerted oxidation of alkenes and aldehydes, a relatively simple process in which acylperoxy-radicals are the sole radical epoxidising agents[43–47,49,50,54]. The effective rate constant of reaction (14) determined for the concerted oxidation of nonene and benzaldehyde is 18000 M^{-1} s^{-1} at 90 °C[47]. The first stage of this reaction is assumed to be addition of acylperoxy-radicals at the double bond of the alkene.

One of the two views held concerning the structure of the radical adduct is that[43–45] reaction between acylperoxy-radicals and alkenes involves intermediate formation of a π-complex radical (as in the interaction of peracetic acid with propene[48]). The suggested general scheme of epoxidation[46]

(15)

indicates that the initially formed π-complex $[RCO_3.C_nH_{2n}]^{\cdot}$ can react in two ways: it can decompose with formation of an oxiran or rearrange with fission of the π-bond. The latter process leads to subsequent formation of polymeric products:



(16)

The alternative view[47] does not exclude the possibility of initial formation of a π-complex between radical and alkene. However, its concentration is considered[47] to be far lower than that of acylperoxy-radicals: a π-complex, even if formed, would rearrange rapidly into a β-peroxyalkyl radical

Thus formation of a complex is not a stage determining the macrokinetics of the process, and the mechanism of epoxidation by acylperoxy-radicals is assumed to resemble that by alkylperoxy-radicals:

(14′)

(14″)

The kinetics of the concerted oxidation of alkenes and aldehydes can be described on both views.

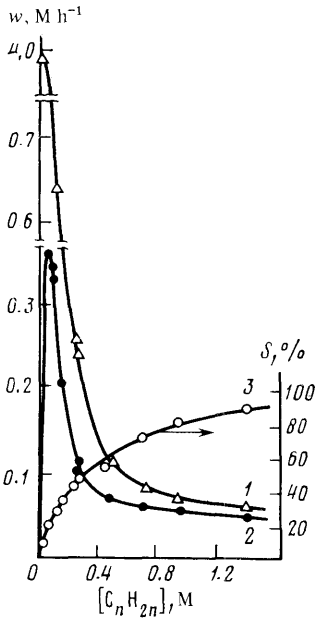


Figure 2. Effect of concentration of non-1-ene in chlorobenzene at 90 °C[47] on: 1) rate of consumption of benzaldehyde; 2) rate of accumulation of nonene oxide; 3) variation in yield of nonene oxide based on the benzaldehyde that has reacted.

Above a certain limiting value the alkene concentration ceases to affect the rate of accumulation of oxiran. Such a relation has been observed in the concerted oxidation of propene[45] and of nonene[47] with aldehydes (Fig. 2). In terms of

the hypothetical formation of an intermediate complex radical the explanation is that at a certain alkene concentration all acylperoxy-radicals are bound in the complex, and further increase in the alkene concentration leads to no increase in the concentration of the intermediate complex and hence in the rate of formation of the oxiran[45].

However, attainment of a limiting rate of epoxidation is not unequivocal evidence of existence of the complex $[RCO_3.C_nH_{2n}]_{\sim}$. This relation can be explained by compensation of the increase in rate of epoxidation due to increase in alkene concentration by decrease in the steady-state concentration of $RCO_{3\sim}$ radicals as a consequence of reaction (14')[47]. Thus this reaction produces a linear loss of such radicals. The dimeric (polymeric) peroxy-radical $MO_{2\sim}$ thus formed does not undergo the exchange reaction during development of the primary chain:

$$MO_{2\sim}^{\cdot} + RCHO \xrightarrow{O_2} RCO_{3\sim}^{\cdot} + MOOH. \qquad (17)$$

In the concerted oxidation of alkenes and aldehydes the dependence of rate of epoxidation (and yield of oxiran) on the oxygen concentration is similar to that observed for the oxidation of saturated compounds. Thus the rates of formation of the oxides of propene[45] and of a substituted norbornene[46] in the concerted oxidation of these alkenes with acetaldehyde increase continuously with the concentration of molecular oxygen up to a certain value, after which they cease to depend on this concentration (Fig. 1, curve 2).

Thus the dependence of rate of epoxidation on oxygen concentration changes qualitatively with the nature of the epoxidising agent (as mentioned above, a fall in rate with increase in oxygen concentration over a certain range has been observed for reactions of alkylperoxy-radicals[10,46]). One explanation for this difference is that reaction (16) with oxygen is improbable for a π-complex radical devoid of a free valency localised on a carbon atom[45]. Hence the epoxidation of alkenes by acylperoxy-radicals does not involve the competition between breakdown of a π-complex and its interaction with oxygen that can produce a fall in yield of alkene oxide with increase in oxygen concentration.

If the direct precursor of the oxiran is a σ-bound not a π-complex radical, the near independence of the yield (and rate of formation) of the oxiran from the oxygen concentration is interpreted as due to the rate of reaction (14") exceeding the rate of reaction (16) in the competition for radicals of type $RCO_3-C-C_{\sim}$[49].

The ratio of the rate constants k_{16}/k_{14}" estimated for the concerted oxidation of valeraldehyde and cyclohexene[49] supports the hypothetical rapidity of unimolecular decomposition (14"). However, it was admitted[49] that the accuracy of such an estimate was low, since the ratio was determined from constants *A* and *B* in Eqn.(4a), although the yield of the cyclohexene oxide varied very little with the oxygen concentration.

The stereochemical consequences of epoxidation by acylperoxy-radicals also support the concept of formation of the oxiran in decomposition of a σ-bound radical (14") having a carbon–carbon single bond. The concerted oxidation of benzaldehyde separately with *cis*- and *trans*-but-2-ene[50] and also the oxidation of isobutyraldehyde with the stereoisomers of oct-2-ene[54] yield mixtures of the *cis*- and *trans*-oxirans. Two trends were distinguished[50,54] in this process—stereospecific epoxidation of alkenes by peroxy-acids[51–53] and non-stereospecific epoxidation by acylperoxy-radicals.

Reaction (14) is accepted as the main path to formation of the oxides of propene[55–57,59], unbranched nonene[58], and hexene[60] in the direct oxidation of these alkenes by molecular oxygen. Involvement of acetylperoxy-radicals in the epoxidation step in the oxidation of propene is confirmed by experiments on the concerted oxidation of propene with acetaldehyde in the presence of iminoxyl radicals at 150 °C[57,59]. Under these conditions oxidation of propene is inhibited by iminoxyl radicals, and the only processes that occur are the oxidation of acetaldehyde and the epoxidation of propene by acylperoxy-radicals.

Table 4.

$[O_2]$, vol.%	21	12	8.0	2.5
Propene	0.8	—	2.0	—
Isobutene	1.1	—	2.1	2.2
Propene / Acetaldehyde	0.51	0.51	0.52	—

* Oxidation was conducted in the presence of stable iminoxyl radicals.

If acylperoxy-radicals are the sole epoxidising agents, the stoichiometry of reaction (14) requires that the rates of formation of the oxidation products should satisfy the relation†

$$\alpha = w_{Ox}/(w_A + w_{CO_2}) \leqslant 1,$$

in which w_{Ox} and w_A are the rates of formation of oxide and acid respectively. Such a relation has indeed been observed in the concerted oxidation of alkenes and aldehydes[43–47,59]. In the direct oxidation of alkenes, however, e.g. of propene[59] and isobutene[23], the parameter α increases to ~ 2–2.2 with decrease in the oxygen concentration of the oxidising gas. Table 4 gives the values obtained for α.

These results indicate that epoxidation of alkenes when oxidised by molecular oxygen has a complicated mechanism and that several epoxidising agents are involved in the formation of alkene oxides (e.g. alkylperoxy-radicals, which exhibit an increase in yield of alkene oxides with fall in oxygen concentration).

IV. INFLUENCE OF STRUCTURE OF ALKENES AND PEROXY-RADICALS ON RATE OF EPOXIDATION

The relative rates of epoxidation of alkenes by peroxy-radicals depend on the structure of the initial alkenes and on the reactivity of the double bond towards different epoxidising agents, as well as on the conditions of oxidation. We shall examine specific examples of the formation of alkene oxides involving various types of peroxy-radicals. Unfortunately, rigorous quantitative comparison of reaction rate constants is impossible because of the lack of appropriate data (different workers conducted oxidation under conditions that could not be compared, in several cases rates of initiation and chain-termination rate constants were not determined, etc.).

† The acid and carbon dioxide are products of further conversion of the alkylperoxy-radical, and are formed also in parallel chain oxidation reactions of aldehydes, e.g.

$$RCO_3^{\cdot} + RH \rightarrow \begin{cases} RCO_3H \\ \rightarrow RCO_2H. \end{cases}$$

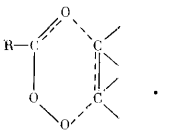
The epoxidation of propene by peroxy-radicals formed in the oxidation of various compounds—aldehydes, butan-2-one, alkylated arenes, and saturated hydrocarbons—exhibits (Table 5)[43] clear selectivity of propene towards the epoxidising agents: the yield of methyloxiran is several times higher in the presence of acylperoxy-radicals than in epoxidation by peroxy-radicals e.g. of cumene or ethylbenzene. These results are consistent with experiments showing[62] that at 90 °C propene undergoes hardly any epoxidation by peroxy-radicals of ethylbenzene, whereas cyanoisopropylperoxy-radicals under the same conditions give only ~ 1% yield of methyloxiran calculated on the epoxidising compound.

Epoxidation by acyl- and alkyl-peroxy-radicals has been compared[46] in the oxidation of methyl *exo*-2-methylbicyclo.[2,2,1]hept-5-ene-*endo*-carboxylate by molecular oxygen in the presence of an initiator and in the concerted oxidation of this ester with acetaldehyde. The rate of formation of the alkene oxide via acylperoxy-radicals exceeded that via alkylperoxy-radicals by factors of ~ 30–40. Similar results have been obtained for the direct and concerted oxidation of cyclohexene[8,49]: whereas the former leads mainly to the formation of cyclohexenyl hydroperoxide (negligible quantities of cyclohexene oxide were detected), in the concerted oxidation of this alkene with valeraldehyde the oxiran becomes the main oxidation product.

Table 5. Yield S of alkene oxides calculated as a percentage of compound consumed.

Compound	t, °C	S, %	Compound	t, °C	S, %
Acetaldehyde	55—80	30.0—70.0	Butane	145	11.0
Propionaldehyde	70	50.0	Cumene	130	13.4
Butan-2-one	145	96.0	Ethylbenzene	120—140	15.0

The greater epoxidising power of acylperoxy- than of alkylperoxy-radicals can be explained in terms of the relative rates of the two competing reactions[49]—addition of peroxy-radicals to the ethylenic double bond



$$RCO_3^{\cdot}\ (\text{or}\ RO_2^{\cdot}) + \rangle C{=}C\langle \rightarrow RCO_3{-}\overset{|}{C}{-}\overset{|}{C}^{\cdot}\ (\text{or}\ RO_2{-}\overset{|}{C}{-}\overset{|}{C}^{\cdot}) \qquad (14')$$

and abstraction of an α-hydrogen atom relative to this bond

$$RCO_3^{\cdot}\ (\text{or}\ RO_2^{\cdot}) + RH \rightarrow R^{\cdot} + RCO_3H\ (\text{or}\ RO_2H)\ . \qquad (18)$$

The ratio of the rate constants of reactions (14′) and (18) for the interaction of the acetylperoxy-radical with cyclohexene exceeds the ratio for that of the cyclohexenylperoxy-radical by a factor of 30. This was attributed[49] to better stabilisation of the partial positive charge induced on the alkene in the transition state corresponding to addition of acylperoxy-radicals than in that arising on abstraction of a hydrogen atom. Such behaviour of acylperoxy-radicals will explain the high yields of alkene oxide obtained with respect not only to the alkene consumed but also to the organic compound introduced (Table 5).

In terms of scheme (15), which involves formation of π-complex radicals, the higher rates of epoxidation of alkenes by acylperoxy-radicals are explained[46] by stabilisation of π-complexes of alkenes with the latter radicals due to formation of six-membered structures of the type

Because of the relatively greater stability of such a complex with acylperoxy-radicals the equilibrium (15) will be displaced to the left, and it appears that only breakdown of the complex into the alkene oxide and the $RCOO_2^{\cdot}$ radical will take place[46].

Hypotheses[46,49] advanced to explain the great epoxidising power of acylperoxy-radicals are not inconsistent, since they concern different primary stages in the oxidation of alkenes. However, the epoxidation of alkenes by such radicals is not effective in all cases. Thus chloromethyloxiran could not be obtained at all by the concerted oxidation of acetaldehyde and allyl chloride (at 70–100 °C)[64]. Comparison of the reactivities of several hydrocarbons towards acetylperoxy-radicals shows that the rate of epoxidation depends significantly on the nature of the substituent adjacent to the double bond in the alkene[63,64]. This is illustrated by Table 6, in which w_0 is the initial rate of formation of the oxiran; the rate of chain initiation is in all cases 0.039 mM s^{-1} at 90 °C and 50 atm.

Table 6.

Alkene	Propene	Styrene	Cyclohexene
$10^5 w_0$, M s^{-1}	47	2.6	6.4
$10^2 k_2/k_6^{1/2}$, $M^{1/2}$ $s^{-1/2}$	24	1.3	3.3

Table 7. Rates of formation w and yields S (based on alkene that has reacted) of alkene oxides in the action of isobutylperoxy-radicals on alkenes at 120 °C.[20]

Alkene	$10^6 w_0$, M s^{-1} (120° C)	S, %
α-Methylstyrene	16	86.5
Styrene	29	86
Propene	1.65	30
2,3-Dimethylbut-2-ene	1.55	38
Hex-1-ene	0.42	11.5

The epoxidising power of alkylperoxy-radical also is strongly dependent on the structure of the alkene and the conditions of oxidation. Thus epoxidation of cyanonorbornene—an alkene containing a reactive double bond (due to deformation of bond angles at the carbon atoms forming the double bond[65])—by peroxy-radicals of alkylarenes is observed even at 80 °C.[42] Under these conditions, however, the peroxy-radicals of ethylbenzene, as noted above, cause hardly any epoxidation of propene, an alkene containing a less reactive terminal double bond[43,62]. Epoxidation of propene by peroxy-radicals of alkyl groups—t-butyl[20] and apparently allyl[59]—begins to occur at an appreciable rate only at higher temperatures (120–150 °C—Table 7). Similarly, in the gas-phase oxidation of propene epoxidation by alkylperoxy-radicals becomes the predominant mode of formation

of methyloxiran only at high temperatures (above 350 °C). Under these conditions methyloxiran and acetaldehyde are formed simultaneously[66] (not consecutively, as would have been observed in epoxidation by acylperoxy-radicals).

Another illustration of the selectivity of epoxidation by alkylperoxy-radicals is the oxidation of conjugated dienones and diene ethers in cumene or xylene at 120–130 °C, when peroxy-radicals of the solvents act as epoxidising agents[19]. Cumenylperoxy-radicals react with conjugated alkenes, e.g.

to give oxides of the alkenes in high (50–95%) yields. However, these radicals do not epoxidise molecules containing isolated double bonds or cross-conjugated systems such as

Two factors govern selectivity according to the above mechanisms of epoxidation of alkenes by alkylperoxy-radicals. The first is the ratio of the rate constants of the two reactions between these species—addition at the double bond (1′) and (14′) and detachment of a hydrogen atom (18)—the kinetic consequences of competition between reactions (1′) and (18) having been examined first in 1958[63] and also subsequently[7–10,20,49]. Selectivity of epoxidation of various alkenes by t-butylperoxy-radicals in an inert atmosphere at 120 °C (Table 7) has in particular been related[20] to three factors—(*a*) the reactivity of the double bond (which varies with the substituents attached to the ethylenic carbon atoms), (*b*) the number of hydrogen atoms located α to the double bond (the greater the number of allylic hydrogen atoms the more rapid the detachment of a hydrogen atom (18), which competes with addition), and (*c*) characteristics of the allylic hydrogen atoms (whether primary, secondary, etc.). Table 7 shows that the maximum yield of alkene oxide is obtained with styrene derivatives, which interact with t-butylperoxy-radicals almost solely by addition of the latter at the double bond.

Table 8. Ratios $k_{1'}/k_r^{1/2}$ and $k_{18}/k_r^{1/2}$ $M^{-1/2}$ $h^{-1/2}$ at 70 °C.[9]

Alkene	$k_{1'}/k_r^{1/2}$	$k_{18}/k_r^{1/2}$	Alkene	$k_{1'}/k_r^{1/2}$	$k_{18}/k_r^{1/2}$
Propene	0.014	0.013	Isobutene	0.051	0.012
But-1-ene	0.017	0.019	2-Methylbut-2-ene	0.111	0.102
trans-But-2-ene	0.033	0.040	2,3-Dimethylbut-2-ene	0.25	0.67

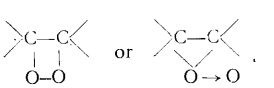
Published results[9] also permit comparison of the ratios $k_{1'}/k_r^{1/2}$ and $k_{18}/k_r^{1/2}$ (in which k_r is the rate constant of quadratic recombination of peroxy-radicals) for the interaction of alkenes with allylic peroxy-radicals of the same structure as the initial alkene. Comparison was based on the postulate that variation of these parameters was due mainly to change in $k_{1'}$ and k_{18}. Although this approximation is not entirely accurate (as was admitted[9]), a general tendency for the reactivity of alkenes to vary with their structure can be quite definitely traced (Table 8). Maximum values of $k_{18}/k_r^{1/2}$ were obtained for alkenes having the largest number of allylic hydrogen atoms; the ratio $k_{1'}/k_r^{1/2}$ increases with the number of substituents attached to the ethylenic carbon atoms in the alkenes investigated.

Data on the influence of temperature on competition between reactions (18) and (1′) are few and disconnected. An example is provided by chain-propagation rate constants obtained for the oxidation of cyclohexene[68]:

$$k_{18} = 4.8 \cdot 10^6 \exp[(-6300 \pm 300)/RT] \ (M^{-1}\,s^{-1})$$
$$k_{1'} = 1.2 \cdot 10^8 \exp[(-14000 \pm 600)/RT] \ (M^{-1}\,s^{-1}).$$

These results show that rise in temperature should lead to a relative increase in the rate of addition of peroxy-radicals to the double bond in cyclohexene.

Table 9.



Alkene	*t*, °C	$k_4/k_{1''}$, M^{-1}	Alkene	*t*, °C	$k_4/k_{1''}$, M^{-1}
2,3-Dimethylbut-2-ene	50	32	But-2-ene	70	110
Cycloheptene	60	34	2-Methylbut-2-ene	60	150
Cycloheptene (*in benzene*)	90	25	α-Methylstyrene	50	5.9–11.0
2-Methylpent-1-ene	70	110	Styrene	50	53–154

The second factor governing selectivity of epoxidation is the ratio of the rates of the two conversions undergone by β-peroxyalkyl radicals—decomposition with formation of alkene oxide (1″) and reaction with oxygen (copolymerisation of alkene with oxygen) (4)—competition between which has already been discussed in connection with the influence of oxygen concentration on the yield of alkene oxides (Section II). Table 9 shows that the ratios of the rate constants $k_4/k_{1''}$ for various alkenes differ more than tenfold (cf. styrene and ethylene derivatives)[10]. This is due to variation in both k_4[31] and $k_{1''}$, the latter of which increases[27] from 2000 to 700000 s^{-1} with the number of methyl groups in the β-peroxyalkyl radical. It is noteworthy also that values of $k_{1''}$, estimated from the ratio $k_4/k_{1''}$ (using values of k_4 from Ref. 31) lie in the range 10^4–10^6 s^{-1}. This is consistent with results obtained for the decomposition of β-peroxyalkyl radicals prepared from the corresponding bromo-peroxides[27].

The ratio $k_4/k_{1''}$ diminishes with rise in temperature, since estimated[26] activation energies of decomposition of β-peroxyalkyl radicals are 14–15 kcal $mole^{-1}$, whereas addition of R_2 radicals to oxygen takes place with almost zero activation energy[4]. As a consequence, oxidative polymerisation predominates at low temperatures[61,69], but rise in temperature produces an increase in yield of monomeric decomposition products of the radicals—carbonyl compounds and alkene oxides[13,61].

V. EPOXIDATION OF ALKENES BY INTERMEDIATE MOLECULAR OXIDATION PRODUCTS

We have hitherto examined known routes to the formation of alkene oxides involving free radicals. An alternative view found in the literature (the earliest idea on the mechanism of epoxidation) regards the process as involving intermediate molecular oxidation products—hydroperoxides[73–75] and cyclic peroxides having the structure[39,76,77]

However, later work showed[4] that alkene oxide and hydroperoxide are formed in parallel in the oxidation of cyclohexene, and the rate of formation of the oxiran far exceeds the rate of epoxidation by the hydroperoxide

(19)

in the absence of a catalyst. Nor were alkene oxides detected in the thermal decomposition of hydroperoxides in the presence of alkenes[78,79].

The role of cyclic peroxides (dioxetans) in the mechanism of the oxidation of alkenes, and in epoxidation in particular, has recently been the subject of renewed attention[80], for experimental results have been obtained indicating the possibility of their formation in the oxidation of certain alkenes by molecular oxygen[81]. The chemiluminescence method suggests[81] that dioxetans are formed by a radical process in chain-propagation reactions, not by direct addition of oxygen at the double bond of the alkene, as had earlier been postulated[76]. Chain formation of dioxetans has been assumed[82] also in the oxidation of pent-1-ene.

An epoxidising role of dioxetans

(20)

has been postulated for the oxidation of norbornene[83] and of 7,7-binorbornylidene[84] by singlet oxygen under conditions such that the rate of radical oxidation by triplet molecular oxygen is negligible. However, the hypothetical involvement of dioxetans in epoxidation has not yet found direct experimental confirmation. Detailed investigation of the dependence of the yield of alkene oxide on the nature and concentration of the sensitiser used and also on additions of inhibitors of free-radical reactions in the oxidation of biadamantylidene[85] indicated the occurrence of two independent processes—(i) formation of a dioxetan by a molecular process and (ii) radical epoxidation involving sensitiser molecules.

Results have been obtained recently[80] indicating a molecular mechanism of epoxidation in the oxidation of alkenes. A solution of styrene in chlorobenzene with additions of a polymeric product (of the copolymerisation of styrene with oxygen) when oxidised gives a nearly 100% yield of styrene oxide calculated on the styrene that has reacted (Fig. 3)#. Additions of an inhibitor of free-radical reactions do not halt epoxidation. Table 10 shows the changes in concentration (molarity) of styrene, benzaldehyde, and styrene oxide 20 min after addition of the inhibitor (0.01 M 1-naphthol) to the reaction mixture in the oxidation of styrene§. It is evident that the oxide accumulates as the sole reaction product under the inhibited conditions of oxidation.

It has been shown also[80,86] that such molecular epoxidising agents as hydroperoxides and peroxy-acids are absent from the reaction mixture, and that the polymeric product is a precursor of styrene oxide in the sequence of primary oxidation stages. These results suggest that oxygen transfers from the polymer molecule, the "matrix", to the double bond of the alkene. The structure of the oxygen-containing polymer is being further investigated. Perhaps the active agent in epoxidation is the dioxetan group

on the polymer matrix[80].

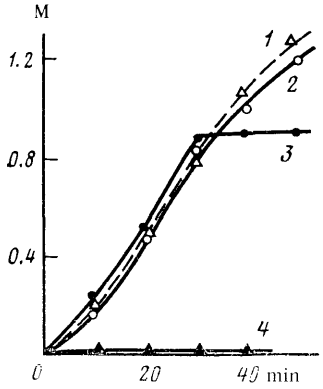


Figure 3. Rate curves for the oxidation of styrene in chlorobenzene solution with addition of 30 vol.% of a styrene–oxygen copolymer[80] at 120 °C: 1) consumption of styrene ($[RH]_0-[RH]_{inst}$); 2) accumulation of styrene oxide; 3) accumulation of benzaldehyde; 4) accumulation of polymeric product.

Table 10.

Styrene	oxide Styrene	Benzaldehyde
1.25 — 1.00	0.42 — 0.62	0.30 — 0.32

Thus the above results[80,81,86] indicate that formation of alkene oxides involving peroxy-radicals is not the sole mode of epoxidation. Under certain conditions a molecular mechanism makes a contribution to epoxidation. Its inclusion provides an explanation of facts that are not covered in generally accepted schemes of epoxidation.

Benzaldehyde is formed by decomposition of the polymeric product.

§ The initial concentration of styrene was 1.8 M, and that of the polymeric product 30 vol.%; the solvent was chlorobenzene, and the temperature 120 °C.

Sterically Hindered Porphyrins

A.V.Bogatskii and Z.I.Zhilina

Data on the chemistry of sterically hindered porphyrins as well as dimeric and trimeric prophyrins are examined and described systematically. Attention has been concentrated on sterically hindered porphyrins as synthetic models of natural oxygen-transferring agents—haemoglobin and myoglobin.
The bibliography includes 94 references.

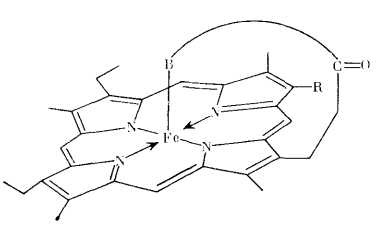
I. INTRODUCTION

Iron-porphyrins are classified in terms of their functions as the prosthetic groups of an important class of proteins and enzymes—haemi- and haemo-proteins[1-3]. The main function of natural haemoproteins such as haemoglobin and myoglobin is based on their ability to combine reversibly with oxygen. The structures of haemoglobin[4] and myoglobin[5] have been determined by X-ray diffraction. The studies by Perutz and Kendrew showed that the iron-porphyrin complex is located in a hydrophobic "protein pocket". The iron atoms in the molecules of both proteins are coordinated to the four nitrogen atoms of protoporphyrin-IX and to the nitrogen atom of the imidazole ring in the histidine residue forming part of the polypeptide chain of the haemoglobin molecule. In oxygenation a second azial ligand (oxygen) is added. The decisive factor in the biological function of haemoproteins is the spin state of iron. In haemoglobin and myoglobin the Fe^{II} atom is pentacoordinate in the deoxy-form. The high-spin form has an ionic radius which is too large for the Fe^{II} atoms to be accommodated within the cavity of the porphyrin. The iron atom in the high-spin state lies outside the limits of the plane of the four nitrogen atoms of porphyrin towards the "proximal" imidazole.

Whereas the Fe^{II} atom is hexacoordinate, the low-spin iron atom of the diamagnetic oxyhaemoglobin or oxymyoglobin lies within the cavity in the porphyrin ring. It can be assumed that Fe^{II} oscillates very rapidly between these states and that the part of the protein molecule linked directly to the iron atoms via the "proximal" imidazole also undergoes rapid changes[6].

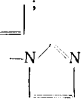


The nature of the regulation of the oxygen affinity, of the control of the axial binding, and of the means used by the protein to ensure the kinetic stability of the dioxy-form in haemoglobin and myoglobin can be most readily understood by obtaining and fully characterising model compounds which are capable of binding oxygen reversibly. In recent years the problem of such modelling has aroused much interest. Various teams of investigators have devoted their attention to problems of the modelling of natural haemoproteins based on metalloporphyrins.

In modelling account is usually taken of the following factors[7]: (1) the steric hindrance around the "active centre"; (2) the role of the "proximal" imidazole in coordination to the Fe^{II} atom in the 5-position; (3) the influence of the "distal" imidazole on the kinetic stability of the oxy-form of haemoglobin and myoglobin and the search for ways of modelling it; (4) the basicity of the "proximal" imidazole; (5) the characteristics of the stereochemistry of the "hydrophobic pocket" formed by the protein around haem and the search for ways of its chemical modelling.

By virtue of the advances in the development of bioorganic chemistry, a need has arisen for well-defined dinuclear metal complexes such as haemoerythrin, haemocyanine[6], and superoxide disnutase, which serve as models of various metalloenzymes[6,8]. Model systems which are of interest from the standpoint of the study of interionic interactions have also been synthesised[9,10]. Since 1973, the principal trend in the development of the chemistry of porphyrins has been the creation of model compounds on the basis of sterically hindered porphyrins. The present review is devoted to the analysis of the literature on this extremely interesting question published during the last seven years.

II. THE SYNTHESIS AND PROPERTIES OF STERICALLY HINDERED PORPHYRINS



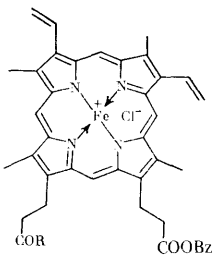
In contrast to haemoglobin and myoglobin which are capable of being reversibly oxygenated, simple iron-porphyrins are rapidly and irreversibly oxidised by atmospheric oxygen. Wang[11] was the first to establish that simple porphyrins can undergo reversible oxidation when they are placed in a specially prepared polymer film. Somewhat later, a series of papers were published[12-17] describing the reversible attachment of oxygen to Fe^{II}-porphyrins (I) in solutions at a low temperature. In these experiments, compounds (I) were modified in such a way that the base was covalently bound to the carboxy-groups in the porphyrin ring:

(I)

(a) R = H, B = $-NH(CH_2)_3-$  ;

(b) R = $-CH_2CH_2COOCH_3$, B = $-NH(CH_2)_3-$  ;

(c) R = $-CH_2CH_2CONH(CH_2)_3-$  , B = $-NH(CH_2)_3-$  ;



(d) R = $-CH_2CH_2COOCH_3$, B = $-O(CH_2)_3-$  ;

(e) R = $CH_2CH_2COO(CH_2)_3-$  , B = $-O(CH_2)_3-$  .

Pyrroporphyrin-*N*[3-(1-imidazolyl)propyl]amide (Ia) has been obtained[12] by treating pyrroporphyrin-XV [18] with 1-(3-aminopropyl)imidazole at room temperature in a solvent mixture (2:1:1 methylene chloride–acetone–pyridine); the amides (Ib) and (Ic) have been obtained[15] by treating the acid chloride of the monomethyl ester of mesoporphyrin-IX with 1-(3-aminopropyl)imidazole, while compounds (Id) and (Ie) [15] have been synthesised by treating the acid chloride of the monomethyl ester of mesoporphyrin-IX with 3-(3-pyridyl)-1-propanol.

In contrast to these methods, a number of workers[19–21] used the methyl ester of histidine and substituted histidine-containing peptides as ligands in iron-haemin. The peptides comprised the methyl ester of t-butoxycarbonyl-leucyl-histidine, the benzyl ester of t-butoxycarbonylhistidyl-leucylglycyl-*S*-benzylcysteine, and the benzyl ester of t-butoxycarbonyl-leucylhistidylalanyl-*S*-benzyloxycarbonyl-lysylglycyl-*N*-benzylcysteine[19–21].

A series of *C*-aminoacyl derivatives of haemin (IIb)–(IIf) have been obtained from the monobenzyl ester of haemin (IIa):[20]

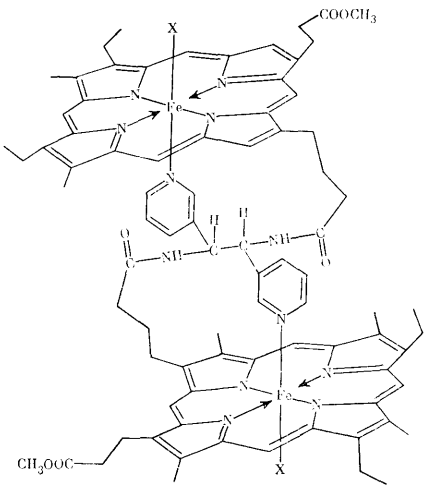
(II)

(a) R=OH;

(b) R = Ala — OMe;

(c) R = His — OMe;

(d) R = Leu—His—OMe



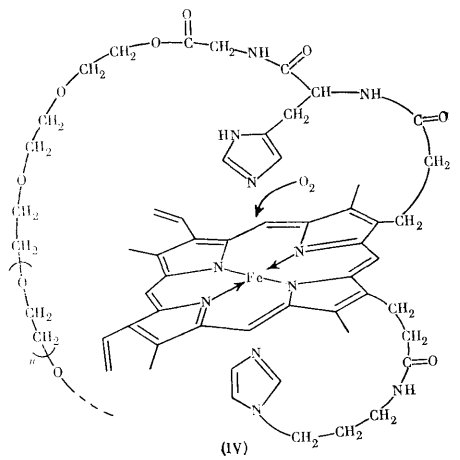
(e) R = Leu—His—Leu—Gly—Lys(Bz)—OBz

(f) R = Leu—His—Ala—Lys(Z)—Gly—Lys(Bz)—OBz.

Compounds (IIb)–(IIf) were synthesised by condensing the monobenzyl ester of haemin with the methyl esters of alanine and histidine and also with the *N*-unsubstituted di-, penta- and hexa-peptides enumerated above—by the mixed anhydride method involving interaction with ethyl chloroformate in dimethylformamide (DMF) in the presence of triethylamine. The bis-*C*-aminoacyl derivatives of haemin have been obtained analogously[19].

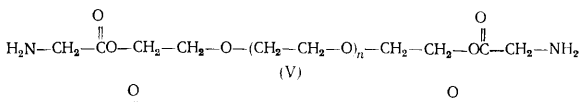
It has been shown[20] that the pentacoordinate complexes of iron-porphyrins, obtained by reducing compounds (IIe) and (IIf) with an aqueous solution of sodium dithionite in an atmosphere of nitrogen, are able to combine reversibly with oxygen in the course of 35–40 min at room temperature.

In order to investigate the interaction of haem molecules within a single conformational system, Traylor et al.[22] obtained the model compound (III) from the monomethyl ester of mesoporphyrin and 1,2-di-(3-pyridyl)ethylenediamine[23], in which two haem molecules are conformationally linked via the common central ethylenic linkage. Any change in the conformation of the "upper" iron-containing porphyrin ring must influence the conformation of the identical "lower" ring via this bond. Compound (III) combines reversibly with oxygen in solution, being converted into compound (IIIb), and reacts with carbon monoxide in two stages (in contrast to model monohaem compounds[24,25]), forming compound (IIIc): (a) X absent; (b) X = O_2; (c) X = CO.



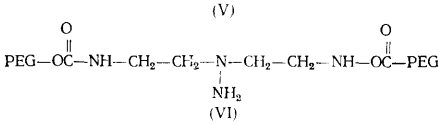
(III)

In 1977 German investigators[26] synthesised the haem polymer (IV) capable of reversible transfer of molecular oxygen. This haem polymer had the properties of the natural oxygen carrier—haemoglobin: high solubility in water, difficult irreversible oxidation of the oxygen complex by the functional polymer, and similarity to the "distal" imidazole. The principal initial polymers were poly(ethylene glycol)–bis-(glycine ester) (V) [27] and the polyurethane (VI) obtained from poly(ethylene glycol) (PEG) and di-isocyanate.



Di-t-butoxycarbonylhistidine was attached to the free amino-groups of polymers (V) and (VI) by means of liquid-phase peptide synthesis[27]. After the removal of the protecting group from histidine, poly(ethylene glycol)–bis(glycyl-histidylhaemin) (VII) and the histidylhaem derivative of the polymeric urethane (VIII) were obtained.

The histidine in the polymeric haemins (VII) and (VIII) is linked to the carboxy-group of haemin via the amide group. In this structure the optimum coordination of the imidazole nitrogen atom of histidine is sterically hindered. Consequently this histidine may be compared with the "distal" histidine in myoglobin and haemoglobin.



3-(1-Imidazolyl)propylamine has been attached to two carboxy-groups of the haem polymer (VII) by liquid-phase peptide synthesis[26] and compound (IV) was obtained. The imidazole residue in the polymeric haemin (IV) is optimally coordinated to the iron atom. In this haem polymer the oxygen coordination site is shielded both by histidine and by the synthetic polymer. The iron(II) complex of the haem polymer (IV) is readily soluble in water and combines reversibly with oxygen in solution. After frequent repetitions of the oxygen addition and liberation process, complex (IV) is oxidised to a haemin polymer, which, however, can be again reduced to compound (IV). The reversible oxygenation cycle is then again repeated.

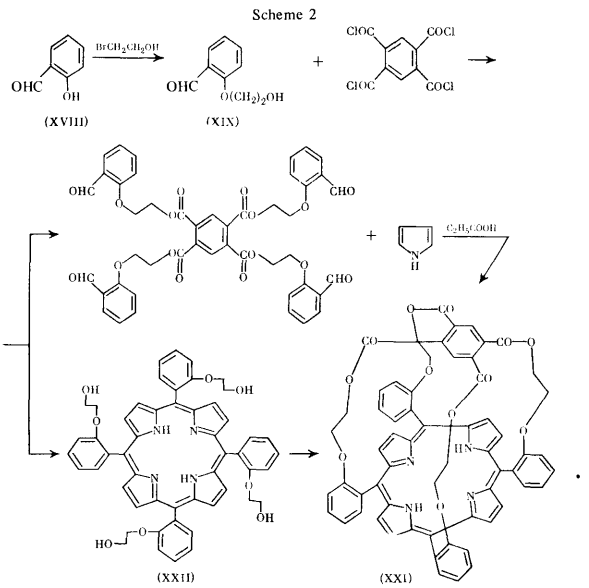
The copper and iron complexes of the first cyclophane (bridged) porphyrin compounds (XVI) and (XVII) were obtained for the first time by Diekman et al [28] from dipyrromethenes (XIV) linked by both ends of the aromatic chain. Friedel–Crafts acylation of 5-ethoxycarbonyl-2,4-dimethylpyrrole (X) [29] with the acid dichloride (IX) in the presence of aluminium chloride and nitrobenzene yielded dipyrrole (XI), [30] whose keto-group was reduced with B_2H_6 in tetrahydrofuran (THF) with formation of compound (XIIa): [31]

Scheme 1

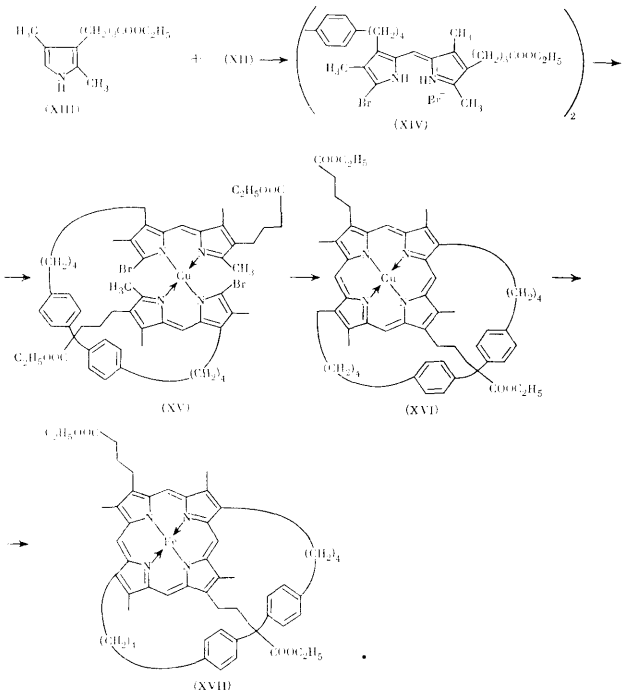


(IX) (X)

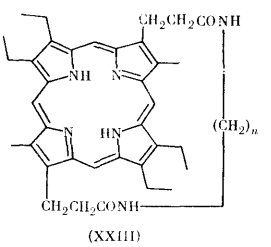
(XI) (XII)

(a) R^1=CH_3, R^2 = $COOC_2H_5$; (b) R^1=CH_3, R^2=$COOC_6H_5$; (c) R^1=CHO, R^2=$COOC_6H_5$; (d) R^1=CHO, R^2=COOH

Scheme 2



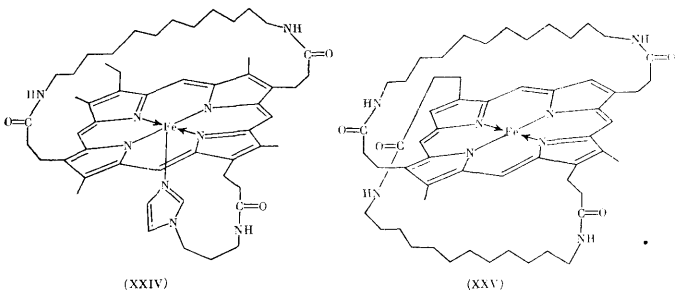
(XVIII) (XIX) (XXII) (XXI)



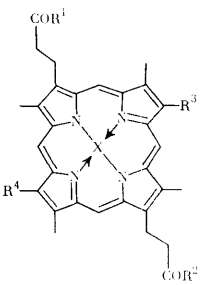
Transesterification with sodium benzilate and subsequent treatment with sulphuryl chloride in the presence of diethylamine then gave rise to the aldehyde (XIIc), the catalytic hydrogenolysis of which led to compound (XIId). [32,33] Condensation of the substituted pyrrole (XIId) with the substituted pyrrole (XIII) [34] in the acetic acid–hydrogen bromide mixture followed by bromination of the product led to the formation of dibromopyrromethene (XIV). [35] On treatment with copper acetate in the presence of ammonia, the latter forms the copper complex (XV), which cyclises on heating in xylene with formation of the copper complex of the cyclophane porphyrin (XVI). [36] The free porphyrin is formed from compound (XVI) under the influence of sulphuric acid. Complex (XVII), containing iron(III), was obtained from the free porphyrin by treatment with iron sulphate (Scheme 1).

The second cyclophane porphyrin (XXI), called the capped porphyrin, has been obtained by Baldwin and coworkers [37–39]. The crystalline iron(II) complex of this model undergoes reversible oxygenation in solution in pyridine or benzene containing *N*-methylimidazole; the oxygenation of the iron(II) complex of the model compound (XXI) in solution in pyridine requires 20 h. [38] The capped porphyrin (XXI) has been obtained [82] by the direct condensation of the tetra-aldehyde (XX) with pyrrole in propionic acid. The tetra-aldehyde (XX) has been obtained by alkylating salicylaldehyde (XVIII) with the aid of bromohydrin to the corresponding ester (XIX), which was converted into compound (XX) by interaction with pyromellitic acid chloride in a THF–triethylamine mixture [37] (Scheme 2). The capped porphyrin (XXI) has also been synthesised by esterifying compound (XXII) with pyromellitic

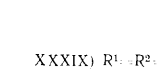
acid chloride[37]:



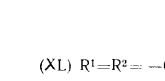
Japanese investigators[40–43] synthesised a series of cyclophane porphyrins (XXIII) with different lengths of the aliphatic bridge connecting the symmetrically located carboxy-groups of the propionic acid residues of the porphyrin:

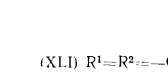


The interaction of 4,8-di-(2-carboxyethyl)-1,2,5,6-tetraethyl-3,7-dimethylporphyrin[44] with diamines $NH_2(CH_2)_nNH_2$, where n = 6, 7, 8, 9, 10, or 12, and also (for comparison) with propylamine in the presence of isobutyl chloroformate and triethylamine in THF under the conditions of high dilution, the reaction products being subsequently treated with zinc or iron acetate, yielded the corresponding complexes of cyclophane porphyrins[43].

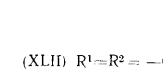


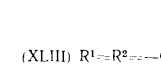
Compounds (XXIV) and (XXV), which are models of haemoglobin and myoglobin, have been obtained[45,46] from porphyrins in which the "bridges" form a belt around the porphyrin ring on either side of its plane. The necessary initial porphyrins (XXVI), (XXVII), and (XXVIII) were obtained via *ac*-biladienes[47]:



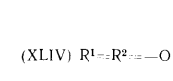


Scheme 3





(XXVI) R^1 = OH, R^2 = OH, R^3 = R^4 = H, X = 2H;
(XXVII) R^1 = OH, R^2 = OH, R^3 = $COOC_2H_5$, R^4 = H, X = 2H;
(XXVIII) R^1 = OH, R^2 = OH, R^3 = $COOC_2H_5$, R^4 = $COOC_2H_5$, X = 2H;
(XXIX) R^1 = Cl, R^2 = Cl, R^3 = R^4 = H, X = 2H;
(XXX) R^1 = $-O(CH_2)_4C{\equiv}CH$, R^2 = $-O(CH_2)_4C{\equiv}CH$, R^3 = R^4 = H, X = 2H;
(XXXI) R^1 = $-O(CH_2)_4C{\equiv}CH$, R^2 = $-O(CH_2)_4C{\equiv}CH$, R^3 = R^4 = H, X = $Fe^{III}Cl$;
(XXXII) R^1 = R^2 = $-O(CH_2)_4C{-}C{\equiv}C{-}C(CH_2)_4O$, R^3 = R^4 = H, X = $Fe^{III}Cl$;
(XXXIII) R^1 = R^2 = $-O(CH_2)_4C{-}C{\equiv}C{-}C{-}(CH_2)_4O$, R^3 = R^4 = H, X = Cu;
(XXXIV) R^1 = R^2 = $-O(CH_2)_{12}O$, R^3 = R^4 = H, X = Cu;
(XXXV) R^1 = R^2 = $-O(CH_2)_{12}O$, R^3 = R^4 = H, X = 2H;
(XXXVI) R^1 = R^2 = $-NCH_3(CH_2)_5COCH_3$, R^3 = R^4 = H, X = 2H;
(XXXVII) R^1 = R^2 = $-NCH_3(CH_2)_5CO(CH_2)_5NCH_3$, X = 2H;
(XXXVIII) R^1 = R^2 = $-NH(CH_2)_{12}NH$, R^3 = R^4 = H, X = 2H;



XXXIX) R^1 = R^2 = $-O(CH_2)_3$–  –$(CH_2)_3O$, R^3 = R^4 = H, X = 2H;

(XL) R^1 = R^2 = $-O(CH_2)_3$–  –$(CH_2)_3O$, R^3 = R^4 = H, X = 2H;

(XLI) R^1 = R^2 = $-O(CH_2)_3$–  –$(CH_2)_3O$, R^3 = R^4 = H, X = 2H;

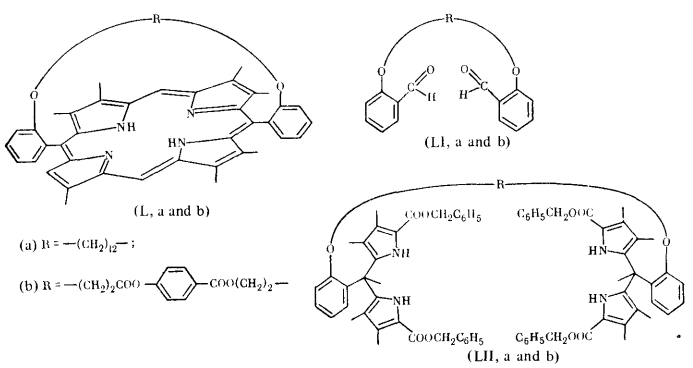
(XLII) R^1 = R^2 = $-O(CH_2)_3$–  –$(CH_2)_3O$, R^3 = R^4 = H, X = $Fe^{III}Cl$;

(XLIII) R^1 = R^2 = $-O(CH_2)_3$–  –$(CH_2)_3O$, R^3 = R^4 = H, X = $Fe^{III}Cl$;

(XLIV) R^1 = R^2 = $-O(CH_2)_3$–  –$(CH_2)_3O$, R^3 = R^4 = H, X = $Fe^{III}Cl$;

(XLV) R^1 = R^2 = $-NH(CH_2)_{12}NH$, R^3 = $-CONH(CH_2)_3$–  ,

R^4 = H, X = 2H;

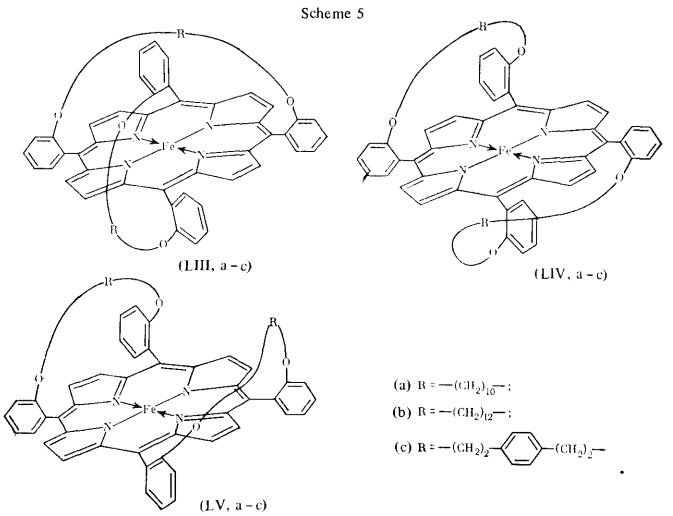


(XLVI) R^1 = R^2 = $-NH(CH_2)_{12}NH$, R^3 = $-COOC_2H_5$, R^4 = H, X = 2H;
(XLVII) R^1 = R^2 = $-NH(CH_2)_{12}NH$, R^3 = R^4 = $-CONH(CH_2)_{12}NHCO$, X = 2H;
(XLVIII) R^1 = R^2 = $-NH(CH_2)_{12}NH$, R^3 = R^4 = $-CONH(CH_2)_{12}NHCO$, X = $Fe^{III}Cl$;

(XLIX) R^1 = R^2 = $-NH(CH_2)_{12}NH$, R^3 = $-CONH(CH_2)_3$–  , R^4 = H, X = $Fe^{III}Cl$.

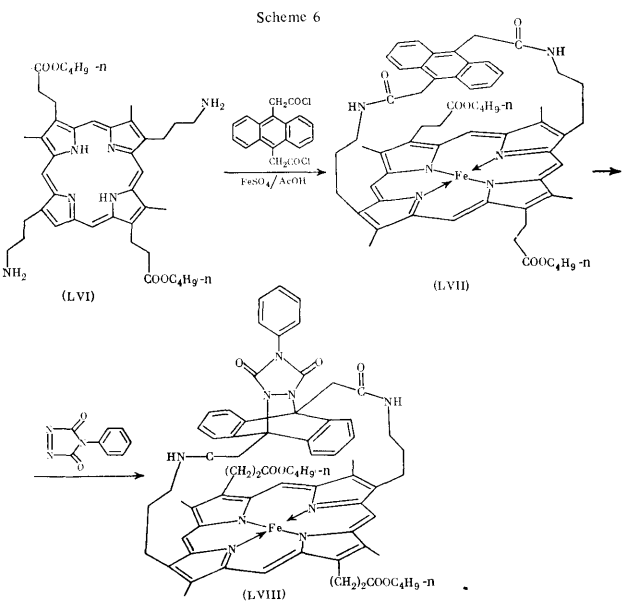
The acid dichloride (XXIX) was made to react with hex-5-yn-2-ol [48], which led to the formation of the corresponding diester (XXX). The oxidation of the iron(III) complex of the diester (XXXI) with copper acetate in the pyridine–ether mixture leads to the bridged porphyrin (XXXII).[49] When the metal-free diester (XXX) is oxidised, the copper complex of the bridged porphyrin (XXXIII) is obtained. Reduction of the latter yielded the porphyrin (XXXIV); its demetallation leads to compound (XXXV). The diamide (XXXVI) has been obtained[50] by the reaction of the acid dichloride (XXIX) with $CH_3NH(CH_2)_5COOCH_3$. When the diamide (XXXVI) is refluxed with t-BuOK in toluene, the bridged porphyrin (XXXVII) is obtained[50]. Condensation of the acid dichloride (XXIX) with 1,12-diaminododecane at a high dilution[43] leads to the bridged porphyrin (XXXVIII) and the reaction of the acid dichloride (XXIX) with 2,6-di(γ-hydroxypropyl)pyridine, 3,5-di(γ-hydroxypropyl)pyridine, and 3,5-di(γ-hydroxypropyl)dimethylpyridine yielded the bridged porphyrins (XXXIX)–(XLI) respectively[46]. The complexes (XLII)–(XLIV) have been synthesised by a standard method[51]. The cyclophane porphyrin (XLV) with a covalently bound ligand has been obtained[46] by the reaction of the acid chloride corresponding to compound (XLVI) with 3-aminopropylimidazole. A series of successive transformations of the diethyl ester of the tetracarboxylic acid (XXVIII) led to the formation[46] of the porphyrin (XLVII) in which two "bridges" are located on either side of the plane of the porphyrin ring system (Scheme 3). The introduction of iron[51] into the bridged porphyrins (XLV) and (XLVII) made it possible to obtain the models (XLVIII) and (XLIX) of the active centres in myoglobin and haemoglobin.

The bridged ("belted") porphyrins (L) (Scheme 4) have been obtained[52] by the direct condensation of the dialdehydes (LI, a and b) with the benzyl ester of 3,4-dimethylpyrrole-2-carboxylic acid in the presence of hydrogen chloride with subsequent catalytic debenzylation of the intermediate (LII).[53] The dialdehyde (LIa) has been synthesised by the condensation of salicylaldehyde with 1,12-dibromododecane and the dialdehyde (LIb) has been obtained from *o*-(β-hydroxyethyl)-benzaldehyde by reaction with terephthalic acid dichloride[52].



Scheme 4

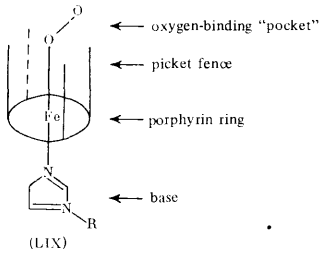
The acid condensation of 1,10-di(2′-formylphenoxy)decane, 1,12-di(2′-formylphenoxy)dodecane, and 1,4-di[γ-(2′-formylphenoxy)propyl]benzene with pyrrole by the method of Kim et al.[54] yielded porphyrins of the "basket handle" type[55]. The three isomers (LIII), (LIV), and (LV) with crossing *trans*-binding, adjacent *trans*-binding, and adjacent *cis*-binding respectively, have been isolated by preparative chromatography (Scheme 5).



If the solution contains *N*-methylimidazole, then the iron(II) complexes of compounds (LIII), (LIV), and (LV) initially combine with two *N*-methylimidazole molecules, forming hexacoordinate complexes. The formation of these complexes with the isomers (LIII, a–c) requires a large excess of *N*-methylimidazole, apparently due to steric hindrance. When atmospheric oxygen is passed into a solution containing these complexes, one of the ligands (*N*-methylimidazole) is displaced by the oxygen. The oxygenating complexes formed are extremely stable[55].

Scheme 5

In order to increase the steric effects of the "distal" side of compounds modelling haemoglobin and myoglobin, the cyclophane porphyrins (LVII) and (LVIII) have been obtained[56] (Scheme 6).



Scheme 6

The model compound (LVII) has been synthesised by the reaction of the diamino-derivative of the porphyrin (LVI) with the dichloride of anthracene-9,10-dicarboxylic acid[57]. The effect of the steric shielding of the "distal" side of the

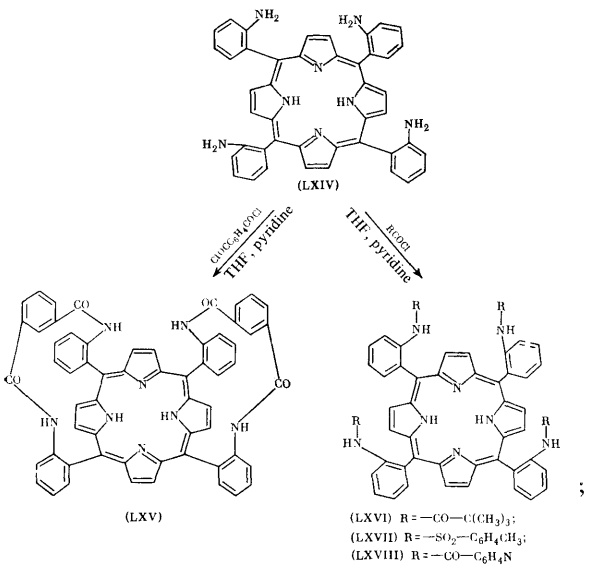
model compound (LVIII) has been enhanced by the Diels–Alder reaction of the model compound (LVII) with 1-phenyltriazine-2,5-dione.

New sterically hindered porphyrins of the so-called "picket fence" type (LIX) have been synthesised[58–68]:

The acid condensation of *o*-nitrobenzaldehyde and pyrrole followed by the reduction of the product yielded *meso*-tetra-(*o*-aminophenyl)porphyrin (LX), which is a mixture of four atropisomers[59]. All the isomers have been isolated by preparative chromatography and have been identified on the basis of the results of Gottwald and Ullman[69] as the α,β,α,β-atropisomer (LXI), the α,α,β,β-atropisomer (LXII), the α,α,α,β-atropisomer (LXIII) and the α,α,α,α-atropisomer (LXIV).

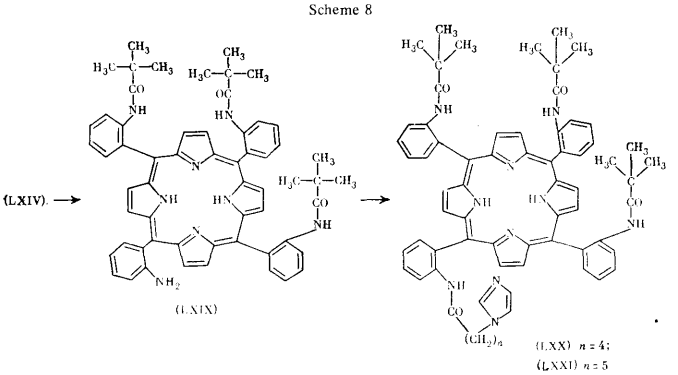
The tetra-amides (LXV)–(LXVIII) have been synthsised by the reaction of *meso*-tetra-α,α,α,α-(*o*-aminophenyl)porphyrin with the chlorides of isophthalic, trimethylacetic, toluene-*p*-sulphonic, and nicotinic acids[58] (Scheme 7).

The interaction of compound (LXIV) with a limited amount of the chloride of trimethylacetic acid resulted in the formation of *meso*-tri-α,α,α-(*o*-pivalamidophenyl)-β-(*o*-aminophenyl)porphyrin (LXIX). Treatment of compound (LXIX) with 4-(*N*-imidazolyl)butyl chloride and 5-(*N*-imidazolyl)-penyl chloride led to the formation of the amides (LXX) and (LXXI) respectively[68] (Scheme 8).



The iron(II) complexes of compounds (LXV)–(LXVIII), (LXX) and (LXXI) have been obtained by reducing the corresponding iron(III) complexes with chromium acetylacetonate. Their pentacoordinate and hexacoordinate compounds with axial ligands have also been obtained. After isolation, the crystalline oxygenating complexes of compounds (LXVI), (LXX), and (LXXI) are stable for a long time both in the solid state and in solution[58,68].

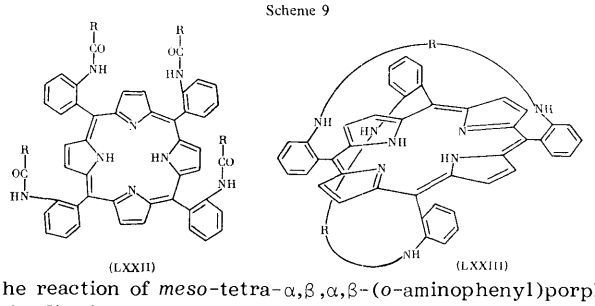
The iron(II) complexes of compounds (LXX) and (LXXI), in which one of the substituents is a base, namely 4-(*N*-imidazolyl)butyl or 5-(*N*-imidazolyl)pentyl, are of special interest. The length and conformation of this substituent can be controlled, which has a significant influence on the oxygen affinity.



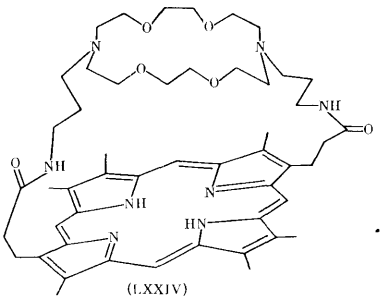
Bogatskii et al.[70] synthesised the "picket fence" and "belted" porphyrins (LXXII) and (LXXIII).

The steric shielding of one side of the porphyrin ring in the model compounds *meso*-tetra-α,α,α,α-(*o*-adamantamidophenyl)porphyrin (LXXIIa), *meso*-tetra-α,α,α,α-[*o*-3,4,5-trimethoxybenzamido)phenyl]porphyrin (LXXIIb), *meso*-tetra-α,α,α,α-(*o*-trimethylacetoamidophenyl)porphyrin (LXXIIc),[58] *meso*-tetra-α,α,α,α-(*o*-aminoacetamidophenyl)porphyrin (LXXIId), and *meso*-tetra-α,α,α,α-(*o*-acetamidophenyl)-porphyrin (LXXII) has been achieved using acid residues of different bulk (Scheme 9).

Scheme 7

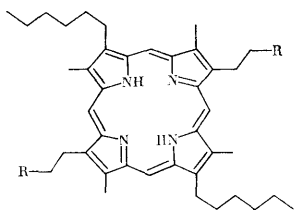


Scheme 8



The tetra-amides (LXXII, a–e), where R = adamantyl for (a), R = 3,4,5-$(CH_3O)_3C_6H_2$ for (b), R = $C(CH_3)_3$ for (c), R = CH_2NH_2 or $-COCH_2OCH_2CH_2OCH_2CO-$ for (d), and R = CH_3 for (e), have been obtained by the reaction of *meso*-tetra-α,α,α,α-(*o*-aminophenyl)porphyrin (LXIV) [58] with the chlorides of adamantanecarboxylic, 3,4,5-trimethoxybenzoic, acetic, aminoacetic, and trimethylacetic acids in a THF–pyridine mixture at room temperature.

Scheme 9



The reaction of *meso*-tetra-α,β,α,β-(*o*-aminophenyl)porphyrin (LXI) with the acid dichloride of triethyleneglycolic acid in a THF–pyridine mixture at a high dilution[43] yielded the cyclophane porphyrin (LXXIII) in which the two "bridges" form a belt around the porphyrin on either side. These porphyrins also form complexes capable of reversible oxygenation.

The crown-porphyrin (LXXIV) was obtained by Chang[57]. This dinuclear ligand permits the subsequent synthesis of composite complexes with both identical and different metals.

(LXXIV)

Dihexyldeuteroporphyrin (LXXVb) was chosen as the initial porphyrin for the synthesis of compound (LXXIV) because of its high solubility in organic solvents, which is very important for the successful separation and purification of the final bicyclic products from the starting material.

(f) R = —$CH_2NHCH_2C_6H_5$

The hexyl side chains were introduced into the pyrrole components by acylating the pyrrole (LXXVI) in the presence of tin(IV) chloride with subsequent reduction of the resulting pyrrole (LXXVII).[71] Treatment of the pyrrole (LXXVIII) with sulphuryl chloride at high dilution yielded[72] the pyrrolealdehyde (LXXIX). After catalytic debenzylation, the free acid (LXXIXb) was mixed with an equimolar amount of the acid (LXXX)[73] and was treated with 48% hydrobromic acid at the boiling point. The pyrromethene (LXXXI) was formed instantaneously. After the removal of the solvent, the pyrromethene was subjected to self-condensation in hot formic acid in the presence of an excess of bromine, which resulted in the formation of the porphyrin (LXXVa); the latter can also be obtained in a high yield by condensing the pyrrole (LXXVIIIb) and the pyrrolealdehyde (LXXXII) via the intermediate dipyrromethene (LXXXI)[57] (Scheme 10).

Scheme 10

The crown-ether component was synthesised from diaza-18-crown-6 derivative (LXXXIII).[74] The cyanoacetylene side chains were introduced by stirring the initial compound (LXXXIII) in acrylonitrile for 72 h. The diaminopropyl derivative of compound (LXXXIV) was obtained by reducing the cyano-group of compound (LXXXIV) in the presence of Raney nickel in a methanol solution of ammonia. The two ligands were coupled under the conditions of high dilution[57]. Compounds (LXXXVc) and (LXXXIVb) were poured simultaneously into a stirred 1 : 1 benzene–methylene chloride mixture over a period of 4 h. The crown-porphyrin (LXXIV) was isolated by column chromatography (Scheme 11):

Scheme 11

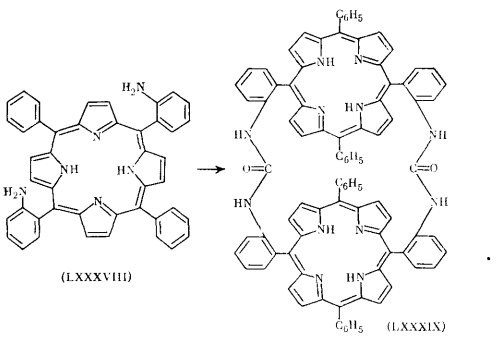
In the presence of *N*-methylimidazole and *N*-isobutylimidazole the iron(II) complex of the model compound (LXXIV) gives rise to a visible absorption spectrum typical for a hexacoordinate haemochrome compound. For a larger ligand, such as 1-triphenylmethylimidazole, the visible spectrum differs appreciably from the haemochrome spectrum; the oxygen-saturated specimen is stable at 25 °C for 1 h.[57]

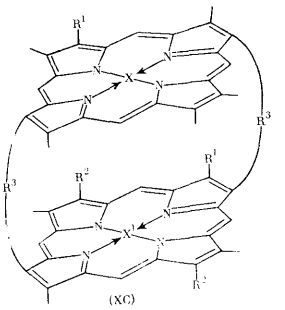
III. PORPHYRIN DIMERS AND TRIMERS

Dimeric porphyrins of the "face-to-face" type (LXXXVII) and (LXXXIX) were first obtained by Collman et al.[75] Condensation of pyrrole (2 equivalents) with benzaldehyde (1 equivalent) and 2-nitrobenzaldehyde (1 equivalent) yielded a mixture of mono-di-, tri-, and tetra-(o-nitrophenyl)-porphyrin isomers and atropisomers. The reduction of the mixture of dinitroporphyrins, isolated by preparative chromatography, with tin(II) chloride led to a mixture of diaminoporphyrins, whose separation yields the α,α-*cis*-diaminoporphyrin (LXXXV)† and the *trans*-isomer (LXXXVIII).



A solution of the diaminoporphyrin isomer (LXXXV) in benzene containing traces of pyridine was treated with phosgene and the excess phosgene was then removed. The

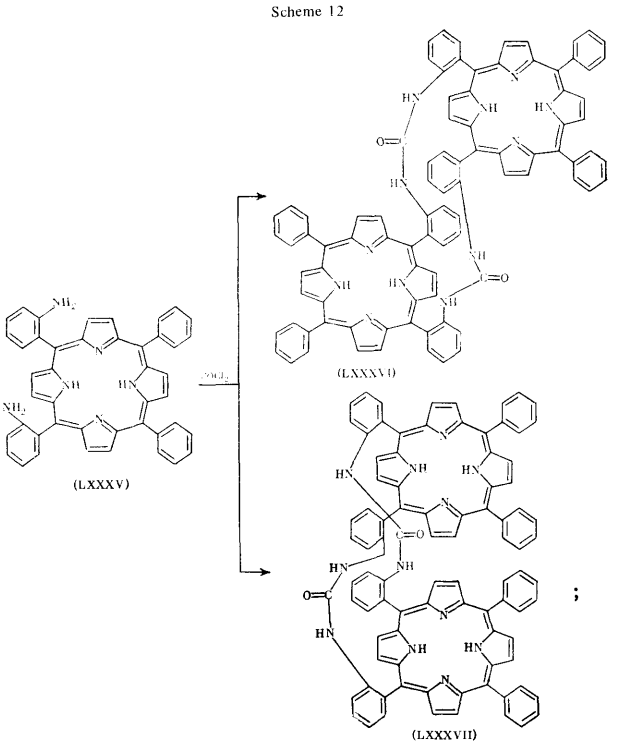
†The symbols α and β denote the opposite surfaces of the porphyrin plane; the *cis*- and *trans*-positions denote the adjoining and opposite *meso*-positions in tetraphenylporphyrins. Thus compound (LXXXV) is called 5-α-10-α-di(2-aminophenyl)-15,20-diphenylporphyrin or α,α-*cis*-diaminoporphyrin.



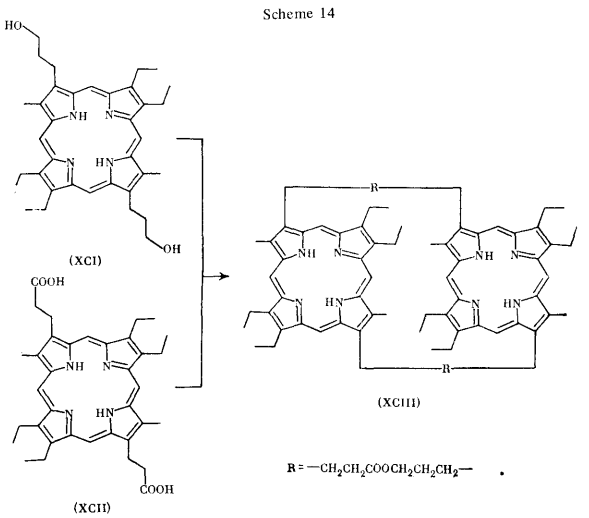
resulting solution was treated with an equivalent amount of a benzene solution of compound (LXXXV) (in nitrogen at 25 °C). Two diporphyrins, (LXXXVI) and (LXXXVII), linked by two urea "bridges", were obtained in this way. The porphyrin rings in the diporphyrin (LXXXVI) are located on different sides relative to one another, while in compound (LXXXVII) the porphyrin rings are arranged one above the other (Scheme 12). When α,α-*trans*-diaminoporphyrin (LXXXVIII) is used as the starting compound, only a single diporphyrin (LXXXIX) is formed. Two of the binary porphyrins (LXXXVII) and (LXXXIX) obtained are in the "face-to-face" conformation. The distance between the porphyrin rings in the copper and cobalt complexes of these compounds is approximately 6.5–6.8 Å.[75]

Diporphyrins of type (XC) [76–78] have been obtained similarly to compound (LXXIV), by the gradual introduction of equimolar amounts of the diamino-derivatives (LXXV, e and f) and the acid dichloride (LXXVc) in a methylene chloride–benzene mixture. The diporphyrin (XC) exists in the *syn*- and *anti*-isomeric forms; attempts to separate them by thin-layer chromatography were unsuccessful[76] (Scheme 13).

The dinuclear bimetallic complexes (XCc), (XCd), and (XCe), containing two identical metal atoms, have been obtained by a standard method[79]. The diporphyrin complex (XCf), containing only one copper atom, has been obtained[76] by the reaction of the copper complex (LXXVe) with the acid dichloride (LXXVc). The bimetallic complex (XCg) has been synthesised by introducing iron into the monometallic complex (XCf).[79]



Scheme 13

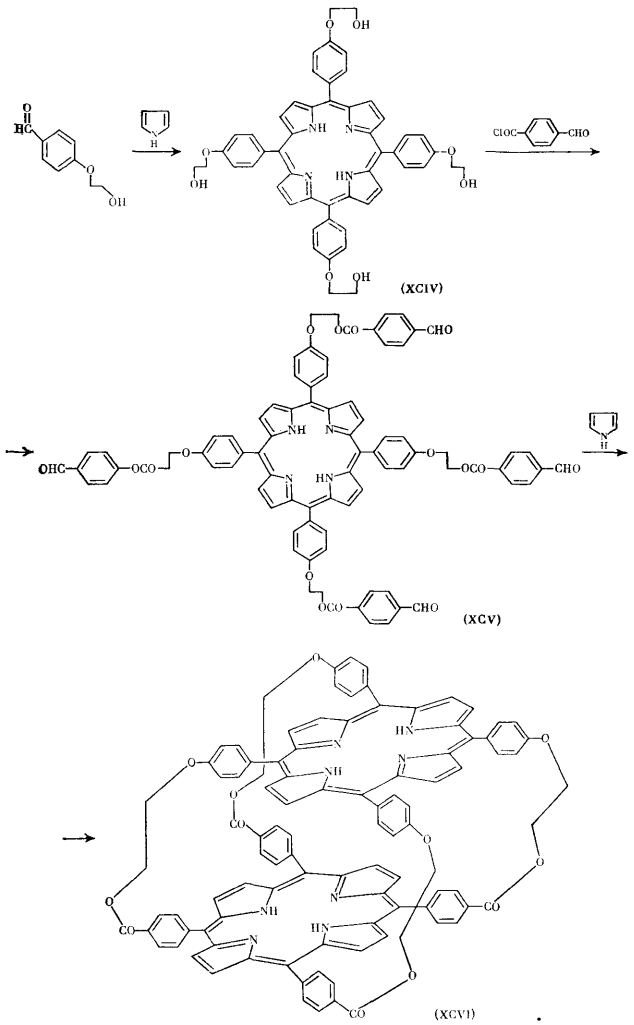


(a) $R^1=R^2=-(CH_2)_5CH_3$, $R^3=-(CH_2)_2CON(n\text{-}C_4H_9)(CH_2)_3$, $X=X^1=2H$;
(b) $R^1=R^2=-(CH_2)_5CH_3$, $R^3=-(CH_2)_2CON(CH_2C_6H_5)(CH_2)_3$, $X=X^1=2H$;
(c) $R^1=R^2=-(CH_2)_5CH_3$, $R^3=-(CH_2)_2CON(n\text{-}C_4H_9)(CH_2)_3$, $X=X^1=Fe^{III}Cl$;
(d) $R^1=R^2=-(CH_2)_5CH_3$, $R^3=-(CH_2)_2CON(n\text{-}C_4H_9)(CH_2)_3$, $X=Cu$, $X^1=Fe^{III}Cl$;
(e) $R^1=R^2=-(CH_2)_5CH_3$, $R^3=-(CH_2)_2CON(n\text{-}C_4H_9)(CH_2)_3$, $X=X^1=Zn$;
(f) $R^1=R^2=-(CH_2)_5CH_3$, $R^3=-(CH_2)_2CON(n\text{-}C_4H_9)(CH_2)_3$, $X=2H$, $X^1=Cu$;
(g) $R^1=R^2=-(CH_2)_5CH_3$, $R^3=-(CH_2)_2CON(n\text{-}C_4H_9)(CH_2)_3$, $X=Fe^{III}Cl$, $X^1=Cu$.

Scheme 12

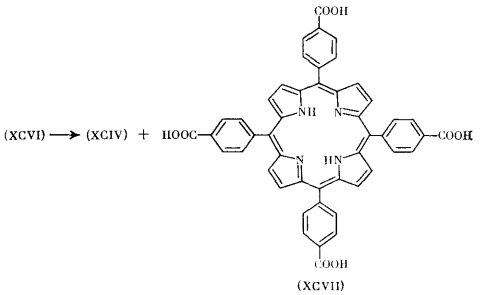
The dimeric porphyrin (XCIII),[80] in which the two porphyrin rings are joined together by an ester fragment, has been obtained by treating a solution of the 3-hydroxypropyl derivative (XCI) and the carboxyethyl derivative (XCII) with isobutyl chloroformate in THF (Scheme 14). The attempt to separate the diester (XCIII) into the *syn*- and *anti*-isomers was unsuccessful, as before.

Scheme 14



$R=-CH_2CH_2COOCH_2CH_2CH_2-$.

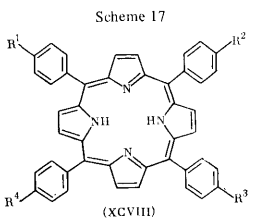
Treatment of the dimeric porphyrin (XCIII) with zinc acetate yielded[79] the corresponding bimetallic complex, for which the distance between the porphyrin rings was calculated and proved to be approximately 7 Å.



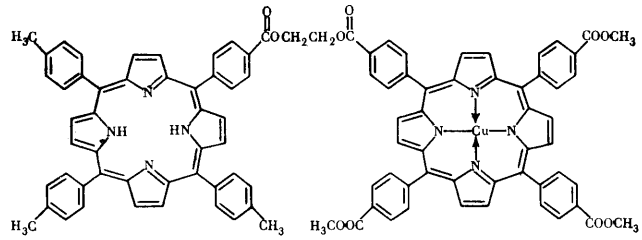
A layer (strati) diporphyrin (XCVI) has been obtained[81] by condensing the modified tetra-aldehyde (XCV) with pyrrole by the method of Adler et al.[82] The tetra-aldehyde (XCV) was obtained by the reaction of tetrahydroxyporphyrin (XCIV) with formylbenzoyl chloride[37] (Scheme 15).

Scheme 15

The structure of compound (XCVI) was proved[81] by identifying the products of its acid hydrolysis. Hydrolysis yielded only two products—compound (XCIV) and tetracarboxyporphyrin (XCVII) (Scheme 16).

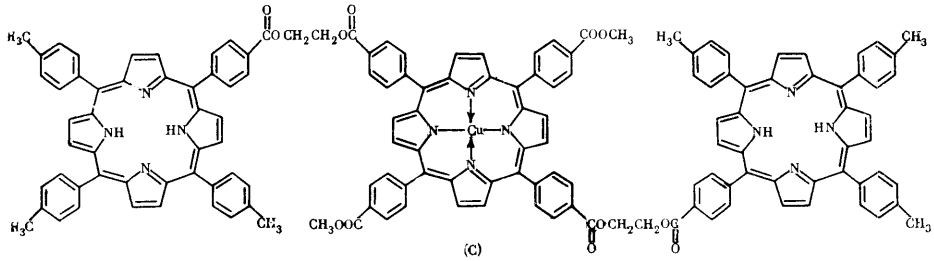


Scheme 16

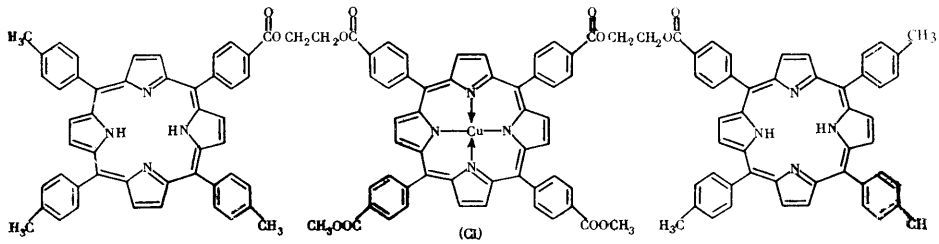


The synthesis of covalently linked porphyrins—the dimer (XCIX) and the trimers (C) and (CI)—has been achieved[83–85] and the transfer of the energy of the excited states between the two centres of the porphyrins has been investigated.

Transesterification of the tetramethyl ester (XCVIIIa) with ethylene glycol[84] leads to five isomers (XCVIII, b–f) after chromatographic separation. The condensation of 0.5 mole of *p*-toluic aldehyde, 0.1 mole of *p*-carboxybenzaldehyde, and 0.6 mole of pyrrole yielded a mixture of substituted *meso*-tetraphenylporphyrins, from which compound (XCVIIg) was isolated chromatographically[84]. The dimer (XCIX) has been obtained by the reaction of the acid chloride (XCVIIIh), synthesised by treating the corresponding acid (XCVIIIg) with oxalyl chloride, with the copper complex of 5-[4-(2-hydroxyethoxy)carbonylphenyl]-10,15,20-tri(4-methoxycarbonylphenyl)porphyrin[83]. The trimers (C) and (CI) have been obtained analogously from the copper complexes of substituted *meso*-tetraphenylporphyrins (XCVIIIc) and (XCVIIIf) respectively and the acid chloride (XCVIIIh) [84,85] (Scheme 17).

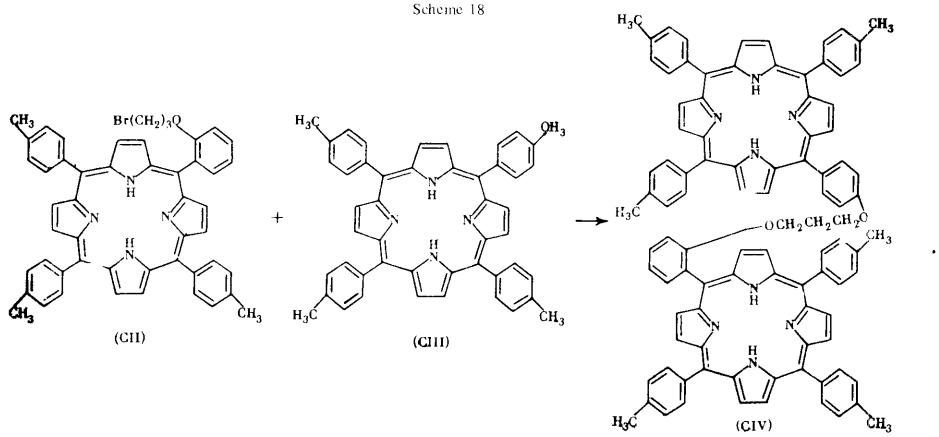


Scheme 17

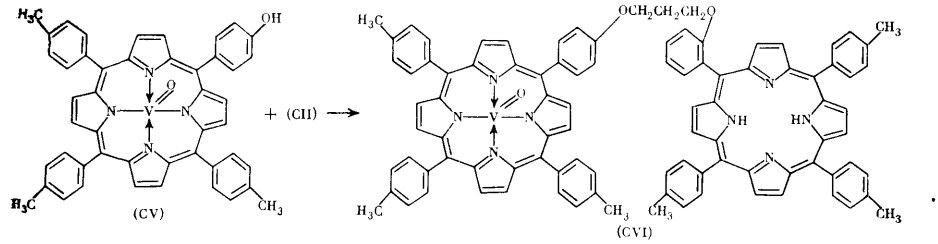


(a) $R^1=R^2=R^3=R^4=-COOCH_3$;
(b) $R^1=-COOCH_2CH_2OH$, $R^2=R^3=R^4=-COOCH_3$;
(c) $R^1=R^3=-COOCH_2CH_2OH$, $R^2=R^4=-COOCH_3$;
(d) $R^1=R^2=R^3=-COOCH_2CH_2OH$, $R^4=-COOCH_3$;
(e) $R^1=R^2=R^3=R^4=-COOCH_2CH_2OH$;
(f) $R^1=R^2=-COOCH_2CH_2OH$, $R^3=R^4=-COOCH_3$;
(g) $R^1=-COOH$, $R^2=R^3=R^4=-CH_3$;
(h) $R^1=-COCl$, $R^2=R^3=R^4=-CH_3$

(XCIX)



(C)

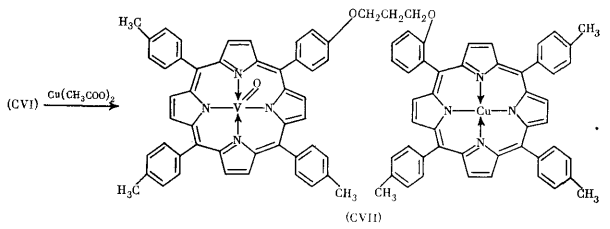


(CI)

Scheme 18

(CII) (CIII) (CIV)

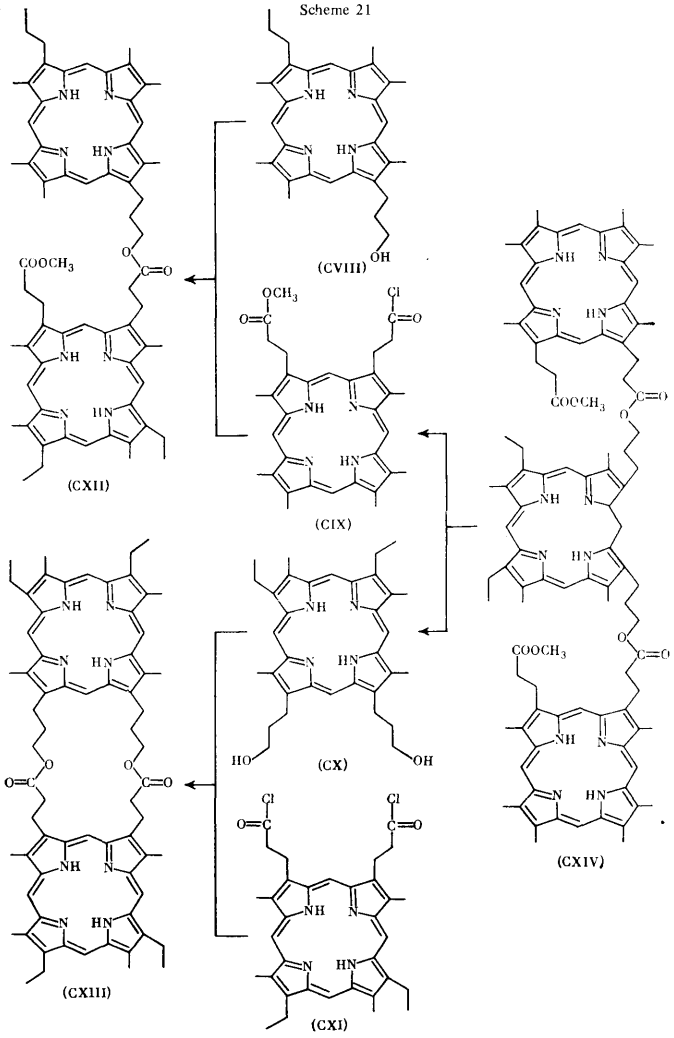
Scheme 19



(CV) (CVI)

The covalently linked dimer (CIV) has been obtained[86] by the reaction of 5-[*o*-(3-bromopropoxy)phenyl]-10,15,20-tritolylphenylporphyrin (CII) with one equivalent of 5-(*p*-hydroxyphenyl)-10,15,20-tritolylphenylporphyrin (CIII) [87] (Scheme 18).

Vanadylporphyrin (CV), obtained by the usual methods[51,88], readily reacts with the porphyrin (CI) to form the vanadium-containing dimer (CVI) (Scheme 19).

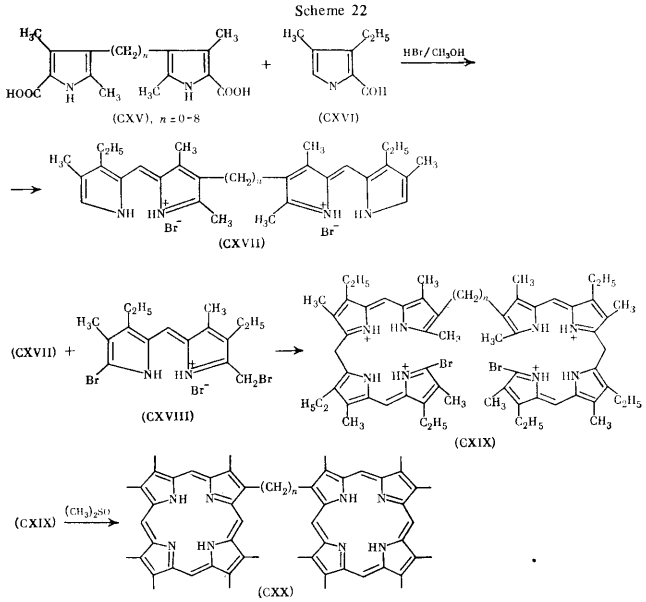


The mixed copper–vanadium complex (CVII) can be synthesised by Falk's method[51] involving the treatment of compound (CVI) with copper acetate in pyridine (Scheme 20).

Scheme 20

Japanese investigators[89,90] obtained the covalently linked dimers (CXII) and (CXIII) and the trimer (CXIV) of natural porphyrins (Scheme 21).

Scheme 21

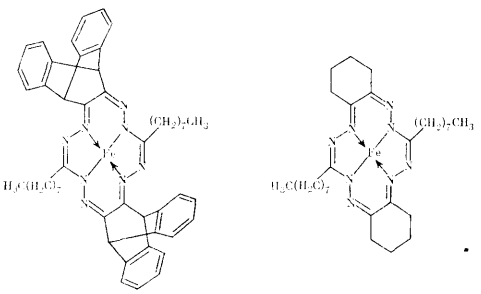


2-(2-Ethoxycarbonylethyl)-3,7,8,17,18-hexamethyl-12-propylporphyrin has been synthesised by Johnson's method[91] and then converted by hydrolysis into the acid; reduction of the latter[92] leads to the 3-hydroxypropyl derivative (CVIII). The dimethyl ester of mesoporphyrin-IX has been converted by partial hydrolysis into a mixture of two isomers of the monomethyl ester of mesoporphyrin-IX and then into the acid chloride (CIX) by treatment with thionyl chloride. Reduction of the dimethyl ester of mesoporphyrin-IX yielded di(3-hydroxypropyl)porphyrin (CX), [92] while treatment with thionyl chloride afforded the dichloride (CXI).

The covalently linked dimer (CXII) has been obtained by the reaction of the 3-hydroxypropyl derivative of the porphyrin (CVIII) with the acid chloride (CIX) in methylene chloride in the presence of triethylamine at a high dilution. The diporphyrin (CXIII) has been obtained analogously from the dihydroxy-derivative (CX) and the acid dichloride (CXI), while the trimer (CXIV) has been synthesised from two moles of the acid chloride (CIX) and one mole of the dihydroxy-derivative (CX). [89]

The covalently linked diporphyrin (CXX) has been obtained[93] from the dipyrrole (CXV). Condensation of the dipyrroles (CXV) with 2-formylpyrrole (CXVI) in a mixture of acetic and hydrobromic acids yielded the corresponding dihydrobromides of bisdipyrrolylmethenes (CXXII), from which the bisporphyrins (CXX) were obtained by reaction with the hydrobromide of the bromo-derivative of dipyrrolylmethene (CXVIII) and the Johnson cyclisation[91] of the intermediate bisbiladienes (CXIX) [93] (Scheme 22).

Scheme 22



IV. CONCLUSION

The data presented show that in recent years there has been a rapid development of the research into the synthesis of sterically hindered porphyrins. Attention has been concentrated on the preparation of stereochemical models of the "hydrophobic pocket", the size of which has been estimated as 5.6–6.0 Å.

In this connection attempts have been made at a wider employment of the ideas of such modelling. Thus Baldwin and Huff[94] proposed models of the tetra-aza-compounds (CXXI) and (CXXII), which are not porphyrins but have

"hydrophobic pockets" of different depth, in order to demonstrate the validity of the approach under discussion. Baldwin showed that compound (CXXI), which has a 5.0 Å "hydrophobic pocket", is capable of reversible oxygenation, while the related compound (CXXII), where the "pocket" is less deep (~2.2 Å) is incapable of such oxygenation:

(CXXI) (CXXII)

We believe that the study of Baldwin and Huff[94] is extremely important, since it demonstrates the universality of the stereochemical approach to the problem of the reversible oxygenation and leads to extensive possibilities for molecular design in this field. The creation of stereochemical models of this kind on the basis of different macrocyclic tetra-aza-compounds might give rise to a new additional field of research in the synthesis of effective oxygen transferring agents.

Further development of studies on the synthesis of new models of sterically hindered porphyrins and the investigation of their properties appear to be exceptionally important both for physicochemical biology and for catalysis, the chemistry of biologically active substances, and the chemistry of medicinal preparations. It may be hoped that compounds effectively modelling not only the work of haemoglobin but also that of chlorophyll will be synthesised in the immediate future.

Surface and Porosity of Adsorbents

M.M.Dubinin

The validity of adsorption methods of measuring specific surface areas of solids (and, in particular, of adsorbents) is limited by the characteristics of the porosity. Methods based on the concept of multilayer adsorption, like the BET method and de Boer's *t*-method, are applicable only to non-porous or coarsely porous (including mesoporous) adsorbents.
There is no general method of calculating the surface area of microporous adsorbents from adsorption data. For the "crack" model of the micropores in carbon adsorbents we can calculate the size and the geometrical area of the micropores from the parameters of the adsorption equation given by the theory of the volume filling of micropores, using a standard vapour (benzene). Almost identical results are obtained by using the adsorption of water vapour, which forms continuous monolayers in the micropores because of the dominant role of the hydrogen bond in adsorption. The geometric surface of micropores in carbon adsorbents is not a measure of the adsorption capacity of the sample, which is determined by dispersion forces, but it is relevant in kinetics and catalysis.
The presence of micropores in non-porous or coarsely porous adsorbents makes the measurement of surface area by the BET or the de Boer method physically meaningless. In this case we can use the t/F method of Dubinin and Kadlets, which gives a measure of the volume of micropores and of the specific surface of mesopores. Kistler and Kiselev's capillary condensation method gives similar values for the specific area of the mesopores. 23 References.

I. INTRODUCTION

The two extreme cases of physisorption are adsorption on non-porous adsorbents and adsorption in the finest pores (the micropores). The porosity of adsorbents is one of the main factors in adsorption. On the basis of adsorption and capillary phenomena pores can be conveniently classified according to their linear size x into micropores (x < 0.6 to 0.7 nm), supermicropores (0.6–0.7 < x < 1.5–1.6 nm), mesopores (1.5–1.6 < x < 100–200 nm), and macropores (x > 100–200 nm).[1] The smallest pores in adsorbents (the micropores) are comparable in size with adsorbed molecules. As a result of the superposition of the fields of dispersion forces from opposite walls of the micropores, adsorption energies in micropores are relatively high. As an example, we show in Fig.1 the dependence of the differential heat of adsorption of benzene on an activated and on a non-porous carbon adsorbent (gas carbon heated *in vacuo* at 950 °C) on the relative adsorption $\theta = a/a_{0.2}$.[2] This large difference in adsorption energy is the fundamental reason for the

difference between adsorption in micropores and adsorption on a non-porous carbon adsorbent. Adsorption in micropores is characterised by volume filling of the adsorption space of the micropores, i.e. of the adsorption field of force.

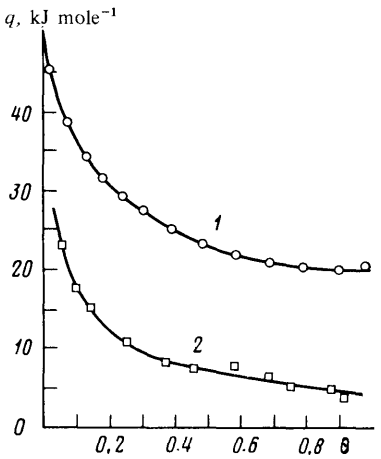

Figure 1. Differential heats of adsorption of benzene (q) for active carbon (*1*) and for "950 carbon" (*2*).[13]

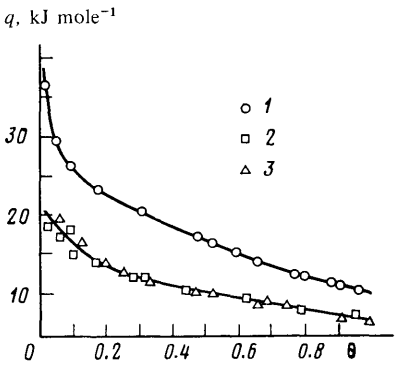

Figure 2. Differential heats of adsorption of benzene for supermicroporous (*1*) and non-porous (*2*, *3*) silicas[13].

Adsorption in mesopores, like adsorption on non-porous adsorbent surfaces, leads to the formation of successive adsorbed layers on the mesopore walls, and ultimately results in filling of the mesopores by the capillary condensation mechanism. Supermicropores occupy a porosity region intermediate between those of micropores and mesopores, in which the properties of micropores gradually disappear and those of mesopores become evident. We note from Fig. 2 that the adsorption energy is increased also in the supermicropores of silica adsorbents, but the effect is less marked than in micropores.

Pores having a diameter greater than 100–200 nm cannot be filled by capillary condensation in practice, and therefore they are usually treated as a form of macropore. Macropores (and, in many cases, mesopores) act as transport pores in adsorption. On the other hand, micropores and supermicropores determine the capacity of the adsorbent towards gases and vapours, and therefore they are called adsorption pores.

The linear dimensions of zeolite holes, usually less than 0.5–0.6 nm, are typical of micropores. Their adsorption space contains cations whose charge is compensated by the excess of negative charge in the alumino-silicate skeleton. The cations behave as active centres, giving a locally enhanced electrostatic interaction (especially for the adsorption of polar molecules). Therefore in many cases the adsorption energy in zeolites is greater than in microporous carbon adsorbents, i.e. the adsorption capacity of the zeolites is greater, especially towards adsorbates having a low equilibrium pressure. The mesopores in formed zeolites are the gaps between adjacent crystallites, held together by the binder.

II. SPECIFIC SURFACE OF NON-POROUS AND OF RELATIVELY COARSELY POROUS ADSORBENTS

In mesoporous (and even more so in macroporous) adsorbents the effect of surface curvature on adsorption is negligible. Therefore we can assume that the adsorption of gases and vapours per unit surface area occurs by the same mechanism in non-porous, macroporous, and mesoporous adsorbents of the same chemical type.

A general theory of physisorption of gases and vapours on non-porous adsorbents has not yet been developed. The Brunauer, Emmett, and Teller (BET) multimolecular vapour adsorption theory[3] is applicable only over a narrow range of equilibrium relative pressures: for example, 0.05–0.35 for the low-temperature adsorption of nitrogen. Therefore the BET isotherm equation is more useful for calculating (from one of its parameters) the specific surface area than for describing the dependence of the physisorption of a vapour on its equilibrium relative pressure. The equation is usually written

$$a = a_m ch/(1-h)[1+(c-1)h] ,$$

where a is the adsorption at the equilibrium relative pressure p/p_s, and $h = p/p_s$. The parameters of the equation are the adsorption a_m, corresponding to the formation of a monolayer of adsorbed molecules (the monolayer capacity), and the constant c, related to the adsorption energy. These parameters are easily determined graphically by linearising the equation. If ω is the area occupied by one molecule in the filled monolayer (the molecular area), and the monolayer capacity a_m is given in mmole g^{-1}, the surface area per unit mass of adsorbent (or specific surface) S can be written

$$S = a_m \omega N , \qquad (1)$$

where $N = 6.02 \times 10^{20}$ is the number of molecules in 1 mmole of adsorbate.

The standard adsorbate usually chosen for measuring specific surfaces of adsorbents is nitrogen at its boiling point (78 K) and atmospheric pressure: its molecular area ($\omega = 0.162$ nm^2 or 16.2 Å^2) is calculated from the density of liquid nitrogen. This molecular area gives the best agreement with measurements of the specific area of porous solids by other methods (for example, by electron microscopy). However, if molecular areas calculated in the same

way for other vapours are used, significant deviations in the BET specific surface areas are obtained. Table 1 (from Ref.4) lists ω values and the corresponding ratios of the specific surface obtained experimentally to the surface obtained with nitrogen, S/S_{N_2}. We note that the deviation can be as high as 34%. The BET method is basically empirical, and it can be used to measure the specific surface of non-porous or coarsely porous adsorbents by the low-temperature adsorption of nitrogen to a precision of ~15–20%.

The reduced adsorption isotherm method[5] is far simpler to use in estimating specific surfaces of non-porous or coarsely porous adsorbents.

Table 1.

Vapour	T, K	ω, nm^2	S/S_{N_2}
Nitrogen	78	0.162	1.00
Krypton	78	0.152	0.73
n-Butane	273	0.321	0.68
Freon-21	273	0.204	0.66

The method is based on the isotherm equation for the adsorption of the experimental vapour on a non-porous adsorbent whose specific surface has been determined with nitrogen by the BET method. Calculation of the adsorption γ for unit surface of the adsorbent gives the adsorption isotherm

$$\gamma = f(h). \qquad (2)$$

For the coarsely porous adsorbent (with a chemically similar surface) whose specific surface area is required we can write the isotherm as

$$a = S\gamma = Sf(h). \qquad (3)$$

Eqns.(2) and (3) for each adsorbent can be displayed as tables of the parameters γ and a for identical equilibrium relative pressures, obtained by interpolation from plots of the experimental adsorption isotherms. According to Eqn.(3) the plot of $a = \psi(\gamma)$ is a straight line passing through the origin, with a slope numerically equal to the specific surface of the adsorbent. The reduced isotherm method is not limited by the nature of the adsorbed vapour: the only validity condition is chemical similarity between the two surfaces, which determines the similarity of the adsorption isotherms (2) and (3). A solution of the problem in the absence of similar isotherms has also been proposed[6].

The t-method (de Boer and Lippens[7]) is very similar to the above. The only difference is that in the analogue of Eqn.(3) adsorptions are expressed as the volume of liquid adsorbate V. Eqn.(3) then becomes

$$V = St = S\varphi(h), \qquad (4)$$

where t is the average thickness of the adsorbed layer of nitrogen. In this case an equation of the type of (2), i.e.

$$t = F(p/p_s),$$

expresses the dependence of the thickness of the adsorption layer on the relative pressure. This dependence is called the t-curve, and for nitrogen at 78 K it is summarised below[7]:

p/p_s	0.050	0.080	0.100	0.160	0.200	0.240	0.280	0.340	0.400	0.450
t, nm	0.321	0.348	0.359	0.401	0.428	0.455	0.486	0.533	0.575	0.607

By plotting, as above, V against t according to Eqn.(4) we obtain a straight line passing through the origin whose slope is numerically equal to the wanted specific surface. The t-method was proposed by de Boer and Lippens to study the low-temperature adsorption of nitrogen on alumina or silica minerals. The t-curves for these types of mineral are almost identical.

III. ADSORPTION IN MICROPORES AND GEOMETRIC SURFACE AREA OF MICROPOROUS ADSORBENTS

The effective increase in the heat of adsorption or adsorption potential in micropores radically changes the way in which the adsorption space is filled during adsorption in the case of micropores. The formation of successive adsorbed layers (on non-porous adsorbents) is replaced by the volume filling of the adsorption space, i.e. of the field of adsorption forces[8,9]. The writer's theory of adsorption in micropores[10–13], which has been called the theory of volume filling of micropores (TVFM), has been widely used, especially in systems involving microporous carbon adsorbents or active carbons.

The basic equation of this theory is

$$a = \frac{W_0}{v^*} \exp\left[-\left(\frac{A}{\beta E_0}\right)^n\right], \qquad (5)$$

where a is the adsorption at the equilibrium relative pressure p/p_S and temperature T, and A is the change in Gibbs free energy, taken with the negative sign and expressed as

$$A = RT \ln(p_s/p). \qquad (6)$$

Also, W_0 is the maximum volume of the adsorption space (or micropore volume), E_0 is the characteristic adsorption energy for the standard vapour, β is a similarity coefficient, defined in terms of physical constants of the experimental and the standard substance, and n is a parameter (integer). The molar volume (v^*) of the substance in the adsorbed state, i.e. of the adsorbate at unit relative pressure, is a function of temperature and can be calculated from the physical constants of the adsorbate or adsorband.

The TVFM adsorption equation (5) has three parameters: W_0, E_0, and n. For microporous adsorbents we usually have $n = 2$. In the case of the adsorption of gases or vapours on zeolites the integer n can take values between 2 and 6, depending on the size of the zeolite holes and on the density of active centres (i.e. cations) within the holes. An approximate estimate of n can be obtained from the TVFM equation (5) by taking logarithms twice (see Ref.13). Knowing n, we can determine W_0 and E_0 by plotting Eqn.(5) in a linearised form (taking logarithms of both sides).

Very many examples of the satisfactory application of the TVFM equation (5) to the adsorption of vapours on active carbons in temperature ranges over 100–150 K wide have been reported. Some examples of the application of the TVFM equation to zeolites are given below. A detailed discussion of the determination of the parameters of the equation is given in Ref.13.

1. Adsorption of methane on zeolite L between 156 and 243 K.[14] The parameters of Eqn.(5) at normal temperature and pressure, determined from the adsorption isotherm for 192 K, were: $W_0 = 46.8$ cm^3 g^{-1} and $E = 9.84$ J mole^{-1} (for CH_4) with $n = 3$. Experimental and calculated adsorption isotherms are compared in Fig.3.

2. Adsorption of carbon dioxide on K,Na-erionite at 293–413 K (from data obtained by Meerson and Stepanov, see Ref.13). The parameters of Eqn.(5) were determined

from the adsorption isotherm for 383 K: $W_0 = 12.4\%$, $E = 21.9$ kJ mole^{-1}, and $n = 3$. Calculated and experimental adsorption isotherms are shown in Fig. 4.[13] In both cases the agreement between calculation and experiment is satisfactory.

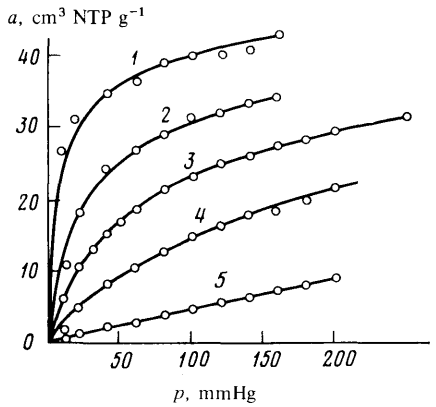

Figure 3. Calculated (curves) and experimental (points) isotherms for the adsorption of methane on zeolite L at: *1*) 156, *2*) 178, *3*) 193, *4*) 212, *5*) 243 K.[13]

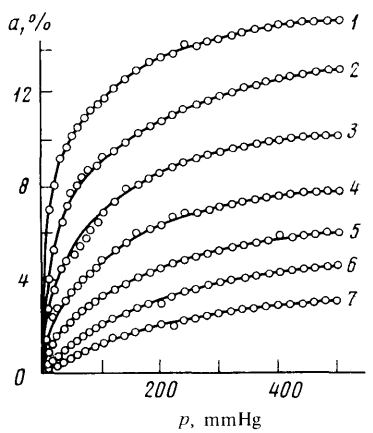

Figure 4. Calculated (curves) and experimental (points) isotherms for the adsorption of carbon dioxide on K,Na-erionite at: *1*) 293, *2*) 313, *3*) 333, *4*) 353, *5*) 373, *6*) 393, *7*) 413 K.[13]

It is interesting to compare the adsorption properties of natural clinoptilolite from the Dzegbi deposits with those of active carbon from coconut shells (combustion loss 50%) for CO_2 at 293 K and $n = 2$:[15]

Sorbent	Clinoptilolite	Carbon
W_0, cm³ g⁻¹	0.100	0.230
E, kJ mole⁻¹	28.5	10.3

In clinoptilolite the micropore volume is one-half that of active carbon, and the characteristic energy of adsorption of carbon dioxide is higher by a factor of 3. The adsorptions (a, mmole g^{-1}) of carbon dioxide on clinoptilolite and on active carbon at 293 K are compared in Table 2: at relatively low pressures (up to $p \approx 400$ mmHg) the adsorption on clinoptilolite is between 17 and 1.4 times greater than on active carbon in spite of the smaller (2.3-fold) adsorption volume in the zeolite than in the carbon. This is due to the higher characteristic energy of adsorption in the zeolite.

Table 2. Adsorption of carbon dioxide at 293 K.[15]

p/p_s	a, mmole g⁻¹	
	clinoptilolite	active carbon
$5\cdot10^{-5}$	1.26	0.075
$1\cdot10^{-4}$	1.46	0.12
$5\cdot10^{-4}$	1.61	0.29
$1\cdot10^{-3}$	1.72	0.49
$5\cdot10^{-3}$	1.99	1.38

Active carbons and zeolites are the most widely used microporous adsorbents. Their pores are the smallest of all adsorbents, comparable in size with adsorbed molecules. The volume of the micropores usually lies between 0.1 and 0.6 cm^3 g^{-1}. However, the micropore structure of zeolites (unlike that of active carbons) is due to the crystal structure of these materials and hence is strictly regular. This allows us to calculate with great precision the size, volume, and geometric surface of the micropores from X-ray diffraction data. Thus, for CaA zeolite crystals we found[16] a total volume of large holes $v = 0.278$ cm^3 g^{-1} and a geometric surface area of pore walls $S_g = 1640$ m^2 g^{-1}, and for NaX zeolite $v = 0.322$ cm^3 g^{-1} and $S_g = 1400$ m^2 g^{-1}.

However, in contrast to non-porous and coarsely porous adsorbents (for which the adsorption is directly proportional to the specific surface), in the case of volume filling of micropores the adsorption is not determined by the geometric surface of the micropores. The concept of a monolayer also becomes meaningless for adsorption in micropores. Formally, a "monolayer capacity" a_m can be obtained according to formula (1) if the geometric surface area of the pores is known. For a CaA zeolite with $S_g = 1640$ m^2 g^{-1} we obtained $a_m = 16.6$ mmole g^{-1} for the adsorption of nitrogen ($\omega = 0.162$ nm^2) at 78 K. Experimentally, the limiting adsorption of nitrogen on CaA zeolite for $h = 1$ is $a_0 = 8.27$ mmole g^{-1}, i.e. approximately one-half of the estimated monolayer capacity. We conclude that for zeolites the geometric specific surface cannot be determined from adsorption measurements.

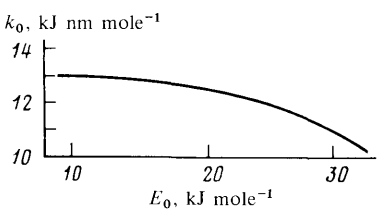

Figure 5. Dependence of the parameter k_0 on E_0.[19]

Unlike those of zeolites, the geometric surface areas of microporous carbons can be calculated and determined experimentally from adsorption data. According to

currently held views the micropores in carbon adsorbents resemble flat cracks, and their main parameter is the half-width x of the crack. We have used[17] X-ray diffraction and adsorption data to show that the half-width x of the micropores is inversely proportional to the characteristic adsorption energy of the standard vapour (benzene):

$$x = k_0/E_0, \quad (7)$$

where the parameter k_0 is only weakly dependent on E_0 (see Fig.5).[17,18].

Knowing the parameters of the TVFM equation (5) for $n = 2$, i.e. the micropore volume W_0 ($cm^3\ g^{-1}$) and the characteristic adsorption energy E_0 (kJ $mole^{-1}$), we can easily calculate by Eqn.(7) the half-width of the plane-parallel micropores (x, nm), and by using the elementary formula (8) we can arrive at the geometric surface of the micropore walls in active carbon[19]:

$$S_g,\ m^2\ g^{-1} = 10^3 W_0/x. \quad (8)$$

Unlike the adsorption of organic vapours on active carbons, in which the role of dispersion forces is predominant, the adsorption of water is controlled by hydrogen bonds both between the primary adsorption centres (oxygen surface compounds) and between the water molecules. In this case the dispersion interaction energies are weaker than the hydrogen bond energies and can be ignored. Since the interactions arising from hydrogen bonding are not amplified in the micropores the adsorption on micropore walls takes place by the same mechanism as on the surface of a non-porous carbon adsorbent (gas carbon heated at 950 °C in vacuum[19]).

Table 3. Specific surface areas ($m^2\ g^{-1}$) of model microporous carbon adsorbents (benzene, 293 K, $W_0 = 0.500\ cm^3\ g^{-1}$).[19]

E_0, kJ mole^{-1}	x, nm	S_g	S_{BET}	S_t
18.9	0.67	750	1200	1450
13.3	0.97	520	1170	1280
9.4	1.38	360	1040	1050

From the experimental results, an average monolayer of water molecules adsorbed on "950 °C" carbon black of known specific surface area is formed at an equilibrium relative pressure of water vapour $h = 0.60$ at 293 K. Taking the molecular area of water as $\omega = 0.105\ nm^2$ we conclude that 1 mmole of water in the form of a monolayer occupies an adsorbent surface $K = \omega N = 63.2\ m^2\ mmole^{-1}$. If the adsorption of water on an active carbon at $T = 293$ K and with $h = 0.6$ is $a_{0.6}$ mmole g^{-1}, the geometric surface of the pore walls can be expressed as[19]

$$S_g^{H_2O},\ m^2\ g^{-1} = Ka_{0.6} = 63.2a_{0.6}. \quad (9)$$

The geometric surface areas of micropores in different types of active carbon, obtained[19] from the adsorption isotherms of benzene and of water by using Eqns.(8) and (9) respectively, are compared below:

Active carbon	KL2	KL3	AG1	V3	KL4	EK3	V4	KL5	KL6
S_g	560	680	640	540	720	580	680	840	870
$S_g^{H_2O}$	610	620	740	660	710	690	730	880	990
$S_g^{H_2O}/S_g$	1.09	0.91	1.16	1.22	0.99	1.19	1.07	1.05	1.14

The discrepancies between the two sets of results are well within the uncertainty limits of different methods of measuring the surface area of adsorbents.

It may be useful also to compare different methods of calculating the surface area of micropores in order to assess their physical reality. In this analysis we used model adsorption isotherms for benzene, calculated by the TVFM equation for $n = 2$ and $W_0 = 0.50\ cm^3\ g^{-1}$ and for a range of E_0 values determined by low-angle X-ray diffraction measurements[19]. As we have already shown, the TVFM equation is satisfactorily consistent with experimental data. The adsorption isotherms obtained in this way were treated by the BET method and by the de Boer t-method. The geometric surface areas of micropores S_g were calculated by formula (8): the results are shown in Table 3.

Table 4. Specific surface areas ($m^2\ g^{-1}$) of industrial active carbons[9].

Active carbon	S_g	$S_g^{H_2O}$	S_{BET}
AG2	460	470	800
SKT	1350	1460	2160

The geometric surfaces S_g seem to give a realistic indication of the surface area of the walls of the plane-parallel micropores. Their physical reality is confirmed by two independent methods, whose results for water and benzene adsorption are mentioned above[19]. The BET and de Boer specific surfaces are mutually consistent, but far from compatible with real values. The results shown in Table 4 were obtained in a similar way for industrial active carbons from the experimental adsorption isotherms for benzene and water at 293 K. We again note the almost identical geometric surface areas for each type of carbon given by the adsorption isotherms for benzene and for water, and the large discrepancies with the S_{BET} values. Hence we conclude that the specific surface areas of microporous adsorbents based on the multilayer adsorption model, i.e. the values given by the BET and the de Boer t-method, are physically unjustifiable. On the other hand the geometric surfaces have a clear physical meaning. However, they are only relevent to the adsorption of water, and possibly of ammonia, whose isotherms on active carbons have similar shapes. The geometric surface area of micropores bears no relationship whatever to the adsorption characteristics of other vapours on active carbon.

Nevertheless, the geometric surface of micropores could be kinetically significant in the description of surface mass transfer processes and in catalysis, when the microporous carbon adsorbents are used as catalysts or as carriers of catalytically active additives.

IV. ADSORPTION IN MICROPORES AND MESOPORES

If the adsorbent contains micropores as well as mesopores we can expect adsorption on both types of pore under the conditions in which the t-method is applied. The total adsorption V (expressed as volume of liquid adsorbate) will include contributions from the adsorption in micropores (V^{mi}) and in mesopores (V^{me}). The adsorption on the surface of macropores is negligibly small and will be ignored in this analysis. Therefore we have

$$V = V^{mi} + S_{me}t, \quad (10)$$

where the product $S_{me}t$ gives the adsorption in mesopores. For equilibrium relative pressures in the range $h = 0.05-0.4$, for example in the case of the low-temperature adsorption of nitrogen, the changes in adsorption in the micropores (ΔV^{mi}) are comparable to the changes in adsorption in the mesopores. Therefore the dependence of the total adsorption on the thickness of the adsorption layer is not linear, and the t-method is not applicable.

According to the TVFM equation (5) the extent of filling of the micropore volume F for $n = 2$ can be expressed, in this case as

$$F = V^{mi}/W_0 = \exp[-(A/E)^2] ,$$

where E is the characteristic adsorption energy for the vapour being studied. Dividing both sides of Eqn.(10) by F gives

$$V/F = W_0 + S_{me}t/F . \qquad (11)$$

This is the basic equation of the Dubinin–Kadlets t/F method[20]. To a good approximation W_0 is equal to the volume of micropores ($v_{mi} = W_0$). In V/F against t/F coordinates Eqn.(11) gives a straight-line plot which intersects the vertical axis at v_{mi}. The slope of the straight line is a measure of the specific surface area of the mesopores S_{me}.

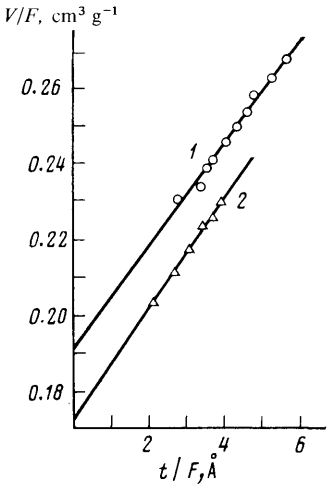

Figure 6. Plots of the t/F method for AU11 active carbon: *1*) nitrogen at 78 K, *2*) benzene at 293 K.[20]

As an example we show in Fig.6 some plots by the t/F method for the AU11 active carbon. According to the almost identical slopes of the two straight lines the specific surfaces of mesopores given by experiments with nitrogen and with benzene are also identical (133 and 140 $m^2\ g^{-1}$ respectively). The micropore volumes of the carbon measured with nitrogen are greater by 0.02 $cm^3\ g^{-1}$ than those measured with benzene. This difference can be explained by the molecular sieve properties of the carbon. Thus the t/F method allows us to determine from a single adsorption isotherm the specific surface of mesopores and the volume of micropores in the adsorbent. The parameter E is obtained from the low relative pressure region ($p/p_S = 10^{-6}-10^{-3}$) of the same isotherm, in which the adsorption on the mesopore surfaces is negligible in comparison to the adsorption in micropores.

In conclusion we should mention the thermodynamic method of determining the specific surface of mesopores from the surface of adsorbed film which disappears when the mesopores are filled by capillary condensation. The method was first formulated by Kistler[21] but its development into a practically useful form is due to Kiselev[22]. The method assumes that the specific surface of the adsorbed multilayer in the mesopores is indistinguishable from the specific surface of the mesopores themselves.

The differential molar heat of adsorption of a vapour initially saturated at the stated temperature is given by Eqn.(6). The ratio of the integral work of adsorption of the vapour between a_0 (the adsorption corresponding to the onset of capillary condensation) and the limiting adsorption a_S for $p/p_S = 1$ to the surface free energy of the adsorbed film σ gives the specific surface area of the adsorbed film S':

$$S' = \frac{1}{\sigma}\int_{a_0}^{a_S} A\,da .$$

The integral is usually evaluated graphically.

Table 5. Specific surface areas ($m^2\ g^{-1}$) of mesopores in active carbons[23].

Active carbon	S_{me}	S'	S_{me}	S'
	benzene, 273 K		nitrogen, 78 K	
AU 10	100	93	95	87
AU 11	140	117	133	105
AU 12	135	157	165	135
AU 13	110	93	90	77
AU 14	197	186	190	166

The specific surface areas of mesopores in highly porous active carbons listed in Table 5 were calculated from experiments with benzene and with nitrogen[23]. The results most closely consistent with experiments for different vapours were obtained by the t/F method. Comparing the average values for each method, the specific surfaces of the adsorbed films are found to be slightly low, as expected from the assumed equality of the surface of the adsorbed film and that of the adsorbent.

In formed zeolites the micropores are part of the zeolite crystallites, and the gaps between crystallites in contact are equivalent to mesopores. Hence the t/F method is applicable (in principle) to formed and to natural zeolites.

Use of the Classical Trajectory Method in Modelling the Dynamics of Atom-Molecule Collisions in Chemical Reactions

M.Ya.Gol'denberg and N.M.Kuznetsov

This review discusses methods of modelling atom - molecule collisions in chemical reactions by calculating the classical trajectories, and the application of these methods in studies of the dynamics and kinetics of bimolecular and unimolecular reactions. The discussion includes methods of defining and analysing the potential energy surface, methods of calculating the trajectories in multidimensional phase space, and statistical methods of controlling numerical experiments (selection of initial parameters, calculation of the distribution function of the active molecule with respect to life-time, etc.). 154 references.

I. INTRODUCTION. FORMULATION OF THE MOLECULAR DYNAMICS PROBLEM

Rapid progress is being made in experimental and theoretical studies of the kinetics of chemical reactions at the microscopic level. The exchange of energy between different degrees of freedom during molecular collisions and intramolecular motion are being studied as component parts of chemical reactions and of relaxation processes. The formulation of the problem is closely associated with practical aspects of non-equilibrium chemical kinetics: the determination of the rate constants of fast processes and of the role of different degrees of freedom in the kinetics of chemical reactions taking place in strong shock waves and in rarefaction waves, with controlled external stimuli applied to specified degrees of freedom of the reacting molecules, etc. On the other hand, rate constant data for these processes obtained by modern methods of diagnosing initial, intermediate, and final states of reacting gases can be used as the experimental foundations for the solution of the problem.

In addition to quantum-mechanical calculations of the probability of elementary transitions, the theory increasingly uses numerical methods of solving the equations of molecular motion (i.e. the methods of molecular dynamics). In a strict formulation of the problem the motion of an isolated molecule as a whole, and that of its component parts, are described by the Schroedinger equation, which takes into account the interactions of all electrons and nuclei. Molecular dynamics in the widest sense is concerned with the motion of both the nuclear and the electronic subsystem. However, a large class of problems in molecular dynamics and chemical kinetics can be solved by determining only the motion of the nuclei. Under these conditions the electronic subsystem acts as a field of forces in which the nuclear motion takes place, and no allowance for it is needed beyond determining this field.

In the Born–Oppenheimer adiabatic approximation the motions of electrons and of nuclei can be treated separately. The effective interaction between the nuclei is defined by the potential energy surface (PES), which depends on the internuclear distances and on the quantum state of the electronic subsystem. The conditions under which the adiabatic approximation is valid are determined by the difference in energy between the electronic levels and by the velocity of the nuclei, and are characterised by the Massey parameter[1].

The motion of nuclei in a potential field can be studied by classical mechanics. The error associated with the classical approximation can be evaluated by comparing the solutions of the quantum and of the classical motion problem. A detailed analysis of the approach to the classical limit in the theory of molecular collisions is given in Ref.2.

Many workers[3–11] (for example, by using model PES of the LEPS type†) have solved the dynamics problem both within the framework of the classical equations of motion and quantum-mechanically. The two types of solution were used to calculate the probability of elementary transitions with different types of averaging over the initial and the final states. It follows from that work[3–11] that for "reasonable" PES with high activation barriers the difference between the averaged process parameters calculated in the classical approximation or quantum-mechanically is small. Only the classically forbidden processes (for example, tunnelling and reflection above barriers) are exceptional in this respect. These processes involve light atoms, and are very important for the kinetics of reactions at low temperatures. For a wide range of reactions with thermal energies of ~1000 K the classical approximation is adequate.

In Slater's dynamical theory[15] the molecule is treated as a set of classical harmonic oscillators. This model allows analytical treatment, but the harmonic approximation is not even qualitatively correct when used to describe the nature and rate of intramolecular energy redistributions and the localisation of energy along the reaction coordinate. The models used in modern molecular dynamics allow as far as possible for the real interactions in the molecule. Numerical studies of these models by computer calculations provide the modern "experimental" basis for further developments in

†The LEPS potential[12–14] is named after its proposers (London–Eyring–Polanyi–Sato). It is an empirical potential, with many adjustable parameters. In 1929 an attempt was made to construct the potential surfaces for three hydrogen atoms. Subsequently many empirical parameters were introduced into the potential, which gradually lost its quantum-mechanical significance. The LEPS potential is widely used at present to describe three-particle interactions.

dynamical theory. Dynamical calculations for molecules containing more than two nuclei are possible only with the most advanced computing techniques, even within the confines of the classical description (the "classical trajectories method"). The volume of the computational work is so enormous that even on the best computers the problem can be solved only by exploiting new and efficient methods of computing mathematics.

Several review articles on numerical modelling in molecular dynamics using classical trajectory calculations have appeared in the last decade[16–20]. The aim of the present review is to examine the most recent advances in this area and to acquaint the reader with practical results. The second section is devoted to methods of modelling atom–molecule collisions and chemical reactions by using classical trajectories, and the third section deals with the application of these methods to studies of the dynamics and kinetics of bimolecular and unimolecular reactions.

II. METHODS OF STUDYING INTRAMOLECULAR MOTION BY USING CLASSICAL TRAJECTORIES

Three basic tasks can be distinguished in the development of numerical methods of solving the molecular dynamics problem in the framework of the classical equations of motion.

1. Determining the PES. Numerical solution of the Schroedinger equation for complex molecules is impossible at present even on the most modern computers, and therefore the number of non-empirical PES calculations so far reported is very small. Model surfaces which adequately describe the molecular system in the asymptotic regions of phase space are usually employed: the models correctly describe the energetics of the main paths of the reaction, and the vibration frequencies and the geometries of the initial molecule and of the reaction products. By using these PES the general features of the dynamic behaviour of molecular systems can be identified, and methods of numerically modelling the dynamic processes can be developed.

2. Determining the initial conditions. In order to obtain kinetic expressions for analysing the molecular dynamics we must examine a set of trajectories to allow for the statistical nature of the initial data in a real physical experiment. At the same time the number of trajectories must not be too great, since the calculation of each trajectory is very costly in computer time. These conflicting requirements add to the difficulty of determining the initial conditions.

3. The choice of an effective numerical algorithm for solving the classical equations of motion, capable of calculating the trajectory of motion reliably over long integration times. The solutions usually show a large scatter of characteristic times, and are oscillatory functions, but they must keep the integrals of motion constant. As a result, a need for special numerical methods of calculating trajectories has arisen.

The PES can be adequately described in a number of ways. One of these is based on *ab initio* calculations of the potential in a limited region of configurational space.

Leforestier[21] calculated the dynamic characteristics of the reaction $H^- + CH_4 \rightarrow CH_4 + H^-$ by using an *ab initio* potential for a small region of the transition state, and obtained the classical trajectories of motion for a small translational energy along the reaction coordinate. This choice of initial conditions in the region of the transition state leads to rapid dissociation, and the motion is observed only in a limited region of configurational space. Hence this very interesting method does not allow us (unfortunately) to analyse the dynamics of a reaction over the whole of phase space.

From the potential energy at a few reference points, calculated by numerical solution of the Schroedinger equation, and knowing the asymptotic behaviour of the potential, a polynomial surface (called a spline[24]) was calculated[22,23]. This approximation allows wide variations in the PES, while keeping constant the reference points and the general structure, and therefore it offers detailed information on the effect of the shape of the PES on the dynamics and kinetics of the reaction.

As we have already pointed out, the Born–Oppenheimer adiabatic approximation is often used in the classical description of molecular dynamics. However, some molecular processes are strongly non-adiabatic, but this can be allowed for in the dynamical approach. The interactions between two adiabatic energy levels have been studied[25–30], and the classical problem has been solved by first considering only one potential surface but allowing for the probability of transition to another PES (calculated by the Landau–Zener formula[1]) in the region where the two surfaces approach each other closely or intersect. Further classical motion up to the next intersection lines takes place on the old and the new PES with probabilities $1 - P$ and P respectively, and so on. This method of allowing for non-adiabaticity is applicable when the section of the classical trajectory in which transitions between PES have a high probability is relatively short.

The first reported application of the classical trajectory method was to bimolecular collision processes between an atom and a diatomic molecule[31–33], i.e. a special case of the three-body problem. Because of the relatively small number of dimensions of the phase space for a three-body system, fairly detailed computer calculations of the trajectories are possible. The most successful numerical calculations and analyses of classical trajectories so far reported have been in studies of the three-body problem.

The classical trajectory method as applied to collisions between an atom and a diatomic molecule has been described in detail[34] for the exchange reaction $H + H_2 \rightarrow H_2 + H$. The choice of the coordinate system for the classical trajectories is considered in special detail. The initial conditions are chosen so as to describe the quantum states of the reactants as exactly as possible. Equations relating the initial and the final quantum states of the system to the classical variables are given.

Statistical treatment of the calculated trajectories yields kinetic information with a varying amount of detail. The probability of the reaction is first determined, and hence the full cross-section of the reaction as a function of the initial states of the reactants and the final states of the products are obtained. The rate constant of the reaction is then calculated as the integral of the full reaction cross-section for a given distribution of the initial states of the reactants. The thermal (equilibrium) rate constant is calculated by assuming a Maxwell distribution of the molecules with respect to velocity and a Boltzmann distribution with respect to the internal initial states.

Obviously, the results of dynamical calculations can be used in the same way to calculate the rate constants under non-equilibrium conditions, for example for different temperatures of the different degrees of freedom, or for other stated deviations from the Maxwell–Boltzmann distribution. This allows us, in particular, to apply the classical trajectory treatment to non-equilibrium processes in the upper layers of the atmosphere, and also (under laboratory conditions) to the excitation of molecular degrees of freedom by laser radiation or to the excitation of a gas by a laser, by powerful shock waves, or by chemical activation.

Raff and coworkers[35] have developed a method of calculation for the four-centre problem which allows (by a special choice of coordinate system and of initial conditions) the following collisions to be studied: atom–atom, atom–diatomic molecule, atom–triatomic molecule, and diatomic molecule–diatomic molecule. The method has been used to examine various alternative mechanisms of the $I_2 + H_2$ reaction and to calculate the rate constant of the recombination reaction $I + I + H_2 \rightarrow I_2 + H_2$. The calculated constant agrees exactly with experiment.

These methods are valid only for systems in which the number of atoms taking part in the reaction is small. They cannot be applied to reactions involving polyatomic molecules.

A method which can be applied to studies of the dynamics and kinetics of those reactions has been described[36]. Within the limits of the proposed model schemes, different mechanisms for the decomposition of excited molecules can be examined and the conditions for selective and for thermal activation can be defined. For modelling the decomposition of a polyatomic molecule over an activation barrier the following procedure is used to define the initial conditions: the origin of each trajectory is chosen in the region of phase space corresponding to the activated complex, and the trajectories are calculated twice (once for positive and once for negative time changes). By "fusing" these two trajectories the trajectory of the motion of the molecule leading to decomposition is obtained. This method of defining the initial conditions allows a correct choice of the trajectories leading to decomposition, and can be used to calculate the maximum spontaneous decomposition time for each trajectory. The method can also be used to model reactions such as $(AB)^* \rightarrow A + B$ and $A + BC \rightarrow (ABC)^* \rightarrow AB + C$, including those in which the fragments A, B, and C have a complex structure. It has been applied to studies of the decomposition of molecules such as N_2O and CHF_3.[37,38] The practical application of the method requires a knowledge of the geometry of the activated complex. In reactions with a well defined activation barrier the position of the activated complex is usually given by the saddle point of the PES. The directions of the reaction coordinates at the saddle point are the directions of decreasing potential energy.

In dynamic studies of chemical reactions the configuration of the activated complex (reaction path) often needs to be known. If the saddle point of the PES is known, and if the configuration of the activated complex is determined by the saddle point, the identification of the reaction path presents no difficulty. We only need to follow the potential energy surface downwards from the saddle point to the valleys of products and of reactants in the direction of the reaction coordinate. However, the most difficult part of the procedure is to find the saddle point, because paths leading to extrema and to saddle points are not easily identified by using local methods of describing the energy surface.

A localised method of studying the energy surface which nevertheless allows the saddle point to be identified has been described[39]. The step of the algorithm consists in moving along the constant energy surface and searching for the point where the surface is least steep. This method is a mathematical realisation of the idea put forward by Pencir[40]. Another method of searching for the saddle point of the PES[36] relies on a global description of the surface. The PES is intersected by a hyper-plane passing through the valleys of products and of reactants. The descent to the saddle point begins at the point in the section where the potential energy is a maximum. The saddle point in the PES is easily located by this procedure.

If the initial conditions are chosen arbitrarily not all the trajectories lead to reaction: in other words, phase space can be divided into reaction-active and reaction-inactive regions. Dynamical studies[41–43] have established the general condition for distinguishing these two types of region in phase space for reactions of the $A + BC \rightarrow AB + C$ type. This condition depends on the activation energy and on the form of the saddle point in the region of the activated complex.

Statistical methods of evaluating multidimensional integrals are used to calculate rate constants by the classical trajectory methods. The first attempts at calculating the constants relied on the standard Monte Carlo procedure, in which each variable was arbitrarily associated with one particular distribution law, irrespectively of the other variables[34]. More exact methods of calculating the integrals from a limited number of chosen trajectories were subsequently developed. These include a Monte Carlo scheme[44] for modelling the three-particle interaction act. By specifying the initial conditions as suggested it is possible to choose trajectories in the part of phase space which makes the most substantial contribution to the wanted kinetic parameters. The method was used to calculate the rate constant for the $H + H + H \rightarrow H_2 + H$ recombination reaction, which was found to agree with experiment for temperatures between 2000 and 5000 K, as well as giving the distribution in energy of the hydrogen molecules.

A recently developed method of evaluating multidimensional integrals for calculating reaction rate constants[45,46] relies on a non-random sampling of the initial conditions. The error in the calculation of the integral was shown to be smaller than in the standard Monte Carlo method. This allows a smaller number of trajectories to be used to achieve a prescribed level of accuracy in the evaluation of the integrals.

A statistical procedure (the modified method of moments) has been used[47] to calculate the distribution functions with respect to the spontaneous disintegration time of excited molecules. The modification of the standard method of moments consists in limiting the region for which the changes in the arbitrary quantity are calculated. This modification was introduced because the distribution of spontaneous decomposition times for excited molecules gave a set of random values concentrated in a limited range of time, although the true range of spontaneous decomposition times extends over the whole of the positive time axis.

A new procedure[48,49] for choosing initial conditions (importance sampling) offers an even lower error in the calculation of multidimensional integrals. It has been used to calculate the rate constants of the bimolecular reactions $F + H_2$, $C + H_2$, and $O(^3P) + H_2$, and shown to be superior to the standard method.

Some workers[50–52] have avoided the direct calculation of multidimensional integrals by expanding the differential scattering cross-section into a Legendre polynomial series. The coefficients of the expansion are obtained by statistical methods. In this case the evaluation of the multidimensional integral reduces to a statistical calculation of a discrete set of one-dimensional quantities. It has been shown that this method differs from the methods based on the direct calculation of multidimensional integrals in not causing a loss of information when the averaging is carried out over small angles. Some calculations[53–57] of the rate constants of various reactions in terms of flows through the critical surface in phase space have been based on Keck's variational theory[58].

The postulates of the statistical theories can be tested by combining the methods of molecular dynamics with estimates of the kinetic parameters. Dynamical calculations can be

used to confirm the hypothesis of an equilibrium distribution of active molecules in the region of the transition complex, and also to evaluate the transmission coefficients, i.e. to test the interpretation of the rate constant as a flow of representative points through the critical surface in the direction of the reaction products, and finally they can also be used to test the assumed statistical nature of the redistribution of energy in the active polyatomic molecule.

In some recent papers[59-63] the results of the classical trajectory method are compared with those obtained by applying statistical theories to the same PES. Good agreement between the two theories is obtained if the surface has a relatively simple structure, without sharp curvatures or excessively steep slopes.

Other recent papers[64-66] examine the relationship between the redistribution of energy and the stability of the classical motion. An analogue of the Lyapunov function, describing the behaviour of a specially defined gap between trajectories, is used as a criterion of the degree of randomisation of the system. A statistically randomised energy is revealed by an exponential increase in this distance. The degree of ergodicity of the system is determined by the nature of the PES.

A detailed dynamical analysis of the statistical behaviour of molecular systems has been published[67,68]. The degree of ergodicity of a polyatomic molecule is characterised by the spectra of the autocorrelation functions of the generalised momenta of the normal vibrations, obtained in the calculation of the classical trajectories. The area under the spectrum defines the energy of the given normal mode, and energy redistribution processes within the molecule can be characterised by the time-changes in the shape of the spectrum. At low energies the molecule behaves as a set of weakly coupled harmonic oscillators, and the spectra consist of discrete lines, but at higher energies additional lines and a continuum appear in the spectrum.

The autocorrelation function method has been applied in studies of the dynamics of intramolecular energy redistribution in a model of the CD_3X molecule (where X = H, Cl). Different PES were used to model the reaction with and without an activation energy barrier. Initial excitation of the molecule was by chemical or by thermal activation. It was found that the possibility of randomising the initial energy distribution of the active molecule depends on the characteristic features of the PES and on the total energy of the system. An equilibrium distribution of energy among the products is observed if the PES has no barrier in the output channel, and also in cases of strong intermolecular interactions.

Modelling studies of unimolecular reactions of complex molecules are reviewed in Refs.69 and 70. Some universal principles for the construction of model PES are formulated: they allow the equilibrium structure of the molecule, the force constants, and the relative masses of the particles to be varied. Three methods of selecting the initial conditions for polyatomic molecules are discussed: 1) selective excitation of normal modes, 2) non-selective (equal-probability) filling of phase space along the coordinates, 3) gradual selection, each set of initial conditions being used to generate the next set. The last two methods of defining the initial conditions ensure that all additions to the phase space are equally probable (if the number of samples is large enough), and can be used for modelling thermal activation. These principles have been used in a study[70] of the unimolecular decomposition of CD_3Cl, and the results have been compared with those of Ref.68. For small excitation energies it was shown that the polyatomic fragment CD_3 can be treated as a heavy structureless particle.

We should note that in a phase space with a large number of dimensions (~12–15 measurements) the modelling of thermal activation by equal-probability or by gradual selection requires an extremely large number of initial points for filling the phase space with a dense and uniform distribution of trajectories. A dynamical-statistical description of the excited molecules, applicable to barrierless unimolecular decomposition reactions, has been proposed[71] in order to overcome the need to calculate a large number of trajectories to obtain adequate kinetic information. This description is based on assessments of the stability of the distribution of spontaneous decomposition times with respect to variations in the configuration of the critical surface, and it allows the distribution function to be calculated from a relatively small number of trajectories. The distribution over maximum times for spontaneous decomposition can also be obtained from this description of the excited molecules.

To conclude this section we should stress that dynamical descriptions of unimolecular reactions usually deal with long-lived (in comparison to the molecular vibration period) polyatomic systems. This imposes very stringent requirements on the numerical solution procedure applied to the differential equations of motion. The effectiveness of the solution of the classical equations of motion has been improved[45] by an algorithm which allows a system of differential equations to be solved by local linearisation. At each integration step the initial PES is fitted to a parabolic expression. The resulting new system of differential equations is linear, and therefore can be solved exactly. By improving the approximation (i.e. by shortening the integration step) the new solution of the problem can be made convergent over the whole integration range. The additive integrals of motion of the original problem are retained (within the stated precision) in the numerical solution by choosing a parabolic approximation for the PES.

We have described[36] a procedure which allows neighbouring trajectories to be calculated, once the trajectory for the specified initial conditions has been obtained, by expanding the solution of the equation of motion in a Taylor series in increments of the initial data. This procedure allows new trajectories of motion to be obtained at a small additional cost in computer time, and thus it offers a substantially greater volume of data and an effectively filled initial phase space. The effectiveness of these new programs has been compared with that of the previously most widely used procedure: that of Kutta and Meerson. The algorithm proposed in Ref.45 was found to be the most effective for trajectories of motion of polyatomic systems extending over long times and showing a large scatter of characteristic times.

Practical applications of different methods of calculation based on classical trajectories have shown that surfaces which adequately describe experimental results can be constructed by varying the PES parameters and by comparing the results of model calculations with kinetic data.

III. DYNAMIC BEHAVIOUR OF MOLECULES AND KINETIC ASPECTS OF REACTIONS

1. Dynamics of Bimolecular Reactions

The rate constants of chemical reactions and the relaxation times of the associated processes calculated by the classical trajectory method are relatively insensitive to the lack of precision of the classical approach, to the errors of the numerical integration, and to the detailed features of the PES, since they are averaged over many trajectories.

However, both the rate constants and the relaxation times are sensitive to the overall characteristics of the PES.

Polanyi and coworkers[72-82] have carried out an extensive investigation of the effect of the position of the PES barrier on the kinetic behaviour of a molecular system. For exchange reactions such as A + BC → AB + C the PES is classified into different sections along the reaction path. Depending on whether the kinetic energy of the system is converted into internal energy of the products during the approach of the reactants or during the separation of the products, the PES is said to be of the attractive or of the repulsive type. In the intermediate case the surface is called "mixed". PES of the attractive type are shown to be characteristic of exothermic reactions, and those of the repulsive type of endothermic reactions. The energy distribution functions for the products have been determined as a function of the type of surface. Thus, for exothermic reactions the attractive nature of the potential causes strong vibrational excitation of the products. The degree of vibrational excitation of the products is determined also by the mass ratio of the reactants. The effectiveness of rotational and of vibrational excitation in overcoming an activation barrier has also been analysed as a function of the location of the barrier. It was found that the translational energy of the reactants is more effective than their vibrational energy in overcoming barriers located in the reactant region. The vibrational energy of the reactants is converted into vibrational energy of the products with a high efficiency.

Classical trajectory analysis has been used to study a large number of molecular collision processes and to identify their kinetic features. The vibrational transitions in the exchange reactions

$$\begin{aligned} H + H_2(v = 1,2) &\rightarrow H_2(v = 1,2) + H \\ H + HCl(v = 1,2) &\rightarrow HCl(v = 1,2) + H \\ Cl + HCl(v = 1,2) &\rightarrow HCl(v = 1,2) + Cl \end{aligned}$$

have been studied[83] by using the LEPS potential. Vibrational excitation of the initial molecules are shown to lower the activation energy in every case, the magnitude of this effect depending on the combination of nuclear masses. It was also shown that this path to changes in vibrational energy is an efficient vibrational relaxation mechanism in sufficiently dense atomic gases.

The displacement reactions

$$\begin{aligned} Br + HBr &\rightarrow H + Br_2 \\ Cl + HX &\rightarrow HCl + X \\ X &= I, Br \end{aligned}$$

have also been studied[84-88], together with the vibrational relaxation of HCl and DCl in the gas phase. The rate of the reactions was found to be increased by a preliminary vibrational excitation of the reactants. The agreement of these results with those of molecular beam experiments is good on the whole, and confirms the validity of the theory.

Several papers[89-95] deal with vibrational relaxation processes and the role of vibrational energy displacement reactions.

The first attempt at describing the vibrational relaxation of diatomic molecules by classical trajectories related to the O_2 + Ar reaction[96,97]. The potential of the molecule was approximated by the Rydberg–Klein–Rees method. The probabilities of changes in vibrational states and of dissociation of the molecules were calculated over a wide temperature range (from 1000 to 20000 K), in which the probability of one-quantum and two-quantum transitions decreases as the vibrational level number n increases, and for $n \geq 20$ it is independent of temperature. The calculations were satisfactorily consistent with scattering experiments in molecular beams and with direct measurements of relaxation times.

The classical trajectory method has been applied to the relaxation processes in the Br_2 + Ar system[98]. The effect of molecular rotation on the rate of vibrational relaxation was examined, and $V-R$ exchange was shown to be more effective than $V-T$ exchange in this system. Results obtained by the "breathing sphere" and the "rough sphere" model[99] were compared, and recommendations on the relative merits of these models were given.

Another group of papers[100-109] discusses the redistribution of vibrational, rotational, and translational energy in excited diatomic molecules (H_2, N_2, KBr) in their own atmosphere or in an atmosphere of inert gas (Ar, He). The differential transition cross-sections were calculated as a function of the vibrational and rotational quantum numbers, together with the full cross-sections of the transitions from the given quantum states. The effect of variations in the PES on these cross-sections was estimated, and it was shown that the full cross-section is less sensitive to these variations than the differential cross-section. The probability of a vibrational–rotational transition and the characteristic vibrational relaxation time were studied as a function of the initial vibrational energy of these diatomic molecules and of temperature. The limiting value of the total collision energy, for which the rotational relaxation of the diatomic molecule can be expressed in the rigid rotator approximation, was also calculated.

The classical trajectory method has been used in models of interatomic interactions in molecular systems[99,110-112].

Another series of papers[113-116] discusses the reactions

$$\begin{aligned} H + F_2 &\rightarrow HF + F \\ F + H_2 &\rightarrow HF + F \\ HF + H &\rightarrow HF + H \end{aligned}$$

and the corresponding reactions of the deuteriated analogues. The differential reaction cross-sections and the deactivation rate constants were calculated, the distribution of energy among the products was found, and the relative role of translational and rotational energy in the reactions was determined. In the deactivation of HF and DF the vibrational energy was found to be converted mainly into translational energy of the products, i.e. the relaxation occurs by the $V-T$ mechanism, but at higher levels of rotational energy the $V-R-T$ mechanism contributes increasingly to the deactivation.

The effect of the vibrational state of the molecule on the reactive scattering characteristics has been studied[117] for the reactions

$$\begin{aligned} O + N_2 &\rightarrow NO + N \\ O + H_2 &\rightarrow OH + H \\ N + O_2 &\rightarrow NO + O, \end{aligned}$$

and an analytical expression for the rate constant in terms of the initial vibrational energy and of the translational temperature of a diatomic molecule was obtained.

Numerical solutions of the classical equations of motion by the Monte Carlo method have been used[118-126] to calculate the rate constants and the angular and energy distributions of the products for various reactions in triatomic systems:

$$\begin{aligned} H_2 + H &\rightarrow H + H_2 \\ D_2 + F &\rightarrow DF + D \\ O + N_2^* &\rightarrow NO + N \text{ etc.} \end{aligned}$$

Isotope effects and the dependence of the kinetic parameters on the type of PES were also investigated.

The classical trajectory method can be applied to the analysis of reaction mechanisms as a function of the type of PES. From the solution of the dynamical problem the reaction mechanism corresponding to the given PES is determined. The inverse problem can also be solved: to construct a PES consistent with the experimentally established mechanism.

A series of papers[127-131] discusses the study of reaction mechanisms on the basis of dynamical calculations. A special study was made of the recombination reaction Br + Br + E (where E = He, Ar, Xe), assuming:

a) an energy transfer mechanism, i.e.

$$\begin{aligned} &Br + Br \rightleftarrows Br_2^* \\ &Br_2^* + E \rightarrow Br_2 + E\ , \end{aligned}$$

or b) a radical–molecule complex mechanism, i.e.

$$\begin{aligned} &Br + 2E \rightleftarrows BrE + E \\ &BrE + Br \rightarrow Br_2 + E\ . \end{aligned}$$

In a He atmosphere the first mechanism is predominant, and in an Ar or Xe atmosphere the opposite is true. By allowing for both these mechanisms the calculations can be satisfactorily reconciled with experimental data. Dynamical calculations have shown that when the reaction takes place by the energy transfer mechanism the pre-exponential factor of the rate constant is almost independent of temperature, whereas if the radical–molecule mechanism is predominant this factor decreases as the temperature increases.

An example of the determination of the PES parameters from experimental data is given in Ref. 132. The parameters of the PES in the LEPS form for the reaction $O + H_2 \rightarrow OH + H$ were found by minimising the target function $\Phi = \ln(k_r/k_e)$, where k_r is the rate constant of the reaction, calculated by the classical trajectory method, and k_e is the experimental rate constant.

The PES have been constructed[133-135] for four classes of chemical reaction mechanisms of the exchange type $A + BC \rightarrow AB + C$. The influence of special features of the PES on the energy distribution of the reaction products and on the type of reactive scattering was clearly revealed.

We have discussed[37] a model of the decomposition of linear molecules of the N_2O type. The aim was to find the distribution function of the spontaneous decomposition time of the molecules and to investigate the distribution of energy among the reaction products. The distribution function was determined from the maximum spontaneous decomposition times, and it was found (by a numerical experiment) to have two maxima. The first maximum corresponds to the trajectories for elastic scattering, whereas the other trajectories describe the behaviour of the excited molecules. The distribution function of the maximum lifetimes $[f_m(\tau)]$ for these trajectories is satisfactorily described by a gamma-distribution. We found that $f_m(\tau)$ depends on the initial kinetic energy of the vibrational degrees of freedom and on the kinetic energy along the reaction coordinate. According to the assumed model, the initial kinetic energy of the vibrational degrees of freedom (including the reaction coordinate) is converted, on average, into internal energy of the N_2 molecule, whereas the rotational energy appears as kinetic energy of the relative (translational) motion of the products.

A detailed dynamical study of the following reactions has been reported[136,137]:

$$\begin{aligned} &Br + H_2 \rightarrow HBr + H \\ &H + H_2 \rightarrow H_2 + H\ . \end{aligned}$$

The results were compared with those of the statistical theory for the same reactions. The reaction probability P_r was calculated by the classical trajectory method. The probability P_s of the system reaching the transition state was also calculated, and compared with the probability of the reaction obtained by the transition state method (P_{ts}). The transmission coefficient P_r/P_s and the distribution of active molecules in the region of the transition state were found to be strongly dependent on the structure of the PES, and in particular on the location of the barrier. The distribution function of the active molecules in the region of the transition state was determined. For an endothermic reaction with a relatively low barrier located in the valley of the products the probabilities were found to decrease in the sequence $P_{ts} > P_r \cong P_s$. For the reverse reaction ($H + HBr \rightarrow Br + H_2$), on the other hand, we have $P_{ts} \cong P_s < P_r$. For an endothermic reaction with a barrier in the valley of products the transmission coefficient is close to unity, but the distribution function of the active molecules for reactants in their equilibrium state differs from the equilibrium distribution. For exothermic reactions with a barrier in the valley of reactants, e.g.

$$\begin{aligned} &H + H_2 \rightarrow H_2 + H \\ &HBr + H \rightarrow H_2 + Br\ , \end{aligned}$$

the opposite situation exists: the transmission coefficient is smaller than unity, and an equilibrium distribution exists.

2. Dynamics of Unimolecular Reactions

Many recent publications describe studies of unimolecular reactions by numerical methods. A detailed formulation of the problems in the theory of unimolecular reactions which can be solved by the classical trajectory method has been given[138]. One of these problems is the calculation of the distribution function $f(\tau)$ in time (τ) of spontaneous decomposition of molecules. In the RRKM (Rice–Ramsperger–Kassel–Marcus) statistical theory[139] this function is assumed to be exponential for τ values greater than the average vibration period of the thermally activated molecule. To test the validity of this hypothesis and to calculate $f(\tau)$ for a specific molecule as a function of the type of activation and of the parameters of the potential is one of the fundamental problems in molecular dynamics, to which the classical trajectories method is applicable. This problem is very closely related to the validity of the model of weakly coupled harmonic oscillators and of the model of free redistribution of energy between normal vibrations.

The effect of the initial vibrations on the form of the function $f(\tau)$ as a function of the assumed model of the potential has been studied[140] in the case of the dissociation of a triatomic molecule. The calculation was carried out for two models of the potential: harmonic, and anharmonic. Two types of initial state were also considered: 1) a random initial distribution of total internal energy, and 2) the total internal energy is initially finite, and only the kinetic energy is randomly distributed. In the former case the function $f(\tau)$ is found to decrease exponentially with increase of τ for either type of potential, whereas in the latter case this function has a sharp maximum for a harmonic potential and a diffuse maximum for an anharmonic potential.

The influence of anharmonicity on the exchange of energy between modes in unimolecular reactions has been studied[141] in the triatomic CO_2 molecule. The bond energies in this molecule were fitted to a harmonic potential and to a Morse potential. The initial conditions were chosen to give the

molecule a zero total momentum. The interaction between the rotational and the vibrational motion was found to be greater in the case of an anharmonic potential.

The exchange of energy between the normal vibration modes of the triatomic molecules H_2O, O_3, and ClNO has also been studied[142] for different initial excitations of the vibrational and rotational degrees of freedom. According to these calculations there is no exchange of energy between modes when the excitation energy is of the order of one vibrational quantum. As the initial energy of the vibrations increases, the energy of each mode begins to vary, both the amplitude and the rate of this variation increasing with the initial vibration energy.

The spontaneous decomposition of X–C–C–X molecules (where X = H, Cl) has been studied[143–145]. The stretching vibration energy of the bonds for this type of molecule was approximated by a Morse potential, and the bending energy by a potential proportional to the square of the angular variable. The function $f(\tau)$ was calculated for different initial excitations of the molecule. For an equal-probability distribution of the energy over the initial states the distribution function is exponential, i.e. the decomposition is a random process. If only some of the bonds are affected by the initial excitation the function $f(\tau)$ is no longer monotonic, and one of the initially excited bonds is usually the first to break. If the molecule lives long enough, this type of excitation is converted into equal-probability excitation, and the decomposition of the molecule becomes random. From the position of the maximum of the $f(\tau)$ function the duration of the non-statistical behaviour of the system can be calculated. If the maximum occurs at a value of τ significantly shorter than the average lifetime of the molecules the non-statistical behaviour of the system occupies a time much shorter than the decomposition time.

Intramolecular energy redistribution processes have been studied, and the function $f(\tau)$ has been calculated, for the unimolecular decomposition reactions[146,147]

$$C_2H_6 \rightarrow CH_3 + CH_3$$
$$C_2H_6 \rightarrow C_2H_5 + H \ .$$

Calculations by the classical trajectory method and by the statistical theory give divergent results, suggesting that in these reactions the dynamic effects play a predominant role in intramolecular relaxation and unimolecular decomposition processes. Similar conclusions were reached from a study of the methyl isocyanide molecule[148–150].

The dynamical–statistical description has been used[71] to model the unimolecular decomposition of the CH_2FI molecule, which produces[151] strong branching in the fluorination of methyl iodide. The distribution function of the lifetime under chemical activation was obtained for the system: it was found to go through a maximum, and to be satisfactorily approximated by a gamma-distribution. Statistical processing of the experimental results yielded the coefficients of the gamma-distribution, and their dependence on the parameters of the potential. Varying the adjustable parameters of the potential, without affecting the fundamental characteristics of the unexcited molecule, was shown to affect the rate constant of the dissociation by C–I bond breaking. The values of these parameters corresponding to the maximum rate of dissociation were calculated.

The decomposition of the penta-atomic CHF_3 molecule by the biradical mechanism

$$CHF_3 \rightarrow CF_2 + HF$$

has also been modelled[38] for given initial conditions of the activation barrier. Decomposition by a biradical mechanism is typical of a large group of (unimolecular) reactions, and is also important in chain reactions[152]. Modelling a decomposition which yields polyatomic fragments is also of theoretical interest. The main feature of the model used[38] for this reaction is the presence of two negative eigenvalues in the parabolic approximation of the PES at the saddle point, so that the reaction coordinate becomes "two-dimensional". The dynamics of decomposition along a two-dimensional reaction coordinate were studied by numerical methods. Even with this more complex model it was confirmed that when the reaction has a sharply defined activation barrier the position of the activated complex is determined by the saddle point of the PES. Under these conditions the reaction coordinates correspond to eigenvectors of quadratic form which approximate the PES at the saddle point and have negative eigenvalues. The distribution in energy of the reaction products was studied: most of the energy evolved by the decomposition of CHF_3 was shown to be converted into vibrational excitation of the HF molecule. The CF_2 molecule remains practically unexcited.

* *
*

The practical realisation (by computer calculations) of the classical trajectory method has provided answers to a number of important problems in the dynamics of polyatomic systems whose solution could not previously be attempted.

Our analysis of recent publications has shown that the study of atom–molecule collisions and of intramolecular motions by the classical trajectory method is potentially applicable to a wide range of chemical reactions.

The number of publications dealing with calculations of classical trajectories is continually rising as a result of the more general availability of powerful computers, of improvements in modelling techniques, and of the easier access to detailed information on the elementary chemical act.

The large fund of data on different classes of reaction, with different potential energy surfaces, allows us to define some general relationships between the fundamental laws of the kinetic process and the characteristic features of the PES. This leads, in turn, to the development of improved models of the PES.

Thermal Reactions of Polonium

A.S.Abakumov

Published information on the interaction of polonium with the chemical elements has been surveyed and systematised. Attention is paid to specific features of experimental methods for investigating the properties of polonium compounds. Conditions for the direct synthesis of binary polonium compounds and their thermal properties are given. The applicability of the Samsonov classification of chalcogenides to polonium compounds is shown.

I. INTRODUCTION

The first papers containing communications about phenomena connected with thermal reactions between polonium and chemical elements[1,2] appeared in 1932.

Rona[1] studied the influence of the material of the substrate on which polonium had been deposited electrochemically on the vaporisation of the polonium; vaporisation starts at 280 °C from a gold substrate, at 300 °C from a platinum substrate, and at 550 °C from a palladium one. After a specimen of polonium on a gold substrate had been stored for five months the temperature for the start of the vaporisation of the polonium had increased to 400 °C. Tamman and Löwis of Menar[2] investigated the behaviour of poloniun during the crystallisation of metals by melting filings of silver, copper, lead, bismuth, tin, antimony, cadmium, zinc, or tellurium on which trace amounts of polonium had been deposited electrochemically. Radiographic study of sections of the ingots showed that the polonium is located at the grain boundaries of the metals; it was concluded that polonium differs from other metals in its insignificant tendency to form solid solutions.

The systematic investigation of the thermal reactions between polonium and the chemical elements was begun after milligramme amounts of it had been obtained by irradiating bismuth in atomic reactors.

Detailed information about polonium and its compounds (discovery, distribution, methods of production, physical and chemical properties, state and behaviour in solutions, electrochemistry, analytical chemistry, applications, and safety techniques) has been given in monographs[3-8]. Early American work was surveyed in a review paper[9].

The present review deals with thermal reactions between polonium and the chemical elements which proceed in the interaction of polonium vapour with the liquid or solid elements or the interaction of the gaseous elements with metallic polonium. This information is scattered in the earlier literature. Special attention is paid to works which have appeared in the last decade (after the reviews mentioned above were written). Many experimental investigations have shown that in accordance with its position in the Mendeleev Periodic Table polonium and its compounds exhibit properties close to those of the other chalcogens (especially to tellurium) and their compounds; consequently the material is presented mainly in accordance with the scientific classification of the chalcogenides proposed by Samsonov[10].

II. METHODS OF INVESTIGATION

The use of many contemporary methods of investigation is restricted in working with milligramme amounts of polonium-210 because of the high toxicity of polonium, its ability to form radioactive aerosols, and its tendency to migrate along surfaces; it is also necessary to allow for its high energy release (144 W g^{-1}), the destructive power of the nuclear recoil during radioactive decay (166 TBk g^{-1}) [sic. The energy of the recoiling nucleus is 100 keV (Ed.of Translation)], and the constant accumulation of the radiogenic lead-206 in the specimens (0.5% per 24 h). In addition, the strong α-emission of the polonium brings about ozonisation of the atmospheric oxygen, leading to intense oxidation of the specimens. In working with gramme amounts of polonium the radiogenic heating of the specimens is so great that forced cooling of them is necessary. Safety control of the investigations imposes limitations on the choice of methods (the possibility of carrying out the experiment in glove-boxes, simplicity of the equipment, hermetic sealing of the specimens, and remoteness of the quantitative and qualitative determinations).

Direct vacuum-thermal synthesis[11] in the various versions used industrially was employed in most studies of the interaction of polonium vapour with the chemical elements. In some papers[12] it is called the differential-thermal or ampoule method.

X-Ray powder diffraction, metallographic (determination of the microhardness of layers and their dimensions), and tensimetric (various versions) methods were used for studying some of the properties of the polonium compounds obtained. The composition of the vapour during the heating of the specimens was usually determined by the simplest method—from the sublimation temperature of the condensed vapour. In some investigations the atomic ratio of a component of the vapour was found by using radioactive nucleides and determining their amounts with a γ-spectrometer or the mass characteristics of the vapour found with a mass spectrometer. The melting points of the lanthanide polonides were determined with an optical pyrometer from the change in the emissivity of tungsten when the powder of the compound being studied was deposited on it. The amount of polonium in the specimens was determined calorimetrically or radiometrically.

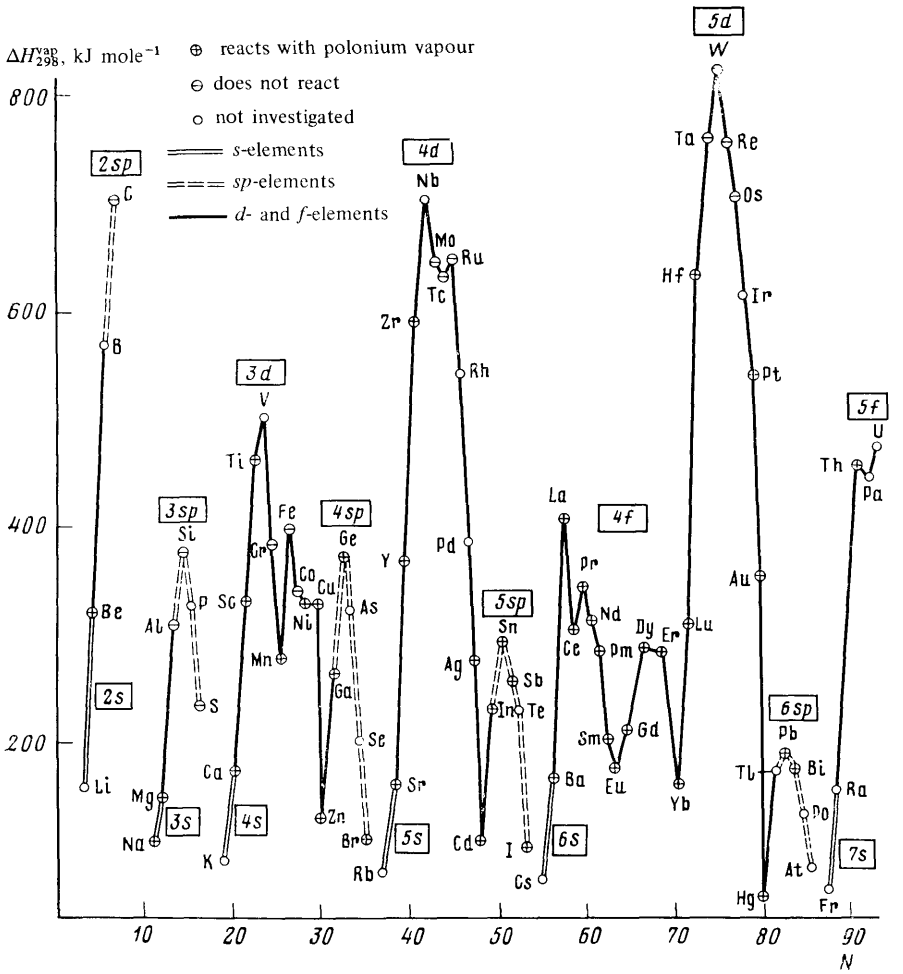

Figure 1. Periodic change in the heats of vaporisation of the chemical elements as a function of their atomic number.

III. CHEMICAL AND PHYSICAL PROPERTIES OF POLONIUM

According to its position in Group VI of the Periodic Table and its electronic structure ...$5s^25p^65d^{10}6s^26p^4$, polonium has a valence shell of six electrons; consequently it (like all the chalcogens—the representatives of this group) can have the following valence states: −2, +2, +4, +6. In accordance with the general rule, the stability of the +6 state becomes weaker with increase in the atomic number of the element along the series of chalcogens. Polonium(IV) is formed under extreme conditions (high concentrations or pressures of the oxidants) and is unstable under ordinary conditions. The existence of polonium exhibiting a valency of −2 (hydride, dimethylpolonium, alkali and alkaline earth metal polonides), +2 (halides), or +4 (dioxide, halides) has been proved in many investigations. The +4 valence state is most characteristic of polonium.

The appearance of the great "metallicity" of polonium in comparison with the other, lighter chalcogens is connected with the decrease in the energetic stability of the s^2p^4-configuration of the outer electrons as the number of the element is increased. This is shown by the periodicity of the change in the enthalpy of vaporisation of the elements (as a measure of the energetic stability of the solid substance in relation to its passage into the gaseous state) as a function of the atomic number of the element (Fig.1). As Fig.1 shows, the enthalpy of vaporisation of polonium is considerably less than those of sulphur, selenium, and tellurium, which corresponds to the general rule for *s*- and *sp*-elements. However, for the *d*- and *f*-elements an increase in the enthalpy of vaporisation with the atomic number is observed. The similarity of the energetic stabilities of the outer electron shells of the 6*sp*-elements is responsible for the similarity in their physical properties.

The temperature dependence of the vapour pressure of polonium was determined by direct (with a Bourdon manometer)[13] and indirect-static (from the radiometrically determinable amount of vapour in a known volume, assuming that polonium vapour is monatomic)[14] methods and is expressed by the equation

$$\lg p[\text{Pa}] = A - B/T, \qquad (1)$$

with the following coefficients:

t, °C	A	B
438—745	9.3545±0.0068	5377±6.7
368—604	9.46±0.05	5440±60

The heats of vaporisation of polonium calculated from equations with these coefficients are 103 and 104 kJ mole^{-1} respectively. The slight difference between the vapour pressures calculated from the results of these methods shows there is a small proportion of diatomic molecules in polonium vapour. The existence of Po_2 molecules has been established spectroscopically[15].

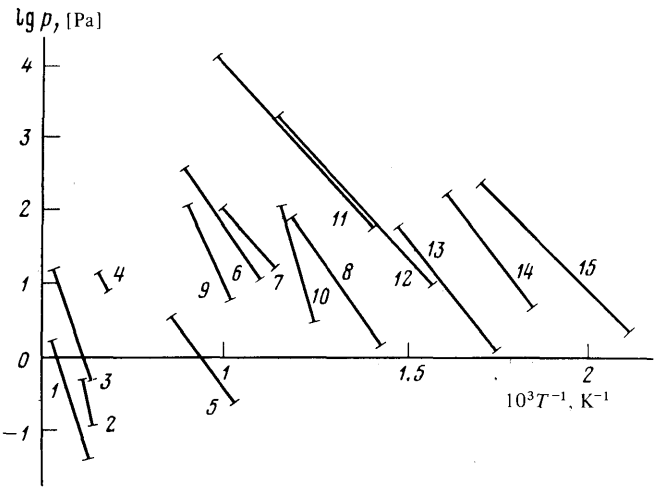

Figure 2. Vapour pressure of polonium above the polonides: *1*) yttrium; *2*) holmium; *3*) dysprosium; *4*) scandium; *5*) hafnium; *6*) lead; *7*) gallium; *8*) indium. Vapour pressure of polonium dioxide during vaporisation (*9*) and its dissociation (*10*); vapour pressure of polonium according to Brooks[13] (*11*) and Abakumov and Ershova[14] (*12*); vapour pressure of polonium hexa-, tetra-, and di-iodides (*13*, *14*, and *15*).

IV. INTERACTION OF POLONIUM WITH THE CHEMICAL ELEMENTS

From a consideration of the peculiarities of the electronic structure, bond type, and properties Samsonov[10] proposed a principle for the classification of the chalcogenides, in which they are divided into three main groups: (1) chalcogenides of metals having outer *s*-electrons in a completed shell, or more deeply lying incomplete electron shells with an ionic–covalent type of bond; (2) chalcogen compounds of elements having outer *sp*-electrons with a covalent–ionic type of bond; (3) chalcogenides of the transition metals having completed *d*- and *f*-electron shells, with a covalent-metallic type of bond in the superposition of a definite fraction of ionic bond.

For convenience in finding general rules the information on the interaction of polonium with the chemical elements and the properties of its compounds are grouped in the present review in accordance with Samsonov's classification. Special attention is paid to polonium compounds with hydrogen and helium.

Hydrogen does not react with polonium when heated. A volatile polonium hydride is formed in insignificant amounts by the action of 0.2 *N* HCl on magnesium foil on which polonium had been deposited and is released from solution when nitrogen, hydrogen, or oxygen is bubbled through. Polonium hydride is formed in lower yield (0.2%) when magnesium powder is added to an acid solution containing trace amounts of polonium. An even lower yield of hydride is obtained by the action of acid on zinc on which trace amounts of polonium had been deposited. Polonium hydride is condensed at −84 °C, its melting point is −36 °C, and boiling point +35.5 °C; it is an unstable compound and belong to the group of covalent hydrides with weak molecular bonds.

Helium forms a volatile compound with polonium under the action of an electric discharge at reduced pressure (0.4–1 kPa). A high temperature favours the occurrence of this reaction[3]. The existence of such a compound is questionable. Probably, we are speaking about the reaction of polonium with He^+ ions, isoelectronic to hydrogen, which can arise in the electric discharge.

1. Polonides of the *s*-Metals

The thermodynamic characteristics of the polonides of the alkali and alkaline earth metals, calculated by Krestov[16], are given below:

Polonide	Na_2Po	K_2Po	Rb_2Po	Cs_2Po	MgPo	CaPo	SrPo	BaPo	RaPo
$-\Delta H^\circ$, kJ mole^{-1}	347	368	335	343	54	255	268	305	284
$-\Delta G^\circ$, kJ mole^{-1}	343	364	335	339	54	255	268	305	284
S°, J mole^{-1}K^{-1}	138	163	186	202	83	95	110	119	127

Sodium polonide Na_2Po (f.c.c. lattice of CaF_2 type, a = 7.473 Å, density 4.08 g cm^{-3}) is observed in specimens of polonium which have been stored in Pyrex capillaries[15]. When an alkaline solution of sodium dithionite containing polonium acts on elemental tellurium at 80 °C and is then crystallised at 0 °C, 40% of the polonium passes into the sodium telluride crystals from the solution. The distribution of polonium in the crystal is constant, which shows isomorphous cocrystallisation and confirms the formation of sodium polonide[17].

Beryllium polonide BePo (a black substance, f.c.c. lattice of ZnS type, a = 5.838 Å, density 7.3 g cm^{-3}) is formed when beryllium is heated (600 °C) in polonium vapour. It is volatile at temperatures above 600 °C.[12]

Magnesium polonide MgPo (a black substance, hexagonal lattice of NiAs type, a = 4.345 Å, c = 7.077 Å, density 6.7 g cm^{-3} [12]) is formed when magnesium is heated (350–450 °C) in polonium vapour. It is volatile at 650 °C and is condensed as magnesium polonide[1].

Calcium polonide CaPo (a grey nonmetallic substance, f.c.c. lattice of NaCl type, a = 6.514 Å, density 6.04 g cm^{-3}) is formed when calcium is heated (550 °C) in polonium vapour. It is volatile at temperatures above 600 °C.[12]

Strontium polonide SrPo (grey metallic substance, f.c.c. lattice of NaCl type, a = 6.796 Å, density 6.3 g cm^{-3}) is formed when strontium is heated (500 °C) in polonium vapour. It is volatile at temperatures above 650 °C.[12]

Barium polonide BaPo (grey metallic substance, f.c.c. lattice of NaCl type, a = 7.119 Å, density 6.3 g cm^{-3}) is formed when barium is heated (525 °C) in polonium vapour. It is volatile at temperatures above 650 °C.[12]

Copper polonide is formed by the condensation of polonium vapour on copper. At 400 °C it is unstable and volatilises[12].

Silver polonide Ag_2PO? (orthorhombic, a = 1.327, b = 5.565, c = 1.404 Å) was obtained in 1950 when silver was heated (400 °C) in polonium vapour. It decomposes at

559 °C.[9] Reliable X-ray diffraction results have not been obtained[12].

Gold dissolves polonium vapour at a temperature above 650 °C; the solubility depends on the temperature of the gold and the vapour pressure of the polonium[12].

Zinc polonide ZnPo (f.c.c. lattice of ZnS type, $a = 6.309$ Å, density 7.2 g cm^{-3}) is formed when zinc is heated (550 °C) in polonium vapour. It sublimes at 400 °C. The saturated vapour pressure of zinc polonide at 500 °C is ~13 Pa.[12] It was first obtained in 1947.[15]

Cadmium polonide CdPo (f.c.c. lattice of ZnS type, $a = 6.665$ Å, density 7.2 g cm^{-3}) is formed when cadmium is heated (550 °C) in polonium vapour. It sublimes at 525 °C. The saturated vapour pressure of cadmium polonide at 500 °C is ~13 Pa.[12]

Mercury polonide HgPo (black crystalline substance, f.c.c. lattice of NaCl type, $a = 6.25$ Å, density 11.1 g cm^{-3}) is formed when polonium is heated (200–325 °C) in mercury vapour. It sublimes at 400 °C. The saturated vapour pressure of mercury polonide at 300 °C is ~13 Pa. An amalgam of mercury polonide is formed in the presence of an excess of mercury[12].

2. Compounds of Polonium with the *sp*-Elements

Aluminium in the solid state does not react with polonium vapour[18].

Gallium polonide GaPo (orange metallic substance) is formed when liquid gallium is heated (340–470 °C) in polonium vapour. Under these conditions a stationary concentration of polonium in gallium is reached, 51–52 at.% (the system can be regarded as a solution of polonium in gallium monopolonide, from which volatilisation of polonium starts at 420 °C). The temperature dependence of the dissociation pressure of gallium monopolonide at 605–735 °C and polonium concentrations of 50–39 at.% is described by Eqn.(1) with the coefficients: $A = 7.39 \pm 0.72$ and $B = 5410 \pm 670$. The enthalpy of the process is 103 ± 13 kJ mole^{-1}. At polonium concentrations <39 at.% the vaporisation of polonium depends on its concentration in the melt, which shows the formation of a solution[19].

Indium polonide InPo (bluish metallic substance) is formed when liquid indium is heated (340–490 °C) in polonium vapour. Under these conditions a constant concentration of polonium in indium (50 at.%) is achieved and is retained, but a loss of indium (and polonium correspondingly) from the specimen is noted. After equilibrium had been reached in the ampoule between the polonium condensate and the specimen it was found that the polonium condensate contained ~40 at.% of indium, which corresponds to the composition of indium sesquipolonide In_2Po_3; the latter seems to be volatile at 490 °C. The temperature dependence of the dissociation pressure of indium monopolonide at 425–575 °C and polonium concentrations of 47–41 at.% is described by Eqn.(1): $A = 9.87 \pm 0.16$, $B = 6740 \pm 120$. The enthalpy of the process is 129 ± 3 kJ mole^{-1}. At polonium concentrations <41 at.% the vapour pressure depends on its concentration in the melt, showing the formation of a solution[19].

Carbon does not react with polonium vapour during heating to 700 °C.[12]

Silicon does not react with polonium vapour during heating to 850 °C.[20]

Germanium starts to absorb polonium vapour when it reaches the melting point (940 °C). The amount of polonium absorbed by the germanium depends on the pressure of the polonium vapour. Raising the temperature of the melt to 980 °C leads to release of the polonium. It is assumed that polonium dissolves in the molten germanium[11].

Tin polonide is formed during the heating of molten tin (370–455 °C) in polonium vapour. After a layer of tin polonide (30 μg mm^{-2}) has formed on the surface the reaction rate is reduced by a factor of ~100, despite the temperature being raised to 590 °C, showing the low solubility of tin polonide in tin. Release of polonium from the resulting specimen on heating starts at 670 °C.[20]

Lead polonide PbPo (f.c.c. lattice of NaCl type, $a = 6.59$ Å, density 9.6 g cm^{-3}) is formed when lead is heated (350 °C) in polonium vapour and also appears in the condensate of metallic polonium during its α-decay[12]. The temperature dependence of the vapour pressure of lead polonide at 640–850 °C is described by Eqn.(1) with $A = 9.06 \pm 0.07$, $B = 7270 \pm 80$. The enthalpy of vaporisation is 139 ± 2 kJ mole^{-1}. When more than 3% radiogenic lead has accumulated in polonium the vapour pressure of the latter falls, negative departures from the vapour pressures calculated by Raoult's law being observed[14].

Nitrogen does not react with polonium during heating to 850 °C, since the polonium sublimes in an atmosphere of nitrogen without undergoing any changes[21]. An explosive polonium nitride is probably formed when ammonium hexabromopolonate(IV) is heated (200 °C).[22].

Antimony in the solid state starts to absorb polonium vapour at 340 °C; the process takes place more vigorously at 470–600 °C. When heated in a vacuum, antimony containing 7.5 at.% polonium starts to lose polonium at 420 °C. During vacuum distillation (600 °C) separation of the polonium and antimony is observed as distinct condensation rings, which shows that an alloy is formed[11].

Bismuth starts to absorb polonium vapour at 350 °C; the Bi–Po phase is assigned two structures: rhombohedral ($a = 4.456$–4.503, $c = 3.602$ Å) and f.c.c. ($a = 3.602$ Å), but there are no definite results for this system[18]. Analysis, by pyrochemical and distillation methods, of the polonium isolated from irradiated bismuth shows that a high degree of separation could be achieved but the polonium could not be completely freed from bismuth[7].

Polonium dioxide is formed slowly from the elements without additional heating, but this reaction is most vigorous at 250 °C. The composition of the oxide was determined from the change in oyxgen pressure during the oxidation of polonium[23]. When polonium dioxide is heated its colour changes gradually from pale yellow to reddish brown owing to a change in the structural modifications (yellow: f.c.c. lattice of UO_2 type, $a = 5.626$–5.687 Å; red: tetragonal, $a = 5.44$, $c = 8.34$ Å [23,24]). Polonium dioxide dissociates in a vacuum at 500 °C. The temperature dependence of the saturated vapour pressure of polonium during the dissociation of polonium dioxide (530–595 °C) is described by Eqn.(1) with $A = 21.57 \pm 0.71$, $B = 16\,920 \pm 500$. The enthalpy of the process is 324 ± 10 kJ mole^{-1}.[25]

Polonium dioxide starts to vaporise in oxygen at 690 °C. The temperature dependence of its saturated vapour pressure in oxygen (700–835 °C) is described by Eqn.(1) with $A = 11.13 \pm 0.11$, $B = 10\,070 \pm 150$. The enthalpy of vaporisation is 192 ± 3 kJ mole^{-1}. An oxygen pressure of 8.7 Pa is required to suppress the thermal dissociation of polonium dioxide at 500 °C, but 13 kPa is needed at 790 °C.[26] The coefficients of the temperature dependence of the polonium dioxide vapour pressure in the interval 718–932 °C were determined by a transpiration method: $A = 14.69 \pm 0.46$, $B = 14\,270 \pm 510$. The enthalpy of the process at 825 °C is 273 ± 10 kJ mole^{-1}.[27]

However, perhaps Steinmeyer and Kershner[27] were not observing the dissociation of polonium dioxide, as is shown by the similarity between the enthalpy of vaporisation they obtained[27] and the enthalpy of vaporisation of polonium dioxide with simultaneous flow dissociation (264 kJ mole^{-1}).[26]

Sulphur does not react with polonium. Polonium sulphide PoS is precipitated by hydrogen sulphide from acidic solutions of polonium and decomposes when heated (275 °C) in a vacuum[3].

Fluorine. Volatile polonium hexafluoride could not be obtained by the fluorination of polonium[9]. Metallic polonium is readily soluble in hydrofluoric acid, probably with the formation of fluoro-complexes. A white solid substance (probably polonium tetrafluoride) is formed by the action of dilute hydrofluorice acid on polonium hydroxide or tetrachloride[3,15].

Polonium dichloride and tetrachloride are obtained as a mixture by direct synthesis from the elements at 125–200 °C. At low chlorine pressures and temperatures polonium dichloride is formed preferentially (ruby-red substance, orthorhombic); at high chlorine pressures and temperatures polonium tetrachloride (lemon-yellow substance, monoclinic or triclinic) is formed. Polonium dichloride is more volatile than the tetrachloride therefore they can be separated by sublimation[9]. Polonium tetrachloride in a medium of chlorine melts at 300 °C with the formation of a pale yellow melt; the melt becomes ruby-red at 350 °C, possibly as a result of decomposition to the dichloride, and at 390 °C it boils with the release of purple-brown vapours, which become bluish green above 500 °C, probably owing to a change in the degree of association. In a vacuum, polonium tetrachloride decomposes at 200 °C to the dichloride, which sublimes in an atmosphere of nitrogen at 190 °C with slight decomposition. Polonium dichloride is reduced to the metal during prolonged heating in hydrogen or hydrogen sulphide[28].

Polonium tetrabromide (bright red) is obtained when metallic polonium is heated (250 °C) in bromine vapour (27 kPa) and melts in a medium of bromine at 330 °C with the formation of a dark liquid, which broils at 360 °C. Polonium tetrabromide decomposes to the dibromide in a vacuum at 200 °C and is reduced to the dibromide by hydrogen sulphide (without heating) and sulphur dioxide (on heating). Polonium dibromide (purple-brown) sublimes in a vacuum at 110 °C and melts at 270–280 °C in a sealed volume (nitrogen atmosphere), probably with disproportionation[22].

Polonium tetraiodide (black) is formed when metallic polonium is heated (40 °C) in iodine vapour (133 Pa) and sublimes in an atmosphere of nitrogen at 200 °C with partial decomposition to the metal. Polonium tetraiodide is reduced to the metal when heated in hydrogen sulphide and does not react with ammonia[29]. When heated, polonium tetraiodide dissociates into polonium di-iodide and iodine. The temperature dependence of the vapour pressure of polonium di-iodide at 200–315 °C is described by Eqn.(1): $A = 10.7 \pm 0.71$, $B = 4905 \pm 362$. The enthalpy of the process is 93.7 kJ mole^{-1}.

At an iodine pressure of 4–9 kPa polonium hexaiodide is formed in the condensed phase; it dissociates into polonium tetraiodide and iodine when heated. The temperature dependence of the vapour pressure of polonium tetraiodide at 270–350 °C is described by Eqn.(1) with $A = 12.75 \pm 0.52$, $B = 6533 \pm 300$. The enthalpy of the process is 125 kJ mole^{-1}. At an iodine pressure of 101–147 kPa the temperature dependence of the vapour pressure (probably of polonium hexaiodide) at 300–540 °C is described by Eqn.(1) with $A = 10.94 \pm 0.48$, $B = 6200 \pm 300$. The enthalpy of the process is 119 kJ mole^{-1}.[30]

3. Polonides of the *d*- and *f*-Metals

Lanthanide polonides are obtained by heating these metals in polonium vapour. Table 1 shows that the sesquipolonides Ln_2Po_3 are obtained after 1–10.5 h at 1000 °C; the monopolonides LnPo are formed after 0.75–2 h at lower temperatures.

Table 1. Synthesis temperatures (t) and melting points (M.p.) of the lanthanide polonides (n = atomic radio Po/Ln).

Lu	1000	1.02	1898	1.56	1898

*t = 900 (Ref.33).

After reaction with polonium the lanthanide powders have become black and finely dispersed[31] and their specific volume is either retained (lanthanum, gadolinium) or doubled (praseodymium, samarium, dysprosium, holmium). The compounds of polonium with cerium or erbium give a dark red luminescence; those with gadolinium or lanthanum give red; with yttrium, orange; with erbium or scandium, yellow; with thulium, pale yellow; and with lutetium, light green; the compounds with terbium, neodymium, and yttrium do not emit light[33]. All the lanthanide polonides melt incongruently with a great loss of polonium. The promethium[32], samarium, terbium, dysprosium, holmium, thulium, ytterbium, lutetium[31], and yttrium[34] monopolonides have NaCl-type f.c.c. lattices, scandium monopolonide an NiAs-type hexagonal lattice[35].

The start of the reaction between polonium vapour and certain lanthanides is observed at lower temperatures (praseodymium 400 °C, gadolinium 500 °C,[11] scandium 850 °C,[36] yttrium 350 °C [37]). The mean reaction rate of polonium

vapour with yttrium at 700 °C is 6.2×10^{-3}, that at 900 °C is 0.13 μg mm^{-2} h^{-1},[38] but the rate is higher (0.34 μg mm^{-2} h^{-1}) during the most vigorous part of the process[39]. The interacetion of the polonium takes place frontally both at the yttrium grain boundaries and within the grains. After metallographic examination a quantitative estimate of the layers of yttrium polonide for yttrium shows the formation of the monopolonide—a black, crumbling and fragmenting substance with a lower microhardness (84–93 kgf mm^{-2}) than yttrium (103–137 kgf mm^{-2}).[38] The temperature dependence of the polonium vapour pressure during the dissociation of yttrium monopolonide (1300–1600 °C) is described by Eqn.(1) with $A = 8.52 \pm 0.13$ and $B = 15\,600 \pm 190$. The heat of dissociation is 298 kJ $mole^{-1}$. The radiogenic lead which accumulates and the care in setting up the experiment [sic] have no significant influence on the results in the determination of the dissociation pressure of yttrium polonide[37]. The temperature dependences of the vapour pressure above scandium, dysprosium, and holmium polonides are described by Eqn.(1) with the coefficients:

Polonide	Sc	Dy	Ho
t, °C	1200—1250	1300—1600	1300—1350
A	6.83	8.90	17.88
B	8695	14509	29543
ΔH kJ $mole^{-1}$	166	277	565

During the vaporisation of polonium from these polonides, the lanthanide is vaporised simultaneously[36]. The great differences in the enthalpies of the processes (ΔH) show that they are different (vaporisation, dissociation, and probably association, respectively).

Mass-spectrometric investigations of the thermal stability and of the vaporisation of lanthanum, neodymium, gadolinium, and dysprosium monopolonides showed that their vaporisation is incongruent, with decomposition into the elements. Appearance of polonium vapour starts to be observed at 1300 °C for lanthanum polonide, at 1100 °C for gadolinium polonide, at 1040 °C for dysprosium polonide, and 850 °C for neodymium polonide[40].

Thorium polonide is formed when thorium is heated (700 °C) in polonium vapour, the mean reaction rate at 700 °C being 3.1×10^{-3} mg mm^{-2} h^{-1}. The interaction takes place at centres[38].

Titanium monopolonide (NiAs-type hexagonal lattice) is formed when titanium is heated (540–550 °C) in polonium vapour; it dissociates at ~700 °C.[41] The loss of polonium from titanium polonide starts at 650 °C; it is almost complete after 8 h at 710 °C.[42]

Zirconium monopolonide (NiAs-type hexagonal lattice) is formed when zirconium is heated (460 °C) in polonium vapour; it dissociates at ~700 °C.[41]

Hafnium monopolonide (NiAs-type hexagonal lattice) is formed when hafnium is heated (380–400 °C) in polonium vapour; it dissociates at ~700 °C.[41] The temperature dependence of the polonium vapour pressure in the dissociation of hafnium polonide (700–900 °C) is described by Eqn.(1) with $A = 5.91 \pm 0.05$ and $B = 6335 \pm 704$. The enthalpy of the process is 121 kJ $mole^{-1}$.[43]

Notes: "+" = reacts with polonium vapour; "–" = does not react; investigated up to t, °C; "ind." = synthesised by an indirect route. In the first row is shown the temperature for the start of synthesis; in the second row, the vaporisation (v) or dissociation (d) temperature; in the third row, the atomic ratio of polonium to the element.

Manganese polonide is formed when manganese is heated (350 °C) in polonium vapour; it dissociates at 660 °C.[11] It was found earlier[9] that a large number of phases is probably formed in the manganese–polonium system, but a single hexagonal lattice is observed.

Nickel polonide is formed when nickel is heated (300 to 600 °C) in polonium vapour. The polonium : nickel atomic ratio in the compound varies between 1 and 2 and the lattice (NiAs-type hexagonal) parameters are variable. Nickel polonide is extremely volatile, it condenses at 500 °C, and its melting point is ~625 °C.[12]

Platinum polonide $PtPo_2$, obtained in 1949, probably has a hexagonal lattice of $Cd(OH)_2$ type and decomposes at 450 to 600 °C.[9]

Tantalum, molybdenum, tungsten (up to 700 °C), *chromium* (up to 1000 °C),[39] *rhenium* (up to 1040 °C),[11] *cobalt* (up to 900 °C), *technetium* (up to 1000 °C), *ruthenium, osmium* (up to 1050 C),[19] and *iron*[3] do not react with polonium vapour when heated to the temperatures stated in parentheses.

Tantalum, molybdenum[36,37] and tungsten[31,33] are used as materials of construction for supporting polonium preparations in high-temperature investigations, therefore it can be considered that these metals do not react with polonium, at least up to 1600 °C.

V. CONCLUSION

The interaction of polonium with most of the chemical elements has now been studied (cf. Table 2). All the alkali and alkaline earth metals investigated, which comprise the *s*-group elements, and the elements of the copper and zinc subgroup react with polonium to form the corresponding polonides.

The *sp*-elements investigated, when in liquid or gaseous state, react with polonium. The exceptions are nitrogen and sulphur probably because of the strong molecular bonds in these elements. The *sp*-metals and semimetals form unstable compounds which decompose rapidly. Beyond the limits of existence of these compounds, solutions are formed. Gaseous oxygen and the gaseous halogens react with metallic polonium to form the corresponding dioxide or halides of various compositions.

The *d*- and *f*-transition metals behave variously in their interaction with polonium vapour. The lanthanides form the most stable compounds. The metals of the IVB subgroup also form compounds, but their thermal stability is lower. The other metals investigated do not react with polonium. Because of the peculiar electronic structures of manganese, nickel, and platinum they are exceptions and do form compounds with polonium.

In most of the investigations the properties of the polonium compounds are compared with the properties of the tellurium compounds and their similarity is reported in accordance with the position of polonium in the Periodic Table.

Despite the considerable number of papers on the thermal reactions of polonium which have now been published there have been relatively few studies of its binary compounds and these are limited by the specific features of this element and the experimental difficulties in carrying out such investigations.

Advances in Enantioselective Hydrogenation in the Presence of Chiral Complexes of Rhodium, Palladium, and Cobalt

E.I.Klabunovskii

Data on the enantioselective hydrogenation of the C=C and C=O bonds in prochiral compounds in the presence of homogeneous and heterogeneous chiral complexes of rhodium, palladium, and cobalt are surveyed. They are examined from the standpoint of the influence of the structure of the ligand on the asymmetric effectiveness of the complex.
The bibliography includes 90 references.

I. INTRODUCTION

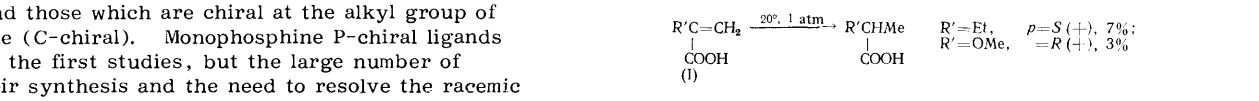
A new field of homogeneous catalysis—enantioselective reactions under the influence of chiral metal complex catalysts—has arisen recently and has been developing successfully. Such processes became possible after Wilkinson's rhodium—phosphine catalysts were converted in 1968 into chiral catalysts[1-4] by introducing into them chiral phosphines, the method of synthesis of which had just been developed. In the first studies[5,6] it was already shown that catalysts based on rhodium—phosphine chiral complexes exhibit an appreciable enantioselectivity not only in hydrogenation but also in many other reactions. Subsequently catalytic systems were found which effect asymmetric syntheses on the basis of certain prochiral substrates with an optimum yield reaching up to 95-99%.[4,7] These studies dealt mainly with the hydrogenation of the C = C bond in prochiral compounds, leading to optically active aromatic hydrocarbons or acids. The enantioselective hydrogenation of the C = O and C = N bonds in the presence of rhodium complexes as well as the use of chiral complexes of cobalt, nickel, and palladium as hydrogenation catalysts have been less thoroughly studied.

The enantioselective hydrogenation of acylaminoacrylic acids is of special interest as a method of synthesis of optically active natural aminoacids. In the study of this reaction, which is of practical importance and at the same time serves as a model, attention was concentrated on the selection of an effective ligand for rhodium complexes.

In the synthesis of new chiral ligands the availability of the initial optically active compounds is a decisive factor. At the present time mainly two types of phosphine ligands are used: those which are chiral at the phosphorus atom (P-chiral) and those which are chiral at the alkyl group of the phosphine (C-chiral). Monophosphine P-chiral ligands were used in the first studies, but the large number of stages in their synthesis and the need to resolve the racemic phosphine into enantiomers led to the wide use of C-chiral phosphines, which proved to be just as effective and which can be synthesised from readily available natural products.

This review represents an attempt at a systematic account of studies on the enantioselective hydrogenation reactions catalysed by homogeneous (and heterogeneous) metal complex catalysts containing transition metals and chiral ligands; the influence of the structure of the ligand on the optical yield is discussed. We may note that the reviews of studies in this field published previously[1-4] are extremely incomplete and are already obsolete.

Mention should be made of the principal definitions used in asymmetric catalysis. The efficiency of the asymmetric reaction is defined in terms of the optical yield (p, %):

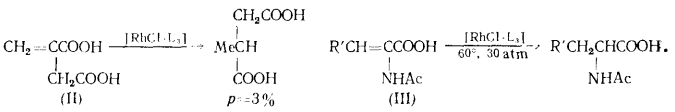


$$p = \{([R] - [S] / [R] + [S])\} \cdot 100$$

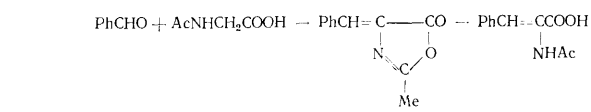
which represents the excess of one of the enantiomers in the product. The optical yield is determined experimentally from the ratio of the specific optical rotation of the reaction product to the specific optical rotation of the pure compound: $p = \{[\alpha]_{prod}/[\alpha]_{opt.pure\ comp.}\} \times 100$.

In this review the optically active product is characterised by the configuration, the sign of the optical rotation, and the optical yield; in terms of an abbreviated notation, we have, for example, $R(-)$, 25%. In a kinetically controlled process the optical yield does not vary with the degree of conversion; however, in practice p frequently changes in opposition to the overall specific rate of hydrogenation v and the efficiency of the enantioselective reaction can therefore be usefully characterised also by the rate of formation of the excess of one of the enantiomers w_R: $w_R = pv$ (mmol min^{-1}) per gramme of the catalyst.

II. CATALYSTS WITH P-CHIRAL LIGANDS

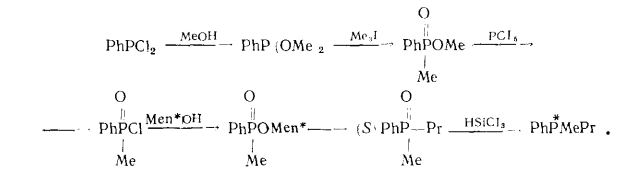


Enantioselective hydrogenation in the presence of Wilkinson's catalysts containing chiral phosphines was first achieved[5] in the hydrogenation of unsaturated acids in the presence of a rhodium complex containing the P*MePhR ligand with a chiral phosphorus atom P*:



The catalyst was obtained *in situ* by mixing solutions of S(+)-P*MePh(n-Pr) and [Rh(hexa-1,5-diene)Cl]. The replacement of Et by MeO in the prochiral substrate reverses the sign of the enantioselectivity and leads to an R-product[6]. Presumably the methoxy-group is involved in coordination [as in the hydrogenation of methyl acetoacetate in the presence of the Ni-modified (+)-tartaric acid[7,8]], as a result of which the conformation of the immediate complex is inverted. In

the hydrogenation of α-substituted styrenes [PhC(R') = CH_2, R' = Et, Pr, iso-Pr, OEt, α-naphthyl, Br, or benzyl] in the presence of complexes containing other phosphines [P*MePhR, R = Pr, benzyl, iso-Bu, or t-Bu), a yield p = 12 to 14% was obtained[9].



Almost simultaneously with the paper of Horner et al.[5], the communication of Knowles and Sabacky[10] was published, presenting data on the hydrogenation of atropic acid (I, R' = Ph) [p = (+), 15%] and itaconic acid (II):

The hydrogenation was carried out in a benzene–methanol mixture in a mixture of complexes containing the P*MePhR ligands, where R = Pr, iso-Pr, cyclohexyl, or *o*-anisyl. The complex with the ligand containing the *o*-anisyl group proved to be particularly effective: cyclohexyl-*o*-anisylmethylphosphine (CAMP) (here and henceforth the abbreviations adopted for ligands names in the original literature are employed). The complex is active in the hydrogenation of *N*-acylaminoacrylic acids (III), which can be readily obtained by the Erlenmeyer synthesis for substituted ligands via an intermediate azlactone, for example:

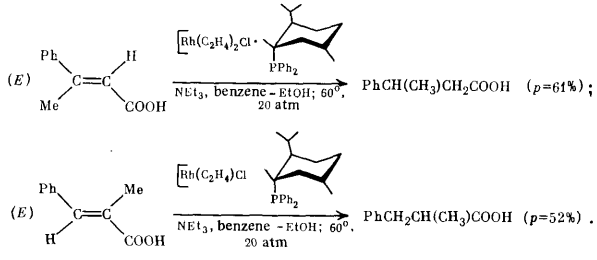
The optically active P-chiral monophosphine is synthesised in accordance with a mechanism involving a stage where the racemate is resolved into the enantiomers:

where Men* is the optically active methyl group. P*MePh-*o*-anisyl and P*Me-cyclohexyl-*o*-anisyl were obtained analogously. The complex is synthesised *in situ* by adding a solution of the ligand to the complex [RhCl(hexa-1,5-diene)]. All the hydrogenation reactions of the prochiral substrates are performed at 25 °C at a pressure of 2–3.5 atm in methanol with added NaOH. The results[11–13] are presented in Table 1. A patent[11] mentions also the possibility of using in this reaction the complexes of other metals (Ir, Ru, Os, Pd, and Pt) and the synthesis of optically active aminoacids (without indicating, however, the optical yields of the products).

The synthesis of optically active 3,4-dihydroxyphenylalanine (DOPA)—the preparation for the treatment of Parkinson's disease[13]. In relation to DOPA, asymmetric catalysis was first used for the industrial application of an asymmetric reaction in order to obtain a valuable product despite the difficulty of the preparation of the catalyst, which is the complex [Rh(hexa-1,5-diene)Cl.(+)P*MePh-*o*-anisyl], and the impossibility of regenerating it. The starting compound for the synthesis of L-DOPA was 4-acetoxy-*N*-acylamino-3-methoxycinnamic acid. A DOPA derivative was obtained with p = 60% and "pharmaceutically pure" DOPA was isolated from it after hydrolysis and recrystallisation. A DOPA derivative has been obtained with the yield p = 70.7% from *N*-acylamino-4-hydroxy-3-methoxycinnamic acid using the complex with P*Me-cyclohexyl-*o*-anisyl at 60 °C,[13] the addition of NEt_3 increasing p to 72%.

The high efficiency of rhodium (and also iridium and osmium) complexes with chiral diphosphine ligands in the hydrogenation of prochiral dehydroaminoacids and also α-(trifluoromethyl)vinyl acetate[14] has been reported[13]. Complexes having the general formula RR'P–CH_2–CH_2–PRR', where R = *o*-anisyl or ethoxyphenyl and R' = phenyl or tolyl, are obtained *in situ* from $[Rh(COD)Cl_2]BF_4$ (where COD = cyclo-octadiene) in methanol; the hydrogenation is carried out at 50 °C under a pressure of 4 atm. After recrystallising the products, the aminoacids phenylalanine (Phe), DOPA, and tryptophan (Trp) were obtained with optical yields of 92.8, 90.9, and 93.5% respectively.

Table 1. Hydrogenation of aminoacid precursors in the presence of rhodium catalysts with monophosphine ligands[10–13]:



R	R'	R''	Product: amino-acid	Product: p, %
Pr	H	PhCO	Ala	6
o-Anisyl	H	PhCO	Ala	32
o-Anisyl	Ph	Ac	Phe	45
Pr	Ph	Ac	Phe	14.5
Pr	3-MeO-4-(OH)C_6H_3	Ac	DOPA	28
Cholesteryl	3-MeO-4-(OH)C_6H_3	Ac	DOPA	1.1
iso-Pr	3-MeO-4-(OH)C_6H_3	Ac	DOPA	20
Benzyl	3-MeO-4-(OH)C_6H_3	Ac	DOPA	8
m-Anisyl	3-MeO-4-(OH)C_6H_3	Ac	DOPA	0.1
o-Anisyl	3-MeO-4-(OH)C_6H_3	Ac	DOPA	46
o-Anisyl	3-MeO-4-Ac-C_6H_3	Ac	DOPA	50
Methylcyclohexyl-*o*-anisylphosphine*	3-MeO-4-(OH)C_6H_3	Ac	DOPA	70.7
Methylcyclohexyl-*o*-anisylphosphine**	3-MeO-4-(OH)C_6H_3	Ac	DOPA	65

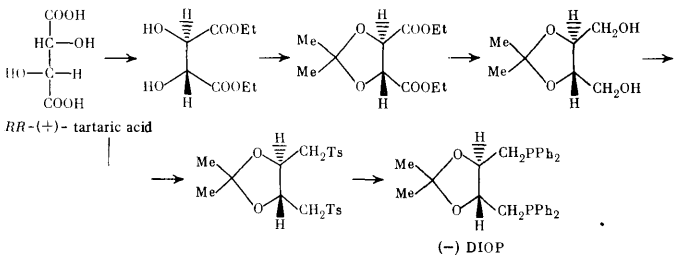
III. CATALYSTS WITH C-CHIRAL LIGANDS

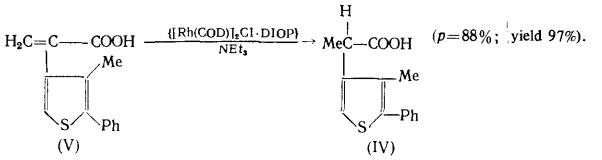


Catalysts of this type have come to be widely used. The first attempt to employ a complex containing a C-chiral ligand $PPh(CH_2C^*HCH_3C_2H_5)_2$, obtained from natural isopentyl alcohol, was unsuccessful[1]. Successful enantioselective hydrogenation was achieved[1,15,16] in 1971 using rhodium complexes with comparatively readily synthesised C-chiral ligands based on menthol; PPh_2Men (MDPP) and neomenthyldiphenylphosphine (NMDPP), the latter being more effective in the hydrogenation of compound (I, R = Ph) (p = 28%); other examples are given below:

The difference between the effects of complexes with these phosphines has been explained[1] by the fact that menthol and neomenthol are diastereoisomers with different properties and that the phosphines obtained from them exhibit different

capacities for coordination. MDPP apparently forms a more stable complex with rhodium than NMDPP, which is the reason for its lower efficiency.

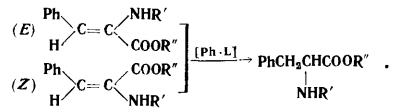
A very effective and readily available diphosphine ligand (DIOP) was synthesised[17] from (+)-tartaric acid via the scheme



The comparative simplicity of the synthesis and the high enantioselectivity of the reaction of the complex containing DIOP attracted attention to this ligand and it became a common readily available reagent used in many preparative syntheses of optically active compounds.

The complex is obtained under conditions ruling out contact with air by adding a solution of the ligand mixed with NEt_3 to a benzene solution of $[RhCl(CoCt)_2]$ (CoCt = cyclooctene). The hydrogenation of prochiral compounds containing the C = C bond at room temperature and atmospheric pressure leads to the formation of products with very high optical yields. The following results were obtained already in the first study[17]: $p = 63\%$ for (I, R′ = Ph) and $p = 72\%$ for (III). With increase of the ratio P/Rh above two, the activity of the complex disappears as a consequence of the formation of the catalytically inactive complex $[Rh(DIOP)]^+Cl^-$. The complex [Rh-DIOP] is particularly active in the asymmetric synthesis of aminoacids by hydrogenating their precursors—substituted acrylic acids or their amides. The use of methyl esters or *N*-benzoyl derivatives as well as aliphatic acids reduces *p*, while the azlactone of *N*-acetamidocinnamic acid, benzoylhydanatoin, and dehydrobenzoylvaline are not hydrogenated at all.

The optical yields of the aminoacids obtained were enhanced further by recrystallising the products. Thus phenylalanine with $p = 88\%$ was obtained after a single crystallisation from crude *N*-acetylphenylalanine ($p = 72\%$); the overall yield was 66%. The catalyst based on (−)-DIOP leads to unnatural aminoacids of the D-series. In order to obtain the natural L-aminoacids, it is necessary to employ (+)-DIOP, which is synthesised from synthetic *SS*(−)-tartaric acid, which significantly reduces the practical value of the synthesis of aminoacids by this procedure. The chiral diarsine which is an analogue of DIOP makes it possible to obtain the natural aminoacid isomers but with low optical yields[18].

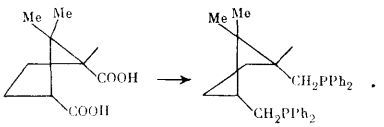


The DIOP ligand is a typical C-chiral diphosphine. The high enantioselectivity of the complex based on it can be accounted for by the configurational rigidity of the ligand molecule and the *trans*-position of the dioxolan ring relative to the chelate unit. This model of the complex explains satisfactorily its asymmetric activity[19]. The presence of the carboxy-group in compound (III) increases *p* under the influence of [Rh.DIOP], while the introduction of the ester group reduces the optical yield as a consequence of the weakening of the coordination of the substrate molecule. Bulky groups, for example adamantyl or bornyl groups, have a particularly marked effect[19].

The complex [Rh.DIOP] has been used in the synthesis of the anti-inflammatory compound (+)-(IV) by hydrogenating compound (V). Although compound (V) contains the sulphur atom of the thiophen ring, the hydrogenation proceeds smoothly and the optical yield is higher than in the hydrogenation of atropic acid [an analogoue of compound (V)], in the presence of this complex[20]:

The influence of the *E*,*Z*-isomerism of the substrate on enantioselectivity has been studied mainly in relation to the hydrogenation of substituted acrylic acids in the presence of rhodium complexes of DIOP[21] and bis(ethylidenephenylanisylphosphine) (EPAP).[14] Table 2 shows that there is a significant difference between the enantioselectivity of the hydrogenation of the *E*- and *Z*-isomers of *N*-acylaminoacrylic acids. Esterification of the acid in general reduces *p* for both *E*- and *Z*-isomers. The asymmetric hydrogenation of the latter is more effective than that of the *E*-isomers.

Table 2. Enantioselective hydrogenation of *E*,*Z*-isomers of acylaminocinnamic acids and their esters in the presence of rhodium complexes with the DIOP and EPAP ligands[14] [the optical yields (*p*,%) are quoted]:



Substrate	R′	R″	Ligand DIOP	Ligand EPAP	Substrate	R′	R″	Ligand DIOP	Ligand EPAP
Z	Ac	H	81	94	*Z*	PhCO	Me	37.5	—
E	Ac	H	—	47	*Z*	PhCO	H	70	93
Z	Ac	Me	55	96	*E*	PhCO	H	25	39
E	Ac	Me	—	23	*E*	PhCO	Me	5.3	—

Table 3. Comparative catalytic efficiences of chiral rhodium complexes with various ligands in the enantioselective hydrogenation of prochiral *Z*- and *E*-substrates [the configurations and optical yields (*p*,%) of the corresponding products are quoted][124].

Substrate	Ligand Camphos	NMDPP	MDPP	CAMP	DIOP
Atropic acid	*S*; 6.1	*S*; 29.6	0	—	*S*; 44
(*E*) α-Methylcinnamic acid	*R*; 15.2	*R*; 60	*S*; 16.8	*R*; 12	*S*; 25
(*Z*) α-Methylcinnamic acid	*S*; 11.0	*R*; 25.2	0	*R*; 24	*R*; 33
(*E*) α-Phenylcinnamic acid	*S*; 11.8	*S*; 34.4	*R*; 27.2	*S*; 24	*R*; 15
(*Z*) α-Phenylcinnamic acid	*S*; 13.9	*S*; 9.1	*S*; 3.2	*R*; 1.5	*S*; 1
(*E*) β-Methylcinnamic acid	*S*; 9.7	*S*; 61.8	*S*; 1.2	*S*; 37	*R*; 14
(*Z*) β-Methylcinnamic acid	*R*; 11.4	*R*; 31.2	*S*; 30.6	*R*; 13	*S*; 28
Itaconic acid	*R*; 10.7	*R*; 8.1	*R*; 18.1	—	—
Mesaconic acid	*R*; 1.8	*R*; 5.9	*S*; 7.2	—	—

Table 3 shows that, when a monodentate molecule (α,β-unsaturated acids or esters) is hydrogenated, the influence of the *E*,*Z*-isomerism becomes less definite. The same picture has been observed also in hydrogenation in the presence of rhodium–amide catalysts[22,23] (see Table 10 below).

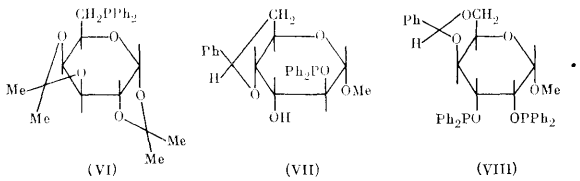


Table 3 presents comparative data on the catalytic efficiency of complexes with various ligands, including the diphosphine Camphos, obtained from (+)-camphoric acid[24]:

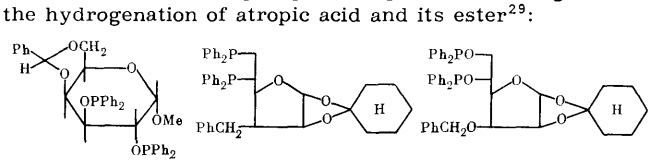
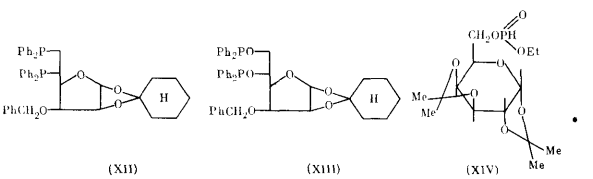
Thus interesting data have been obtained in the study of the simultaneous effect of the C- and P-chiral centres in the phosphine. Such a ligand was first used in the asymmetric dimerisation of olefins in the presence of the complex [NiP*Me-t-Bumen*]. The rhodium complex [Rh(COD)Cl. .P*MePhMen*], containing both the optically pure (i.e. C- and P-chiral) ligand(A) and the ligand(B) 87% epimerised at the P centre, has been used for hydrogenation[25]. The optical yields in the presence of the complexes with (A) and (B) were 13.5 and 27.5% for the *R*- and *S*-isomers in the hydrogenation of itaconic acid and 67.1 and 70.6% respectively for the *R*- and *S*-isomers in the hydrogenation of *E*-β-methylcinnamic acid. Apparently the presence of the ligands (A) and (B) in the catalytic complexes leads to enantiomeric products in both cases which indicates a significant influence of the P-chiral centre in the ligand of the rhodium complex on the stereochemistry of the products.



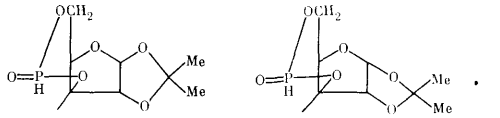
Rhodium complexes with chiral phosphinites (Camphinit) are also extremely effective catalysts[26]. A special comparison of the catalytic effect of the complexes [Rh.Camphos] and [Rh.Camphinit] demonstrated their similar enantioselectivities, the complex with phosphinite being more suitable for the hydrogenation of substrates without COOH or NHAc groups[26]. In this connection, the use of natural monosaccharides for the synthesis of both phosphines and phosphinites is extremely promising.

Ligands based on galactose (VI) and altrose (VII) have been synthesised[27]:



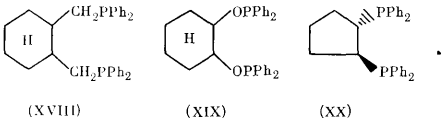
(VI) (VII) (VIII)

The catalyst was obtained *in situ* by the reaction of compound (VI) or (VII) with $[Rh(COD)Cl_2]_2$. The hydrogenation was carried out at 20 °C and atmospheric pressure. The hydrogenation of tiglic acid gave a higher optical yield (39%) than the hydrogenation of *N*-acetamidocinnamic and itaconic acids (1.7 and 2.7%). Catalysts containing diphosphonites based on glucopyranose (VIII) or galactopyranose (IX) are more effective[28]. In the presence of the complex of compound (VIII), *N*-acetamidocinnamic acid and its methyl ester give products with $p = 71$ and 60% respectively. Comparison of the enantioselectivities of the rhodium complexes of diphosphines and diphosphinites derived from glucofuranose [compounds (X) and (XI)] and idofuranose [compounds (XII) and (XIII)] demonstrated their similar efficiences in the hydrogenation of substituted acrylic acids; the enantioselectivity of the complexes with phosphinites proved to be higher in the hydrogenation of atropic acid and its ester[29]:



(IX) (X) (XI)

(XII) (XIII) (XIV)

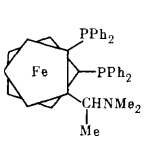


The chiral palladium complexes ($L_2PdCl_2PdL_2$), based on the acid galactose phosphite (XIV), also exhibit enantioselectivity in hydrogenation although it is weaker than that of the rhodium complexes. When compound (XIV) is treated with (−)-phenylethylamine, the derivative (XV) with a chiral P atom is formed and reacts with bis(π-palladium chloride) to produce a more effective complex. Palladium complexes with the cyclic phosphites (XVI) and (XVII) also exhibit an appreciable enantioselectivity[30–32].

(XVI) (XVII)

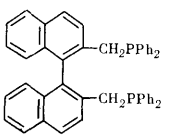
The efficiency of this palladium complex in the hydrogenation of citraconic acid is noteworthy, while in the presence of rhodium complexes with a wide variety of ligands the acid cannot by hydrogenated enantioselectively[1].

Cyclic diphosphines and diphosphinites (XVIII)–(XX) have also been used to synthesise rhodium complexes:



(XVIII) (XIX) (XX)

Table 4. Comparison of the enantioselectivities of rhodium complexes with the ligands (XIX), (XX), and DIOP in the hydrogenation of prochiral unsaturated compounds [the configurations and optical yields (p,%)] are quoted[35].



Substrate	*t*, °C	Ligand		
		(XIX)	(XX)	DIOP

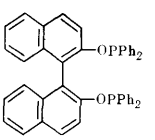
cis-2-Phenylbut-2-ene	50	*S*; 14.4	—	—
Atropic acid	50	*S*; 0.7	0	*S*; 6.3
Methyl atropate	50	*S*; 4.5	*S*; 20	*R*; 7
N-Acetamidocinnamic acid	0	*S*; 68.5	*S*; 12	*R*; 63
Methyl-*N*-acetamidocinnamate	50	—	*S*; 43	*R*; 55
N-Acetamidoacrylic acid	−20	*S*; 78.5	0	*R*; 73
N-Acetamido-*p*-hydroxycinnamic acid	50	*S*; 48.5	—	—

The compound *trans*-(+) (XIX) and the complex [RhCl(hexa-1,5-diene)$_2$] form a chelate which has a rigid structure and in its presence the enantioselective hydrogenation of prochiral precursors of aminoacids proceeds with an extremely high efficiency[34]. The contraction of the ring and the binding of $P(Ph_3)$ groups directly to the ring increase the enantioselectivity of the complex [ligand-(+)-*trans*-(XX)].[35] Even the hydrogenation of α-ethylstyrene, which has no polar groups, proceeds with a high efficiency in this instance. In the hydrogenation of unsaturated acids the yield p is low, but it increases somewhat in the hydrogenation of the esters. Table 4 presents the values of p obtained using complexes with the ligands (XIX) and (XX) and for comparison also with DIOP.



Isomeric atropisomericphosphines constitute another type of chiral ligands. The ferrocenyl derivatives of mono- or diphosphines, which exhibit simultaneously planar and central chirality of type (XXI), have been used in a complex with [RhCl(hexa-1,5-diene)] in the hydrogenation of acetamidocinnamic acids. The complexes (particularly the cationic complex) exhibit a very high enantioselectivity in the synthesis of the most important aminoacids—phenylalanine, tyrosine, and DOPA. The optical yield depends greatly on the polarity of the medium and on the presence of the NMe_2 group in the ligand[36] (Table 5). Tamao et al.[37] were the first to use the atropisomeric ligands (XXII) and (XXIII). The complex with compound (XXIII) proved to be more effective, the aminoacid esters and not the free aminoacids being formed in a high optical yield[38]:

(XXI)

(XXII)

(XXIII)

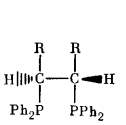


Table 5. Hydrogenation of acylacrylic acids in the presence of rhodium catalysts with atropisomeric ligands[36]:

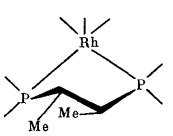

R	R'	R''	Ligand	Product	p, %	Solvent
H	Ph	H	(XXIII)	Phe	9	—
H	Ph	Me	(XXIII)	MePhe	76	—
H	H	H	(XXIII)	Ala	6	—
H	H	Me	(XXIII)	MeAla	76	—

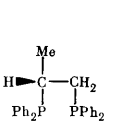
H	4-$AcOC_6H_4$	H	(XXI)	Tyr	87	MeOH—H_2O
H	3-MeO-4-$AcOC_6H_3$	H	(XXI)	DOPA	36	EtOH
H	3-MeO-4-AcO-C_6H_3	H	(XXI)	DOPA	86	MeOH—H_2O
H	3,4-$(CH_2O_2)C_6H_3$	H	(XXI)	DOPA	52	MeOH—H_2O

* The NHAc group in the initial substrate has been replaced by H.



A highly effective complex is formed also when[39] the five-membered chelate ring, formed, for example, from ligand (XXIV), has a fixed conformation[39] with two asymmetric carbon atoms and equatorial methyl groups [compound (XXV)]. The cationic complex $[Rh.(XXV)]^+.ClO_4^-$ (XXVI) also exhibits a high enantioselectivity. However, it has been shown[39] that the complex with the ligand (XXVII), having a single asymmetric carbon atom, is no less effective. The most typical results, using the complex [Rh.(XXIV)] (Chiraphos) in the hydrogenation of substituted aminoacrylic acids, are presented in Table 6.

(XXIV)

(XXV)

(XXVII)

It is seen that the complex exhibits an exceptionally high enantioselectivity in the case of aminoacids, leucine and phenylalanine having been obtained with $p = 100\%$. The disadvantages of the method include the necessity to synthesise the ligand from S(+)-lactic acid, which is difficult to obtain in a pure form. King et al.[40] attempted to eliminate this disadvantage and synthesised compound (XXII, R = Ph) from the enantiomers of mandelic acid.

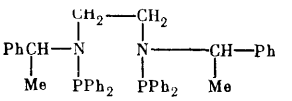


Table 6. Enantioselective hydrogenation in the presence of the complex [Rh.Chiraphos] [the optical yields (p, %) are quoted][39,40]:

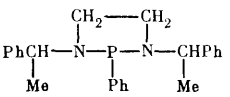

Substrate	R'	R''	Aminoacid product	Solvent	
				THF	EtOH
Z	H	Ac	AcAla	88	91

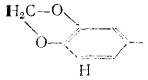
—	Ph	Ac	AcPhe *	82	—
—	Ph	Bz	BzPhe *	86	—

* L = (XXIV), R = Ph; in the remaining cases R = Me.

Morrison and Masler[16] were the first to report an attempt to employ chiral aminophosphines. A series of diaminodiphosphines have been synthesised[41] using S-α-phenylethylamine and the high efficiency of complexes with the ligands (XXVIII)-(XXX) has been demonstrated:

(XXVIII)

(XXIX)



(XXX)

The catalyst was obtained *in situ* by the reaction of [RhCl.$(CH_2=CH_2)]_2$ with compound (XXVI). Although the chiral centre in the ligand is remote from the reaction centre, the efficiency of the catalyst proved to be extremely high and comparable to that of [Rh.DIOP], the data for which are presented in brackets in Table 7.[41] The high efficiency of the complex with ligand (XXVIII), particularly when a polar solvent is used, has been explained[42] by the ionisation of the complex and the formation of a hydrogen bond between the solvent and substrate molecules. This has been confirmed by the finding that the cationic complex $[RhL_2(Solv)].BF_4$ is still more active than the chlororhodium complex; aminoacids are formed with $p = 82.5\%$. A high yield can be achieved both by the coordination of the polar groups in the substrate to the metal and by the interaction of the substrate with the ligand containing functional groups other than the

phosphine group. This has been shown in the hydrogenation of itaconic acid for which complexes containing chiral phosphines have been in general not particularly effective, although in certain cases the optical yield reached 53%.[20]

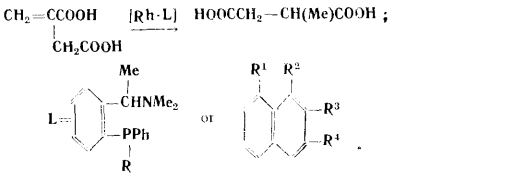


Table 7. Enantioselective hydrogenation in the presence of complexes containing aminophosphine ligands [the configurations and optical yields (p,%) of products are quoted][41]:

R	R′	R″	Configuration; p,%	Ligand

The influence of the structures of a series of aminophosphine complexes of rhodium has been studied[43]. The results presented in Table 8 have been obtained under comparable conditions for the ratio L/Rh = 2.

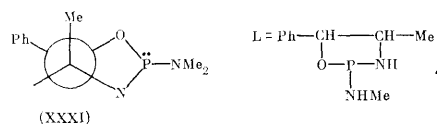

Table 8. Enantioselective hydrogenation in the presence of rhodium complexes containing aminophosphine ligands [the configurations and optical yields (p,%) of products are quoted][43]:

Ligand						Neutral complex	Cationic complex

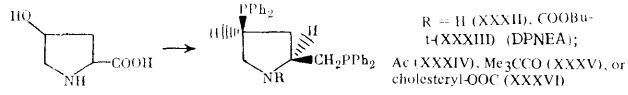
R	—	H	PPh_2	$CHMeNMe_2$	H	*S*; 5	0
R	—	H	H	$CHMeNMe_2$	PPh_2	*S*; 3.5	*S*; 15

The maximum yield was obtained in the presence of a complex with ligand (XXX), whose effect is comparable to that of [Rh.DIOP]. The introduction of a chiral P centre into the ligand [the aminophosphine (XXIX)] leads to the inversion of the configuration of the product, which occurs also when the H atom in the amino-group is replaced by Me, for example in the diphosphine derivative 1,2-bis(diphenylphosphinoamino)cyclohexane[45]. The replacement of the chiral α-phenylethyl group in compound (XXVIII) by the pinanyl group reduces the enantioselectivity of the catalyst[44]. The monoaminophosphines (XXIX) and (XXX) are less effective than the diphosphines. An attempt has been made[42] to repeat the results of Florini et al.[41] who used the ligands (XXIX) and (XXX). Despite the data of Florini et al.[41], the effect of the complex with compound (XXIX) could not be reproduced[42].

The derivatives of oxazaphospholan (XXXI) have been synthesised from (−)-ephedrine and used as ligands in palladium complexes of the following type[46]:



(XXXI)

The presence of chiral C and P centres in ligand (XXXI) was established by circular dichroism[46]. The hydrogenation of *N*-acetamidocinnamic acid, its azalactone and dimethyl itaconate took place with yields of 16.4, 4.0, and 9.9% respectively. The complex is one of the few chiral palladium complexes capable of effecting asymmetric hydrogenation. The low optical yield in the reaction is apparently associated with the partial decomposition of the complexes in the reaction.

A new synthesis of a chiral rhodium complex involving the substitution of one ligand in the coordination sphere of the triphenylphosphine complex by chiral α-phenylethylamine has been achieved[47]. The complex exhibits enantioselectivity in the hydrogenation of *N*-acetamidocinnamic acid (p = 20.2%) and its methyl ester (p = 11.8%). The optical yield increases with increase of the ratio amine/$RhCl(PPh_3)_3$ to a definite limit.

Ligands having two phosphine groups and the NH and NR groups have been obtained[48] from hydroxyproline[48]:

The catalyst was obtained *in situ* by the interaction of the ligand with the complex [Rh.hexa-1,5-diene]Cl; its efficiency was investigated in the hydrogenation of substituted aminocinnamic acids; the complex with compound (XXXIII) is more effective than that with (XXXII). NEt_3 influences the optical yield for complexes with a substituted NH-group, whereas in the case of [Rh.(XXXII)] this influence is absent as a consequence of the interaction of the free NH group in the ligand with the COO group in the substrate molecule. The [Rh.(XXXIII).NEt_3] system exhibits a greater enantioselectivity (p = 80–90%) when the reaction is carried out in ethanol than in methanol or water, which indicates the more effective interaction of the complex with the substrate in a less polar solvent[48]. Other substrates normally employed yielded the following results: p = 15 and 24% were obtained for (Z)-α-methylcinnamic acid and dimethyl itaconate in the presence of [Rh.(XXXIII)], and p = 29.5% was obtained in the presence of [Rh.(XXXVI)].[49] In addition, hydrogenation of olefins in the presence of the last complex yielded hydrocarbons:

$$CH_2=C(Et)R \rightarrow MeCH(Et)R$$

R = n-Bu, p=5.8 %, R=Ph, p=24.7%

If the NH-group of the ligand is acylated [compounds (XXXIV) and (XXXV)], the addition of Et_3N impairs the enantioselectivity and can actually lead to a configuration of the product which is the opposite to that obtained in the presence of the complexes with compounds (XXXII) and (XXXIV) (Table 9)[50]. The activity of the complexes of compounds (XXXIV) and (XXXV) in the hydrogenation of benzyl derivatives of the alanine precursor, which is of great interest for peptide synthesis, has been studied[50].

Table 9. Hydrogenation of acylacrylic acids in the presence of rhodium complexes containing heterocyclic diphosphines(L): [50]

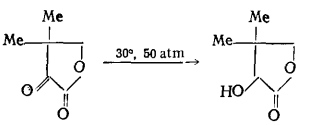
The efficiences of [Rh.(XXXIII)] and other rhodium-phosphine complexes have been compared in the hydrogenation of itaconic acid[51]. At 20 °C and a pressure of 20 atm in the presence of the complex [Rh.(XXXIII)]with added NEt_3, methylsuccinic acid was obtained with $p = 92\%$. This high optical yield was achieved after converting the complex into the cationic form $[L.Rh(COD)]^+ClO_4^-$ † with the ratio NEt_3 : itaconic acid = 1. For the neutral complex, p increases from 78.8 to 90.6% with increase of this ratio, i.e. in fact when the complex is converted into the cationic form. Thus the role of NEt_3 reduces to activating the carbonyl substrate and the formation of the carboxylate anion, which then interacts with rhodium in the coordination sphere of the complex and is converted into a cationic complex[51]. Comparative hydrogenation of itaconic acid in the presence of a number of complexes showed that, in the series of the chiral ligands PMePhPr-n,[10] NMDPP,[1] MDPP,[1] Camphos[20], PMePhMen,[25] DIOP,[16] BPPA,[43] Amphos[43], and DPNEA [48,51] the last proved to be the most effective; the optical yield reaches 92% in the presence of the complex with the ligand (XXXIII) (DPNEA).

The enantioselective hydrogenation of the C = O and C = N bonds has been less well studied than the hydrogenation of the C = C bond. Wilkinson's catalyst is known to be relatively inactive in the hydrogenation of the C = O bond and also it induces the decarbonylation of aldehydes. However, the use of cationic rhodium complexes with phosphine ligands made it possible to achieve the hydrogenation of certain ketones and Bonvicini et al.[52] reduced ketones for the first time under the influence of the rhodium complex with the P-chiral ligand $PMePhCH_2Ph$ (the PMePhEt ligand proved to be relatively ineffective according to Tanaka et al.[53] owing to the small difference between the bulks of the phosphine groups). The reaction was performed at 20 °C and atmospheric pressure in anhydrous ethanol[52]. The catalyst is in general relatively inactive and the overall rate of reaction decreases in the course of the hydrogenation. Phenylbutanol ($p = 8.6\%$) and 2-butanol ($p = 1.9\%$) were obtained from the corresponding ketones. The optical yields are small but are comparable to those obtained in the presence of the same complex in the hydrogenation of prochiral C = C substrates[6]. The introduction of DIOP into the complex in place of the P-chiral phosphine permits the enantioselective hydrogenation not only of the C = O but also of the C = N bond[54].

The use of the cationic rhodium (and also iridium) complex[55] $[Rh(COD)(CAMP)_2]^+BF_4^-$ with the CAMP ligand in the hydrogenation of ketones at 75 °C and 6 atm in isobutyric acid solution with added 0.1% of water is much more effective[10]: the ketones MeCOR (R = ET, Hex, iso-Bu, Bz, or Ph_2CH) give rise to alcohols with optical yields of 12, 14, 14, 19, and 32% respectively. The antiparallel variation of p and of the overall rate of reaction has been observed[55]. Methyl acetoacetate reacts much faster than ketones in alcohol (25°, 34 atm) with formation of methyl β-hydroxybutyrate ($p = 56\%$). The yield p is greatly influenced by the hydrogen pressure, temperature, the added water, and the nature of the solvent. It has been shown for the hydrogenation of 2-octanone (75 °C, 6 atm) that p increases from 0.3 to 12% in the series of solvents tetrahydrofuran (THF) < ethyl acetate < dimethylacetic acid < acetic acid. When the reaction is carried out in isobutyric acid, an increase of the water content in the solvent to 8% reduces sharply the optical yield (from 10–14 to 5%).[55]

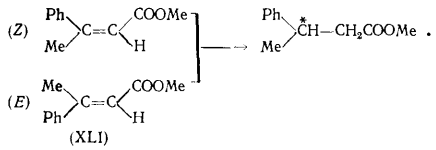


The complex (Rh(norbornadiene).(XXVIII)] is able to catalyse the hydrogenation of ketones (25°, 12 atm): the corresponding alcohols were obtained with $p = 17$ and 8% respectively from acetophenone and hexyl methyl ketone[41]. The complex [Rh(XX)] exhibits an appreciable enantioselectivity[35]. The hydrogenation of acetophenone at 80 °C leads to the corresponding alcohol with $p = 22\%$, while that of propiophenone gives rise to the alcohol with $p = 3.5\%$. The enantioselective dehydrogenation of the racemic α-phenylethyl alcohol takes place in the presence of the complex $[RuCl_2 \cdot PPh_3 \cdot (neomenthylPPH_2)]$. From this it follows that a rigorous determination of the degree of asymmetric synthesis in each individual case requires a detailed study in order to be able to show that the enantioselective reaction does not occur.

The hydrogenation of the intermediate (XXXVII) in the synthesis of prostaglandin (XXXVIII), which is a reaction of practical importance, has been achieved[56] in the presence of the complex [Rh.CAMP] ($p = 68\%$):

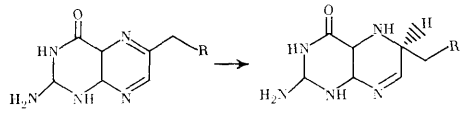
(XXXVII) (XXXVIII)

The complexes of the ligands (XXXIII) and (XXXVI) are capable of hydrogenating enantioselectively the keto-group in the pyruvates MeCOCOOEt and MeCOCOOBu-n with $p = 62$–65%.[49] Ketopanthoyl-lactone is hydrogenated to R(−)-panthoyl-lactone (XXXIX) with a high optical yield ($p = 86.7\%$).[57]



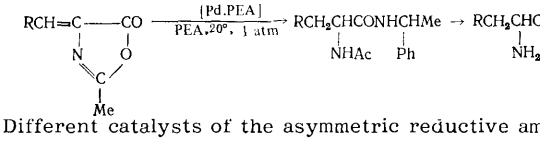
(XXXIX)

† COD = 1,5-cyclo-octadiene (Ed. of Translation).



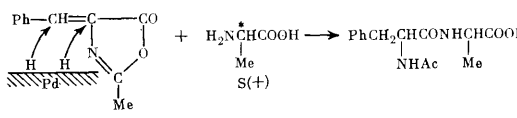
IV. RHODIUM AND PALLADIUM CATALYSTS CONTAINING AMIDES AND AMINES

Chiral rhodium-amide catalysts, capable of the enantioselective hydrogenation of unsaturated acids[22,23] as well as acetamidoacrylic acid[58], are obtained *in situ* when $[(Py)_3.RhCl]$ is treated with $NaBH_4$ in a solution of an optically active amide. With decrease of the concentration of the chiral amide to 5% in solution in the methyl ether of diethylene glycol, the enantioselectivity of the catalyst is preserved, which shows that, instead of the solvation of the complex by the chiral solvent, the chiral (apparently ionic) complex $[(Py)_2(amide)RhCl(BH_4)]^+Cl^-$ (XL) is formed. Various amides have been investigated as ligands (Table 10). The interesting fact (see Table 10, Nos.7–10) that the *Z,E*-isomerism of the substrate has almost no influence in this instance on the enantioselectivity is striking[22]



(XLI)

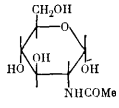
Apart from this model reaction involving the hydrogenation of compound (XLI), the application of the complex with the amide (XL) made it possible to hydrogenate the C = C bond in the precursor of the aminoacid (III, R = Ph) and to obtained acetylphenylalanine with $p = 75.3\%$ and an overall yield of 66%.[56] Another example of a reaction of practical importance is the synthesis[59] of folic acid (XLII) under the influence of the rhodium complex containing α-phenylethylformamide as the chiral ligand, via the reaction:

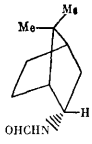


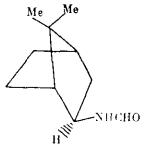
(XLII)

In the presence of palladium- or rhodium-based metal complex catalysts incorporating α-phenylethylamine (PEA), enantioselective reductive aminolysis of the azlactones of substituted acylaminoacrylic acids take place with formation of the corresponding aminoacid amides and, after their hydrolysis, of the aminoacids[60]:

Different catalysts of the asymmetric reductive aminolysis of azlactones have been obtained by the reduction of $PdCl_2$ or $RhCl_3$ in aprotic solvents containing *S*(−)-PEA, H_2, $NaBH_4$, and *S*(−)-α-phenylethylaminoborane have been used as the reductants[60]. In *trans*-$Pd(PEA)_2Cl_2$-*S*(−)-α-phenylethylaminoborane system the excess of the *SS*-amide formed on reduction was 53%. An important component of the catalytic system is the chiral nucleophile, which can be PEA or S-alanine. In the latter case the reaction leads to the formation of a dipeptide, which is of considerable practical interest because dipeptides are assimilated by organisms more readily than aminoacids:







V. CHIRAL COBALT HYDROGENATION CATALYSTS

The development of effective chiral hydrogenation catalysts without platinum metals is of special interest. Cobalt complexes are extremely active dissymmetric catalysts capable of hydrogenating both C = C and C = O bonds. Two types of catalysts are known. They are based on $Co(CN)_5$ or $Co(DMG)_2$ (where DMG = dimethylglyoxime) and contain chiral ligands. The complex with $Co(CN)_5$, containing coordinated isoleucine as the aminoacid L, exhibited a weak enantioselectivity ($p \cong 0.1\%$) in the hydrogenation of atropic acid (I, R = Ph).[62] The replacement of the coordinated aminoacid by *R*(−)-propylenediamine increases *p* to 1.1%, while the introduction of *S*(+)-*N,N'*-dimethylpropylenediamine makes it possible to obtain a product with $p = 7.1\%$ from (I, R = Ph). The low enantioselectivity is apparently associated[63] with the difficulty of achieving the coordination of the substrate in the complex. It has been noted that amines with opposite configurations lead to the same *S*-acids.[64,65]

Table 10. Enantioselective hydrogenation of *E*- and *Z*-methyl β-methylcinnamates in the presence of rhodium—amide catalysts[22,23]:

(*Z*) (*E*)

9		100	*Z*	*S*; 28
10	ditto	100	*E*	*S*; 22

It is known that the complex $[Co(DMG)_2.amine]$ is active in the hydrogenation of the carbonyl group and azo-, azoxy-, and nitro-groups. A high enantioselectivity in the hydrogenation of the C = O bond has been observed for this complex after the introduction into its composition of a chiral

aminoalcohol or amine. Thus [Co(DMG)$_2$.quinine] exhibited a high enantioselectivity in the hydrogenation of benzil[66]:

$$\underset{S(+)\text{-benzoin}\quad p=61.5\%}{\text{PhCO—COPh} \rightarrow \text{PhCH(OH)COPh}};$$

The reaction proceeds under mild conditions (room temperature and atmospheric pressure). The ratio substrate/Co = 10–20, quinine/Co = 2, and the solvent is benzene or THF. In a polar solvent p decreases. Under the reaction conditions, enantioselective separation of the racemic benzoin does not occur and the chirality of the product therefore rises at the catalytic stage[66].

The hydrogenation of the ketones of the type PhCOCOR also leads to $S(+)$-benzoins. Since the product readily racemises, the true value of p was found by extrapolating the time variation of p to the time $\tau = 0$. The hydrogenation of diacetyl and ethylphenyl glyoxylate is accompanied by reductive dimerisation, which also leads to chiral products; this shows that the intermediate chiral complex reacts with the second substrate molecule without the dissociation of the Co–C bond[67]. The results are presented in Table 11.

Table 11. Enantioselective hydrogenation of α-diketones and α-ketoesters in the presence of the complex [Co(DMG)$_2$. .quinine][67].

Substrate	t, °C	Product			
		formula	yield, %	$[\alpha]_D$	p, %
PhCOCOPh *	−10	PhCH(OH)COPh	95	(+)0.86	*S*; 73

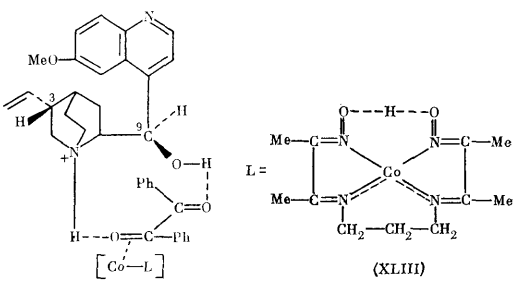
PhCOCOOPr-iso	—	PhCH(OH)COOPr-iso	62	(+)0.18	*S*; 11.5

* The reaction was carried out in toluene and in the remaining cases in the absence of a solvent.

The introduction of various chiral amines and aminoalcohols into the complex as ligands showed that the configuration of benzoin formed on hydrogenation of benzil is determined by the coordination of the C*–NH$_2$ and C*–OH centres in the ligand molecule: one amino-group is insufficient for enantioselective hydrogenation. For example, when brucine, O-acetylquinine, or α-phenylethylamine is introduced into the complex, the latter is incapable of effecting the enantioselective reaction, while the introduction of quinine, quinidine, or cinchonidine is approximately equally effective ($p \cong 33\%$). In the sequence *N*-methylephedrine > ephedrine > ψ-ephedrine the yield p decreases from 28 to 7.8%. These data indicate the diminution of the efficiency of the catalyst for the threo-disposition of the amino- and hydroxy-groups in the ligand[68]. The introduction of an additional amine (or triphenylphosphine) into the complex as well as the decrease of the reaction temperature to −10 °C made it possible to increase p to 78%. The base is then coordinated in the axial position, displacing the chiral aminoalcohol. The use of the aminoalcohol hydrochloride increases p, while the increase of the basicity of the amine greatly reduces p (Table 12). It has been suggested[69] that the chiral aminoalcohol is not linked directly to the complex Co(DMG)$_2$ and the entire complex thus resembles an oxidoreductase enzyme in which the catalytic and specific centres are separated. In this case the chiral aminoalcohol corresponds to the apoenzyme. The independence of p of the overall rate of the reaction, which can increase by an order of magnitude while p remains unaltered, is regarded as confirmation of this view[69]. However, one should note that this conclusion by the authors is not entirely convincing, since the reaction kinetics were not investigated and the process was inferred from the initial velocity.

Table 12. The influence of the amine (B) introduced into the complex [Co(DMG)$_2$.Q] on the optical yield and rate of hydrogenation of benzil[68,69].



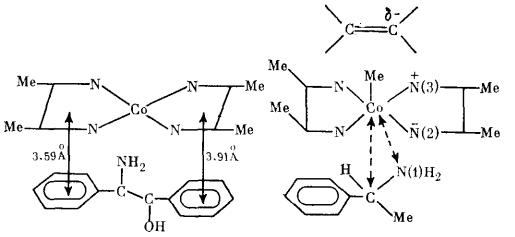
Q	B	B/Co	Q/Co	Q·HCl/Co	p, %	v *
Quinidine	Benzylamine	1	1	0	*R*; 48	6.0
Quinidine	Benzylamine	1	3	0	*R*; 51	12.0
Quinine	—	0	1	1	*R*; 61.5	1.5
Quinine	Benzylamine	1	0	1	*S*; 59	6.5
Quinine	Benzylamine	1	1	1	*S*; 61	13.6
Quinine	Triphenylphosphine	1	1	1	*S*; 61.5	0.3

* v is the rate of reaction expressed in millimoles of absorbed hydrogen per second per mole of catalyst.

If the hydrogenation is carried out at the interface in such a way that the benzene layer contains the substrate and quinine and the aqueous layer consists of a solution of the complex containing the amine (ammonia or aminoacid), then the course of the asymmetric reaction shows that the aminoalcohol does not enter directly into the cobalt complex. The chiral agent can be either in the benzene layer (quinine) or in the aqueous layer (ascorbic acid, aminoacid)[70].

This unusual mechanism of the reaction involving chiral cobalt complexes has been investigated for the chelate[71,72] formed *in situ* from compound (XLIII), quinine, and benzylamine in solution in a propanol-toluene mixture.

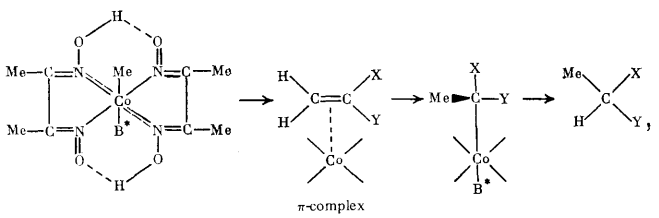
Scheme 1



(XLIII)

The hydrogenation was carried out below −8 °C for 24 h. The products of the reactions involving methyl benzoylformate, benzoin, and methylpyruvate were obtained in yields of up to 48, 79, and 48% respectively.

A reaction mechanism, postulating the simultaneous coordination of the substrate, quinine, and hydrogen molecules to a single catalytic centre, was put forward[72] on the basis of the results of a number of studies[63–69]. This unusual mechanism is based on the hypothesis that the chiral centre in the ligand (quinine) is linked to the substrate and not to the metal (Scheme 1). In this connection it was of interest to investigate the influence of the chiral C(3) and C(9) centres on the enantioselectivity by replacing quinine by its



derivative and by diastereoisomers. This situation resembles that of enzyme systems where the centre determining the stereochemistry of the reaction is remote from the catalytically active centre. The observed independence of p of the overall rate of reaction can be understood in terms of this mechanism.

X-Ray diffraction analysis of a model compound—the complex (XLIV) having an analogous structure[73]—showed that N(1) and O(1) are in the *trans*-positions but the OH group in the chiral aminoalcohol is remote from $Co(DMG)_2$ and does not form a hydrogen bond with it: coordination takes place via the amino-group.

(XLIV) (XLV)

A more detailed study of the structure of the complex was performed on the model compound (XLV).[73] α-Phenylethylamine was used as the chiral amine, but one should note that this complex has no chiral catalytic properties. It contains the methyl group, which distinguishes it from the enantioselective catalytic complex, but it was assumed[73] that the methyl group does not influence the properties of the complex. Nor is it clear how hydrogen is activated in such a complex. The study of this model established that the introduction of a chiral amine into the complex [Me.(α-phenylethylamine).$Co(DMG)_2$] results in the deformation of the plane of the $Co(DMG)_2$ molecule. The strong repulsion between the amine and $Co(DMG)_2$ causes a shift of the N(1) atom towards N(2) and the  plane is then distorted. The polarisation of the N(2) and N(3) atoms in $Co(DMG)_2$ causes the orientation of the prochiral olefin. A mechanism of the hydrogenation of the C = C bond via the formation of π- and σ-complexes was proposed on the basis of a study of the structure of the complex (XLV)[73]:

where B* is the optically active base.

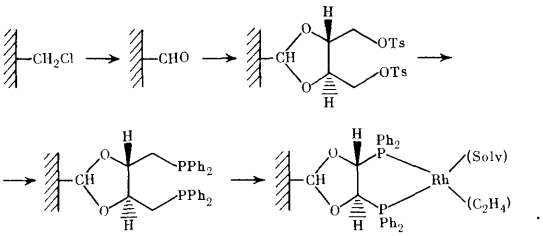
Catalytically active systems of the type of Ziegler–Natta catalysts based on cobalt, namely [$Co(acac)_2$.$AlEt_3$.$P(Ph)_2$-(neomenthyl)] and [$Co(L\text{-}I\ leu)_2$.$AlEt_3$], also exhibit enantioselectivity in the hydrogenation of isomeric 2-phenylbutanes: the optical yields of 2-phenylbutane were 5.4 and 25% respectively[74].

VI. HETEROGENEOUS METAL COMPLEX CATALYSTS LINKED TO A POLYMERIC CHIRAL LIGAND

It is evident that metal complex catalysts linked to a polymeric carrier have many advantages over their soluble analogues. These are mainly the technological usefulness of the catalyst—the ease of its separation after the reaction, the possibility of its re-use and regeneration, and sensitivity to poisoning. It is not easy to draw a line between metallic catalysts on carriers and metal complex catalysts linked to polymeric ligands. Complex formation on the surface of a solid (polymeric) carrier takes place when the carrier exhibits a definite complex-forming capacity. Otherwise, for example, as in asymmetric hydrogenation on metals deposited on quartz crystals, one is dealing with deposited catalysts.

Catalysts can be subdivided into the following groups on the basis of the increase of the strength of the bond between the catalytic centre (metal or complex) and the carrier surface.

1. Metal deposited on an inert carrier (for example, nickel on quartz).

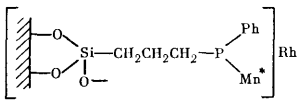


2. Metallic catalyst modified with an optically active organic complex: the complex formed is coordinated to the surface of the catalyst (for example nickel—tartaric acid or nickel—leucine).

3. The complex, which becomes chemically bound to the carrier or metal when a polymeric ligand (a complex forming polymer) is introduced into it (for example, rhodium—polyacrylamide—ethylidenealanine).

A catalyst of the last type is considered below.

Phosphinated polystyrene resins have been used as ligands for metal complex rhodium and platinum hydrosilylation and hydroformylation reactions[75]. The polymeric ligand can be obtained in two ways: (1) by introducing an achiral phosphine into a chiral synthetic or natural polymer; (2) by binding a chiral phosphine to an achiral polymer.



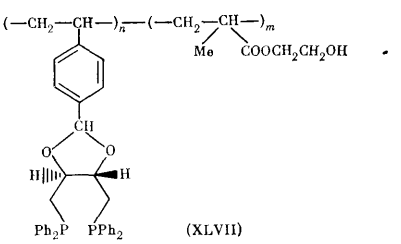
An active chiral metal complex hydrogenation catalyst containing a chiral polymeric ligand was first obtained by Poulin and coworkers[75,76] from Merrifield's resin (polystyrene cross-linked with 2% of divinylbenzene and chloromethylated to an extent of 0.7 mequiv. g^{-1}) bound to DIOP. The chiral polymer was synthesised and the complex [$RhCl(CH_2CH_2)_2$] was immobilised in accordance with the following scheme:

The rhodium complex is formed *in situ*. The hydrogenation was carried out at 20 °C for 12 h in benzene. *R*(−)-2-Phenylbutane with $p = 1.5\%$ was obtained from α-ethylstyrene, while the corresponding soluble complex [Rh.DIOP] gave a product with $p = 15\%$; repeated hydrogenation in the presence of the same catalyst gives a product with $p = 0.6\%$. The relatively inactive *S*(+)-phenyl propionate was also obtained from methyl atropate (the soluble complex gives $p = 7\%$). *N*-Acetamidocinnamic acid, which is insoluble in non-polar solvents, is not hydrogenated at all under the conditions investigated, while in an alcoholic medium the reaction could not be achieved owing to the hydrophobic nature of the polymeric catalyst. Thus the catalyst proved to be relatively unsuitable for hydrogenation, although it exhibited an appreciable enantioselectivity in the asymmetric hydrosilylation of acetophenone by Ph_2SiH_2: the product is *S*(−)-α-phenylethyl alcohol with $p = 29\%$. When the catalyst was re-used, the product with $p = 22\%$ was obtained. For the analogous soluble complex, $p = 28\%$. The use of naphthylphenylsilane as the silylating agent[77] increases the optical yield to 58.5%.

The increase of the ligand/Rh ratio above 2 for the soluble complex results in a loss of enantioselectivity, while that of the polymeric analogue is retained in this instance, an increase of p being observed in other cases. This shows that in the last case the active centres are distributed at fairly long distances from one another and the rigid polymer chain prevents the coordination of the excess diphosphine to rhodium. At the same time it follows from these results that the hydrogenation reaction is much more sensitive to the catalyst structure than hydrosilylation, whereas the enantioselectivities are the same for both the polymeric catalyst and for its soluble analogue.

Immobilised complexes of another type are also active in hydrosilylation. The compound $(EtO)_3Si(CH_2)_2PPhMen$, which reacts with $RhCl_2(CO)$ to form the homogeneous complex (XLVI), has been obtained[77]. Binding of the complex (XLVI) to silica gel yields the complex

(XLVI),



which exhibits enantioselectivity in the hydrosilylation of acetophenone or propiophenone:

$$PhCOR + H_2SiPh_2 \rightarrow PhCH(OSiHPh_2)-R \rightarrow Ph-CH(OH)-R \ .$$

For the optimum ratio Rh/P = 1 : 5, the action of the homogeneous catalyst is comparable to that of the effective [Rh.DIOP] catalyst. It is of interest to note that the alcohol formed has different configurations: S in the former case and R in the latter, although only the S-alcohol is obtained when the complex is re-used or in the presence of an excess of the ligand, apparently as a consequence of the shift of the equilibrium to the left:

$$RhL_n \rightleftarrows RhL_{n-1}Cl + L \ .$$

The employment of a carrier which swells in polar solvents made it possible to obtain an effective hydrogenation catalyst. A cross-linked polymer containing the DIOP residue, swelling in alcohols and other polar solvents, has been synthesised[78]:

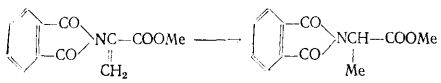
(XLVII)

The catalyst was obtained by the interaction of $[RhCl.(C_2H_4)_2]_2$ with compound (XLVII). Acylaminoacrylic acids were hydrogenated at 1–3 atm, which gave a high optical yield of the product (60–86%), comparable to the value of p for the homogeneous complex containing DIOP (63–81%). The antiparallel variation of p and of the overall rate of reaction was noted.

A somewhat different approach was used in a study[79] where $S(-)$-α-phenylethylamine was introduced as the chiral ligand into a rhodium complex containing PPh_3 groups. Two types of polymeric catalysts were obtained. The catalyst based on the IRC-50 ion-exchange resin was prepared by converting the resin into phenylethylammonium salt and by the reaction with $RhCl(PPh_3)_3$. Hydrogenation of N-acetamidocinnamic acid leads to a 50% yield of R-Phe with 17.7% [?(Ed. of Translation)].

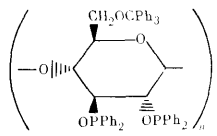
Methyl acetoacetate is hydrogenated to $R(-)$-methyl-β-hydroxybutyrate in the presence of a ruthenium complex bound to poly-L-methylethyleneimine (the monomer was obtained from L-alanine).[80,81] The catalyst is obtained *in situ* by adding $RuCl_3$ to a solution of the ligand in an acetate buffer at pH 5.5. The hydrogenation is carried out at 80 to 100 °C and 80 atm. With increase of the ligand/Ru ratio from 2.5 to 10, p increases only slightly (from 0.5 to 5.3%). The antiparallel variation of p and of the overall rate of reaction was noted. The complex $[RuH(PPh_3)poly\text{-}L\text{-}glu]$ is also relatively ineffective in this reaction ($p = 3\%$) and the use of a polymeric ligand—a copolymer of maleic anhydride with S-2-methylbutyl ether—did not lead to the optically active methyl β-hydroxybutyrate[82].

In these examples the manifestation of enantioselectivity by the heterogenised complex is apparently influenced by the chiral structure of the polymeric ligand in the inner sphere of the complex, since it has been shown by the method of the optical rotary dispersion[83] that the polymer does not have a chiral secondary structure. The opposite picture is observed in the case of the complex Cu-poly-L-lysine, in which the helical structure of the polymer plays a decisive role in the manifestation of chiral catalytic properties by the complex[83]. Although this catalyst effects an oxidation and not a hydrogenation reaction, the example is of interest because here the secondary polymer structure has a major influence on the enantioselectivity of the catalyst.



Poly-L-lysine (PLL) has a more rigid helical structure than poly-DL-lysine (PDLL), which has a random uncoiled structure[84,85]. This difference in the secondary structures of the polymers is manifested in the catalytic properties of copper chelates based on them. In the oxidation of D- and L-DOPA (3,4-dihydroxyphenylalanine) in aqueous solution at pH 10.5 in the presence of copper complexes of PLL and PDLL, a difference between the initial rates of oxidation of L- and DL-DOPA in the presence of Cu-PLL was observed. In the helical structure of Cu-PLL four NH_2 groups are coordinated to the copper atom in a plane almost parallel to the axis of the helix, while the amide and OH groups occupy apical positions. The ratio of the rates of oxidation of D- and L-DOPA (v_D/v_L) increases from 1.07 to 1.53 with increase of the fraction of the helical structure of the polymer from 15.6 to 27.6%.[84,85] On the other hand, when the polychelate copper complex of poly-L-α,γ-diaminobutyric acid, which has no helical polymer chain, is used, the specificity of the oxidation vanishes and $v_{DL}/v_L = 1$, which indicates the decisive importance of the helical structure for the manifestation of stereo-selectivity by the polychelate. The distance between the Cu-complexes distributed around the polymer chain is important for the manifestation of the asymmetrising activity. The helical structure of the polymer binds the copper complexes into a three-dimensional structure. The thermodynamic parameters of activation have been determined from the temperature variation of the Michaelis constants, $T\Delta S$ being more negative for L-DOPA than for D-DOPA, indicating a denser transition state with D-DOPA and a correspondingly higher rate of its decomposition.

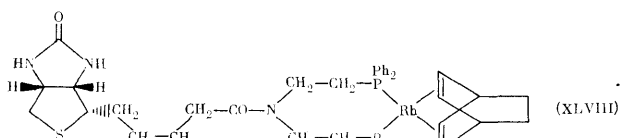
Metallic hydrogenation catalysts modified by chiral polymers can be assigned to the type of heterogenised metal complex catalysts considered only as a matter of convention.



Raney nickel and palladium black have been modified by a chiral copolymer of styrene with D- and L-alanine derivatives of maleimide[86]. The copolymer has three pseudoasymmetric atoms in the chain and in the chiral side group. The question whether the carbon atoms of the polymer chain become chiral was not investigated. Methyl N-acetamidocinnamate was hydrogenated in the presence of nickel and

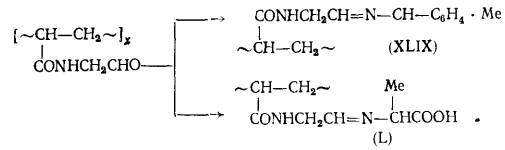
palladium in solution at atmospheric pressure and 20 °C. The catalysts were modified with 1% solutions of copolymers. *R*(+)-Phe is formed in dioxan, cloroform, and methanol solutions with yields $p = 1.6$ and 1.8%. The change in the acidity of the medium on modification from pH 4 to 9 alters the configuration of the product from *R* to *S*. In acid and neutral media modification apparently results in the formation of imide complexes while in an alkaline medium carboxylate complexes, giving rise to a different stereochemical environment in the complex formed, are produced[86].

Similar studies have been carried out using natural chiral polymers—polysaccharides and proteins. It has been stated that palladium deposited on polysaccharide resins based on dextran and cellulose, can be used in asymmetric hydrogenation[87]. A patent[88] describes the catalyst obtained by treating cellulose with Ph_2PCl and subsequent interaction with $[RhCl(PPh_3)_3]$; the catalyst is active in the reaction



resulting in the formation of the product with $p = 28\%$. The low value of p can be explained[88] by a non-uniform distribution of phosphinite groups in the polymer base. The effect of rhodium catalysts, obtained on the basis of cellulose phosphinite

has been studied in detail[89]. The hydrogenation of α-ethylstyrene to *R*-phenylbutane at 50–120 °C and atmospheric pressure takes place with $p = 57$–77%. An increase of p with increase of the ratio P/Rh to 10 is observed. The antiparallel variation of p and the overall reaction rate has been noted. The re-use of the catalyst leads to a decrease of p to 35%. *N*-Acetamidocinnamic acid is also hydrogenated in the presence of the catalyst with $p = 52\%$ and an overall yield of 17.5% (reaction conditions: P/Rh = 11.5, 50 °C, benzene–ethanol solvent, reaction time 7 days).



The binding of $Rh(PPh_3)_2$ to proteins leads to the formation of a chiral catalyst for the hydrogenation of *N*-acetamidoacrylic acid[90]. In this case the chiral tertiary structure of the protein (avidin, lysozyme, albumin) creates the necessary chiral environment for the metal complex. The study has been carried out mainly on avidin, whose molecule consists of four identical subunits linked to biotin. The complex is synthesised as follows: biotin is converted into a diphosphine derivative, which gives rise to the complex(XLVIII) *in situ*:

(XLVIII)

The protein and the complex (XLVIII) are added to a solution of the substrate and the reaction is carried out at 1.5 atm and 0 °C for 48 h. Optically active *N*-acylalanine is formed. The complex (XLVIII) is itself a chiral catalyst and the introduction of the protein has little effect on the overall reaction rate. However, whereas in the absence of the protein $p < 2\%$, when one equivalent of avidin is introduced the optical yield rises to 44%. Lysozyme and albumin proved to be relatively ineffective: $p \leq 2$–5%. Preliminary treatment of avidin with biotin reduced sharply the enantioselectivity of the catalyst and p falls to 4%. Hence it follows that the active centre constitutes a formation in which the complex (XLVIII) is linked to the protein via the biotin in the protein molecule.

The catalyst based on a polymer containing aldehyde groups exhibited a high enantioselectivity. The aldehyde groups in the polymer were bound to PEA or alanine with formation of a polymer swelling in organic solvents:

(XLIX)

(L)

On treatment of compound (XLIX) or (L) with $[Rh(COD).Cl]_2$, enantioselective heterogenised metal complex catalysts are formed and the catalyst based on compound (XLIX) does not differ in its enantioselectivity from low-molecular-weight catalysts containing chiral PEA or Schiff bases, while the catalyst based on compound (L) as well as the complex [Rh.benzylidenealanine] exhibited a very high enantioselectivity: the hydrogenation of methyl-*N*-acetamidocinnamate (50 °C, atmospheric pressure, methanol solvent) results in the formation of *S*-phenylalanine with $p = 94.9$–97.6%.[91]

---oOo---

Thus an extensive search has been carried out for effective metal complex catalysts based on chiral ligands, mainly phosphines, starting with readily available sources of optically active compounds (tartaric acid, phenylethylamine, menthol, hydroxyproline, and monosaccharides). Highly effective catalysts have been obtained, but these exhibit a high enantioselectivity only for a limited number of substrates and the spectrum of their activity is difficult to guess beforehand. The catalytic systems created on the basis of readily available optically active compounds can be used for the preparative synthesis of certain valuable chiral compounds (for example DOPA in an optically pure state). However, the unsuitability for technological applications of soluble metal complex catalysts limits their applicability and makes it necessary to seek systems incorporating a polymeric ligand, i.e. the catalytically active complex must be bound to a polymer chain or a carrier in order to convert the homogeneous catalyst into an insoluble "heterogenised" catalyst. The present review has shown that promising data have been obtained on these lines.

Despite the advances made in enantioselective hydrogenation, the deficiencies of these investigations should be noted: the studies have been performed with a purely experimental selection of systems and detailed investigations of the reaction mechanism in order to discover the relation between the enantioselectivity and reactivity of the complexes and the relation between the structure of the ligand and the complex, on the one hand, and the structure of the substrate molecule, on the other, have not been made. So far no attempts have been made to find general rules governing the action of chiral metal complex catalysts in a specific reaction, relating, for example, the thermodynamic stability of the complex to its overall activity and enantioselectivity. The discovery of such rules, for example, in asymmetric hydrogenation on metallic catalysts modified with chiral aminoacids, proved to be extremely useful in predicting their enantioselective activity[7].

The Chemistry of Perfumes Based on Labdane Diterpenoids

P.F.Vlad

The advances in the synthesis of C_{14}–C_{19} perfumes derived from bicyclic labdane diterpenoids and their enantiomers as well as data concerning the sources of the starting materials are presented. The dependence of the odour of the above compounds on their structure and stereochemistry and the questions arising in the manufacture of some of them and their practical applications are considered.
The bibliography includes 242 references

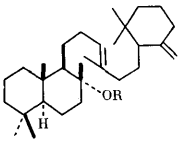
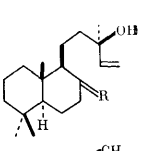
I. INTRODUCTION



Derivatives of labdane (I) [1–4] occupy an important place among diterpenoids. They are stable biosynthetic intermediates in the conversion of aliphatic compounds into cyclic compounds, including kauranoids, which are precursors of gibberellins[5]. Derivatives of both labdane and *enantio*-labdane (II) (eneruane) are widely distributed in nature[3]. In certain plants they are present in large amounts, can be readily isolated, and have therefore been known for a long time. Labdanoids have frequently been used as the starting materials in syntheses (including biomimetic syntheses) of tricyclic and tetracyclic diterpenoids[6]. All these factors led to the accumulation of extensive factual data on the chemistry of these compounds.



An important stimulus for the development of the chemistry of labdanoids proved to be the discovery among their transformation products of substances with an intense smell of ambergris[7,8]—full substitutes of ambergris, which is a product of the metabolism of sperm whales and is one of the most valuable types of raw material for perfumery[9]. Its odour is due to the products of the autoxidation of the main component—ambrein (3) (a triterpene)[10,11]. Simultaneously with the elucidation of the chemical nature of the perfume components of ambergris, it was noted[7] that the products of the oxidation of the labdanum glycol sclareol (4), isolated from the muscat sage, also have the odour of ambergris. These observations gave rise to a series of studies on the resolution of sclareol[8,12,13], which culminated in the preparation of a series of interesting compounds with the ambergris odour.

Subsequently such substances were obtained also from other labdanoids. The majority of these contain 16–18 carbond atoms and have effective fixative properties.

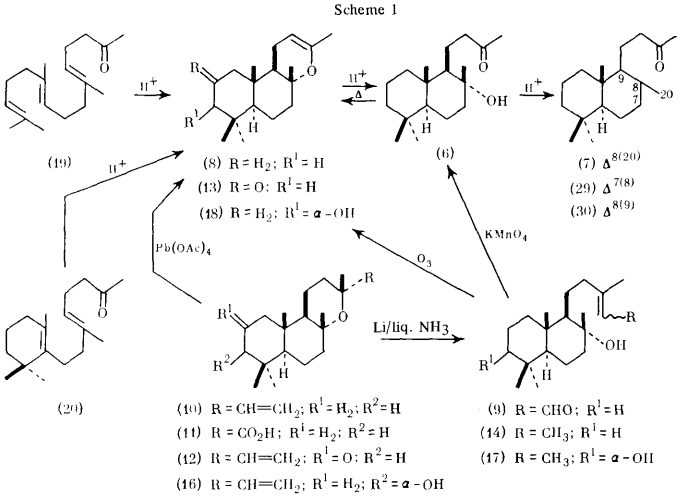
The industrial manufacture of perfumes based on readily available labdane diterpenoids was begun in the 1950's[14–20]. These include sclareol, isolated from the waste products of the essential oil industry[21–29], and manool (V), isolated from the wood of the yellow pine[30,31]. The main raw materials for the manufacture of sclareol are in the USSR. Our perfume industry manufactures on its basis two products with the odour of ambergris—ambrial[19,32–34] and ambroxide[20,32].

During the last 10–15 years, there has been a considerable growth of interest in the perfumes obtained from labdanoids, as shown by the numerous publications. The reason for this is the continually growing demand for these substances throughout the world and the continuously decreasing number of sperm whales.

Another cause of the intensification of this research is the study of the dependence of odour on the structure of substances, a problem which is far from being solved[35]. The rigid *trans*-decalin skeleton, the possibility of obtaining enantiomeric compounds, as well as the extensive factual data which have accumulated make perfumes based on labdane diterpenoids a convenient model for tracing the dependence of odour on structure.

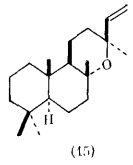
The intensification of studies on labdanoids was also promoted by the fact that large amounts of these substances as well as their cleavage products are present in tobacco[36–44], imparting to it valuable organoleptic properties. The addition of these compounds to various kinds of tobacco improves its quality[45–48].

The majority of the perfumes considered have been obtained from labdanoids. Several oxides of the *enantio*-labdane series, which also proved to have the odour of ambergris, have been synthesised quite recently[49,50].



The present review surveys data on the chemistry of perfumes obtained from labdane diterpenoids and published up to 1981. Certain reviews[51–53] and monographs[3,54] devoted to other problems include isolated information concerning the topic under consideration, but there have been no systematic surveys. We have used the system of numbering of carbon atoms in labdane proposed by Kocker and Halsall[1].

II. 14,15-BISNOR-13-LABDANONES—IMPORTANT INTERMEDIATES IN THE SYNTHESIS OF PERFUMES

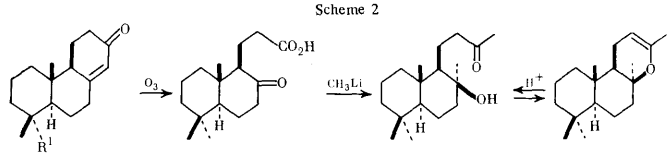


When labdanoids are cleaved to C_{15}–C_{18} compounds, derivatives of 14,15-bisnor-13-labdanone are always formed. 8α-Hydroxy-14,15-bisnor-13-labdanone (6) and 14,15-bisnorlabd-8(20)-en-13-one (7) are of greatest interest for the synthesis of perfumes. The hydroxyketone (6) was

obtained on oxidising sclareol[55–57]. It is unstable and is converted into the oxide (8) on standing or heating (Scheme 1).

Scheme 1

The melting point indicated for this compound therefore varies from 90° to 122 °C.[55,58–60] The reverse reaction, involving the opening of the oxide (8), takes place on treatment with acids or semicarbazide[56,58]. By altering the conditions, the sclareol oxidation reaction can be directed preferentially towards the formation of substances (6) or (8), which have been obtained also on oxidation of certain sclareol transformation products, for example the aldehyde (9):[58,60]

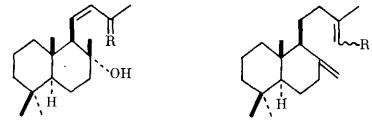


(15)

The enol ester (8) has also been synthesied from manoyl oxide (10) as a result of its oxidation with the acid (11) [61] and the decarboxylation of the latter[62]. The keto-oxide (13) has been obtained similarly from 2-oxomanoyl oxide (12) [63] (see Scheme 1). 2-Oxomanoyl oxide can also be reduced quantitatively to manoyl oxide without isolating it from the pine resin[63]. On a preparative scale, a different method of converting the oxide (10) into the hydroxyketone (6) is more convenient: the hydrogenolysis of the oxide to dihydroabienol (14) [64] and its oxidation [the yield of the hydroxyketone (6) was 94%]. The hydroxyketone (6) can be obtained in this way also from 13-epimanoyl oxide (15). The hydrogenolysis of 3α-hydroxymanoyl oxide (16) leads to the product (17), whose ozonisation gives rise to the alcohol oxide (18).[65]

The enol ester (8) has also been synthesised by cyclising *trans, trans*-farnesylacetone (19) [66] or *trans*-β-monocyclofarnesylacetone (20) [67] (see Scheme 1). Its stereoisomers have been obtained analogously[68]. However, the method is complex, since the starting materials are difficult to obtain.

The epimer (21) of the hydroxyketone (6) at the C(8) atom is formed together with the enol ester (22) [58] when methyl-lithium reacts with the ketoacid (23)—the product of the ozonisation of podocarp-8(14)-en-13-one (24). The unsaturated ketone (24) was synthesised from manool[30,69] and neoabietic acid (25) [70] or *m*-methoxyphenylacetylene[58] (see Scheme 2).

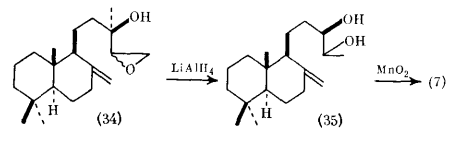


Scheme 2

The enol ester (8), the hydroxyketone (6), and its dehydro-derivative (26) have been detected in tobacco[39]. Compound (26) was first isolated from the resin of the Siberian larch[71]. It is the product of the autoxidation of neoabienols (27) and (28).[72–75] Its hydrogenation gives rise to the hydroxyketone (6).[71]

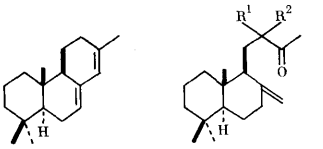
14,15-Bisnorlabd-8(20)-en-13-one is a product of the dehydration of the hydroxyketone (6). However, the dehydration of the latter leads to 14,15-bisnorlabd-7-en-13-one (29) [56,58,76] or to a mixture of the isomeric compounds (7), (29), and (30),[77] which has also been obtained in the oxidation of sclareol[78,79]. On dehydration of the stereoisomeric hydroxyketone (21), a mixture of the ketones (29) and (30) is obtained[70].

14,15-Bisnorlabd-8(20)-en-13-one was first obtained in the oxidation of manool with potassium permanganate[30]. The structure was demonstrated by Schenk et al.[80], who modified the method of oxidation described in another communication[81] (see also Ohloff[82] and Demole and Weust[83]).



(26) R = O
(27) R = CHCH3; Δ13-*cis*
(28) R = CHCH3; Δ13-*trans*
(31) R = CH2Br
(32) R = CHO
(33) R = CH2OAc

The yield of the ketone (7) is 36–40% and does not increase when the oxidation conditions are varied[84–86]. It is also formed in a low yield of (14%) in the ozonisation of manool[84].

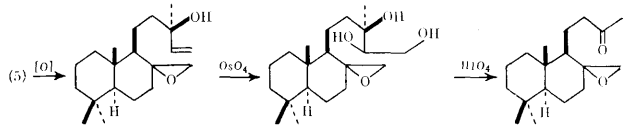


Two- and three-stage methods of synthesising the ketone (7) from manool are known. Thus on treatment with certain oxidants[85,87] or via the bromide (31),[88] manool is converted into a mixture of the *cis*- and *trans*-aldehydes (32), which are oxidised to the ketone (7).[85] The acetate (33), which is a product of the substitution of the bromide (31), also gives rise to the ketone (7) on oxidation[88]. Compound (31), in a mixture with its isomers and dibromides, is also formed on bromination of sclareol[88–91], which permits the synthesis of the ketone (7) from sclareol. On the other hand, it is known[82] that sclareol diacetate yields manool acetate on pyrolysis. This reaction can be achieved more simply by heating sclareol with acetic anhydride and calcium carbide[92] or pyridine[93]. In the latter case the product consists of a complex mixture of substances.

An interesting conversion of manool into the ketone (7) in 90–95% yields, involving its selective epoxidation to a mixture of epoxides (34), the reduction of the latter to a mixture of diols (35), and the cleavage of the latter by various oxidants, the best of which is manganese dioxide, has been described (see Scheme 3)[94]. This series of transformations can be achieved without isolating the intermediates.

Scheme 3

14,15-Bisnorlabd-8(20)-en-13-one has been detected in tobacco[42] and in certain types of resin[95,96]. In one of them[95] it is present together with its Δ^{11}-dehydro-derivative, formed on dehydration of the hydroxyketone (26).[71] We may note that the ketone (7) is unstable: it undergoes autoxidation on standing[79] and cyclises to the hydrocarbon (36) under the influence of acids[13,97,98].

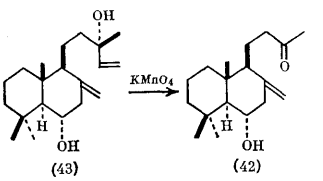


(36) (44) $R^1 + R^2 = CH_2$

(45) $R^1 = CH_2OCH_3$; $R^2 = H$

8,20-α-Epoxy-14,15-bisnor-13-labdanone (37), detected in *Dacrydium kirkii*, is of great importance for the synthesis of perfumes[99]. It was obtained from the manool monoepoxide (38), which is formed together with its steroisomer (39) when manool is oxidised by peracids (see Scheme 4). The ratio of the stereoisomers (38) and (39) varies within wide limits as a function of the reactants and the reaction conditions[91, 99-101]. On interaction with osmic acid, the epoxide (38) gives the epoxytriol (40), which is cleaved by periodic acid to the epoxyketone (37).[100,102] This transformation can be achieved in a single stage, using catalytic amounts of osmic acid[100,102,103]. The same result is obtained when the unsaturated epoxide (38) is ozonised[104].

Scheme 4



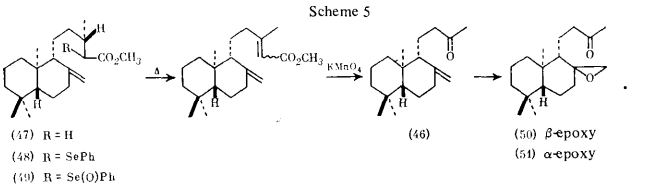
(38) α-epoxy (40) (37) α-epoxy

(39) β-epoxy (41) β-epoxy

Compound (37) and a small amount of its stereoisomer (41) are formed when the ketone (7) is oxidised with *m*-chloroperbenzoic acid[85,100,104]. Monoperphthalic acid leads mainly to its further transformation products[85]. The expoxyketones (37) and (41) have been detected among the sclareol oxidation products[79].

6-α-Hydroxy-14,15-bisnorlabd-8(20)-en-13-one (42)—the product of the oxidation of larixol (43) [105-109] which is one of the main components of the resins of different species of larch[110-115]—is of great interest for the synthesis of perfumes.

The forms of the ketone (7) oxidised in the C(19)-position have been detected in natural sources[116,117].



(43) (42)

When the ketone (7) is condensed with formaldehyde, it gives rise to a mixture of C_{19} products (44) and (45), which have also been used to synthesise perfumes[118].

The synthesis of the optical isomer (46) to the ketone (7) via Scheme 5 from the ester of eperuic acid (47) [119] has been achieved recently[49]. The selenium derivatives (48) and (49) are of key importance in this synthesis. Thus the possibility, in principle, of using labdanoids and their optical isomers with a saturated side chain in the syntheses of perfumes has been demonstrated, which makes it possible to extend significantly the range of starting materials for such syntheses.

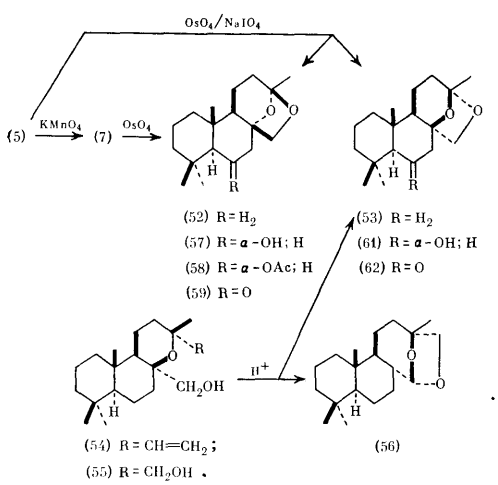
Scheme 5

(47) R = H (46) (50) β-epoxy

(48) R = SePh (51) α-epoxy

(49) R = Se(O)Ph

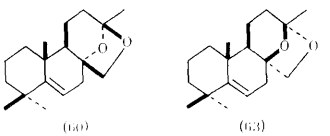
When the ketone (46) is epoxidised with *m*-chloroperbenzoic acid, it gives rise to a mixture of the epoxides (50) and (51), in which the former predominates.



III. THE SYNTHESIS OF PERFUMES FROM LABDANE DITERPENOIDS

1. C_{18} and C_{19} Perfumes

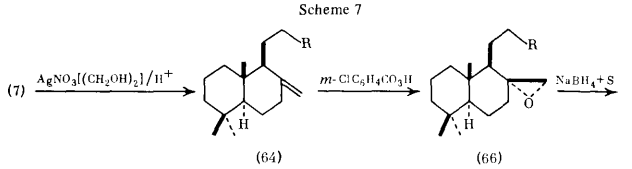
The group of C_{18} perfumes consists mainly of intramolecular ketals. The first of these [compound (52)], which has an intense odour of ambergris, was discovered among the products of the oxidation of manool with permanganate[81] (see Scheme 6). Its structure was confirmed by the fact that it is formed on interaction of the ketone (7) with osmic acids[8,103] and also by NMR and data for its hydrogenolysis[100]. Compound (52) has also been obtained on oxidation of manool with osmic acid and sodium periodate[100] or, together with its diastereoisomer (53), on isomerisation of the epoxyketone (37),[100,102-104] which occurs in the course of its formation on oxidation of the ketone (7) with monoperphthalic acid[86]. It was thought that the ketal (53) also has a powerful odour of ambergris, but, according to the latest data[50], it lacks such an odour.



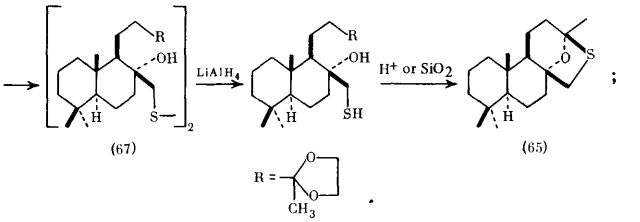
The main method of opening the epoxide ring in compound (37) involves nucleophilic attack by the carbonyl oxygen on the C(8) atom with inversion of configuration, since, for a ratio of the epoxyketones (37) and (41) in the initial mixture of 16:1, the content of the ketal (53) in the reaction products changes from 50% [118] to 70%,[100,102-104] depending on the conditions. Partial opening of the epoxide ring occurs also via the S_N1 mechanism, since, in the presence of 6% of the epoxyketone (41) in the initial mixture, the yield of the ketal (52) reaches 25% and, in the isomerisation of the pure epoxyketone (37) under the same conditions, the yield is 10%.[83] If the isomerisation of the mixture of the epoxyketones (37) and (41) is carried out with silicic acid in a heterogeneous medium, then the opening of the opoxide ring in compound (37) takes place preferentially via the S_N1 mechanism and the ketal (52) predominates in the reaction products[83].

Scheme 6

A theoretically interesting method of converting manool into the ketal (53) has been described[120]. Manool monoepoxide is isomerised with an acid to the alcohol oxide (54). Successive ozonisation, reduction, and hydrolysis of its acetate lead to the diol (55), which is converted by acids into a mixture of the ketals (53) and (56) (see Scheme 6).

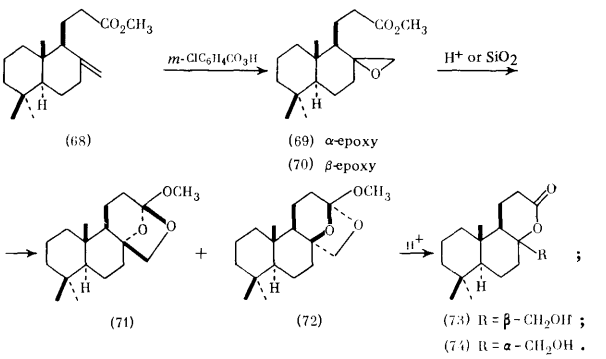


In order to expand the raw material resources for the preparation of the ketals (52) and (53) and their analogues, methods have been developed for their synthesis from other labdanoids. Thus the oxidation of larixol[108] and its acetate[106–110] results in the formation of the hydroxyketal (57) and its acetate (58) respectively. The product of the oxidation of the former—the ketoketal (59)—undergoes the Wolff-Kishner reduction to the ketal (52),[109] which has also been obtained from compound (57) on dehydration of the latter to compound (60) and its subsequent hydrogenation[108, 121]. Only the ketal (60) has an odour. An analogous synthesis of the ketals (53) and (61)–(63) from the hydroxyketone (42) has been described in a patent[121]; one of the products [compound (63)] is a perfume[118]:

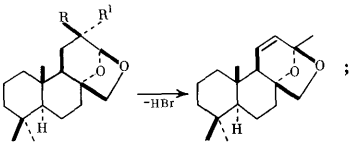


Compounds (52) and (53) have been discovered also among the products of the oxidation of sclareol[122,123].

The thio-analogue (65) of the ketal (52) has been synthesised from the ketal (64) of the ketone (7).[97] The conversion of the ketone (7) into the ketal by treatment with silver nitrate and the formation of the sulphur-containing dimer (67) when the epoxide (66) interacts with the sulphur-treated sodium tetrahydroborate are key stages in the synthesis. The thioketal (65) has a weak woody odour.

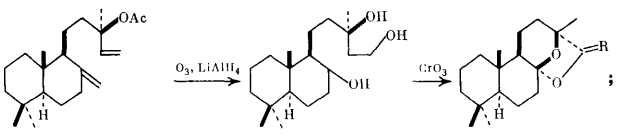


Scheme 7

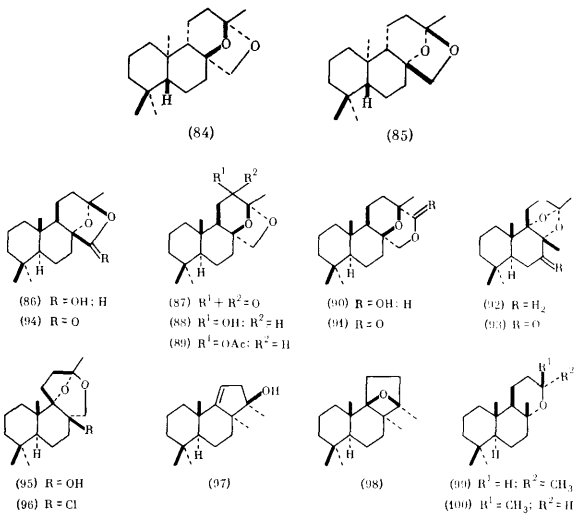


Interesting perfume analogues of the ketals (52) and (53) have been described[83]. The ester (68), which is the product of the oxidation of the ketone (7),[81,85] is oxidised by *m*-chloroperbenzoic acid to an 8 : 1 mixture of the epoxyesters (69) and (70) (Scheme 8), which isomerise on treatment with acid to a mixture of the orthoesters (71) and (72), in which the latter predominates. This conversion of the ester (68) can be achieved in a single stage when the epoxidation is carried out at a higher temperature. When the epoxyester (69) is isomerised with silicic acid, the orthoester (71) predominates in the reaction product, i.e. there is a complete similarity in the behaviour of compounds (37) and (69). The structure and stereochemistry of the orthoesters (71) and (72) have been confirmed by spectroscopic methods and by the formation, following their acid hydrolysis, of the known 20-hydroxyambreinolide (73) and its epimer (74).

Scheme 8



The reaction of the ketal (52) with bromine converts it into a mixture of compounds (75)–(77).[124] The monobromo-derivative (75) is resistant to the action of alkalies, while its isomer (76) splits off hydrogen bromide, albeit with difficulty, and is converted into the scented ketal (78):



When manool acetate (79) was ozonised, the triol (80), which can be oxidised to the perfume (81), was isolated in a low yield (see Scheme 9)[125]. The ozonisation of manool itself leads to the formation (together with other products) of the hemiacetalketal (82), which has no odour. However its oxidation product, the lactone (83),[126] which can be obtained from manool in a single stage[85], is a perfume.

Scheme 9

(79) (80) (81) R = H_2; (82) R = OH; H; (83) R = O.

The enantiomers (84) and (85) of the ketals (52) and (53), the first substances of the *enantio*-labdane series which also possess the odour of ambergris[50], have been obtained recently[49] by the isomerisation of the epoxyketones (50) and (51):

(84) (85)

(86) R = OH; H (94) R = O

(87) $R^1 + R^2$ = O (88) R^1 = OH; R^2 = H (89) R^1 = OAc; R^2 = H

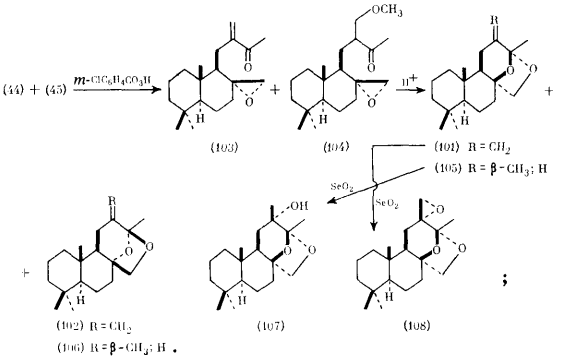
(90) R = OH; H (91) R = O

(92) R = H_2 (93) R = O

(95) R = OH (96) R = Cl

(97)

(98)



(99) R^1 = H; R^2 = CH_3 (100) R^1 = CH_3; R^2 = H

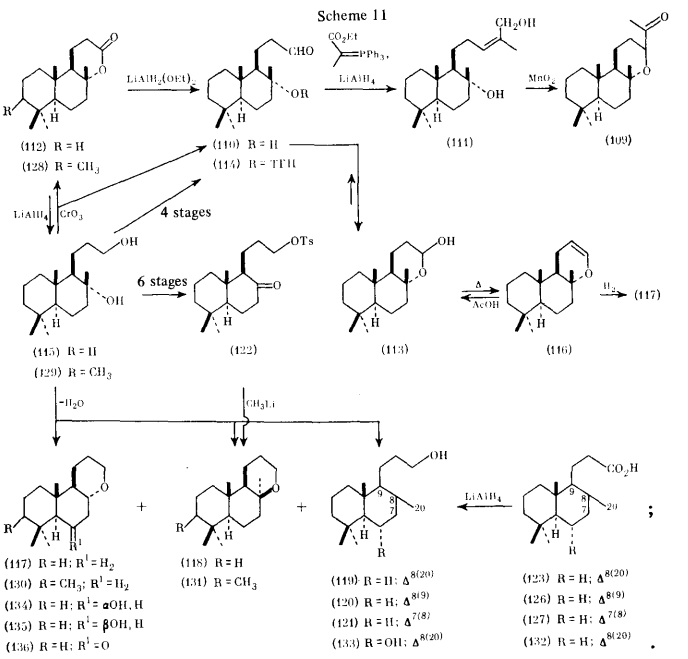
In the course of the search for perfumes, the intramolecular ketals (86),[124] (87)–(91),[100] (92) [125] (this substance has also been found in tobacco[43]), (93),[80] (94),[85] and (95) and (96) [127] were synthesised, but none of them are scented.

When the ketone (7) is irradiated with ultraviolet light, a mixture of 12 substances is formed, two of which, compounds (97) and (98), have the odour of ambergris[128]. When the enol ester (8) is hydrogenated, a mixture of oxides (99) and (100), which have also been detected in tobacco[43], is produced. The oxide (100) has the odour of ambergris[129].

Few C_{19} perfumes are known. The reason for this is apparently their low volatility owing to their high molecular weights. The scented substances (101) and (102) have been obtained by treating the epoxides (103) and (104), which are the products of the oxidation of the ketones (44) and (45),[118] with acid (see Scheme 10). Simultaneously with isomerisation, the epoxyketone (104) splits off methanol. The products (105) and (106) of the hydrogenation of the ketals (101) and (102) and the products (107) and (108) of the oxidation of the ketals (101) and (105) with selenium dioxide are also scented.

Scheme 10

(102) R = CH_2 (106) R = β-CH_3; H. (103) (104) (101) R = CH_2 (105) R = β-CH_3; H (107) (108)

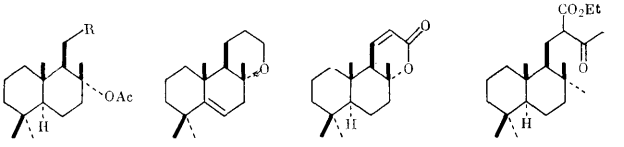


Yet another C_{19} perfume [compound (109)] has been synthesised in accordance with Scheme 11 below from ambreinolal (110). The oxidation of the diol (111) with activated manganese dioxide takes place in an unusual manner with the cleavage of the C–C bond and the formation of a tetrahydropyran ring[130].

2. C_{17} Perfumes

This group of substances includes the perfume components of ambergris. Depending on the conditions, the oxidative cleavage of ambrein leads to the formation of ambreinolal[131–133] or ambreinolide (112).[10,11,131,134] Under natural conditions, this is caused by light and atmospheric oxygen and is catalysed by copper ions[9] and photosensitisers[135]. Ambreinolal exists in the form of the cyclic hemiacetal (113) [131] and its derivatives, for example, the tetrahydropyranyl derivative (114), can be obtained only indirectly from ambrein[136] or ambreinolal (115)—the product of the reduction of ambreinolide[8,131,137].

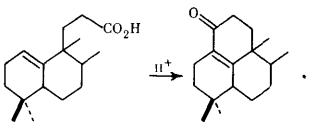
On vacuum distillation, compounds (113) and (114) are converted into the oxide (116) [131–133,136–141]—the first known derivative of *trans*-decalin with the odour of ambergris, which enters into the composition of the volatile component of ambergris. The reverse hydration of the oxide (116) to the hemiacetal (113) is also possible (Scheme 11).



Scheme 11

(112) R = H (128) R = CH_3 (110) R = H (114) R = THH (111) (109) (115) R = H (129) R = CH_3 (122) (113) (116) (117) (117) R = H; R^1 = H_2 (130) R = CH_3; R^1 = H_2 (134) R = H; R^1 = αOH, H (135) R = H; R^1 = βOH, H (136) R = H; R^1 = O (118) R = H (131) R = CH_3 (119) R = H; $\Delta^{8(20)}$ (120) R = H; $\Delta^{8(9)}$ (121) R = H; $\Delta^{7(8)}$ (133) R = OH; $\Delta^{8(20)}$ (123) R = H; $\Delta^{8(20)}$ (126) R = H; $\Delta^{8(9)}$ (127) R = H; $\Delta^{7(8)}$ (132) R = H; $\Delta^{8(20)}$.

The hydroxyaldehyde (110) has been obtained in a low yield (~20%) by the reduction of ambreinolide by complex hydrides[130,142] and by the oxidation of the diol (115) by chromium trioxide[136] (see Scheme 11). According to Demole and Wuest[83], ambreinolide is formed in the latter case.

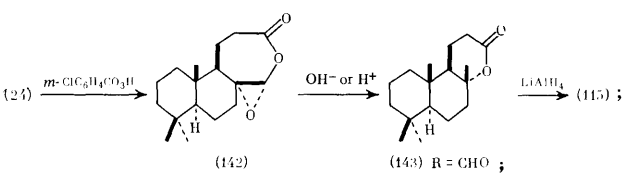


When the oxide (116) is hydrogenated, the dihydro-derivative (117), with a strong odour of ambergris, is formed[133]; it has also been synthesised by the dehydration of ambreinolol (115) by various reagents[8,15,131,137,143]. The stereochemistry of compound (117) follows from the fact that its oxidation yields ambreinolide[137]. Apart from the oxide (117), the dehydration of the diol (115) leads to the formation of the oxide (118) and a mixture of scented alcohols (119)–(121). The stereoselective synthesis of the oxide (118) from the diol (115), in which the key stage is the interaction of the ketotosylate (122) with methyl-lithium, has been achieved recently[50] (see Scheme 11). In contrast to its epimer (117), the product has no odour. The alcohol (119) has also been obtained from the acid (123), synthesised from ambreinolide[144] and the hydroxyacetate (124)—the product of the ozonolysis of the oxide (8),[7] or by the reduction of the acetoxyaldehyde (125), which is also formed when the oxide (8) is ozonised[144]. The last synthesis of the acid (123) constitutes one of the possible ways of converting labdane diterpenoids into C_{17} compounds, a characteristic of which is cleavage to C_{16} compounds. Finally the acid (123) has been synthesised by the hypohalite oxidation of the ketone (7).[80,81] Ambreinolide has also been converted into the isomeric acid (126)[10,145] and into the mixture of the acids (123), (126), and (127)[85,137] and their esters[10], which can be reduced to a mixture of the alcohols (119)–(121). The acid (126) has been detected among the products of the cleavage of the diterpenoid marrubiin[146]. Its most convenient synthesis is the hypohalite oxidation of the ketone (30).[58,77,85] The full multistage synthesis of the racemic acid (126) has been achieved using *m*-methoxyphenylacetylene as the starting material[58]. The synthesis can be greatly simplified by taking into account the fact that the intermediate (8-epi-ambreinolide) can be converted into a mixture of esters of the acids (123), (126), and (127), like ambreinolide, and can be synthesised from podocarp-8-(14)-en-13-one in only two stages[58].

(124) R = CH_2OH
(125) R = CHO
(137) (140) (141)

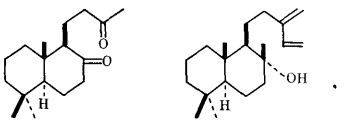
Scented analogues of the oxides (117) and (118) are known. Thus the product of the reduction of 3-methylambreinolide (128), namely the diol (129), gives rise on dehydration to a mixture of the oxides (130) and (131), which have a fruity smell[147], while the product of the oxidation of the hydroxy-ketone (42), i.e. the hydroxyacid (132), has been reduced to the diol (133), which cyclises with simultaneous epimerisation at C(6) to a mixture of the oxides (134) and (135).[120,148] Like the keto-oxides (136), they are not scented[62], but the oxide (137) obtained on their dehydration has the odour of ambergris[121,148].

On treatment with sulphuric acid, ambreinolide rearranges to the acid (138), which subsequently cyclises to the carbonyl compound (139), with a phenalan structure which has a strong odour of ambergris[137,149]:



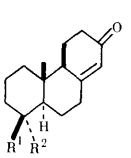
(138) (139)

The above data show that ambreinolide is an important substance for the synthesis of valuable perfumes. Ambreinolide and Δ^{12}-dehydroambreinolide (140) are present in small amounts in tobacco[39], but there are no natural sources with a high content of these substances. The problem therefore arose of the synthesis of ambreinolide. In one of its first syntheses it was obtained from the hydroxyketone (6) (yield 68%)[59,150]. On interaction with diethyl carbonate, it gives rise to the hydroxyketoester (141), the ketone cleavage of which leads to ambreinolide. The latter has also been obtained by the cyclisation of the acid (123)[80] or by the reduction of the product of the epoxidation of its ester (69) to the diol (115) and subsequent oxidation of the latter with chromium trioxide[83]. The isomeric acid (126) also cyclises to ambreinolide[58,85]. In the method of its synthesis described by Bigley et al.[58], the intermediate is podocarp-8-(14)-en-13-one, which was converted into ambreinolol in accordance with Scheme 12.[151]



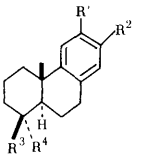
Another pathway leading to the tosylate (144) was mentioned earlier by Demole and Wuest[83].

Scheme 12



(142)
(143) R = CHO;
(73) R = CH_2OH;
(144) R = CH_2OTs.

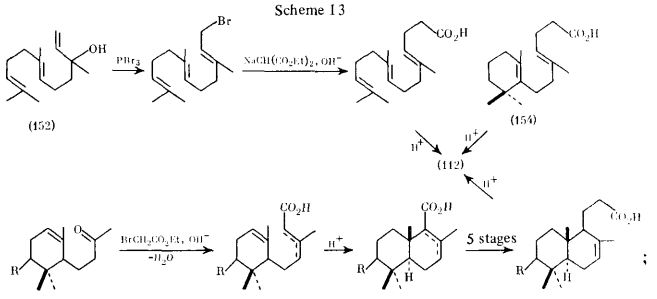
The ketone (24) is an important intermediate in the synthesis of many compounds. It is formed on cyclisation of the diketone (145), produced as a result of the oxidation of manool by various oxidants[30,70,80,84,85,151,152]:



(145) (151)

Podocarpenone (24) and its derivatives with functional groups at the C(18) and C(19) carbon atoms can be obtained relatively simply from readily available substances such as resin acids. Thus neoabietic acid has been converted into the ketoester (146),[153] 13-desisopropyl-13-methoxydehydroabietate (147) has been converted into the hydroxyketone (148),[154] and podocarpic acid (149) has been converted into the hydroxyketone (150).[155] The ketoester (146) has been converted into podocarpenone[70].

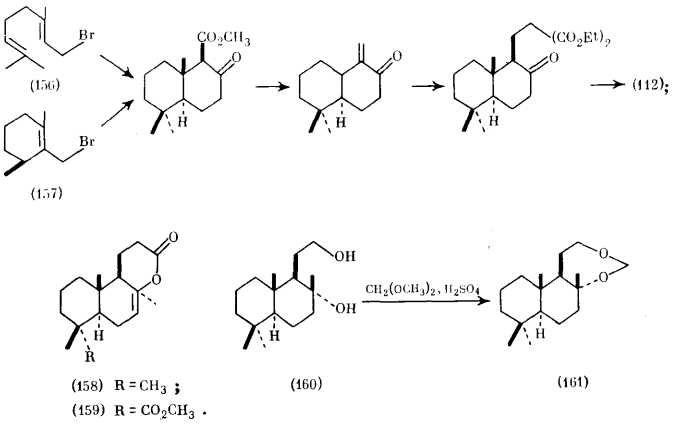
(146) $R^1 = CH_3$; $R^2 = CO_2CH_3$
(148) $R^1 = CH_3$; $R^2 = CH_2OH$
(150) $R^1 = CH_2OH$; $R^2 = CH_3$



(147) $R^1 = H$; $R^2 = OH$; $R^3 = CH_3$; $R^4 = CO_2CH_3$
(149) $R^1 = OH$; $R^2 = H$; $R^3 = CO_2H$; $R^4 = CH_3$

A convenient method of synthesis of ambreinolide consists in the oxidation of isoabienol (151),[156] which has been synthesised from sclareol[156] and enters into the composition of the resin of the Siberian fir[157,158] and the evergreen cypress[75]. However, isoabienol is difficult to obtain. The situation changed after it was observed[159] that it is contained in a large amount in the needles of the common pine.

Several syntheses of racemic ambreinolide have been developed. They all consist of many stages and the starting materials are difficult to obtain. Scheme 13 shows that nerolidol (152),[160] dihydro-α-ionone (153),[161] or β-monocyclofarnesylacetic acid (154) [162] have been used as the starting materials. 3-Methylambreinolide has been obtained analogously from methyldihydro-α-ionone (155).[147]

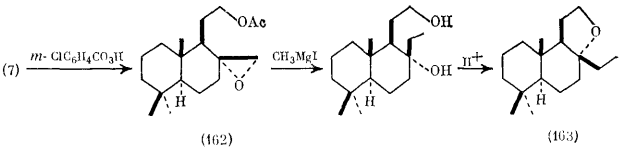


Scheme 13

(153) R = H;
(155) R = CH_3.

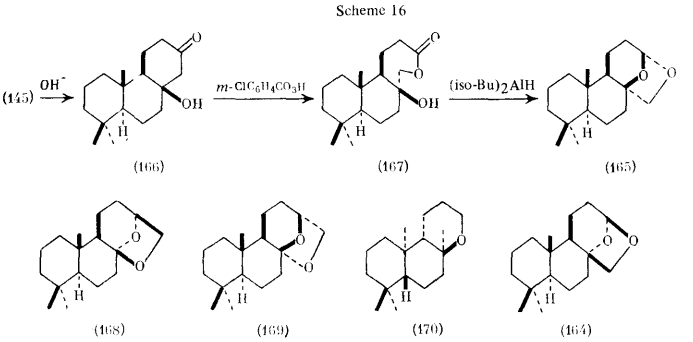
A novel synthesis of ambreinolide from geranyl bromide (156) and β-cyclogeranyl bromide (157), the principal stages of which are presented in Scheme 14, has been described[163]. On the whole, very numerous syntheses of ambreinolide have been described, but none is suitable for industrial application.

Scheme 14



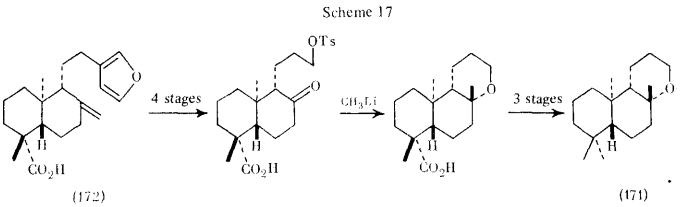
(158) R = CH_3;
(159) R = CO_2CH_3.

The enol lactone (158), obtained from the ketoacid (23), is used as an odorant for tobacco. The ketoacid (23) is formed together with other substances when the pyrolysis products of ambreinolide or the dehydration products of sclareol are ozonised[48]. The lactone (159) has been synthesised for the same purpose[164].



The interaction of the glycol (160), which is a product of the transformation of sclareol[8], with dimethoxymethane gives a low yield of the acetal (161) with a strong odour of ambergris[125]. The scented C_{17} oxide (163) has been obtained from the ketone (7), as shown in Scheme 15.[165].

Scheme 15



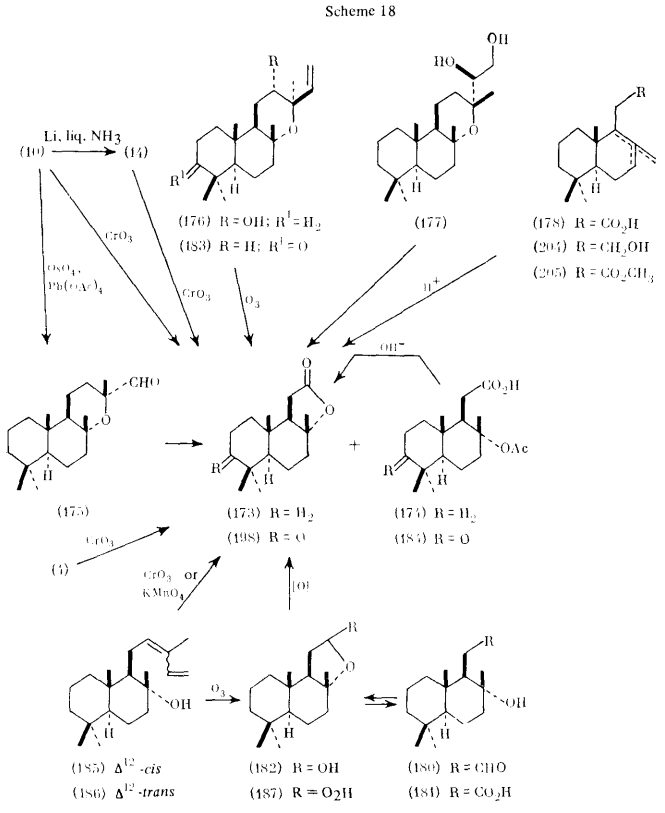
When 20-hydroxyambreinolide is reduced with di-isobutylaluminium hydride, the scented ketal (164) is formed. Its diastereoisomer (165) has been obtained analogously from the hydroxylactone (167)—the product of the oxidation of 8-β-hydroxy-13-podocarpanone (166) (see Scheme 16)[151]. The isomers (168) and (169) of these ketals, which have been synthesised from podocarpenone (24),[166] are not scented.

Scheme 16

As in the case of compounds of the labdanum series, the oxide (170) of the *enantio*-labdane series has been recently obtained from the ketone (46).[50] Its epimer (171) has been synthesised stereoselectively from daniellic acid (172) in accordance with Scheme 17:

Scheme 17

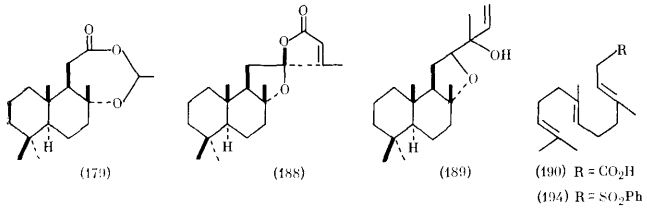
The oxides (179) and (171) have the odour of ambergris.



3. C_{16} Perfumes

This group includes a whole series of substances which can serve as full substitutes of ambergris and can be obtained fairly simply from many readily available labdanoids.

One of the main starting materials for these syntheses has been the γ-lactone norambreinolide (173), obtained in a small amount among the ambrein oxidation products[167] and found in tobacco[39]. Together with the acetoxyacid (174), it



was obtained for the first time by the oxidation of sclareol[23, 55,168,169]. The acetoxyacid (174) gives rise to the lactone (173) on hydrolysis[125] (Scheme 18). According to a patent[170], when the oxidation product is hydrolysed and converted into a lactone, the yield of the lactone reaches 65%, but this method is fairly cumbersome. The method involving the oxidation of sclareol with chromic acid mixture is simpler and more convenient[79,171]. A method analogous[170] to the direct oxidation of manoyl oxide to norambreinolide (173) [172] and a two-stage method via the aldehyde (175) (see Scheme 18)[64] have also been developed. The pathway involving the hydrogenolysis of manoyl oxide [or its epimer (15)] to dihydroabienol[64], which is oxidised to a mixture of compounds (173) and (174), is much more effective[62]. Although many sources of compounds (10) [3,75,95,96,173–178] and (15) [74,179–182] or their mixture[3,183–186] are known, so far only a few of them[187] are of preparative value.

Scheme 18

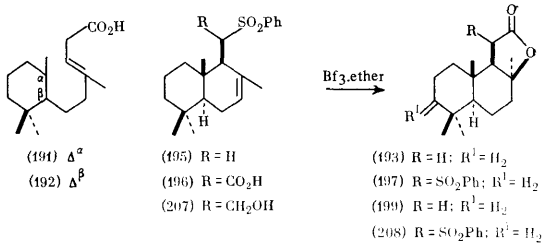
The mixture of compounds (173) and (174) is formed on ozonisation of 12α-hydroxy-13-epimanoyl oxide (176) [37] and in the multistage transformation of borjatriol (177),[188,189] which is a fairly readily available diterpenoid[190,191]. In principle, the familiar derivatives of the oxy-compounds (10) and (15) with oxygen-containing groups in the 2- and 3-positions[95], in the 3-position[192,193], in the 6-position[117], in the 11-position[176,177], in the 1- and 18-positions[194], and in the 3- and 18-positions[192] can serve as the starting materials for the synthesis of compounds (173) and (174).

In the synthesis of norambreinolide from the above diterpenoids the oxide (8) was found to be an intermediate. It is oxidised to the acetoxyacid (174), which gives rise to norambreinolide on intramolecular transesterification or after the elimination of acetic acid and cyclisation of the mixture of isomeric unsaturated acids (178) formed[162]. The acid (174) has been obtained from sclareol in two stages[195]. It is also formed in the ozonolysis of the oxide (8),[56] but the main product in this instance is the acetoxyaldehyde (125) [7,12] (see above), as in the study of Corey et al.[144]; the lactone (179) and the hydroxyacetate (124) are side products. The latter becomes the main product when the ozonide is reduced[7]. The hydrolysis of the acetoxyaldehyde (125) gives a mixture of sclaral (180) and the hydroxyacid (181). Oxidation can be avoided by carrying out the hydrolysis in an inert atmosphere or by protecting the aldehyde group[7]. The hydroxyaldehyde (180) exists in the form of the hemiacetal (182), which gives rise to a norambreinolide on oxidation[12]. The hemiacetal (182) has been discovered in tobacco[39] and has been suggested as an odorant for the latter[47]. The conversion of the oxide (8) into the acetoxyacid (174) on oxidation with a peracid is of interest[125].

The keto-oxide (183) is apparently converted analogously into the 3-oxoacetoxyacid (184) on treatment with Jones' reagent[65].

Norambreinolide can be conveniently synthesised from *cis*- and *trans*-abienols (185) and (186),[3] since it is the only product of their oxidation by different reagents[156,196,197]. In contrast to *trans*-abienol, the ozonisation of *cis*-abienol led to the peroxide (187) [198] (see Scheme 18). Abienols have been discovered in larches[3,183], for which they are taxonomic characteristics, in other conifers[75,174,180,186,199,200], and in tobacco[41,201]. In some of these plants the content of abienols is fairly high. Nevertheless, owing to their lability[156,202] and the lack of convenient methods for their isolation, abienols have not found practical applications. In particular, on heating *cis*-abienol isomerises to the neoabienols (27) and (28) [73] and it cannot therefore be isolated by distillation.

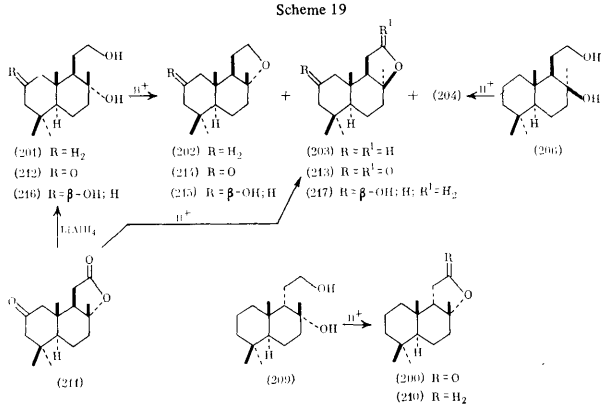
Norambreinolide is also formed on oxidation of α-levantenolide (188) [36] and the stereoisomeric oxides (189),[203] which are present in small amounts in tobacco.



Racemic norambreinolide has been obtained by the cyclisation of homofarnesylic acid (190) [204] or α- and β-monocyclohomofarnesylic acids (191) and (192),[205–207] but the reaction products are complex mixtures of substances and the yield of the lactone (173) is low.

On treatment with acids, norambreinolide isomerises to 8-epinorambreinolide (193).[13,79,204,208] A stereospecific synthesis of this lactone has been achieved[209] as a result of the cyclisation of the sulphone (194) to drimenyl phenyl sulphone (195) [210,211] and the conversion of the latter into the acid (196), its transformation into the lactone (197), and desulphurisation. Compound (196) can be desulphurised and the resulting Δ^7-isomer of the acid (178) can then be converted into a lactone.

The ketoacid (184), whose hydrolysis gives rise to a mixture of the ketolactones (198) and (199), has been obtained from 3α-hydroxymanoyl oxide[65].

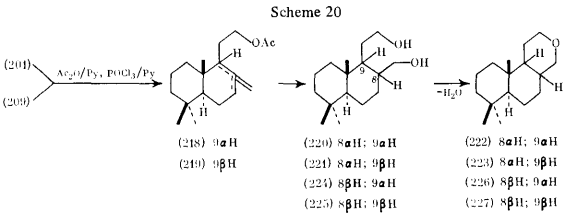


Hydrobromic acid[56] or a mixture of sulphuric and formic acids[207] isomerise the lactones (173) and (193) to the *cis*-lactone (200). Compounds (193) and (200) are also of interest for the synthesis of perfumes.

The diol (201) is formed on reduction of compounds (124), (125), (173), (174), and (179)–(181) with lithium tetrahydroaluminate[8,12,15,125] or on hydrolysis of the hydroxyacetate (124).[7] The possibility of the preparative reduction of norambreinolide with sodium in alcohol[15] has not been confirmed[32].

The diol (201) was obtained also in the reduction of the products of the ozonisation of the oxide (8) [6] and α-levantenolide[36]. In the former case a small amount of the oxide (202) was also isolated. The synthesis of the glycol (201) from the ketone (7), whereby manool can be converted into C_{16} compounds, has been described[83]: the ketone (7) is oxidised with a peracid to the epoxyacetate (162) and the latter is reduced.

Scheme 19

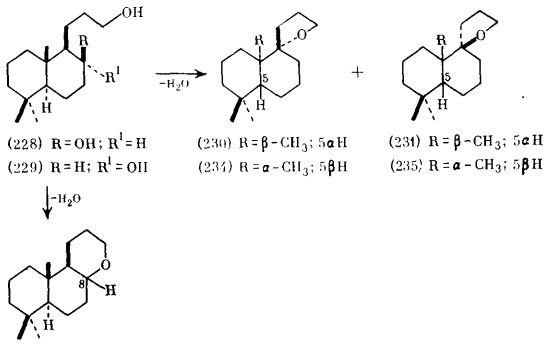


The dehydration of the diol (201) yields the oxides (202) and (203), a mixture of the isomeric alcohols (204), and a mixture of hydrocarbons whose structure has not been elucidated. The hydrocarbons have no odour, the alcohols (204) have a weak odour, while the oxide (203) and particularly the oxide (202) have a strong odour of ambergris and are of great value for the perfume industry. The dehydration of the glycol (201) has therefore been investigated in fair detail and it has been established that the ratio of the products depends on the catalyst and the reaction conditions. The oxide (202) predominates when the dehydration is carried out with naphthalene-β-sulphonic acids[7,14,15], toluene-*p*-sulphonic acid[208], sulphuric acid[32,62], alumina[8,14,15], and toluenesulphonyl chloride[62]. Alumina causes the simultaneous formation of a large amount of hydrocarbons, while toluene-*p*-sulphonic[171] and sulphuric acids give rise to a large amount of the alcohols (204). The latter predominate only on dehydration with dimethyl sulphoxide[212]. They can be obtained by reducing the mixture of the isomeric acids[178] produced by the pyrolysis[7,15] or treatment with sodium carbonate[48] of the acetoxyacid (174) of a mixture of its esters (205), which is a product of the interaction of norambreinolide with alcoholic solutions of acids[15,137,213]. The preparation of individual acid esters (205) [196] and the corresponding alcohols[94,212] has also been described. We may note that the oxide (202) is formed in the reduction of norambreinolide (173) with diborane, but its yield is low (~30%)[62].

If the diol (201) is dehydrated with hydrogen chloride, then the oxide (203) and a mixture of alcohols (204) predominate in the reaction products (see Scheme 19)[14,15,214]. This is also the case when the diol (206), formed by the reduction of the isolactone (193),[13] is dehydrated. Under the influence of acids, the oxide (202) isomerises to the epimer (203).[13] The stereospecific synthesis of the racemic oxide (203), in which the key stage is the cyclisation of the alcohol (207) to the tetrahydrofuran (208), has been achieved[209].

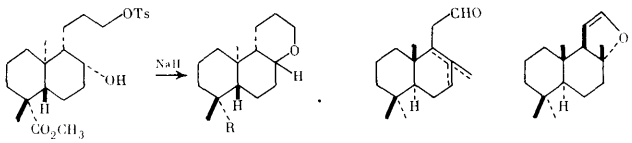
When the diol (209), produced by the reduction of the lactone (200), was dehydrated, the scented oxide (210) was obtained[215].

Like manoyl oxide, 2-oxomanoyl oxide or its ethylene ketal have been converted into compounds (211)–(214). On reduction, the last compound gives rise to the alcohol oxide (215).[63] When the ketolactone (211) is first reduced to the triol (216) and the latter is dehydrated, the yield of the oxide (215) is much lower. The reduction of the lactone (213) with diborane results in the formation of the alcohol oxide (217) (see Scheme 19). Compounds (210), (214), (215), and (217) have the odour of ambergris.



Scheme 20

The diols (201) and (209) have served as the starting materials for the synthesis of perhydronaphthopyran derivatives. They have been converted into mixtures of the acetates (218) and (219), in which the isomers with a semicyclic double bond predominate[216] (see Scheme 20). Their hydroboration led to the glycols (220) and (221), which can be dehydrated to the scented oxides (222) and (223).[217] On the other hand, if the mixture of the acetates (218) and (219) is epoxidised and the products isomerised by treatment with boron trifluoride etherate and reduced, the diols (224) and (225) are obtained[218]; on dehydration, these give rise to the oxides (226) and (227) with the odour of ambergris[219].



A series of oxy-derivatives of the labdane and *enantio*-labdane series have been described[50]. The reduction of the product of the ozonisation of podocarpenone leads to the epimeric glycols (228) and (229). The interaction of the former with toluene-*p*-sulphonic acid gives rise to a mixture of the spiro-oxides (230) and (231) while the corresponding reaction with the latter gives rise to the oxide (232). Compound (233) is the product of the dehydration of the glycol (228) with toluene-*p*-sulphonyl chloride. The syntheses of the enantiomeric compounds (234)–(236) have been achieved via the same scheme. The oxide (237) has been synthesised from the product of the cleavage of daniellic acid (238). The key stage in this synthesis is the formation of compound (239) on treatment of the hydroxytosylate (238) with sodium hydride (see Scheme 21).

The vacuum distillation of the acetoxyaldehyde (125) leads to a mixture of unstable bicyclohomofarnesanes (240), which have been discovered in tobacco[43] and possess the odour of ambergris[7,12,220,221]. Their mixture as well as the individual γ-isomer are formed on oxidation of the corresponding alcohols[94,212]. The aldehydes (240) could not be obtained by the dehydration of the hydroxyaldehyde (180), since the latter dimerises on treatment with acids[12], but on vacuum distillation it is converted into a mixture of the aldehyde (240) and the oxide (241).[15] However, the attempts to obtain the hydroxyaldehyde (180) by oxidising the diol (201) [12,83,222] or by reducing norambreinolide[142] were unsuccessful, although 8-epinorambreinolide was reduced to the corresponding hydroxyaldehyde[142]. The reports that the γ-isomer of the aldehyde (240) is formed on oxidation of sclareol[16,19,32] were not confirmed[60].

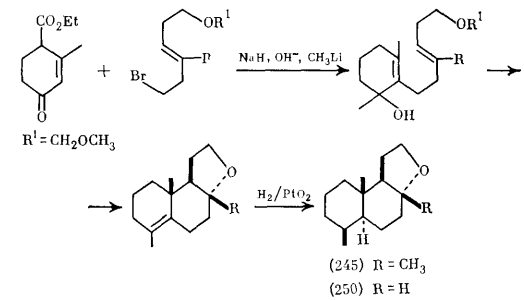
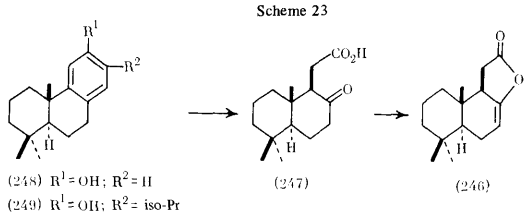
4. C_{15} and C_{14} Perfumes



The sesquiterpene ketone (242) [223] with the odour of ambergris[224], which had been isolated previously from tobacco[43,225] and had been synthesised from drimenol (243),[225] has been discovered among the products of the oxidation of sclareol. However, it is much simpler to obtain it from a mixture of the esters (205). It is oxidised to the ketoester (244), whose hydrolysis yields the ketone (242).[226] If the mixture of the acids (178) is oxidised, the yield of the ketone (242) is lower[223]:

(243)
(242) R = CH₃
(244) R = CH₂CO₂CH₃

The scented noranalogue (245) of the oxide (202) without one methyl group at C(4) has been achieved recently[227] via Scheme 22.

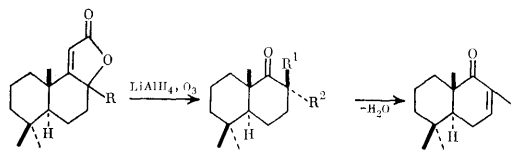


Scheme 22

(245) R = CH₃
(250) R = H

The enol lactone (246), synthesised together with its homologue (158) from certain labdanoids, has been recently used as an odorant for tobacco[48]. The corresponding keto-acid (247) was obtained from 12-hydroxypodocarpane (248) [228] and ferruginol (249) [229] (see Scheme 23), i.e. from readily available products of the conversion of resin acids.

Scheme 23



(248) R¹ = OH; R² = H
(249) R¹ = OH; R² = iso-Pr
(247)
(246)

The scented C_{14} analogue (250) of the oxide (202), lacking the methyl groups at C(4) and C(8), was also synthesised in accordance with Scheme 22.[227]

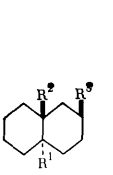
The scented ketone (251) has been found in the products of the oxidation of sclareol[123]. It had been synthesised earlier[46] from $\Delta^{9,11}$-dehydronorambreinolide (252) (Scheme 24), which had been obtained in its turn from norambreinolide[46,129] and has been recommended as a tobacco odorant. The synthesis of its C(8)-epimer (253) has also been described[129].

Scheme 24

(252) R = β-CH₃
(253) R = α-CH₃
(254) R¹ = CH₃; R² = OH
(255) R¹ = OH; R² = CH₃
(251)

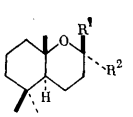
On reduction with lithium tetrahydroaluminate and ozonisation, the lactones (252) and (253) give rise to the hydroxyketones (254) and (255). The lactone (252) can be converted into the hydroxyketone (254) by ozonisation and hydrolysis (223), but this procedure is less effective. The dehydration of the hydroxyketones (254) and (255) leads to the ketone (251).[129,223] The synthesis of the latter from drimenol is more complex[230].

IV. DEPENDENCE OF THE ODOUR OF PERFUMES OBTAINED FROM LABDANOIDS ON THEIR STRUCTURE



The question of the dependence of odour on the structure of substances is fairly complex and has not so far been solved. There does not exist a single theory of odour which would explain all the known facts and would have predictive

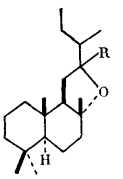
power. There is no objective criterion even for a qualitative estimation of odour. The human nose, capable of distinguishing several thousands of smells, is sufficiently sensitive, but the information obtained with its aid is to some extent subjective[231,232].



Two aspects of olfaction are distinguished: (1) the interaction of the molecules of the scented substance with the receptors of the olfactory nerve cells of the nasopharynx and (2) the transformation of the resulting primary excitation into a signal and its transmission to the olfactory brain hemisphere. The chemist is interested primarily in the way that the molecules of perfumes interact with the receptors of the olfactory nerve cells giving rise to the perception of a specific odour, i.e. how the structure of the given substance determines its odour[232].

Among the existing theories (more precisely hypotheses) of odour, the stereochemical theory of Amoore[233–235] has been most widely accepted; according to this theory, on the surface of the receptor there are alveoles of definite shape and size, each of which corresponds to a particular primary odour. Within the alveoles, there are strictly localised sections having an enhanced chamical affinity, which interact with the functional groups of scented substances. Consequently the odour is determined by the form of the molecule (or part of it) and by the nature and position of the functional groups. If the molecules of a given substance can be accommodated within an alveole of only one type, it possesses a primary odour and if it can be accommodated in alveoles of several types it has a complex odour.

Taking into account the structure of the perfumes (116), (117), (119)–(121), (202)–(204), and (240), Stoll[14,15] concluded that the odour of ambergris is characteristic of decalin derivatives of the type indicated with an oxygen-containing ring or a double bond at C(2) and an alcoholic or aldehyde group in the side chain. Compounds (52), (53), (71), and (72) as well as other substances with the same odour were discovered later. Ohloff[35] surveyed the data which had accumulated in the light of the sterochemical theory of odour and formulated the 1,2,4-triaxial rule. According to this rule, the odour of ambergris or any of its six constituent primary odours[53,236] is characteristic of compounds with a *trans*-decalin skeleton and three axial substituents (one of which can be an oxygen-containing group) located in the 1-, 2-, and 4-positions, as shown in formula (256), or molecules with a similar steric structure (or structural fragment), for example, tetrahydrochroman derivatives[129]: (52), (100), (109), (257), and (258). In the last case it is not essential that one of the substituents should contain oxygen. Incidentally, the nature of the substituent is not very important and affects only the shade or intensity of the odour. The data of Ohloff et al.[50] have shown that the oxygen-containing group need not necessarily be axial, provided that it is attached to a carbon atom with one more substituent. The environment of the centres responsible for the odour also does not play a special role. Indeed, despite structural changes, the oxides (163), (202), (214), (215), (245), and (250) and the ketals (52), (71), (72), (78), (81), (101), (102), (105)–(108), (164), and (165) have the odour of ambergris.



(256)

(257) $R^1 = CH_3$; $R^2 = H$

(258) $R^1 = CH_2{=}CH_2$; $R^2 = CH_3$

(259) R = α-H

(260) R = β-H

The π-electrons of the double bond or the keto-group can play the role of one of the axial substituents[35]. This explains the odour of compounds (119)–(121), (204), (240), (242), and (251), as well as a series of decalin derivatives with the keto-group at C(2).[237] Although compounds (53), (56), (92)–(96), (99), and (118) contain ketal and oxy-groups, they do not satisfy the triaxial rule and have no odour. Compounds (10), (15), and their derivatives, (259) and (260),[238] apparently have no odour owing to their high molecular weight.

The ambergris odour of *enantio*-labdane derivatives is as a rule weaker and has a different shade than that of their labdane enantiomers[50], which indicates yet again the chirality of the olfactory receptors and supports the stereochemical theory of odour.

However, a whole series of facts conflicting with the triaxial rule are known. Thus compounds (97), (98), (139), (171), (222), (223), (226), (227), and (233) do not satisfy its requirements but nevertheless have the odour of ambergris and conversely compounds (206), (168), (169), and many others, which do satisfy the requirements of the rule, nevertheless lack odour. If the environment of the centres responsible for the ambergris odour is not important, it is difficult to account for its disappearance on passing from the ketal (52) to its keto- and hydroxy-derivatives (57)–(59), on passing from the oxide (117) to its derivatives (113), (130), and (134)–(136), and also on conversion of compound (116) into compound (8), of compound (232) into compound (118), and of compound (52) into compound (65).

Thus small changes in the structure of the substance, which are insignificant from the standpoint of the triaxial rule, sometimes lead to unpredictable and inexplicable changes in odour or even to its disappearance. In view of the numerous exceptions, the rule so far lacks reliable predictive power and its value is reduced. Nevertheless it is already evident that odour is a property of the molecule as a whole and in this sense it should depend on its structure and stereochemistry. Further accumulation of factual data will probably help to elucidate the essential features of this dependence.

V. THE MANUFACTURE AND PRACTICAL APPLICATIONS OF PERFUMES BASED ON LABDANE DITERPENOIDS

As already mentioned, sclareol, manool, manoyl oxide, larixol, and others are quite readily available. This as well as the great value for perfumery of the compounds obtained from them having the odour of ambergris has made the synthesis of the latter not only of academic but also of practical interest. The method of synthesis of the oxide (202), known as "ambrox" and "ambroxide" from sclareol was the first to be patented[14,15]. Subsequently individual stages of its synthesis were frequently modified in order to adapt them to industrial conditions[20,32,171,208,239,240]. The industrially manufactured ambroxide and other products are mixtures of substances.

Simpler methods of synthesis of perfumes from sclareol and manool have also been developed. They consist in their oxidation by chromium(VI) compounds and the pyrolytic distillation of the oxidation products[16–18]. The method of preparation of this type of mixture of substances (ambrial) from sclareol was improved[19,32,33]. It was also shown that the distillation of the oxidation product can be replaced by its treatment with ascarite[34,241], although the nature of the perfumes is then altered[242]. However, their structure cannot be regarded as finally established, since it has been found[78] that the composition of the sclareol oxidation product

is in reality much more complex than had been previously believed[60].

The method of synthesis of the mixture of ketals (52) and (53) from manool has been reproduced under semi-industrial conditions[104].

Ambrial and ambroxide are used in the perfumery industry. Certain cleavage products of labdanoids are used to improve the quality of tobacco products. The following compounds have been patented for such purposes: (201), (202),[45] (173), (181), (252),[46] (180),[47] (158), and (246).[48]

---o0o---

Very substantial advances have been made in the chemistry of perfumes bases on labdanoids. Several tens of substances with the odour of ambergris have been obtained from readily available diterpenoids (sclareol, manool, and others). The manufacture of some of these has been started. Interest in these compounds has been growing, because they have not only highly effective properties as perfumes but also possess a complex odour which embraces a fairly wide range of different shades.

During the last 10–15 years sources of new labdanoids, which can also be used in the syntheses of perfumes, have been discovered. The recently discovered method of introducing a double bond into the side chain of saturated labdanoids via organoselenium compounds leads to estensive possibilities. The search for perfumes based on *enantio*-labdane diterpenoids, already discovered in more than 30 plants, is promising. It is desirable to continue the study of the dependence of odour on structure since extensive factual data have been accumulated on these compounds; they also have a rigid carbon skeleton, which is very important in the solution of this problem. Finally, so far there are few methods of preparation of perfumes from labdane diterpenoids which are suitable for industrial applications.

Transition Metal Complexes of Cyclopentadienylides and Pentafulvenes

V.I.Zdanovich, A.Zh.Seitembetova, and V.N.Setkina

The π-complexes of cyclopentadienylides and pentafulvenes with six-electron coordination are examined. The question of the influence of the π-coordination with the transition metal atom on the properties of the cyclopentadienyl ring carrying a full or partial negative charge are discussed.
The bibliography includes 70 references.

I. INTRODUCTION

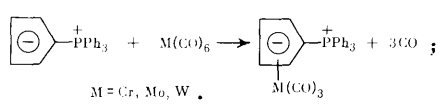
Complexes with cyclopentadienyl ligands are particularly widely represented among the π-complexes of transition metals. Typical examples of such compounds are ferrocene and cymantrene. The chemistry of these π-complexes has already developed extensively but some of their features have not been adequately explained. In particular, one of the cardinal problems remains obscure, namely how the properties and reactivity of the cyclopentadienyl anion change on π-coordination to the transition metal atom. The study of the properties of coordinated and non-coordinated cyclopentadienyl anions under comparable conditions involves considerable experimental difficulties. Fairly stable dipolar compounds, namely dicyclopentadienylides, in which the negative charge is distributed over the cyclopentadienyl ring linked to a heteroatom carrying a positive charge, as well as pentafulvenes, which are related to cyclopentadienylides, are therefore of great interest.

The structures of compounds of both types can be represented by two extreme forms: the ylide form (A) and the ylene form (B), whose contributions to the molecular structure depend significantly on the nature of the onium-forming atom E and the nature of the substitutents at this atom:

(A) (B)

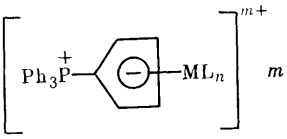
In cyclopentadienylides the onium-forming atoms are usually those of Group V—VII elements. The contribution of structure (A) in such systems is fairly large. For example, the contribution of the ylide structure in triphenylphosphonium cyclopentadienylide $C_5H_4PPh_3$ exceeds 80%.[1] In pentafulvenes the atom E is carbon and the ylene structure (B) makes the greatest contribution. However, when powerful electron-donating groups with O, N, and S heteroatoms are attached to the exocyclic bond of the pentaulvenes, as, for example, in $C_5H_4CHN(CH_3)_2$, then pentafulvenes of this kind have large dipole moments and are characterised by a considerable contribution of the dipolar structure (A).

It has been found that cyclopentadienylides and pentafulvenes are capable of being coordinated to transition metal atoms, forming π-complexes. Thus it has been observed in 1959 [2] that the cyclopentadienyl fragment of triphenylphosphonium cyclopentadienylide is capable of being coordinated to Group VIB metal carbonyls as a six-electron ligand, forming π-cyclopentadienylide complexes.



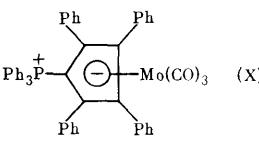
During the past 20 years, a wide variety of transition metal complexes have been synthesised, in which cyclopentadienylides and pentafulvenes play the role of π-ligands. However, hitherto there have been no surveys of cyclopentadienylide π-complexes in the literature (a review of fulvene complexes was published in 1970).[3] Presumably, examination of the literature data on transition metal π-complexes of cyclopentadienylides will make it possible to elucidate the nature of the influence of the π-coordination to the transition metal atom on the properties of the cyclopentadienyl ring carrying a full or partial negative charge. This review deals in detail only with the π-complexes of pentafulvenes in which they are coordinated to a transition metal atom as six-electron ligands. Such π-complexes of pentafulvenes are in many respects similar to the π-complexes of cyclopentadienylides and it is therefore of interest to compare the physical and chemical properties of complexes of the two types.

II. TRANSITION METAL COMPLEXES OF CYCLOPENTADIENYLIDES

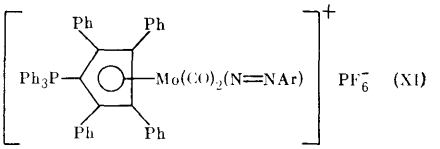


Group IV, VI, VII, and VIII transition metal π-complexes of phosphorus, sulphur, nitrogen, and arsenic cyclopentadienylides are known at present. All the complexes described in the literature are presented on page 660.

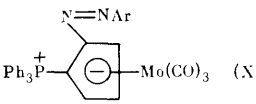
1. Synthesis



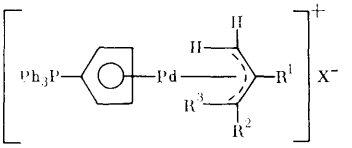
The complexes of cyclopentadienylides with metal carbonyls were first obtained by the reaction of triphenylphosphonium cyclopentadienylide with chromium, molybdenum, and tungsten hexacarbonyls in diglyme[2]:



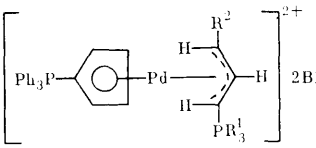
M = Cr, Mo, W.



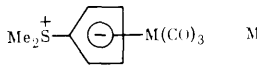
$m X^-$ (I)-(IX)



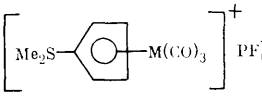
(X);



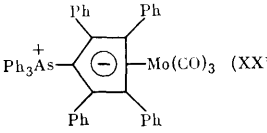
(XI)



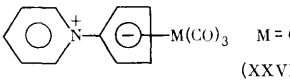
(XII);



$R^1, R^2, R^3 = H$ or Me, $X = BF_4$ or CF_3SO_3 (XIII)-(XVIII);



$2BF_4^-$ $R^1 = Et$ or Ph; $R^2 = H$ or Me (XIX)-(XXI);



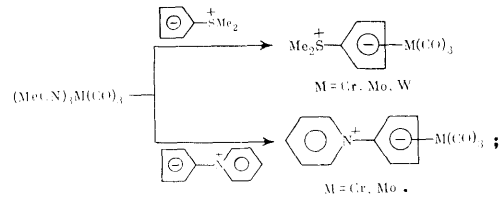
M = Cr, Mo, W (XXII)-(XXIV);

M = Mn, Re (XXV)-(XXVI)

(XXVII);

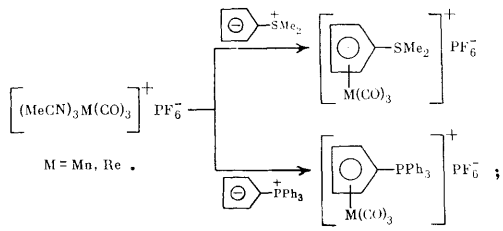
M = Cr, Mo

(XXVIII)-(XXIX)



No.	ML_n		X^-
(I)	$Cr(CO)_3$	0	—
(II)	$Mo(CO)_3$	0	—
(III)	$W(CO)_3$	0	—
(IV)	$Mo(CO)_2(N{=}NAr)$	1	PF_6^-
(V)	$W(CO)_2(N{=}NAr)$	1	PF_6^-
(VI)	$Mo(CO)(PPh_3)(N{=}NAr)$	1	PF_6^-
(VII)	$Mn(CO)_3$	1	PF_6^-
(VIII)	$Re(CO)_3$	1	PF_6^-
(IX)	$Co(CO)_2$	1	$Co(CO)_4^-$

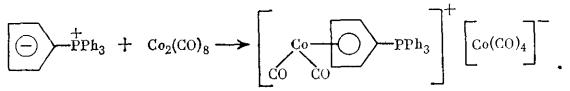
$(Ph_3PC_5H_4)_2WCl_6$ (XXX); $(Ph_3PC_5H_4)MoCl_3(CH_2$ (XXXI);
$[(Ph_3PC_5H_4)HgX_2]_2$ (X = Cl, Br, I) (XXXII) — (XXXIV);
$(Ph_3PC_5H_4)_2TiCl_4$ (XXXV); $(Ph_3PC_5H_4)TiCl_3$ (XXXVI);
$(Ph_3PC_5H_4)ZrCl_4$ (XXXVII); $(Ph_3PC_5H_4]HfCl_4$ (XXXVIII).



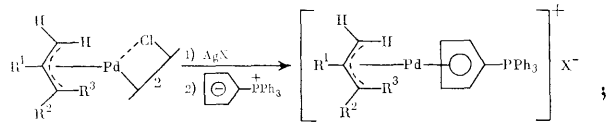
The yield of the complexes was up to 60%. Their compositions and structures were established by elemental analysis, infrared spectroscopy, and ^1H NMR. Subsequently a method of synthesis of cyclopentadienylide complexes from acetonitrile derivatives of Group VIB metal carbonyls was proposed[4]. Tetraphenyl-substituted triphenylphosphonium and triphenylarsonium cyclopentadienylidemolybdenum tricarbonyls have been obtained in high yields via the acetonitrile complex of molybdenum[5]. The attempt to obtain the molybdenum complex with stibonium cyclopentadienylide was unsucessful[5].

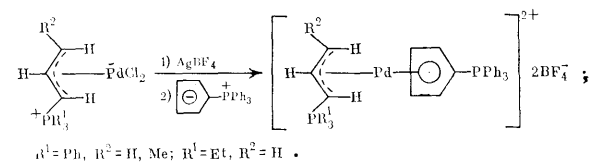
Complexes of dimethylsulphonium cyclopentadienylide with Group VIB metal carbonyls were obtained in 1974, also via the acetonitrile derivatives of the metals in diglyme[6,7] (yield up to 50%).

Complexes of pyridinium cyclopentadienylide with chromium and molybdenum carbonyls have been synthesised by an analogous method[8]. The tungsten analogue has not so far been obtained:



It has been found that, on treatment with charged acetonitrile complexes of manganese and rhenium, cyclopentadienylides form π-complexes with Group VII metal carbonyls[9,10].





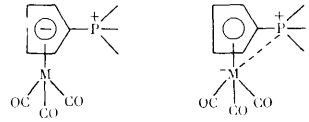
The reaction was carried out in tetrahydrofuran at room temperature in the case of the manganese complexes and with refluxing in the case of the rhenium complexes, the yields being 20–50%.

A report concerning the reaction of triphenylphosphonium cyclopentadienylide with cobalt carbonyl was published in 1978 [11]:

A series of palladium complexes containing triphenylphosphonium cyclopentadienylide as the π-ligand have been synthesised by the reaction of halogen-containing palladium compounds with cyclopentadienylide in the presence of silver salts[12]:

Reports of the synthesis of triphenylphosphonium cyclopentadienylide complexes with transition metal salts have appeared in the literature in recent years[13,14]. This ylide reacts with tungsten hexachloride in dry benzene[13]:

$$2Ph_3PC_5H_4 + WCl_6 \rightarrow (Ph_3PC_5H_4)_2WCl_6 .$$



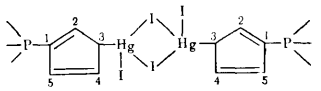
On the basis of ^1H and ^{13}C NMR spectra, the authors attribute a sandwich structure to the complex.

In an analogous reaction $MoCl_5$ gives rise to the complex $(Ph_3PC_5H_4)MoCl_3(OH)_2$, whose structure and authors do not discuss[14]. Complexes with mercury halides, namely $[Ph_3PC_5H_4HgX_2]_2$ (X = Cl, Br, or I), which are stable in air in the solid state, have also been obtained[14]; the complex with X = I has been comprehensively investigated.

Complexes of triphenylphosphonium cyclopentadienylide with titanium, zirconium, and hafnium salts have also been described: $(Ph_3PC_5H_4)_2TiCl_4$, $(Ph_3PC_5H_4)TiCl_3$, $(Ph_3PC_5H_4).ZrCl_4$, and $(Ph_3PC_5H_4)HfCl_4$.[15] The study of these complexes, which are very sensitive to atmospheric oxygen, involves considerable experimental difficulties; their structures have not so far been finally established. The authors[15], proposed the metallocene structure for $(Ph_3PC_5H_4)_2.TiCl_4$.

2. Structure

There have been two points of view concerning the structure of the π-complexes of phosphorus cyclopentadienylides with Group VIB metal carbonyls. On the one hand, such complexes have been treated as analogues of arenemetal tricarbonyls, assuming that the charges are neutralised in the ligand itself [structure (C)].[2] On the other hand, Cashman and Lalor[16] assumed that triphenylphosphonium cyclopentadienylide complexes are similar to cyclopentadienylmetal tricarbonyl anions $[C_5H_5M(CO)]_3^-$ (M = Cr, Mo, or W) and are stablised by the interaction of one of the filled non-bonding metal orbitals with the vacant *d* orbital of the phosphorus atom [structure (D)]:



(C) M = Cr, Mo, W. (D)

However, X-ray diffraction analysis of dimethylsulphonium cyclopentadienylide and its π-complexes with chromium and molybdenum carbonyls[17,18] showed that the chromium atom in dimethylsulphonium cyclopentadienylidechromium tricarbonyl is symmetrically coordinated (by an octahedron) with the cyclopentadienyl ring (three coordination sites) and with three carbonyl groups. The distance between the sulphur and chromium atoms (3.478 Å) greatly exceeds the sum of the covalent radii of the chromium and sulphur atoms (2.52 Å). The absence of the Cr...S interaction is also indicated by the deviation of the S atom from the plane of the cyclopentadienyl ring by 0.110 Å towards the opposite chromium atom.

Comparison of the structural parameters of dimethylsulphonium cyclopentadienylide and its π-complex with chromium showed that the π-coordination to the transition metal is not accompanied by sharp changes in the structure of the cyclopentadienylide but leads to an increase of the contribution of the ylide structure. For example, the C–C bond lengths in the cyclopentadienyl ring of the π-complex are somewhat more equalised than in the initial cyclopentadienylide, while the partial double bond character of the sulphur–cyclopentadienyl ring bond is more pronounced in the ylide than in the complex.

The X-ray diffraction analysis of the complex of triphenylphosphonium cyclopentadienylide with cobalt carbonyl was carried out in 1978.[11] The authors noted that the structure of this cationic complex resembles that of the complex of dimethylsulphonium cyclopentadienylide with chromium carbonyl. On the other hand, there is similarity with the $C_5H_5Co(CO)_2$ structure.

The complex of triphenylphosphonium cyclopentadienylide with mercury iodide has a different structure[14]. In the solid state the complex exists as a dimer with two bridging iodine atoms:

The mercury atom is linked by a π-bond to the C(3) carbon atom of the five-membered ring of the ylide. The C(1)–C(2) and C(4)–C(5) bonds are appreciably shorter than the other bonds, which indicates their double bond character. From the ^{13}C NMR spectrum, the authors assume that in solution the mercury atom is linked alternately to the C(2), C(3), C(4), and C(5) atoms.

3. Physicochemical Properties

The complexes of cyclopentadienylides with metal carbonyls are solid crystalline substances. With the exception of pyridinium cyclopentadienylide complexes, they are relatively resistant to the action of atmospheric oxygen. In the solid state the complexes decompose slowly in air, but their solutions are relatively unstable.

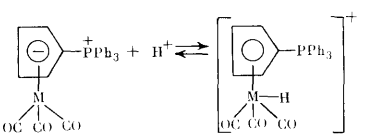
(a) *Infrared and NMR spectra.* The parameters of the infrared and ^1H NMR spectra of the cyclopentadienyl complexes of metal carbonyls are presented in Table 1. Evidently, the infrared spectra of these complexes are characterised by intense absorption bands in the region of the vibration frequency of the terminal CO groups. Two signals due to the protons of the five-membered ring and the multiplet due to the protons of the benzene rings can be observed in the ^1H NMR spectra of triphenylphosphonium cyclopentadienylide complexes with Group VIB metal carbonyls. In these complexes the metal is coordinated to the five-membered and not the six-membered ring of the ylide since the signals of the protons in the five-membered ring of the complexes are displaced upfield, relative to the initial ylide, while the chemical shifts of the protons in the benzene rings hardly charge on formation of the complexes[2].



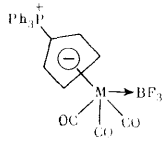
The most interesting information about the influence of coordination to the metal on the physicochemical properties of cyclopentadienylides has been obtained in the study of the ^{13}C NMR spectra[10,20]. Comparison of the $^{13}C\{^1H\}$ spectra of triphenylphosphonium and dimethylsulphonium cyclopentadienylides and their complexes with Group VIB metal carbonyls showed that the π-coordination to the $M(CO)_3$ group (M = Cr, Mo, or W) leads to an appreciable equalisation of the electron density in the five-membered ring of the coordinated cyclopentadienylide[20].

It has also been shown[20] that the shielding of the nuclei of all the carbon atoms of the cyclopentadienyl fragment of the ligand increases on π-coordination, the degree of shielding depending on the nature of the central metal atom and varying in the sequence Cr > W > Mo.

(b) *Electrical conductivity and degree of dissociation.* The complexes of cyclopentadienylides with Group VII and VIII metals are saltlike compounds. Solutions of complexes of triphenylphosphonium and diphenylsulphonium cyclopentadienylides with manganese and rhenium carbonyls in acetone conduct electricity; the molar conductances Λ_M are close to the average value for binary electrolytes formed by coordination compounds[10]. The degrees of dissociation α of these complexes in solution have been calculated from the molecular weights determined ebullioscopically in ethyl methyl ketone[10]. Comparison of the values of α for different complexes showed that the cyclopentadienylide complexes of rhenium are weaker electrolytes than the analogous manganese compounds and that, for the same central metal atom, the triphenylphosphonium cyclopentadienylide complexes are more dissociated in solution than the dimethylsulphonium cyclopentadienylide complexes. The electrical conductivities of the saltlike complexes of palladium with triphenylphosphonium cyclopentadienylide have also been measured[12], but the results are not discussed by the authors.

4. Chemical Properties

(a) *Protonation.* It was shown in 1970 that the complexes of triphenylphosphonium cyclopentadienylide with chromium, molybdenum, and tungsten carbonyls dissolve rapidly in trifluoroacetic acid, forming pale-blue solutions. The infrared and ^1H NMR spectra of the solutions (Table 2) indicate the reversible protonation of the complexes at the metal atom:



Thus the high-field signal (δ in the range between −5 and −8 p.p.m.) in the ^1H NMR spectra of these solutions is characteristic of the proton linked to the metal atom, as in the corresponding hydrides $C_5H_5M(CO)_3H$. The signal of this proton in the spectrum of the tungsten complex is split owing to the interaction with the ^{183}W nucleus; the spin–spin coupling constant (36 Hz) is close to the value of $J_{^{183}W-^1H}$ for $C_5H_5W(CO)_3H$ and $[(C_5H_5)_2W_2(CO)_6H]^+$.

The stretching vibration frequencies of the carbonyl groups of the protonated complexes were found to have undergone a hypsochromic shift relative to the non-protonated complexes by more than 100 cm^{-1} (Table 2). This fact indicates an increase of the C–O bond order in the protonated complexes as a consequence of the appearance of a positive charge on the metal atom. The study of the parameters of the ^1H NMR spectra of the protonated complexes of triphenylphosphonium cyclopentadienylide with various central metal atoms showed[14] that the basicity of the cyclopentadienylide complexes of Group VIB metals increases with increase of the atomic weight of the metal.

Table 2. Parameters of the ^1H NMR and infrared spectra of the protonated complexes $[(Ph_3PC_5H_4)M(CO)_3H]^+$.[4]

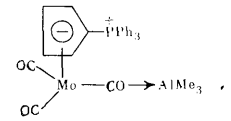
(b) *The formation of adducts with Lewis acids.* The cyclopentadienylide complexes of Group VIB metals form adducts with Lewis acids. Triphenylphosphonium cyclopentadienylidemolybdenum tricarbonyl and its tungsten analogue form solid dark-red adducts with BF_3, which have been investigated by elemental analysis and infrared spectroscopy[4]:

M = Mo, W.

The chromium complex also reacts with BF_3, but the adducts could not be isolated in a solid state owing to their dissociation. The boron trifluoride in these adducts forms a bond with the metal, which follows from the infrared spectra; the basicity of the complexes relative to BF_3 increases with increase of the atomic number of the metal.

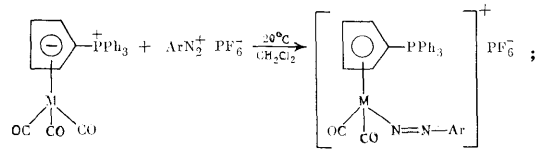
A study has also been made of the interaction of triphenylphosphonium cyclopentadienylidemolybdenum tricarbonyl and its tungsten analogue with other Lewis acids: CdI_2, $HgCl_2$, $HgBr_2$, HgI_2, $GaBr_3$, and $InBr_3$.[5] The products were 1:1 adducts, moderately resistant to the action of air but sensitive to light. No 1:2 adducts were detected although an excess of Lewis acids was used. Since all the vibration frequencies of the carbonyl groups of the adducts have undergone a bathochromic shift relative to the initial complexes, it was concluded that the central metal atom is the site of attack by the Lewis acid. The authors[5] were unable to make a choice between two structures of the adducts:



M = Mo, W $\quad$ $M'X_n$ = CdI_2, $HgCl_2$, $GaBr_3$ etc.

They believe that the ready formation of the adducts indicates the presence of a negative charge on the metal atom in the cyclopentadienylidemetal tricarbonyl complexes and also that the interaction of the metal with the phosphonium centre in these complexes is weak and does not prevent the reaction with the Lewis acid.

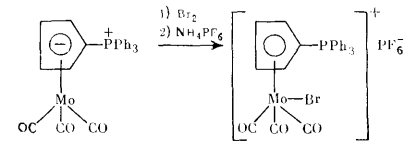
The study of the reactions of Group VIB metal complexes of triphenylphosphonium cyclopentadienylide in methylene chloride with strong Lewis acids such as $AlCl_3$ and $TiCl_4$[21] also demonstrated the occurrence of interaction via the metal atom.



The formation of an adduct via the metal atom between triphenylphosphonium cyclopentadienylidemolybdenum tricarbonyl and liquid SO_2 has been decribed[5].

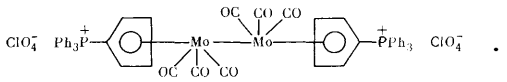
In contrast to the interaction with Lewis acids described above, trimethylaluminium reacts with triphenylphosphonium cyclopentadienylidemolybdenum tricarbonyl to form an adduct having a different structure[22]:

Tensimetric titration of the resulting compound with trimethylamine indicates the formation of a 1:1 adduct. The infrared spectrum contains bands at 1932, 1845, and 1665 cm^{-1} in the region corresponding to the vibrations of the CO group. Thus the stretching vibration frequencies of one CO group diminish markedly (by more than 100 cm^{-1}) due to the coordination to $AlMe_3$, while the stretching vibration frequencies of the two non-coordinated CO groups increase by ~15–30 cm^{-1}.



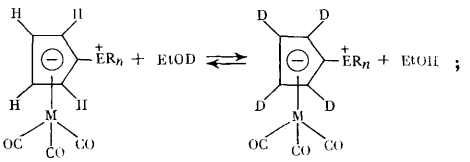
(c) *Reactions with arenediazonium salts.* *p*-Methoxybenzenediazonium hexafluorophosphate readily reacts with molybdenum and tungsten complexes of triphenylphosphonium cyclopentadienylide, giving rise to quantitative yields of products of the substitution of one carbonyl groups by the areneazo-group[5]:

M = Mo, W; Ar = *p*-$MeOC_6H_4$.



The corresponding chromium complex decomposes under the same conditions. The reaction is analogous to that of $[C_5H_5Mo(CO)_3]^-$ with $ArN_2^+X^-$.[5]

(d) *Reactions with halogens.* Triphenylphosphonium cyclopentadienylidemolybdenum tricarbonyl reacts with chlorine, bromine, or iodine at room temperature, the halogen adding to the metal[5]:



The reaction takes place more smoothly when the intial complex (or its tungsten analogue) is treated with carbon tetrachloride or tetrabromide in CF_3COOH. The halogen adds to the metal atom of the complex $(Ph_3PC_5H_4)Mo(CO)_3$ also on treatment with $SbCl_5$ or $C_5H_5Co(CO)I_2$.[5]

(e) *Oxidation.* The effect of one-electron oxidants, namely tri(*p*-bromophenyl) ammonium salts, has been investigated in relation to the molybdenum complex of triphenylphosphonium cyclopentadienylide[5]. Treatment with $[(BrC_6H_4)_3N]^+ \cdot [SbCl_6]^-$ results in the formation, analogously to the reaction involving halogens, of the salt $[Ph_3PC_5H_4Mo(CO)_3Cl]^+ \cdot [SbCl_6]^-$. On the other hand, on treatment with the substituted ammonium perchlorate, the complex is oxidised with formation of a dimer:

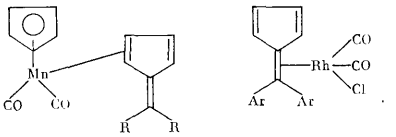
(f) *Hydrogen isotope exchange.* It has been recently observed that the complexes of cyclopentadienylides with Group VIB metal carbonyls can undergo the hydrogen isotope exchange (HIE) reaction with deuteroethanol in neutral media [19,23]:

M = Cr, Mo, W; ER_n = Me_2S, Ph_3P.

Table 3. The rate constant for hydrogen isotope exchange involving cyclopentadienylides and their π-complexes with Group VIB metals (in acetone at 50 °C).[19,23]

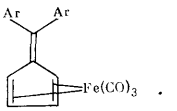
Compound	k, s^{-1}	Compound	k, s^{-1}
$(Me_2SC_5H_4)$	$7.0 \cdot 10^{-5}$	$Ph_3PC_5H_4$	$6.7 \cdot 10^{-5}$
$(Me_2SC_5H_4)Cr(CO)_3$	$2.1 \cdot 10^{-7}$	$(Ph_3PC_5H_4)Cr(CO)_3$	No exchange
$(Me_2SC_5H_4)Mo(CO)_3$	$2.9 \cdot 10^{-5}$	$(Ph_3PC_5H_4)Mo(CO)_3$	$8.2 \cdot 10^{-6}$
		$(Ph_3PC_5H_4)W(CO)_3$	$7.1 \cdot 10^{-7}$

The authors used the hydrogen isotope exchange method to compare the reactivities of cyclopentadienylide complexes containing various metals and various onium atoms. Table 3 presents the rate constants for the HIE of cyclopentadienylides and their π-complexes with EtOD in acetone. The results show that the influence of π-coordination to a transition metal on the reactivity of cyclopentadienylides is determined to a large extent by the nature of the central metal atom. For example, the rate constants for the hydrogen isotope exchange under identical conditions are similar in magnitude for dimethylsulphonium cyclopentadienylide and its π-complex with $Mo(CO)_3$, whereas the rate constants for triphenylphosphonium cyclopentadienylide and its complex with $Mo(CO)_3$ differ only by an order of magnitude. On the other hand, the influence of π-coordination to the $Cr(CO)_3$ group is manifested much more intensely and the rate of HIE involving the chromium complex of dimethylsulphonium cyclopentadienylide diminishes by a factor greater than two compared with the non-coordinated ylide. The $W(CO)_3$ group occupies an intermediate position between $Cr(CO)_3$ and $Mo(CO)_3$ as regards its influence on the HIE of cyclopentadienylides.



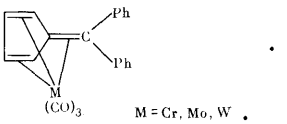
Thus the reactivity of the cyclopentadienyl ring in isotope exchange between cyclopentadienylides and their π-complexes with Group VIB metal carbonyls varies in the sequence S- or P-cyclopentadienylide ≧ Mo complex of ylide > W complex of ylide > Cr complex of ylide.

It has also been shown for the π-complex of dimethylsulphonium cyclopentadienylide with $Mo(CO)_3$ [20] that the π-coordination to the transition metal leads to the abolition of the differences between the rates of exchange in the α- and β-positions of the five-membered ring of the π-ligand, in contrast to the non-coordinated cyclopentadienylide, where the α-position is more reactive.



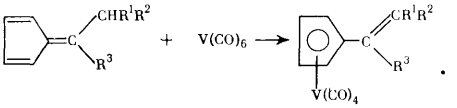
III. TRANSITION METAL COMPLEXES OF PENTAFULVENES

Pentafulvenes can be coordinated to transition metals in various ways:

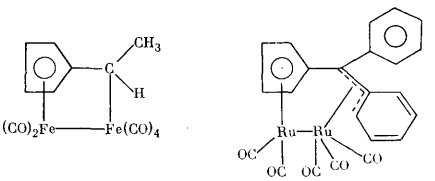


1. Via one double bond[25,27]:

2. Via two double bonds[26]:

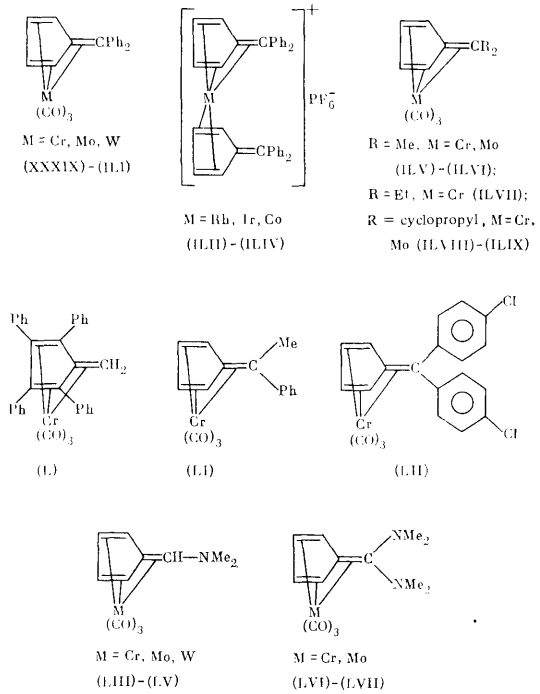


3. Via three double bonds[28,40]:



M = Cr, Mo, W.

4. To the cyclopentadienyl ring as the donor of five electrons[29]:



5. In a complex manner[30,31]:

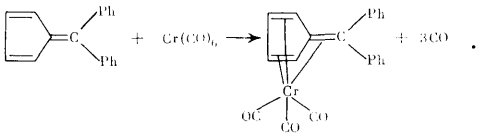
Pentafulvenes are structural units of molecules of compounds such as calicenes, fulvalenes, azulenes, etc. Some of these compounds form complexes with transition metals; for example, the complex of azulene with $Cr(CO)_3$ was described in 1978.[24] However, in this review we shall not consider the complexes of such compounds. We shall deal only with the complexes of pentafulvenes in which the coordination to the metal takes place via three double bonds of the pentafulvene, i.e. the pentafulvene is a six-electron ligand. Such π-complexes of pentafulvenes are comparable

to the π-complexes of cyclopentadienylides with metal carbonyls. All the pentafulvenes with six-electron coordination described in the literature hitherto are presented below:

M = Cr, Mo, W (XXXIX)-(XLI)

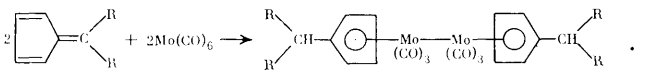
M = Rh, Ir, Co (XLII)-(XLIV)

R = Me, M = Cr, Mo (XLV)-(XLVI); R = Et, M = Cr (XLVII); R = cyclopropyl, M = Cr, Mo (XLVIII)-(XLIX)



(L) (LI) (LII)

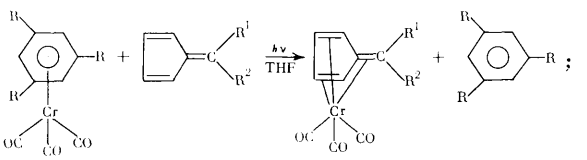
M = Cr, Mo, W (LIII)-(LV)



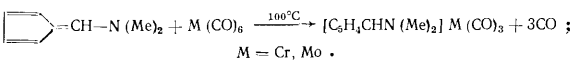
M = Cr, Mo (LVI)-(LVII)

1. Synthesis

The complex of 6,6-diphenylfulvene with chromium carbonyl was first obtained in 1961 by the reaction of fulvene with $Cr(CO)_6$ in hydrocarbon solvents[32]:



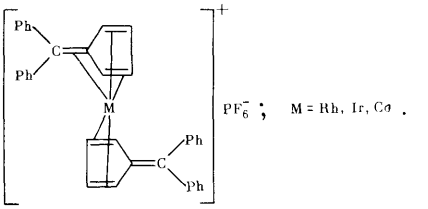
The analogous reactions of the metal carbonyls $Mo(CO)_6$ and $W(CO)_6$ with pentafulvenes in solvents of the type of ethers or in the absence of a solvent form only dimeric complexes (with breakdown of the fulvene structure)[33,34]:



However, it was shown in 1977 that the reactions of 6,6-dialkyl- and 6,6,-diarylpentafulvenes with acetonitrile derivatives of chromium, molybdenum, and tungsten carbonyls in tetrahydrofuran (THF) lead to the formation of fulvene complexes in the case of all three metals[28].

It has been found recently that pentafulvene can substitute the π-arene ligand in arenechromium tricarbonyl complexes with formation of pentafulvene complexes[35]:

R = H, Me; R^1 = Me, R^2 = Ph; $R^1 = R^2 = C_6H_4Cl$.

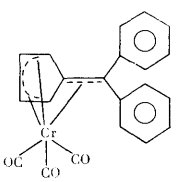


Complexes of 6-(*N*,*N*-dimethylamino)- and 6,6-bis(*N*,*N*-dimethylamino)-fulvenes with chromium and molybdenum carbonyls can be obtained by the direct reaction of the fulvenes with $Cr(CO)_6$ and $Mo(CO)_6$ in cyclohexane[36]:

M = Cr, Mo.

Under these conditions, $W(CO)_6$ does not react with 6-(*N*,*N*-dimethylamino)fulvene and the acetonitrile derivative of tungsten is used to obtain the fulvene complex[37].

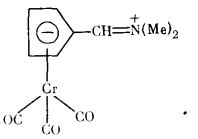
Sandwich complexes of 6,6-diphenylfulvene with rhodium, iridium, and cobalt salts were obtained[38] as early as 1967:



These charged complexes were obtained by the reaction of 6,6-diphenylfulvene, the metal salt, and isopropylmagnesium bromide followed by ultraviolet irradiation, hydrolysis of the reaction mixture, and oxidation with atomospheric oxygen. The yield of the complexes is very low: 6, 0.8, and 0.04% in the case of $CoCl_2$, $RhCl_3$ and $IrCl_3$ respectively. Only charged biscyclopentadienyl complexes of the metals have been isolated after the analogous reaction of 6,6-dimethylfulvene with $RhCl_3$ and $CoCl_2$, i.e. the fulvene structure of the ligand decomposed as a result of the addition of hydrogen to the exocyclic double bond.

2. Structure

It was postulated previously[32] that in the reaction of 6,6-diphenylfulvene with chromium carbonyl the complex formation process involves the benzene ring of the fulvene. However, later the same investigators[39] established by ^1H NMR that the five-membered and not the six-membered ring of 6,6-diphenylfulvene is coordinated to the chromium atom.



Complete X-ray diffraction analysis of 6,6-diphenylfulvene chromium tricarbonyl confirms the coordination to the five-membered ring[40,41]. It was shown that in the molecule of the complex the chromium atom is linked to all six carbon atoms of the pentafulvene ligand and to the three carbonyl groups, assuming a distorted octahedral coordination. The planarity of the fulvene system is then appreciably disturbed as a result of the deviation of the exocyclic carbon atom towards the chromium atom. Thus the coordination of the chromium atom in 6,6-diphenylfulvenechromium tricarbonyl can be represented as coordination to the butadiene system of the cyclopentadienyl ring and to the exocyclic double bond of the fulvene:

Theoretical analysis[42] of the preferred conformation of the complex (fulvene)$Cr(CO)_3$ showed that the calculated angle of the deviation of the exocyclic carbon atom from the plane of the five-membered ring is close to the experimental value[41].

Comparison of the structure of 6,6-diphenylfulvenechromium tricarbonyl with that of dimethylsulphonium cyclopentadienylidechromium tricarbonyl shows that they differ sharply. In the case of the fulvene complex the exocyclic carbon atom is involved in coordination to the metal, while in the case of the cyclopentadienylide complex the sulphur atom is displaced from the plane of the five-membered ring in the direction opposite to that of the chromium atom and is not linked to the latter.

From X-ray diffraction data for 6-(*N*,*N*-dimethylamino)-fulvenechromium tricarbonyl, it has been concluded[43] that the molecule of this complex contains the fulvene ligand in a dipolar form stabilised by the complex formation reaction between the negatively charged five-membered ring and the $Cr(CO)_3$ group. Thus it has been shown that complex formation results in a significant equalisation of the C–C bond lengths in the cyclopentadienyl ring of the ligand and an increase of the multiplicity of the bond between the nitrogen atom and the exocyclic carbon atom:

3. Infrared and NMR Spectra

The infrared spectra of the metal carbonyl complexes of pentafulvenes with six-electron coordination are characterised by intense absorption bands in the same region of absorption by terminal CO groups as in the spectra of the metal carbonyl complexes of cyclopentadienylides (Table 4). The ^1H NMR spectra of pentafulvene complexes (Table 4) exhibit under the usual conditions two signals due to the α- and β-protons of the five-membered ring, the signals having undergone an upfield displacement relative to the non-coordinated pentafulvene, as in the case of the cyclopentadienylide π-complexes.

The study of the ^{13}C NMR spectra of the chromium tricarbonyl complexes of 6,6-diphenylfulvene and 6-(*N*,*N*-dimethylamino)fulvene[44] showed that the π-coordination of pentafulvenes to the $Cr(CO)_3$ group is accompanied by an increase of the energy of the shielding of the nuclei of all the carbon atoms of the cyclopentadienyl ring, as in the cyclopentadienylide complexes, the effect being observed to a more marked extent in systems with a more pronounced ylene structure. It has also been found that the coordination of 6,6-diphenylfulvene to the chromium atom entails an appreciable increase of the shielding of the exocyclic carbon atom (there is an upfield shift of the signal due to the ^{13}C atom by 26 p.p.m.), while the coordination of 6-(*N*,*N*-dimethylamino)fulvene to the $Cr(CO)_3$ group is accompanied by the deshielding of the exocyclic carbon atom (there is a downfield shift of the signal due to the ^{13}C atom by 6 p.p.m.). The authors[44] explained these facts by a difference between the structures of the complexes. According to X-ray diffraction analysis, the exocyclic double bond of 6,6-diphenylfulvene is involved in coordination to the chromium atom, which leads to an increase of the shielding of the nuclei of the carbon atoms in this bond. On the other hand, if the coordination of 6-(*N*,*N*-dimethylamino)fulvene to the $Cr(CO)_3$ group is accompanied by an increase of the contribution of the ylide structure, one would expect the deshielding of the nucleus of the C_{ex} atom adjoining the onium nitrogen atom and also an increase of the barrier to rotation about the $C_{ex}=N^+Me_2$ bond. The authors found confirmation of this hypotheis in the observation that, apart from the deshielding of the $^{13}C_{ex}$ nucleus, two signals also appear in the ^{13}C NMR spectra due to the CH_3 groups at the nitrogen atom (in contrast to the initial fulvene). The hypothesis of an increase of the contribution of the ylide structure on π-coordination of 6-(*N*,*N*-dimethylamino)fulvene to $Cr(CO)_3$, based on the study of the ^{13}C NMR spectra, was subsequently confirmed by X-ray diffraction[43].

4. Chemical Properties

The chemical properties of the π-complexes of pentafulvenes have been studied extremely little. It has been shown[39] that 6,6-diphenylfulvenechromium tricarbonyl is readily reduced by sodium tetrahydroborate with formation of an anionic cyclopentadienyl complex of chromium:

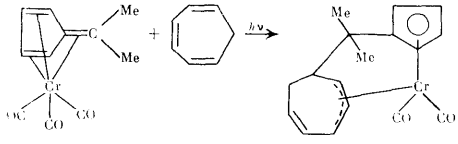
*The infrared spectra were recorded in liquid paraffin; in the remaining cases the spectra were measured using discs with KBr.

An analogous reaction involving the nucleophilic addition of alkyl-lithium was described in 1977 [28]:

The hydrogen isotope exchange involving the molybdenum complex of 6-(*N*,*N*-dimethylamino)fulvene on treatment with deuteroethanol in a neutral medium has been studied recently under the same conditions as for the corresponding molybdenum complexes of triphenylphosphonium or dimethylsulphonium cyclopentadienylide[20]. It has been shown that the rate of isotope exchange in ylide–ylene systems coordinated to a transition metal atom increases with increase of the contribution of the ylide form to the structure of the ligand:

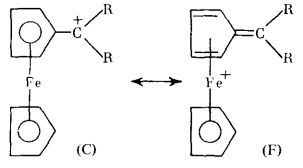
$$[Me_2NCHC_5H_4]Mo(CO)_3 < (Ph_3PC_5H_4)Mo(CO)_3 < [Me_2SC_5H_4]Mo(CO)_3 .$$



The protonation of complexes of 6-(*N*,*N*-dimethylamino)-fulvene with chromium, molybdenum, and tungsten carbonyls was studied in 1980 by ^{1}H NMR and infrared spectroscopy under the conditions of different acidities in solutions of trifluoroacetic and acetic acid in methylene chloride[45]. It was established that in CF_3COOH the complexes are reversibly protonated at the metal atom and that the rate of protonation varies linearly with the acidity of the medium:

$$(C_5H_4CHNMe_2)M(CO)_3 \underset{Et_2NH}{\overset{H^+}{\rightleftharpoons}} [(C_5H_4CHNMe_2)M(CO)_3H]^+ ;$$
$$M = Cr, Mo, W .$$

Signals are then observed in the ^{1}H NMR spectra in the range of δ values between −3 and −8 p.p.m., which are characteristic of hydrogen atoms linked to a metal. With increase of the atomic number of the metal, the signals are displaced to higher field, which indicates an increase of the degree of shielding of the hydrogen atom attached to the metal. The authors estimated quantitatively the relative basicities of the complexes of 6-(*N*,*N*-dimethylamino)fulvene with Group VIB metal carbonyls and found that the basicity of the complexes increases in proportions of ~1 : 150 : 1800 with increase of the atomic number of the metal from Cr to Mo and then to W.

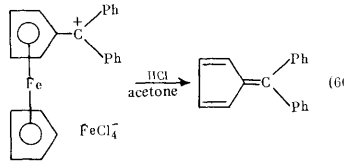


As already stated, previously the qualitative conclusion was reached that the basicity of the complexes of triphenylphosphonium cyclopentadienylide with Group VIB metal carbonyls increases with increase of the atomic number of the metal.

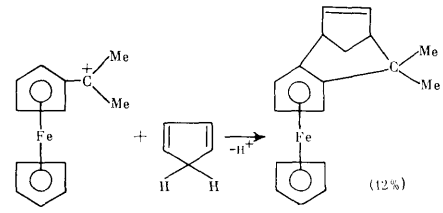
The reaction of 6,6-dimethylfulvenechromium tricarbonyl with cycloheptatriene in hexane under irradiation, which leads to the formation of a complex having a composite structure, has also been described[46]:

5. Metallocenylcarbenium Ions

The metallocenylcarbenium ions, which are readily formed and exhibit an unusual stability, can also be included in the class of pentafulvene complexes with transition metals:



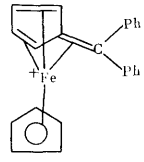
(C) (F)



The authors of a review on fulvene complexes[3] regard α-ferrocenylcarbenium ions as complexes with a fulvene ligand. Although the nature of the unusually high stability of the α-ferrocenylcarbenium ions has been the subject of prolonged discussion and there have been many publications on this subject (original and review publications)[47–49], the structure of these species has still not been finally established.

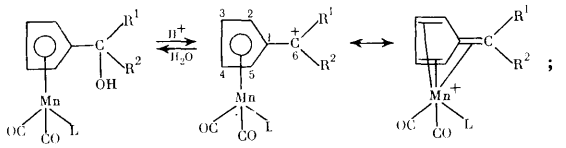
Being unable to consider this question in detail, we shall confine ourselves only to listing the pieces of evidence characterising the interrelation between the fulvene (F) and ferrocenylcarbenium (C) structures and to a discussion of the results of a recent investigation[50] undertaken to determine the structure of the tetrafluoroborate of the diphenylferrocenylcarbenium ion.

One of the pieces of evidence in support of the fulvene structure of the ferrocenylcarbenium ion is the spontaneous formation of fulvenes from the latter in hydrochloric acid solution or under irradiation[51–54], for example:



Another important piece of evidence is the ability of ferrocenylcarbenium ions to interact with cyclopentadiene to form a cycloaddition product[55]:

Quantum-chemical calculations on ferrocenylcarbenium ions have shown that a considerable proportion of the positive charge is located at the iron atom[56]. The study of the ^{1}H and ^{13}C NMR spectra (see, for example, Refs.57–59) has shown that the positive charge is distributed throughout the molecule of the complex.



A complete X-ray diffraction analysis of the tetrafluoroborate of the diphenylferrocenylcarbenium ion has been carried out quite recently[50]. The experimental data enabled the author to conclude that the compound is a salt of the fulvene-cyclopentadienyliron cation:

In this system the exocyclic carbon atom is displaced from the plane of the cyclopentadienyl ring in the direction of the iron atom by 20.7°. The exocyclic carbon–carbon bond is appreciably shorter than the simple C–C bond and alternation of bond lengths is observed in the cyclopentadienyl ring, in a manner similar to that established previously for the isoelectronic diphenylfulvenechromium tricarbonyl[40,41]. Analysis of the results led the author[50] to the conclusion that the metallocenylcarbenium ion is stabilised not only as a result of the interaction of the orbital of the exocyclic carbon atom with the molecular orbital of the cyclopentadienyl ring but also as a consequence of the formation of a bond between this carbon atom and the central iron atom.

Like ferrocene, ruthenocene and osmocene greatly stabilise the neighbouring cationic centre[60,61] and therefore α-ruthenocenyl- and α-osmocenyl-carbenium ions can also be regarded as fulvene complexes.

The systematic study of cymantrenylcarbenium ions has been begun comparatively recently[62-69]. Like the ferrocenylcarbenium ions, these ions are formed when the corresponding carbinols are dissolved in acid. Solutions of the cations are extremely stable:

R^1, R^2 = Ph, C_6H_4Me, $C_6H_4CMe_3$, Me, Et etc.,
L = CO, PPh_3, $P(OPh)_3$, PEt_3, $SbPh_3$ etc.

The structure of the cymantrenylcarbenium ions is apparently analogous to that of the corresponding ferrocenyl ions. This is indicated, for example, by the study of the ^1H and ^{13}C NMR spectra, whose results indicate a pronounced delocalisation of the positive charge over the cymantrenyl fragment[65]. Diastereotopy of the protons in the 2- and 5-positions[68,69] similar to that observed earlier for ferrocenyl ions[70], has been observed for cymantrenylcarbenium ions[68,69]; it can be accounted for by the hindered rotation about the C(1)–C(6) bond, which has some double bond character. However, the lack of X-ray diffraction data for carbenium ions stabilised by cymantrenyl residues precludes a final conclusion concerning the full similarity of their structure with that of ferrocenylcarbenium ions.

---oOo---

The extremely important and interesting available information about the influence of π-coordination to a transition metal atom on the properties of the cyclopentadienyl ring, carrying a full or partial negative charge, cannot as yet be regarded as sufficiently complete. It has been shown from the results of an X-ray diffraction study of dimethylsulphonium cyclopentadienylide (~80% contribution of the dipolar structure) and of its π-complex with the $Cr(CO)_3$ group that the π-coordination of this ylide is not accompanied by sharp changes in the structure of the cyclopentadienylide, but leads to an appreciable equalisation of the C–C bond lengths in the five-membered ring, i.e. to an increase of the contribution of the ylide structure in the π-ligand. In contrast to this, in the case of 6,6-diphenylfulvene, which has the ylene structure, π-coordination to the $Cr(CO)_3$ group leads to the breakdown of the planarity of the fulvene system owing to the deviation of the exocyclic carbon atom in the direction of the chromium atom. In this case the butadiene system of the five-membered ring and the exocyclic double bond are coordinated to the metal. As a result of the coordination of 6-(*N*,*N*-dimethylamino)fulvene (contribution of the dipolar structure ~50%) to the $Cr(CO)_3$ group, the molecule of the complex contains the fulvene ligand in its dipolar form.

The results of the study of the ^{13}C NMR spectra of the complexes of dimethylsulphonium and triphenylphosphonium cyclopentadienylides with Group VIB metal carbonyls showed that the differences between the chemical shifts of the carbon nuclei in the cyclopentadienyl ring diminish sharply on π-coordination to transition metals and an appreciable equalisation of the electron density in the five-membered ring occurs as a result. The observed ability of the π-complexes of cyclopentadienylides with Group VIB metal carbonyls to undergo hydrogen isotope exchange with deuteroethanol in neutral media made it possible to employ the hydrogen isotope exchange method to compare the reactivities of the ylide and their π-complexes.

Polymerisation Filling by the Method of Radical Polymerisation as a Procedure for the Preparation of Composite Materials

S.S.Ivanchev and A.V.Dmitrenko

Studies devoted to the polymerisation of monomers in the presence of dispersed fillers are surveyed. Attention is concentrated on systems where polymerisation accompanied by the formation of a chemical bond between the polymer matrix and the filler takes place. Procedures for polymerisation filling and the preparation of filled polymer compositions are described systematically and analysed; the characteristics and general features of radical polymerisation initiated from the surface of the solid phase, usually from the surfaces of dispersed inorganic fillers, are discussed. Cases of improvement of the physicochemical and operational properties of compositions resulting from the formation of the chemical bond between the polymer matrix and the filler are examined.
The bibliography includes 127 references.

I. INTRODUCTION

In recent years filled polymer compositions have been finding increasing applications in various branches of technology[1,2]. The introduction of solid dispersed or fibrous inorganic or organic substances into the polymer phase makes it possible not only to reduce significantly the cost of polymeric materials by employing cheap and readily available fillers but also this frequently leads to the strengthening of the materials, i.e. to an improvement of their physicochemical, mechanical, thermal, electrical, friction, and other properties. There is then a possibility of replacing expensive constructional plastics (polyamides and polyesters) by cheaper filled polymers[3-5].

Cheap and readily available mineral fillers constitute an increasing proportion of the overall volume of fillers employed and their assortment is being continuously increased[2,6,7]. Thus it is believed that the employment of fillers for plastics will have increased from 1.06×10^6 tonnes in 1975 to 15×10^6 tonnes in 2000, including the following substances (in million tonnes): carbonates (mainly chalk) from 0.7 to 9.0, asbestos from 0.18 to 1.7, aluminium hydroxide from 0.05 to 1.6, talc from 0.04 to 1.8, cellulose from 0.4 to 0.5, silicates from 0.025 to 0.5, and glass from 0.1 to 0.2.

We may note that the criterion of cost-effectiveness of filled compositions is not their absolute cost (the composition can be more expensive than the matrix polymer). It is in fact the difference in cost relative to the material replaced. For this reason, the most expensive fillers, which also have the greatest reinforcing effect, for example carbon fibre, are sometimes used in compositions based on fairly cheap polymers[8,9].

The most important factor which determines the strengthening effects of fillers in polymers is the adhesion of the polymers to the surfaces of the fillers[1,10,11], which depends on the adsorption and chemical linkages between the surface of the filler and the polymer matrix. The interaction of the polymer with the surface of the filler determines the nature of the deformation and breakdown of the filled polymer and many other properties. It is noteworthy that in the general case organic polymers are as a rule poorly compatible with inorganic fillers.

One of the ways of improving adhesion may be the employment of a third component (dressing agent) which forms an intermediate layer between the polymer matrix and the filler[1]. This approach can be conveniently employed in the stage involving the processing of the polymer by dressing the filler before mixing it with the polymer. In many cases expensive dressing agents with a complex structure must be used to achieve the necessary effect[12,13]. The mixing equipment and technology, which are in many instances specific to a particular polymer–filler combination, must be chosen taking into account the abrasive effect of the filler, which frequently becomes the key factor in the solution of the problem of preparation of filled compositions[7].

The mechanism of the strengthening effect of fillers in filled compositions has not so far been completely elucidated[14-17]. A common idea is that the difference between the moduli of elasticity of the polymer matrix and the filler is the cause of the "concentration" of the breaking stress at the interface between the polymer mass and the filler particle[18,19]. This phenomenon can be eliminated if the filler particle has been encapsulated in a polymer phase bound closely to it and having a modulus of elasticity close to that of the filler. It is believed[18] that such a capsule may consist of a polymer matrix linked by covalent bonds to the filler particle.

Together with the improvement of the physicomechanical and operational properties of the composition on formation of a chemical bond between the polymer matrix and the filler, the possibility of improving the rheological characteristics of the melt of the composition and its capacity for being worked has been noted in a number of studies[20].

The commonest methods ensuring the formation of a chemical bond between the polymer matrix and the filler consist in the introduction of the filler into the polymer and at the stage involving its processing, using dressing agents or functional groups on the surface of the filler and the polymer matrix[1]. However, the method of polymerisation filling, a realistic version of which has been recently proposed and applied by Enikolopov[21,22], is of greatest interest. Its essential feature reduces to the polymerisation of the monomer in the presence of a dispersed filler with a catalytic system deposited on its surface. In this case it is easy to ensure the encapsulation of the filler in a polymer "jacket".

The advantage of polymerisation filling as a procedure for the preparation of compositions consists in the ease of measuring out the amounts of the components and the elimination from the technological scheme of a series of

operations associated with the dressing of the filler and the homogenisation of the components.

Fairly numerous literature data concerning various procedures for polymerisation filling by radical polymerisation have been published recently; a number of specific features of the polymerisation of vinyl monomers, accompanied by the formation of a polymer bound chemically to the surface of the filler, have been discovered. However, there has been no systematic account of these data so far. The review of Kroker et al.[23] partly reflects the essential feature of the problem, but the intense development of this field in recent years makes it necessary to supplement significantly and analyse these data.

The aim of the present communication is to give a systematic account and to analyse the methods for polymerisation filling and the preparation of filled polymer compositions described in the literature. The general characteristics of radical polymerisation initiated from the surface of a solid phase, usually from the surfaces of dispersed inorganic fillers, are discussed.

II. PROCEDURES FOR THE POLYMERISATION FILLING OF POLYMERS BY THE METHOD OF RADICAL POLYMERISATION

The earliest communications concerning the possibility of preparing polymers bound chemically to the surfaces of mineral fillers directly in the polymerisation stage are associated with the initiation of the process by mechanochemical reactions. This possibility arises when fillers subjected to grinding and cleavage with the aid of a wide variety of apparatus for the comminution of solids are employed. The active centres formed on the surface of the filler under these conditions can initiate polymerisation.

One of the first communications on this field[24] dealt with the polymerisation of styrene, α-methylstyrene, butadiene, and chloroprene on grinding with silica in a ball mill in an atmosphere of nitrogen; the amount of non-extractable polymer was ~0.2–2%. Polymers grafted onto the surface of the filler have been obtained[25] as a result of the polymerisation of a number of monomers in the milling of titanium dioxide. Grafted polymers have been obtained[26] on vibration of monomeric specimens filled with Group III or VIII metal oxides. Vibration of dried sodium bentonite in the presence of methyl methacrylate[27] leads to polymerisation and the formation of a polymer bound chemically to the filler (yield up to 22%); a homopolymer is not then formed. On the other hand, when benzoyl peroxide was added to the reaction mixture, homopolymerisation took place.

It is striking that in the above communications no direct evidence is presented for the presence of covalent bonds between the macromolecules and the solid surface nor are any ideas concerning the mechanisms of the processes involving mechanochemical reactions described. Nevertheless Kroker et al.[23] assumed that the radicals formed on the solid surface as a result of the homolytic cleavage of chemical bonds by mechanical influences are responsible for the initiation of polymerisation. However, it has been shown in a number of studies by Kargin and Plate[28–31] and by Tsetlin[32,33] that radical-ions are the active centres which are formed on the surfaces of the solid particles during their comminution and initiate polymerisation.

A systematic study of the mechanochemical graft polymerisation on a wide variety of solid surfaces of different monomers[34–37] enabled the authors to establish a series of common features, on the basis of which a mechanism of the grafting process has been proposed[38]. Grafting was achieved in the course of the dispersion of coarsely disperse powders (calcium carbonate, barium sulphate, ionic single crystals of NaCl, LiF, and CaF_2, magnesium oxide, iron oxide, graphite, amorphous glasses, quartz, metals, and polymers) in a vibromill in the presence of the monomer in air or on powders and cleaved single crystals obtained in air or in argon with subsequent contact between the specimen and the monomer (styrene and methyl methacrylate).

The authors[34–38] reached the following conclusions. The degree of grafting depends quantitatively on the nature of the surface, but grafting does not exhibit specificity and occurs on the surfaces of solids with a wide variety of structures and chemical bonds. The formation of the homopolymer together with the grafted polymer is not due to polymerisation but is a consequence of the stripping off and dissolution of part of the layer of the grafted macromolecules formed. A proportion of the homopolymer can be formed as a result of the radiation effect of electron emission[39] and the influence of the latter can be manifested only when the filler is dispersed directly in the presence of the monomer. The aftereffect in the initiation of polymerisation persists for a long time, exceeding by several orders of magnitude the electron emission time.

The main conclusion reached in the series of the above studies[34–39] is that the mechanochemical initiation of polymerisation takes place via a free-radical mechanism. The role of the centre stimulating the initiation of polymerisation can be assumed also by the free (static) charges arising on comminution of the solid and persisting on the freshly formed surface for a very long time after electron emission has stopped.

Certain additional ideas about the mechanism of graft polymerisation or the mechanochemical method of initiation can be derived from recently published studies[40–42]. In a study of the polymerisation of styrene on the freshly formed surfaces of NaCl, KCl, and LiF [40,42] and shale of different origin[41], the authors concluded that the polymer is grafted to the negatively charged centres of the crystals[40,42] and on the charged defects of the surface of shale[41].

It is seen from the foregoing that, despite the growing interest in the mechanochemical initiation of graft polymerisation, the problem of the mechanisms of initiation and the formation of the grafted polymer has not been ultimately elucidated.

The mechanochemical method of activating the surfaces of solid inorganic substances for the initiation of graft polymerisation is not unique. Thus extremely effective initiation of polymerisation by molecular beams of crystallised substances has been achieved[28]. The possibility of the polymerisation of methyl methacrylate and styrene using the surface energies of specimens comprising the oxides SiO_2, BeO, and Al_2O_3, having atomically clean dehydrated surfaces, has been established[43]. Such an "unsaturated" surface of a solid inorganic substance, free from extraneous adsorption layers, exhibits a considerable reactivity by virtue of the large excess of free energy, which is the reason for the ease of the chemisorption of the monomer and the subsequent initiation of its polymerisation by the active surface centres (ionic or radical).[29] The polymerisation was carried out in a layer of monomer deposited on the surface either from solution or from the vapour phase. It has been suggested[43] that the polymerisation of methyl methacrylate is accomplished by the grafting of the polymer to the surface, judging from the amount of the non-extractable polymer (80–90%). However, in contrast to poly(methyl methacrylate), the grafting of polystyrene was not observed. We therefore believe that the presence of the non-extractable poly(methyl methacrylate) is most probably associated with the chemisorption of the polymer on the surfaces of the

oxides with formation of carboxylate ions of the type $(R - C(=O)-O)^- Me^+$ and not the formation of polymer–filler covalent bonds. Infrared spectroscopic studies revealed[43] the chemisorption of methyl methacrylate on both hydrated and atomically clean Al_2O_3 surfaces.

An interesting method for the activation of the surfaces of mineral fillers in order to achieve polymerisation filling has been proposed by Berg et al.[44], who reported the ability of styrene and ethyl vinyl ether to polymerise on the surface of SiO_2 (in the form of Aerosil) activated with the aid of plasma. The yield of polymers is then higher when the activation is carried out in an oxygen and not an argon plasma. The average molecular weight of the products was 4×10^3 and the main bulk of the polymer formed was grafted to SiO_2.

One of the first productive methods for the preparation of polymers grafted to the surfaces of fillers is based on the use of irradiation. Thus the preparation of grafted polystyrene and poly(methyl methacrylate) on the surfaces of a wide variety of mineral fillers subjected to preliminary γ-irradiation has been reported[45,46]. According to Dinh-Ngoc et al.[45], γ-irradiated fillers have reaction centres capable of existing for up to 20 days and distributed exclusively on the surface. The amounts of grafted polymer per unit area are approximately of the same order of magnitude for different fillers (Table 1); the homopolymer is hardly formed under these conditions.

Table 1. The results of the polymerisation[45] of styrene and methyl methacrylate on a filler surface subjected to preliminary irradiation.

Monomer	Filler	Yield of grafted polymer			s
		w_1	w_2	$10^4 w_3$	
Methyl methacrylate	Silica gel	0.06	0.57	12.7	450
Methyl methacrylate	Woelm	0.03	0.40	8.9	—
Methyl methacrylate	Sikron	0.0008	0.0035	5.8	6
Methyl methacrylate	$CaCO_3$	0.003	0.009	14.5	1.5
Styrene	Silica gel	0.05	0.19	4.1	—
Styrene	Calcite	0.00	0.0045	7.3	—

Notation: w_1 and w_2 are the yields on a non-irradiated surface and in postpolymerisation (grammes per gramme of filler), w_3 is the yield in postpolymerisation (g m^{-2}), and s the specific surface (m^2 per gramme of filler).

Polymerisation in the presence of fillers initiated directly by γ-irradiation has been investigated in a number of studies[46–63]. The reaction takes place in a layer of monomer adsorbed from the gas phase on the surface of the specimen of the mineral filler (silica gel and Aerosil). It has been suggested that surface silanol groups are responsible in this instance for the grafting of the polymer[47–49]. The polymerisation of vinyl acetate and acrylonitrile on the surfaces of inorganic fillers has been interpreted[47,48] as an inhibited reaction occurring under conditions where the concentration of a relatively ineffective inhibitor—surface hydroxy-groups involved in degenerate chain transfer—is high. It is assumed that the surface radicals $\geqslant SiO^\cdot$ and $\geqslant Si^\cdot$—arise under the influence of irradiation, which can lead to the formation of grafted polymers[50].

In contrast to an earlier study[51], it has been noted[52] that the polymerisation of vinyl acetate and acrylonitrile adsorbed from the vapour phase on the surface of Aerosil results in the formation, already in the initial stage, of a considerable amount (50%) of a polymer which is not grafted to the surface and the authors believe that this is caused by the formation in the system, as a result of the radiolysis of silanol groups, of low-molecular-weight radical species $H^\cdot$ and $OH^\cdot$, which are not bound chemically to the solid support. Radicals arising in chain transfer to the monomer can play a definite role in the formation of the grafted polymer[48], whereas the role of the radicals formed as a result of the direct absorption of the radiation energy by the adsorbed monomer is apparently not great[47,48].

A considerable influence of adsorption–desorption processes on the formation of the polymer phase on a solid support in such systems has been noted[53]. The amount of styrene adsorbed on silica gel has been varied[54] from the value corresponding to less than a monolayer up to the level of uniform adsorption. It has been shown that the rate of graft polymerisation and the molecular weight distribution (MWD) (Fig. 1) of the polymer formed vary with the amount of adsorbed styrene; the maximum effectiveness of the grafting has bee achieved under the conditions of monolayer adsorption.

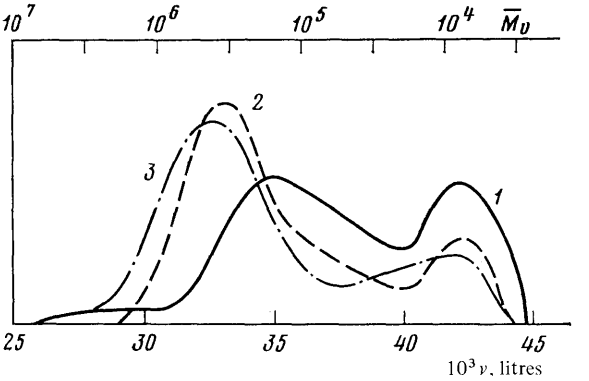

Figure 1. The molecular-weight distribution (MWD) of polystyrene grafted to silica gel and obtained in 1 h at a dose rate of 1×10^6 rad h^{-1} for different amounts of the monomer adsorbed on the filler; number of monolayers; *1*) 0.5; *2*) 1; *3*) 3 (v is the volume of eluent).[54]

A considerable change in the kinetic parameters of the polymerisation of vinyl acetate adsorbed on Aerosil relative to the liquid-phase polymerisation has been observed[55]: the rate constants for chain propagation and bimolecular termination decrease by 1–1.5 and 5 orders of magnitude respectively.

Believing that surface silanol groups are responsible for grafting, Japanese investigators[46,49,54,56–62] have adopted a different point of view concerning the mechanism of radiation-induced graft polymerisation. When the study of the polymerisation of styrene and methyl methacrylate in the presence of silica gel and Aerosil established that both grafted polymer and the homopolymer are formed simultaneously via both ionic and radical mechanisms over the entire range of dose rates. This conclusion is based on the analysis of GPC (gel permeation chromatography) peaks

which in the case of both the grafted polymer and homopolymers are bimodal, and also in the study of the influence of the dose rate and reaction temperature[57,60] and the presence of the inhibitors of radical and ionic reactions[61,62] on the nature of the GPC peaks. Analysis of the results of the polymerisation of styrene in the presence of various fillers (Aerosil and silica gel) led to the conclusion that the impurities and microporosity do not influence the reaction mechanism[59].

It has been noted in all the studies that the yield of the homopolymer always exceeds that of the grafted polymer but the molecular weight of the grafted polymer is higher (Fig.2) than that of the homopolymer. The grafted polymer, formed via a radical mechanism, has a higher molecular weight than the polymer formed via an ionic mechanism. It has been noted that in the presence of fillers (Aerosil, silica gel, and alumina) the rate of polymerisation is higher than in their absence. It has been suggested that this acceleration is associated with the excitation of the monomer molecules or of the growing chain by energy transfer from the filler[55,58].

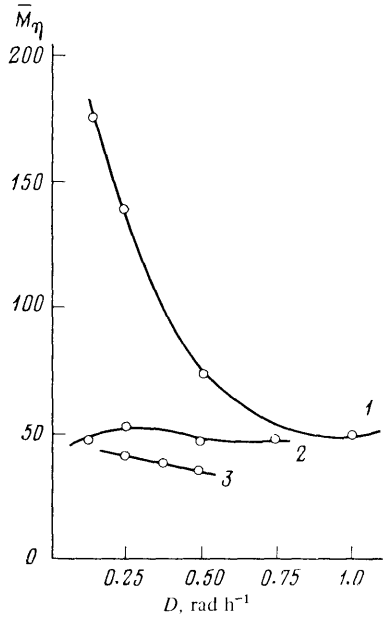

Figure 2. Dependence of M_η for polystyrene on the irradiation dose D: *1*) polystyrene grafted to silica gel; *2*) homopolymer; *3*) polymer obtained in the absence of the filler[56].

From a practical point of view, it is not without interest that on γ-irradiation a mixture of silica gel and styrene forms a greater amount of grafted polymer than in the grafting of styrene on silica gel subjected to preliminary irradiation[63].

The photochemical vapour-phase graft polymerisation of acrylonitrile, methyl methacrylate, and styrene on Aerosil with a peroxide coating, obtained using t-butyl hydroperoxide under conditions described by Poletukha[65], has been achieved[64]. Acrylonitrile has also been polymerised on Aerosil with a chlorosilylated coating[66] and on Aerosil with adsorbed quinones[67]. Analysis of infrared spectroscopic and gravimetric data led the authors of[64,66] to the conclusion that, when the modified silica is acted upon by ultraviolet light, the peroxide and chlorosilylated coatings decompose photochemically with formation of the corresponding radicals:

$$\equiv\!Si{-}O{-}O{-}C_4H_9 \xrightarrow{h\nu} \equiv\!Si{-}O^{\cdot} + C_4H_9O^{\cdot}\ ;$$

$$\equiv\!SiCl \xrightarrow{h\nu} \equiv\!Si^{\cdot} + Cl^{\cdot}\ .$$

It has been shown[68] that the quinone adsorbed on Aerosil is reduced by ultraviolet light as a result of the phototransfer of hydrogen atoms from the surface hydroxyls with formation of the radicals $\equiv$SiO$^{\cdot}$, which are also believed to be formed[68] in the photodehydration of the silanol groups of silica. The surface radicals $\equiv$SiO$^{\cdot}$ and Si$^{\cdot}$ initiate the graft polymerisation of monomers, particularly acrylonitrile:

$$\equiv\!Si{-}O^{\cdot} + n\,CH_2{=}CH \rightarrow \equiv\!Si{-}O{-}(-CH_2{-}\underset{CN}{CH}{-})_n{-}\ ,$$

$$\equiv\!Si^{\cdot} + n\,CH_2{=}CH \rightarrow \equiv\!Si{-}(-CH_2{-}\underset{CN}{CH}{-})_n{-}\ .$$

According to extraction data, the content of the homopolymer in the overall amount of polyacrylonitrile does not exceed 20%.[67]

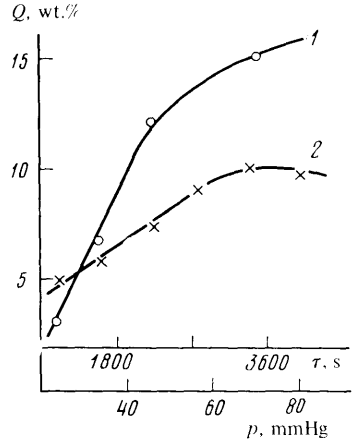

Figure 3. Dependence of the yield Q of the grafted polyacrylonitrile (at a monomer vapour pressure of 80 mmHg) on the time τ (curve *1*) and on the vapour pressure of the monomer p (curve *2*); irradiation for 45 min at 25 °C.[67]

The radical mechanism of the graft polymerisation of acrylonitrile on Aerosil is also indicated by the reaction order with respect to the intensity of the irradiating light (0.5) and by the inhibition of the reaction by oxygen[67,69]. The authors[67,69] investigated certain features of the mechanism of the photochemical vapour-phase graft polymerisation of acrylonitrile on Aerosil with quinone and peroxide coatings. It was established that, in contrast to the gas-phase radiation-chemical graft polymerisation, the yield of the polymer after prolonged ultraviolet light irradiation reaches a maximum value (Fig.3). This finding as well as data obtained in the study of the effect of the acrylonitrile vapour pressure on the rate of polymerisation (Fig.3) and the

observed[69] negative temperature coefficient of the reaction have shown that the rate of graft polymerisation of acrylonitrile on Aerosil is determined by the concentration of the monomer in the sorption layer and not in the vapour phase, i.e. the process proceeds via a sorption mechanism.

It is noteworthy that postpolymerisation is not observed in the system investigated, which shows that the radicals $\equiv SiO^{\cdot}$ are rapidly deactivated under the experimental conditions. The absence of an aftereffect served as a basis for the hypothesis[33] that the initiation of the radiation-chemical graft polymerisation, where postpolymerisation takes place, is due to other radicals, whose nature has not been established. It has been noted[69] that the Aerosil surface has no specific catalytic effect on the polymerisation taking place in the test systems, because the activation energy for the given process is close to the value for the photochemical polymerisation of acrylonitrile in bulk.

Table 2. The influence of the nature of the monomer, the inorganic compound, and the initiator on the yield of the grafted polymer[70].

No.	Filler	s, m^2 per gramme of filler	Initiator	Polymer	Yield of polymer		α, %
					m_1	m_2

Notation: APS = ammonium persulphate; BP = benzoyl peroxide; PAN = polyacrylonitrile; PAA = poly(acrylic acid); PMAA = poly(methacrylic acid); PMMA = poly(methyl methacrylate); PVA = poly(vinyl acetate); m_1 and m_2 = amount of polymer formed and the amount of polymer after extraction (% of weight of substrate); α = fraction of grafted polymer in the overall yield of polymer.

The graft polymerisation of a series of monomers has been achieved[70] under the influence of initiators preadsorbed on the surfaces of mineral fillers (Al_2O_3, TiO_2, $CaCO_3$, and Al). The polymerisation was carried out in a layer of monomer deposited from the liquid phase onto the surface of the filler. It has been observed (Table 2) that the effectiveness of the grafting depends to a large extent on the nature of the substrate, its specific surface, and the nature of the modifying polymer and the polymerisation initiator. When an initiator (benzoyl peroxide) soluble in monomers was used, the effectiveness of grafting was lower in all the experiments. Other conditions being equal, the effectiveness of grafting is higher for polymers insoluble in their own monomers (Table 2, Nos.1, 3, 5, and 10). It is believed[70] that this can be associated with the fact that, in the case of a monomer dissolving its own polymer (methyl methacrylate), the possibility of chain transfer via the monomer is greater. In many instances an extremum has been observed in the relation between the degree of conversion of the monomer and the amount of initiator (Fig.4) due to the fact that the initiator participates in the reaction not only in the initiation stage but also in the chain termination occurring both on the growing macroradicals and on the primary radicals. It has been suggested[70] that the graft polymerisation proceeds in this instance via a mechanism involving chain transfer from the initiator radicals, which has been examined in detail[71].

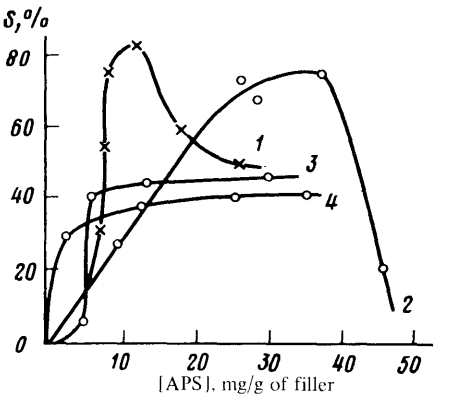

Figure 4. Dependence of the degree of conversion S of the monomer on the concentration of the ammonium persulphate (APS) initiator for the systems TiO_2–PAN (curve *1*), Al_2O_3–PMAA (curve *2*), Al_2O_3–PMAA (curve *3*), and Al_2O_3–PAM[PAN?] (curve *4*) at 60 °C (curves *1*, *2*, and *4*) and 70° (curve *3*) and for reaction times of 2.5 h (curve *1*), 4 h (curve *2*), and 5 h (curves *3* and *4*).[70]

Notation: m_1 and m_2 = amount of polymer formed and amount of polymer after extraction (% of weight of filler); g = amount of Fe^{2+} absorbed by the filler (mequiv.g^{-1}).

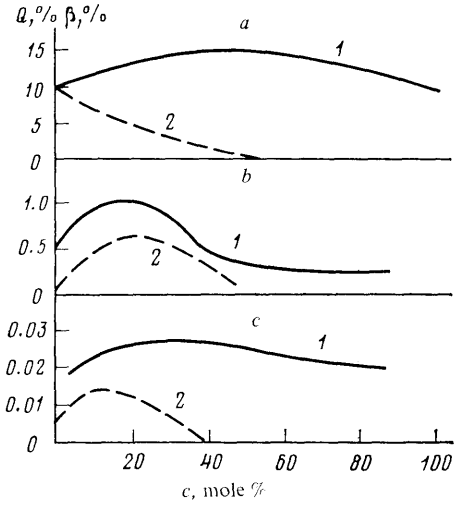
A simple method has been proposed[72–74] for the preparation of grafted polymers on transition metal ion-modified (via an ion-exchange reaction) aluminosilicates and silica gel, which serve as components of oxidation-reduction systems initiating polymerisation in solutions and emulsions. In particular, it has been shown that acrylonitrile vinyl acetate, 4-vinylpyridine and acrylamide polymerise on the surfaces of a

series of $Fe^{2\pm}$ and $Cr^{3\pm}$ containing aluminosilicates in the presence of peroxy-compounds, part of the polymers being grafted to the solid surface (Table 3).

Graft polymerisation on chemically unmodified fillers in the presence of initiators has been described in a communication[75] dealing with a study where grafted copolymers used as pigments were obtained by dispersing a carbonaceous material (soot, coke, or graphite) in an aqueous medium together with the vinyl monomer (vinyl halides, styrene derivatives, unsaturated carboxylic acids, and dienes) in the presence of an oxidation-reduction initiating system.

It has been reported[76] that carbon fibres subjected to an oxidising treatment are capable of undergoing copolymerisation with methyl, ethyl, and n-butyl acrylates initiated by benzoyl peroxides. The rate of graft copolymerisation increases with increase of the degree of oxidation of the surfaces of the fibres and their monomer concentration.

An interesting method of initiating the graft polymerisation of vinyl monomers on the surface of glass has been described[77,78]. Reactive trichlorosilyl and trichloromethyl groups, which initiate the graft polymerisation of vinyl monomers in the presence of $Ni(CO)_6$ and $Mo(CO)_6$ respectively, were introduced onto the surface of glass beads by modifying the surface hydroxy-groups. The grafted polymer chains on the surface of the glass usually form a uniform monomolecular layer.



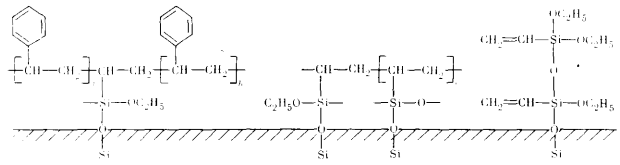


Figure 5. The influence of the composition of the monomer mixture on the yield Q of the grafted polymer (curve *1*) and the content of styrene units β in the grafted polymer (curve *2*): *a*) silica gel; *b*) broken brick; *c*) glass beads[79] (*c* is the content of triethoxyvinylsilane in the monomer mixture).

The polymerisation of binary monomeric triethoxyvinylsilane–styrene and triethoxyvinylsilane–methyl methacrylate systems on silica gel, quartz, glass beads, and brick dust has been investigated[79] with the reaction initiated by benzoyl peroxide or γ-radiation. In order to solve the problem of the sequence in which the copolymerisation and surface grafting reactions occur, a study was made of the influence of the composition of the monomer mixture on the yield of the grafted polymer, the content of the styrene and methyl methacrylate units in the grafted polymer, and the composition of the polymer. It was established (Fig.5), that, whereas the total amount of the grafted polymer does not depend greatly on the composition of the monomer mixture, the content of styrene and methyl methacrylate units in it is a maximum only in the mixture enriched in the corresponding monomer. The content of triethoxyvinylsilane in the grafted polymer is in all cases higher than in the monomer mixture.

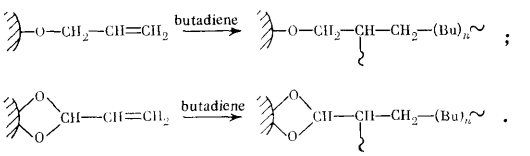
On the grounds that the copolymerisation constants calculated from these data, namely r_1 (styrene) = 0.06 and r_2 (triethoxyvinylsilane) = 4.2, differ significantly from the literature values r_1 = 26 and r_2 = 0 (the corresponding values for methyl methacrylate are respectively r_1 = 37 and r_2 = 0), a conclusion has been reached[79] concerning the mechanism of the formation of the grafted copolymers. In the first place triethoxyvinylsilane condenses with the surface silanol groups and part of the triethoxyvinylsilane can polymerise with the partial opening of the double bond and another part gives rise to grafted polyethoxyvinylsilane as a result of the polycondensation of the ethoxy-groups. Next, some of the grafted triethoxyvinylsilane molecules undergo vinyl copolymerisation with the monomer under the influence of benzoyl peroxide or γ-radiation. It is of interest that the authors[79] were unable to separate the grafted polymer from the filler by dissolving the latter in hydrofluoric acid. They believe that this is due to the fact that the grafted copolymer closely shields the surface of the filler and hinders the access of HF to the latter.

Methacryloylmethyltriethoxyvinylsilane mixed with a monomeric dye has been polymerised[80] after impregnating fibres with the mixture (to achieve a more stable colour and more hydrophobic properties of the fibres. Conditions ensuring the quantitative grafting of the polymer have been determined. However, the quoted yield of the grafted polymer is apparently too high; this can be postulated bearing in mind the extremely low solubility of copolymers containing methacryloylmethyltriethoxysilane units[81] and their branching as a result of chain transfer to the methyl group of methacryloylmethyltriethoxysilane[82] and hence the difficulty of the separation of the grafted and ungrafted copolymers by the extraction method.

When 2,3-epoxypropyl methacrylate is polymerised on contact with a large area of a glass surface[83], the epoxy-groups are cleaved quantitatively, which leads to the formation of at least three different products. One of these, 2,3-dihydroxypropyl methacrylate, forms a polymer chemically bound to the glass in the course of the polymerisation process.

The possibility of obtaining graft polymers in polymerisation in the presence of inorganic fillers with the process initiated by free-radical initiators containing functional groups (carboxy-groups, etc.) has been described[84,85]. It is suggested that the functional groups of the initiator ensure the grafting of the polymer to the surface of the filler in the reaction with the surface silanol groups.

Organic peroxides have been used as initiators of this kind: t-butylperoxymaleic acid, peroxysuccinic acid, and their salts as well as a series of common organic and

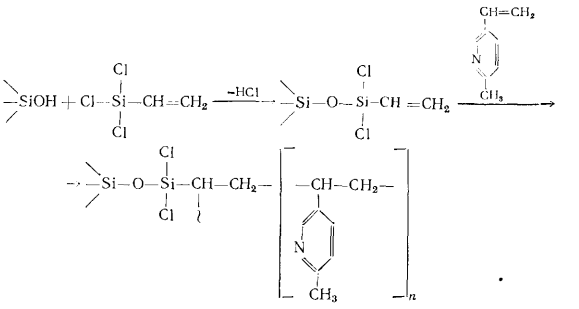


inorganic peroxides in combination with a reductant containing a carboxy-group, in the free state and in the form of the salt (malonic, oxalic, L-ascorbic, thioglycolic, and other acids and their salts). In order to obtain the maximum yield of the grafted polymer, the peroxide was added in an amount corresponding to 0.1–2.0 parts by weight to 100 parts by weight of the dispersion in water, ketones, ethers, and alcohols, while the reductant was added in an amount corresponding to 0.2–2.0 parts by weight for one part by weight of the peroxide. A wide variety of inorganic and organic solids in the form of a powder, fibre, film, sheets, etc. have been used as supports: metals and their oxides, sulphur, nitrogen, carbon, silicon, boron and chlorine compounds, the salts of various acids, hydroxides, and inorganic pigments.

It has been noted[84,85] that coating of the support with a mixture of grafted and ungrafted polymer in an amount corresponding to 3–50 parts per weight, about half of which corresponds to the polymer bound chemically to the filler, is in most cases the optimum procedure from the standpoint of the uniform coverage of the filler particles by the polymer and a satisfactory capacity of the product for being worked by pressing, extrusion, and casting under pressure. The specimens have a high bending strength. Thus a specimen made up of compressed filings coated with the product of the polymerisation of a mixture of ethyl acrylate, methyl methacrylate, and *N*-(hydroxymethyl)acrylamide in an aqueous suspension in the presence of benzoyl peroxide and oxalic acid had a bending strength of 840 kg cm^{-2}.

A procedure[85] for a uniform stable encapsulation of the filler in a polymer jacket which is bound chemically to it is noteworthy; the reaction is performed in a liquid medium containing the filler, the vinyl monomer, and the polymerisation initiator under conditions such that at least one reactant, giving rise to radicals, contains in its molecule a substituted or unsubstituted amino-group. Such a reactant can be both the monomer (mainly amino-derivatives of acrylates and methyl and ethyl methacrylates or monomers with nitrogen-containing heterocycles) and the initiator, for example the salt 2,2-azobis(2-amidinopropane) hydrochloride, as well as the peroxide–amine redox system usually employed as the radical polymerisation initiator. In most cases a high yield of the grafted polymer has been noted (80–90%). The composition produced has a high ultimate bending strength. Thus the ultimate bending strength of the specimen obtained by pressing grass charcoal coated with poly(methyl methacrylate) in an amount of 0.09 g per gram of filler was 383 kg cm^{-2}.

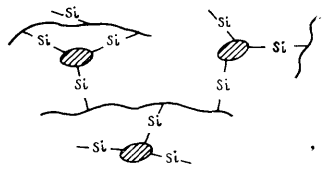
Publications concerning the polymerisation of monomers on the surfaces of fillers with grafted groups capable of polymerisation have appeared only recently. A method of binding the polymer to a silicon-containing support has been described[86]. The silicon-containing material in the form of individual particles is treated initially with an inorganic acid to increase the content of OH groups on its surface and then with an unsaturated silane (alkenyltrialkoxysilane or alkenyltrichlorosilane), after which the product is copolymerised with an unsaturated monomer having the general formula RCH = CHR', where R and R' = H, C_1–C_{10} alkyl or alkenyl, phenyl, amide group, or trichlorosilyl. These products are subjected to an additional treatment in order to introduce ion-exchange or chelate groups and are used to fill chromatographic columns.



It has been shown[87,88] that unsaturated ethers and acetals, formed on interaction of the silanol groups of silica gel with allyl alcohol or acrolein respectively, copolymerise with butadiene in the presence of benzoyl peroxide:

The degree of conversion of butadiene is between 10 and 100%. An increased initial rate of polymerisation was noted when silica gel with unsaturated surface acetal groups was used. It is suggested that this finding is associated with the formation of additional radical centres owing to the thermal abstraction of hydrogen atoms from the allylic carbon atoms of the acetal group. The same workers[89] modified a silica filler with acrylonitrile and *N*-vinylpyridine. The use of such modified silica for copolymerisation with butadiene leads to an increase of the moduli of rupture and the resistance of the compositions to rupture.

The polymerisation of various monomers of the vinyl series, adsorbed from the gas phase on the surface of silica gel containing vinyl groups, has been investigated[90]. The reaction was initiated by adsorbed azobisisobutyronitrile at 60 °C. Up to 40 wt.% of the polymer bound chemically to silica gel is formed together with the homopolymer. It was found that the reaction order with respect to the initiator is 0.47, while that with respect to the monomer varies from 1 to 2.3. The reaction is of first order with respect to the monomer in polymolecular adsorption of the monomer, while higher reaction orders are obtained for degrees of adsorption corresponding to less than the monolayer coverage. The experimental data can be accounted for in terms of a kinetic reaction mechanism including as one of the elementary stages the grafting of the polymer to the surface by chain transfer and chain termination reactions on the free sections of silica gel with participation of both vinyl and silanol groups. The authors[90] believe that, as a consequence of the low concentration of the monomer in the gas phase and also the short lifetime of the surface radicals, the grafting of the polymer to the filler via the direct reaction of the monomer with the macromolecules growing on the surface is unlikely. The authors believe that the involvement in the copolymerisation of the vinyl groups grafted to the surface is insignificant by virtue of their low concentration on the surface and reduced reactivity caused by the resonance stabilisation due to the silicon atom.

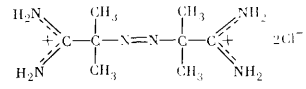


New mineral absorbents have been obtained[91] by the chemical grafting of certain monomers (vinylpyridines and *N*-vinylpyrrolidinone). For this purpose, a study was made of the graft copolymerisation of 2-methyl-5-vinylpyridine on vinyl-silica gel (silica gel with vinyl groups deposited on its surface by treatment with trichlorovinylsilane):

The process was carried out in the temperature range 70–80 °C and the initiator (diniz) and monomer concentrations were varied from 0.015 to 0.045 *N* and from 0.3 to 1.5 *N*

respectively. It was established that the yield of the grafted polymer increases with temperature, the initiator and monomer concentrations, and the amount of trichlorovinylsilane taken for surface treatment, but does not exceed ~12%. The kinetic features of the copolymerisation of monomers with a vinyl-substituted surface were discovered for the first time in systems of this kind. The reaction rate constants at 60°, 70°, and 80 °C are respectively 0.034, 0.128, and 0.376 litre$^{1/2}$ mol$^{-1/2}$ h^{-1}; the process activation energy is 25.9 kcal mol^{-1}. With the aid of computer search programmes, the authors[91] showed that the kinetics of the copolymerisation process can be described with the aid of the equation for ideal radical polymerisation.

Clay has been used in polymerisation filling[92]. After its treatment with (γ-methacryloyloxypropyl)trimethoxysilane followed by copolymerisation with styrene at 80 °C in the presence of azobisisobutyronitrile, the yield of the grafted polymer was 4.1–8.4% of the weight of the composition. The polymer consists of a gel which swells in benzene. Since the analogous copolymer obtained without a filler is soluble in benzene, it has been suggested that cross-linking via the following scheme takes place in the course of the graft copolymerisation:



It has been noted that the analogous finished copolymer reacts less effectively with clay and does not form a gel, which has been explained by the reduced reactivity of the methoxysilane groups in the copolymer. These results agree with the features noted[79] in the copolymerisation of a binary monomer mixture in the presence of a filler where the active monomer is first attached to the surface and then the surface copolymerised with the second monomer.

The use of methacryloyloxymethyltriethoxysilane for the modification of Aerosil[93] makes it possible to obtain polymer compositions in which a considerable proportion (up to 23%) of poly(butyl methacrylate) is bound chemically to the surface of the filler. This results in a significant increase (by a factor greater than 4) of the tensile strength of the film based on the composition obtained relative to the composition based on unmodified Aerosil. It was established that the influence of the filler surface on the polymerisation kinetics is observed only when there is a possibility of the physical or chemical interaction of the monomer with the solid surface. The presence of the free comonomer of methacryloyloxymethyltriethoxysilane comonomer in an amount equal to that introduced together with the modified Aerosil did not affect the rate of the process.

The physicochemical and thermomechanical properties of certain polymerisation-filled systems have been investigated[94]. It has been noted that, as a result of the cross-linking of the poly(methyl methacrylate) macromolecules in the polymerisation of the monomer on allyl-substituted silica, the polymer becomes more rigid, which is reflected in its thermomechanical properties. The glass point of such a filled polymer is higher than that of the pure polymer by 12° and 19° respectively in the presence of 2.5 and 5 wt.% of allylsilica.

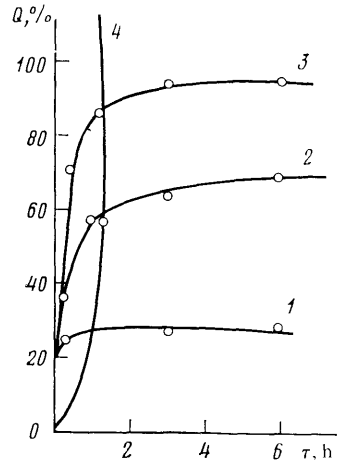
One of the new trends in the chemical modification of fillers is activation of the filler surface by initiating systems with subsequent polymerisation of the monomers on such a filler, serving as a carrier of active centres, and the formation of a chemically bound polymer. In this connection one should note studies[95,96] on the attachment of 2,2-azobisisobutyramidine hydrochloride to the surface of the filler (kaolin and bentonite) via an ion-exchange reaction and the initiation of the emulsion polymerisation of vinyl monomers by such systems.

(I)

According to Dekking's results[95], the attachment of the initiator to the surface entails an increase of the rate constant for its decomposition; the values of $10^4 k_{decomp}$ (s^{-1}) for compound (I) in a free form and attached to the filler surface are given below:

t, °C	(I)	(I)-kaolin	(I)-bentonite
60	0.358	0.666	—
70	1.41	2.17	3.33
80	5.01	9.91	10.13

The enthalpy and entropy of activation for the decomposition of the immobilised initiator have been determined (32.048 kcal mol^{-1} and +18.16 e.u. for kaolin and 30.227 kcal mol^{-1} and +13.20 e.u. for bentonite), their values being almost independent of the immobilisation of the initiator on the surface.



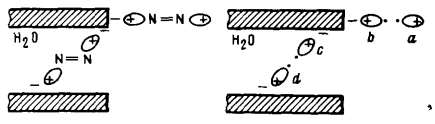


Figure 6. The yield of polymers Q in the emulsion polymerisation of methyl methacrylate initiated by the initiator–bentonite system (curves *1*–*3*) and by the initiator (curve *4*): *1*) grafted polymer; *2*) homopolymer; *3*) and *4*) overall yield of polymers[95].

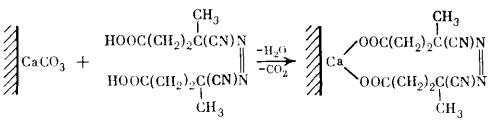
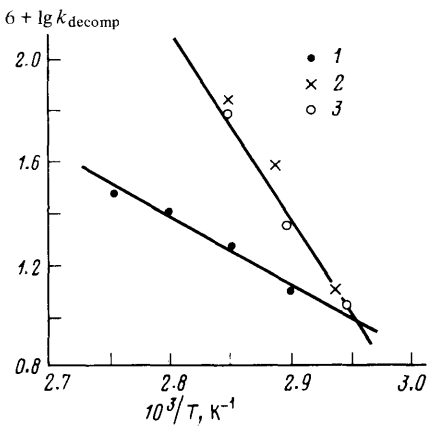


On immobilisation, the molecules of the initiator can behave in an ion-exchange reaction as monofunctional compounds, when they are located on the outer surface of the filler plates, and as bifunctional compounds when they are located between the plates and form monolayers of dications:

Determination of the ion-exchange capacity showed that in the case of bentonite ~80% of the initiator molecules are present on the surface in the form of dications and ~20% in the form of monocations. Radicals of types *b*, *c*, and *d* lead to the formation of polymers grafted to the filler, while radicals of type *a* lead to the homopolymer.

It was observed that the rate of formation of the homopolymer in the emulsion polymerisation of methyl methacrylate is approximatley twice as high as that of the grafted polymer (Fig.6), which can be explained by the difficulty with which the monomer approaches radicals of types *c* and *d*. The rate of formation of the homopolymer by a radical of type *a* is then six times higher than the rate of homopolymerisation of methyl methacrylate under analogous conditions but in the absence of the filler; the author[96] finds it difficult to account for this finding.

The influence of the grafting of the initiator to the particles of the solid filler on the rate of its thermal decomposition and its initiating activity in the polymerisation of vinyl monomers has been examined in a recently published communication[97]. The initiator was 4-azobis-4-cyanopentanoic acid (ACA) and the filler was calcium carbonate (chalk), their interaction resulting in the chemical grafting of the initiator to the surface of the chalk particles:



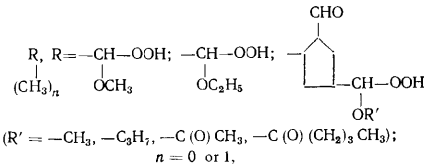


Figure 7. Temperature dependence of k_{decomp} for grafted ACA (curve *1*), ACA (curve *2*), and the calcium salt of ACA (curve *3*).[97]

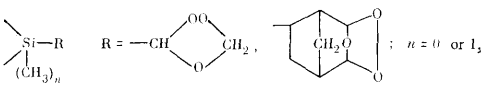
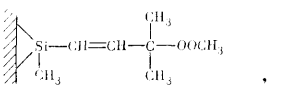


It has been established that the kinetic parameters of the thermal decomposition of the initiator change significantly in the chemical grafting of initiators to the surfaces of fillers. Thus the grafting of ACA to the solid phase lowers $k^{80°}_{decomp}$ (from 6.8×10^{-5} to 2.1×10^{-5} s^{-1}) and E^{a}_{decomp} (from 123.9 to 53.1 kJ mol^{-1}) (Fig.7). A sharp decrease of the rate of polymerisation of methyl methacrylate has been noted in the case where the initiator was grafted to the surface of the solid phase. The authors[97] explained these effects by the limited diffusional mobility of the radicals linked to the solid phase, which leads to the rapid recombination of the primary radicals, and also by topochemical factors due to the localisation of the initiation, propagation, and termination reactions at the surface of the particles. It has been shown that 3% conversion of methyl methacrylate into the polymer is sufficient to cover the entire surface of the chalk with a polymer "coating".

A simple method has been proposed recently[98] for the preparation of peroxidised mineral fillers, containing peroxy-groups with the general formula

which are capable of initiating polymerisation.



The method consists in the ozonisation of the mineral filler containing the grafted vinylmethylvinyl or norbornenylsilyl groups at temperatures between −20° and +20 °C in alcohol or in organic acid. When the ozonisation process is carried out in a hydrocarbon or its halogeno-derivative[99] at temperatures between −40° and +20 °C, peroxidised fillers with grafted ozonide peroxy-groups having the general formula

are obtained.

It has been shown[100] that the compounds produced when the temperature is raised may serve as a source of radicals bound to the filler, incapable of initiating the polymerisation of vinyl monomers, and giving rise to grafted polymers.

The same workers[101] investigated the characteristics of the polymerisation of styrene on the Aerosil A-175 filler with grafted dialkylperoxy-groups having the structure

The method of preparation of such fillers has been described[102].

An increased order of the reaction with respect to the monomer (1.68) was observed. The order of the reaction with respect to the initiator depends on the surface concentration of the latter and varies from 0.48 to 0.65 with increase of the density of the peroxy-groups on the surface of Aerosil (the concentration of active oxygen in the filler varies from 0.35 to 0.75 wt.%). The polystyrene formed consists of a polymer both grafted to the surface of Aerosil and the ungrafted homopolymer extractable with hot benzene. It has been established that the fraction of the polymer grafted to the surface of the filler depends on the polymerisation conditions and increases with increase of the temperature of the reaction, its duration, and the concentration of the peroxy-groups on the surface of Aerosil (Table 4 and Fig.8). When the monomer concentration is raised from 1.14 to 6.90 M, the yield of the grafted polymer increases from 0.38 to 2.75 g per gramme of Aerosil. The ratio of the amount of grafted polymer to that of the homopolymer increases with increasing surface concentration of peroxy-groups (Table 4) and the degree of conversation (Fig.8). It has been shown that k_{decomp} and E^{a}_{decomp} for the peroxide are independent of its concentration on the surface.

III. CHARACTERISTICS OF POLYMERISATION INITIATED FROM THE SURFACE OF A SOLID PHASE

The above analysis of the comparatively few studies on polymerisation filling, which have not always been combined in a single approach, indicates an endeavour to develop a method of preparation of composite materials which would permit the polymerisation of monomers (in bulk, in solution, or in an emulsion) in the presence of fillers with subsequent isolation of the finished composition using the familiar methods for the extraction of polymers from the reaction medium.

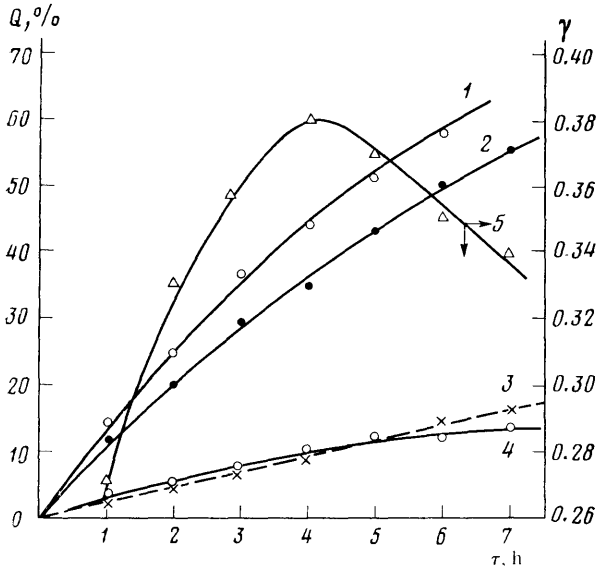


Figure 8. Dependence of the yield Q of polystyrene on the polymerisation time: *1*) overall product; *2*) homopolymer with allowance for the thermopolymer; *3*) thermopolymer; *4*) grafted polymer; *5*) ratio of the amounts of the grafted polymer and homopolymer γ (in the absence of thermopolymer); [M] = 2.02 M; [I] = 8.8×10^{-3} M; concentration of active oxygen on the filler surface 0.62 wt.%; 120 °C.[101]

The bond between the polymer and the surface of the filler arises directly during polymerisation and is due either to the effect of physical factors on the surface of the filler (γ- or ultraviolet irradiation, comminution and cleavage, or an increased temperature), inducing the formation of radicals which initiate the grafting of the polymer formed, or the copolymerisation of the vinyl monomers with monomers containing functional groups capable of chemical interaction with the surface functional groups of the filler (in the course of the copolymerisation or after its completion). Finally, there is a possibility of a third variant, where the polymerisation filling is achieved using fillers subjected to a preliminary modification by the grafting to the surfaces of polyfunctional monomers capable of copolymerisation or polyfunctional initiators capable of forming free radicals under the conditions of the polymerisation reaction.

There is no doubt that each method is distinguished by its specific features both from the standpoint of kinetic deviations from ideal radical polymerisation and from the standpoint of optimum yields of the grafted polymer, its characteristics, and the possibilities for the practical application of the methods. Unfortunately the amount of data concerning the amount of polymeric products bound to the surfaces of fillers and also information about the relative amounts of the grafted polymer and the homopolymer, the molecular weight characteristics of the polymers, and the properties of the compositions obtained are frequently insufficient for the analysis of the advantages of a particular method of polymerisation filling described in the literature quoted. Furthermore, in many instances there is no complete certainty that the solvent has been chosen correctly for the elimination of the homopolymer adsorbed on the surface. In this respect mention should be made of a study[52] where it was shown in relation to poly(vinyl acetate) that the probability of the dissolution of the polymer chain on the surface depends not only on the "quality" of the solvent in relation to the given polymer but also on the energy of the interaction of the solvent with the adsorption centres on the surface. In other words a "good" solvent in relation to the given polymer may prove to be a "poor" displacing agent and the polymer will not dissolve in it, which leads to unduly high results in the determination of the yield of the grafted polymer.

Table 4. Dependence of the rate of polymerisation of styrene ν and the yield of graft polymer Q on the conditions in the reaction initiated by a dialkyl peroxide grafted to the surface of Aerosil {chlorobenzene, [M] = 2.02 M [101]}.

Notation: c_{O_2} = content of active oxygen in Aerosil with grafted peroxy-groups; [I] = initiator concentration.

*In ethylbenzene.

Nevertheless, it is seen from the data presented that many characteristics of the graft polymerisation initiated by γ-irradiation (effective polymerisation only in a thin adsorption layer, influence of adsorption-desorption

processes on the formation of the graft polymer, and complexity of apparatus) are responsible for the limited applications of the given method. Mechanochemical initiation of graft polymerisation, which is frequently simple from the technological standpoint, does not ensure the attainment of the maximum possible coverages of the surface of the filler by the polymer layer, because the polymer is not grafted in a continuous coating but in the form of isolated spherical drops[103]. Photochemical initiation eliminates the disadvantages of other methods of polymerisation filling such as the formation of appreciable amounts of homopolymers and the degradation of the grafted layer. However, this method is not free from disadvantages characteristic of the method of initiation of graft polymerisation by γ-irradiation.

The method of the oxidation-reduction initiation of graft polymerisation is superior to the other procedures by virtue of its simplicity. Since many inorganic substances have ion-exchange properties and can be modified by transition metal ions, this method is fairly promising. The method of synthesising a surface-grafted polymer by the copolymerisation of monomers with a surface containing unsaturated bonds is one of the simple and effective methods of obtaining polymerisation-filled polymers.

The procedure based on the simultaneous polymerisation and grafting via the functional groups of the monomer is promising; this method eliminates the stage involving the preliminary treatment of the filler although it does not ensure the regulation of the density of the growth centres for macromolecules on the surface and is associated with an excess consumption of the active monomer and the formation of the copolymer not linked to the surface. The method based on the initiation of the reaction by agents capable of reacting with the surface via the functional groups of the initiator in the course of polymerisation is not free from these disadvantages either.

The method of polymerisation filling of polymers by filler-initiators is one of the interesting and new procedures for the preparation of composite materials, because it makes it possible to regulate fairly flexibly the process kinetics and the properties of the monomer layer bound to the filler particle by varying the density of the peroxy-groups on the surface and the polymerisation conditions; the stage in which a measured amount of the initiator is introduced is then significantly facilitated. The methods of synthesis of such fillers which have been described are suitable for technological application and the initiators themselves are universal for the polymerisation of many vinyl monomers. The realisation of the advantages of a particular method should apparently depend on the particular problems.

Whatever the nature of different methods of graft polymerisation may seem to be at first sight, in most studies a deviation of the kinetics from the ideal picture for radical polymerisation has been noted[79,90,95-97,101,104-106]. The presence of the filler in the reaction zone exerts a great influence on all the stages of the radical polymerisation regardless of the modification of its surface. In the first place the surface of the filler can influence the rate of decomposition of the peroxide initiator. Thus the acceleration of the decomposition of cumenyl hydroperoxide adsorbed on the surface of refractory titanium compounds (titanium carbide, nitride, carbonitride, and oxycarbonitride as well as the oxides TiO_2 and TiO) has been noted[108]. The decomposition of benzoyl peroxide and azobisisobutyronitrile is influenced only by TiC and TiO_2 respectively. The acceleration of the decomposition of benzoyl peroxide and cyclohexyl peroxydicarbonate has been attributed to the basic nature of the asbestos zeolite[109]. On the other hand Aerosil which has acid properties, does not affect the rate of decomposition of azobisisobutyronitrile[107].

Chemical grafting of peroxy-compounds on the surface of the filler or their fixation in the surface zone leads to a decrease of the mobility of the peroxide molecules and the radicals arising from them and to the formation (in the case of polyfunctional initiators) of strained and less stable cyclic structures. This can result in a significant decrease of E_d for the decomposition reaction[97] and an increase of the rate of decomposition of initiators[95,96].

The fixation of the initiator on the surface hinders the diffusional separation of the radical pair, increasing the probability of the "cage" effect, which is responsible for the decrease of the initiation efficiency, as noted in some investigations[97,108]. For example, when the molecules of 4-azobis-4-cyanopentanoic acid are attached via both ends to the surface of chalk, there is virtually no diffusional separation of the radical pair and the initiation efficiency is low[97].

The localisation of the initiator at the solid surface–liquid interface narrows the initiation reaction zone, increasing simultaneously the concentration of peroxy-groups in this zone. The probability of the recombination of the primary radicals in the surface layer and of the involvement of such radicals in the termination of the growing chains is therefore increased.

Account must be taken of the fact that the efficiency of the initiation of graft polymerisation depends on the concentration of the monomer in the initiation zone, i.e. near the surface. An increase of the monomer concentration in this zone increases the probability of the conversion of primary radicals into growing radicals. The specific features of the surface zone, namely the small difference between the concentrations of the monomer and initiator in this zone, necessitate allowance for the consumption of the monomer in the surface zone during the initiation reaction[110]. This may be the cause of the increase of the reaction order with respect to the monomer noted in a number of instances[101].

Apart from the diffusion-dependent limitations associated with the escape of the radicals from the surface, there can also be difficulties in the transport of monomer molecules to the active centres on the surface. The role of diffusional control increases as the grafted polymer accumulates on the filler surface whereupon the reaction centres are partly shielded by the macromolecules formed. The access of monomer molecules to the polymer phase bound to the surface, formed in the process, becomes hindered and this can then lower the rate of graft polymerisation with increasing degree of conversion[97,101,111]. At the same time, the escape from the surface zone of primary radicals which are not bound to the surface and which are capable of initiating homogeneous polymerisation, occurring simultaneously with the graft polymerisation, is less hindered. The rate of homopolymerisation can therefore be as a rule higher than the rate of graft polymerisation[95,96,101,111]. It is to be expected that the difference between the rates of graft polymerisation and homopolymerisation will be more appreciable when a "poor" solvent is used, in which the transport of the monomer molecules and radicals through the polymer layers grafted to the filler surface is difficult.

Under the conditions of both chemical and adsorption interaction of the monomer with the active surface at low degrees of polymerisation, mesomeric and inductive effects[112-116] as well as orientation effects[93,117] can make a large contribution to the reactivity of the growing radicals. In most cases the changes in the reaction rate constants are in fact accounted for by such factors.

The specific features of radical polymerisation initiated from the surface of the solid phase may consist not only in the diffusional control of the initiation and propagation reactions but also in an increase of the role of the diffusional

control of the chain termination reaction. The restriction of the mobility of macroradicals on their fixation to the surface leads to a sharp fall of the constant k_0.[55] It is therefore of interest to draw an analogy with studies[118,119] devoted to the gel effect in the polymerisation of many monomers. The authors of these investigations attribute the onset of self-acceleration to structure formation in the reaction systems. The polymerisation systems which we have examined and which contain initially an active solid phase constitute even in the first stages of the process a structural network which hinders termination. At the same time the direct involvement of fillers in the chain termination reaction has been stated in a number of investigations[48,69,90,120].

The deviations of the heterogeneous process considered from ideal radical polymerisation, noted in the above studies, indicates the failure of the assumptions of the stationary or quasi-stationary nature of the processes initiated from the surface of the solid phase. It is important to note that polymerisation on the surface frequently entails specific changes in the structure of the polymer chain formed, which affects the properties of the product. A study[121] where it was shown that the radiation-induced polymerisation of acrylonitrile and methacrylonitrile, pre-adsorbed in the form of monomolecular layers on sodium and calcium montmorillonites, leads to the formation of grafted polymers with a cyclic structure is striking in this respect[121]. Such cyclisation proved to be possible as a result of the favourable orientation of neighbouring macromolecules.

A number of studies[122,123] have shown that the method of graft copolymerisation in a mixture of the vapours of monomeric compounds, containing at least one component which is adsorbed selectively on specific functional groups of the support, can be used for the matrix synthesis of copolymer chains with a regular distribution of monomer units specified by the support. The possibility of additional chemical transformations of the monomers under the influence of the surface on which they are fixed has been noted[124]: when polyacrylonitrile grafted to Aerosil was heated *in vacuo* at 200 °C, the amine structure isomerised to the enamine structure as a result of the interaction of the nitrile groups of the polymer and the surface silanol groups with formation of additional polymer–filler chemical bonds.

* *
*

The data presented in this review on the physicomechanical, rheological, and other properties of the compositions obtained by the method of polymerisation filling confirm yet again the fact that the formation of a chemical bond between the polymer and the filler tends to improve significantly the properties of the filled compositions as a whole[80,84,85,89,92,93,125–127].

Thus the results of the studies examined in this review demonstrate the likely usefulness of polymerisation filling by radical polymerisation as a method of preparation of filled compositions, the fairly wide variety of the methods investigated, and also the specificity of the reactions involved, whose mechanism has not been ultimately elucidated in a number of instances. The continuation of such studies would therefore be of great interest not only from the standpoint of the optimisation of the filling methods but also as a significant contribution to the study of reactions occurring on solid surfaces. Furthermore, a more detailed investigation of the technological properties of the compositions obtained and their comparison with the properties of polymers filled by the usual methods are necessary.

Dielectric Methods of Studying the Chemical Bond and the Concept of Electronegativity

S.S.Batsanov

The history and contemporary theories of the polarisation of molecules and crystals are considered and a systematic survey is given of dipole moments and bond ionicities in molecular chemical compounds and also of the effective charges of atoms in crystals. An interpretation of these results is given from the standpoint of the electronegativity concept. Views concerning the effective valencies and coordination numbers of atoms in crystals are considered. Bibliography of 207 references

I. INTRODUCTION

Polarisation, that is, the separation of charges in an electric field, was the first physical characteristic of molecules which allowed the nature of the chemical bond to be determined quantitatively, and in particular, its degree of ionicity (sometimes termed polarity, from the name of the determining parameter). It is extremely significant that the information which can be extracted from polarisation measurements is unique and constitutes the main component of such structural-chemical characteristics of bonds as dipole moments, effective charges, and valencies of the atoms.

II. POLARISATION AND THE DIPLE MOMENTS OF MOLECULES

In general, molecular polarisation can be represented as:

$$P_m = \frac{M}{\rho}\frac{\varepsilon-1}{\varepsilon+2} = \frac{4}{3}\pi N\left(\alpha + \frac{\mu^2}{3kT}\right), \qquad (1)$$

where P_m is the molecular polarisation, M the molecular mass, ρ the density of the substance, ε the dielectric permittivity, N the Avogadro number, α the polarisability of the molecule, and μ the dipole moment. Clearly, when $\mu = 0$, P_m will be independent of temperature.

A method for the experimental determination of μ follows from Eqn.(1): by measuring P_m at various T the polarisability and dipole moment can be found separately. Information about dipole moments is of independent interest and there is a considerable literature on this subject, which we will not deal with. Table 1 gives the dipole moments of the molecules of the alkali metal, silver, thallium, carbon, and phosphorus halides and also the tin and lead chalcogenides, from Lovas and Tiemann[1].

Since by definition

$$\mu = e^* r , \qquad (2)$$

where e^* is the effective charge on an atom and r the length of a chemical bond, clearly the ratio μ/r should characterise the polarity of the chemical bond (p). In addition to μ, Table 1 gives the ratio $p = \mu/4.8r$.

The second term on the right-hand side of Eqn.(1) corresponds to the orientation part of the total polarisation and is usually denoted by P_0. When a molecule is inserted into an electric field, not only its orientation, but also its deformation—extension of polar atoms in the field direction—take place. This part of the polarisation is termed atomic polarisation, P_a. The deformation of the electronic cloud of the molecule is denoted by P_e. Consequently, the total polarisation consists of P_0, P_a, and P_e. In solids, where $P_0 \cong 0$, we obtain $P_m = P_a + P_e$. Obviously, for non-polar substances $P_a = 0$ and $P_m = P_e$. Hence a comparison of the experimental values of P_a and P_e or of P_m and P_e can give qualitative information about the bond polarity.

Table 1. Dipole moments and bond polarities.

Li	6.33	0.84	7.13	0.73	7.27	0.70	7.43	0.65
Na	8.155	0.88	9.00	0.79	9.12	0.79	9.24	0.71
K	8.59	0.82	10.27	0.80	10.63	0.78	10.82	0.74
Rb	8.55	0.78	10.51	0.78	10.86	0.77	11.48	0.75
Cs	7.88	0.70	10.39	0.74	10.82	0.73	11.69	0.73
Ag	6.22	0.65	5.70	0.52	—	—	—	—
Tl	4.23	0.42	4.54	0.38	4.49	0.36	4.61	0.34
C	1.41	0.22	1.46	0.17	1.38	0.13	1.19	0.12
P	0.77	0.10	0.81	0.08	0.36	0.03	0	0
	O		S		Se		Te	
Sn	4.32	0.49	3.18	0.30	2.82	0.25	2.19	0.18
Pb	4.64	0.50	3.59	0.33	3.28	0.28	2.73	0.22

Despite the qualitative validity of such comparisons the precise relation between the polarisation and the electronic structure of a substance has been found only within the framework of a spectroscopic approach[2,3], which has established a connection between the polarisability of the vibrations of the atom which are taking place and its effective charge (e^*). Some investigators[4-6] used this approach to determine the charges on the atoms in halides of Group IV elements.

Another direction of the work to find bond polarities by a spectroscopic method is based on the measurement of the intensities of infrared absorption bands of molecules to determine e^* as a function of the derivative of the dipole moment with respect to bond length. The history of the problem and the results of the determination of effective charges in Group IV element hydrides have already been given[7].

Hence the spectroscopic values of the atomic charges are also approximate owing to the neglect of a series of factors, namely, anharmonicity and the changes in the orbital overlaps during vibrations, but where molecules are concerned—and consequently the inductive influence of substituents—mainly due to the complexity of the "dipole moment" concept itself.

Without dwelling on the history of the development of theoretical opinions on the nature of dipole moment, we will refer only to Brumer and Karplus's work[8], in which a quantum-mechanical basis was given for the well-known Rittner formula, according to which

$$\mu \simeq er\left(1 - \frac{\alpha_A + \alpha_B}{r^3} + \frac{4\alpha_A\alpha_B}{r^6}\right), \qquad (3)$$

where α_A and α_B are the polarisabilities of ions A and B.

The last theoretical investigation of the dipole moments of ionic molecules is that of Matcha and King[9], who took into account not only effective charges and the polarisability of atoms, but also the moments of the orbital overlaps and the repulsion of the electron clouds. The experimental values of e^* determined in that work[9] are given in Table 2; extrapolated values of the charges on the atoms are also given there (in parentheses).

Table 2. Charges of the atoms in alkali halide molecules.

A	B			
	F	Cl	Br	I
Li	0.87	0.82	(0.79)	(0.76)
Na	0.89	0.86	0.84	0.81
K	0.93	0.91	(0.89)	(0.86)
Rb	0.94	0.92	(0.90)	(0.87)
Cs	0.99	0.96	(0.94)	(0.91)

The relation between the bond polarity (p.1202) and e^* [9] is expressed by the formula:

$$e^* \simeq p\left(1 - \frac{\alpha_A + \alpha_B}{r^3}\right)^{-1}. \qquad (4)$$

Hence it is clear that the reduced value of p in CsF in comparison with other alkali metal fluorides (cf. Table 1) is due to the greater polarisability of the caesium ion.

As for the dipole moments of covalent bonds, Mulliken[10] found by LCAO MO theory that the dipole moment consists of three terms: the ionic moment, $\pm e^* r$; a covalent term, $\mp 4eabs$ where a and b are the weighting factors of the atomic wave functions, and S is the overlap integral; and the moment of the isolated electron pair, $\pm\mu_S$.

The next broad step on the theory of dipole moments was taken by Coulson[11], who, by analysing the charge distribution in the C–H bond by the MO method, concluded that for hybrid orbitals in addition to the three Mulliken terms allowance must be made for the hybridisation moment.

Hence bond ionicities can only be calculated from measured dipole moments if the remaining components of the bond moment are determined empirically or theoretically. Therefore subsequently in addition to the accumulation of new experimental results the main attention was directed at these particular problems[12–18].

III. BOND IONICITY AND ELECTRONEGATIVITY OF ATOMS IN MOLECULES

Since in general the charges on atoms cannot be determined in the simplest manner—by Eqn.(2)—Pauling proposed that the variation of bond ionicity† with the electrochemical properties of its component atoms be found and then the charges determined directly from these characteristics of the atoms.

The concept Pauling used as such a property was the electronegativity of an atom, that is, its ability to attract valence electrons. The history of this[19–22] will not be discussed here other than to point out that electronegativity can be determined:

(1) from thermodynamic data by the equation:

$$X_A - X_B = E(A-B) - \frac{1}{2}[E(A-A) + E(B-B)], \qquad (5)$$

where X_A and X_B are the electronegativities of the atoms A and B, and E(A–A), E(A–B), E(B–B) are the A–A, A–B, and B–B bond energies.

(2) from ionisation potentials and electron affinities:

$$X = \frac{1}{2}(I + A), \qquad (6)$$

where I is the first ionisation potential and A the affinity for one electron of the atom in the valence state;

(3) from the covalent radii (r) and effective nuclear charge (z^*):

$$X = az^*/r^b + c; \qquad (7)$$

(4) from the spectroscopic characteristics of the bonds between the atoms:

$$k = a(X_A X_B/r^2)^b + c \text{ or } \Delta X_{AB} = m\nu_{AB} + n, \qquad (8)$$

where k is the force constant of the bond; ν the characteristic frequency of the vibrations of the bond A–B; and a, b, c, m, and n are constants.

The literature on the determination and use of atom electronegativities is so great that it cannot be cited completely in a journal paper. Therefore we will quote only the principal, mainly review, papers plus investigations carried out after 1968.

Thermochemical determinations of electronegativity based on Pauling's equation, Eqn.(5), have been carried out[23–26]; the averaged results of these studies are given in the first sub-lines of Table 3.

Electronegativities have been determined with Mulliken's equation, Eqn.(6).[27–39] The ionisation potentials of atoms in the valence state cannot be determined experimentally when the valence state does not coincide with the ground state, since then a knowledge of the promotion energies of the electrons is required. Consequently most studies in this direction are quantum-mechanical. The ideas of the electronegativity of an atom depending on the orbital type of its bonds ("the orbital electronegativities of atoms") arose in this particular region.

† Bond ionicity is essentially a synonym for the effective charge of an atom; the ionicity is usually expressed in percentages of the formal charge, the effective charge in fractions of the electronic charge.

Many investigators regard the determination of electronegativities from ionisation potentials as the most substantiated physically. Consequently the difference in the dimensionalities of the thermochemical and ionisation electronegativities was thought[40] to be a defect of the electronegativity concept. However, Martynov and Batsanov[37] have shown that the use of not the first ionisation potential but the mean value of the potential for all the outer electrons ($\bar{I}$) leads to an equation of the type:

$$X = a(\bar{I})^{1/2} + b \quad , \qquad (9)$$

where X has the same dimensionality as the thermochemical electronegativity of the atoms. The ionisation electronegativities are given in the second sub-lines of Table 3.

Calculations of the electronegativities of the atoms from their radii and the effective charges of the atomic nuclei by equations of the type of Eqn.(7) also have a history of many years and are continuing vigorously to the present time[41-50]. Averaged electronegativities from these studies are given in the third sub-lines of Table 3.

Spectroscopic determinations of electronegativities are based either on the use of the force constants of the bonds[51,52] or the wavenumbers of the vibrations in the

ultra-violet[53–59] infrared[60–64], or radio-wave[65–67] regions of the spectrum, or chemical shifts in the Mössbauer spectra[68,69]. The averaged atomic electronegativities from optical spectroscopic results are given in the fourth sub-lines of Table 3.

As Table 3 shows, the results of the electronegativity calculations by various methods agree very well, which allows a universal system of electronegativities of the elements to be constructed. Table 4 gives such a system for the atoms in various oxidation states.

Pauling deduced the following relation from a comparison of the dipole moments and electronegativities of the atoms[23]:

$$i = 1 - e^{-a\Delta X^2}, \qquad (10)$$

where a is a constant, which, determined after refinement of the dipole moment of HF, equals 0.18. Analysis of Eqn.(10) and confirmation of its validity by independent methods are considered in a book[19].

Nethercot[70] recently took the next step in the direction of the formal development of Eqn.(10). He suggested that i should be expressed as a function not of ΔX but of the normalised difference in the electronegativities of the atoms:

$$i = 1 - e^{-a\Delta \bar{X}^2}, \qquad (11)$$

where

$$\Delta \bar{X} = \Delta X/(X_A X_B)^{1/2}.$$

The successful solution of the problem of finding i from ΔX (using the dipole moments of the HHal molecules) allowed the reverse problem to be solved also—the finding of μ (for example, for organic molecules) from the electronegativity and i.[71]

IV. POLARISATION OF CRYSTALS: BORN AND SZIGETI'S THEORETICAL APPROACH

The development of the theory of polarisation of ionic crystals began with the well-known equation of Born and Göppert-Meyer, in which the dielectric permittivity is linked with the natural frequency of the transverse lattice vibrations:

$$\varepsilon = n^2 + \frac{4\pi(ze)^2}{\omega_i^2 \bar{M} V}. \qquad (12)$$

Here ω_i is the frequency of the transverse lattice vibrations, V the volume associated with one particle, $\bar{M}$ the reduced mass of the vibrating particle, n the refractive index, and z the valency of the ion.

Comparison of the experimentally measured and theoretical (calculated from the Born formula) values of ε showed that usually the calculated ε were less than the experimental values. The reason for the discrepancy between theory and experiment is in the assumption, made in the theory, that the interaction of the ions is coulombic and that P_a and P_e are additive. Actually, the electron clouds of the ions in the crystals are deformed and are overlapped during the vibrations of the lattice, as a result of which the atomic and electronic components of the polarisation are no longer independent additive quantities.

Szigeti[72] showed that the deformation of the electron cloud of the ions due to the transverse vibrations of the lattice increases the atomic polarisation. On taking into account also that the field strength E in the dielectric is less than the external field due to the polarisation of the specimen, Szigeti obtained the following equation:

$$\varepsilon = n^2 + \frac{4\pi(ze)^2}{\omega_i^2 \bar{M} V}\left(\frac{n^2+2}{3}\right)^2. \qquad (13)$$

The Szigeti equation differs from the Born formula by the factor $[(n^2+2)/3]^2$, which takes into account the contribution from electronic polarisation to atomic polarisation. This term plays a greater part the higher the refractive index, that is, the greater the covalency of the bond; it is in just these circumstances that Born's assumption that isolated ions are not deformed is least valid.

Comparison of the result of calculations by Eqn.(13) with experiment showed that the calculated values of ε are always greater than those measured experimentally. This led Szigeti to the idea of changing the formal charge of the ion z to some quantity s which characterises the departure of the actual charge e^* from the theoretical value. It is easy to see that in the physical sense the parameter s is the effective charge of the atom: $s = e^*$. On taking into account that

$$\omega_t = 2\pi\nu_t,$$

where ν is the experimentally determinable linear transverse vibration frequency of the lattice, Szigeti deduced that

$$e^* = \frac{3\nu_t c}{ze\,(n^2+2)}[\pi(\varepsilon - n^2)\bar{M}V]^{1/2}. \qquad (14)$$

where e^* is the effective charge of the atom, which reflects the bond ionicity in the crystal.

Hence on the basis of characteristics of the crystal such as its molecular mass, volume, the frequency of the vibrations of the atoms the dielectric permittivity, and the refractive index, the Szigeti equation allows the departure of the bond character from the purely ionic state to be determined.

* Charges of the atoms recalculated according to the X-ray densities[97].

** Estimated value.

The Szigeti equation was used initially to calculate the effective charges of the atoms for only simple cubic crystals, but as time elapsed more and more complex crystalline compounds were studied, both isotropic and anisotropic. The

development of the Szigeti method is linked with the perfection of the measuring techniques and with the refinement of the method of calculating the optical characteristics of anisotropic crystals.

Most anisotropic crystals are characterised by infrared spectra so complex that the choice of the frequencies of the transverse and longitudinal vibrations—ν_t and ν_l—for calculation of charges is a special problem. This has been considered by Loudon[73] for uniaxial crystals as example. It was found that usually some of the bands in the infrared reflection spectra of the uniaxial crystals hardly shift on going from the orientation of the electric field parallel to the c axis towards a perpendicular orientation, that is, $\nu_\parallel \cong \nu_\perp$. If the inequality

$$|\nu_\parallel - \nu_\perp|_{t \text{ or } l} \ll (\nu_l - \nu_t)_{\parallel \text{ or } \perp}, \qquad (15)$$

holds in this, then these bands correspond to isotropic oscillators, since the internal field is then analogous to the field of the cubic crystals. Here it has been shown[73], that the strength of the isotropic field is a maximum for the highest frequency vibrations which satisfy inequality (15).

Tables 5 and 6 give the results of experimental investigations on crystalline compounds by the Szigeti method. The literature reference in Tables 5 and 6 are usually for the latest papers on these compounds, which have been studied repeatedly, or for those papers in which there are the most accurate physical characteristics of the crystals, although the calculations of effective charges were not carried out.

* Since the atoms O and F have similar sizes and masses, these compounds are close to type AB_2.

Table 5 allows a series of conclusions to be drawn. The values of e^* increase with the difference in the electronegativities of the atoms A and B, and also with the coordination numbers of the atoms in the crystal structures. Thus going from α- to β-HgS is accompanied by an increase in the number of nearest neighbours from 2 to 4, and for α- and γ-MnS the coordination numbers are changed from 6 to 4. The bond ionicity increases with the coordination of the atoms, which is in complete agreement with Pauling's postulate[23]. It should also be noted that the difference in the bond ionicities of analogous compounds of the elements of the A and B subgroups was significantly less than could be expected from a comparison of the electronegativities of atoms in molecules (Table 4).

Table 6 gives the results of studies on crystalline compounds of type A_nB_m by the Szigeti method. When the values of e^* in the papers cited were calculated by the Born equation they were recalculated by Eqn.(14). In the treatment of the published data for MnF_2, Cu_2O, GeS_2, and $GeSe_2$ the choice of the lattice vibration frequencies was made with allowance for Eqn.(15).

The data in Table 6 agree with the changes in the electronegativities of the atoms but there are significant discrepancies for several compounds. Thus the bond ionicities in the Pb halides are very high, which Axe and coworkers[124] explained by the increased valency of lead in these compounds; the bond ionicities in the molybdenum chalcogenides were unexpectedly low, which Lucovsky and coworkers[116] explained by the formation in this instance of the radicals S_2 and Se_2, the oxidising abilities of which are considerably lower than those of S and Se atoms.

The low bond ionicity for copper(I) oxide compared with copper(II) oxide (and with the calculation by the electronegativity method) must show a decrease in the effective valency of copper in Cu_2O. We will return to the problem of effective valencies; here we will only note that according to X-ray diffraction studies[125], there is a Cu–Cu bond in Cu_2O.

Not only binary compounds, but also double salts and complexes have been studied by the Szigeti method. In every instance it was found that the ionicity of the bonds in the inner sphere of complexes is higher than that in the corresponding binary compounds.

Analysis of the infrared spectra of binary oxides and complexes allows the Szigeti equation to be used for determining the effective charges not only on ionic complexes but also in the inner sphere of these complexes. Table 7 gives the results of investigations of the effective charges of the atoms in complexes[111,126,127].

Table 7. Effective charges of the atoms in oxygen compounds.

Be_2SiO_4	0.65	0.46	0.55	$LiTaO_3$	0.79	0.67	0.69
Mg_2SiO_4	0.73	0.42	0.58	$CaMoO_4$	0.80	0.42	0.52
$ZrSiO_4$	0.83	0.38	0.60	$CaWO_4$	0.82	0.47	0.56

Comparison of the results in Tables 5–7 shows that in compounds of the M_nEO_m type the ionicity of the M–O bond is greater, and that of the E–O bond less, than in the corresponding binary oxides of M and E. Such a distinctive compensation dependence in the ratio of various properties of complexes is constantly encountered.[128] It has been shown by the Szigeti method that there is an analogous dependence for solid solutions of binary compounds, for example, in mixed alkali halides[129].

As the KCl concentration in KCl–KBr solid solution is reduced the frequency of the vibrations and the crystal cell volume will vary monotonically from the values characteristic of KCl to those characteristic of pure KBr; the reduced

mass M also changes analogously. In addition, a peculiarity of the Szigeti equation is that the relation

$$\nu_t \sqrt{\overline{M}V} = \text{const} \quad (16)$$

is valid. This follows from the theory of a harmonic oscillator and the calculation of a force constant according to Coulomb's law. Therefore changes in the reduced mass (or molar volume) are compensated by a change in the vibration frequency, that is, for low concentrations of KCl in KCl–KBr solid solution the values of ν_t, $\overline{M}$, and V for pure KBr can be inserted into the Szigeti equation.

On considering the characteristics of an individual KCl particle in a continuous matrix of KBr, it must be assumed that the value of ε for such a solid solution will be the same as for pure KBr, since the dielectric permittivity in its physical essence relates to the medium in which this particle is located. As for the refractive index, that depends on the change in the volume of the KCl particle in the solid solution compared with the free state.

Without dwelling on the details of the calculation of the optical dielectric constants (cf. Batsanov[129]) we will pass to a statement of the results of applying the Szegeti method to the determination of the effective charges of atoms in solid solutions. Table 8 gives the bond ionicities for infinitely dilute solid solutions; in real materials there will be an intermediate situation.

Table 8. Effective charges of the atoms in pure and mixed crystals [solid solutions] MHal.

M	Initial substance MCl	Solid solution MCl–MBr		Initial substance MBr
Li	0.74	0.83	0.59	0.71
Na	0.76	0.85	0.60	0.72
K	0.80	0.88	0.67	0.77
Rb	0.85	0.89	0.72	0.80
Cs	0.86	0.92	0.72	0.81
Hal	KHal	KHal–RbHal		RbHal
F	0.93	0.90	1.00	0.95
Cl	0.80	0.76	0.92	0.85
Br	0.77	0.72	0.88	0.80
I	0.74	0.69	0.86	0.78

As Table 8 shows, the difference in the bond ionicities of the components of the solid solution is increased in the formation of a mixed crystal: the bond in the more ionic crystal becomes even more ionic, that in the less ionic becomes more covalent. The oppositely directed changes in the character of the chemical bonds of the components of the solution lead to the mutual compensation of a large part of these changes, but in all examples the integral effect is never zero; here solid solutions differ from mechanical mixtures.

It is extremely important that the opposing changes in the charges of the atoms entering into the composition of the components of the solid solution lead to the spatial approach of the atoms, which is responsible for the possible formation of a stable solution. In addition, the compensation nature of the variation of the effective charges and radii of the atoms in the solid solution leads also to compensation of the energies of the various chemical bonds, which appears thermochemically in the low enthalpies of formation of solid solutions (which, incidentally, are not equal to the simple difference of the standard bond energies of the atoms participating in the formation of the solid solution).

It is extremely tempting to study the change in the nature of the chemical bond in crystals as the thermodynamic conditions are varied, since all the components of the Szigeti equation can be determined experimentally. However, complete certainty has not been acheived even in the sign of the change in the charge on an atom as the volume of the crystal is varied. In fact, an increase in the volume of a crystal during heating should lead to a decrease in the overlap of the atomic orbitals (and consequently to an increase in the charges on the atoms), but since this increase in volume takes place due to the increase in the amplitude of the vibrations of the atoms, there should be an increase in the overlap of the electron orbitals. Hence the total change in the character of the chemical bond during the heating of the crystal should be small and, generally speaking, can be of either sign[100,130–132].

V. EFFECTIVE CHARGES AND ELECTRONEGATIVITIES OF ATOMS IN CRYSTALS

The problem of the determination of the effective charges of atoms in a molecule or in a crystal reduces to the separation of that fraction of the space in the crystal or molecule in which the calculation or measurement of the electron density of the atoms is carried out. The minima on the curves or surfaces of electron density distribution can serve as a criterion of the division of the space into atomic regions[133–135]. A comparison of the effective charges, that is, of the difference in the formal and real numbers of electrons in the region of a given atom, determined by X-ray diffraction, with the independent determination of e* gives good agreement[21,135].

Mulliken and coworkers[136–138] developed a quantum-chemical approach to the determination of the electron density of a chemical bond; calculation by the Hartree-Fock method of the electron densities of isolated atoms and of the appropriate compounds including these atoms in their composition allows the fine peculiarities of the chemical bond to be found by comparison. Essentially, the change in the electron density distribution in the formation of covalent molecules does not exceed 10% in comparison with the isolated atoms[139], and the charge transfer (from the metal to the non-metal atom) in polar molecules correlates with the difference in the electronegativities of these atoms[140].

The problem of the theoretical calculation of the effective charges of atoms in crystals has been considered in detail in many monographs on quantum chemistry and even in simple listing of these studies would take up much space. We are therefore limited to references to the main reviews in this field, in which either original approaches are reported or summaries are given of appropriate investigations, mainly from published results. First of all there are the classical books of Pauling[23], Coulson[141], and Slater[142], but there are others[41,135,143–148].

The most important result of the numerous theoretical investigations is that despite all the stipulations and limitations the concept of "effective charge of an atom in a crystal" plays an important part in structural chemistry and allows not only many physicochemical properties of crystals to be explained but also new properties to be predicted.

In this review we will consider only those studies in which the problem of the effective charges of atoms in crystals was studied from the viewpoint of dielectric methods and the concept of electronegativity, based on this approach.

The first quantitative estimate of the charges of the atoms in crystals from results for corresponding molecules was proposed by Pauling[23]. According to him, the covalency of the

bond in the crystals will be the same fraction of the covalency in the corresponding molecules as the valency of the atoms (z) is of the coordination number (N_C):

$$i = 1 - \frac{z}{N_c} e^{-a\Delta X^2} \quad . \qquad (17)$$

This rule was confirmed by an analysis of the interatomic distances in molecules and crystals, by comparison of the bond ionicities in molecules and crystals, in the X-ray spectroscopic and photoelectronic study of the chemical bond in crystalline compounds.

As he showed himself, Pauling's rule is valid, however, only for compounds of cations of the noble gas type, since the atoms of the B subgroups can form a larger number of bonds than their valency. Additional bonds in crystalline compounds are formed by the free orbitals of the metal atoms and the unpaired electrons of the non-metal atoms. In addition, the change in N_e on going from the isolated molecules to the crystalline state is accompanied by a change in the polarisation interaction of the ions; for crystals of the alkali halides this change is responsible, for example, for 50–80% of the total e*.[149]

Therefore for calculating the total electron density on the atoms in crystals it was proposed to take into account not only the coulombic but also the ion-dipole interaction of atoms on the basis of the ionisation potentials and the electron affinity for the valence state[19,150]. Comparison of degrees of bond ionicity thus calculated with the experimental values shows satisfactory agreement[150].

Sanderson[151,152] proposed an original method for determining bond ionicities in molecules. He suggested that the electronegativities of the atoms, or, more precisely, quantities proportional to them, the "stability ratios" S are given by:

$$S = N/qr^3 \qquad (18)$$

where N is the atomic number of the element, r the covalent radius, and q a constant, will be equalised in the formation of molecules. Hence the relation of the stabilities of the atom in the molecule AB is

$$S_{AB} = (S_A S_B)^{1/2} \quad . \qquad (19)$$

Knowing the set of covalent and ionic S, the degree of ionicity of a bond can be calculated by the equation:

$$i = (S_{AB} - S_A)/(S_{A+} - S_A) \quad . \qquad (20)$$

Comparison of the degrees of ionicity calculated by the Sanderson and Pauling methods shows a statistical mean deviation of ~10%.

The Sanderson method was developed for the calculation of the bond ionicities of molecular compounds of complicated composition[41,153,154]. The quantum-chemical aspect of the Sanderson method was developed by many investigators and these investigations were surveyed by Jolly and Perry[155].

A variant of the Sanderson method suitable for calculating bond ionicities in coordination crystals was proposed recently[156]. This consists essentially in the calculation of S of the atoms A and B in crystals AB by the equation:

$$\bar{S}_A = (S_A \cdot S_B^{\alpha})^{1/(\alpha+1)} \text{ or } \bar{S}_B = (S_B S_A^{\alpha})^{1/(\alpha+1)} \quad , \qquad (21)$$

where α is the reduced Madelung constant.

Then $\bar{S}_A$ and $\bar{S}_B$ are compared with the values of S of the same atoms in the purely ionic and purely covalent bonds in the crystalline state with the aid of an equation of type (20), since the effective charges for cation A and for anion B in the crystal AB should equal one another.

Table 9 gives, as an example, the results of calculating the effective charges of the atoms in alkali halides (cf. Batsanov[156]). The agreement of these results with the independently determined effective charges of the atoms is also rather good, which indicates the correctness of the method of calculation and the objective significance of the effective charges themselves.

Table 9. Effective charges of the atoms in crystals calculated by the method of equalising S.

AB	e^*_A	e^*_B	AB	e^*_A	e^*_B
NaF	0.92	0.92	RbF	0.98	0.95
NaCl	0.80	0.82	RbCl	0.85	0.85
NaBr	0.76	0.79	RbBr	0.81	0.82
NaI	0.63	0.68	RbI	0.69	0.71
KF	0.95	0.94	CsF	0.99	0.96
KCl	0.83	0.83	CsCl	0.87	0.86
KBr	0.79	0.80	CsBr	0.83	0.83
KI	0.66	0.69	CsI	0.71	0.72

However, such a position occurs only for ideal crystal structures of the type of ZnS, NaCl, CsCl, etc., in which the coordination number (C.N.) is known precisely. When the coordination polyhedron is distorted, the distances from the centre to the various vertices in it differ appreciably, which raises the question of how the C.N. is to be used in calculating the bond ionicity. The difficulty in choosing the C.N. for calculating bond ionicities in crystals with irregular coordination polyhedra has been discussed in the literature.[108,157]

The escape from this position can be twofold: either the theoretical calculation of effective C.N. taking into account the non-equivalence of the bonds between the central atom and various ligands[158–163], or an empirical allowance for the real coordination of the atoms in the crystal. In the latter approach we[164] used the sublimation energy of the crystal (ΔH_S), since it is just this that distinguishes a molecular from a crystalline compound. Use of the sublimation energy permits going from the electronegativity of atoms for molecules to the electronegativities of atoms for crystals (X^*). To do this the well-known Pauling equation:

$$\Delta X_{AB} = 0.208\,[\Delta E(AB)]^{1/2}$$

is transformed into the form:

$$\Delta X^*_{AB} = 0.208\,[\Delta E(AB) + \Delta H_s]^{1/2} \quad . \qquad (22)$$

Combination of this equation with formula (5) gives the following expression:

$$\Delta\Delta X = \Delta X^*_{AB} - \Delta X_{AB} = 0.208\{[\Delta E(AB) + \Delta H_s]^{1/2} - [\Delta E(AB)^{1/2}]\} \quad , \qquad (23)$$

which allows the difference in the electronegativities of the atoms for the molecular and crystalline states to be calculated, and hence also the electronegativity of the atom for the crystalline state if the problem of which of the partners in the bond A–B is responsible for the change in electronegativity on going from the molecular to the crystalline state can be solved. Since the enthalpies of sublimation of the elements playing the part of anions are significantly less than those of metals, clearly the influence of the ΔH_S should appear mainly on the electronegativity of the cation. The results of such calculations of the electronegativities of the atoms in crystals have been given[164].

The electronegativities of the atoms in crystals can also be calculated from the electronic work function (Φ). Stevenson[165] suggested that the electronegativities of atoms of metals in the crystalline state could be calculated by the equation:

$$X^* = 0.355\Phi \quad . \qquad (24)$$

Later[166] the coefficient in Eqn.(24) was changed to 0.318 and the electronegativities of the atoms of almost all metals in the crystalline state were calculated. It was found that electronegativity$_{met}$ < electronegativity$_{mol}$, which is explained by the greater screening of the nuclear charge of atoms in the solid state compared with that of an atom in a molecule.

The closest approaches to thermodynamic values of the electronegativities of atoms in the crystalline state are obtained in calculations with the formula:

$$X^* = 0.4\Phi - 0.5 \quad . \qquad (25)$$

The values of the electronic work function for pure metals corrected from the enthalpies of formation of intermetallic compounds were used[167-172] for interpreting the structure and properties of metallic phases.

In using methods of calculating the electronegativities of atoms in crystals starting from geometric considerations, then in equations of type (7) instead of the usual covalent radius it is necessary to use the covalent radius of the same atom for the crystalline state and to allow also for the bond multiplicities in coordination crystals (cf. Batsanov[164]). The calculation of the electronegativities of atoms in crystals by a method similar to that of Sanderson but based on Fermi statistics has also been described; the results of these calculations agree well with the independent determinations of the electronegativities of corresponding atoms[173]. The optical determination of the electronegativities of atoms in crystals has been described[56,58,59].

Table 10 gives the system of electronegativities of atoms in crystals, averaged from the results of various methods.

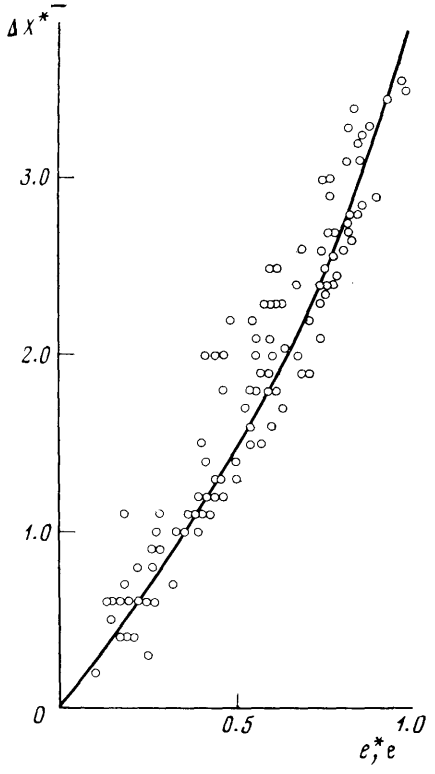

Figure 1. Variation of the effective charges of the atoms according to Szigeti with the differences of the electronegativities of atoms in crystals.

Table 10. System of electronegativities of atoms in crystals.

On constructing graphs of the effective charges of atoms in crystalline compounds (Tables 5 and 6) against the difference in the electronegativities of the corresponding atoms (Fig.1), then the best curve obtained by the least squares method, can be used to find the function $i_{cr}(\Delta X)$, which allows the effective charges of atoms in crystals to be estimated. Table 11 gives the numerical values of the bond ionicities in the molecules, from formula (10), and in crystals as a function of ΔX.

The discrepancy between the experimental and calculated (Tables 10 and 11) effective charges of the atoms averages ±0.05 e or 10% of the absolute value of e^*. The exceptions are certain compounds of the B subgroups, for example, Cu, Ag, and Tl.

Table 11. Variation of the bond ionicity (%) with the difference in the electronegativities of the atoms.

ΔX	i_{mol}	i_{cr}	ΔX	i_{mol}	i_{cr}	ΔX	i_{mol}	i_{cr}	ΔX	i_{mol}	i_{cr}
0.1	1	4	1.0	20	36	2.0	51	64	3.0	80	85
0.2	2	8	1.2	26	42	2.2	58	69	3.2	84	88
0.4	5	16	1.4	32	48	2.4	64	73	3.4	88	91
0.6	9	23	1.6	38	54	2.6	70	77	3.6	91	94
0.8	14	29	1.8	44	59	2.8	75	81	3.8	93	97

The question of the reasons for this exception were recently considered by the example of compounds of the AB type[174]. The widely held opinion that the bonds for compounds of the B subgroup metals are more covalent than those for the compounds of the corresponding analogues in the A subgroups is based on the peculiarities of the geometric structure, the significantly different atomisation energies and melting points, the solubilities of the corresponding salts in water, and other physicochemical properties. In addition, the effective charges of the atoms determined by Eqn.(14) for Cu, Ag, Tl, and Pb halides are higher than for their analogues from the A subgroups. In the first stages of the development of the Szigeti method this circumstance even cast doubt on the legitimacy of the approach itself. However attention was subsequently paid to the following circumstance.

When valency is treated in the classical approach as the number of electrons provided by a given atom for the formation of chemical bonds, then can Cu be regarded as univalent in CuCl, and Pb as bivalent in $PbBr_2$? In fact, the energy of atomisation of univalent metals of the A subgroup K, Rb, and Cs are 21.3, 19.3, and 18.2 kcal $mole^{-1}$ respectively, whereas their analogues in the B subgroup Cu, Ag, and Au have energies of 80.7, 68.1, and 88.2 kcal $mole^{-1}$ respectively[175]. This difference is due to additional metal–metal bonds, which are formed by the atoms of elements of the copper subgroup in the solid state. According to Pauling[23], these elements in the pure metallic state have effective valencies (owing to the use of the *d*-electrons of the preceding layer), equal to $\nu^* = 5.6$. Coulson[141] in comparing the atoms Na and Cu, notes that the 3d-orbitals of neighbouring Cu atoms are overlapped much more strongly than the 2*p*-orbitals of the Na atoms. Therefore for copper it is impossible to think that bonds are formed exclusively with the aid of 4*s*-electrons. On taking into account the features of the zone structure of the copper and silver halides other investigators[83,176] took the effective valency of Cu and Ag to be 1.5. The valency (z) is in the denominator of Eqn.(14) and on dividing the experimentally determined effective charges in the copper and silver polyhalides by 1.5, this leads to an approach between the experimental and calculated values of the bond ionicities in these compounds. An X-ray spectroscopic investigation[177] confirmed the theoretical estimates.

The problem of the increased formal valency due to the participation of the lone electron pairs in the chemical bonds was investigated in the lead dihalides. As already mentioned, Axe and coworkers[124] were the first to suggest that the 6*s*-electrons of lead participate in the chemical bonds in compounds of the $PbHal_2$ type. Investigations of the electron structure of the lead dihalides[178–181] confirmed that the 6*s*-electrons of the Pb atom interact with the *p*-orbitals of the halogen atoms, and only on allowing for this interaction do the calculated bond polarities agree with those determined experimentally.

The above results of the theoretical and experimental investigations pose the important question of what is the real valency of the atoms in crystalline compounds and whether in the interpretation of physicochemical parameters we are restricted to only the formal valencies. A possible way of settling this question could be the comparison of the effective charges of atoms in crystals determined experimentally by the Szigeti method and estimated theoretically, for example, by the electronegativity method. A marked discrepancy between the results from these approaches will show the necessity of allowing for additional interactions of the atoms.

In the papers cited above[174] in addition to Cu, Ag, and Tl halides the chalcogenides of the metals of the zinc subgroup and the compounds of Ga and In with the group V elements are also considered. The mean effective valencies of the metals of subgroups IB–IIIB in compounds of AB type are 1.5, 2.4, and 3.1 respectively; that is, they increase with participation of the $(n-1)d$-electrons in comparison with the formal valency. The simple division of the effective charges of the atoms of the corresponding elements in crystalline compounds (listed in Table 5) by these quantities greatly improves the agreement between the experimental results and those calculated by the electronegativity method.

VI. THE PHILLIPS–VAN VECHTEN ZONE THEORY, BOND IONICITY AND THE STRUCTURE OF CRYSTALS

The Szigeti method gives good results in studying the nature of chemical bonds in dielectrics—ionic-covalent crystals. Essentially, it is based on the assumption of the total localisation of the valence electrons on the atom-partners of the chemical bond and does not take into account the possibility of the appearance of even a partly metallic character at the chemical bond of a crystalline compound.

The approach described in the present section, on the other hand, is based on the assumption that all the valence (outer) electrons of atoms in crystals are delocalised just as happens in metals and the laws of an electronic gas are applicable to them. In accordance with the Penn theory[182]:

$$n^2 = 1 + (h\nu_p/E_g)^2 , \qquad (26)$$

where E_g is the distance between the centres of the valence zone and the conductivity zone (Fig.2), and ν_p the plasma frequency of the vibrations of the valence electrons:

$$\nu_p = (4\pi e^2 N/mV)^{1/2} . \qquad (27)$$

Here N is the number of valence electrons, m their mass, and V the volume of the formula unit of the crystal.

Phillips[42,183–188] and van Vechten[186,187,189] developed, on the basis of these relations, the "dielectric theory of a chemical bond". On writing Eqn.(28) for such elements as diamond and silicon, then for them

$$\varepsilon = n^2 \quad \text{and} \quad E_g = E_{gc},$$

where the index "c" denotes a covalent crystal:

$$\varepsilon = 1 + (h\nu_p/E_{gc})^2 \ . \qquad (28)$$

On assuming that Eqn.(28) is valid for all crystals and that the value of E_g is made up of ionic (E_{gi}) and covalent (E_{gc}) terms, Phillips deduced the equation:

$$E_g^2 = E_{gc}^2 + E_{gi}^2 \ . \qquad (29)$$

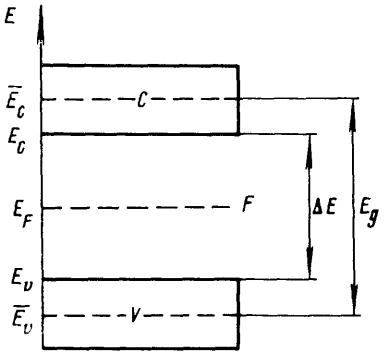

Figure 2. Schematic representation of the zone structure of crystals according to Phillips: V and C are the valence zone and conductivity zone, ΔE is the band gap, E_g the mean energy of transition of the valence electrons into the conductivity zone, and F the Fermi level.

It should be noted that before Phillips the papers of Suchet[190] and Batsanov[191] had already calculated the width of the zone gap of semiconductors from ionic and covalent components; however, Phillips approach is better based physically, which provided a possibility of obtaining fundamental results.

Since the use of Eqns.(26) and (28) led to values in good agreement with experiment, it became possible to determine E_{gi} on the basis of relation (29). Analysis of values of E_{gi} obtained empirically established that these characteristics can be presented as functions of the charges and radii of the atoms:

$$E_{gi}(\mathrm{AB}) = 1.5\left(\frac{z_A e^2}{r_A} - \frac{z_B e^2}{r_B}\right) e^{-k_S r} \ , \qquad (30)$$

where z_A and z_B are the valencies and r_A and r_B the radii of atoms A and B, $r = \frac{1}{2}(r_A + r_B)$, and k_S is the Thomas–Fermi screening factor. The last term ($e^{-k_S r}$) signifies that the valence electrons in a semiconducting crystal are considered to be free (as in metals) and therefore Thomas–Fermi statistics are completely applicable to them.

Expression (30) provided Phillips[188] with a basis for calculating the electronegativities of atoms by the formula:

$$X = 4.0\,(z/r)\,e^{-k_S r} + 0.5 \ , \qquad (31)$$

in which the coefficients 4.0 and 0.5 were chosen so that the Pauling scale was satisfied for the elements C and N. The results of the calculations by formula (31) have been published[47,192,193].

According to Phillips, the bond ionicity in a crystal is determined on the basis of Eqn.(29) by the formula:

$$f_i = E_{gi}^2/E_g^2 \ . \qquad (32)$$

Results of calculations by this formula are given in Tables 12 and 13.

Table 12. Bond ionicity (%) in crystals of type AB (according to Phillips).

A (I)	B (I)			
	F	Cl	Br	I

In	50	42	36	33

Kolmykov[194] carried out an interesting transformation of the Phillips equations. On taking the unity over to the left-hand side of each equation (26) and (28), and then dividing one equation by the other, we obtain:

$$\frac{n^2 - 1}{\varepsilon - 1} = \frac{E_{gc}^2}{E_g^2} = f_c \ , \qquad (33)$$

where

$$f_c = 1 - f_i.$$

Hence

$$f_i = \frac{\varepsilon - n^2}{\varepsilon - 1} \ . \qquad (34)$$

Calculation by Eqn.(34) is the simplest method of calculating the bond ionicity according to Phillips.

In the initial Phillips–van Vechten theory the value of f_i was calculated for crystals of the ZnS and NaCl structure types consisting of sp-elements. Subsequently, the theory was extended to crystals of other structure types and to d-elements. A significant contribution to the dielectric theory was made by Levin[195,196] who in calculating the number of valence ("plasma") electrons for the B subgroup elements took into account all $(n-1)d$-electrons, and not only the ns- and np-electrons. This interpretation is similar to that used in calculating the effective charges of the atoms

of the *d*-elements according to Szigeti. Levin demonstrated very convincingly the correctness of this approach for the example of Cu_2O, where in allowing for only the 4*s*-electron of copper $f_i \cong 0$ is obtained and only when all the 3*d*-electrons are included in the number of plasma electrons was $f_i = 0.56$ e obtained.

Tables 12 and 13 give the Phillips bond ionicities obtained by Levin and also those we have calculated by Eqn.(34) (the latter values are marked by an asterisk).

Table 13. Bond ionicity (%) in crystals of type A_nB_m (according to Phillips).

AB_2	f_i	AB_3	f_i	A_2B_3	f_i
MgF_2	91	SiO_2	57	Al_2O_3	80
CaF_2	97	Ge^4O_2	51	Cr_2O_3	78
SrF_2	97	Ge^6O_2	73	Fe_2O_3	68
BaF_2	97	SnO_2	75*	As_2S_3	29*
ZnF_2	89	SnS_2	49*	As_2Se_3	28*
CdF_2	93	$SnSe_2$	44*		
$CdCl_2$	66*	TiO_2	94*		
$CdBr_2$	68*	TiS_2	84*		
CdI_2	68*	$TiSe_2$	69*		
PbF_2	94	ZrS_2	75*		
PbI_2	80	HfS_2	76*		
		$HfSe_2$	81*		

Comparison of the results in Tables 12 and 13 and Tables 5 and 6 shows that the bond ionicities determined by the Szigeti and the Phillips methods are not the same. The physical reason for the differences was discussed above and we will now consider the interconnection between i (Pauling–Szigeti method) and f_i (Phillips method).

Lawaetz[176] found that

$$e^*/z \sim E_{gi}/h\nu_p.$$

Hence by using Eqn.(26) Uemil[192] obtained the expression:

$$(e^*/z)^2 \sim f_i/(n^2-1) \quad . \tag{35}$$

The physical significance of this relation is completely understandable, since the charges according to Szigeti are identical to the Pauling bond ionicity and the latter, according to Eqn.(11), is determined by the energies, whereas the charges according to Phillips depend on the square of the energy—cf. also the exponent of the powers of $(\varepsilon - n^2)$ in Eqns.(14) and (34).

The Phillips–van Vechten theory was modified in several subsequent studies. Thus Unger and Neumann[200] found that

$$f_i = \frac{1}{2}\left(1 - \cos\pi\frac{E_{as}}{E_{vb}}\right) \tag{36}$$

where E_{as} is the antisymmetric energy gap [within the valence band (Ed. of Translation)] and E_{vb} the total valence band width of the crystal. Later the same formula was used by Hübner[201,202] for calculating the bond ionicities in a series of transition metal oxides and halides.

Hübner also considered the application of the Phillips–van Vechten method to amorphous materials. Since according to Phillips

$$E_{gi} \backsimeq r^{-1}, \quad E_{gc} \backsimeq r^{-2.5} \tag{37}$$

it is easy to see that

$$\begin{aligned} E_{gc}^2(\text{am}) &= E_{gc}^2(\text{cr})\,(\rho_{\text{am}}/\rho_{\text{cr}})^{5/3}, \\ E_{gi}^2(\text{am}) &= E_{gi}^2(\text{cr})\,(\rho_{\text{am}}/\rho_{\text{cr}})^{2/3}, \\ \nu_p^2(\text{am}) &= \nu_p^2(\text{cr})\,(\rho_{\text{am}}/\rho_{\text{cr}}) \end{aligned} \tag{38}$$

where ρ_{am} and ρ_{cr} are the densities of the amorphous and crystalline phases. The dielectric constants of amorphous substances calculated by these formulae agree satisfactorily with experiment.

Hübner[203] investigated in special detail the bond ionicity in various forms of SiO_2 crystals. He found that the refractive index of silicon dioxide obeys the equation:

$$n = 1.04 + 0.19\,\rho,$$

where ρ is the density of various modifications of SiO_2. On taking into account that $\nu_\rho \cong \rho$, we obtain:

$$n = [1 + (n_\alpha^2 - 1)\,\rho/\rho_\alpha]^{1/2} \tag{39}$$

where the subscript α denotes α-quartz. Later, Hübner obtained the formula:

$$n^2 = 1 + 1.26r^2(1 - f_i) \tag{40}$$

where r is the minimal Si–O distance in the corresponding structure. Hence the following values are obtained for f_i: α-quartz 0.57; β-quartz 0.60; α-tridymite 0.59; α-cristobalite 0.58; β-cristobalite 0.61; coesite 0.53; keatite 0.59; glass 0.65.

A new variant of the Phillips formula was proposed[204]:

$$f_i = V_a^2/(V_s^2 + V_a^2), \tag{41}$$

where V_a and V_s are antisymmetric and symmetric form-factors of the potential of the crystal which are determined from the value of E_g. Comparison of the results obtained by Eqn.(41) with Phillips' results shows their agreement.

In conclusion, we note that the Phillips–van Vechten theory went firmly into the arsenal of the methods of solid-state quantum chemistry and physics, and it is now difficult to list all the studies where the dielectric theory of the chemical bond is used or developed. The present review surveys only the main works on this method of studying the chemical bond in crystals. Additional information can be obtained elsewhere[192,196,205–207].

---oOo---

Having considered the history and contemporary state of the use of dielectric methods in studying the nature of the chemical bond in chemical substances in any state of aggregation, it is easy to be persuaded that the information obtained with this method is in complete agreement with structural theory and with the results of independent methods of investigating bond polarities. The relative simplicity and rapidity of the measurements, together with their universality and low requirements for the quality of the test specimens makes this method extremely attractive for chemists.

For the future, the most interesting problem is the study of changes in the nature of the chemical bond at high pressures (up to the transformation of a dielectric into the metallic state).

The Possibility of Predicting the Retention Parameters in Gas-Liquid Chromatography

A.N.Korol'

Various methods for the calculation of retention parameters used in gas-liquid chromatography are critically examined in this review. They have been divided into four groups in accordance with their fundamental postulates. Attention has been concentrated on the physicochemical foundations of the methods considered, their generality, and the errors of the calculated quantities. The bibliography includes 325 references.

CONTENTS

I. Introduction 698
II. The use of the principle of the additivity of the increments in the molar free energy of solution 698
III. Correlation between the retention parameters and the physicochemical properties of sorbates 701
IV. The possibility of using theories of solutions for the calculation of retention parameters 706
V. Semiempirical calculations of the molar heats and entropies of solution 709

INTRODUCTION

Like any other analytical method, analytical gas–liquid chromatography (GLC) involves qualitative and quantitative analyses. The physical detection methods and the fairly simple calculations from output data made it possible to solve, in the main, the problems of quantitative analysis. However, the problems of qualitative analysis have not so far been fully solved. The situation can be accounted for by the unsatisfactory level of development of the theory of solutions, which is mainly concerned with the concentration dependence of the solubility of spherical molecules[1,2] rather than by the deficiencies of the gas-chromatographic method. The experimental data on the properties of infinitely dilute non-electrolyte solutions, one of the components of which is highly volatile and the other is involatile, have become available only after the introduction of the GLC method and have not so far been examined with the theory of solutions.

The practice of qualitative analysis in GLC requires the creation of fairly simple and universal methods for the *a priori* calculation of the retention parameters of the substances to be separated (sorbates); such calculation is essential despite the availability of a fairly large number of auxiliary identification methods in GLC.[3] This is because each identification method yields an answer with some degree of uncertainty, which diminishes when data obtained by another, independent method, are resorted to.

Although more than 400 communications describing various methods for the *a priori* calculation of retention parameters in GLC have been published, their results have not so far been surveyed. The aim of the present review is to examine the *a priori* and correlation methods for the calculation of retention parameters in GLC and to discuss their physicochemical basis.

The physicochemical picture of retention in GLC is fairly complex[4] and is determined not only by solubility (liquid–gas equilibrium) but also by a number of adsorption processes at the interfaces. For a more unambiguous treatment of retention parameters, we shall examine below mainly systems where adsorption processes play a negligible role (non-polar systems or systems with low polarity). The questions of complex formation via hydrogen bonding are outside the framework of this review; its limited size also precludes the consideration of the influence of changes in the nature of the stationary phase on retention parameters. The data described are grouped in terms of the methodological principles of the approach to the calculation of retention parameters.

II. THE USE OF THE PRINCIPLE OF THE ADDITIVITY OF THE INCREMENTS IN THE MOLAR FREE ENERGY OF SOLUTION

The molar free energy of the gas–liquid phase transition ΔG_S (in the chromatographic literature it is usually referred to as the molar free energy of solution) is related to the gas–liquid partition coefficient K by the expression

$$\Delta G_S = -RT \ln K = -RT \ln V_N, \quad (1)$$
