Fluorine-containing Phosphorus Ylids

V.V.Tyuleneva, E.M.Rokhlin, and I.L.Knunyants

The methods of preparation and properties of phosphorus ylids containing fluorine atoms in the "alkylidene" component are considered with the exception of halogenomethylenephosphoranes and ylids which contain fluorine atoms only at an appreciable distance from the carbanionic centre.
The bibliography includes 87 references.

CONTENTS

I. Introduction 1
II. Preparation 2
III. Properties 7

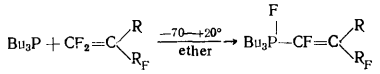
I. INTRODUCTION

A review dealing with fluorine-containing halogenomethylenephosphoranes was published previously[1]. In contrast to these, other fluorine-containing phosphorus ylids are characterised by a wide variety of properties, are frequently entirely stable, and can be isolated and characterised. However, in certain instances, for example, when triphenylphosphine interacts with perfluoroisobutene, the intermediate formation of fluorine-containing phosphorus ylids is only postulated.

The Wittig reaction ("carbonyl-olefination"), which represents the main synthetic application of phosphorus ylids[2-7], has been less thoroughly investigated in relation to fluorine-containing phosphorus ylids. At the same time the chemistry of these compounds involves many interesting reactions, which are frequently unusual.

This review describes the methods of preparation and properties of phosphorus ylids containing fluorine atoms in the "alkylidine" component†. Fluorine-containing halogenomethylenephosphoranes have been excluded from consideration[1]. Phosphorus ylids containing fluorine atoms only at a considerable remove from the carbanionic centre, for example, $Ph_3P{=}CHC_6H_4CF_3$ [8] or $Ph_3P{=}CH(CH_2)_3CF_3$,[9] have also been disregarded, because in this case the influence of these atoms on the properties of the ylids is insignificant.

† The AIPS-FTOR (VINITI) automated information-seeking system was used in selecting the literature.

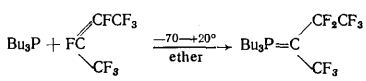


II. PREPARATION

The commonest methods of synthesising fluorine-containing phosphorus ylids are based on the reactions of tertiary phosphines with various fluorine-containing compounds—fluoro-olefins, fluoroalkyl halides, fluorothioketones, etc. Furthermore, it is possible to make use of methods involving the introduction of fluorine-containing groups into non-fluorinated phosphorus ylids.

1. Interaction of Tertiary Phosphines with Fluoro-olefins

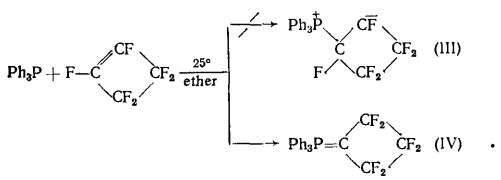
The ability of fluoro-olefins to react with nucleophilic tertiary phosphines is due to the electrophilic properties of the former[10]#. The result then depends on the structure of the initial compounds and sometimes on the reaction conditions.



Substituted vinylfluorophosphoranes (I) have been obtained by the reaction of perfluoropropene and other terminal fluoro-olefins with tributylphosphine under mild conditions[11,12]§:

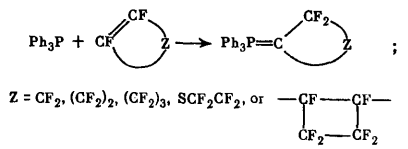
(I)

R	F	F	F	Ph	Ph
R_F	CF_3	n-C_3F_7	n-C_5F_{11}	CF_3	C_2F_5



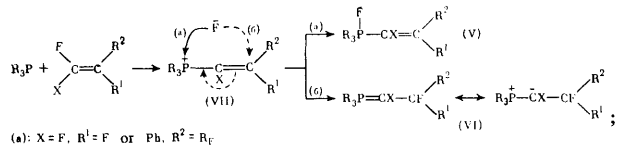
On treatment with tributylphosphine, perfluorobut-2-ene readily gives rise to the fluorine-containing phosphorus ylid (II):[11]

(II)



The structure of the ylid was demonstrated by NMR.

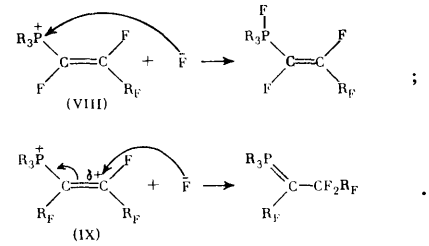
An anomalous reaction takes place when perfluorocyclobutene reacts with triphenylphosphine. Initially the betaine structure (III) was attributed to the reaction product[14], but later it was shown by X-ray diffraction[15] that perfluorocyclobutylidenetriphenylphosphorane (IV) is in fact formed¶:



(III) (IV)

Other perfluorocycloalkylidenetriphenylphosphoranes have also been obtained by a similar procedure[16,19]:

Perfluorocyclohexene does not react with triphenylphosphine[16].



Thus, depending on the structure of the fluoro-olefin, either an alkenylfluorophosphorane (V) or a phosphorus ylid (VI) is formed on treatment with a tertiary phosphine. Evidently, the initial product must be an alkenylphosphonium fluoride (VII) in all cases. From the examples investigated (still very few), it has been suggested[11] that alkenylfluorophosphoranes are obtained only under conditions where the intermediate phosphonium cation contains a fluorine atom in the α-position†, while phosphorus ylids are produced when there is no α-fluorine atom:

(a): X = F, R^1 = F or Ph, R^2 = R_F

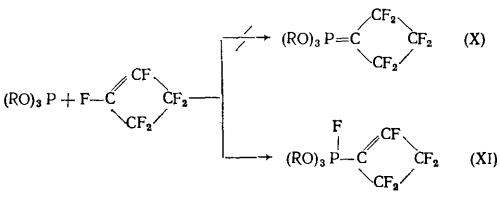
(b): X = CF_3, R^1 = F, R^2 = CF_3; XR^1 = $(CF_2)_2$, R^2 = F.

Probably in the latter case the crucial factor is not only the absence of a fluorine atom, but also the presence of the perfluoroalkyl group in the α-position. Perfluoroalkyl groups linked to the carbanionic centre impart stability to the phosphorus ylids (VI) (cf. Chambers[21]), while α-fluorine atoms destabilise the carbon ion (the Hine effect[22]). Another approach to the explanation of the results, associated with the consideration of the competitive influence of substituents on the polarisation of the C=C bond in the alkenylphosphonium cation, is also possible. In the cation (VIII) the partial positive charge on the β-carbon atom is insufficient to allow the attack on the latter by the F^- ion; therefore the positively charged phosphorus atom is attacked. In the cation (IX) the electron-accepting ability of both the perfluoroalkyl and the phosphonium group leads to an appreciable electrophilicity of the β-carbon atom, which promotes the formation of the phosphorus ylid:

(VIII) (IX)

It must be emphasised that the results obtained in the reaction of perfluorocyclobutene with trialkyl phosphite are apparently inconsistent with the proposed schemes. Under

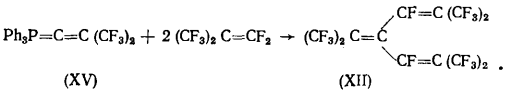
---



See Johnson[3] about the synthesis of phosphorus ylids by the interaction of tertiary phosphines with α,β-unsaturated carbonyl compounds.

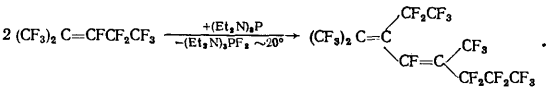
§ The hydrolysis of these phosphoranes leads to α-hydroperfluoro-olefins[12]; thus a convenient method has been found for replacing the "vinyl" fluorine atom by a hydrogen atom. When perfluorobutadiene is treated with tertiary phosphines, relatively unstable cyclic phosphoranes are produced[13].

¶ Analogous ammonium[16-18] and arsonium[16] ylids have also been obtained. When perfluorocyclobutene reacts with tris-(dimethylamino)phosphine, only the products of the substitution of the fluorine atom by the dimethylamino-group are formed[16].



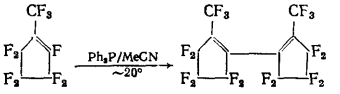
† There is evidence[20] that the phosphorus ylid $Ph_3P=CFCF_2CF_3$ rapidly isomerises to the fluorophosphorane $Ph_3PFCF=CFCF_3$.

these conditions, the product is the substituted vinylfluorophosphorane (XI) and not the phosphorus ylid (X):[23,24]#

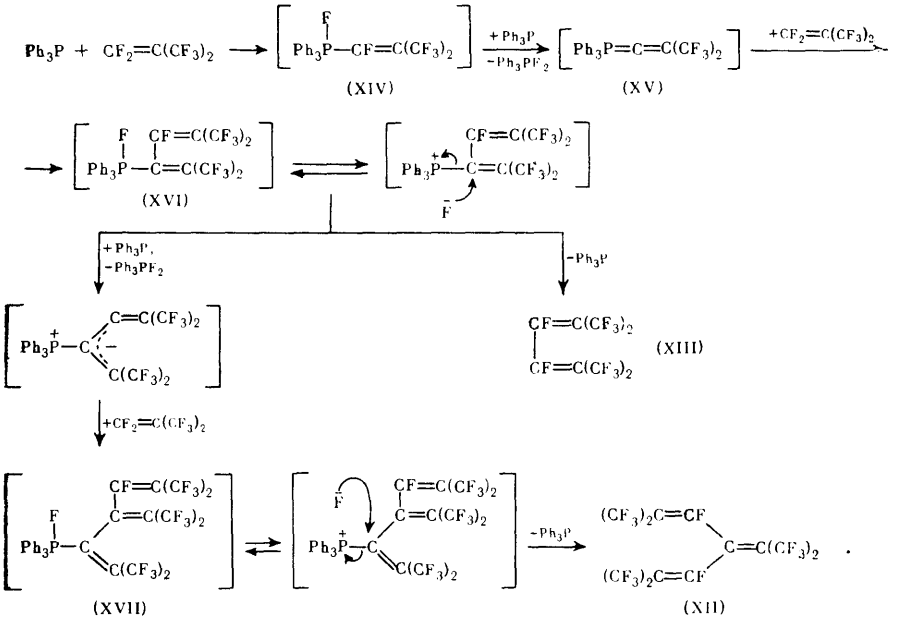


A particularly electrophilic fluoro-olefin—perfluoroisobutene—reacts with tertiary phosphines in an unusual manner. The reaction with triphenylphosphine[25] or with tributylphosphine[26] in acetonitrile§ led to the formation of a cross-conjugated perfluorotriene (XII). The diene (XIII) is formed together with this compound[26]. It has been suggested[25] that the reaction proceeds via a mechanism involving the intermediate formation of perfluoroisobutenylfluorophosphorane (XIV) and its defluorination product—the fluorine-containing cumulene ylid (XV). The addition of a second perfluoroisobutene molecule to the ylid (XV) led to the dienylfluorophosphorane (XVI), which split off triphenylphosphine and gave rise to the diene (XIII). On the other hand, the defluorination of the phosphorane (XVI) and subsequent addition of a third perfluoroisobutene molecule resulted in the formation of the trienylfluorophosphorane (XVII); the perfluorotriene (XII) was produced as a result of the elimination of triphenylphosphine.

The proposed mechanism of the defluorodimerisation and defluorotrimerisation of perfluoroisobutene has found some confirmation by the fact that the reaction of the known ylid (XV) with perfluoroisobutene also yielded the triene (XII):[26]



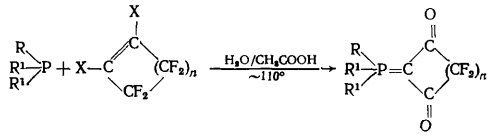
In contrast to perfluoroisobutene, perfluoropropene[25] and the ester of perfluoromethacrylic acid[28] merely dimerise on treatment with triphenylphosphine; analogous reactions on treatment with other bases had been described earlier[27,29,30]¶.



Perfluoropropene reacts vigorously with tris(dimethylamino)phosphine (the relevant paper gives no information about the products)[11]. The perfluoropropene dimer—perfluoro-2-methylpent-2-ene—undergoes defluorodimerisation on treatment with tris(diethylamino)phosphine[32]:

Perfluoro-1-methylcyclopentene reacts similarly with triphenylphosphine[32]:

Scheme

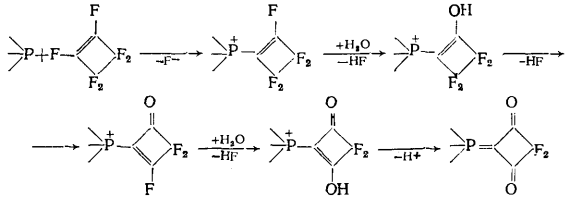


The decomposition of the adduct (XI) on heating leads to products of the substitution of the β-fluorine atom by an alkoxy-group[24] in addition to the products of the Arbuzov rearrangement[23].

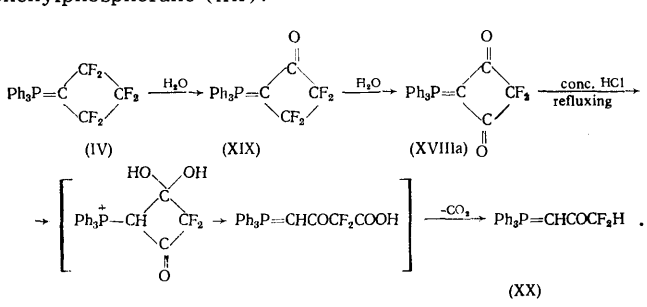
§ The reaction in ether yielded the phosphoranes $(CF_3)_2C{=}CFPF_2Bu_2$ and $(CF_3)_2C{=}CBuPF_2Bu_2$, probably via the intermediate formation of the phosphorane $(CF_3)_2C{=}CFPFBu_3$.[26] When perfluoroisobutene was treated with trialkyl phosphites, the stable phosphoranes $(RO)_3PFCF{=}C(CF_3)_2$ were obtained; on heating they give rise to products of the Arbuzov rearrangement[23,27].

¶ Trialkyl phosphites react with perfluoropropene to give the products of the Arbuzov rearrangement[31], while the reactions with perfluoromethacrylic acid esters give rise to the fluorophosphoranes $(RO)_3PFCF{=}C(CF_3)COOR^1$, which decompose on heating into $ROPF_2$ and $(RO)_2C{=}C(CF_3)COOR^1$.[27]

The mechanism of these reactions is probably analogous to that of the conversion of perfluorisobutene into the diene (XIII).



On treatment with tertiary phosphines in the presence of acetic acid and water, the cyclic diketo-ylids (XVIII) are formed from 1,2-dichloroperfluorocycloalkenes or perfluorocycloalkenes (C_4 and C_5):[14,33,34]

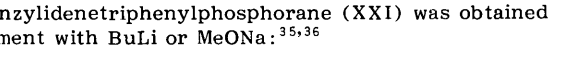


n	1	1	2	2	2	2
R	Ph	Ph	Ph	Ph	Bu	Bu
R^1	Ph	Ph	Ph	Ph	Ph	Bu
X	Cl	F	Cl	F	Cl	Cl

(XVIII): a—R=R^1=Ph, n=1; b—R=R^1=Ph, n=2; c—R=R^1=n-Bu, n=2; d—R=n-Bu, R^1=Ph, n=2.

A mechanism involving vinyl substitution on treatment with phosphine followed by the hydrolysis of the fluorine atoms has been proposed for this reaction[14], for example:

The hydrolysis of perfluorocyclobutylidenetriphenylphosphorane (IV) leads to the monoketo-ylid (XIX) [16] or the diketo-ylid (XVIIIa).[14,15]. Under more severe conditions, the diketo-ylid decomposes, forming difluoroacetylmethylenetriphenylphosphorane (XX):[34]

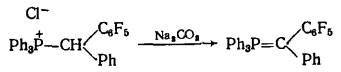


(IV) (XIX) (XVIIIa) (XX)

On refluxing with a tertiary phosphine in aqueous acetic acid solution, perhalogenocyclohexenes do not give rise to the corresponding diketo-ylids[14]. Triphenylphosphine oxide and 2-chloro-1-hydroperfluorocyclohexene are formed from 1,2-dichloroperfluorocyclohexene and Ph_3P under these conditions[34].

2. Interaction of Tertiary Phosphines with Other Organofluorine Compounds

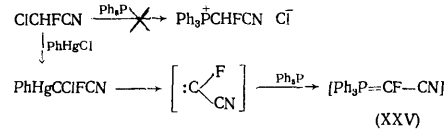
Certain fluorine-containing phosphorus ylids can be obtained by the method most widely used for the synthesis of phosphorus ylids in general—by the dehydrohalogenation of phosphonium salts (the "salt method").[3] Thus alkylation of triphenylphosphine with pentafluorobenzyl bromide led to the corresponding phosphonium salt, from which pentafluorobenzylidenetriphenylphosphorane (XXI) was obtained on treatment with BuLi or MeONa:[35,36]



(XXI)

Triphenylphosphine was used as the dehydrobrominating agent in the reaction with α-bromopentafluoroacetophenone[37]:

(XXII); m.p. 134—137°.



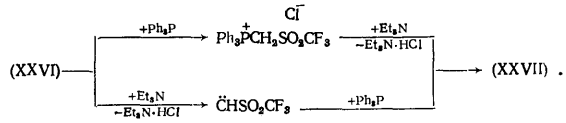
Pentafluorodiphenylmethyltriphenylphosponium chloride (XXIII) is converted into pentafluorodiphenylmethylenetriphenylphosphorane (XXIV) even on treatment with sodium carbonate[38]:

(XXIII) (XXIV); m.p. 206—209°.

According to patent data[39-42], the ylid $Ph_3P{=}CH(CH_2)_2CF_2$. .COOH has been obtained by treating the corresponding phosphonium salt with sodium hydride.

The "salt" method is frequently unsuitable for the synthesis of fluorine-containing phosphorus ylids. Thus, in contrast to pentafluorobenzyl bromide, decafluorodiphenylmethyl bromide[43] and the compounds $(CF_3)_2CHX$ [20,44] are incapable of alkylating triphenylphosphine. 2,2,2-Trifluoroethyl iodide reacts slowly with Ph_3P on irradiation, but trifluoroethyl idenetriphenylphosphorane $Ph_3P{=}CHCF_3$ cannot be obtained from the phosphonium salt formed[45]. The ester of chlorofluoroacetic acid[46] and its nitrile[47] also failed to give rise to quaternary salts on reaction with triphenylphosphine. However, the corresponding phosphorus ylid (XXV) can be obtained from the nitrile by a different method—via chlorocyanofluoromethyl(phenyl)mercury:[47,48]

(XXV)



A carbene (cyanofluoromethylene) may be formed as an intermediate in this process†.

The stable trifluoromethanesulphonylmethylenetriphenylphosphorane (XXVII) has been obtained from chloromethyl trifluoromethyl sulphone (XXVI) and triphenylphosphine in the presence of triethylamine[50]:

(XXVI) (XXVII); m.p. 155°.

A phosphonium salt is probably formed initially and is then dehydrohalogenated by triethylamine, although the "carbene" mechanism is not ruled out:

Another mechanism has been proposed for the reaction of the sulphone (XXVI) with the chlorides of diphenyl- and diethyl-phosphinous acids. It has been suggested that this involves the initial substitution of the chlorine atom attached to the phosphorus atom with formation of tertiary phosphines (XXVIII), which rearrange to the more stable *P*-chlorosubstituted phosphorus ylids (XXIX),[50] probably as a result of

† The phosphorus ylid $(CF_3)_3F{=}CFCHF_2$ is formed when tris(trifluoromethyl)phosphine interacts with trifluoroethylidene generated from the silane $HCF_2CF_2SiF_3$ or from difluoromethylperfluorocyclopropane[49].

the nucleophilic attack by the phosphorus atom on the halogen, which has been rendered positive:

$$R_2PCl + ClCH_2SO_2CF_3 \xrightarrow[-Et_3N\cdot HCl]{+Et_3N} \left[R_2\overset{+}{P}-CHSO_2CF_3 \;\; Cl^-\right] \longrightarrow R_2P(Cl)=CHSO_2CF_3 ;$$

(XXVI) (XXVIII) (XXIX)

R = Et (XXIXa) or Ph.

The ylid (XXIXa) has also been obtained by the reaction of trifluoromethanesulphonylmethyldiethylphosphine (XXX) with carbon tetrachloride in the presence of triethylamine[51,52]:

$$Et_2PCH_2SO_2CF_3 \xrightarrow[ether,\ 0-20^\circ]{Et_3N} \left[Et_2P-\overset{-}{C}HSO_2CF_3 \leftrightarrow Et_2\overset{+}{P}=CHSO_2CF_3\right] \xrightarrow[-CCl_3^-]{+CCl_4} Et_2P(Cl)=CHSO_2CF_3$$

(XXX)

The chlorine atom in the phosphorus ylids (XXIX) is readily substituted by the diethylamino-group on treatment with Et_2NH.[50,51,53]

Sulphonylmethylphosphine (XXX) reacts with chlorodiethylphosphine in the presence of triethylamine to form an unusual phosphorus ylid (XXXI) containing the P–P bond[51,53]. The same phosphinophosphorus ylid is formed on heating sulphonylmethylphosphine in the absence of other reactants[51] and also from chlorodiethylphosphine and methyl trifluoromethyl sulphone[53]:

$$Et_2PCH_2SO_2CF_3 \xrightarrow[Et_3N]{Et_2PCl} Et_2P(Et_2P)=CHSO_2CF_3$$

(XXX) (XXXI); m.p. 51–53°;

$$2\ (XXX) \xrightarrow[\longleftarrow]{120^\circ/0.1\ mmHg} (XXXI) + CH_3SO_2CF_3 ;$$

$$2Et_2PCl + CH_3SO_2CF_3 \xrightarrow[ether]{Et_3N} (XXXI) ;$$

$$2Et_2PCl + M_2CHSO_2CF_3 \xrightarrow{THF} (XXXI) ;$$

M = Li or MgCl.

The structure of the *P*-substituted ylids (XXIX) and (XXXI) as well as related compounds has been confirmed by spectroscopic data. Thus the infrared spectra exhibit a characteristic bathochromic shift of the SO_2 absorption frequencies under the influence of the electron-donating "ylid" carbon atom[50,51]. The non-equivalence of the two dialkylphosphinyl groups is clearly manifested in the ^1H and ^{31}P NMR spectra of ylids of type (XXXI).[51]

The salts of phosphinodisulphone (XXXII) are alkylated with transfer of the reaction centre and the formation of the phosphorus ylids (XXXIII):

$$Ph_2P-\overset{-}{C}(SO_2CF_3)(SO_2Ph) \xrightarrow{RX} Ph(R)P(Ph)=C(SO_2CF_3)(SO_2Ph) ;$$

(XXXII) $H_2\overset{+}{N}Et_2$ (XXXIII); R = Me, m.p. 158°; R = Et, m.p. 174–176°.

The structure of ylids of type (XXXIII) has been inferred from their infrared spectra[51,54].

A promising method of synthesising fluorine-containing ylids apparently involves the interaction of tertiary phosphines with fluorine-containing thioketones#. Thus the unstable hexafluoroisopropylidenetriphenylphosphorane (XXXV) has been obtained from triphenylphosphine and thiohexafluoroacetone [in the form of the dimer (XXXIV)]:[20]

$$2Ph_3P + (CF_3)_2C\langle S\rangle C(CF_3)_2 \xrightarrow[-78^\circ]{ether} 2\,[Ph_3\overset{+}{P}-S-\overset{-}{C}(CF_3)_2] \rightarrow$$

(XXXIV)

$$\xrightarrow[-2Ph_3PS]{} 2\,[:C(CF_3)_2] \xrightarrow{+2Ph_3P} 2\,[Ph_3P=C(CF_3)_2] .$$

(XXXV)

The reaction mechanism has not been demonstrated. It may be that bis(trifluoromethyl)carbene is formed as an intermediate.

The phosphorus ylid (XXXV) has been used successfully *in situ* in the Wittig reaction (see below). The use of tributylphosphine or tris(dimethylamino)phosphine instead of triphenylphosphine in an analogous reaction leads to a decrease of the yield of olefins[20]. In an earlier study[60] of the interaction of the dimer (XXXIV) with tributylphosphine only Bu_3PF_2 was isolated.

It was not possible to obtain the ylid (XXXV) from triphenylphosphine and other sources of bis(trifluoromethyl)carbene. Triphenylphosphine does not react with bis(trifluoromethyl)diazirine even under severe conditions[61], while the reaction with bis(trifluoromethyl)diazomethane yields the iminophosphorane (XXXVI):[62]

$$Ph_3P \xrightarrow{+(CF_3)_2C(N=N)} \text{(XXXV)}$$

$$Ph_3P \xrightarrow{+(CF_3)_2\overset{-}{C}-\overset{+}{N}\equiv N} Ph_3P=N-N=C(CF_3)_2 .$$

(XXXVI)

The stable hexafluoroisopropylidenetrialkoxyphosphoranes have been obtained from the dimer (XXXIV) and trialkyl phosphites(XXXVII):[60,63]

$$4\,(RO)_3P + (CF_3)_2C\langle S\rangle C(CF_3)_2 \xrightarrow{-30^\circ} 2\,(RO)_3P=C(CF_3)_2 + 2\,(RO)_3PS$$

(XXXIV) (XXXVII)

R	Me (a)	Et	iso-Pr	n-$C_{12}H_{25}$
b.p.	61–62°/0.35 mmHg	74–75°/0.25 mmHg	75–76°/0.05 mmHg	– (decomp.)

The interaction of tertiary phosphines with hexafluoroacetone *N*-alkenylimines (XXXVIII) led to the formation of substituted phosphorus ylids (XXXIX), probably as a consequence of the prototropic rearrangement of the intermediate betaines (XL):[64,65]

$$R^1_3P + R^2CH=CH-N=C(CF_3)_2 \xrightarrow[\text{hexane or benzene}]{0-20^\circ} [R^1_3\overset{+}{P}-CH(R^2)-CH=N-\overset{-}{C}(CF_3)_2] \xrightarrow{O}$$

(XL)

$$\longrightarrow R^1_3P(R^2)=C-CH=N-CH(CF_3)_2 .$$

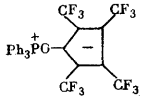
When trialkyl phosphites are used instead of phosphines, the relatively unstable ylids (XLI) are formed and readily rearrange (see below):[64,65]



$$(R^1O)_3P + R^2CH=CHN=C(CF_3)_2 \xrightarrow{\sim 20^\circ} (R^1O)_3P(R^2)-C-CH=NCH(CF_3)_2$$

(XXXVIII)

The interaction of tertiary phosphines with perfluoroketones and perfluoroaldehydes has been described[55–58]. The betaine

has been obtained from perfluorotetramethylcyclopentadienone and triphenylphosphine[59].

§ The boiling point of compound (XLI) with $R^1=R^2$=iso-Pr is indicated.

3. Interaction of Phosphorus Ylids with Fluorine-containing Compounds

Phosphorus ylids are very readily acylated[3], such reactions including also those occurring on treatment with derivatives of fluorine-containing carboxylic acids. Thus the stable trifluoroacetylmethylenetriphenylphosphorane (XLII) has been obtained from methylenetriphenylphosphorane and ethyl trifluoroacetate[66]. When the initial ylid is generated with the aid of butyl-lithium, butyldiphenylphosphorane (XLIII) is formed in addition to triphenylphosphorane (XLII); it has been shown that the phenyl group in the ylid (XLII) is substituted by the butyl group on treatment with n-BuLi:[66]

$$Ph_3P{=}CH_2 \xrightarrow[-70\to+25^\circ]{CF_3COOEt} Ph_3P{=}CHCOCF_3 \xrightarrow[25^\circ]{n\text{-}BuLi} \underset{\text{n-Bu}}{Ph_2P{=}CHCOCF_3}$$

(XLII) m.p. 233°; (XLIII); m.p. 138°.

The chlorides of perfluorocarboxylic acids can acylate also inactive phosphorus ylids. Thus perfluoroacylphosphorus ylids have been obtained from methoxycarbonylmethylenetriphenylphosphorane and the chloride of trifluoroacetic or perfluorobutyric acid (XLIV):[67]

$$Ph_3P{=}CHCOOMe \xrightarrow{R_FCOCl} \underset{\underset{COR_F}{|}}{Ph_3P{=}CCOOMe}\ ;$$

(XLIV)

$R_F = CF_3$, or $n\text{-}C_3F_7$.

Cyanomethylene- and ethoxycarbonylmethylene-triphenylphosphoranes react with the dichloride of perfluoroglutaric acid to give stable bisylids (XLV):[45]¶

$$4Ph_3P{=}CHR + ClCO(CF_2)_3COCl \xrightarrow[\text{benzene}]{25^\circ} \underset{\text{(XLV)}}{Ph_3P{=}CRCO(CF_2)_3COCR{=}PPh_3} + 2Ph_3\overset{+}{P}CH_2R\ Cl^-\ ;$$

m.p. 248–260° (R=CN), 194–195° (R=COOEt).

The initial phosphorus ylid is taken in excess in order to bind the HCl evolved.

The acylation of benzylidene- and pentafluorobenzylidenetriphenylphosphoranes by pentafluorobenzoyl chloride led to stable fluorine-containing phosphorus ylids (XLVI)[35]:

$$Ph_3P{=}CHR + C_6F_5COCl \xrightarrow[\text{benzene}]{15^\circ} \underset{\text{(XLVI)}}{Ph_3P{=}CRCOC_6F_5}\ ;$$

m.p. 244–247° (R=Ph), 245–246° ($R=C_6F_5$).

Active phosphorus ylids are capable of reacting with hexafluorobenzene[38] and with 2-phenylperfluoropropene[68] to form pentafluorophenylylids [(XXI) or (XXIV)] and the phenylperfluoropropenylylid (XLVII):

$$Ph_3P{=}CHR + C_6F_6 \xrightarrow[\text{ether}]{\sim 20^\circ} [Ph_3\overset{+}{P}CHRC_6F_5\ \bar{F}] \xrightarrow[-Ph_3\overset{+}{P}CH_2R\ \bar{F}]{+Ph_3P{=}CHR} Ph_3P{=}CRC_6F_5\ ;$$

R=H (XXI), or Ph (XXIV);

$$2Ph_3P{=}CHMe + CF_2{=}CPhCF_3 \xrightarrow{\sim 20^\circ} \left[Ph_3P{=}\underset{\underset{Me}{|}}{C}{-}CF{=}C\begin{matrix}Ph\\CF_3\end{matrix}\right] + Ph_3\overset{+}{P}CH_2Me\ \bar{F}\ .$$

(XLVII)

Under the reaction conditions, the ylid (XLVII) splits off an F^- anion and is converted into the allenylphosphonium salt (XLVIII), whose hydrolysis gives rise to the allene (XLIX) as well as its isomerisation [compound (L)] and dehydrofluorination [compound (LI)] products[68]:

$$(XLVII) \rightarrow \left[Ph_3\overset{+}{P}{-}\underset{\underset{Me}{|}}{C}{=}C{=}C\begin{matrix}Ph\\CF_3\end{matrix}\ \bar{F}\right] \xrightarrow{H_2O} MeCH{=}C{=}C\begin{matrix}Ph\\CF_3\end{matrix} +$$

(XLVIII) (XLIX)

$$+ MeC{\equiv}C{-}\underset{\underset{Ph}{|}}{CH}{-}CF_3 + MeC{\equiv}C{-}\underset{\underset{Ph}{|}}{C}{=}CF_2\ .$$

(L) (LI)

The chemistry of cumulene phosphorus ylids has appreciably developed recently[5]. In particular, hexaphenylcarbodiphosphorane (LII) and the "ylidoketen" (LIII) are of interest.

The ylid (LII) reacts with hexafluoroacetone to form the extremely stable "ylido-oxaphosphetan" (LIV);[69–73] an analogous result was obtained using dodecafluorotetramethylethylenedioxytriphenylphosphorane (LV) instead of hexafluoroacetone[72]:

$$Ph_3P{=}C{=}PPh_3 + (CF_3)_2CO \xrightarrow[\text{diglyme}]{40\text{–}50^\circ} \underset{\text{(LII)}}{\quad} \xrightarrow{} Ph_3P{=}\underset{\underset{(CF_3)_2C{-}O}{|}}{C}{-}PPh_3$$

(LII) + Ph_3P (LV) $\xrightarrow[\text{diglyme}]{65\text{–}75^\circ}$ (LIV), m.p. 157–158°

Thus a stable cyclic adduct of a phosphorus ylid with a ketone—the intermediate of the Wittig reaction—was in this instance isolated and characterised for the first time. The structure of the adduct (LIV) was demonstrated by X-ray diffraction[74]. Its stability can be accounted for by the strengthening of the C–O bond by the influence of the trifluoromethyl groups and the high electron density at the carbon atom linked to the phosphorus atom, which apparently prevents the dissociation of the C–P bond[72].

However, when the adduct (LIV) is heated above 110 °C, the second stage of the Wittig reaction nevertheless takes place—the adduct splits into the phosphine oxide and hexafluoroisobutenylidenetriphenylphosphorane (XV):[69–73]

$$(LIV) \xrightarrow[5\text{–}10\ min]{120\text{–}125^\circ} Ph_3P{=}C{=}C(CF_3)_2 + Ph_3PO\ .$$

The cumulene ylid (XV) cannot be fully separated from triphenylphosphine oxide.

When the adduct (LIV) reacts with various acids, phosphonium salts are formed and these can also be regarded as substituted phosphorus ylids[70–73] (see Section III, 3 below).

The "ylidoketen" (LIII) reacts with hexafluoroacetone and p-chloro-α,α,α-trifluoroacetophenone to form diketo-ylids (LVI), probably as a result of the cycloaddition of the initial ylid to the alkylideneketen (LVII), formed by the Wittig reaction[75]:

$$Ph_3P{=}C{=}C{=}O + \underset{R}{\overset{CF_3}{C{=}O}} \xrightarrow{-Ph_3PO} \left[\underset{R}{\overset{CF_3}{C{=}C{=}C{=}O}}\right] \xrightarrow{+(LIII)}$$

(LIII) (LVII)

$$\longrightarrow Ph_3P{=}\underset{\underset{\underset{O}{\|}}{C}}{\overset{\overset{O}{\|}}{C}}{=}\underset{\underset{R}{|}}{\overset{CF_3}{C}}\ ;$$

(LVI)

R=n-ClC_6H_4 (m.p. 246–247°), or CF_3.

¶ The ylid $Ph_3P{=}CFCN$ (XXV) cannot be obtained from cyanomethylenetriphenylphosphorane by fluorination with $FClO_3$.[43]

4. The Preparation of Wittig–Horner Reagents

The α-phosphonate carbanions, formed when the esters of alkylphosphinic acids are treated with bases, are analogues of phosphorus ylids:

$$(RO)_2PCHXY \xrightarrow[-BH]{+B^-} (RO)_2\bar{P}-CXY \leftrightarrow (RO)_2P=CXY \ .$$

These carbanions are widely used for the "olefination" of carbonyl compounds (the Wittig–Horner reaction).

The diethyl ester of α-fluoroethoxycarbonylmethylphosphonic acid was obtained by the Arbuzov reaction from the ester of bromofluoroacetic acid and triethyl phosphite and was converted on treatment with sodium or sodium hydride into the stable fluorine-containing anion (LVIII):[76–78]

$$(EtO)_3P + BrCHFCOOEt \xrightarrow[-EtBr]{145^\circ} (EtO)_2PCHFCOOEt$$

$$\xrightarrow[ether,\ \sim 0^\circ]{Na \text{ or } NaH} (EtO)_2\bar{P}CFCOOEt \ .$$

(LVIII)

The phosphonate carbanion obtained was used to synthesise the esters of unsaturated α-fluorine-substituted carboxylic acids (see Section III, 2 below).

The phenyl-substituted phosphonate carbanion (LIX), obtained from the ester of α-hydroxybenzylphosphonic acid, has been used to synthesise α-fluorostilbene (see Section III, 2 below):[79]

$$(EtO)_2PCHPh \xrightarrow{Et_2NCF_2CHFCl} (EtO)_2PCHPh \xrightarrow{-H^+} (EtO)_2\bar{P}CFPh \ .$$

(LIX)

III. PROPERTIES

The properties of fluorine-containing phosphorus ylids depend to a large extent on the nature of the substituents at the phosphorus atom and at the carbanionic centre.

1. Stability. Physical and Physicochemical Properties

The phosphorus ylids containing acyl or sulphonyl groups capable of delocalising the negative charge are distinguished by a special stability[4,7]†. Polyfluoroacyl- and polyfluoroalkanesulphonyl-methylenephosphoranes should be still more stable owing to the electron-withdrawing effect of the polyfluoroalkyl groups. Special studies in this field have not been made. However, there are data indicating a special stability of fluorine-containing phosphorus ylids such as trifluoroacetylmethylenetriphenylphosphorane (XLII),[66] pentafluorobenzoylmethylenetriphenylphosphorane (XXII),[37] and trifluoromethanesulphonylmethylenediethylchlorophosphorane (XXIXa).[51] Pentafluorodiphenylmethylenetriphenylphosphorane (XXIV) is still more stable than its non-fluorinated analogue[38].

† In general the phosphorus ylids $R_3^3P=CR^1R^2$ can be divided into three groups: the reactive ylids (R^1, R^2 = H or alkyl), the "moderate" ylids (R^1 = 1-alkenyl, 1-alkynyl, aryl, or halogeno-group; R^2 = ditto, H, or alkyl), and the stable ylids (R^1 = COR, COOR, CN, or SO_2R; R^2 = any group)[7].

Like the alkoxycarbonyl groups, the trifluoromethyl groups can stabilise carbanions[21]. It was therefore to be expected that ylids of the type $R_3P=C(CF_3)_2$ are extremely stable. However, it was found that hexafluoroisopropylidenetriphenylphosphorane (XXXV) is unstable and can be used in the Wittig reaction *in situ*[20]. It may be that the instability of such compounds can be accounted for by their stability to eliminate fluoride ion from the β-position. Analogous β-elimination in the case of the alkenylylid (XLVII) leads to the allenylphosphonium salt (XLVIII)[68] (see Section II, 3 above). However, ylids such as hexafluoroisopropylidenetrialkoxyphosphoranes (XXXVII)[60] and perfluorocyclobutylidenetriphenylphosphorane (IV)[17] proved to be extremely stable.

The stable fluorine-containing phosphorus ylids isolated are usually high melting crystalline substances. However, under the usual conditions some of them are liquids [for example, $Et_2PCl=CHSO_2CF_3$ (XXXIXa)[50,52] or $(R^1O)_3P=CR^2CH=NCH(CF_3)_2$ (XLI)[64,65]].

Table 1. The chemical shifts in the ^{31}P NMR spectra of fluorine-containing phosphorus ylids.

Ylid	Chemical shift, p.p.m.	References	Ylid	Chemical shift, p.p.m.	References
(II)	−23.7*	[11]	(XVIIIc)	−21.7**	[14]
(IV)	−5.6**	[14]	(XVIIId)	−12.8**	[14]
(XV)	−4.1*	[72]	(LIV)	−7.3 and +54.0*	[71, 72]
(XVIIIa)	−3.0*, −4.1**	[75, 14]	(LVI)	−1.9*	[75]
(XVIIIb)	−10.2**	[14]	(LXII)	−21 ÷ −22*	[72]

*Relative to the external standard—85% H_3PO_4.
**Relative to the internal standard—$(EtO)_3PO$.

The spectra of certain fluorine-containing phosphorus ylids have been investigated: infrared[14,34,45,50–52,54,64–66,75], ^1H NMR,[14,34,51,52,65,66,70–72] ^{19}F NMR,[11,14,17,34,38,50,60,70–73,75] ^{31}P NMR,[11,14,51,65,70–72,75] and mass spectra[75]. The structure of the ylids (IV) and (LIV) was confirmed by X-ray diffraction[15,72,74].

Table 2. The spin–spin coupling constants between ^{19}F and ^{31}P nuclei in fluorine-containing phosphorus ylids.

Ylid	*m**	*J*, Hz	Refs.	Ylid	*m**	*J*, Hz	Refs.
(XV)	4	3.5	[72]	(XXXVIIa)	3	13	[60]
(XVIIIa)	4	20.5	[34]	(LIV)	4	0.8	[72]
(XVIIIb)	4	1.1	[34]	(LVI)**	6	1.1	[75]

*Here *m* is the number of bonds separating the ^{19}F and ^{31}P nuclei.
**R = CF_3.

In the ^{31}P NMR spectra of fluorine-containing phosphorus ylids with three phenyl groups at the phosphorus atom the chemical shift due to the "ylid" phosphorus nucleus is in the range from −2 to −10 p.p.m. (Table 1). The replacement of the phenyl group by the n-butyl group leads to a downfield displacement of the ^{31}P NMR signal. Spin–spin interaction between the ^{19}F and ^{31}P nuclei, even those fairly remote from one another, is frequently observed in the ^{19}F NMR spectra (Table 2).

2. The Wittig Reaction

In contrast to halogenomethylenephosphoranes[1], the behaviour of other fluorine-containing phosphorus ylids in the Wittig reaction has still been inadequately investigated. As a rule these ylids exhibit a moderate or even a low reactivity in relation to carbonyl compounds. However, in certain cases it is possible to obtain fluorine-containing unsaturated compounds.

Hexafluoroisopropylidenetriphenylphosphorane (XXXV) reacts *in situ* under mild conditions with various aliphatic, aromatic, and heterocyclic aldehydes to form the corresponding olefins[20]#:

$$\underset{\text{(XXXV)}}{[Ph_3P{=}C(CF_3)_2]} + RCHO \xrightarrow[\text{ether}]{-78\div+20^\circ} \underset{\text{(yield = 26–62\%)}}{RCH{=}C(CF_3)_2} + Ph_3PO;$$

R=Ph, *p*-MeC_6H_4, *p*-$MeOC_6H_4$, $O_2NC_6H_4$, C_6F_5, PhMeCH, n-C_6H_{13}, PhCH=CH, 2-furfuryl, 2-pyridyl, or *m*-$CF_3C_6H_4$.

The reaction of the ylid (XXXV) with ketones cannot be achieved—owing to its low reactivity, there is sufficient time for its decomposition[20].

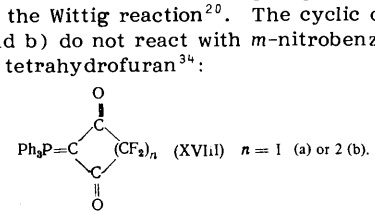
The cumulene ylid (XV) readily reacts with both aldehydes and ketones, but this leads to the formation of complex mixtures of unidentified substances[73]. The cumulated triene (LX) was isolated in the reaction with diphenylketen[72]:

$$\underset{\text{(XV)}}{Ph_3P{=}C{=}C(CF_3)_2} + Ph_2C{=}C{=}O \rightarrow \underset{\text{(LX)}}{Ph_2C{=}C{=}C{=}C(CF_3)_2} + Ph_3PO.$$

Pentafluorobenzylidenetriphenylphosphorane (XXI) reacts with pentafluorobenzaldehyde[36], *p*-chloro and *p*-nitro-benzaldehydes[38], and *t*-butyl- and trimethylsilyl-propiolaldehydes[80] to form the corresponding olefins:

$$\underset{\text{(XXI)}}{Ph_3P{=}CHC_6F_5} + RCHO \rightarrow RCH{=}CHC_6F_5;$$

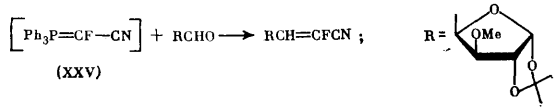
R=C_6F_5, *p*-ClC_6H_4, *p*-$O_2NC_6H_4$, $Me_3CC{\equiv}C$, or $Me_3SiC{\equiv}C$.



The *trans*-olefins are then usually formed preferentially.

trans-Decafluorochalcone (LXI) has been obtained by the reaction of pentafluorobenzoylmethylenetriphenylphosphorane (XXII) with pentafluorobenzaldehyde[37]:

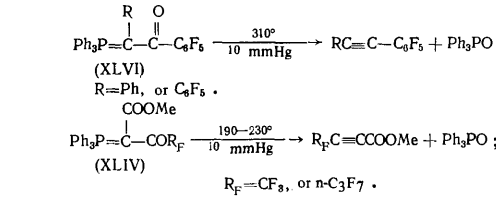
$$\underset{\text{(XXII)}}{Ph_3P{=}CHCOC_6F_5} + C_6F_5CHO \rightarrow \underset{\text{(LXI)}}{C_6F_5CH{=}CHCOC_6F_5}.$$



According to patent data[39–42], the phosphorus ylid $Ph_3P{=}CH(CH_2)_2CF_2COOH$ is used to synthesise fluorine-containing analogues of prostaglandin.

Perfluorocyclobutylidenetriphenylphosphorane (IV) does not undergo the Wittig reaction[20]. The cyclic diketoylids (XVIII, a and b) do not react with *m*-nitrobenzaldehyde on refluxing in tetrahydrofuran[34]:

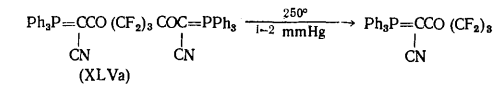
(XVIII) $n = 1$ (a) or 2 (b).



Cyanofluoromethylenetriphenylphosphorane (XXV) reacts with aldehydosugars to form the products of the Wittig reaction[47,48]:

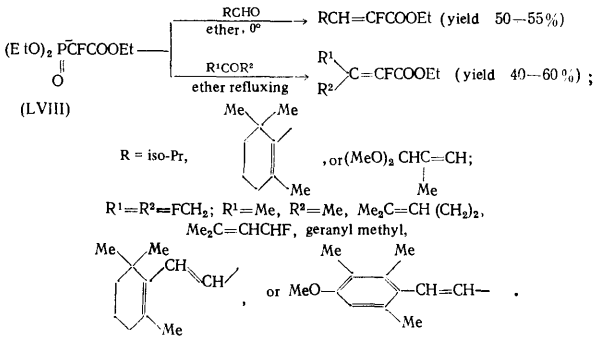
(XXV)

It has been claimed[20] that the trimethoxy-ylid $(MeO)_3P{=}C(CF_3)_2$ (XXXVIIa) does not react either with benzaldehyde or with trifluoroacetophenone.



Like the usual acylmethylenephosphoranes, their fluorine-containing analogues—pentafluorobenzoylylids (XLVI) [35] and also trifluoroacetyl- and perfluorobutyryl-ylids (XLIV) [67]—are capable of undergoing the intramolecular Wittig reaction to form the corresponding acetylenes:

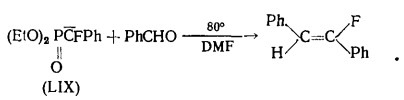
(XLVI) R=Ph, or C_6F_5.



(XLIV) R_F=CF_3, or n-C_3F_7.

The diacetylenes $RC{\equiv}C(CF_2)_3C{\equiv}CR$ could not be obtained from the bisylids $Ph_3P{=}CRCO(CF_2)_3COCR{=}PPh_3$ (XLV, R=CN or COOEt); in the case of the dinitrile (XLVa) an ylid containing the C≡C triple bond was isolated[45]:

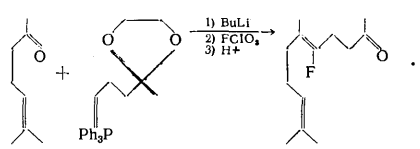
(XLVa)



The Wittig–Horner reaction has also been used to synthesise fluorine-containing unsaturated compounds. The reaction of the stable α-phosphonatecarbanion (LVIII) with aldehydes and ketones yielded various unsaturated fluorine-containing esters[76–78]:

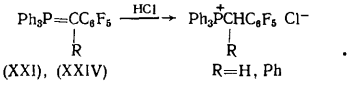
(LVIII)

In the reaction of the anion (LVIII) with ketones the yields of unsaturated compounds are lower than in the case of the analogous non-fluorinated anions. The reactions with asymmetric ketones give rise to mixtures of the *cis*- and *trans*-isomers, but the reaction with aldehydes is stereospecific—only the *cis*-isomers are obtained[76].



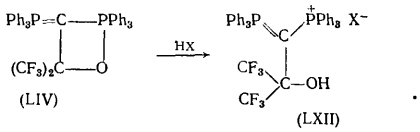
Trans-α-fluorostilbene has been obtained in 40% yield from the phenyl-substituted anion (LIX) and benzaldehyde[79]:

(LIX)



Fluorine-containing analogues of prostaglandin have been obtained with the aid of the Wittig–Horner reaction[81].

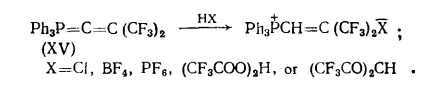
The SCOOPY (α-Substitution plus Carbonyl Olefination via β-Oxido Phosphorus Ylids) reaction is also used to synthesise fluorine-containing unsaturated compounds[7,82–85] (cf. Tyuleneva et al.[1]), for example:



3. Other Reactions

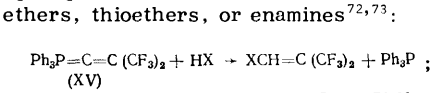
Phosphorus ylids usually combine very readily with acids to form phosphonium salts[3]. Fluorine containing phosphorus ylids behave similarly. Thus the reaction of pentafluorophenylylids (XXI) and (XXIV) with dry HCl yielded phosphonium chlorides[38]:

(XXI), (XXIV) R=H, Ph



Analogous reactions with the cyclic ylid (LIV) lead to the dissociation of the P–O bond and the formation of the salts (LXII):[73]

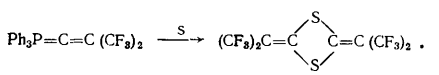
(LIV) (LXII)



The salts (LXII) with X = Cl,[71] Br,[70] BF_4,[70,72] PF_6,[70–72] BPh_4,[70] or CF_3COO [72] have been obtained in this way.

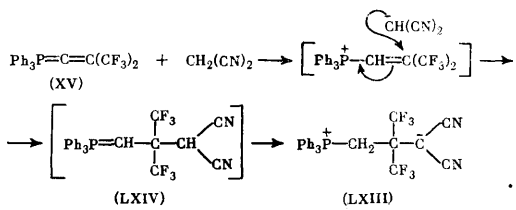
Alkenylphosphonium salts have been synthesised from hexafluoroisobutenylidenetriphenylphosphorane (XV):[72]

(XV) X=Cl, BF_4, PF_6, $(CF_3COO)_2H$, or $(CF_3CO)_2CH$.



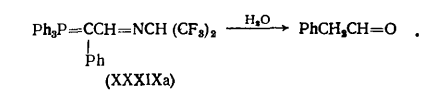
When the ylid (XV) is treated with alcohols, phenols, amines, or mercaptans the C–P bond is split with elimination of a tertiary phosphine and the formation of the corresponding alkenyl ethers, thioethers, or enamines[72,73]:

(XV) X=3, 4, 5-$Me_3C_6H_2O$, EtO, EtS, C_6Cl_5, or Ph_2N .



The reaction with *O*-deuteromethanol produced the deuterated ether $MeOCD{=}C(CF_3)_2$.[72]

The dimer of bis(trifluoromethyl)thioketen has been obtained from the ylid (XV) on treatment with sulphur:



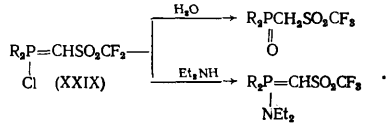
(XV)

Yet another reaction pathway is observed on treatment with malonodinitrile: this results in the formation of the betaine (LXIII), probably as a result of the prototropic isomerisation of the ylid (LXIV):[72]

(XV) (LXIV) (LXIII)

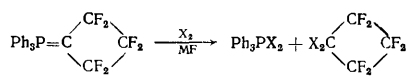
Hydrolysis of the phosphorus ylid (XXXIXa) leads to the splitting of the C=P and C=N bonds[65]:

(XXXIXa)



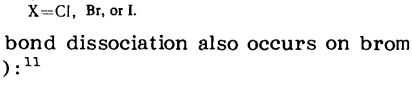
When perfluorocyclobutylidenetriphenylphosphorane (IV) is hydrolysed under mild conditions, the β-fluorine atoms are hydrolysed[14–16], whereas under severe conditions the ring is ruptured[34] (see Section II, 1 above). The diketo-ylid (XVIIIb) does not change on being refluxed with 50% sulphuric acid[34].

Hydrolysis of the trimethoxyphosphorus ylid (XXXVIIa) leads to a phosphonate ester[60]:



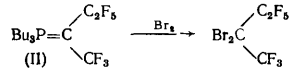
(XXXVIIa)

P-Chloro-ylids (XXIX) are converted on hydrolysis into phosphine oxides[50], while on treatment with diethylamine they give rise to phosphorus ylids containing the diethylamino-group at the phosphorus atom[50,51,53]:

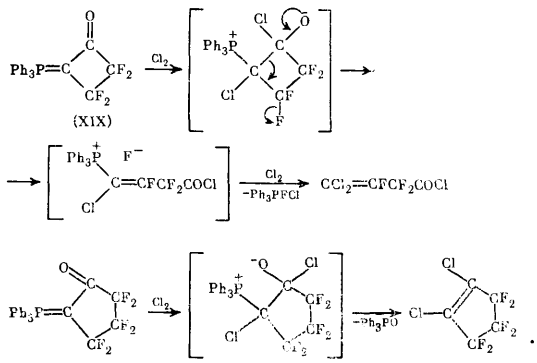


(XXIX)

The ylid (XXXVIIa) is readily brominated[60]:



The diketo-ylids (XVIII, a and b) are not brominated and are not oxidised by permanganate[34]§. In the presence of metal fluorides, the more reactive ylid (IV) is halogenated with dissociation of the C=P bond[16]:



(IV) X=Cl, Br, or I.

A similar bond dissociation also occurs on bromination of the ylid (II):[11]

(II)

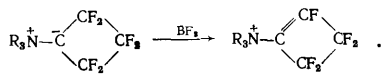
When the four-membered cyclic monoketo-ylid (XIX) is chlorinated, the ring is ruptured with formation of perhalogenovinylacetyl chloride; the five-membered analogue gives rise to dichloropentafluorocyclopentene[16]:

(XIX)

Stable cyclic diketoylids (XVIII, a and b) cannot be alkylated with methyl iodide on refluxing in acetone[34]. The ylid (LIV), containing the oxaphosphetan ring, also does not react with methyl iodide[71,72].

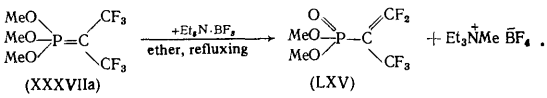
---

§ On oxidation with CrO_3 in acetic acid, the ylid (XVIIIb) gives rise to perfluorosuccinic acid[34].



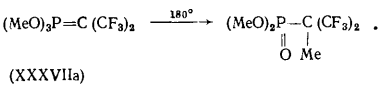
Pentafluorobenzylidenetriphenylphosphorane (XXI) is acylated at the "ylid" carbon atom[35] (see Section II, 3 above).

On treatment with metal salts, perfluorocyclobutylidenetriphenylphosphorane (IV) is converted into polyfluorocyclobutenylphosphonium salts[16]:



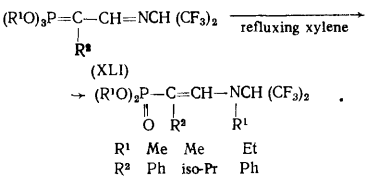
(IV)

The ylid structure is similarly converted into the cycloalkenylammonium structure on treatment of trialkylammonium perfluorocyclobutylids with boron trifluoride etherate[17]:



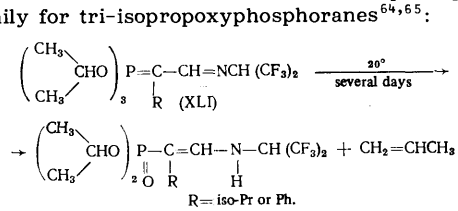
An analogous reaction is apparently possible also for the corresponding phosphorus ylids and the reverse reaction, involving the conversion of cycloalkenylphosphonium tetrafluoroborate into a phosphorus ylid—takes place on treatment with KF (cf. Burton and Shinya[11]). Treatment of the trimethoxyphosphorane (XXXVIIa) with the adduct of triethylamine and boron trifluoride leads to the simultaneous elimination of the alkyl group and the fluorine atom with formation of the phosphorus analogue of perfluoromethacrylic acid ester (LXV):[86]

(XXXVIIa) (LXV)



Certain phosphorus ylids containing alkoxy-groups at the phosphorus atom are capable of rearranging with transfer of the alkyl group from the oxygen atom to a carbon or nitrogen atom. Thus hexafluoroisopropylidenetrimethoxyphosphorane (XXXVIIa) is converted into the ester of hexafluoro-t-butylphosphonic acid on heating to 180 °C:[60]

(XXXVIIa)



In the presence of SbF_5, the reaction temperature is reduced to 140 °C.[87]

The phosphorus ylids (XLI) are converted slowly at room temperature and rapidly on heating into substituted phosphonate esters containing an alkyl group at the nitrogen atom[64,65]:

R^1	Me	Me	Et
R^2	Ph	iso-Pr	Ph

Apart from a rearrangement, when the ylids (XLI) are heated, the elimination of the alkyl group R^1 in the form of an olefin is observed. Such a reaction takes place particularly readily for tri-isopropoxyphosphoranes[64,65]:

R= iso-Pr or Ph.

Thus fluorine-containing phosphorus ylids exhibit a varied reactivity. Further investigation of the chemistry of these interesting compounds is necessary.

The Chemistry of Radon

V.V.Avrorin, R.N.Krasikova, V.D.Nefedov, and M.A.Toropova

We shall review the discovery of this element, studies of its chemical nature, and modern ideas on its chemical and physical properties. Possible chemical and nuclear-chemical methods of synthesising new radon compounds and of determining their properties and their identity will be discussed, using information published up to May 1980. 121 references.

I. INTRODUCTION

Only 20 years have passed since Bartlett[1] prepared the first compound of xenon. In this relatively short time many compounds of the elements of Group O of the Periodic Table have been synthesised and studied in detail. The large volume of work in this new branch of chemistry has already been reviewed several times[2-10], and the most recent work is discussed in a comprehensive review[11]. However, most of this work is aimed at the chemistry of xenon and krypton, and the chemistry of radon has attracted much less attention, no doubt as a result of the special problems presented by the chemistry of this element.

The aim of this review is to examine in detail the known chemical compounds of radon, and to discuss possible directions of further research into the chemistry of this element.

Radon, the last (and heaviest) member of Group VIIIa (the zero group) of the Periodic Table, is unique among the inert gases in not having stable isotopes. The presence of isotopes of the element "eka-xenon" in natural radioactive series was established shortly after the discovery of radioactivity. In 1899 Marie Curie found[12] that air which has been in contact with a radium compound acquires a substantial amount of radioactivity. Rutherford and Owens[13] measured the activity of thorium salts, and noted a lack of reproducibility in the electrometer readings which Rutherford ascribed to the diffusion of a gaseous radioactive substance evolved from the thorium samples. Somewhat later, Dorn observed a similar phenomenon in a study[14] of radium-containing barium salts.

Later work showed that these gaseous radioactive substances, which had been called radium and thorium emanations (from the Latin *emanatio*, discharge), are inert gases with a high molecular weight. A third radioactive gas, evolved from actinium preparations, was discovered (independently) by Giesel[15] and Debierne[16]. Shortly after the detection of the radioactive emanations from radium and thorium their chemical nature was studied in depth[17,18], using the strongest possible oxidising or reducing conditions in order to induce compound formation.

Thus, Rutherford and Soddy[17] passed thorium emanation over platinum or palladium black, lead chromate, zinc dust, and magnesium powder (at red heat) using air, hydrogen, or carbon dioxide as the carrier gas. They failed to detect any chemical reaction. Similar results were obtained by Ramsay and Soddy[18] after lengthy exposure of a mixture of radium emanation and oxygen to an electric discharge, and also after passing radium emanation over magnesium oxide at red heat.

Table 1. Radon isotopes[19].

Isotope	Type of reaction	$T_{1/2}$	Nuclear reactions yielding the given nucleus
^{202}Rn	α	13 s	^{197}Au—^{14}N—9 *n*; Pt(^{16}O); Hg(^{12}C); ^{197}Au(^{16}O)
^{203}Rn	α	45 s	^{197}Au—^{14}N—8 *n*; Pt(^{16}O); Hg(^{12}C); Au(^{14}N)
^{203m}Rn	α	28 s	^{197}Au—^{14}N—8 *n*; Pt(^{16}O); Hg(^{12}C)
^{204}Rn	α	75 s	Hg(^{12}C); ^{197}Au(^{16}O); Pt(^{16}O); ^{197}Au—^{14}N—7 *n*
^{205}Rn	α	1.8 min	^{197}Au(^{16}O); Tl(^{12}C)
^{206}Rn	α(65%), ε(35%)	6.5 min	^{197}Au—^{14}N—5 *n*; Pb(^{12}C); Hg(^{12}C); Pt(^{16}O); Tl(^{12}C); ^{197}Au(^{16}O)
^{207}Rn	α(4%), ε(96%)	10 min	^{197}Au—^{14}N—4 *n*; Hg(^{12}C); Pt(^{16}O)
^{208}Rn	α(20%), ε(80%)	21 min	^{232}Th(*p*); ^{197}Au—^{14}N—3 *n*
^{209}Rn	α(17%), ε(83%)	30 min	^{232}Th(*p*); ^{213}Ra(2,7 min)α
^{210}Rn	α(96%), ε(4%)	2,42 h	^{232}Th(*p*)
^{211}Rn	α(26%), ε(74%)	15 h	^{232}Th(*p*)
^{212}Rn	α	25 min	^{232}Th(*p*); ^{212}Fr (19.3 min) ε
^{213}Rn	α	—	^{209}Bi(^{12}C); Pb(^{12}C)
^{215}Rn	α	10^{-6} s	^{227}U (1,3 min)α; ^{219}Ra (1 ms) α
^{216}Rn	α	$4{,}5\cdot10^{-5}$ s	^{238}U α..., ^{220}Ra (10^{-2} s)α; ^{228}U (9,1 min)α, ε
^{217}Rn	α	$5.4\cdot10^{-4}$ s	^{229}U (58 min)α; ^{221}Ra (31 s)α
^{218}Rn	α	0.035 s	^{222}Ra (38 s)α
^{219}Rn(An)	α(β⁻)	4.00 s	^{223}Ra (11,2 day)α; ^{219}At (0,9 min) β⁻; ^{227}Th (18,2 day)α...
^{220}Rn(Tn)	α	51 s	^{228}Th (1,9 year)α
^{221}Rn	α(20%), β⁻(80%)	25 min	^{232}Th(*p*)
^{222}Rn(Rn)	α	3.825 day	^{230}U (21) day)α; ^{238}U α... ^{226}Ra (1622 year)α
^{223}Rn	β⁻	43 min	^{222}Rn—*n*—γ; ^{232}Th(*p*)
^{224}Rn	β⁻	1.9 h	^{232}Th(*p*)

This degree of chemical inertness was known only in gases of the "argon family", discovered shortly before radioactivity. There were therefore strong reasons for assigning the radioactive emanations to the zero group of the Periodic Table.

The term "emanation" was used for a long time as a "combined" name for the elements of atomic number 86, though even in 1912 Ramsay had proposed the name "niton", by analogy with the names of the inert gases, in order to stress the position of element 86 in the Periodic Table. In 1923 this element was given the name "radon" in keeping with international chemical nomenclature (from its longest-lived natural isotope ^{222}Rn, $T_{\frac{1}{2}} = 3.825$ days, formed by α-disintegration of radium), and the other two natural isotopes thoron Tn and actinon An became ^{220}Rn and ^{219}Rn respectively.

The nuclear characteristics of the radon isotopes known at present are summarised in Table 1 (taken from Ref. 19).

II. PHYSICAL PROPERTIES

Under normal conditions radon is a colourless monatomic gas. The earliest measurements on radon samples prepared by gas diffusion gave seriously inconsistent values for the density and the atomic weight of this element: for example, atomic weights in the range 40–234 a.m.u. were reported. Later measurements by Debierne[21], using the diffusion method, gave an atomic weight of 220–221 a.m.u. for radon, in good agreement with the value obtained by Gray and Ramsay[22] by density measurements, using a specially designed buoyancy microbalance in which small volumes (0.1 mm^3) of radon could be weighed with an error not greater than 1%. The density of gaseous radon measured in this way was 9.727×10^{-3} g cm^{-3}, from which the atomic weight of radon was calculated as 222.4 a.m.u. Liquid radon is a colourless phosphorescent substance having a density[3,20] of 5.7 g cm^{-3}. The other physical properties of radon are listed in Table 2.

Table 2. Physical properties of radon.

Parameter	Value
Boiling point, K	208 [23]
Melting point, K	202 [24]; 160 [25]
Critical temperature, K	377.5 [24]
Critical pressure, Pa	$6.12 \cdot 10^6$ [24]
Molar heat of melting, kJ	2.717 [24]
Molar heat of evaporation, kJ	16.553* [27]; 18,338** [27] 19.228* [28]
Diameter of molecule, Å	3.64 [27]; 3,70 [29]
Viscosity at 273 K, Pa s	$2.13 \cdot 10^{-5}$ [30]
at T_{crit}, Pa s	$2.954 \cdot 10^{-5}$ [30]
Absorption cross-section for thermal neutrons (^{222}Rn), barn	0,72 [31]

*Calculated from the temperature dependence of the vapour pressure.
**Calculated by Trouton's rule.

Radon is sparingly soluble in water, its solubility being higher than that of the higher inert gases. The solubility of radon in water has been measured at low temperatures[32–35], and found to be lowered by the presence of various salts[36,37]. A study[36] of the distribution of radon between carbon tetrachloride and calcium chloride solutions of different concentration has shown that the decrease in solubility (salting-out effect) is due to the change in the activity of water in solution, which affects the hydration of the radon atoms.

Radon is appreciably more soluble in organic liquids than in water[35,37,38]. The solubility in alcohols and in fatty acids has been found[39,40] to increase with the number of the homologous group in the solvent molecule.

III. CLATHRATE COMPOUNDS OF RADON

The many unsuccessful attempts at preparing compounds of Group 0 elements led to the widespread belief (among chemists) in the absolute chemical inertness of these elements[21,41,42]. Theoretical calculations of the heats of formation of hypothetical halides and oxides of the inert gases, based on a Born cycle, confirmed that these compounds cannot be formed because all the reactions which might lead to them are strongly endothermic[43]. Only for radon fluoride was a heat of formation of ~41.8 kJ $mole^{-1}$ obtained. Thus it appeared useless, at the time, to search for compounds in which the inert gases are held by an ionic or covalent bond.

However, many compounds formed by van der Waals forces are known in chemistry. Compounds of this type involving the inert gases have been known for a long time: they include argon hydrate, discovered by Villard[44], and the hydrates of krypton[45] and xenon[46], discovered by Forcrand. All these compounds were obtained by compressing the inert gas (over water) to a pressure in excess of the dissociation pressure of the hydrate at the experimental temperature: thus, according to Forcrand, the dissociation pressure of argon hydrate at 273 K is 9.61×10^6 Pa, that of krypton hydrate is 1.42×10^6 Pa, and that of xenon hydrate is 1.13×10^6 Pa. The exact composition of these compounds was not determined at the time, but on general grounds it was assumed to be $Y_b \cdot 6H_2O$, where Y_b is an atom of the inert gas[47,48].

There can be no doubt about the existence of a similar compound of radon. However, its detection by the conventional method (change in vapour pressure) would require an impossibly large amount of radon.

Table 3. Stability of the hypothetical hexahydrates $A \cdot 6H_2O$.[42]

A	$10^{-25}\alpha$	$10^{-18}\mu$	I, kJ $mole^{-1}$	p, Pa
H_2S	37.8	0.93	100	95 980
Cl_2	46.1	0.23	127	33 730
Rn	54.2	0	103	39 990
SO_2	37.2	1.6	128	33 320

A new method of preparing and studying the molecular compounds of the inert gases, based on the phenomenon of isomorphous co-crystallisation, was proposed by Nikitin[42]. The method consists in co-precipitating the experimental substance (gas) with crystals of a known molecular compound (carrier). The method allows the formation of a molecular compound of the inert gas to be studied irrespectively of its absolute concentration. Nikitin showed that if two substances have similar van der Waals force components, and similar sizes, the molecular compounds which they form with a third substance should be similar, of comparable stability, and able to form mixed crystals. This rule can be used to define series of analogues among substances giving rise to molecular compounds.

Thus, by comparing the molecular characteristics of known hydrates with those of hydrates which had not yet been prepared (including that of radon) Nikitin concluded that the stability of radon hydrate should be of the same order as the stabilities of the hydrates of chlorine and sulphur dioxide, and significantly higher than the stability of the hydrate of hydrogen sulphide.

Indeed, in a study of the behaviour of radon during the deposition of SO_2 and H_2S hydrates Nikitin[42] demonstrated the formation of radon hydrate, co-precipitated isomorphously with the above hydrates. By using ultramicroscopic amounts of radon (~10^{-11} g) Nikitin was able to study the distribution of the element between the gas phase and the crystals of SO_2 and H_2S hydrates at a temperature (269.6 K) below the eutectic points of the SO_2–H_2O (270.5 K) and H_2S–H_2O (272.7 K) systems. The distribution coefficient of radon was found to be a constant irrespective of the direction from which equilibrium had been approached and of the relative volumes of solid and of gaseous phase. This demonstrated the isomorphous incorporation of radon into the lattice of SO_2 and H_2S hydrates as a radon hydrate of similar composition ($Rn \cdot 6H_2O$).

The relative values of the dissociation pressure of the inert gas hydrates show that the stability of these compounds increases with the atomic number of the inert gas (see Table 4): this suggests that polarisability effects are dominant in determining the stability of molecular hydrates. A method of separating the inert gases can be based on the difference between their dissociation pressures[42].

Table 4. Relative stability of the inert gas hydrates[42].

Inert gas	$10^{25}\alpha$	I, kJ mole^{-1}	$10^{8}r$, cm	$10^{-4}P_{diss}$, Pa
Rn	54.2	103	2.2	3.92
Xe	40.0	117	2.18	$1.13 \cdot 10^{2}$
Kr	24.6	134	1.98	$1.42 \cdot 10^{2}$
Ar	16.3	151	1.82	$9.66 \cdot 10^{2}$
Ne	3.9	207	1.6	—

Molecular compounds of the inert gases other than the hydrates have also been prepared by isomorphous co-crystallisation, including compounds of radon with phenol ($Y_b \cdot 3C_6H_5OH$), toluene ($Y_b \cdot 2C_6H_5CH_3$), and *para*-chlorophenol ($Y_b \cdot 3p\text{-}ClC_6H_4OH$).[42] Attempts to prepare molecular compounds of radon with aluminium halides, analogous to the hydrogen sulphide compounds $AlBr_3 \cdot H_2S$ and $AlCl_3 \cdot H_2S$, were unsuccessful[42].

According to current views on the structure of clathrate compounds[49–51] these materials should be treated as "intercalation" compounds, in which the included gas atoms or molecules are held by van der Waals forces in holes of the crystal lattice of the "host" substance.

IV. STABILITY OF RADON COMPOUNDS

The rapid development of the chemistry of the inert gases began with the discovery, in 1962, of the xenon compounds[1]. Within a relatively short time many compounds of different members of this group of elements (though mostly of xenon) had been prepared and studied in detail. Advances in radon chemistry were on a far more modest scale: only the lower fluoride of radon (RnF_2) and some of its complexes are known at present.

A comparison of the stabilities of compounds of the various inert gases suggests that the chemistry of radon should be at least as varied as the chemistry of the lighter inert gases (in particular, xenon). Thus, the heats of formation of argon, krypton, and xenon fluorides show a clear tendency for the stability of the fluoride to increase with the atomic number of the inert gas. This is ascribed to the increase in the ionisation potential from argon to krypton and xenon (see Table 5). Hence the radon fluorides should be even more stable than the corresponding xenon compounds.

Table 5. Ionisation potentials of the inert gases[62].

Element	He	Ne	Ar	Kr	Xe	Rn
$10^{-3}I$, kJ mole^{-1}	2.371	2.079	1.519	1.350	1.170	1.034

Quantum-mechanical calculations[52] of the bond ionicity and of the stability of the inert gas halides (Table 6) show an increase in the heat of formation with the atomic number of the inert gas and with the electronegativity of the ligands. The heats of formation of the radon compounds were not calculated because the ionisation potential of the element was not adequately known, but the existence of the compounds RnF_4, RnF_2, and $RnCl_2$ was thought to be possible[52].

Table 6. Bond ionicity (a), dissociation energy (E_{diss}), and heat of formation (ΔH_f°) of some inert gas halides[81,116].

Halide	a, %	E_{diss}, kJ mole^{-1}	ΔH_f^0, kJ mole^{-1}	Halide	a, %	E_{diss}, kJ mole^{-1}	ΔH_f^0, kJ mole^{-1}
XeF_4	58	208.0	−515	$KrCl_4$	37	−24.0	571
KrF_4	47	78.7	−2	XeF_2	63	101.3	−46
ArF_4	53	46.1	225	KrF_2	63	59.0	22
NeF_4	33	−452.0	2123	$XeCl_2$	54	29.7	180
$XeCl_4$	45	66.2	213				

Similar conclusions were reached[53] in a comparison of the electronegativities of the inert gas atoms and of the ligands, which led to the following stability sequences for the compounds of the group zero elements: radon fluoride > xenon fluoride > krypton fluoride; xenon fluoride > xenon oxide > xenon chloride.

Table 7. Electronegativity of the inert gases, halogens, and oxygen[8].

Element	κ	Element	κ
He	4.53	F	3.98
Ne	3.98	Cl	3.16
Ar	2.91	Br	2.96
Kr	2.58	I	2.66
Xe	2.24	O	3.44
Rn	1.98		

The electronegativities of the inert gases, halogens, and oxygen are listed in Table 7.

These qualitative estimates of the stability of the radon halides were confirmed by thermodynamic calculations of the heat of formation of the compounds. Thus, by using

Pitzer's method[54] Vasilesku[55] was able to calculate the heats of formation of the radon fluorides and chlorides, and he concluded that the chlorides as well as the fluorides of radon are thermodynamically stable. The calculation was based on the iso-electronicity principle, according to which compounds with the same number of valence electrons have similar structures and bond dissociation energies (examples of iso-electronic pairs are ZeF_2 and IF_2^-, XeF_4 and IF_4^-, XeO_3 and IO_3^-, etc.). By using this principle we can treat the halogen monofluorides as pseudo-inert gas atoms. The enthalpy of formation of the inert gas halide XY_bX (where Y_b is an inert gas atom and X is a halogen) can therefore be related to the heats of formation of the halides of other group zero elements or to the heats of formation of their iso-electronic inter-halogen compounds by the equation

$$\Delta H_{ab}=\Delta H_a+\Delta I_{ab},$$

where ΔH_{ab} is the heat of formation of Y_bX_2, ΔH_a is the heat of the reaction $Y_a + X_2 = Y_aX_2$, and ΔI_{ab} is the difference between the ionisation potentials of the central atoms in Y_bX_2 and Y_aX_2. The heats of formation of the radon halides calculated[55] by this equation are given in Table 8.

Table 8. Heat of formation of some radon halides[8].

Standard compound	$10^{-3}\Delta I_{ab}$, kJ mole^{-1}	$10^{-3}\Delta H_a$, kJ mole^{-1}	Radon compound	ΔH_f^0, kJ mole^{-1}
ClF_3	2.21	−1.06	RnF_2	−314
BrF_3	1.05	−2.03	RnF_2	−297
XeF_2	1.39	−1.54	RnF_2	−314
XeF_2	1.39	−2.17	RnF_4	−360
ICl_3	−0.29	−0.61	$RnCl_2$	−31.8

More accurate values of the heat of formation of the radon fluorides, calculated by the same method but using more reliable values of the heats of formation of the xenon fluorides and of the ionisation potential of radon, are given in Ref.11: $\Delta H_f^\circ(RnF_2)_g = -240$ kJ mole^{-1}, $\Delta H_f^\circ(RnF_4)_g = -340$ kJ mole^{-1}, and $\Delta H_f^\circ(RnF_6)_g = -412$ kJ mole^{-1}.

Radon octafluoride should be much less stable than the hexafluoride[56], because the transition from the fifth to the sixth period of elements is accompanied by a sharp fall in the stability of the higher-valency compounds, due to the "inert pair" effect. This tendency is clearly displaced by all the elements of the sixth period from thallium to polonium[57].

As regards oxygen compounds of radon, the tendency for the stability of the compound to increase with the atomic number of the inert gas suggest that oxides of six- or eight-valent radon (iso-electronic with the known astatine forms AtO_3^- and AtO_4^-) could exist[58]. The existence of radon dioxide, which should be more stable than the (unstable) xenon dioxide, is also a possibility.

Thus there are grounds for the belief that the chemistry of radon is rich and complex: however, its study so far has been complicated by many special problems.

V. SPECIAL ASPECTS OF THE STUDY OF RADON CHEMISTRY

Experimental studies of the chemistry of radon are complicated by the unfavourable nuclear characteristics of the known isotopes of this element. The longest-lived isotope (^{222}Rn) has a half-life of only 3.825 days. Working with relatively large amounts of radon (in order to make use of the standard methods of physicochemical analysis) causes difficulties, due to the high activity and to the resulting decomposition of the compounds by auto-radiolysis under the influence of the emitted α-particles. Chemical identification of the compounds in experiments with submicroscopic amounts of radon is possible only by comparing the properties and the behaviour of the radon compounds obtained with those of known compounds (of the same type) of neighbouring elements in the Periodic Table. However, we should note that the filling of the 4*f* sub-shell in elements of the sixth period could magnify the difference in properties between the compounds of elements in periods 6 and 5 (as compared with the same differences for elements of the higher periods). Thus we can expect radon to be more "metallic" than xenon[59–61], and this expectation is borne out by the ionic form of radon difluoride (in contrast to the molecular form of the corresponding fluoride of xenon)[56,60]. Quantum-mechanical calculations[60] have confirmed that an increase in the ionicity of the fluoride should occur also between radon and element 118.

These problems in the synthesis and identification of radon compounds add further complication to the study of the chemistry of radon. Adloff, in a special publication[62] on the radiochemistry of the inert gas compounds, wrote that "the chemistry of radon will never reach the same level of development as that of xenon because of the difficulties arising from the specific properties of this element".

VI. RADON COMPOUNDS

As stated above, the most useful isotope for the preparation of radon compounds and the study of their properties is the longest-lived of the isotopes (^{222}Rn). For experiments under dynamic conditions we can also use the short-lived radon isotopes ^{219}Rn and ^{220}Rn, formed by the reactions

$$^{226}Th_{1,9\ yr} \xrightarrow{\alpha} {}^{224}Ra_{3,64\ day} \xrightarrow{\alpha} {}^{220}Rn_{54,5S} \xrightarrow{\alpha} {}^{216}Po$$
$$^{227}Th_{18,17\ day} \xrightarrow{\alpha} {}^{223}Ra_{11,7\ day} \xrightarrow{\alpha} {}^{219}Rn_{3,92S} \xrightarrow{\alpha} {}^{215}Po$$

There are several methods of preparing inert gas fluorides, differing either in the choice of fluorinating agent or in the method of initiating the reaction.

Elementary fluorine, halogen fluorides, oxygen[63] or nitrogen[64] fluorides, fluorinated organic compounds[65], and some other substances have been used as fluorinating agents. The reaction can be initiated by heating the mixture, by u.v. irradiation[66,67], by an electric[68–71] or a microwave discharge[72], or by exposing the reaction mixture to γ-rays[73], to high-energy electrons[74,75], or to protons[76].

Radon fluoride can be prepared, apparently, by all these methods. It was first obtained by the most widely used of them (reaction between the inert gas and fluorine at high temperature). Heating a mixture of a small amount (1–100 μCi) of radon with fluorine at ~4×10^4 Pa pressure for 30 min at 673 K produced radon fluoride[77]. The evidence for the formation of a chemical compound was the large decrease in the volatility of radon (elemental radon sublimes easily at 195 K) produced by the admission of fluorine into the reaction vessel. The resulting fluoride had a very low volatility, and could not be sublimed in a vacuum of 10^{-4} Pa at temperatures below 500–520 K. Fluorination of a mixture of xenon and radon by a ten-fold excess of fluorine at 673 K and 3.4×10^5 Pa pressure produces di- and tetrafluorides of xenon, which readily sublime in a vacuum at 323 K, and radon fluoride which is fully retained in the reaction vessel[52]. However, when the experiment was repeated with a 100-fold excess of fluorine (573 K, 9.8×10^6 Pa) a significant amount

of radon was distilled at room temperature together with the xenon hexafluoride which was formed under these conditions[5]. The radon fluorides obtained in this work were not identified: the only comment[77] was that the product can be quantitatively reduced by hydrogen at 773 K. Micro-quantities of radon fluoride do not show any radiation-induced decomposition[77].

Chemical combination of radon by reacting with ClF_3, KrF_2, or xenon fluoride at room temperature has been reported[5], and also by reacting with oxygen monofluoride at 173 K.[78] These reactions can take place in metal, quartz, or Teflon vessels, but the reaction in a Teflon vessel yields a more volatile compound: the product of the reaction in a glass vessel is less volatile, and a still less volatile product is obtained in a metal vessel. These observations show that the surface of the reaction vessel plays an important role in the synthesis of radon fluoride.

Sufficiently large samples of radon react with liquid fluorine or solid ClF_3 (but not with chlorine) under the influence of the intrinsic α-radiation to give an involatile product. Unfortunately, a detailed description of these experiments[5] has not yet been published.

The oxidation of microgramme quantities of radon with liquid BrF_3, BrF_5, or ClF_3 also yields involatile forms of radon[61]. Between 0.12 and 0.32 Ci of radon was condensed at 73 K in a reaction vessel containing the freshly prepared fluorine halide, the mixture was thawed out, and it was allowed to warm up to room temperature over 1.5 h. Under these conditions the radon was concentrated in the lower part of the reaction vessel, and the fluorine halide which was pumped out was inactive. Dilution of an aliquot of the solution (containing 15 mCi of radon per mole of BrF_3) with fresh bromine trifluoride caused a change in specific activity strictly related to the dilution. The solutions could be centrifuged and decanted without loss of radon. The solid obtained by evaporating the solution to dryness was not identified, but the similarity between its hydrolysis and that of xenon difluoride was pointed out. It was suggested[61] that the radon is present as Rn^{2+} cations in these solutions.

The same method was used to prepare stable solutions of oxidised radon in a large number of non-aqueous solvents[79]: ClF, ClF_3, ClF_5, BrF_3, BrF_5, IF_7, an equimolar mixture of bromine and BrF_3, solutions of BrF_3 in HF and in IF_5, of BrF_5, in HF, and of K_2NiF_6 in HF. The use of arsenic, antimony, or iodine pentoxides as fluorinating agents, like the use of hydrogen fluoride, did not yield radon compounds. These observations allowed an estimate to be made[79] of the free energy of formation of radon fluoride, which must lie between the highest value of the reduction energy in the series of fluorides which oxidise radon [$E(BrF_3)$ = 167 kJ mole^{-1}] and the lowest value in the series of fluorides which fail to oxidise it [$E(AsF_5)$ = 256 kJ mole^{-1}]. When recalculated for the standard state this estimate becomes 121–214 kJ mole^{-1}.

The electro-migration of the radon compound in various solutions was studied in order to determine the charge and the chemical properties of the oxidised forms of radon[79]. The results were surprising. In pure BrF_3 solutions the radon migrates only to the cathode, but it is not discharged and it accumulates in the cathode compartment. Evidently in this solution the radon fluoride is ionised as follows[80].

$$RnF_2 \rightleftarrows RnF^+ + F^-$$
$$RnF^+ \rightleftarrows Rn^{2+} + F^- .$$

In solutions of BrF_3 in HF small quantities of radon are found in the anode compartment, and in a solution of BrF_3 in IF_5 no migration is observed. However, by saturating this solution with a strong electrolyte (KF or CsF) both cationic and anionic forms of radon are produced. This behaviour can be explained by assuming that the radon fluoride (for example, RnF_2) behaves as a Lewis base towards BrF_3 (i.e. as a donor of fluoride ions), and as a Lewis acid (i.e. as an acceptor of fluoride ions) towards compounds with a strongly developed donor function such as KF:

$$RnF_2 + BrF_3 \rightleftarrows RnF^+ + BrF_4^-$$
$$RnF_2 + KF \rightleftarrows K^+ + RnF_3^- .$$

Processes of this type are known for the fluoride of many elements in solutions of BF_3, BrF_3, BrF_5, ClF_3, etc.[81]

These workers assumed that the most likely product of the interaction between radon and fluorine or other fluorinating agents is radon difluoride, though no strict proof was given. Attempts to analyse the radon fluoride mass-spectrometrically were unsuccessful: no peaks could be recorded other than those for the full decomposition products (radon and fluorine)[79].

As stated above, one way of determining the composition of the resulting radon compounds is to compare their properties with those of the known xenon compounds. This approach has been used[82,83] to identify the chemical forms of radon produced by oxidation with strong fluorinating agents. The co-precipitation of the resulting radon fluoride with the xenon fluorides and their derivatives was studied in a special series of experiments. The macro-components were molecular crystals of the xenon fluorides themselves (XeF_2 and XeF_4), adducts of xenon difluoride and iodine pentafluoride ($XeF_2 \cdot 2IF_5$), or ionic crystals of a fluorine–xenon salt ($XeF^+Sb_2F_{11}^-$), and the solvent was iodine pentafluoride or bromine pentafluoride. The radon fluoride was prepared by treating radon with elemental fluorine and bromine pentafluoride, or with xenon di- and tetrafluoride or their solutions in iodine pentafluoride[82] or in bromine pentafluoride[83]. The co-crystallisation experiments showed that whatever the choice of fluorinating agent the radon compound obtained can be incorporated in the lattice of both molecular (XeF_2, $XeF_2 \cdot 2IF_5$)[58] and ionic compounds of bivalent xenon ($XeF^+Sb_2F_{11}^-$),[59] but not in quadrivalent xenon compounds. This suggests a similarity, both chemical and structural, between the radon compound and xenon difluoride.

Only the lower fluoride of radon is formed, apparently, because of the appearance of stable complexes of the $RnF^+MF_6^-$ type on the (fluoridised) metal surface of the reaction vessel, which prevents further fluoridation. The formation of complex fluorides is known to cause a substantial increase in the stability of inert gas fluorides. Thus, in contrast to krypton difluoride (which is unstable at room temperature), its adducts with antimony pentafluoride $KrF^+SbF_6^-$ are stable up to 353 K, and the $KrF^+Sb_2F_{11}^-$ adducts are stable up to 323 K.[84] The energy of the Kr–F bond is increased from 48 kJ mole^{-1} in KrF_2 to 135 kJ mole^{-1} in $KrF^+SbF_6^-$.[85]

Among the xenon compounds the tendency to form these adducts is more marked in the difluoride than in the tetrafluoride. The same is true, apparently, in the case of radon: furthermore, the stability of the radon double fluorides can be expected to be very much greater than that of the corresponding xenon compounds.

The radon double fluorides $RnF^+MF_6^-$ and $RnF^+M_2F_{11}^-$ can also be formed by treating radon with oxidising agents such as ClF_2SbF_6, BrF_2SbF_6, $BrF_4Sb_2F_{11}$, $IF_4(SbF_6)_3$, BrF_2BrF_6,[86] and O_2SbF_6.[87] We shall discuss these reactions and their potential practical applications in the next Section.

All attempts to prepare radon compounds other than fluorides have been unsuccessful. A study of the interaction (both thermal and photochemical) of radon with chlorine gave

inconclusive results[88]. No definite proof of compound formation was obtained in attempted reactions between radon and oxygen, ozone, or iodine monochloride[88], even when u.v. radiation and electrical or microwave discharges were used as reaction initiators[88,89]. The application of electrical or microwave discharges caused fixation of the radon on the walls of the quartz reaction vessel, possibly through the formation of very stable radonates. Thus, the radon daughter products ^{214}Bi, ^{218}Po, and ^{214}Pb are evolved when the vessel is heated to 873 K, but radon itself remains bound to the surface. However, the possibility of chemical stabilisation of the radon through the formation of oxides or silicates is not excluded[88].

VII. RADIOCHEMICAL SYNTHESIS OF RADON COMPOUNDS

In addition to the classical methods of synthesis, radiation-chemical methods and methods based on the chemical after-effects of nuclear reactions have been used in the preparation of compounds of the inert gases (β^-, β^+, and α disintegration, electron capture, isomeric transition, fission reactions, etc.). By using some of these reactions we can not only prepare known compounds but also (in some cases) predict the synthesis of new compounds.

The processes which have been most widely used in the synthesis of inert gas compounds involve the β^- disintegration of halogens incorporated in various compounds. The chemical reactions occurring during the β disintegration of atoms in molecular systems are the after-effects of nuclear, atomic, and molecular processes. The composition and charge of the nucleus (and, therefore, its nature) are altered by nucleonic processes such as the conversion of a neutron into a proton or a proton into a neutron. At the atomic level these processes can be described as

$$[^AM_z]^q \xrightarrow{\beta^-} [^AN_{z+1}]^{q+1};$$
$$[^AM_z]^q \xrightarrow{\beta^+} [^AN'_{z-1}]^{q-1},$$

where z is the charge on the nucleus, A is the mass number, M is the nucleus of the parent atom, N and N′ are nuclei of the daughter atoms, and q is the charge on the parent atom.

Table 9. Main physical characteristics* of nuclear reactions leading to the formation of radon isotopes[107].

Parent isotope	$T_{1/2}$	Type of reaction	$10^{13}E$, J	Daughter isotope	$T_{1/2}$
^{213}Ra	2.7 min	α	11.0	^{209}Rn	30 min
^{212}Fr	19.3 min	EC (56%)	—	^{212}Rn	25 min
^{219}Ra	10^{-3} s	α	12.8	^{215}Rn	10^{-6} s
^{220}Ra	10^{-2} s	α	11.9	^{216}Rn	10^{-4} s
^{221}Ra	30 s	α	10.8	^{217}Rn	10^{-3} s
^{222}Ra	38 s	α	10.4	^{218}Rn	$2\cdot10^{-3}$ s
^{223}Ra	11.2 day	α	9.2	^{219}Rn	3.92 s
^{219}At	0.9 min	β (3%)	—	^{219}Rn	3.92 s
^{224}Ra	3.64 day	α	9.1	^{220}Rn	54.5 s
^{226}Ra	1620 year	α	7.6	^{222}Rn	3.82 day

*$T_{1/2}$ is the half-life, E is the energy of the particles.

If an atom undergoing β disintegration is part of a stable molecular system, the resulting molecular system should also be stable[90] (by the iso-electronic triad rule).

Methods based on β disintegration processes have yielded a large number of inorganic (or organic) neutral (or charged) molecular forms of xenon[91–105], such as

$$*IO_3^- \xrightarrow{\beta^-} *XeO_3$$
$$*IO_4^- \xrightarrow{\beta^-} *XeO_4$$
$$*IF_5 \xrightarrow{\beta^-} *XeF_5^+$$
$$C_6H_5{}^*I \xrightarrow{\beta^-} [C_6H_5{}^*Xe]^+.$$

We should stress that organic compounds of the inert gases have not so far been prepared by classical chemical methods.

Unfortunately, in the case of radon the use of these methods is limited by the small choice of radioactive reaction chains suitable for the synthesis and identification of radon compounds. Radon isotopes are formed by the β^- disintegration of astatine, K-capture of francium isotopes, and α disintegration of radium isotopes. The main characteristics of these nuclear reactions are listed in Table 9.

We note from these results that only one case of β disintegration leading to the formation of a radon isotope is known:

$$^{219}At \xrightarrow{\beta^-} {}^{219}Rn .$$

However, the practical application of this transformation to the synthesis and study of radon compounds is complicated by the very small number of transitions leading to the formation of ^{219}At (6×10^{-5}%), the small probability of disintegration by the emission of β^- particles (3%), the very short half-lives of the parent astatine isotopes (54 s) and daughter radon isotopes (3.92 s), and our inadequate knowledge of the chemistry of astatine.

Table 10. Retention of ^{212}Rn in a chemically bound state in the disintegration of ^{212}Fr in a caesium salt[107].

Salt	Retention, %	
	in solutions	in crystals
$CsClO_4$	13±5	29±5
$CsIO_4$	11±2	25±5
$CsXeO_3F$	12±4	32±12

A more promising method of radiochemical synthesis of radon compounds is electron capture (EC) in ^{212}Fr nuclei. Following the disintegration of the nucleus by electron capture from one of the inner shells, the atoms of the daughter element acquire a large positive charge by a sequence of Auger transitions. The redistribution of this charge between the structural units of a complex molecule, and the subsequent Coulombic interaction between charges of the same sign, cause the molecule to dissociate into fragments. The neutralisation of these fragments by electrons can bring about a situation conducive to the formation of new chemical bonds. Thus, the Mössbauer effect has been used[106] to detect chemically bound forms of krypton produced by electron capture in the ^{83}Rb isotope present in isotopically enriched rubidium halides.

The possible use of electron capture processes in the synthesis of radon compounds is discussed in a study[107] of the chemical after-effects of the reaction $^{212}Fr \xrightarrow{E.C.} {}^{212}Rn$ in various caesium salts. Francium-212 ($T_{1/2}$ = 19.3 min) was obtained by irradiating a thorium target with protons of energy $E = 1.1 \times 10^{-10}$ J. The francium was removed from the target by a rapid method[108] involving co-precipitation of the francium with silicotungstic acid and separation of the francium by partition chromatography. Accumulation of

radon took place in the crystals of caesium salts containing the francium, or in solutions of these salts in 0.05 M xenon trioxide. The retention of radon in a chemically bound state is summarised in Table 10. It was suggested[107], by analogy with the xenon compounds, that the stabilisation form of the radon is the trioxide, but attempts at isolating the trioxide by coprecipitation with barium xenate or by chromatographic methods with XeO_3 as the carrier were unsuccessful.

Thus the chemical form of the trapped radon has not yet been established. However, the extent to which radon is retained in a chemically bound state strongly suggests the formation of oxygen-containing radon compounds.

The α disintegration of radium in various salts could also be a convenient radiochemical method of synthesis of radon compounds. Though α disintegration processes are far less commonly used for synthetic work than β disintegration, they have often been applied with success. For example, the formation of volatile lead compounds by the reaction $^{216}Po \xrightarrow{\alpha} {}^{212}Pb$ in the presence of gaseous hydrocarbons has been demonstrated[109]. A study of the after-effects of the α disintegration of ^{238}U in the uranylbenzoylacetonate complex has revealed a retention of $^{234}Th(UX_1)$ as high as 20–50% in acetone solution and 80–90% in the solid phase[110].

The recoil energy of the radon atoms formed by the α disintegration of radium-226 is ~1.4×10^{-14} J, and the mean free path of the radon recoil nuclei in the radium fluoride lattice is 200–300 Å.[62] Local temperature rise may favour the recombination of radon and fluorine atoms to give radon difluoride or even higher fluorides. Stabilisation of the radon formed by the α disintegration of radium in $RaCl_2$ as $RnCl_2$ cannot be excluded[62].

The first practical application of α disintegration processes to the synthesis of radon compounds was a study[111] of the stabilisation form of the radon produced by the α disintegration of ^{226}Ra in strongly oxidising solutions. The authors[111] noted differences in the amount of elemental radon extracted by hexane from a 10^{-7} M aqueous solution of $RaBr_2$ and from solutions containing HNO_3, $K_2S_2O_8$, $KMnO_4$, and other oxidising agents. A chromatographic study of the chemical state of the resulting radon indicated the formation of radon trioxide in acid media and (by analogy with the xenon compounds) $HRnO_4^-$ in alkaline solutions. However, these results were obtained only when the radon was in equilibrium with its parent ^{226}Ra: all attempts to oxidise elemental radon separated from the radium were unsuccessful[111].

On repeating these experiments it was found[112] that the whole of the "oxidised" radon can be removed from the solution by centrifuging: in other words, the decreased extractability of the radon arises not from the formation of oxygen-containing radon compounds but from the formation of ^{226}Ra colloids.

Further studies of the possible application of chemical changes accompanying the α disintegration of ^{226}Ra to the synthesis of oxygen-containing radon compounds involved the accumulation of radon in solutions of barium (radium) salts in HCl, HNO_3, HNO_3 containing XeO_3 (as a carrier for RnO_3), $HClO_4$ containing XeO_3, and also in crystals of barium (radium) perxenate[113]. However, the whole of the radon formed by α disintegration was found to be in the elemental state. The absence of oxygen-containing radon compounds was explained[113] by postulating a zero mean charge on the radon recoil nucleus.

Other types of nuclear reaction can also be used to study the possible formation of chemical compounds by radon: in particular, nuclear reactions induced by accelerated elementary particles. These methods have been used successfully in the radiochemical synthesis of compounds of the lighter inert gases. Thus, irradiation of sodium perbromate crystals with protons of energy $E = 1.6 \times 10^{-10}$ J gave high retentions of krypton in a chemically bound state, possibly through the formation of oxygen-containing compounds[114].

A very interesting study of the chemical behaviour of radon formed by irradiating uranyl sulphate crystals with high-energy protons (1.6×10^{-10} J) has been reported[107]. The retention of radon in a chemically bound state was measured by blowing off the radon after adding a reducing agent (KI solution) to the solution from which the free radon had already been removed by a stream of carrier gas[113]. The various fractions of entrained radon were collected in traps containing activated charcoal at 195 K, and the contents of all the traps were analysed in a γ spectrometer. The retention values were determined by comparing the intensities of the spectral lines given by the trap contents before and after the addition of the reducing agent (with appropriate time corrections). For the radon isotopes the retention values were less than 5%. Because of these small retentions, and of the complexity of the emission spectra, the authors[107] were unable to identify the radon compounds chemically.

VIII. POSSIBLE APPLICATIONS OF RADON COMPOUNDS

The chemistry of radon is of practical as well as theoretical interest, since it underlies the solution of one of the most fundamental problems in the protection of the environment: the purification of air from radioactive isotopes of the inert gases. The need to solve this problem has been brought into sharp focus by the growing number of nuclear power stations, and also by the serious contamination by radon of the air of uranium mines.

New developments in the chemistry of the inert gases and of inorganic fluorine-containing oxidising agents have suggested new methods of removing radioactive isotopes of the inert gases from the atmosphere. All these methods rely on chemical interaction between the inert gases and strong fluorinating oxidisers. The possibility of using these processes was first suggested[115] in 1963, and the first practical application (reported[86] in 1972) used complex salts of composition ClF_2SbF_6, BrF_2SbF_6, and $IF_4(SbF_6)_3$ as solid oxidising agents able to remove radon quantitatively from the air. In later work the choice of oxidising agents was widened very substantially. Radon can be removed from the atmosphere also by using as oxidising agents BrF_4SbF_6, O_2SbF_6, N_2FSb_6, $N_2F_3Sb_2F_{11}$,[116] $XeFSbF_6$, and some fluorine halides[117].

Among the most convenient reagents for removing radon from the atmosphere are the dioxygenyl salts (in particular, O_2SbF_6). This salt interacts with radon with evolution of oxygen according to the equation

$$Rn(g) + O_2SbF_6(s) \rightarrow RnF^+Sb_2F_{11}^-(s) + O_2(g).$$

Dioxygenyl hexafluoro-antimonate is a fairly strong oxidising agent, and it can also oxidise xenon. Using air samples artificially contaminated with ^{223}Rn and ^{133}Xe, Stein[87] showed that the radon is quantitatively adsorbed in a column (5 cm long, 6.3 mm in diameter) packed with O_2SbF_6 powder, using a gas flow rate of 45 ml min^{-1} cm^{-2}. Dilution of the dioxygenyl salt with antimony pentafluoride lowers its oxidising power below the oxidation threshold of xenon, but not of radon. It is suggested[87] that this method of chemically binding radon could find practical application for the purification of radon-contaminated air in uranium mines and for the analysis of traces of radon in the air. However, the use of this type of oxidising agent in practice is complicated by the very high reactivity of dioxygenyl salts towards common atmospheric contaminants such as water and nitrogen and carbon oxides, as well as organic compounds[118,119,120].

The interaction of radon with the salts ClF_2SbF_6 and BrF_2SbF_6 has also been studied in detail[121]. Both these oxidising agents when supported on nickel powder can effectively absorb radon from a gas stream at 213–383 K and gas flow rates up to 50 litre h^{-1}. The efficiency of radon removal is strongly dependent (as in the case of O_2SbF_6) on the presence of water vapour in the gas. Thus, the volume of air which can be freed from radon by 1 mg of oxidiser is 50–60 litre if the air is dried with P_2O_5, approximately 15 litre after drying with anhydrone, and less than 0.5 litre after drying with calcium chloride.

This very effective reaction could be used as a method of concentrating radon in the determination of ultra-micro amounts of it, and also to purify air to a residual concentration of radon isotopes not greater than 10^{-15} Ci $litre^{-1}$, i.e. well below any likely statutory threshold.

The number of radon compounds likely to find practical application is probably not limited to those listed above. Further studies of the potential uses of the compounds of the inert gases are likely to prove rewarding.

Metal Selenocyanates

V.V.Skopenko, G.V.Tsintsadze, and E.I.Ivanova

The literature data on the complex formation reactions involving the SeCN groups in aqueous and non-aqueous solutions are surveyed. The syntheses and properties of metal selenocyanate coordination compounds are described. The bibliography includes 156 references.

CONTENTS

I. Introduction 21
II. Selenocyanate complexes in solutions 21
III. Selenocyanato-compounds containing ligands with electron-donating nitrogen 21
IV. Heteroligand compounds incorporating ligands with electron-donating oxygen 24
V. Coordination selenocyanato-compounds of the acido-type 25
VI. Compounds containing metal-phosphorus and metal-carbon bonds as well as certain other compounds 27

I. INTRODUCTION

Until comparatively recently, selenocyanates were virtually uninvestigated. Compounds of this class have been studied most vigorously in recent years. In view of the increased interest in complex formation reactions involving SeCN groups, we attempted to survey the available literature data on selenocyanates during the period 1970–1979. Other reviews deal with earlier studies[1-5].

II. SELENOCYANATE COMPLEXES IN SOLUTIONS

Since the SeCN groups decompose in aqueous solutions in the presence of the majority of metal ions[1], selenocyanate complexes have been studied mainly in non-aqueous media (Table 1). Naturally the nature of the solvent has a significant influence on the stability and composition of the complexes. The most stable selenocyanate complexes are formed as a rule in acetone. For example, the formation of fairly stable molybdenum complexes $MoOX_{5-n}(NCSe)_n$ and $MoO.(NCSe)_5^{2-}$ (X = Cl [17] or Br, [22] $n = 1-4$) and tungsten complexes $[WCl_{5-n}(NCSe)_n]$ ($n = 1-5$) has been demonstrated in acetone solution[23]. In other non-aqueous solvents the SeCN groups decompose fairly rapidly in the presence of molybdenum and tungsten halides.

Table 1 shows that stable complexes, among those investigated in aqueous solutions, are formed by mercury. It is therefore not surprising that mercury(II) oxide readily dissolves in solutions of potassium selenocyanate[24]. At 25 °C the heat of solution of red HgO in 1 M KNCSe solution is −103 kJ mol^{-1}.[24]

III. SELENOCYANATO-COMPOUNDS CONTAINING LIGANDS WITH ELECTRON-DONATING NITROGEN

In the presence of amines the stability of the SeCN groups increases sharply, which explains the finding that, among the selenocyanato-compounds investigated, the selenocyanato-amine compounds are the most numerous.

When pyridine was saturated with lead selenocyanate (at 80–90 °C) with subsequent cooling of the mixture, pale yellow crystals of $PbPy_2(NCSe)_2$, containing bridging SeCN groups, were precipitated[25]. The properties of the octahedral compounds $MPy_4(NCSe)_2$ (M = Mn, Co, or Ni)[26] and $MPy_2(NCSe)_2$ (M = Mn, Co, or Ni), described previously[1], were investigated[27]. The octahedral configuration of $MPy_2.(NCSe)_2$ is achieved as a result of the bridging function of the SeCN groups.

$[Co(NCSe)(NCS)Py_2]$ has been obtained by the reaction of $Co(NCS)_2$ with KNCSe in an acetone–dioxan mixture, the mixture being subsequently kept in a vacuum desiccator over calcium chloride impregnated with pyridine[28]. Treatment of $[HIr(pip)_4Cl]Cl$ (pip = piperidine) with a saturated aqueous solution of KNCSe led to the isolation of *trans*-$[HIr(pip)_4.NCSE]NCSe$.[29] The compound is diamagnetic; although the formation of the Ir–SeCN bond is characteristic of iridium, ionic NCSe groups and NCSe groups coordinated via the nitrogen atom are present in the compound.

The compound $K[CuR_2SeCN]$, where R is a pyridine-2-carboxylic acid residue, in which the copper atoms have an octahedral environment and the SeCN groups are linked to copper by weak bonds via selenium, has been synthesised[30].

Fairly numerous compounds containing 2,2′-bipyridyl (bipy) and 1,10-phenanthroline (phen) have been isolated in recent years, mainly from non-aqueous solutions, and investigated (Table 2).[31-46] The compound $[Fe_3(bipy)_7(NCSe)_6]$ has been obtained[47]. Its magnetic moment at 294 K is 3.24 μ_B. Its crystals have an orthorhombic lattice with the parameters $a = 21.77 \pm 0.05$ Å, $b = 25.33 \pm 0.05$ Å, $c = 13.88 \pm 0.04$ Å, and $D_m = 1.66 \pm 0.03$ g cm^{-3}; the probable space group is $Pmnb$.[47]

The complexes $Cu(bipy)(NCSe)_2$, $Cu(phen)(NCse)_2$, and $Cu(bipy)_2(NCSe)_2$ have been isolated from aqueous acetone solutions[35]. In the first two compounds the octahedral configuration of copper is achieved via bridging SeCN groups. Judging from EPR data[35], the copper in the compound $Cu(bipy)_2(NCSe)_2$ has a coordination number of 5. The complex $Mn(phen)_2(NCSe)_2$, isostructural with the corresponding thiocyanate, has also been obtained. The compound contains isoselenocyanato-groups. Its magnetic moment is 5.98 μ_B at 24 °C.[42]

The isoselenocyanato-compounds $Nb(bipy)_2(NCSe_4)$ and $Nb(DMbipy)_2(NCSe)_4$, where DMbipy = 4,4′-dimethyl-2,2′-bipyridyl, have been isolated from acetonitrile solutions, and $Ta(bipy)(NCSe)_5$ has been obtained from dichloromethane[43]. The compound $[Co(bipy)_3][Zn(NCSe)_4(bipy)]$, whose magnetic moment is 5.31 μ_B, has been obtained by the reaction of solutions containing $Co(NCSe)_2$, $Zn(NCSe)_2$, and 2,2′-bipyridyl[48]. A number of lanthanide compounds containing urotropine have been isolated from non-aqueous solutions (Table 2).

The compounds $[Ru(NH_3)_5SeCN]X_2$, where $X = ClO_4^-$, I^-, or PF_6^-, have also been described[49]. The zinc and cadmium compounds incorporating benzimidazole and its derivatives proved to be fairly stable in air[33].

Table 1. The stability constants of selenocyanate complexes in solution*.

*The following abbreviations have been adopted in Table 1 and in the other tables: Thio = thiourea; DMF = *N*,*N*-dimethylformamide; DMSO = dimethyl sulphoxide; I = ionic strength.

**Notation: PG = polarography; SP = spectrophotometry; PM = potentiometry.

***With addition of 50 vol % of acetone.

The interaction of alcoholic solutions of $M(NCSE)_2$ (M = Co, Ni, or Cu) with 1,1,7,7-tetraethyldiethylenetriamine [$(C_2H_5)_4$..dien] and diethylenetriamine (R) led to the solution of $[M(C_2H_5)_4dien](NCSe)_2$ (M = Co or Ni) and $[CuR_2](NCSe)_2$. In all the compounds the bond between the NCSe groups and the central atom is formed via nitrogen[45].

The kinetics of the substitution of SeCN ligands in $\{Pd..(C_2H_5)_4dien]SeCn\}^+$ by methanol and the influence of Hg^{2+} ions on the rate of the process have been investigated in methanol at 25 °C. It was established that if the SeCN group is linked to palladium via selenium, then the rate of substitution is proportional to the mercury(II) concentration; otherwise the rate is independent of [Hg(II)].[50]

The synthesis of tetragonal bipyramidal compounds $[(Cu..(Pn)_2(SeCN)]NO_3$ and $[Cu(dien)_2(SeCN)]NO_3$, where Pn = propylenediamine and dien = diethylenediamine[51], as well as $[Cu(DBen)_2(NCSE)X]$, where $X = ClO_4^-$ or NO_3^- and DBen = *N*, *N'*-dibenzylethylenediamine[52], has been described. The copper atom in $\{Cu[(C_2H_5)_4dien]NCSe\}(BPh_4)$ has a square planar environment[45].

The octahedral nickel isoselenocyanate complexes $Ni(R-NH_2)_4(NCSe)_2$ and [NiL(NCSe)]NCSe, where $R = CH_3$, $n-C_3H_7$, or $n-C_4H_9$ and L = tetraethylenepentamine, have been isolated from ethanol solutions[44]. It is of interest to note that, in the presence of piperidine, nickel(II) can form not only the octahedral compounds $[Ni(pip)_4(NCSe)_2]$ but also the pentacoordinate compound $[Ni(pip)_3(NCSe)_2]$.[26]

A series of nickel(II) and cobalt(II) compounds with *p*- and *m*-phenylenediamines (phn) have been obtained[53]. The compounds $Co(m\text{-phn})_2(NCSe)_2$, $Ni(m\text{-phn})_2(NCSe)_2$, $Ni(m\text{-phn})(NCSe)_2$, $Ni(p\text{-phn})(NCSe)_2$, and $Co(p\text{-phn})(NCSe)_2$ contain bridging SeCN groups. An octahedral structure was attributed to all the nickel(II) complexes on the basis of their effective magnetic moments[53].

The magnetic properties and EPR, infrared, and electronic spectra of the complexes $[ML_2(NCSe)_2][BPh_4]_2$, where M = Ni or Cu and L = 2,2',2''-triaminotriethylamine, have been investigated. It was established that the nickel complexes have a dimeric structure with octahedral coordination established via bridging SeCN groups, while the copper complexes have a trigonal bipyramidal structure[54].

* The following abbreviations have been adopted in Table 2: Q = benzoxazole; Z = 2-methylbenzoxazole; Bia = benzimidazole; MBiA = methylbenzimidazole; DMBia = dimethylbenzimidazole; Urt = urotropine; dien = diethylenediamine; Dmbipy = 4,4'-dimethyl-2,2'-bipyridyl.

Copper(II) selenocyanate complexes with diguanide (L) derivatives having the composition $[CuL_2](NCSe)_2$, in which the NCSe groups are ionic judging from infrared absorption spectra, have been studied; on the other hand, the Cu–SeCN bond is present in the compound $CuL(SeCN)_2$.[55]

The compounds $Cu(Ben)_2(SeCN)(NO_3)$ and $Ni(Ben)_2.(SeCN)(NO_3)$ have been isolated after the interaction of nickel and copper nitrates with benzylethylenediamine (Ben) in ethanol and subsequent treatment of the product with potassium selenocyanate, while the interaction with *N,N'*-dibenzylethylenediamine (DBen) led to $Ni(DBen)_2(NCSe)_2$ and $Co(DBen)_2(NCSe)_2$. It was shown that the last two complexes are octahedral, while $Cu(Ben)_2(SeCN)(NO_3)$ and $Ni(Ben)_2(SeCN)(NO_3)$ are tetrahedral[56]. Bridging SeCN groups have been detected in the compound $Cu(Ben)_2(SeCN).(NO_3)$, while the remaining complexes contain isoselenocyanato-groups[56].

The nickel and cobalt complexes of certain diamines can also be classified as isoselenocyanates: $ML_2(NCSe)_2$, where $L = NH_2NH_2$, o-$(NH)_2C_6H_4$, or ethylenediamine (En).[57] The interaction of hot solutions of $M(ClO_4)_2.6H_2O$ (M = Mn, Fe, Co, Ni, or Cu) in ethanol with LiNCSe in the presence of 2,3,5,6-tetrakis (6-methyl-2-pyridyl)pyrazine (L) led to the formation of the isoselenocyanato-compounds $ML(NCSe)_2$.[58] A series of complexes with dihydrazinophthalazine (Dhph) have been isolated from aqueous solutions: $[Cu_2(Dhph)(SeCN)_2].4H_2O$, $[M(Dhph)(SeCN)_2].2H_2O$ (M = Zn, Co, or Ni), and $[M(Dhph)(SeCN)_2]$ (M = Cd or Mn).[59] The copper complex is diamagnetic and its organic ligand has a bridging function and is bidentate, i.e. the coordination number of copper is 4. In the remaining compounds dihydrazinophthalazine is tetradentate and the coordination of the metal is 6.[59]

The compound [CoL(NCSe)]NCSe, where L is the corresponding Schiff base, has been obtained by the reaction of cobalt(II) acetate with pyridine-2-carboxaldehyde and bis-(3,3'-aminopropyl)amine in the presence of triethyl orthoformate in an atmosphere of nitrogen with subsequent addition of KNCSe.[60] A series of cobalt compounds $Co(NCSe)_2.nA$, where A = diaminobiphenyl and its derivatives, have been described. They are all high-spin compounds in which the cobalt atom has a hexacoordinate environment[61]. Isoselenocyanato-groups are present in the compounds $NiL_2.(NCSe)_2$, where L = 3,3'-bis(aminopropyl) ether, while the nickel ion has a pseudo-octahedral environment[62].

Manganese(II), cobalt(II), zinc, and cadmium compounds containing *N,N*-diethylnicotinamide (DENA) have been isolated from acetone solution: $[Ni(DENA)_2(NCSE)_2].2H_2O$,[63] $[Cd(DENA)_2(NCSe)_2$,[64] $[Zn(DENA)_2(NCSe)_2(H_2O)_2]$,[65] $Mn(DENA)_2(NCSE)_2$, $[Co(DENA)_2(NCSe)_2(H_2O)_2]$, and $[Co(DENA)_4(NCSe)_2]$.[66] The state of bivalent manganese, cobalt, nickel, zinc, and copper complexes with *N,N'* diethylnicotinamide, nicotinamide, acetamide, and propionamide in aqueous solutions and in solutions in organic solvents has been studied[67]. The cadmium complex of nicotinamide $Cd(NA)(NCSe)_2$ has also been obtained. The coordination of nicotinamide in this compound is via the nitrogen heteroatom, while the NCSe groups are also coordinated via nitrogen[68].

A series of analogues of vitamin B_{12} of the type $Co(NCSe).(OH)_2R$, where R = purine or pyrimidine derivative, have been described[69].

Manganese selenocyanate complexes with *o,o'*-, *m,m'*-, and *p,p'*-diaminobiphenyls (Q) and with *p,p'*-diaminodiphenylmethane (L) have been synthesised by adding concentrated solutions of Q or L to an alcoholic solution of $Mn(NCSe)_2$; $Mn(o,o'\text{-}Q)_2(NCSe)_2$, $Mn(m,m'\text{-}Q)_2(NCSe)_2$, $Mn(p,p'\text{-}Q)_3(NCSe)_2$, and $Mn(p,p'\text{-}L)_3(NCSe)_2$.[70] Infrared

absorption spectra and magnetic properties led to the conclusion that the manganese atom in the complexes has coordination number 6.[70]

The complexes $MnL_4.(NCSe)_2$ have been synthesised by refluxing an ethanol solution of $Mn(NCSe)_2$ with pyridine, β- and γ-picolines, 3,5-lutidine, 4-ethylpyridine, and isoquinoline. The compounds contain isoselenocyanato-groups and the manganese atom has an octahedral environment[71].

The complexes $M(BH)_2(NCSe)_2$ have been synthesised by the reaction of manganese, cobalt, nickel, and zince selenocyanates with benzoylhydrazine (BH) in ethanol or acetone. It was established that the nickel and cobalt complexes are isostructural[72]. The compounds $CdL_2(NCSe)_2$, where L = benzoxazole and its derivatives, have been isolated from non-aqueous media[34]. The compounds $Zn(Ampy)_2(NCX)_2$ (X = O or Se and Ampy = 2-aminopyridine) have been shown to be isostructural. In these compounds zinc has a tetrahedral environment and some of the aminopyridine molecules are coordinated to zinc via the nitrogen of the amino-group, while others are coordinated via the nitrogen of the heterocycle. The NCSe groups are monodentate and are linked to zinc via nitrogen[73].

New cobalt(III) chelates of the type $[CoLA_2]SeCN$, incorporating ethylenediaminobisacetylacetone (L), ethyl- or n-propyl-amine (A), and SeCN groups, have been synthesised[91].

Copper(II) compounds containing ethylenediamine (En) have been isolated from aqueous ethanol solutions: $CuEn_2.(SeCN)X$, where $X = Cl^-$, Br^-, SCN^-, or NO_3^-. The coordination polyhedron of the central atom consists of a distorted pseudosquare pyramid or a square bipyramid[75]. The interaction of $Cu(CH_3COO)_2$ with L and KNCSe, where L = β-(2-pyridyl)ethylamine or 2-pyridylmethylamine, in absolute methanol in an atmosphere of nitrogen led to the formation of the compound $CuL(NCSe)_2$, where L behaves as a tridentate ligand[76].

The interaction of $CuLCl_2$, where L = 1,4-diphenyl-2-thioammeline, with KNCSe in dry *N,N*-dimethylformamide yielded the compound $CuL(SeCN)_2$, in which the SeCN groups are coordinated via the selenium atom, while the organic ligand is coordinated via the nitrogen and sulphur atoms[77]. Tetrahedral isoselenocyanate complexes with benzimidazole (Bia) and its derivatives have been obtained from ethanol solutions: $Co(MBia)_2(NCSe)_2$, $Co(DMBia)(NCSe)_2$, and $Co(Bia)(NCSe)_2$; here the organic ligand is bound to the metal via the nitrogen atom in the 3-position in the imidazole ring[78].

Much attention has been devoted recently to the study of the cobalt(III) complexes of *trans*-dioximes having the general composition $[Co(HD)_2L(SeCN)].nH_2O$, where HD is a dimethylglyoxime residue and L = 3-cyanopyridine[79], 4-cyanopyridine, pyridine, 4-aminopyridine[80], 2-aminopyridine[81], PPh_3, $PPh_2(n\text{-}Bu)$, PPh_2Me, P(n-Bu), $P(OPh)_3$, $P(O\text{-}n\text{-}Bu)_3$, $P(OMe)_3$, $P(O\text{-}iso\text{-}Pr)_3$, 4-acetylpyridine[82], piperidine, 3-chloropyridine, NH_3, or $PrNH_2$.[83] In all these compounds the bond between the SeCN groups and the central atom is formed via selenium. They have been shown to exhibit an antibacterial activity and the spectrum of the antimicrobial activity of dioxime complexes of this type (in which L are various sulphanilamides[84,85] and sulphanilylpyridines[86-88]) has been expanded relative to the initial complexes and sulphanilylpyridines.

The complexes *trans*-$[Co(HDph)_2LNCSe].H_2O$, where HD is diphenylglyoxime, and L = *p*-aminobenzenesulphonylguanidine[89], 2-(*p*-aminobenzenesulphonyl)pyridine[88], or 4-sulphanilylpyridine[86], have been obtained. The thermal stability of the complexes with the last ligand depends on the nature of the acido-ligand X (Cl, Br, I, NCO, NCS, or NCSe), reaching a maximum in the selenocyanate complex[86].

Dinuclear complexes of the type *trans*-$[ACo(HD)_2\text{–}SeCN\text{–}Co(HD)_2SeCN]$, where HD is a dimethylglyoxyme residue and A = PPh_3, $PPh_2(n\text{-}Bu)$, $P(OPh)_3$, or $P(OCH_3)_3$, are formed in solvents with a low dielectric constant, for example in dichloromethane; in these complexes the terminal SeCN groups are coordinated to cobalt via the selenium atom regardless of the nature of A.[82] The bridged complexes $\{RCo(HL)_2\}\text{–}NCSe\text{–}\{Co(HL)_2Q\}$, where R = CH_3 or CF_3 and Q = piperidine, have been isolated from chloroform[83].

The compounds $[Co(HL)_2(NO_2)(NCSe)]$, where HL is a methylisopropylglyoxime residue[90] and the new cobalt(III) chelates $[CoZQ_2]SeCN$ (H_2Z is a tetradentate ligand consisting of the Schiff base obtained from acetylacetone and ethylenediamine, namely ethylenedi-iminobisacetylacetone, and Q are amines ($C_2H_5NH_2$, $n\text{-}C_3H_7NH_2$, or $CH_2=CH\text{–}CHNH_2$),[91] have also been obtained. The complex acid $H[Co(DH)_2.(NCSe)_2].H_2O$, which is sparingly soluble in water and is resistant to the action of inorganic acids, as well as a whole series of its salts (DH = cyclohexane-1,2-dione dioxime residue)[92] and $H[Co(HL)_2(NCSe)_2]$, where HL = diaminoglyoxime residue[93], have been isolated.

IV. HETEROLIGAND COMPOUNDS INCORPORATING LIGANDS WITH ELECTRON-DONATING OXYGEN

The majority of the compounds considered here are presented in Table 3. In all the compounds with dimethyl sulphoxide (DMSO) the latter is bound to the central atom via oxygen. On the other hand, the mode of coordination of the SeCN groups depends both on the nature of the central atom and on the composition of the complex (Table 3). In the isostructural complexes $M(DMSO)_4(NCSe)_2$ (M = Fe, Co, Mn, or Ni) the central atom has the octahedral configuration Mo_4N_2, probably with the *trans*-location of the isoselenocyanato-groups[96]. In the compound $Cd(DMSO)_2(NCSe)_2$ the cadmium atoms are linked together to infinite chains via bridging SeCN groups. The DMSO molecules complete the polyhedron to form an octahedron. The interatomic distances are Cd–Se = 2.773 Å, Cd–N = 2.26 Å, and Cd–O = 2.30 Å; the SeCN and CdNC angles are 171.5° and 172.6° respectively[100]. The compound $Pb(DMSO)_2(NCSe)_2$ apparently has an analogous structure[25]. The bonds between the SeCN groups and the central atom in the compounds $M(MFA)_4(NCSe)_2$ and $M(DMA)_4(NCSe)_2$ (M = Mn, Co, Ni, or Zn, MFA = *N*-methylformamide, and DMA = *N,N*-dimethylacetamide) are formed via nitrogen, while the organic ligand is linked via oxygen[73,101,102].

Structural study of $Ni(DMA)_4(NCSe)_2$ crystals showed that they are monoclinic and have the lattice parameters $a = 7.67$ Å, $b = 10.40$ Å, $c = 9.74$ Å, and $\gamma = 114°$. The crystals of this compound are isostructural with those of *trans*-$Ni(DMA)_4(NCSe)_2$, in which the SeCN groups are linked to nickel via nitrogen and DMA molecules are linked via oxygen[74].

The compound $Cd(DMF)_2(NCSe)_2$ has been isolated from alcoholic solutions containing $Cd(SeCN)_2$ and *N,N*-dimethylformamide (DMF). It contains bridging SeCN groups, while the bond between DMF and cadmium is formed via oxygen[103], as in the other compounds presented in Table 3. Many selenocyanato-compounds containing antipyrine (A) and diantipyrylmethane (D) are known (Table 3). In all these compounds the organic ligand is linked to the central atom via oxygen, occupying one (antipyrine) or two (diantipyrylmethane) coordination sites. Gallium and indium selenocyanate complexes containing alkyl- or aryl-phosphine oxides have also been studied[37]. Table 3 shows that in all cases

an M–NCSe bond is formed and the central atom acquires an octahedral configuration.

The extraction of uranyl selenocyanates with chloroform solutions of certain oxygen-containing organic reagents has been studied[104]. The composition of the extracted compounds has been established by the equilibrium shift method: $UO_2L_3(NCSe)_2$ (L = antipyrine, triphenylphosphine oxide, or hexamethylphosphoramide) and $UO_2L_2(NCSe)_2$ (L = diantipyrylmethane and phenyldiantipyrylmethane)[104].

Table 3. Fundamental vibrational frequencies of the SeCN groups (cm^{-1})*.

Compound	ν (CN)	ν (CSe)	δ (SeCN)	Type of coordination of SeCN groups	Refs.

* The following abbreviations have been adopted in Table 3: A = antipyrine; D = diantipyrylmethane; HMP = hexamethylphosphoramide; Diox = 1,4-dioxan.

Selenocyanato-compounds containing hexamethylphosphoramide (HMP) are formed readily when acetone or alcoholic solutions of the corresponding metal selenocyanates are treated with HMP [95–99] (Table 3). In all the compounds HMP is linked to the central atom via oxygen. Compounds having the composition $M(HMP)_2(NCSe)_2$ (M = Mn, Co or Zn) are isostructural. The study of the magnetic properties and the electronic absorption spectra indicated an octahedral structure of the cobalt compound. However, the nickel compound is not isostructural with the analogous cobalt, zinc, and manganese compounds. On the other hand, the magnetic moment, which amounts to 3.6 μ_B, rules out a planar structure of $Ni(HMP)_2(NCSe)_2$. Nickel in the above compound probably has a coordination number of 5 owing to the bridging SeCN groups. In air the compound readily combines with water and is converted into the dihydrate. Judging from the electronic absorption spectra and the magnetic moment (3.02 μ_B), the nickel in the compound is octahedral and the SeCN groups are *N*-linked to nickel[97]. Bridging isoselenocyanato-groups are present in $Cd(HMP)(NCSe)_2$ and the cadmium atom has a tetrahedral environment[97].

All the compounds $M(HMP)_3(NCSe)_3$ in Table 3 contain isoselenocyanato-groups. This is somewhat unexpected for bismuth, because the formation of Bi–SeCN bonds is more characteristic of this element[95,99]. Evidently the "inversion" of the bond linking the SeCN groups in this instance is due to the steric hindrance caused by hexamethylphosphoramide.

Blue crystals of $VO(HMP)_3(NCSe)_2$ have been obtained by adding an excess of KNCSe and HMP to an acetone solution of $VOCl_2$. The compound is isostructural with the analogous thiocyanate. The values of ν(VO) for the thiocyanato- and selenocyanato-compounds are the same (965 cm^{-1}), which may be regarded as proof of the *trans*-position of the HMP molecules relative to vanadyl oxygen and not of XCN groups[99]

Lanthanide selenocyanate complexes with nonamethylimidophosphoramide (NIPA) have been isolated from acetone: $Ln(NIPA)_3(NCSE)_3$ (Ln = Pr, Nd, or Sm) and $Ln_2(NIPA)_5 \cdot (NCSe)_3$ (Ln = Gd, Tb, Er, Tm, or Lu), which are isostructural with the analogous thiocyanates. As for thiocyanates, the coordination number in the selenocyanates decreases from nine (Pr, Nd, and Sm) to eight (Gd–Lu).[105]

V. COORDINATION SELENOCYANATO-COMPOUNDS OF THE ACIDO-TYPE

Coordination compounds of the acido-type containing only SeCN groups in the anion can be obtained (with the exception of the mercury compounds) solely from non-aqueous solutions. Table 4 shows that in all the compounds considered the mode of coordination of the SeCN groups most characteristic of the complex-forming metal is retained[1,109]. It is of interest that the octahedral environment of the central atom in the compounds $(UrtH)_2[M(NCSe)_4]$ (M = Co or Ni and Urt = urotropine) is achieved not only via the SeCN groups but also with the aid of the cation[106].

The compounds $[(CH_3)_4N]_4[Fe(NCSe)_6]$, $[(C_2H_5)_4N]_3 \cdot [Fe(NCSe)_5(H_2O)]$, $[C_4H_9)_4N]_2[Fe(NCSe)_4]$, and $[(C_4H_9)_4N]_3 \cdot [Fe(NCSe)_6]$, which are high-spin complexes and contain isoselenocyanato-groups, have been obtained by the method already described[110], isolated, and investigated[111]. A similar type of coordination has also been observed in the octahedral compounds $R_4[Co(NCSe)_6]$, $R_3[Fe(NCSe)_5(H_2O)]$, $R_3[V(NCSe)_6]$, $R_3[Mo(NCSe)_6]$, and $R_3[MoO(NCSe)_5]$, where $R = (C_2H_5)_4N^+$,[112] and also in $R'_3[Cr(NCSe)_6]$, where $R' = K^+$ or $(C_4H_9)_4N^+$.[113]

When $[(C_4H_9)_4N]_2Re_2Cl_8$ was allowed to react with KNCSe in ethanol or acetonitrile, it was possible to isolate the rhenium compound $[(C_4H_9)_4N]_2[Re_2(NCSe)_8]$. Judging from the wavenumber ν(CN) = 2050 cm^{-1}, the SeCN groups are linked to the rhenium atom via nitrogen[114]. In the presence of $SeCN^-$ ions, rhenium pentachloride forms polymeric complexes in acetone via bridging SeCN groups[115].

The compounds of Group V elements $K[M(NCSe)_6]$ (where M = Nb or Ta), $K_2[Nb(NCSe)_6]$, and $[Ph_4As][Ta(NCSe)_6]$ have been obtained from acetonitrile solutions[116]. It also proved possible to isolate from acetonitrile the compounds $K_2[Zr.(NCSe)_6]$, $K_2[Hf(NCSe)_6]$,[117] $[(C_2H_5)_4N]_4[Pa(NCSe)_8]$, and $[(C_2H_5)_4N]_4[U(NCSe)_8]$.[118] X-Ray diffraction study showed that the last two compounds are isostructural and belong to the tetragonal system (the lattice parameters are $a = 11.82$ Å and $c = 23.49$ Å for the first compound and $a = 11.80$ Å and $c = 23.36$ Å for the second)[118].

$[(C_2H_5)_4N]_3[UO_2(NCSe)_5]$	2040, 2060	625	—	U—NCSe	[15]

* The following abbreviations have been adopted in Table 4: Urt = urotropine; Diox = 1,4-dioxan; Act = acetone.

The uranyl selenocyanates $[(C_4H_9)_4N]_3[UO_2(NCSe)_5]$ and $[(C_2H_5)_4N]_3[UO_2(NCSe)_5]$ were isolated from methanol[15]. All the compounds mentioned above contain isoselenocyanato-groups. The formation of the Bi–SeCN bond is more characteristic of bismuth selenocyanates; bridging selenocyanato-groups are present in the mercury, lead, and cadmium compounds (Table 4).

Among heteroligand complexes of the acido-type, the mercury and cadmium compounds have been studied most thoroughly (Table 5). The compounds $K_2[Cd(SeCN_2)SCN)_2]$, $K_4[Cd(SeCN)_4(SCN)_2].0.5$ Act, $K_2[Cd(SeCN)_2(Hal)_2]$ (where Hal = Cl or Br), $K_4[Cd(SeCN)_4I_2].0.5$ Act, and $K_2[Cd(SeCN)_3I].$ Act were synthesised by crystallisation from acetone solutions containing CdX_2 ($X = SCN^-$, Cl^-, Br^-, or I^-) and KNCSe in proportions of 1 : 2 or 1 : 4 [120,124] [Act = acetone (Ed. of Translation)]. It follows from infrared spectroscopic data that $K_2[Cd(SeCN)_2(SCN)_2]$ contains both terminal Cd–SeCN bonds and bridging Cd–SeCN–Cd linkages[120]. Bridging SeCN groups are also present in $K_2[Cd(SeCN)_2(Hal)_2]$, while in the compound $K_4[Cd(SeCN)_4I_2]$ the SeCN groups are linked to the central atom via selenium[120,124]. Cadmium compounds incorporating together with SeCN groups the non-linear $N(CN)_2$ and $C(CN)_3$ groups have also been obtained (Table 5). All these compounds except $K_2\{Cd[C(CN)_3]_2.(NCSe)_2\}$ contain isoselenocyanato-groups. The last compound contains bridging SeCN groups.

The mercury compounds $K_2[Hg(SeCN)_2A_2]$, where $A = Br^-$, I^-, or SCN^-, have been isolated from acetone[124]. SeCN groups linked to mercury via selenium are present in these complexes and also in $Ba[Hg(SeCN)_2(SCN)_2].2Act$, but the presence of SeCN bridges may be suggested in $K_2[Hg(SeCN)_2.Br_2]$, in view of the band at 2138 cm^{-1}.[122] Bridging SeCN groups are also present in the compound $Ba[Hg(SeCN)_2.Br_2].Act$.

When $Hg(SeCN)_2$ is dissolved in acetone solutions of $M(NCSe)_2$ (M = Mn or Co), the compounds $M[Hg(SeCn)_2(SCN)_2]$ are formed[124]. The compounds $M[Hg(XCN)A_2]$, where M = Mn, Co, Ni, Zn, or Cu and X = S or Se, have been obtained similarly[123]. Table 5 shows that the spectra of all the compounds of the type $M[Hg(SeCN)_2(SCN)_2]$, where M = Mn, Co, Ni, or Zn, contain high-frequency ν(CN) components in the range 2135–2160 cm^{-1}, which indicates the presence of bridging XCN groups in these compounds. Bridging XCN groups have also been found in $Cu[Hg(SeCN)_2(SCN)_2]$.[123]

When $M(SCN)_2$ (M = Ni, Zn, or Ba) was allowed to react with $Hg(SeCN)_2$ in ethanol or acetone, the compounds $NiHG(SCN)_2(SeCN)_2.Act$, $ZnHg(SCN)_2(SeCN)_2$, and BaHg.

Table 5. Fundamental vibrational frequencies in heteroligand complexes (cm^{-1}).

.$(SCN)_2(SeCN)_2$.Act were obtained[28]. The interaction of $BaBr_2$ with $Hg(SeCN)_2$ in an acetone–water mixture yielded the complex $BaHg(SeCN)_2Br_2$.Act.[28] The compound *trans*-$[(CH_3)_4N][Au(CN)_2(SeCN)_2]$ was isolated from acetone after the double decomposition reaction between KNCSe and *trans*-$[(CH_3)_4N][Au(CN)Cl_2]$.[119] The mixed bismuth complexes $K_3[Bi(SeCN)_3(SCN)_3]$, $K_2[Bi(SeCN)_2(SCN)_3]$, and KBi(SeCN). .$(SCN)_3$ have also been synthesised[125].

When an aqueous solution of $Rh(CH_3COO)_4.2H_2O$ was allowed to interact with potassium selenocyanate, the complex $Rh_2(CH_3COO)_4$.KNCSe.$2H_2O$ was obtained, in which the SeCN groups are of the bridging type[126,127]. A comparative study of the compounds $Rh(RCOO)_2$.KNCSe.$2H_2O$ (R = H, CH_3, CH_2Cl, or C_2H_5) has been made. In these compounds the SeCN groups are of the bridging type and the formula $K[Rh(RCOO)_4NCSe].2H_2O$ can be attributed to the compounds [126]. The beryllium compounds $[Be(DMF)_3Cl]SeCN.3.5DMF$ and $K[Be(DMF)(NCSe)_3].4DMF$ [128] as well as a series of cobalt, manganese, and zinc compounds, namely $K_2[M(NCS)_2(NCSe)_2]$. .*n*Diox (M = Mn, Co, or Zn) and $Na_2[Co(NCSe)_2(NCS)_2]$. .5.5 Diox, in which the SeCN groups are linked to the central atom via nitrogen, have been obtained from non-aqueous solusolutions[129]. Only one absorption band near 16000 cm^{-1}, indicating a tetrahedral environment of the cobalt atom, has been observed in the electronic spectra of the cobalt compounds. The influence of the size of the outer cation on the coordination of the SeCN group was traced in relation to the cobalt selenocyanates $[(C_4H_9)_4N]_3[Co(CN)_5(NCSe)]$, $Cs_3[Co$. .$(CN)_5SeCN]$, $[(CH_3)_4N]_3[Co(CN)_5SeCN]$, $[(CH_3)_4N]_3$.$[Co(CN)_5$. .NCSe], and $[Co(NH_3)_6][Co(CN)_5SeCn]$. The products are $[Co(CN)_5SeCn]^{3-}$ for M = K or Cs, a mixture of $[Co(CN)_5$. .$SeCn]^{3-}$ and $[Co(CN)_5NCSe]^{3-}$ for M = $(CH_3)_4N$, and $[Co(CN)_5NCSe]^{3-}$ for M = $(C_4H_9)_4N$.

The iron(III) complex $[(C_4H_9)_4N]_3[Fe(CN)_5(NCSe)]$ has been isolated from acetone[131]. A series of mixed chromium(III) compounds have been obtained: $[(C_4H_9)_4N]_3[Cr(CN)(NCSe)_5]$, $[(C_4H_9)_4N]_3[Cr(CN)_2.(NCSE)_4]$, $[(C_4H_9)_4N]_3[Cr(CN)_3(NCSe)_3]$, and $[(C_4H_9)_4N]_3[Cr(CN)_4(NCSe)_2]$.[132] The study of the electronic absorption spectra showed that the 18000 cm^{-1} band, due to the *d*–*d* transition, undergoes a hypsochromic shift with decrease of the number of selenocyanato-groups from six to two. The intensity of the charge-transfer bands in the range 28500–30500 cm^{-1} decreases in the same sequence[132].

Polymeric cobalt, nickel, and mercury compounds containing the SCN and SeCN groups have been synthesised[133,134]. The structure of $MHg(SeCN)_4$, where M = Mn or Fe, has been studied[135]. The Co–NCSe–Ag bridging linkages have been detected in $Co[Ag(SeCN)_2]_2$ [136] and the M–NCSe–Hg linkages have been found in $(SeCN)_2L_2M(NCSe)_2Hg(PPh_3)_2$, where M = Co, Ni, Cu, or Zn and L = nicotinamide[137].

VI. COMPOUNDS CONTAINING METAL–PHOSPHORUS AND METAL–CARBON BONDS AS WELL AS CERTAIN OTHER COMPOUNDS

A series of metal complexes of triphenylphosphine (Ph_3P) and triphenylarsine (Ph_3As) have been obtained from non-aqueous solutions. Thus the SeCN groups in *trans*-$Rh(Ph_3P)(CO)NCSe$, $Ir(Ph_3P)_2CO(Act)NCSe$, $Au(Ph_3P)SeCN$, and $Au(Ph_3As)SeCN$ are linked to the rhodium and iridium atoms via nitrogen and to the gold atom via selenium[138]. According to the authors[139], the compound $Pd(Ph_3P)_2(SeCN)_2$ contains Pd–SeCN bonds in the solid state.

The orange crystals of $Ru(CO)(Ph_3P)_2(NCSe)_2$ have been obtained by the reaction of $Ru(CO)_3(Ph_3P)$ with an excess of $(NCSe)_2$ in benzene. A whole series of iridium compounds have been synthesised: $[IrL_2(SeCN)_2]BPh_4$ (where L = Ph_2. .$PC_2H_4PPh_2$), $Ir(Ph_3P)_2(SeCN)_2Cl$, and $Ir(CO)(Ph_3P)_2$. .$Cl(SeCN)_2$.[140] The compounds *trans*-$M(Ph_3P)_2(SeCN)_2$ (M = Pt or Pd) have been obtained by the reaction of equivalent amounts of $(NCSe)_2$ and the corresponding ML_4 in benzene[140]. The NCSe groups in *trans*-$[(Ph_3P)_2PtHSeCN]$ and $\{[(C_4H_9)_4P]_2PtHSeCN\}$ are linked to platinum via the nitrogen atom[141].

The dimer $[(CH_3)_2Au(NCSe)_2]$ with a bridging SeCN group has been obtained; its interaction with triphenylphosphine in absolute ether gives rise to the complex $(CH_3)_2Au(SeCN)$. .(PH_3P), which, however, has not been isolated in a pure state[142]. The compound [MoOClL]Cl, where L = 1,2-bisdiphenylphosphinoethane, has been isolated from a methanol solution[143]. The pentacoordinate complexes CoLNCSe and CoL′(NCSe), which have a trigonal bipyramidal structure, have been obtained by the reaction of COLBr [HL = $P(CH_2$. .$COCH_2R)O(OEt)_2$, R = NEt_2] and [HL′ = $P(CH_2COCH_2R)O$. .$(OEt)_2$, R = $\overline{NCH_2CH_2CH_2CH_2CH_2}$] with KNCSe in dry acetone[144]. The organic ligand is tridentate in both cases; it is coordinated to the cobalt atom via the oxygen of the C=O and P=O groups and via the nitrogen atom, one of the oxygen atoms behaving as a bridging group[144].

The complexes $M(CO)_5(RSeCN)$, where M = chromium or tungsten and R = alkyl or aryl, have also been obtained. The solid compounds are resistant to heat and light. The SeCN group is coordinated to the central atom via the nitrogen atom[145]. The compounds $R_2TlSeCN$ (R = phenyl or *o*-, *m*-, and *p*-tolyl) in which, judging from infrared spectroscopic data, the SeCN groups are linked to thallium via selenium, have been obtained from non-aqueous solutions[146]. The complex $(CH_3)_2N_4BSeCN$ has been synthesised by refluxing $(CH_3)_2NBCl$ with a small excess of AgSeCN in benzene in an atmosphere of nitrogen[147]. The compound [CuLNCSe[.CH_3OH, where L is the macrocyclic ligand 1,1-difluoro-4,5,11,12-tetramethyl-1-bora-3,6,10,13-tetra-aza-2,14-dioxacyclotetradeca-3,5,10,12-tetraene has been isolated[148].

The sparingly soluble complexes $Cp_2Ti(NCSe)_2$, Cp_2Ti. .$(CN)(NCSe)$, $Cp_2V(NCSe)_2$, $Cp_2Cr(NCSe)(SCN)$, and Cp_2. .$M(CN)(NCSe)$, where M = V or Cr, have been synthesised by the reaction of $Cp_2Ti(CO)_2$, Cp_2V, and Cp_2Cr (Cp = cyclopentadienyl) with $(SeCN)_2$ and $Se(CN)_2$ in ether in an atmosphere of nitrogen[149].

The synthesis of the compounds $(\eta^5\text{-}C_6H_5)RhL(SeCN)_2$ (R = H or CH_3) has been mentioned[150]. The complexes are obtained by the interaction of $(\eta^5\text{-}C_5R_5)RhLCl_2$ with $NCSe^-$, where L = CNR′ and R′ = C_6H_{11}; the SeCN groups are coordinated to rhodium via selenium.

The synthesis of the compound $CF_3HgSeCN$ has been described[151]. After the reaction of $Cu(SeCN)_2$ with a twofold excess of $CpFeC_5H_4HgCl$, where Cp = $\pi\text{-}C_5H_5$, the complex $CpFeC_5H_4SeCN$ was isolated[152].

An X-ray diffraction study has been made of the compound $KSe(SeCN)_3.0.5H_2O$.[153] The selenotriselenocyanate ions are dimerised to form almost planar groups. All six cyano-groups of the dimeric anion are located on one side of its middle plane. The C≡N (1.21–1.45 Å) and Se–C (1.808 to 1.876 Å) bond lengths have been determined.

The selenotriselenocyanate ions in the rubidium compound $RbSe(SeCN)_3.0.5H_2O$ with an analogous composition are combined into dimers with a similar geometry, which can be regarded as two selenodiselenocyanate molecules linked together via the bridging selenium atoms of two selenocyanate ions. The eight selenium atoms of the dimer are located in approximately the same plane, on one side of which there are six cyano-groups. The coordination of the central selenium atoms is square planar and the four Se–Se

bonds (2.391–2.409 Å) are in the *trans*-positions relative to the four long bonds (3.127–3.331 Å).[154]

The structure of the compound $[(CH_3)_4N][C_6H_5Te(SeCN)_2]$ has also been investigated. It was shown to be isomorphous with the corresponding thiocyanate[155]. The parameters of the monoclinic lattice of the selenocyanate are as follows: $a = 15.840$ Å; $b = 9.341$ Å; $c = 23.384$ Å; $\beta = 100.67°$; $Z = 8$; space group $C2/c$. The coordination of the Te atoms in the anions is of the planar trigonal type due to the phenyl carbon atom. The Se–Te–Se groups are almost linear and the selenocyanate group is linear.

---oOo---

Thus, since the $SeCN^-$ ions are fairly stable in non-aqueous media, there are considerable prospects for the use of the latter in the synthesis of new compounds incorporating SeCN groups. Further study of compounds of this class will lead to the discovery of their practical applications, for example, in analytical chemistry and in the synthesis of heavy metal selenides and physiologically active preparations[156].

I. INTRODUCTION

In spite of the very high reactivity of fluorine, reactions involving this element often need to be activated by an electrical discharge or by u.v. radiation. Interest in the reactions of fluorine in discharges was stimulated by recent developments in the synthesis of fine inorganic chemicals, and by the search for new oxidisers and high-energy compounds. The plasmo-chemical synthesis of fluorides is often either the only available method or the most attractive one.

Atomic fluorine, formed by passing molecular fluorine through an electrodeless h.f. discharge (40 MHz, 50 W), has been detected[1] by ESR. A dark red glow discharge, whose spectrum contains strong optical lines from neutral fluorine atoms, develops in a fast flow of the gas at a few hundred Pascal pressure.

Small quantities of atomic fluorine in electrical discharges are usually prepared by using a mixture of fluorine (or volatile fluoride) with an inert gas. For example, the following mixtures have been used: fluorine and argon (0.1–20% F_2),[2-9] fluorine and helium (1–20%),[7,9,10] sulphur hexafluoride and helium[11,12]; atomic fluorine has also been prepared from carbon tetrafluoride[4,13-15]. Power is supplied to the gas reactor from a low-power h.f. or microwave generator, for example a standard microwave generator of frequency 2450 MHz and <200 W output power. The discharge tubes are made of quartz or alumina: the latter is more stable towards atomic fluorine[3-8], but it produces dielectric losses higher than those of quartz tubes. The gas flow emerging from the reactor is used to study the reactions of atomic fluorine (see Ref.16 for a comprehensive review).

The dissociation of fluorine in a microwave discharge can be as high as 60–90%[3,9,10], but the concentration of atomic fluorine in the outlet gas decreases rapidly as a result of recombination and reaction with the wall of the apparatus. The recombination rate constant ($F + F + Ar \rightarrow F_2 + Ar$) is estimated[17] to be $(1.8–6.0) \times 10^{13}$ cm^6 mole^{-2} s^{-1}. A study of the recombination of fluorine atoms in the presence of argon at 295 K and 10–81 mmHg pressure gave an experimental value of $(2.9 \pm 0.2) \times 10^{13}$ cm^6 mole^{-2} s^{-1} for the constant[8]. This value is two orders of magnitude lower than the corresponding rate constants for the recombination of Cl, Br, I, O, and H atoms in argon. Molecular nitrogen (as the third body) is approximately 10 times more effective than argon in bringing about the homogeneous recombination of atomic fluorine[8].

A significant proportion of the fluorine atoms is lost on the apparatus walls. On a quartz surface the loss of F atoms occurs mainly by the reaction with SiO_2, accompanied by the formation of silicon tetrafluoride[4,18,19] and of fluorosiloxane polymers[20]. The probability of disappearance of F atoms as a result of wall collisions has been determined[19,21] for the following surfaces: glass, quartz, mullite–silica, Teflon, copper, stainless steel, nickel, aluminium alloys, and gold.

The formation of fluorine atoms from F_2 molecules in an electrical discharge can take place by different mechanisms: the most probable are described by Eqns.(1) and (2):

$$F_2 + e \rightarrow (F_2^-)^* \rightarrow F + F + e , \quad (1)$$

$$F_2 + e \rightarrow (F_2^-)^* \rightarrow F + F^- . \quad (2)$$

The minimum energy of the colliding electron needed for reaction (1) is 1.5 eV; the dissociative attachment reaction (2) is exothermic, and does not require an activation energy[22]. Reactions (3), (4), and (5)

$$F_2 + e \rightarrow F_2^+ + 2e \quad (3)$$

$$F_2 + e \rightarrow F^+ + F + 2e \quad (4)$$

$$F_2 + e \rightarrow F^+ + F^- + e \quad (5)$$

can take place if the energy of the colliding electrons is not less than 16.6, 19.0, and 15.4 eV respectively[22]. The cross-section of reaction (5) increases monotonically with the electron energy from ~16 to 32 eV: this reaction is predominant for field strengths of ~10^4 V cm^{-1}.[23,24]. The presence of F_2^+ ions in gaseous fluorine passed through a glow discharge (50 mA, 15 kV) has been demonstrated[25] spectroscopically. The reaction $F_2^+ + F^- \rightarrow F + F + F$ is thought to be another probable path for the formation of F atoms[22].

The number of F atoms generated by collisions with electrons is proportional to the energy of the electron beam[22]. The rate of dissociation of F_2 molecules in a glow discharge at 0.5 mmHg pressure increases linearly from 3×10^{16} to 1.2×10^{17} cm^{-3} s^{-1} as the current increases from 4 to 45 mA.[26] The dissociative attachment of electrons to the F_2 molecule has been shown[27,28] to be one of the basic rate-limiting processes in the dissociation of fluorine in the positive column of a glow discharge for currents in the range 0.5–50 mA. The thermal dissociation of fluorine molecules in gas discharge plasmas can be ignored because of the relatively low "molecular" temperature of the plasma[27,29].

From sulphur hexafluoride in a discharge the F atoms are formed mainly by the reaction $SF_6 \rightarrow SF_5 + F$;[30] the dissociation of CF_4 gives not only fluorine atoms and molecules, but also C_2F_6, CF_2, and other fluorinated compounds[4]. Thus, in

spite of their ready availability in a very pure form, SF_6 and CF_4 are not the most convenient sources of fluorine for chemical synthesis in electrical discharges.

Low-frequency glow discharges are used most frequently for the synthesis of fluorides: reactions in electrodeless h.f. and microwave discharges, or in silent (barrier) discharges, have not been studied in detail. Whenever possible, the prepared mixture of fluorine (or volatile fluoride) and the other reactant is introduced into the discharge reactor, or the reactants are condensed on the reactor wall and exposed to fluorine (or a fluoride) which has been activated in the discharge. Reactions involving fluorine or a fluoride are usually carried out in reactors cooled to very low temperatures. Often a valuable product can be synthesised only if the reactor walls are cooled in liquid nitrogen, but this is easily done because the discharge current is usually 20–50 mA, corresponding to a power dissipation of only 100–150 W.

In the following Sections we shall review experimental data on the reactions of fluorine and fluorides in an electrical discharge reported since 1969–1970, and therefore not included in earlier reviews[31,32]. Some older work not mentioned in those reviews will also be discussed here.

II. SYNTHESIS OF THE NITROGEN FLUORIDES, TRIFLUORAMINE OXIDE, AND TETRAFLUORO-AMMONIUM SALTS

1. Synthesis of Nitrogen Trifluoride

Nitrogen fluorides have a variety of applications in the synthesis of fine inorganic chemicals and in preparative organic chemistry[33]. In the absence of external agencies such as electrical discharges or ionising radiation fluorine does not react with nitrogen. The nitrogen fluorides NF_3, N_2F_4, N_2F_2, and N_3F are therefore usually prepared from compounds containing bound nitrogen. However, the synthesis of nitrogen trifluoride from the elements is thought[34] to be thermodynamically possible at temperatures below ~900 K. A calculation[35] of the equilibrium composition of the nitrogen–fluorine system shows that at 200–1000 K, for total pressures of 20 or 760 mmHg, and for atomic ratios F : N = 1 : 3, 1 : 1, or 3 : 1 the main fluorine-nitrogen component of the system at equilibrium is nitrogen trifluoride[36], whose concentration is a maximum and close to 1 (in mole fraction) at 200–600 K. As the temperature increases to 700–1000 K the concentration of NF_3 decreases as a result of dissociation, and at 1500 K it becomes negligibly small[37].

The preparation of NF_3 in 30% yield from the elements in a glow discharge was reported[38] in 1964, but the synthesis of NF_3 in a glow discharge appears[39] to have first achieved in 1960. The synthesis of nitrogen trifluoride is possible whether or not the discharge tube is cooled in liquid nitrogen: if all other conditions are the same, a better yield is obtained by using cooled U-tubes for the reaction. The electrodes can be made of copper, nickel, copper–nickel alloy, or steel, since none of these materials has a significant influence on the yield of NF_3. Electrodes made of silver or silver–copper alloy disintegrate rapidly in an atmosphere of fluorine, but they give a higher yield of NF_3 than (say) copper electrodes[40]. Varying the fluorine to nitrogen ratio in the initial mixture of gases does not lead to the synthesis of additional products (other than nitrogen trifluoride). The yield of NF_3 is almost independent of the composition of the initial mixture, and increases with the energy dissipated per unit volume of reacting gases to a maximum of 60–70%.[31] Because of its high energy consumption the plasmo-chemical method of synthesis of NF_3 has only limited preparative value. Fluorination of $^{15}N_2$ in a glow discharge has been used[41] to prepare $^{15}NF_3$. Nitrogen trifluoride has been synthesised from the elements also in a barrier discharge (though in low yield)[42], and in a pulsed u.h.f. discharge[43].

2. Dissociation of Nitrogen Trifluoride

Nitrogen trifluoride is unstable in electrical discharges, and easily dissociates into fluorine and nitrogen[31]. The dissociation is reversible, and if the flow rate of the NF_3 through the reactor is slow a limiting concentration of the dissociation products is observed, which depends (among other things) on the strength of the discharge current. For example, for a pressure of 15 mmHg in the glow discharge the degree of dissociation is 70, 90, and 96% for discharge currents of 12, 25, and 40 mA respectively[44]. The limiting degree of dissociation of NF_3 in a barrier discharge under circulating flow conditions[42] is 98%; almost complete decomposition of the NF_3 is obtained also in a u.h.f. discharge[43].

The effect of added fluorine, nitrogen, and oxygen on the decomposition of NF_3 has been studied[45] in a glow discharge without cooling the walls of the reactor in liquid nitrogen. Fluorine inhibits the decomposition slightly, probably by displacing the reaction $NF_3 \rightleftharpoons F + NF_2 \rightleftharpoons 2F + NF \rightleftharpoons 3/2F_2 + 1/2N_2$ towards the regeneration of nitrogen trifluoride. Addition of nitrogen accelerates the decomposition of nitrogen trifluoride, possibly by transfer to the NF_3 molecules of the energy of the electronically excited N_2 molecules: it is well known[46] that NF_3 can be decomposed by active nitrogen, though less readily than ammonia. Addition of oxygen also accelerates the decomposition of NF_3. Under these conditions the system contains fluorine, nitrogen, NO_2, and (in some experiments) N_2O_5. The reason for the absence of nitryl fluoride is not clear, since mixtures of NO_2 and fluorine are known[47] to give FNO_2 very readily by the reactions

$$NO_2 + F_2 \rightarrow FNO_2 + F, \quad NO_2 + F + M \rightarrow FNO_2 + M.$$

The tendency of nitrogen trifluoride to dissociate in a discharge allows this material to be used as a fluorinating agent. Thus, a mixture of NF_3 and O_2 in a tube cooled in liquid nitrogen gave oxygen fluorides at a current of 20 mA and 0.6 mmHg pressure[48], though the formation of trifluoramine oxide (F_3NO) was not detected. Yet, this compound was later synthesised by exactly the same reaction (NF_3 and O_2 in a discharge tube at 77 K: see, for example, Ref. 49). The action of a glow discharge on a mixture of bromine and NF_3 produces bromine fluorides[50]. Bromodifluoramine $BrNF_2$, a possible product of the reaction between Br atoms and NF_2 radicals, is not formed in a glow discharge. The NF_2 radicals formed by the decomposition of NF_3 may be in an unstable excited state which rapidly breaks down. The reaction between NF_3 and chlorine in a microwave discharge gave ClF and nitrogen, but not $ClNF_2$ or Cl_2NF.[51]

3. Synthesis of Difluorodiazine and Tetrafluorohydrazine

Difluorodiazine N_2F_2, which can exist as *cis*- and *trans*-isomers, is formed in trace quantities during the synthesis of NF_3 from the elements in a barrier discharge. Tetrafluorohydrazine (N_2F_4) also could not be obtained in reasonable yield, either from fluorine and nitrogen or from the decomposition of nitrogen trifluoride. One of the factors opposing the synthesis of N_2F_2 and N_2F_4 in discharges is the instability of these compounds in the presence of fluorine,

with which they react to give nitrogen trifluoride. Difluorodiazine N_2F_2 frozen on the wall of the discharge tube at 77 K rapidly reacts with fluorine in a glow discharge to give NF_3. The reaction between N_2F_4 and OF_2 in a discharge at 77 K gives NF_3, NOF, and NO_2F.[39] N_2F_2 and N_2F_4 can be prepared from nitrogen trifluoride in a discharge tube if a fluorine acceptor (for example, mercury) is added[31,52].

4. Synthesis of Trifluoramine Oxide

The synthesis of trifluoramine oxide F_3NO was reported[53-55] in 1966, though there is evidence in the Patent literature that the compound has been known in some laboratories since 1961 to 1962. F_3NO can be synthesised by plasmo-chemical and photochemical methods as well as by methods not involving radiation or low-temperature plasmas.

Different combinations of the basic components (nitrogen, oxygen, and fluorine) can be used for the synthesis of F_3NO in electrical discharges: $N_2+O_2+F_2$,[56] $N_2+OF_2+F_2$,[57] NF_3+OF_2,[57-60] NF_3+O_2,[49,55,61,62] NF_3+N_2O,[61] and NO_2+F_2.[56] A calculation[36,63] based on published thermodynamic data[35] shows that the N + O + F system at equilibrium may contain substantial amounts of F_3NO, the shape of the equilibrium diagram being very dependent on the N : O : F ratio. The mole fraction of F_3NO in the system at equilibrium is relatively high only at 200–300 K, and falls off very steeply at higher temperatures. Since F_3NO is stable at low temperatures it is essential to quench the products at the conclusion of the plasmo-chemical preparation of this compound. The synthesis of F_3NO in a glow discharge is carried out in tubes cooled to 77 K by immersing the reaction volume either wholly or partly in liquid nitrogen. Attempts to "extract" the F_3NO from the discharge and to condense it in a remote trap were unsuccessful.

The yield of F_3NO from nitrogen trifluoride and oxygen[49,55,62,64] is 10–15%, with ~70% utilisation of the NF_3. In addition to F_3NO the reaction produces oxygen fluorides, oxides of nitrogen, and ozone. Ozone formation can be suppressed by using an excess of NF_3 (for example, by using $NF_3 : O_2$ ratios between 2 : 1 and 6 : 1 in the initial mixture[62]). The synthesis of F_3NO from mixtures of NF_3 and OF_2 does not differ in principle from the synthesis from NF_3 and O_2, since the OF_2 merely acts as a source of oxygen by decomposing into its elements in the discharge. Trifluoramine oxide has been prepared in 20–40% yield from an $NF_3 : OF_2 : Ar = 1 : 1 : 2$ mixture[65].

Mixtures of fluorine, nitrogen, and oxygen are not a very convenient reagent for the preparation of F_3NO in spite of the ready availability of the starting materials. When these mixtures are used the formation of F_3NO is suppressed by a competing reaction: the formation of O_2F_2, which consumes 94 to 97% of the oxygen reaching the discharge (assuming an $F_2 : N_2 : O_2$ ratio of 3 : 1 : 1 in the initial gas mixture)[64,66]. The yield of F_3NO cannot be improved by adding an excess of oxygen: this could merely convert the whole of the fluorine present in the system into O_2F_2.

The reaction between fluorine and nitrous oxide has been studied in detail[66]. The extent of conversion of N_2O into F_3NO, calculated by the equation $N_2O + 3/2F_2 = F_3NO + 1/2N_2$, is almost independent of the composition of the mixture, and goes through a maximum (~20–22%) as the flow rate of the gas is increased. Up to 40–50% of the oxygen formed by the dissociation of N_2O reacts with the fluorine to give O_2F_2: ozone formation is negligible, making this method of synthesis safer than the preparation of F_3NO from NF_3 and O_2. In the absence of an electrical discharge the reaction between fluorine and nitrous oxide at 573–1073 K produces a mixture of FNO and NF_3.[67]

Trifluoramine oxide has been obtained in small amounts (0.5 mmole h^{-1}) from a mixture of N_2, O_2, and F_2 (1 : 1 : 3) in a microwave discharge at a pressure of ~0.5 mmHg.[68] The low yield of F_3NO is probably due to the low power of the microwave source used, which prevented the use of higher pressures. Another possible reason for the low yield is the difficulty of synthesising F_3NO from the elements, which was mentioned above.

Thus the plasmo-chemical synthesis of F_3NO is fairly laborious, offers only a moderate yield, and is accompanied by the formation of large amounts of side products. The photochemical method of preparing F_3NO[69-71] is similar in many ways to the plasmo-chemical methods and has an even lower yield. The most promising method appears to be the combustion of nitric oxide in fluorine in a flow reactor[72]. All methods of synthesis of F_3NO apparently include the following main steps: 1) formation of nitric oxide, 2) fluorination of nitric oxide in nitrosyl fluoride [$NO + F(F_2) \rightarrow NOF(+F)$], 3) fluorination of the nitrosyl fluoride ($NOF + 2F \rightarrow F_3NO$). The nitric oxide may be introduced as a reactant or formed in the plasma (by the oxidation of nitrogen or by the decomposition of nitrous oxide).

5. Synthesis of Tetrafluoro-ammonium Salts

Even quite recently the synthesis of stable tetrafluoroammonium salts was believed to be impossible. According to Wilson[73], only $NF_4^+BF_4^-$ could have enough thermal stability to exist as a stable compound at temperatures below 153 K. However, two papers[74,75] published in 1966 reported the preparation of the salts $NF_4^+AsF_6^-$ and $NF_4^+SbF_6^-$, which are stable at room temperature but rapidly decompose at temperatures above 543–573 K. In 1970 the compound $NF_4^+BF_4^-$ was synthesised[76], and found to be stable up to 513–623 K. In recent years a few more salts containing the NF_4^+ cations have been prepared. The tetrafluoro-ammonium compounds are powerful oxidising agents: they can be used, in principle, as components of solid rocket fuels[77], in gas generating apparatus[78,79], and in laser technology[80,81]. Tetrafluoroammonium hexafluoro-arsenate and tetrafluoroborate have been synthesised in a glow discharge.

The compound NF_4AsF_6 was prepared by circulating a mixture of NF_3, AsF_5, and F_2 (1 : 1 : 2) in a glow discharge apparatus with a discharge tube cooled to 195 K.[31,75,82,83] In very long (~40 h) experiments with inadequate cooling the reactor wall suffered serious corrosion, forming salts with oxygenated cations which contaminated the desired product. In an experiment[84] with a high-pressure mercury lamp irradiating an equimolar mixture of NF_3, AsF_5, and F_2 in a quartz vessel at room temperature the compound $O_2^+AsF_6^-$ was obtained instead of NF_4AsF_6 as a result of corrosion of the walls of the vessel. At 77 K the same reactants in a quartz reactor irradiated with light from a 900 W mercury lamp yielded NF_4AsF_6 at a rate greater than 1 g h^{-1}.[81]

Attempts to synthesise NF_4BF_4 in a glow discharge with a reactor cooled to 195 K proved unsuccessful[85,86]: instead of NF_4BF_4, $O_2^+BF_4^-$ was obtained together with a salt which hydrolysed to give nitrogen oxides. In order to obtain NF_4BF_4 from NF_3, BF_3, and fluorine the reactor walls must be cooled in liquid nitrogen[76,87-89]. The synthesis is carried out as follows: the NF_3 and BF_3 are condensed on the wall of a U-shaped discharge tube, and gaseous fluorine is slowly allowed to flow through the discharge at 30–55 mmHg with a current of 30 mA. After 1 h of discharge a fluorine flow of 400 cm^3 h^{-1} produces ~3 g of NF_4BF_4 in a yield approaching 100%. Up to 3 g h^{-1} of NF_4BF_4 can be obtained by an improved variant of the photochemical method

of synthesis from NF_3, BF_3, and F_2 at 77 K in a reactor made of steel and sapphire[81].

Reactions in which NF_3^+ or F^+ ions give NF_4^+ (for example, $NF_3^+ + F \rightarrow NF_4^+$, or $NF_3 + F^+ \rightarrow NF_4^+$) are possible, in principle, in an electrical discharge, but not in the photochemical or thermal synthesis of tetrafluoro-ammonium salts, since the u.v. energy or the thermal energy of the reactants at 373 to 473 K is insufficient to ionise NF_3 or F. In this context it is interesting to consider the suggestion[84] that the active particles responsible for the oxidation of NF_3 could be the radicals $AsF_6^{\cdot}$, which have a high electron affinity and are formed from a fluorine atom and a molecule of the Lewis acid AsF_5. The reaction between $AsF_6^{\cdot}$ and NF_3 would give first $NF_3^+AsF_6^-$ and then $NF_4^+AsF_6^-$ (by the addition of a fluorine atom).

The possible existence of the radicals $AsF_6^{\cdot}$, $SbF_6^{\cdot}$, $Sb_2F_{11}^{\cdot}$, and the cation radical $NF_3^{\cdot+}$ was confirmed experimentally[90] by γ-radiolysis of the salts NF_4AsF_6 and $NF_4SbF_6.0.8SbF_5$ at 77 K. It was also shown that $NF_3^{\cdot+}$ can be formed as an intermediate during the photochemical synthesis of NF_4AsF_6 and NF_4BF_4 from mixtures of NF_3, F_2, and a Lewis acid[91]. The radical $BF_4^{\cdot}$ was not detected during the radiolysis of NF_4BF_4, possibly because of its low thermal stability. The instability of $BF_4^{\cdot}$ may also explain the failure to obtain NF_4BF_4 in a glow discharge at 195 K.[85,86]. A study[92] of the thermal decomposition of the salts NF_4BF_4 and NF_4AsF_6 finally led to the rejection of the mechanism of formation of NF_4^+ through the formation of radicals of the $AsF_6^{\cdot}$ type and their reaction with NF_3 molecules, and to its replacement by the mechanism

$$F_2 \rightleftarrows 2F, \quad F + NF_3 \rightleftarrows NF_4,$$
$$NF_4 + AsF_5 \rightleftarrows NF_3^+AsF_6^-, \quad NF_3^+AsF_6^- + F \rightleftarrows NF_4^+AsF_6^- .$$

III. SYNTHESIS OF OXYGEN FLUORIDES

The reaction between fluorine and oxygen and the synthesis of oxygen fluorides in a glow discharge are discussed in earlier reviews[31,32]. The plasmo-chemical method was, for a long time, the only method of preparing the compound dioxydifluoride O_2F_2. In 1969 a radiation-chemical synthesis of O_2F_2 was reported[32], and more recently it was suggested that the compound can be obtained by irradiating a mixture of $O_2 + F_2$ or $OF_2 + F_2$ at 77 K with light from a mercury lamp (365 nm)[93] or by fluorinating the oxygen with thermocatalytically generated atomic fluorine[94].

The reality of the existence of higher members of the polyoxydifluoride series O_nF_2 ($n = 2$–6) had been questioned (see previous reviews[31,32]). Pshezhetskii and coworkers[95] doubt the existence of tetraoxydifluoride O_4F_2 as a pure compound. The electronic absorption spectrum of the product obtained by a method[96] claimed to give O_4F_2 in a glow discharge was assigned to a mixture of O_2F_2 and the radicals $O_2F^{\cdot}$. The compound of empirical formula O_4F_2 is thought[95] to be the radical $O_2F^{\cdot}$, at least in dilute solutions (in liquid argon, oxygen, or CF_4). The reaction between fluorine and oxygen in a glow discharge with reactor walls cooled to 77 K or below apparently gives only one of the "polyoxydifluorides": the dioxydifluoride, which may contain the $O_2F^{\cdot}$ radical in concentrations anomalously high for a free radical.

The action of a barrier discharge on a fluorine–oxygen mixture has been studied[97,98]. Pyrex glass ozonisers made of three coaxial tubes were used as reactors. Power was supplied to the ozonisers from an audio-frequency signal generator and amplifier; the reaction was studied in a circulating regime with the fluorine–oxygen mixture at an initial pressure of 100–600 mmHg. The ozoniser wall was cooled in running water, and the gas flow from the ozoniser was led by a connecting tube to a trap cooled in liquid nitrogen ~50 cm away from the ozoniser. A yellow or orange solid was condensed in the cold trap, though in some experiments the condensate (at 77 K) contained a dark red liquid. The composition of the low-temperature condensate obtained from an ozoniser in which the discharge gap was 1 mm wide varied according to the composition of the initial gas mixture, the power of the discharge, the time for which the gas was circulated, and the initial pressure of the gas. The O : F atomic ratio in the condensate varied between 1.1 and 2.04. The most probable combination of oxygen fluorides (to account for a chemical analysis of $O:F = 1.1$–2.04) is the mixture $O_2F_2 + (O_2F)_x$ (mistaken for "O_4F_2" when $x = 2$). The oxygen content in the condensate tends to increase with the circulation time of the initial gas mixture and with its oxygen content, and with a decrease in the power of the discharge and in the initial pressure in the reactor. On heating the tube connecting the ozoniser to the cold trap from room temperature to 323–333 K the rate of formation of condensate in the trap falls off very steeply, though some condensation persists even under conditions clearly unsuitable for the transport of "cryogenic" compounds. The O : F ratio in the condensate remains close to 2 under these conditions, i.e. the condensate approaches the composition "O_4F_2" corresponding in reality to any agglomerate of the $(O_2F)_x$ type.

Since O_2F_2 is thermally more stable[31] than "O_4F_2" the enrichment of the condensate in the "tetra-oxydifluoride" on heating the connecting tube is unexpected. Evidently, the $O_2F^{\cdot}$ radicals are more stable than the O_2F_2 molecules, and these molecules are decomposed preferentially in the heated gas stream, leading to a change in the $O_2F_2 : O_2F^{\cdot}$ ratio in favour of the $O_2F^{\cdot}$ radicals and to a corresponding change in the composition of the condensate. The $O_2F^{\cdot}$ radicals are stable towards F_2 molecules, and they are fluorinated to O_2F_2 only under the influence of atomic fluorine. The compound dioxygenyl hexafluoroarsenate $O_2^+AsF_6^-$, which dissociates on heating with evolution of $O_2F^{\cdot}$,[99] has been used recently to prepare $O_2F^{\cdot}$ radicals and to study their properties.

The condensate obtained from an ozoniser with a discharge gap 0.5 mm wide contains, in addition to the unstable oxygen fluorides, the stable compound oxygen difluoride[98]. The synthesis of $OF_2^{\cdot}$ is very slow: under the most favourable experimental conditions the yield of $OF_2^{\cdot}$ was only 2 mmole h^{-1}. The low rate of formation of $OF_2^{\cdot}$ is explained by the presence of a competing reaction (the synthesis of the unstable oxygen fluorides) and by the difficulty of stabilising the oxygen difluoride in the discharge apparatus of the chosen type.

As a method of synthesis of oxygen fluorides the barrier discharge is inferior to the glow discharge not only in terms of apparatus complexity and of yield, but also because the composition of the condensate is more sensitive to experimental conditions.

IV. SYNTHESIS OF THE HALOGEN FLUORIDES AND OF CHLORINE OXYTRIFLUORIDE

The compounds of fluorine with chlorine, bromine, or iodine are prepared from the elements at room temperature or with moderate heating[100]; many methods of preparing chlorine oxide fluorides are also known. Electric discharges

have been used in the search for methods of synthesis of higher halogen fluorides and of new chlorine oxyfluorides.

1. Synthesis of Chlorine Pentafluoride

An unsuccessful attempt to prepare ClF_5 from ClF_3 and fluorine in an electrical discharge was reported[39] in 1957. The first disclosure[101] of the synthesis of chlorine pentafluoride at elevated temperature and pressure was in 1963; a patent application for the preparation of ClF_5 in a discharge[102] appeared in the same year. In the glow-discharge synthesis[102,103] a mixture of fluorine and chlorine is passed through a U-shaped discharge tube with copper electrodes (cooled to 195 K), and the gases from the outlet are taken to a trap at 77 K. The pressure (30 mmHg) and current (30 mA) in the discharge are kept constant. The reaction products (ClF, ClF_3, and ClF_5) can be separated by low-temperature sublimation. Fluorine can be made to react with chlorine both in a glow discharge (with direct current or at mains frequency) or in an h.f. discharge[102]. Instead of fluorine and chlorine, binary compounds of fluorine and chlorine can be used[102] for the synthesis of ClF_5 (ClF, ClF_3, NF_3, N_2F_2, N_2F_4, NCl_3) as long as the number of fluorine atoms in the initial mixture is in 1–10 fold stoichiometric excess over the number needed to form ClF_5.

The salt $ClF_6^+PtF_6^-$, whose cation can be formally considered to have been derived from the hypothetical chlorine fluoride ClF_7, has been described (see, for example, Ref.104). It was synthesised by photochemical oxidation of ClF_5, using PtF_6, but attempts to produce ClF_6^+ in a glow discharge were unsuccessful[104]. A glow discharge in a reactor made of Pyrex glass, at 195 K and 20–50 mmHg pressure, yields $ClF_2^+BF_4^-$ (but not $ClF_6^+BF_4^-$) from a mixture of $BF_3 + F_2 + ClF_5$ (1:1 and 42:1). Obviously, the ClF_5 dissociates with formation of ClF_3, which reacts with the BF_3 present in the system to give crystalline $ClF_2^+BF_4^-$.[104,105]

2. Synthesis of Bromine Pentafluoride

The reaction between bromine and fluorine in a glow discharge is carried out by freezing bromine in a U-shaped discharge tube at 195 K and adding fluorine to the discharge, either continuously or in portions, while maintaining a pressure of 20–25 mmHg and a discharge current of 20–30 mA.[50] As the reaction proceeds the deeply coloured bromine is converted into the colourless bromine pentafluoride. An 80 to 85% extent of conversion of the Br_2 (calculated as BrF_5) is reached in a few minutes, but the reaction then slows down, and quite long times are needed for the reaction to go to completion. The final yield of BrF_5 is almost 100%. Cooling the walls of the discharge tube with liquid nitrogen lowers the rate of fluorination very strongly, probably by suppressing the renewal of the frozen bromine surface and thus making the underlying layers of condensate inaccessible to the fluorine. The reaction between fluorine atoms and bromine molecules also gives bromine pentafluoride[9].

Unsuccessful attempts have been made to prepare bromine heptafluoride[106]: apparently, BrF_7 (like ClF_7) is unstable towards dissociation into the pentafluoride and fluorine, even at very low temperatures. However, the salts $BrF_6^+AsF_6^-$ and $BrF_6^+Sb_2F_{11}^-$, which contain the BrF_6^+ cation, are known[106]. They are prepared by oxidising bromine pentafluoride with $Kr_2F_3^+$ or KrF^+. The resulting BrF_6^+ is one of the strongest oxidising agents known, and it can easily oxidise O_2 to O_2^+ or xenon to XeF^+ under normal conditions.

3. Synthesis of Chlorine Oxytrifluoride

Chlorine oxytrifluoride F_3ClO was first synthesised in 1965 by a group of workers in the USA,[107] and the synthesis was later confirmed by an independent group in France[108] in 1970. Several methods of preparing F_3ClO have since been reported (see, for example, Ref.109), but they all have serious drawbacks: they are laborious, the reactants are not easily available, the yield of product is low, etc.

Chlorine oxytrifluoride, like trifluoramine oxide, can be prepared in an electrical discharge. In addition to their formal similarity, the reactions leading to the synthesis of F_3ClO and F_3NO have one important feature in common: the need to stabilise the end product very effectively. The quenching and storage of F_3ClO is complicated by the very high reactivity of this compound, which attacks glass or quartz even at temperatures below 273 K. The synthesis of F_3ClO in an electrical discharge has not been studied fully. The compound was first prepared[107] by freezing Cl_2O at 77 K on a Pyrex glass U-tube reactor and passing fluorine at 20 mmHg pressure through the discharge. The products contained ClF_5 (~45 mole %), $FClO_2$, ClF_3, and only 1–2% of F_3ClO. The formation of F_3ClO from ClF_5 and O_2 in a glow discharge with reactor walls cooled to 77 K has been reported[105]. If the wall temperature is raised to 195 K, a strong acceptor of fluoride ions (like BF_3) is needed to fix the F_3ClO in the form of the salt $F_2ClO^+BF_4^-$. Low-temperature fluorination of the salt $ClO_2^+BF_4^-$ in a glow discharge also gives $F_2ClO^+BF_4^-$.[110] Chlorine oxytrifluoride is one of the products of the reaction of perchloryl fluoride $FClO_3$ with fluorine in a glow discharge at 77 K.[105] The action of a glow discharge on a mixture of F_2, Cl_2, and O_2 yields chlorine oxytrifluoride, but in a yield not exceeding 6%.[105] Similarly low yields were reported (see above) for the preparation of trifluoramine oxide from its elements.

V. SYNTHESIS OF THE INERT GAS FLUORIDES

Early work on the synthesis of krypton and xenon fluorides is reviewed in Ref.31. The most difficult to prepare is krypton difluoride, due to the low reactivity of krypton and the low thermal stability of KrF_2. Yields of ~1 g h^{-1} were obtained[111] in the synthesis of KrF_2 in a glow discharge at a current of 10 mA. When the reactor is at 123 K krypton difluoride is not formed. The use of a barrier discharge in a reactor cooled in liquid oxygen or nitrogen gave a yield[112] of KrF_2 of 50 mg kW^{-1} h^{-1}. In a photochemical method[113] of preparing KrF_2 by irradiating a mixture of krypton and fluorine (condensed at 77 K) with light from a mercury lamp the yield of KrF_2 was 4.7 g after 48 h. The photochemistry of krypton difluoride was studied also by Legasov and coworkers[114–116]. KrF_2 is produced at rates of up to 6 kg h^{-1} by treating krypton frozen at 77 K with atomic fluorine generated by a heated nickel catalyst[117]. The reaction between krypton and fluorine in a glow discharge in the presence of antimony pentafluoride[118] gave $KrF^+SbF_6^-$ if the reactor walls were cooled with liquid nitrogen and the discharge current was 10–30 mA.

Xenon difluoride has been prepared in almost 100% yield from a mixture of fluorine and xenon in a glow discharge at 196 K.[119] In the presence of an excess of fluorine XeF_4 is formed, but the tetrafluoride cannot be prepared free from traces of XeF_2 in a glow discharge. A mixture of fluorine and xenon (3:1) was shown[120] to yield XeF_2 contaminated with $XeF_2.XeF_4$ in the early stages of the reaction, and XeF_6 containing a small amount of $XeF_2.XeF_4$ in the later stages. The absence of XeF_4 crystals at all stages of the reaction

was demonstrated by X-ray phase analysis. The authors conclude[120] that the xenon fluorides are formed by the successive fluorination of XeF_2 to XeF_4, and XeF_4 to XeF_6, at rates one order of magnitude lower for each step.

XeF_4 has been synthesised (in yields of up to 39.3 g h^{-1}) by treating solid xenon in a "fluidised" bed with atomic fluorine generated in an h.f. discharge (8 MHz, 0.1–2 kW).[29] Xenon difluoride has been prepared in a pulsed high-pressure discharge with a current of amplitude 50 kA and frequency 70 kHz.[121] The photochemical reaction of xenon with an excess of fluorine ($Xe:F_2 = 1:4–6$) yields XeF_4 at room temperature[122]; the reaction takes place in two steps, and the fluorination of XeF_2 to XeF_4 is ~20 times slower than the fluorination of Xe to XeF_2. The interaction of F atoms with XeF_2 or XeF_4 was not detected in a kinetic study[9] of the reactions of atomic fluorine: the reason is not clear.

Xenon dichloride for spectroscopic work has been prepared by condensing on a cold surface (10–15 K) a mixture of xenon and chlorine which had passed through a microwave discharge[123].

VI. OTHER REACTIONS OF FLUORINE AND FLUORIDES

Many element–organic compounds containing trifluoromethyl groups can be synthesised by using an h.f. discharge: HgR_2, $RHgX$, R_2Te_2, R_2Te, SnR_4, GeR_4, BiR_3 (where $R = CF_3$, $X = Cl$, Br, I).[124–126] The $CF_3^{\cdot}$ radicals are obtained by the dissociation of hexafluoroethane in an h.f. discharge (8.6 to 13.6 MHz) at 0.5–2 mmHg pressure. The course of the reaction is strongly influenced by the power dissipated in the discharge. The dissociation of C_2F_6 into $CF_3^{\cdot}$ radicals requires only 20–25 W, and the use of higher powers causes more substantial decomposition of the C_2F_6 molecule with formation of fluorine atoms and $CF_2^{\cdot}$ radicals. The C–C bond is much less stable than the C–F bond in the C_2F_6 molecule, and the power of the discharge is used initially in breaking the C–C bonds, thus allowing C_2F_6 to be used as a source of pure $CF_3^{\cdot}$ radicals. These radicals can react with the halides of mercury, tellurium, tin, etc. to give the corresponding element–organic compounds. The reactions are slow: typical rates for the synthesis of HgR_2, SnR_4, and BiR_3 are 8, 1, and 0.2 g day^{-1} respectively. The unstable compound $Xe(CF_3)_2$ has been obtained[127] by the reaction of XeF_2 with $CF_3^{\cdot}$ radicals generated from C_2F_6 in the plasma of an h.f. discharge.

Hexafluoro-acetone is an alternative source of CF_3 radicals in an h.f. discharge. The concentration of $CF_3^{\cdot}$ radicals increases linearly with the function $W(P/P_0)^{1/2}$, where W is the power of the discharge (3–24 W), P is the partial pressure of $(CF_3)_2CO$ (0.016–0.064 mmHg), and P_0 is the pressure of the mixture of $(CF_3)_2CO$ and the argon diluent (0.4 to 0.9 mmHg).[128] On the assumption that the $CF_3^{\cdot}$ radicals disappear only by homogeneous recombination the rate constant of the radical formation reaction $(CF_3)_2CO \rightarrow 2CF_3^{\cdot} + CO$ is proportional to the square of the power. Hexafluoro-acetone in an h.f. discharge also acts as a source of the relatively long-lived difluoromethylene radicals (also obtained from CF_4 in a glow discharge and from perfluorocyclobutane in an h.f. discharge)[129]. The $CF_2^{\cdot}$ radicals play an important role in the decomposition of polytetrafluoroethylene in a microwave discharge[130]. In a glow discharge with the reactor cooled to 77 K the compound tris(trifluoromethyl)-hydroxylamine $(CF_3)_2NOCF_3$ yields both $CF_3^{\cdot}$ radicals and fluorine atoms, forming CF_4, COF_2, CF_3NCF_2, C_2F_6, $(CF_3)_2NF$, and $(CF_3)_3N$.[131] The application of a barrier discharge to CF_3PH_2 produces perfluorohydrocarbons, and also the trifluoromethylphosphines $(CF_3)_2PH$, $(CF_3)_3P$, and $CF_3PHPHCF_3$; from $(CF_3)_2PH$ the compounds CF_3PH_2, $(CF_3)_3P$, and $(CF_3)_4P_2$ have been obtained[132].

Polymeric carbon monofluoride $(CF_x)_n$ can be prepared by the reaction between powdered graphite and a fluorine plasma[133,134]. The reaction is carried out in a pseudo-condensed layer at a pressure of 2–5 mmHg. A stream of fluorine passes through the h.f. discharge (20 MHz, 480 W) and reacts slowly with the powdered graphite, giving a snow-white polymeric powder of composition $CF_{1.19}$. A substance of composition $CF_{0.68}$ is also formed, as well as the volatile side-product CF_4. The $(CF_x)_n$ product is almost black for $x = 0.68–0.8$, grey for $x = 0.8–0.95$, and white for $x = 0.95–1.12$. White samples are stable in air at up to ~873 K. Polymeric carbon monofluoride can be used as a high-temperature lubricant in oxidising atmospheres and for frictional components carrying a high load; another potential application of this compound is as a cathode material for high-capacity accumulators.

The silicon analogue of the carbene (SiF_2) is formed in small amounts during the dissociation of silicon tetrafluoride in a glow discharge[135]. Linear and cyclic fluorosiloxanes have been detected mass-spectrometrically[136] among the products of a microwave discharge in SiF_4. A fluorosiloxane polymer of composition $(SiO_{1.5}F)_n$ was obtained from the reaction of SiF_4 with oxygen in a microwave discharge[20]. Trifluorosilane decomposes in a glow discharge, giving SiF_4, Si_2F_6, and a polymeric compound[137].

Sulphur tetrafluoride gives SF_6 in 80% yield in the plasma of a microwave discharge[138]. Sulphur hexafluoride is formed also by the decomposition of S_2F_{10}, SF_5Cl, or $(SF_5)_2O_2$ in a microwave discharge, and the reactions of SF_6, SF_2F_{10}, or SF_4 with chlorine give SF_5Cl.[139] Passing a mixture of selenium hexafluoride and chlorine through a u.h.f. discharge gives only SeF_4.[139] The plasmo-chemical decomposition of SF_6 in a quartz reactor can yield sulphur oxide fluorides formed by the attack on the reactor walls. Thus, substantial amounts of SOF_4, SO_2F_2. SOF_2, and also SiF_4 have been obtained[140] during the decomposition of SF_6 in a quartz reactor by h.f. discharge. A mass spectrometric study of the interaction of SF_6 with the nitrogen plasma of an h.f. discharge revealed the presence of SF_2 as one of the main components of this plasma system, whereas nitrogen fluorides were formed only in trace amounts[141]; the reaction of SF_6 with an oxygen plasma gave OF_2, SO_2, and SOF_2.

Sulphur hexafluoride or a mixture of SF_6 with oxygen, and also carbon tetrafluoride and other fluorocarbons, have been used as the plasma-forming gases in the plasmo-chemical etching of Si, SiO_2, and photoresist in integrated circuit technology (see, for example, Ref. 142). Both fluorine atoms and fluorine molecules, produced by the decomposition of the fluorides in the discharge, contribute to the etching process[143].

Boron trifluoride (unlike the trichloride) is quite stable in electrical discharges. Nevertheless it can undergo changes under the influence of a discharge: thus, the yield of BF_2NH_2 by the reaction between BF_3 and ammonia can be increased markedly by activating the boron trifluoride in a microwave discharge of 80 W power[144].

Lower uranium fluorides are formed by the dissociation of uranium hexafluoride in a low-temperature plasma[145]. The stability of the discharge in UF_6 is determined by the gas pressure and by the frequency of the generator: at 10 MHz the discharge is stable up to 15–20 mmHg, at 17 MHz up to 30 mmHg, and at 2450 MHz frequency a stable discharge can be obtained at atmospheric pressure. The reaction of atomic fluorine generated in an h.f. discharge with uranium tetrafluoride has yielded up to 240 g h^{-1} of UF_6.[29] The fluorination of platinum with atomic fluorine gives PtF_6.[29]

---oOo---

The reactions of fluorine and of the fluorides discussed above have been carried out in the non-equilibrium plasma of a glow discharge and of h.f., microwave and barrier discharges. The primary effect of an electrical discharge appears to be the generation of atomic fluorine by the dissociation of fluorine (or fluoride) molecules. The fluorine atoms then react with the other component, which may be located (in a gaseous or a condensed state) in the region where the fluorine atoms are generated or outside this region. Furthermore, the discharge may also activate the second component of the reaction (though this is not always a requirement in fluorination reactions). For example, the synthesis of O_2F_2 in an electrical discharge does not require special activation of the oxygen molecules, and the same is true of the fluorination of oxygen to O_2F_2 (in a reactor cooled in liquid nitrogen) by atomic fluorine generated on a nickel catalyst. Similarly, the synthesis of KrF_2 and XeF_2 in a glow discharge does not require activation of the krypton or xenon atoms.

The yield of the reaction products depends on several factors, such as the thermal stability of the product, its stability towards the discharge, and its inertness towards the apparatus walls. The thermally unstable compound O_2F_2, which has a vapour pressure of 0.01 mmHg at 105 K, condenses on the reactor wall when synthesised in a glow discharge and can be prepared in quantitative yield, whereas oxygen difluoride, though stable at up to ~480 K, has a vapour pressure of ~1 mmHg at 77 K and cannot be prepared in a glow discharge: it is not found among the products, possibly as a result of its decomposition in the gas phase under the influence of the discharge.

Fluorination in a discharge tends to give the higher fluorides, though the O + F system is exceptional in this respect and yields its highest and most stable fluoride (OF_2) only in a barrier discharge and in small yield. In the N + O + F and Cl + O + F systems only two members of the large group of oxide fluorides of nitrogen and chlorine have been obtained by plasmo-chemical methods: F_3NO and F_3ClO. This may be due to low stability of the other oxide fluorides in a glow discharge.

The equilibrium low-temperature plasma is not very attractive as a reaction medium for fluorine and the fluorides, though it could be used for pyrolysis reactions involving (for example) chlorofluorocarbon compounds.

The Photochemistry of Bilirubin

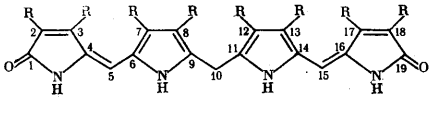
A.E.Myshkin and V.N.Sakharov

The present state of research into the photochemical reactions of bilirubin in various media is examined. Data are presented on certain physical, chemical, and physicochemical properties of bilirubin. Attention is specially concentrated on photodynamic decomposition processes and photoisomerisation of bilirubin. The data are discussed in connection with the urgent problem of the use of light in the treatment of hyperbilirubinemia in children.
The bibliography includes 85 references.

CONTENTS

I. Introduction 40
II. The structure and properties of bilirubin 40
III. Photochemical reactions of bilirubin 43
IV. Phototherapy of neonatal jaundice and its problems 48

I. INTRODUCTION

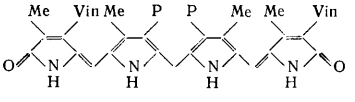


The yellow pigment bilirubin (BR) is formed in the organism mainly by the degradation of haemoglobin released into the blood plasma from decomposing erythrocytes. In contrast to the protein and "free" iron, which are also haemoglobin degradation products, BR is not utilised by the organism and furthermore can have a toxic effect on the latter. Therefore the removal of BR from the organism is an important physiological process, which, however, is to a large extent complicated by the insolubility of BR in aqueous media so that BR is transported in the organism by being bound in water-soluble complexes and as a result of the formation of water-soluble derivatives. In particular, BR circulates in the blood channels in a complex with serum albumin (SA) and with participation of liver cells is removed to the common bile ducts mainly in the form of esters with one or two glucuronic acid molecules. When the system for the removal of BR from the organism breaks down, a pathological state—hyperbilirubinemia—can arise; this state is accompanied by the deposition of BR in the skin, which acquires a yellow hue as a result. This factor is the basis for the common term "jaundice" used in medical practice.

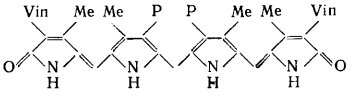
Recently the treatment of neonatal jaundice by irradiating the skin with visible light in a specific wavelength range has come to be widely employed. The successful application of phototherapy led investigators to undertake studies on various aspects of the photochemistry of BR. This review is in fact devoted to this problem. Bearing in mind that in recent years there have been no review communications on BR in Soviet literature we also considered topics necessary for the understanding of the photochemistry of BR, which provide an idea about the most important physicochemical, physical, and chemical properties of BR.

II. THE STRUCTURE AND PROPERTIES OF BILIRUBIN

1. Structure

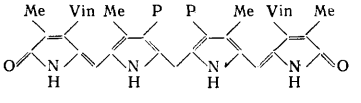


Bilirubin constitutes a set of structural isomers of a tetrapyrrole compound having the general formula



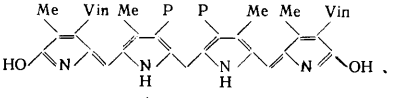
(1)

where R = methyl (Me), vinyl (Vin), or carboxyethyl (P = propionic acid residue) under conditions such that in all instances there are two vinyl, two carboxyethyl, and four methyl groups.



It has come to be assumed that only one of the structural isomers of BR (the so called BR IXα) is formed in the organism:

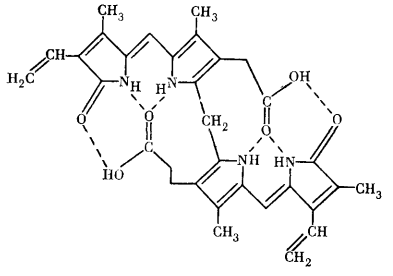
(IXα), (2)



(IIIα), (3)

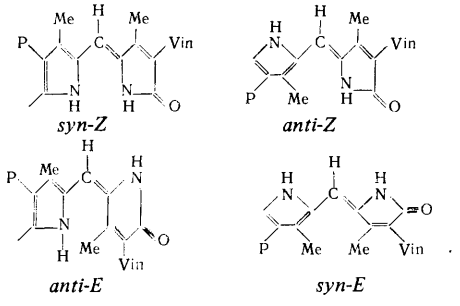
(XIIIα). (4)

This isomer has come to be referred to simply as bilirubin in medical, biological, and chemical practice. However, there are data showing that the blood serum of the newborn suffering from jaundice contains only 62–70% of BR IXα, while the remaining BR consists of the isomers IIIα (10–19%) and XIIIα (16–20%).[1]



The bislactam or dioxo-form [formula (1)] is not the only possible form of BR. In principle one may assume also the existence of the bislactim form

(5)



However, there are at present no reliable data concerning the content of a particular form both in solution and in the solid state. The bislactam form explains the majority of the chemical and physicochemical properties of BR but conflicts with the extremely low solubility of BR in water—at pH 7.4 and an ionic strength of 0.1 M the solubility of BR is only 0.05 mg litre^{-1}.[2] The contradiction disappears if one assumes the formation of a system of fairly strong intramolecular hydrogen bonds involving the propionic acid residues, the hydrogen atoms at the pyrrole nitrogen atoms, and the endocyclic carbonyl groups[3,4].

However, there are data showing that the hydrogen atoms at the pyrrole nitrogen atoms (and furthermore only in the two middle pyrrole rings) form hydrogen bonds only in non-polar solvents, while in the solid state of BR the four hydrogen atoms of the NH groups do not participate in the formation of intramolecular hydrogen bonds[5]. It has been suggested in addition that formula (6) corresponds to a planar conformation of the BR molecule[6], which has been confirmed by X-ray diffraction data[7]. Furthermore, the conformation of the BR molecule is chiral and its rigidity imparts to BR an optical activity[8]. The free energy barrier between the enantiomeric conformations of BR in chloroform, amounting to 17.9 ± 0.5 kcal mol^{-1}, has been determined by NMR.[9]

(6)

Together with structural and mirror isomerism, there is also a possibility of the *cis–trans* isomerism in the BR molecule, because the positions of the substituents relative to the two enamide C=C bonds can be different. The possible geometrical isomeric structures relative to only one of the C=C enamide bonds are illustrated below:

It has been shown by simple semiempirical conformational analysis[10] that the planar configuration holds only for the *syn-Z* isomer. Thus a structure of the type *syn-Z*, *syn-Z* should be ascribed to the planar conformation of the BR molecule. The isomerism associated with the rotation of the central pyrrole rings relative to the exocyclic C–C bond is usually neglected and the shorter designation *Z*, *Z* is used for the principal conformation of BR IXα.

2. Physicochemical Properties

Among the physicochemical properties of BR, its solubility in various media and the formation of complexes with other molecules are of greatest interest for photochemical investigations. Furthermore, the knowledge of these characteristics of BR is significant for the understanding of its behaviour in the organism at various metabolic stages.

The extremely low solubility of BR in water has already been mentioned. Since BR has two amide carbonyl groups and, what is still more significant, two carboxy-groups, the pH of the medium is of decisive importance for the solubility of BR in aqueous media. With increase of pH, the carboxy-groups ionise initially and then the enolic groups, which facilitates the solubilisation of BR in water. It is believed that 0.1 M NaOH, KOH, or Na_2CO_3 are optimal for the preparation of aqueous BR solutions. Potassium cyanide also promotes the dissolution of BR: 0.04 M BR dissolves in 0.1 M KCN.[6] When aqueous BR solutions are neutralised, colloidal solutions are formed. In acid solutions BR is almost insoluble. The majority of non-polar organic solvents do not dissolve BR. Polar solvents such as methanol, ethanol, and acetic acid are also included among solvents which are ineffective for BR. On the other hand, BR readily dissolves in acetone, benzene, isobutyl methyl ketone, formamide, dimethylformamide (DMF), dimethyl sulphoxide (DMSO), pyridine, and chloroform[6]. Chloroform has come to be particularly widely used by investigators.

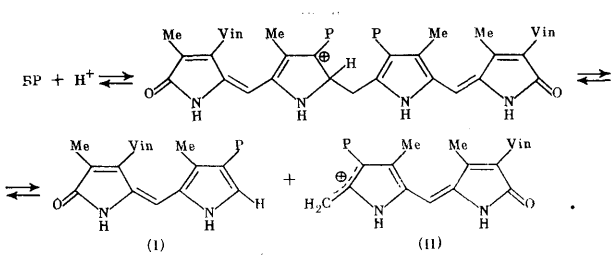
A recently published communication[11] presents data contradicting the widespread concept of the lipophilicity of BR and its consequent neurotoxicity. The author[11] showed that the solubility of BR in triglycerides is low and that its solubility increases with increasing polarity of the medium.

The solubility of BR in aqueous solutions of proteins, particularly blood serum albumins, is of particular importance. It is noteworthy that proteins themselves are incapable of solubilising BR in aqueous solution. When it is necessary to dissolve BR in a neutral aqueous solution of a protein, BR is usually first dissolved in an alkine solution of the protein, which is then neutralised. It follows from this that proteins are incapable of disrupting the intramolecular hydrogen bonds in the BR molecule. On the other hand, proteins form fairly stable complexes with BR in which the above bonds had been ruptured beforehand[6].

Numerous studies have been made on the formation of complexes between BR and SA. It has been established that serum albumins possess centres for "strong" and "weak" binding of BR.[12,13] Between one and two BR molecules are strongly bound to SA and between 10 and 14 molecules are less strongly bound[13]. The less strongly bound BR molecules are comparatively readily displaced from the complexes by carboxylic acids[14–16] and also by certain other compounds.

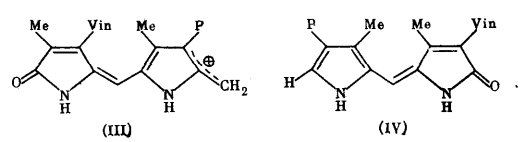
3. Chemical Properties

In considering the structure of the BR molecule, a number of *a priori* conclusions can be reached concerning the most general possibilities for its chemical reactions. In the first place the BR molecule can be regarded as consisting of two conjugated fragments separated by a methylene bridge. Hence it is natural to suppose that the latter is a fairly active reaction centre, since, as a result of the possible dehydrogenation of BR at the bond adjoining this bridge, the conjugation embraces the entire tetrapyrrole system, which should lead to a gain in its energy. The presence of a large number of double bonds, including four exocyclic carbon–carbon double bonds, leads to the expectation of various addition reactions of BR involving the double bonds and also of oxidative cleavage reactions typical for olefins. The propionic acid residues are responsible for the weak acid properties of BR, which can be intensified in an alkaline medium as a result of the tautomeric transition of BR to the bislactim form with two enolic hydroxyls. The basic properties of BR are determined by the nitrogen atoms



in the central pyrrole rings. In the extreme pyrrole rings the nitrogen atoms, which are of the amide type, are not basic.

Strong oxidants, such as potassium permanganate or chromic acid in acetic acid[17], decompose the tetrapyrrole system to monopyrrole compounds, from a mixture of which haematinic acid and methylvinylmaleimide were isolated. Weaker oxidants, such as iodine, a dilute solution of iron(III) chloride[18], cerium salts, or hydroquinone in an alkaline medium[19] oxidise only the central methylene bridge of BR with formation of a biliverdin molecule [see compound (V) below].



The reduction of BR is possible only with the aid of strong reductants. In the catalytic hydrogenation of BR in the presence of colloidal palladium or platinum in an alkaline medium[20], the vinyl group in the 18-position and then the vinyl group in the 3-position were reduced in succession (the formation of mesobilirubin), after which the $C_{(5)}$ and $C_{(15)}$ methylidene bridges were reduced under more severe conditions (the formation of urobilinogens). Sodium amalgam has also been used to reduce BR.[21,22].

The behaviour of BR in the presence of acids is interesting from all points of view. It has been observed[23] that, as a result of the acidification of a solution of BR IXα in DMSO with dry hydrogen chloride at room temperature, a mixture of BR isomers is formed after 1 min: IXα, IIIα, and XIIIα in proportions of 1:2:1. The isomerisation in the DMSO–acetic acid system takes place only on heating. In an alkaline medium (DMSO–NaOH–water) isomerisation was not observed.

On the basis of the products of the acid isomerisation of BR IXα, it is easy to postulate a process mechanism which apparently involves the protonation of the BR molecule at the $C_{(9)}$ or $C_{(11)}$ atoms with subsequent cleavage of the protonated BR molecule into two dipyrrolylmethene fragments. In particular, protonation at $C_{(9)}$ leads to the following transformations of BR IXα:

The protonation at $C_{(11)}$ similarly results in the formation of two fragments:

The recombination of (I) and (II) (the reverse reaction) leads to the reformation of the isomer BR IXα. On the other hand, the recombination of (I) and (III) and of (II) and (IV) leads to the BR isomers IIIα and XIIIα respectively.

A physiologically important reaction of BR is the formation of its water-soluble esters via the propionic acid residues, in particular the formation of esters with glucuronic acid. The mono- and di-glucuronides of BR have been obtained from BR with imidazole-activated carboxy-groups[24].

Numerous studies have been devoted to the formation of metal complexes of BR,[25–27] but these properties of BR are considerably outside the subject of the present review.

4. Optical Absorption Spectra

The optical characteristics, particularly the absorption spectra, of BR are important for the understanding of the mechanism of its photochemical reactions. According to data in a review[6], the absorption spectrum of a neutral aqueous solution of BR has a maximum at 440 nm, the transition to the alkaline region being accompanied by a significant hypsochromic shift (λ_{max} = 420 nm). When proteins are added to an alkaline solution of BR, the absorption maximum shifts towards longer wavelengths (450 nm), approaching the position of the maximum in a neutral protein-free solution. This factor suggests a definite similarity between the states of BR in a protein-free aqueous solution and in the presence of proteins. Since, as stated above, the formation of complexes between BR and proteins requires a preliminary dissociation of the intramolecular hydrogen bonds in the BR molecule, presumably the BR in complexes with proteins has no or virtually no bonds of this kind. On the other hand, the similarity of the spectra permits an analogous conclusion also concerning BR in a protein-free aqueous solution. The same state is apparently characteristic also of BR dissolved in chloroform (λ_{max} = 453 nm) and DMF (λ_{max} = 456 nm). The available data concerning the absorption of BR in the ultraviolet are contradictory owing to the different degrees of purity of the pigment investigated. One of the causes of this is the relatively low stability of BR in solutions. For example, the optical density at the BR absorption maximum in 0.1 M NaOH, NH_4OH, and Na_2CO_3 solutions decreases at a rate of 2–10% per hour[28]. It is therefore recommended that the ultraviolet and visible spectra of BR be measured in the course of several minutes after preparing the solution.

The infrared spectrum of BR in KBr contains the absorption band of the hydroxyl in the carboxy-group at 2500 cm^{-1} and of the carbonyl group at 1680 cm^{-1}. The bathochromic shift of the carbonyl band is due to the involvement of the carbonyl group in a hydrogen bond[29].

5. The Luminescent Properties

The luminescent properties of BR provide the best idea about the nature of the excited states of the molecule, which in its turn permits a deeper understanding of the photochemistry of BR and the associated problems of phototherapy. Neither the fluorescent nor the phosphorescence of BR solutions has been observed at room temperature. On the other hand, a greenish emission at ~525 nm has been noted in various polar solvents at 77 K.[30] The fluorescence quantum yield Q_F = 0.13 has been determined in ethanol at 77 K.[31]

The fluorescence of BR in the ether–isopentane–ethanol–DMF (6:5:3:0.5) system with excitation by the light of a high-frequency pulsing lamp at a wavelength <450 nm has been studied in detail[32]. The emission half-period was <5 ns, which is characteristic of fluorescence. The apparent fluorescence quantum yield (relative to fluorescein at room temperature) was ~0.05. The excitation spectrum, measured at the emission maximum at 520 nm, revealed a fairly sharp maximum at 472 ± 5 nm, which differed significantly from the broad band in the region of 470 nm in the absorption spectrum at room temperature. In their study of the influence of temperature in the range from 293

to 215 K on the absorption of BR in dichloroethane and DMF at 450 nm, the authors[32] observed spectral changes only for the solution in DMF. At the same time a fluorescence appeared in the DMF solution at 215 K, such fluorescence being absent from dichloroethane at the same temperature. On this basis, it was suggested[32] that a fluorescent form of BR is formed reversibly in certain polar solvents, particularly DMF, as the temperature is reduced.

Later it was observed that the fluorescence of a BR solution is possible also at room temperature when the solution contains SA with which BR forms a complex. Depending on the origin of the SA, both the emission maximum and the fluorescence quantum yield can vary[33]. Whereas in the case of human SA these parameters are respectively 527 nm and 0.00102, for bovine, rabbit, and monkey SA their respective values are 546 nm and 0.00085, 531 nm and 0.00084, and 528 nm and 0.00037. However, a higher fluorescence quantum yield of the complex of BR with bovine SA has been published[31] ($Q_F = 0.01$).

Thus a solution of BR, which does not fluoresce at room temperature, begins to fluoresce only when the temperature is reduced on formation of a complex of BR with a protein. In both cases light is emitted by a BR molecule, which has a limited number of degrees of freedom. Matheson et al.[31] therefore reached the fully logical conclusion that the radiationless loss of energy by BR in a liquid solution is determined by molecular vibrations or conformational changes, which completely suppress the emission. This conclusion has been to some extent confirmed by the observation of the fluorescence of BR in an aqueous solution in the micellar environment of cetyltrimethylammonium bromide molecules[34].

The absence of the fluorescence of BR under the usual conditions has been explained[35] by the rapid internal transition ($k \cong 10^{12}$ s^{-1}) of the excited singlet state S_1 formed initially into a state S_1' with a somewhat lower energy, which can undergo a radiationless transition either to the initial singlet state S_0 or to the first excited triplet state T_1, which will be considered later.

III. PHOTOCHEMICAL REACTIONS OF BILIRUBIN

1. Primary Photochemical Reactions

The photoexcited BR undergoes reactions giving rise to products which can in their turn undergo further reactions both under the influence of light and in the dark. In order to approach an understanding of the mechanisms of the photochemical reactions of BR, it is useful to consider separately the primary photochemical reactions and to attempt to isolate them from the overall chain of transformations of BR in the light. We shall introduce a more rigorous limitation by assuming that other molecules, including molecular oxygen, are not involved in the primary photochemical reactions of BR.

By irradiating with light from monochromatic and nonmonochromatic xenon sources a solution of BR in chloroform and also in phosphate buffer at pH 7.4, placed in a quartz cuvette, Davies and Keohan[36] observed by differential spectroscopy the presence of a photolabile product with an absorption maximum at 490 nm. The product could be detected only in the presence of an excess of BR, which played the role of a protecting material (internal filter). This experiment was subsequently reproduced by the same authors[37] using apparatus which permitted the isolation of the exciting emission with a maximum in the range 410–440 nm, having a low energy both below 360 nm and above 470 nm; in particular, this created conditions for a greater stability of the photoproduct with an absorption maximum at 490 nm. It was observed that the photoproduct concentration increases up to a BR conversion of 10–15% and then remains constant.

After a careful analysis of the differential spectra, the authors[37] concluded that, together with the photoproduct having $\lambda_{max} = 490$ nm, a second photoproduct, absorbing at 420 nm, is formed. The similarity of the differential spectra of seemingly different systems such as BR solutions in carbon tetrachloride and chloroform, on the one hand, and a solution of BR in phosphate buffer with added bovine SA, on the other, is noteworthy. In contrast to this, the differential spectrum of an irradiated BR solution in phosphate buffer with added human SA has its own characteristic features. Hence one may conclude that, in contrast to bovine SA, human SA modifies significantly human BR.

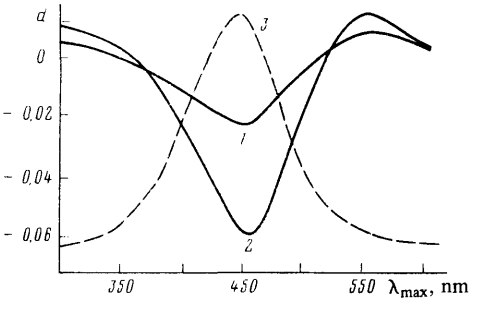


Figure 1. Differential spectra of a solution of BR in chloroform with 1% of ethanol on irradiation at a wavelength of ~440 nm: *1*) 60 s after irradiation; *2*) 360 s after irradiation; *3*) integral spectrum of BR (on an arbitrary scale).

On irradiating BR in chloroform with added 1% of ethanol at a wavelength of ~440 nm, Lightner et al.[38] observed a positive absorption in the region of 350 and 500 nm in the differential spectra (Fig.1) together with a negative maximum at ~460 nm (corresponding to a decrease of the amount of BR). Analogous spectra have also been obtained after irradiating BR solutions in chloroform with 1% of hexane at 420 and 430 nm and also in ammoniacal methanol at 400, 410, and 420 nm. It is significant that the absorption band at ~500 nm arises under both anaerobic and aerobic conditions. The absence of an effect by singlet oxygen in the latter case has been demonstrated by the weak influence on the spectrum by singlet oxygen fluorescence quenching agents—dimethylbutene, diethylamine, and triethylamine. The intensity of the band at ~500 nm gradually increases in the course of irradiation and reaches a constant value after 1–10 min (alkaline solvents accelerate the process). Under more prolonged irradiation, the intensity of this band begins to diminish. If a solution which has reached photoequilibrium is allowed to stand in the dark at 22 °C, a slow but quite appreciable thermal restoration of the initial spectrum takes place. This process is accelerated by the addition of traces of CF_3COOH (the reduction then takes place almost instantaneously) or I_2. An analogous effect also occurs on irradiation of a photoequilibrated solution by light at a

wavelength of ~510 nm with a band width of 10 nm. In the latter case a new photostationary state of the solution with a lower content of the photoproduct arises.

The authors[38] were able to isolate with the aid of thin-layer chromatography the photoproduct formed on irradiation of the BR solution in ammoniacal methanol. The product, which the authors called photobilirubin, consisted of a yellow substance with a broad absorption band at 440 nm but without an absorption peak in the region of 500 nm. Photobilirubin was always contaminated with different amounts of BR, which the authors believe is formed via a reverse thermal transformation of photobilirubin into BR. According to Lightner et al.[38], the peak at 350 and 500 nm in the differential spectra are not absorption maxima of the photoproduct and merely characterise the difference between the absorption of BR and that of the photoproduct in the region of the above wavelengths. The logical hypothesis was put forward that photobilirubin is none other than a mixture of the photoisomerisation products of BR involving the exocyclic C=C enamide bonds, among which the virtually identical *Z*, *E*-, and *E*, *Z*-isomers predominate and there is a small amount of the *E*, *E*-isomer (see the formulae above).

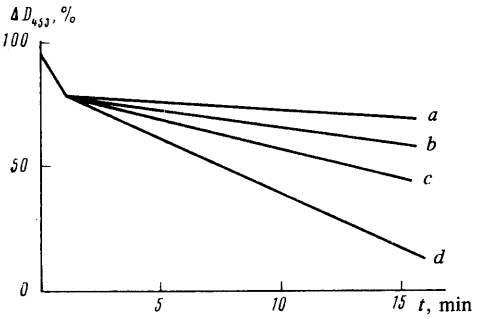

Figure 2. Decrease of the concentration of BR on irradiation of its solution in chloroform (at a concentration of 1.5×10^{-2} M) from a light source at a wavelength >390 nm (for explanation, see text).

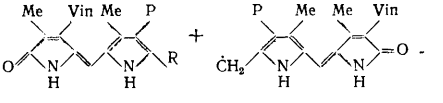

Fig. 2 presents curves characterising the decrease of the BR concentration (decrease of absorption at 453 nm) observed in chloroform solution by light at a wavelength >390 nm.[38] Solutions saturated with argon (*a*), saturated with O_2 in the presence of 0.15 M 1,4-diazabicyclo[2,2,2]octane (*b*), saturated with O_2 in the presence of 10^{-3} M dimethylbutene (*c*), and simply saturated with O_2 (*d*). Evidently all the curves have a common initial section, to which corresponds an irradiation time of ~1 min. The authors[38] suggest that this section characterises the formation of photobilirubin, while the subsequent sections of the individual curves characterise the conversion of BR, the rate of which depends on the mixture composition.

Products similar to the photobilirubin found by Lightner et al.[38] have been discovered also by other workers. In particular, Zenone[39] et al., who irradiated BR in chloroform with visible light, isolated in 7% yield a yellow product with a higher polarity than BR IXα. After irradiating with intense visible light a solution of BR in chloroform, Stoll et al.[40] isolated three BR isomers having the same absorption maximum (442 nm) as BR IXα (the *Z*, *Z*-isomer). Two of these isomers decomposed in the dark with formation of brown products, while the third was reconverted into the initial BR. On irradiation, all three isomers were converted into the *Z*, *Z*-isomer BR IXα.

The studies discussed above permit a conclusion very important for the understanding of the photochemistry of BR: the primary products arising on irradiation of BR with visible light are its geometrical isomers. Possibly one of the causes of the absence of the BR fluorescence and phosphorescence under the usual conditions is the consumption of the excess energy of the excited singlet and triplet states on overcoming the energy barrier separating the *Z*, *Z*-isomer of BR from the other geometrical isomers. Being less stable than the *Z*, *Z*-isomer, these isomers are either reconverted into the initial BR or are irreversibly converted into non-BR products, depending on the conditions. A particularly important property of the BR "photoisomers" is their polarity, which is apparently determined by the complete or partial rupture of the intramolecular hydrogen bonds characteristic of the *Z*, *Z*-isomer of BR. The polarity is responsible for the water solubility of these isomers, which may prove to be one of the decisive factors in the phototherapy of the jaundice of the new-born.

2. Photochemical Formation of Structural Isomers of Bilirubin

As already stated, in the presence of an acid BR IXα isomerises to its structural isomers IIIα and XIIIα. The first stage of the process is the protonation of the BR molecule at the $C_{(9)}$ or $C_{(11)}$ atoms. On the basis of general chemical considerations, one may assume that an analogous reaction can proceed also via a radical mechanism. If a free radical $\dot{R}$ arises for one reason or another in a solution containing BR IXα, one of the possible reactions will be its addition to the BR molecule at $C_{(9)}$ or $C_{(11)}$. Each of the newly formed tetrapyrrole free radicals can decompose into two dipyrrole fragments, for example [after addition to $C_{(9)}$]:

The radical fragment can in its turn add to an unreacted molecule of BR IXα at $C_{(9)}$ or $C_{(11)}$ (chain propagation), after which the dipyrrole fragment, incorporated in the initial molecule, can be split off in the form of a free radical from the hexapyrrole free radical formed, etc. As a result, a further two isomers (IIIα and XIIIα) will be produced instead of the isomer BR IXα present initially in this system. The primary radical $\dot{R}$ can be formed from any one component of the system, including a BR molecule. One of the factors stimulating the generation of free radicals is irradiation by light.

Photoisomerisation of the type IXα ⇌ IIIα ⇌ XIIIα has indeed been frequently observed experimentally. In particular, McDonagh[41] observed this isomerisation after irradiating with visible light solutions of BR IXα (2.5 mg %) in aqueous buffers at pH 8.0 and 8.5 in the absence of O_2. The reaction proved to be less typical for a solution of BR in chloroform and did not occur at all in 0.1 *N* aqueous NaOH solution in DMSO.

The photoisomerisation of BR IXα to its structural isomers is probably one of the causes of the usual contamination of commercial BR preparations by isomers IIIα and XIIIα.

3. Interaction of Bilirubin with Molecular Oxygen on Photoirradiation

Since the photochemical reactions of BR under physiological conditions always take place in the presence of molecular oxygen, studies of the photochemistry of BR in oxygen-containing solutions and, specifically the interaction of BR with O_2 under photoirradiation conditions, are of greatest interest from the practical point of view.

McDonagh[42] was the first to show that BR sensitises the formation of singlet oxygen. He established that, when BR is irradiated with visible light in chloroform, its photochemical oxidation is greatly accelerated by Methylene Blue, octaethylporphin, and other agents photosensitising the formation of $^1O_2$, while $^1O_2$ quenching agents—1,4-diazabicyclo[2,2,2]octane and *trans*-β-carotene—inhibit photochemical oxidation. McDonagh[42] suggested that the photochemical oxidation of BR by molecular oxygen proceeds via a stage involving energy transfer from the excited triplet BR to $^3O_2$. Another piece of evidence for the participation of singlet oxygen in the reaction (predominantly in the $^1\Delta g$ state) is the similarity of the rate constant for the reaction of BR with photophysically generated $^1O_2$ in water (3.5×10^8 litre mol^{-1} s^{-1}) to the rate constants for the photochemical oxidation of BR in chloroform, a mixture of chloroform and methanol, and other solvents. The rate constant for the physical quenching of the fluorescence of bilirubin by $^1O_2$ has been determined as 9×10^8 litre mol^{-1} s^{-1}.[37]

The existence of the triplet state of BR has been demonstrated experimentally[43]. A solution of BR at a concentration of 4×10^{-5} M in benzene with added 0.1 M biphenyl was subjected to pulse radiolysis with a dose of ~1000 rad, after which the absorption spectrum of the excited BR was measured. It was observed that, over the entire range of the experimental spectrum (490–700 nm), after a 20 ns excitation pulse the absorption intensity uniformly increases to a maximum after 5 μs, and then decreases with a half-life of 9 μs. The rate of increase of absorption is the same as the rate of decomposition of the triplet state of biphenyl measured at 360 nm.

An analogous but weaker absorption arises also in the pulse radiolysis of BR in the absence of biphenyl. After adding 10^{-5} M BR to a solution of anthracene in benzene (at a concentration of 3×10^{-5} M), the author[43] noted an appreciable increase of the rate of decomposition of the triplet state of anthracene, whence it follows that the triplet level of BR is lower than that of anthracene. It has also been established that the triplet level of BR is close to that of perylene and has an energy of ~150 kJ mol^{-1}. The yield of the singlet–triplet transition $\phi_T \leq 0.1$ has been determined by laser flash photolysis using anthracene as a standard. The proposed mechanism of the photochemical oxidation of BR includes the following stages:

$$\mathrm{BR} \rightarrow {}^1\mathrm{BR}^*,$$

$${}^1\mathrm{BR}^* \rightarrow {}^3\mathrm{BR}^*,$$

$${}^3\mathrm{BR} + \mathrm{O}_2({}^3\Sigma_g^-) \rightarrow \mathrm{BR} + \mathrm{O}_2({}^1\Delta_g),$$

$$\mathrm{O}_2({}^1\Delta_g) + \mathrm{BR} \rightarrow \text{BR oxidation products}.$$

Since the energy of the $O_2(^1\Delta_g)$ molecule is 94 kJ mol^{-1} and the energy of ^{3}BR* is ~150 kJ mol^{-1}, the reverse energy transfer from $O_2(^1\Delta_g)$ to BR in the ground state with excitation of BR in the triplet state is impossible. The quenching of singlet oxygen in its interaction with BR is therefore accompanied by chemical transformations of BR. On the other hand, agents quenching singlet oxygen, having an energy between 150 and 94 kJ mol^{-1}, can inhibit the decomposition of BR, as suggested by Land[43]; the inhibition takes place via energy transfer from the triplet state of BR. Quenching agents with energies less than 94 kJ mol^{-1} can inhibit the decomposition of BR both as a result of energy transfer from its triplet state and as a result of the quenching of the singlet oxygen (depending on the relative concentrations of O_2 and the quenching agent). As regards sensitisers, those whose energy exceeds 150 kJ mol^{-1} can facilitate the formation of ^{3}BR* mainly before the sensitisation of the formation of $O_2(^1\Delta_g)$. On the other hand, sensitisers with energies between 150 and 94 kJ mol^{-1} can only excite the formation of $O_2(^1\Delta_g)$.

Matheson et al.[35] investigated the influence of various factors on the quantum yields (ϕ) of the photochemical oxidation of BR using its dilute solutions—$(0.5–5) \times 10^{-3}$ M. The latter factor prevented the formation of biliverdin, which is favoured by high BR concentrations. It was established that ϕ increases with increasing O_2 concentration in chloroform, methanol, Freon-113, and water. In aqueous solution ϕ increases with increase of pH from 7 to 11. The following mechanism of the photochemical transformations of a general singlet oxygen acceptor (A) has been proposed:

$$\mathrm{A} \rightarrow {}^1\mathrm{A}\ ,$$

$${}^1\mathrm{A} \xrightarrow{k_1} \mathrm{A}\ ,$$

$${}^1\mathrm{A} \xrightarrow{k_2} {}^3\mathrm{A}\ ,$$

$${}^1\mathrm{A} + {}^3\mathrm{O}_2 \xrightarrow{k_3} {}^3\mathrm{A} + {}^3\mathrm{O}_2\ ,$$

$${}^1\mathrm{A} + {}^3\mathrm{O}_2 \xrightarrow{k_4} {}^3\mathrm{A} + {}^1\mathrm{O}_2\ ,$$

$${}^3\mathrm{A} + {}^3\mathrm{O}_2 \xrightarrow{k_5} \mathrm{A} + {}^1\mathrm{O}_2\ ,$$

$${}^3\mathrm{A} \xrightarrow{k_6} \mathrm{A}\ .$$

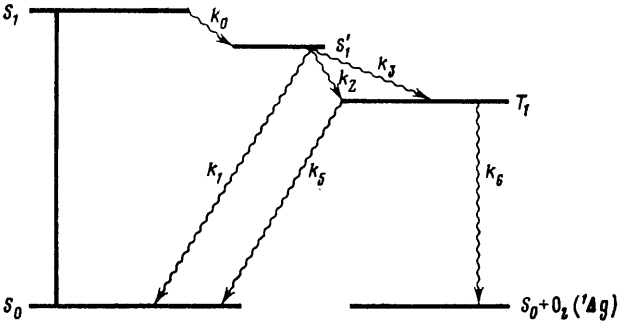

Figure 3. The energy levels of BR on photoexcitation in the presence of O_2; transitions with the rate constants k_3 and k_4 take place in the presence of $^3O_2$.

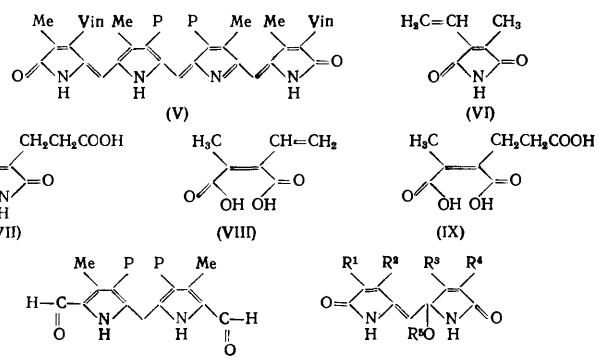
In the case of BR the rate constant k_4 can be neglected, since the energy of the singlet–triplet cleavage for BR (the difference between the energy of ^{1}BR*, which is 240 kJ mol^{-1},[31] and the energy of ^{3}BR*, which is ~150 kJ mol^{-1} [43]) is ~90 kJ mol^{-1}, which is less than the energy of $O_2(^1\Delta_g)$ (94 kJ mol^{-1}). The constant k_3 is largely determined by diffusion and should therefore be much less than



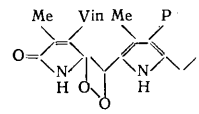
k_1. However, this is true only in chloroform solution, while in other solvents $k_3 > k_1$. On this basis, the authors[35] concluded that the state relaxing with the rate constant k_1 is not the excited singlet state formed initially. A scheme of the interlevel transitions in the photoexcitation of BR and in the relaxation of the excited BR state in the presence of O_2, illustrated in Fig.3, has been proposed. According to this scheme, the state S_1 formed initially is very rapidly converted into the non-fluorescent state S_1'.

The quantum yields of the excitation of BR to the triplet state in various media have been measured in a recently published study[44] (using laser flash photolysis at a wavelength of 347 nm). In particular, in an aqueous solution at pH 9–11 and in ammoniacal methanol the quantum yield was less than 0.005. In a non-polar medium (benzene) $\phi \cong 0.001$. The addition of triethylamine to benzene lowered ϕ to less than 0.005.

4. Photochemical Oxidation of Bilirubin

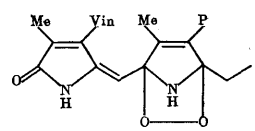
Many workers have frequently noted that the photodegradation of BR in the presence of atmospheric oxygen proceeds much more rapidly than in its absence. As already stated in a previous section, the first stage of the photochemical oxidation of BR is the photoexcitation of its molecule to the triplet state (arising as a result of the intercombination transition from the excited singlet state of BR). The half-life of the state (9 μs) is entirely sufficient for the transfer of the triplet energy to the molecular oxygen. The singlet oxygen formed under these conditions can react in its turn with a BR molecule in the ground state, oxidising it. Thus BR is, on the one hand, a photosensitiser of the formation of molecular oxygen and, on the other hand, it is an acceptor of singlet oxygen. The photochemical oxidation of BR by molecular oxygen has therefore come to be regarded as self-sensitised.

The composition of the products of the photochemical oxidation of BR depends greatly on the medium in which the process takes place. In protic solvents (usually in ammoniacal methanol, ethanol, and water) different workers have detected biliverdin (biliverdin IX) (V), methylvinylmaleimide (VI), haematinimide (VII), methylvinylmaleic acid(VIII), haematinic acid (IX), dipyrroledialdehyde (X), and the adducts of propentdyopents (XI), whose formulae are given below:



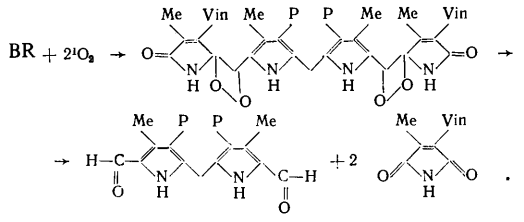
(V) (VI) (VII) (VIII) (IX) (X) (XI)

(XI): (a) R^1, R^3=Me; R^3=Vin; R^4=P; (b) R^2, R^3=Me; R^1=Vin; R^4=P; (c) R^2, R^3=Me; R^4=Vin; R^1=P; (d) R^2; R^4=Me; R^3=Vin; R^1=P; R^5=H, Me or Et.



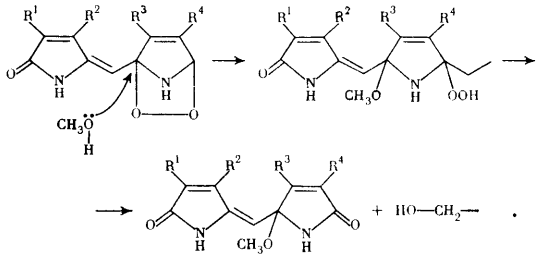
The green pigment biliverdin is the product of the oxidation of the methylene bridge in the BR molecule, which can be achieved fairly readily and occurs even in the dark, albeit at a low rate[45]. The formation of biliverdin from BR also in the absence of oxygen is known[46]. The ease of the conversion of BR into biliverdin served as a basis for the hypothesis that biliverdin is an intermediate in the more far-reaching photodegradation of BR.[47,48] However, there is serious evidence against this claim. After irradiating the dimethyl ester of biliverdin in chloroform (biliverdin itself is sparingly soluble in chloroform), McDonagh[49] established that the biliverdin ester does not sensitise the excitation of oxygen. Comparative experiments with irradiation by visible light showed that the photodegradation of BR is significantly faster than that of the dimethyl ester of biliverdin[49,50]. On the other hand, it has been established that the dimethyl ester of biliverdin is in the first place, like BR, a quenching agent for singlet oxygen and, in the second place, a much poorer $^1O_2$ acceptor than BR.[49] Being a $^1O_2$ quenching agent while at the same time undergoing very slow oxidation, biliverdin therefore inhibits the photochemical oxidation of BR, while the main BR oxidation pathway does not involve the intermediate formation of biliverdin.

Methylvinylmaleimide is formed[47,51] as a result of the attack by singlet oxygen on the exocyclic C = C bond in the 4- or 15-position in the BR molecule with the intermediate formation of a four-membered peroxide ring:

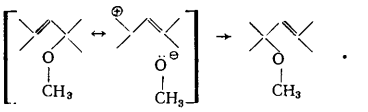


While the detection of methylvinylmaleimide *in vitro* in alcoholic solutions suggested that it can be formed also in the organism, this hypothesis became more definite after its detection also in a number of BR photochemical decomposition products in an aqueous buffer[52]. Under the influence of light, methylvinylmaleimide undergoes further degradation and the process takes place even in the absence of oxygen, albeit more slowly. The methylvinylmaleimide degradation products have not been determined, but it has been suggested that they can be oxidised to methylcarboxymaleimide, the decarboxylation of which can lead in its turn to the formation of methylmaleimide[53]. The latter is a modifying agent for proteins and can interfere with their normal functioning in the organism.

The formation of the imide of haematinic acid is apparently preceded by the interaction of O_2 (dienophile) with the conjugated diene system of one of the central pyrrole rings in the BR molecule, which results in the formation of a peroxide adduct having the following structure[54]:

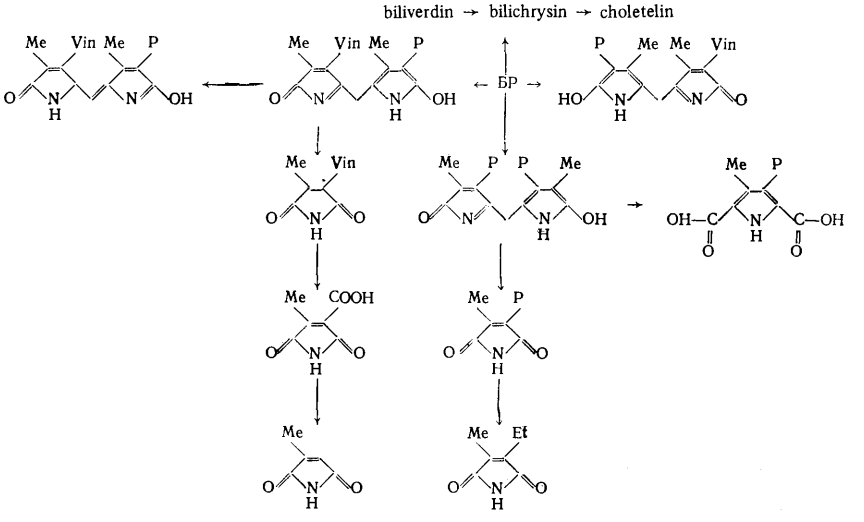


The appearance of methylvinylmaleic and haematinic acids in solutions is a natural consequence of the hydrolysis of the corresponding imides either in the photochemical reaction or in the treatment of the reaction mixture. The dipyrroledialdehyde detected in the reaction mixture[50,54] can be formed by a reaction of the same type as that leading to the formation of methylvinylmaleimide: the interaction of molecular oxygen with the double bonds in the 4- and 15-positions of BR. Theoretically the formation of a single dipyrroledialdehyde molecule is accompanied by the formation of two molecules of



methylvinylmaleimide[55]:

A considerable proportion of the BR photochemical oxidation products in protic solvents consist of adducts of propentdyopents with the corresponding solvent. The mechanism proposed[56] for the formation of adducts of propentdyopents in an ammoniacal methanol solution includes the preliminary formation of an endoperoxide—the product of the diene condensation of O_2 with the diene system of the second or third pyrrole ring—and subsequent methanolysis of the endoperoxide and the decomposition of the intermediate hydroperoxide:



Bearing in mind that the irradiation of BR IXα with light results in the formation of its equilibrium mixture with the isomers IIIα and XIIIα, it follows that, in conformity with the above scheme, each BR isomer should form on irradiation in methanol the corresponding methanol adducts of propentdyopents: IXα–propentdyopents (a and b), IIIα–propentdyopent (b), and XIIIα–propentdyopent (a). However, the formation of propentdyopent (a) was not confirmed in a later study[51]. Together with product (b), its isomers (c) and (d), which are not formed directly from BR IXα and its two isomers via the scheme proposed by Bonnett[56], were detected in the reaction mixture. In model experiments the propentdyopents (b) and (c) were obtained from the pure isomer BR IIIα, while propentdyopent (d) was obtained from BR XIIIα. Thus the formation of a mixture of propentdyopents (b), (c), and (d) from the irradiated BR IXα can be explained, on the one hand, by the photoisomerisation of BR IXα to IIIα to XIIIα and, on the other hand, by the isomerisation of the methanol adducts of the propentdyopents already formed, consisting in the transfer of the methoxy-group via one carbon atom to a neighbouring pyrrole ring with the simultaneous migration of the double bond (the allyl rearrangement):

The isomerisation of the propentdyopent adducts isolated has been confirmed experimentally[51]. On the other hand, the absence of propentdyopent (a) from the reaction mixture is apparently due to the marked shift of the equilibrium (a) ⇌ (d) to the right.

Numerous studies have been made on the photochemical oxidation of BR using its solutions in chloroform[28,42,53,57]. The appearance, together with biliverdin, of vicinal diols, formally representing the products of the hydroxylation of biliverdin at the non-vinyl exocyclic C=C bonds, has been noted in this solvent[57,58]. It has been suggested that the above compounds are produced as a result of the interaction of the excited BR with triplet oxygen. A smaller yield of the di- and mono-pyrrole oxidation products, compared with that observed in reactions in protic solvents was also noted[59,60]. Fundamental differences between the nature of the photochemical oxidation of BR in solutions in chloroform and carbon tetrachloride were not observed despite the difference between the polarities of these solvents. The differential spectra characterising the changes in these solutions on irradiation with light having a band maximum at 410–440 nm were in broad outline the same[37].

In a study of the photochemical oxidation of BR in chloroform under the influence of scattered sunlight over a long period (500 days), Gray et al.[53] isolated various products at different stages of the process, which enabled them to set up a scheme of the probable transformations of BR (see below).

The authors[53] established with the aid of paper chromatography that BR disappears completely from the reaction mixture after 12–25 days (depending on the intensity of illumination). Biliverdin, whose concentration in the mixture never exceeded 13% of the initial BR concentration, disappeared after 40–50 days. On the hundredth day the solution became almost colourless. The observed stability of BR in chloroform under a nitrogen atmosphere led to the conclusion that most of the BR decomposes via oxidation with molecular oxygen.

Gray et al.[53] also compared the BR photodegradation pathways in various solvents. In particular, they noted that in a methanol–chloroform mixture, weakly alkaline methanol and aqueous solutions, BR decomposes with rapid breakdown of the tetrapyrrole structure, as in chloroform solutions. On the other hand, in acid media the decomposition of the tetrapyrrole structure proceeds with much difficulty: propentdyopents, imides, and dipyrrolylmethenes were detected only in weakly acid solutions. Furthermore, the overall rate of decomposition of the BR in acid solutions is lower than in alkaline solutions.

A number of studies have been devoted to the photochemical oxidation of BR in the presence of serum albumin[36,48,61]. On the one hand, a complex of BR with SA is formed in a living organism and is of special interest. On the other hand, this complex is soluble in water, which makes it possible to investigate the behaviour of BR on photoirradiation in neutral aqueous solutions. By varying the pH of the medium in the range 7.4–13.0, Ostrow and Branham[48] established that in a neutral medium SA accelerates the photochemical decomposition of BR, while in an alkaline medium it retards it. It has also been noted[61] that BR becomes more polar in the course of irradiation and that its bond with the protein is consequently weakened. The photochemical oxidation of SA was not observed at the given stage. However, by irradiating the complexes of BR with human and bovine SA in aqueous solution at pH 7.4, Rubatelli and Jori[62] observed changes, occurring as a result of the photodynamic effect, apparently in the two histidine residues in both albumins. The authors suggest that these changes do not alter the tertiary structure of the proteins but decrease their binding capacity in relation to BR. It was also noted that the tertiary structure of bovine SA is more labile than that of human SA.

As already mentioned, the primary photoproducts of the complexes of BR with human and bovine SA are different: bovine SA does not have a specific effect on the nature of the photochemical transformation of BR, while in the complex with human SA BR undergoes an extremely specific photochemical transformation. Complexes of BR dissolved in the serum of rats suffering from congenital and stimulated jaundice also did not exhibit specific features.

IV. PHOTOTHERAPY OF NEONATAL JAUNDICE AND ITS PROBLEMS

The use of light for the treatment of neonatal jaundice began to be practised after it was observed[63] in 1958 that BR in the serum of a jaundiced infant decomposes in the light. Clinical experiments demonstrating the absence of a neurotoxic effect of the BR photochemical degradation products served as a basis for the practical feasibility of the phototherapy of neonatal jaundice[64,65]. It has also been established[66] that a decrease of the level of BR in the organism during phototherapy is caused not only by the photochemical degradation of BR but also by a change in the nature of the elimination of the undecomposed BR: whereas under the usual conditions BR is eliminated from the organism mainly in a bound state, in phototherapy there is a sharp increase in the amount of unbound BR in the bile, while the elimination of BR in a bound form diminishes. As already mentioned previously, this may be a consequence of the *cis–trans* isomerisation of BR with formation of its water-soluble geometrical isomers[38].

As was to be expected, light in the wavelength range 450–600 nm, corresponding to the BR absorption maximum, exhibits the greatest effect in phototherapy[67]. However, a small effect has also been observed on irradiation with light at a wavelength of ~550 nm and also on ultraviolet irradiation[67].

Despite some contradiction between the results reported by different workers, in most instances successful phototherapy has been achieved by irradiating patients from luminescent sources of blue and white light with a power of 20–40 W, between 3 and 12 of which are placed at a distance of 50–100 cm. More details recommendations concerning the phototherapy of neonatal jaundice are given in a review[68].

The site of the photochemical degradation of the BR molecule on irradiation of a jaundiced infant has not been unambiguously established. Some light has been thrown on this problem by a study[59] of the effect of the shading of individual small (up to ~4 cm^2) sections of the skin in phototherapy. These sections proved to be more pigmented in all cases than the exposed sections of the skin. Hence it follows that BR is firmly retained in the intervascular space and that the "bleaching" effect in phototherapy is due mainly to the decomposition of BR in the surface layers of the skin and not in the vessels. In view of the diffuseness of the boundary line between the shaded and exposed sections of the skin, it was suggested that the effect of light extends along the skin over a distance of ~2 mm. Vogl[69] also claims that BR leaves the vessels more readily than it is able to return to them. It has also been reported[70] that the yellow colour of the skin disappears in the course of phototherapy, while the BR level remains unchanged in the organism. Consequently one may assume that the decomposition of BR in the skin under irradiation is faster than the supply of BR from the blood vessels to the skin.

A group of Indian investigators[71] observed in *in vitro* experiments that the epidermis and skin of man absorbed free and serum-bound BR from an aqueous buffer. After this, the bound BR was readily removed when the skin was transferred to a medium free from BR, while the free BR remained in the skin, imparting a yellow colour to the latter. If the skin was irradiated subsequently with the light from a mercury lamp, then the BR decomposition products accumulated in the medium. Using BR labelled with ^3H, Kapoor et al.[71] established an extremely significant fact: the products for the oxidation of BR absorbed by the skin differ from the products of the oxidation of BR present in the buffer solution. It was suggested that, after emerging from the vessels, BR is bound by the skin lipids and collagen, in which the BR concentration can exceed its concentration in plasma.

The problem of the possible complications in phototherapy has been discussed from the very beginning of its application. In the study of children subjected to phototherapy no arrest was observed in their growth or anomalies in their psychological or physical development[72,73]. Nevertheless, in view of the importance of the problem, special consideration must be given to a number of clinically observed and potential complications.

Complications in phototherapy in which a greyish-brown colouring of the skin, serum, and urine was observed have been reported. This phenomenon may be complicated by anaemia. Cases are known where premature new-born babies, suffering from hyperpigmentation of the skin and subjected to irradiation, showed an arrest of growth[74,75]. An instance of acute haemolysis, accompanying the hyperpigmentation of the skin, on irradiation of a premature infant with daylight lamps has been described[76].

The possibility of the haemolysis of erythrocytes on irradiation in the presence of BR cannot be ruled out. As early as 1932 it was shown[77] that erythrocytes suspended in BR solutions haemolyse on irradiation with sunlight. Subsequently[78] it was suggested that BR is bound to erythrocytes and on irradiation can exert a photodynamic effect on the latter. However, the haemolytic effect of BR can be partly inhibited by proteins[79].

For high doses of irradiation by a luminescent lamp of a suspension of erythrocytes containing BR and at concentrations characteristic of the neonatal period, it was observed[80] that haemolysis is preceded by damage to erythrocyte membranes resulting in the loss of potassium by erythrocytes and a decrease of the activity of ATPase. When BR was introduced into erythrocytes at pH 8 and 10 °C, it sensitised the peroxide oxidation of unsaturated lipids on irradiation with blue light, which was inferred from the positive colour reaction with 2-thiobarbituric acid[81]. The peroxide oxidation of lipids was accompanied by the disappearance of a large proportion of the structural proteins of the membranes and by the appearance of polypeptide photoproducts with a molecular weight in excess of 25000. It was suggested that the photodynamic effect of BR *in vivo* may involve not only erythrocytes but also other cells coming into contact with BR. The photodynamic damage to SA [62] was mentioned above.

Another serious complication in phototherapy may be damage to DNA, which, however, is still one of the problems which have been little investigated. A change in the physicochemical properties of single-stranded DNA *in vitro* has been observed[83] after its irradiation in the presence of BR with light at a wavelength of 450 nm. Bearing in mind the possible relation between the ability to modify cell DNA and the potential mutagenic and/or carcinogenic effect, Speck and Rosenkranz[82] concluded that the possibility of dangerous aftereffects must be completely eliminated in phototherapy.

The appearance of a slight rash, an irritation of the skin, an increase of temperature[77], and an increased loss of water through the skin[83] have been observed in some children on phototherapy. Cases of the tanning of the skin in negro children have been described[84].

In 1974 the National Committee on Phototherapy in the USA suggested in its preliminary report[84] that the phototherapy of neonatal jaundice be regarded as an extremely effective albeit still an experimental method. At the present time most of the large maternity establishments in many countries have already been provided with phototherapeutic apparatus and phototherapy is one of the main methods of preventing the severe and irreversible consequences of neonatal jaundice. Some investigators[85] actually recommend that phototherapy be used as a prophylactic procedure for all new-born infants. However, the majority of investigators nevertheless recommend that phototherapy should be resorted to selectively—only in those cases where the necessity for phototherapy has been firmly established on the basis of the analysis of blood for BR.

Kinetic Theory of the Flotation of Small Particles

B.V.Deryagin, S.S.Dukhin, and N.N.Rulëv

The present state of the theory of the elementary step in flotation as a multistage process is surveyed. The characteristics of the flotation of small particles both in the stage where they approach the bubble and in the stage involving their fixation to the surface of the bubble are described. It is shown that the deposition of small particles (in contrast to large particles) on the surface of the bubble takes place without inertia and is not accompanied by a significant deformation of the surface. The usefulness of the application of ionogenic surfactants in order to overcome or modify the sign of the disjoining pressure of electrical double layers, which is the commonest factor hindering the flotation of small particles, is demonstrated. The possible ways of intensifying the flotation of submicron particles by their aggregation are analysed.
The bibliography includes 96 references.

I. INTRODUCTION

Until recently the theory of flotation was limited to the thermodynamic consideration of the adhesion of particles to the surface of a bubble, which permitted the analysis of the most important question, from the point of view of enrichment, namely that of the selectivity of the flotation of large particles (with dimensions of ~100 μm and more). The flotation of small particles constitutes an independent scientific problem, because, on transition from coarse to fine grinding, there is a possibility of qualitative changes in the mechanism of the elementary step in flotation (this is understood as the interaction of a single particle with a single bubble).

In the general case one must distinguish in the elementary flotation step the stage involving the approach of the surfaces of the particle and the bubble and the stage in which the particle is fixed on the bubble. In a more detailed treatment it is found that the number of these stages is greater and that the subdivision into stages is itself arbitrary. On passing from large to small particles, the mechanism of the elementary step in flotation is altered both in the approach stage and in the fixation stage. This was first pointed out almost two decades ago[1-10]. At the present time the theory of the elementary step in the flotation of small particles has been developed in a number of investigations[11-22].

II. CHARACTERISTICS OF THE MECHANISM OF THE FIXATION OF SMALL PARTICLES ON THE SURFACE OF THE BUBBLE

The probability of the fixation of a particle is determined by the probabilities of the adhesion of the particle and its retention on the bubble, since in the general case there is a possibility that the initially adhering particle will break away either under the influence of the gravitational force or under the influence of inertial forces. These forces are proportional to the volume of the particles, i.e. are large for large particles and small for fine particles. This trivial fact leads to cardinal consequences in the analysis of the role of particle size in the mechanism of the elementary step in flotation. The forces tending to break away a 100 μm particle are 10^6 times greater than for a 1 μm particle. Therefore for large particles only one form of fixation is possible—via the formation of a three-phase wetting perimeter able to counteract the large forces tending to break it away; we shall henceforth refer to such flotation as contact flotation. For fine particles, there is a possibility, together with contact flotation, also of non-contact flotation, which is not accompanied by the formation of a three-phase wetting perimeter, because for small particles the stripping forces can be balanced by London–van der Waals molecular attraction forces.

Sheludko[23] points to the difficulty of fixing small particles on the surface of a bubble due to the need to overcome the energy barrier to the formation of a three-phase wetting perimeter. One should note that, owing to the Sheludko effect, only contact flotation of small particles may become impossible. The formation of the wetting perimeter is not obligatory for the flotation of small particles; long-range surface forces, in particular the London–van der Waals molecular attraction forces or, what amounts to the same thing, the molecular component of the wedging pressure of the liquid layer separating them are of primary importance. This is the first fundamental difference between the flotation of small particles and the flotation of large particles.

Furthermore, one must take into account the fact that surface forces comprise also the electrostatic interaction forces arising as a result of the overlap of the electrical double layers (DL) of the particle and the bubble, which usually have charges of the same sign[24,25]. The ionic-electrostatic component of the disjoining pressure, due to the interaction of the DL of the bubble and the particle, is an important factor, which can hinder the adhesion of

small particles to the surface of the bubble. This is the second significant characteristic feature of the flotation of small particles. For large particles, the disjoining pressure is overcome by the inertial impact against the bubble surface; for small particles, there is no such impact and the bubble and the particle approach one another without inertia.

The general characteristics of the influence of both components of the disjoining pressure on the fixation of small particles can be established by considering the familiar relation between the interaction energy and the shortest distance between the surfaces of the particle and the bubble which are not in general charged to the same potential[26]. In the case where the bubble and the particle are charged to the same potential and the molecular component of the disjoining pressure is negative, the general theory of the stability and coagulation of lyophobic colloids is applicable[27-30].

In view of the different natures of the bubble and the particle, the condition of the equality of their potentials is attained extremely rarely. It can be observed mainly when the potentials of both the particle and the bubble are so large that the electrostatic component of the disjoining pressure reaches its maximum value. This case is rarely realised; it is possible only in the presence of ionic surfactants, which are capable of imparting a large charge not only to the particle but also to the bubble. Fig. 1*a* illustrates the free energy of the total interaction W of the identically charged particle and the bubble as a function of the distance H between them. This energy is defined by the expression

$$W = a\int_{H}^{\infty} F(H')\,dH' \qquad (1)$$

where F is the force of the interaction described by the familiar formula

$$F(H) = 2\pi a\int_{H}^{\infty} \Pi_e\,dh\ , \qquad (2)$$

where a is the radius of the particle, h the thickness of the plane-parallel layer between the particle and air, $H = h/a$, and Π_e is the electrostatic component of the disjoining pressure.

Eqns. (1) and (2) were derived on the assumption that the particle is a sphere with a radius a, which is much smaller than the radius of the bubble R. Over long and short distances, molecular attraction forces play the main role, while over moderate distances, electrostatic repulsion can predominate. This leads to the formation of an energy barrier separating the near and far potential wells (Fig. 1*a* and 1*b*).

In reality the bubble and the particles differ not only in the surface potentials but also in their behaviour, which can alter qualitatively the interaction arising under these conditions. Thus the case where the potential of the surface of

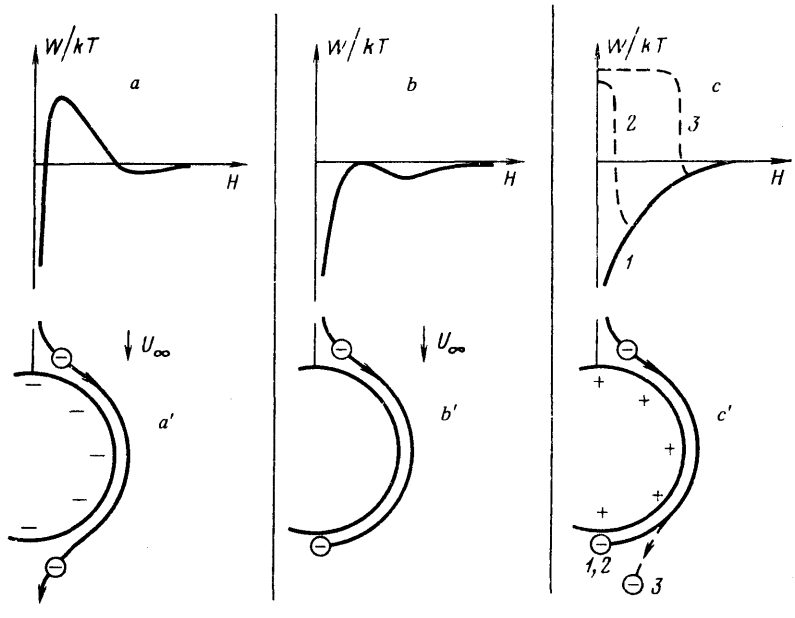

Figure 1. The resultant curves characterising the contribution of molecular attraction forces and electrostatic forces, due to the overlap of the diffuse double layers, to the energy of the interaction W of the bubble and particle at different distances for like surface charges (*a*), on neutralisation of the bubble charge (*b*), and when the bubble charge is altered (*c*, curve *1*). The dashed lines in Fig. 1*c* characterise the contribution of the structural component to the interaction energy over distances shorter (curve *2*) and longer (curve *3*) than the thickness of the double layer. Schemes demonstrating the possibility of flotation for sufficiently large like charges of the particle and bubble (1*a'*), on neutralisation of the bubble charge (*b'*), or on its alteration (*c'*, curve *1*) are shown. Curves *2* and *3* in Fig. 1*c'* illustrate the possibility of flotation for a radius of action of non-electrostatic repulsion forces shorter than the thickness of the double layer (curve *2*) and its impossibility in the opposite case (curve *3*).

the particle and the charge density of the air bubble remain unchanged as h is altered is close to reality. Frumkin[31] and Langmuir[32] showed that, in the special case where the charge of the bubble is zero, a repulsion force arises, which is exactly equal to the repulsion force between two identical particles with a double thickness of the intervening layer. In the light of the theory of heterocoagulation, one should expect that non-inertial flotation is not possible when the bubble and the particles have charges of the same sign, the absolute values of their surface potentials are not small, and the electrolyte concentrations are low (Fig.1*a*). The general theory of heterocoagulation then makes it possible to calculate the potentials (or charges) of the interacting objects for which the electrostatic repulsion force falls so much that the force barrier disappears.

Although the electrostatic repulsion forces persist also when the charge of the bubble is neutralised by the adsorption of surfactants, nevertheless here too the van der Waals attraction forces can predominate and flotation is possible (Fig.1*b*).

Flotation can be ensured by influences of two kinds. When electrolytes are introduced into the system, the thickness of the diffuse component of the double layer diminishes, which leads to a decrease of the electrostatic repulsion forces. The negative surface potential can be reduced by the adsorption of surface-active cations, which also results in coagulation.

The possibility of intensifying the flotation of small particles by lowering the electrostatic repulsion forces was first demonstrated experimentally by Deryagin and Shukakidze[33]. The treatment of the adhesion process in the flotation of small particles on the basis of the heterocoagulation theory, proposed by Deryagin and Dukhin[2], has been described in a series of reviews of the theory of heterocoagulation[34-36]. The importance of reducing the electrostatic repulsion forces for the occurrence of flotation has been proved in recent years in many investigations[37-40]. On varying the electrokinetic potential of silver iodide particles by the adsorption of a cationic surfactant, Jaycock and Ottewill[37] observed a floatability maximum at the isoelectric point. It has been established[37-39] that the rate of flotation is high over a narrow range of pH values and very low outside this range. The above range coincides with the region of very low ζ-potentials of the particle in the vicinity of its isoelectric point. The addition of aluminium hydroxide extends the pH range favouring flotation.

The authors of the above studies interpreted their data as evidence for the decisive influence of the electrostatic component of the disjoining pressure on the adhesion of particles to the bubble. Collins and Jameson[40] assumed in addition the possibility of another interpretation of the results. The disappearance of the electrostatic repulsion force barrier can cause intense coagulation of particles at the isoelectric point. The aggregates thus arising can be more rapidly precipitated on the surface of the bubble than single particles. In order to rule out this possibility, the authors[40] measured the change in the distribution of spherical polystyrene particles 4–20 μm in size, in the flotation process at different electrolyte concentrations and correspondingly for different electrophoretic mobilities of the particles, i.e. for different values of the electrokinetic potential. For each of the eight fractions investigated separately, the rate of flotation increased monotonically with decrease of the ζ-potential of the particles and bubbles. Since these experiments made it possible to follow the influence of both the size and the charge of the particles separately on flotation, the necessity for eliminating the disjoining pressure of the double layers as an essential condition for flotation was demonstrated unambiguously by the above investigators†.

The special introduction of electrolytes in order to ensure floatability is naturally not technologically viable. A more economical method of controlling the electrostatic component of the disjoining pressure and hence the floatability consists in the use of ionogenic surfactants at specific concentrations whose adsorption on the bubble causes a change in its charge. However, very low surfactant concentrations do not ensure floatability if the latter is hindered not only by the electrostatic barrier but also by non-electrostatic factors preventing the mutual approach of the surfaces of the particle and the bubble. One of such factors may be the presence on the surface of the particle of a polymolecular hydrate layer. The possibility of the existence of a polymolecular hydrate layer, preventing a decrease in the thickness of the wetting films as a result of the structural component of the disjoining pressure, on lyophilic surfaces has been established by a number of investigators[41-43].

The barrier due to the structural component of the disjoining pressure is illustrated schematically in Fig.1*b* for those cases where its radius of action is smaller (curve *2*) or greater (curve *3*) than the thickness of the double layer. One of the ways of ensuring or improving floatability in the presence of the structural component consists in employing surfactants whose adsorption renders the surface of the particle hydrophobic, or destroys the structural component of the disjoining pressure, or alters its sign.

Another way of overcoming the difficulty associated with ensuring the flotation of dispersions in the presence of a non-electrostatic factor stabilising colloids has been indicated by Deryagin and Dukhin[2]; it consists in stimulating electrostatic attraction. For this purpose, it is necessary to generate, by means of a high degree of adsorption of surfactants, a high charge on the surface of the bubble opposite in sign to that of the particle; the interaction between the double layers then ensures the operation of attraction forces. If the thickness of the double layer exceeds that of the hydration layer, then, outside the limits of the radius of action of non-electrostatic repulsion forces, attraction forces will operate between the opposite charges of the particle and the bubble. Thus an aggregate comprising the bubble and the particle, between the surfaces of which there is a gap of the order of magnitude of the thickness of the non-electrostatic repulsion force barrier, is produced. If the radius of action of the repulsion forces is increased for the same double layer thickness, then the potential well becomes smaller. It is desirable to select surfactants in such a way that not only the electrostatic attraction is increased but also the repulsion due to the structural factor is reduced. Thus, if the radius of action of electrostatic attraction forces exceeds that of the non-electrostatic repulsion forces (of structural origin), floatability is possible (Fig.1*c*, curves *2*). If the radii of action of these forces are comparable, then in the presence of the non-electrostatic barrier flotation proves to be impossible (Fig.1*c*, curves *3*).

Thus the third characteristic of the flotation of small particles consists in the fact that it can be controlled with the aid of ionogenic surfactants and it is possible to ensure floatability even when non-electrostatic stability factors operate. This conclusion is confirmed by the available experimental literature data. Thus it has been shown[44] that the surface not only of pure but also of methylated

---

†The possibility of the aggregation of particles was ruled out by sufficiently high values of their ζ-potentials.

quartz has hydrophilic sections which ensure the stability of suspensions and hinder flotation. The floatability of quartz has been ensured[45] in the range of dodecylammonium chloride concentrations in which the surface charges of the bubble and the particle have opposite signs.

Systematic studies by Schulze[46,47] have shown that the water–air and water–quartz interfacial films become unstable under the influence of the adsorption of tervalent cations or cationic surfactants if their thickness is smaller than a critical value h_{cr}. The critical thicknesses are 300–450 Å under conditions where the surface of quartz is altered by tervalent cations. The change in the charge of the bubble surface by the adsorption of cationic surfactants leads to the rupture of the film for thicknesses of 150 Å if the electrolyte concentration is high and for thicknesses of 1500 Å if it is low, which agrees with the electrical nature of the attraction arising under these conditions. Schulze also suggests that floatability be increased by altering the surface charge of the bubble as a result of the adsorption of surfactants at the lowest possible electrolyte concentration, which should increase the thickness of the double layer and hence h_{cr}.

The above conclusions by Schulze agree with the data of Goddard and coworkers[48], who ensured the flotation of quartz particles by the adsorption modification of the surface charge of the bubble using amines. A sharp increase in floatability corresponds to a sharp increase in the degree of adsorption of amines. Whereas floatability is usually controlled by rendering the surface of the particle hydrophobic, in the present instance we are dealing with a completely new trend in flotation, where the surface charge of the bubble is modified by introducing a surfactant. The insignificant changes in the surface of quartz are indicated by the fact that in Goddard's experiments the ζ-potential of quartz changed very little after the introduction of the surfactant.

The depth of the potential well arising outside the limits of the non-electrostatic barrier when the surface of the bubble is altered is insufficient for the contact-free flotation of large particles. The contact-free flotation of particles in the presence of the non-electrostatic component of the disjoining pressure can therefore be ensured by altering the charge of only fairly small particles.

III. CHARACTERISTICS OF THE MECHANISM OF THE TRANSFER OF SMALL PARTICLES TO THE SURFACE OF THE BUBBLE

The approach of the particle to the surface of the bubble undergoes qualitative changes on passing from long (compared with the particle size) distances between their surfaces to short distances. Over long distances, the above process is determined by the operation of only two factors—inertial forces and hydrodynamic interaction. Under the influence of inertial forces, a fairly large particle moves almost linearly until its collision with the surface of the bubble, which occurs if $b < R + a$ (Fig.2). The stream of liquid flows around the surface of the bubble, the flow lines of the liquid are curved, and the particle is involved in this movement in one way or another. The smaller the particle size and the smaller the difference between its density and that of the medium, the smaller the inertial forces acting on it and the closer the agreement between its trajectory and the flow lines of the liquid. Thus, for the same target distance, large particles move along virtually straight lines (Fig.2, line *1*), whereas the trajectories of small particles virtually coincide with the corresponding flow lines of the liquid (line *2*). The trajectories of particles of intermediate size are distributed in the region bounded by lines *1* and *2* and, with decrease of particle size, they shift from line *1* to line *2* and the possibility of collision diminishes.

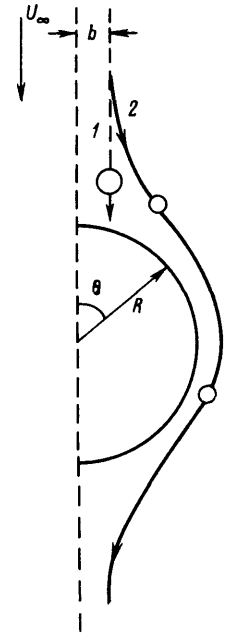

Figure 2. The influence of the inertia of the particles on their trajectories in the vicinity of a rising bubble. The trajectories of large (inertial, line *1*) and small (non-inertial, line *2*) particles for the same target distance *b* are shown.

The deviation of the trajectories of small particles from the linear path towards the surface of the bubble over distances of the order of magnitude of the size of the bubble is caused by a hydrodynamic effect, which can be naturally referred to as a long-range effect. The bubble curves the flow lines of the liquid and thereby curves the trajectories of small particles, i.e. acts on them via the velocity field of the liquid. For large particles, inertial forces greatly exceed the long-range hydrodynamic interaction (LHI) forces and such interaction therefore has only weak effects. On the other hand, for small particles, the inertial forces are small compared with LHI forces[1]. Thus the approach of large particles to the bubble is ensured by inertial forces, whereas in the case of small particles the process is non-inertial and is greatly hindered by the long-range hydrodynamic interaction. This constitutes the first difference in the transport of small particles to the surface of the bubble.

Together with the long-range hydrodynamic interaction, in which the trajectory of the non-inertial movement of the particle coincides with the flow line of the liquid, there exists a hydrodynamic interaction over distances of the order of magnitude of the radius of the particle. The latter leads to the deviation of the particle trajectories from the corresponding flow lines of the liquid. It is natural to refer to such interaction as the short-range hydrodynamic

interaction (SHI). On the basis of Taylor's solution of the hydrodynamic problem of the displacement of liquid from the gap as a spherical particle approaches a planar surface, it has been shown[2] that the SHI can prevent contact between the particle and the bubble. According to Taylor, for a gap thickness $h \ll a$, the hydrodynamic resistance of the film to a decrease of its thickness is given by

$$f = va/h \ , \qquad (3)$$

where v is the rate of approach of the particles to a section of the bubble surface which can be regarded by convention as planar. If the particle is acted upon by a constant adhesional force F, then according to Eqn.(3), we have

$$v \propto Fh/a \ . \qquad (4)$$

Hence it follows that, for the complete removal of the liquid from the gap, an infinitely long time is required:

$$T = \int_h^0 \frac{dh}{Fh} = \frac{1}{F} \ln h \Big|_h^0 \to \infty \ . \qquad (5)$$

The problem therefore arises of the nature of the forces adhering the particle to the surface of the bubble. This paradox is removed if account is taken of the action of the surface attraction forces arising with decrease of the distance faster than the viscous resistance of the film. The decrease of the thickness of the latter for thicknesses of the order of magnitude of the effective radius of action of the surface forces occurs under the influence of the adhesional hydrodynamic force. Above the equatorial plane, the flow lines of the liquid approach the surface of the bubble. This implies that the radial component of the velocity of the liquid is directed to the surface of the bubble. Since in the SHI zone the movement of the particles to the surface is hindered, the radial component of the velocity of the liquid is greater than the radial component of the velocity of the particle and for small gaps and correspondingly for a high viscous resistance it is much greater. As a result the radial flow of the liquid around the particle, which retards its approach to the bubble, clamps it to the bubble. To a first approximation, this hydrodynamic force can be estimated from the Stokes formula by substituting in the latter the radius of the particle and the difference between the local velocities of the liquid and the particle.

Thus the decrease of the thickness of the interfacial film in the case of large particles takes place as a result of inertial impact, while in the case of small particles it is caused by the adhesional hydrodynamic force, which constitutes yet another significant difference characteristic of the flotation of small particles.

The decrease of the thickness of the interfacial film is complicated for large particles by the presence of a dent arising on the surface of the bubble following the inertial impact by the particle. It has been shown[22] that, in the non-inertial deposition of small particles on the surface of the bubble, the deformation of the latter under the influence of the adhesional hydrodynamic force is insignificant. This third considerable difference facilitates the derivation of a quantitative kinetic theory of the flotation of small particles.

IV. A QUANTITATIVE THEORY OF THE FLOTATION OF SPHERICAL PARTICLES OF SMALL AND MODERATE SIZES

The approach of the particles to the surface of the bubble can be described quantitatively by taking into account both the long-range and the short-range hydrodynamic interactions. In order to estimate the efficiency of flotation, we introduce the dimensionless parameter E, given by

$$E = b_{cr}^2/R^2 \ , \qquad (6)$$

where R is the radius of the bubble and b_{cr} the maximum radius of the tube of streaming liquid incident on the bubble, in which all the particles are deposited on the surface of the bubble (Fig.3). The particles moving along a flow line with a target distance $b < b_{cr}$ are deposited on the surface of the bubble (Fig.3, curve *2*); otherwise the particle is carried away by the stream. Fig.3 shows that the calculation reduces to the evaluation of the so-called "limiting trajectory" (Fig.3, curve *1*) and hence of the target distance b_{cr}.#

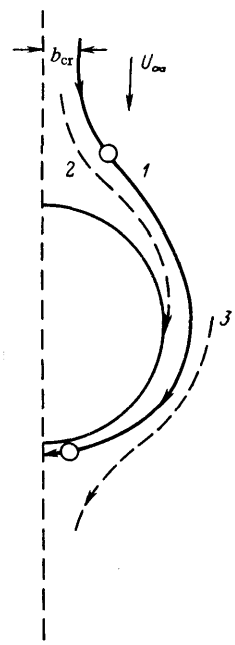

Figure 3. Illustration explaining the concept of the limiting particle trajectory (curve *1*). The trajectories of particles for $b < b_{cr}$ (curve *2*) and $b > b_{cr}$ (curve *3*) are shown by dashed lines.

The flow of liquid around a rising bubble is of the potential type if the movement of its surface is not retarded by the influence of a surfactant and the Reynolds number

$$\mathrm{Re} = \frac{2RU_\infty}{\nu} \qquad (7)$$

greatly exceeds unity (U_∞ is the rate at which the bubble rises and ν is the kinetic viscosity of the medium). If account is taken of the quadratic relation between the velocity of the bubble and its radius, it is easily seen that the Reynolds number varies very rapidly with the radius.

#An analogous approach is used in the theory of aerosols[49].

This number is unity for $R \cong 80$ μm. The concept of the length of the inertial path of the particle l, i.e. the distance which the particle can traverse, despite the viscous resistance of the liquid, as a result of its initial velocity

$$l = \frac{2}{9}\frac{U_\infty a^2 \rho'}{\eta} , \qquad (8)$$

where ρ' is the difference between the densities of the particles and the medium and η is the viscosity of the medium, is important for the understanding of the mechanism of the inertial deposition of particles on a rising bubble.

The normal component of the velocity of the liquid on the surface is zero; the thickness of the layer of liquid in which this component decreases as the surface is approached is of the order of magnitude of the radius of the bubble. The particles traverse this layer of liquid because it falls within the limits of their inertial path. Hence it is clear that the possibility of the inertial deposition of the particle depends on a dimensionless parameter of the type

$$\lambda = l/R . \qquad (9)$$

For $\lambda > 1$, deposition is evidently possible. However, calculations showed that it is possible also for $\lambda < 1$ provided that λ is not too small. This can be understood if account is taken of the fact that a particle in a layer with a thickness R moves to the surface not only as a result of inertia but also together with the liquid. Inertial deposition is impossible if λ is smaller than a critical value λ_{cr}. Under the condition of a potential regime in the flow of liquid around the bubble and when the particle size is neglected, calculation yields the following result[50]:

$$\lambda_{cr} = {}^1/_{2\lambda} . \qquad (10)$$

Using Eqns.(8) and (9), it is easy to obtain a formula for the critical radius of the particle, below which inertial forces do not ensure the approach of the particle to the bubble:

$$a_{cr} = \frac{9}{\sqrt{48}}\sqrt{\frac{\nu\eta}{9\rho' g R}} \simeq 4 \cdot 10^{-1} R^{-1/2} \qquad (11)$$

where g is the acceleration due to gravity.

For $a > a_{cr}$, the inertial deposition of the particles on the surface of the bubble takes place, but its intensity diminishes with decrease of a. This is reflected in the formula for the efficiency of the collision, obtained initially in relation to the coagulation of aerosols[49] and then extended[2] to the elementary step in flotation:

$$E = \frac{\lambda^2}{(\lambda + 0.5)^2} . \qquad (12)$$

This formula has been recently confirmed[52] in the range $\lambda = 0.07-3.5$.

In the light of the studies described above, it is convenient to introduce the subdivision of particles into large, medium, and small. Particles for which E, calculated by Eqn.(12), is close to unity can be regarded as "large". Particles with $a < a_{cr}$ can be naturally referred to as "small", while "medium" particles are those for which inertial deposition is possible but the collision efficiency is less than unity.

As will be seen from what is to follow, in the non-inertial approach of particles to the surface of the bubble, the intrinsic size of the latter plays an important role. The closest approach of the flow lines of the liquid to the surface of the bubble is attained in the equatorial plane. Fig.4 illustrates schematically by a dashed line the flow line of the liquid (curve *1*) whose distance from the surface of the bubble in the equatorial plane is equal to the radius of the particle. Some workers believe erroneously that this is the limiting flow line for particles of this radius, the error consisting in the fact that one does not then take into account the SHI. Under the influence of the SHI the particle is displaced from this flow line of the liquid, since its trajectory (curve *2*) in the equatorial plane is separated from the surface by a distance exceeding the radius. There is therefore no contact with the surface and hence b is not the critical target distance. Bearing in mind that, owing to the SHI, the distance of the particle from the surface in the equatorial plane is greater than the distance along the flow line, with which the particle trajectory coincides over longer distances from the bubble, one may conclude that $b_{cr} < b(a)$. A characteristic feature of the limiting flow line (curve *3*) is that the particle trajectory branching away from it under the influence of the SHI (curve *4*) passes at a distance a from the surface of the bubble in the equatorial plane.

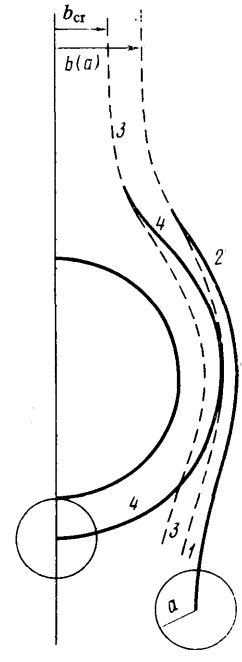

Figure 4. The influence of particle size in non-inertial flotation on their trajectories in the vicinity of the rising bubble. The flow lines in the liquid, corresponding to the target distances b (a) and b_{cr}, are shown dashed. The continuous lines characterise the deviation of the particle trajectories from the flow lines of the liquid under the influence of SHI.

Thus b_{cr} diminishes, firstly, as a result of the deviation of the flow lines of the liquid and the influence of the LHI and, secondly, as a result of the deviation of the particle trajectory from the flow line under the influence of the SHI. The efficiency of the collision is therefore expressed by the product of two factors, E_0 and f, each of which is less than unity; the former expresses the influence of the LHI and the latter that of the SHI.

In the potential flow regime the following expression holds[53]:

$$E_{0p}=3a/R_p \qquad (13)$$

where the subscript p corresponds to the potential regime in the flow around the bubble. For Re < 1, the flow of liquid becomes viscous. The movement of the surface of the bubble is then usually fully retarded by the absorption layer of surfactant, so that the distribution of velocities is then described by the Stokes formula. Furthermore, according to Okazaki[54], for Re < 20 the bubble rises like a solid sphere also in the absence of surfactants. An analogous formula for Stokes regime, which we shall denote by subscript s, is§

$$E_{0s}=\frac{3}{2}\left(\frac{a}{R_s}\right)^2 , \qquad (14)$$

The problem of the adhesional hydrodynamic force, favouring a decrease of the thickness of the interfacial film in the SHI, has been solved for the Stokes regime[56] and for the potential regime[19]. It was established that the adhesional force is 2–3 times greater than the value calculated from the Stokes formula. The adhesional hydrodynamic force cannot ensure contact between the particle and the bubble, since it has a finite value and the resistance increases infinitely as the thickness of the interfacial film diminishes.

It has been shown[2] that non-inertial flotation is possible by virtue of the operation of surface forces. Here there is a possibility of two cases. It is known[57,58] that interfacial films can lose their stability and can be disrupted spontaneously when a critical thickness h_{cr} is reached as the thickness diminishes. On replacing zero by h_{cr} in the integration limits in Eqn.(5), we obtain as a result of integration $\ln(h_0/h_{cr})$ instead of infinity. Thus non-inertial flotation is possible in the presence of flotation agents ensuring the validity of the condition $h_{cr} \neq 0$.

The molecular force of the interaction between a spherical particle and a planar surface is given by the following formula[59] for a sufficiently small value of h:

$$F=Aa/6h^2 , \qquad (15)$$

where A is the Hamaker constant. Since the attractive force defined by Eqn.(15) increases with decrease of h faster than the resistance force of the viscous layer, contact leads to the rupture of the layer. The influence of the SHI on the efficiency of the capture of the particle has been calculated[11,12] for $h_{cr} \neq 0$ neglecting the long-range molecular forces. The formulae obtained using the Stokes and potential distributions of velocities are

$$E_s=E_{0s}f_s , \qquad (16)$$

$$E_p=E_{0p}f_p , \qquad (17)$$

where f_S and f_p are functions reflecting the influence of the SHI on the elementary step in flotation. For any value of the dimensionless parameter $H_{cr} = h_{cr}/a$, these functions are less than unity, decrease with decrease of H_{cr}, and become zero when $H_{cr} = 0$, which agrees with the hypothesis concerning the mechanism of the influence of the SHI on the deposition of the particles described above. With decrease of H_{cr} from 10^{-1} to 10^{-3}, the function f_S diminishes from 0.5 to 0.15, i.e. the dependence of E_S on the absolute value of h_{cr} is very weak. Thus SHI can be taken into account only when one considers the question of the possibility of flotation; this effect diminishes severalfold the number of steps in which the particles come into contact with the bubble.

The SHI theory has been developed[13] without using the phenomenological parameter h_{cr} by allowing directly for the dependence of the molecular forces on h. The following expressions were then obtained:

$$E_s = E_{0s}f_s(w_s);\ w_s=\frac{2AR_s^4}{27U_s\pi\eta a^4} ; \qquad (18)$$

$$E_p = E_{0p}f_p(w_p);\ w_p=\frac{4AR_p}{27U_p\pi\eta a^3} , \qquad (19)$$

where U_S and U_p are the rates at which the bubble rises in the Stokes and potential regimes. Numerical analysis of the universal functions f_S and f_p made it possible to approximate Eqns.(18) and (19) (in the CGS system) as follows:

$$E_s \simeq 0.11\frac{a^{1.4}}{R_s^2}A^{1/6} , \qquad (20)$$

$$E_p \simeq 1.1\frac{a^{0.8}}{R_p}A^{1/1.8} . \qquad (21)$$

Although the absolute value of E depends very slightly on the Hamaker constant, whose value is in the range from 10^{-14} to 10^{-12} erg, nevertheless flotation is impossible for $A < 0$, i.e. when the dispersion force is directed away from this surface of the bubble. Thus molecular forces act almost in accordance with the "yes or no" principle depending on the sign of A.

The adhesional hydrodynamic force can exceed the force barrier due to the disjoining pressure and hence can ensure the possibility of reagent-free flotation. This question can be investigated by considering the movement of the particle along the symmetry axis of the bubble from the side of the advancing stream of liquid[60]. Since the adhesional force is a maximum under this condition, it is possible to obtain the necessary and sufficient condition for the deposition of particles on the surface of the rising bubble.

Along the bubble axis, the tangential flow rate of the liquid is zero, so that the deposition process can take place over an infinitely long period. However, this implies that the viscous resistance of the interfacial film can then be infinitely small and can be neglected in the balance of the acting forces[60]:

$$F(h, a)=F_V+F_E+F_H+F_G , \qquad (22)$$

where F_V is the adhesional hydrodynamic force, F_H the molecular force of attraction, F_E the electrostatic force, and F_G the gravitational force. Condition (22) implies that a force directed towards the surface (to the upper pole) of the bubble should act on the particle for any h, since otherwise deposition is impossible. Condition (22) sets limits to the parameters in the formulae for the four forces at which the "disjoining" pressure can be overcome. These limits are illustrated graphically in Figs.5 and 6 by curves characterising the dependence of the particle radius on the electrolyte concentration and covering the region close to the original of coordinates, where flotation is impossible. The regions of floatability due to the adhesional hydrodynamic force have been calculated for the Stokes (Fig.5) and potential (Fig.6) regimes in the rise of the bubble. As was to be expected, flotation is possible also appreciably below the heterocoagulation theshold when the particle size is not unduly small. In the potential regime, the adhesional

§ Eqn.(14) was apparently first obtained[1] by analogy with the mechanics of aerosols. Eqn.(14), revised by taking into account the gravitational component, has been derived by Reay and Ratcliff[55].

hydrodynamic force is much greater than in the Stokes regime, as a result of which flotation becomes possible for larger electrostatic attraction forces or smaller particles sizes.

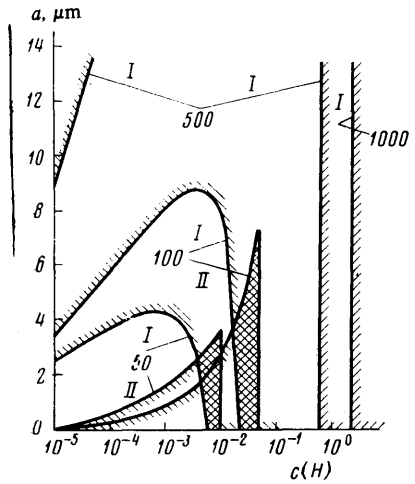

Figure 5. The $a - c$ regions illustrating the floatability in the Stokes regime (shown dashed): I) the lower limit of flotation at the primary minimum; II) the upper limit of flotation at the secondary minimum; 50, 100, 500, and 1000—numerical values of the product $\psi_a\psi_R$ expressed in mV^2. The following quantities are expressed in CGS units: $A = 5 \times 10^{-14}$, $\varepsilon = 80$, $g = 10^3$, and $\rho_{particle} = \rho_{water} = 1$.[60]

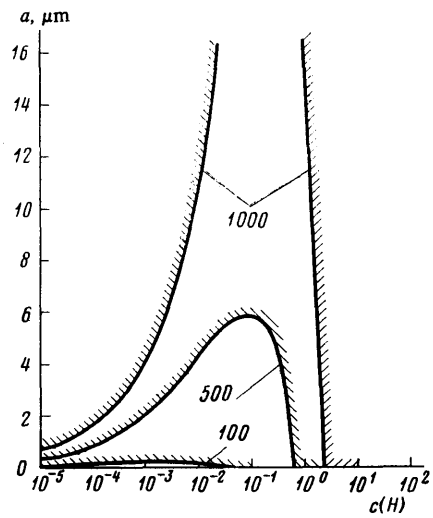

Figure 6. The a–c regions of floatability in the potential regime (shown dashed); 100, 500, and 1000—numerical values of the product $\psi_a\psi_R$ expressed in mV^2. The following quantities are expressed in CGS units: $A = 5 \times 10^{-14}$, $\varepsilon = 80$, $R = 2.5$, $\eta = 10^{-2}$, and $U_r = 15$.[60]

Flotation without overcoming the barrier is difficult owing to the breaking away of the particles at the lower pole of the bubble. The component of the flow rate of the liquid at the upper pole, at right angles to the bubble surface, is responsible for the force adhering the particle to the surface, while that at the lower pole is responsible for the force tending to break it away. Consequently the stripping force differs from the adhesional force only in sign. Therefore the possibility of the fixation of the particles at the secondary energy minimum[30] can be analysed also with the aid of condition (22). Since the stripping force diminishes with particle size, flotation via the fixation of the particles at the secondary minimum proves to be possible for sufficiently small particles. Therefore curve II in Fig.5 sets the upper limit to the size of the particles undergoing flotation. In view of the increasing stripping force, in the potential regime the fixation at the secondary minimum is possible only for very small particles, for which the effect is complicated by thermal movement.

Thus a quantitative description of non-inertial flotation has been given at the present time only in two limiting cases—for sufficiently small and sufficiently large values of the product of the Stern potentials of the particle (ψ_a) and the bubble (ψ_R). In the former case electrostatic interaction does not complicate flotation and Eqns.(20) and (21) can be used; in the latter case flotation is impossible¶.

Since the electrical double layer is compressed with increasing electrolyte concentration and the parameter $\psi_a\psi_R$ decreases, in the light of the data presented in Fig.6 one should expect the possibility of the reagent-free flotation of small particles below the heterocoagulation threshold but at a fairly high concentration of the electrolyte (naturally provided that there are no non-electrostatic stability factors). The significant differences in the Stokes and potential regimes both in the LHI and in the process involving the overcoming of the disjoining pressure already discussed demonstrate the importance of an adequate description of the hydrodynamic field surrounding the bubble in the elementary flotation step. It is useful to employ the hydrodynamic field calculated[62,63] for intermediate values of Re. A formula has been obtained[61] for E [analogous to Eqn.(14)] for conditions under which the hydrodynamic field described by Hamielec and coworkers[62,63] is applicable and the surface of the bubble is stationary.

Within the framework of the general consideration of the equation for particle trajectories, it has been shown[1] that the sedimentation of particles has very little influence on their capture by the bubble, provided that its probability is sufficiently high, so that condition (7) does not hold. For this reason, Deryagin and Dukhin[2] disregarded the sedimentation term in the equation for the particle trajectories. Flint and Howarth[64] regard the force of gravity as the most important factor influencing the capture of small particles by bubbles of any size and object to the neglect of sedimentation, as was done by Deryagin and Dukhin[2,5]. According to Flint and Howarth[64], the quantity E_0 is proportional to the difference between the densities of the particle and the medium ρ' or more precisely to the dimensionless parameter $G = 2\rho' a^2 g/9\eta U_\infty$. However, this implies that, when the densities of the particle and the

¶In the course of the preparation of this review for the press, the paper by Rulev et al.[97] was published in which the kinetic theory of the flotation of small particles was extended to the case of arbitrary values of ψ_a and ψ_R and a quantitative interpretation of the experimental data of Rulev et al.[15] was given.

medium are equal, i.e. when $\rho' = 0$, non-inertial flotation is impossible. This conflicts particularly with Sutherland's equation (13) in which the difference ρ' is not included at all. This conflict arose because Flint and Howarth did not take into account the most important factor in the non-inertial flotation of small particles, namely their finite size.

Anfruns and Kitchener[61] disregarded the finite particle size and Sutherland[53] disregarded the force of gravity. It is easy to take these factors into account simultaneously and to compare their influences on this basis. The functions characterising the particle trajectories in the studies of the above investigators[53,61] differ only by the fact that Anfruns and Kitchener took into account the influence of sedimentation. We shall therefore use the more general formula [Eqn.(6)] of Anfruns and Kitchener[61] describing the family of particle trajectories:

$$\Psi_p^* = \frac{1}{2}\sin^2\theta\left[r^2\left(1 + G - \frac{1}{r^3}\right)\right].$$

Anfruns and Kitchener[61] isolate the limiting trajectory from the entire family of trajectories by taking into account the following condition: $r = 1$ when $\theta = \pi/2$. If this condition is refined by allowing for the finite particle radius ($r = 1 + a/R$ when $\theta = \pi/2$), then the following more general and more accurate formula is obtained:

$$E_0 = \frac{(1+G)\,E_p + G}{1+G} \quad . \qquad (23)$$

If the force of gravity is neglected (we than have $G = 0$), Sutherland's formula is obtained from Eqn.(23). If the finite particle size is neglected, i.e. if we put $E_p = 3a/R = 0$, the equation of Flint and Howarth[64] is obtained.

In the hydrodynamic theory of flotation no account is taken at the present time of the influence of the particle on the hydrodynamic field of the bubble, i.e. the ratio a/R plays the role of a small parameter. The factor G, proportional to $(a/R)^2$, is therefore a small second-order quantity, while the factor E_p, proportional to (a/R) [Eqn.(13)], is a small first-order quantity. The quantity G in Eqn.(23) can therefore be neglected and the equation is transformed into Sutherland's formula also when the force of gravity is neglected. Thus, under the conditions of potential flow, the force of gravity does not influence the kinetics of non-inertial flotation and the conclusions of Flint and Howarth[64] are incorrect.

At the same time one must introduce the correction that, with decrease of the size of the bubble and particularly with increase of the retardation of the movement of its surface, the influence of the sedimentation of particles on the flotation kinetics increases. For example, the allowance for the force of gravity on the kinetics of the flotation by bubbles rising in the Stokes regime, carried out by Reay and Ratcliff[55], is quite appropriate. This is consistent with the finding that in this instance E_{0S} and G are of comparable order of magnitude, as can be seen from Eqn.(14).

V. QUANTITATIVE EXPERIMENTAL STUDIES OF THE FLOTATION OF SMALL PARTICLES

In recent years considerable advances have been made in the experimental study of the influence of the sizes of the bubble and spherical particles on the collision efficiency in the Stokes regime[40,65]. A study has also been made of the flotation[15] of a petroleum emulsion by bubbles whose size ensures a close approach to the potential regime. In satisfactory agreement with Eqn.(21), it was then established that $E_p \propto a$. Studies by Deryagin and coworkers[9,10] confirmed the marked influence of the LHI in non-inertial flotation. Its most important manifestations, observed experimentally, are a rapid decrease of E with decreasing particle size and increasing bubble size and also a sharp alteration of the nature of the dependence of E on R and a on passing from the viscous to the potential flow regime. It must be emphasised that Eqn.(20) is in quantitative agreement with the data of Collins and Jameson[40] and Reay and Ratcliff[65] in relation to the dependence both on the particle size and on the radius of the bubble. The experimental finding that $E \propto a^{1.5}$ implies a better agreement with Eqn.(20) than with Eqn.(14). This can be regarded as experimental confirmation of the influence of the SHI on the elementary step in flotation. However, one must recognise that there have been no systematic experimental studies of the SHI at the present time.

Studies of the efficiency of capture by single bubbles 0.5–1.1 mm in diameter of several fractions of quartz which has been rendered hydrophobic (methylated), confirmed[61] the formula taking into account only the long-range hydrodynamic interaction. The authors[61] therefore concluded that the disjoining pressure of the double layers does not complicate the flotation step at least under the conditions of their experiment. An analogous conclusion could be formulated in relation to the SHI.

However, these conclusions cannot be regarded as firmly justified, since it is possible to propose a different interpretation of these interesting experimental data. This other possibility is associated with the fact that the theory of the SHI and of the influence of the double layer on flotation has been developed for spherical particles, while Anfruns and Kitchener[61] investigated non-spherical particles—fragmented Brazilian quartz. One must therefore postulate the existence of edges separating the faces on the surface of such particles. The resistance to the decrease of the thickness of the interfacial film can be much more readily overcome if the angles between the faces (or between the edges) are sufficiently small, so that the interfacial film can be "pierced" by the sharpened section of the particle surface. Similar geometrical conditions in the elementary step in flotation sharply facilitates also the overcoming of the disjoining pressure. The surface microrelief cannot have a strong influence on the LHI, since Eqns.(13) and (14) and the formula of Anfruns and Kitchener[61], which have been derived for spherical particles, remain in force also as an approximation for non-spherical particles.

In the light of the foregoing and the results of Anfruns and Kitchener, the formulation of the theory of the flotation of small particles has been significantly revised: the characteristics of the influence of the SHI and of surface forces on the elementary step in flotation can differ sharply in relation to spherical and non-spherical particles and must therefore be investigated separately. The deviation of the shape of the particle from the spherical can not only reduce but can also greatly increase the role of the SHI and of the double layer in flotation. The decrease of the thickness of the plane-parallel interfacial film between the bubble and a lamellar particle is even slower than for a spherical particle, so that the role of the SHI sharply increases in this instance. This is to be expected for a thin lamellar particle. On the other hand, if the particle is not thin, one may expect that its migration along the surface of the bubble is accompanied by rocking. In the course of rocking, orientations of the particle relative to the bubble surface arise in which the viscous resistance of the interfacial film and the disjoining pressure of the double layer are overcome so rapidly that the

SHI has only slight influence on E.†

VI. THE BREAKING AWAY OF SMALL PARTICLES IN CONTACT-FREE FLOTATION AND THE DYNAMIC ADSORPTION LAYER OF THE BUBBLE

If flotation is uncomplicated by energy barriers and $h_{cr} \neq 0$, then the approach of the particles terminates with the rupture of the film and the establishment of a wetting angle so that the possibility of breaking away is ruled out under these conditions.

If the double layer does not complicate flotation but there is a non-electrostatic barrier with a thickness h_0, then the possibility of the particle breaking away can be estimated as in the study of Deryagin et al.[60], where the possibility of coagulation at the secondary minimum in flotation was examined (Fig.5). For this purpose, it is sufficient to consider the condition of the equality of the sum of the hydrodynamic and gravitational stripping forces to the molecular attraction force at $h = h_0$ at the lower pole of the bubble. This leads to the following estimate of the particle radius a_{max} below which contact-free flotation is possible in the Stokes regime (in the CGS system):

$$a_{max} = 3 \cdot 10^{-3} \frac{\sqrt{A}}{h_0} \quad . \qquad (23')$$

If it is assumed that A varies in the range 10^{-14}–10^{-13} erg and h_0 varies in the range 10–100 Å, then a_{max} is in the range 3–100 μm. Thus difficulties for contact-free flotation arise when the Hamaker constant A is small or the thickness of the barrier h_0 is large. In this situation the opposite charges of the particle and the bubble must be achieved by introducing an ionogenic surfactant in order to ensure contact-free flotation. This is possible for a greater thickness of the barrier the lower the electrolyte concentration.

By overcoming the disjoining pressure of the double layer via the adhesional hydrodynamic force (Figs.5 and 6), one guarantees that the particle, which has migrated to the lower pole of the bubble, cannot break away only when the depth of the primary (near) potential energy minimum is sufficiently great. It has been shown[65,67,68] that after coagulation subsequent breakdown of the resulting aggregate is possible, since the depth of the primary minimum may be small. Coagulation at the primary minimum does not occur or is reversible with increase of concentration in the range characteristic of the coagulation of lyophobic colloids if the Stern potential is fairly high and the depth of the well is small. The question of the depth of the primary minimum is very complex. In the case of flotation it is complicated still further in view of the lack of information about the charge of the bubble.

Since the question raised in connection with the study described in Refs.65–68 is far from solved, we shall confine ourselves to a single general remark. The depth of the primary potential well decreases with increasing charge of the interacting surfaces. Therefore the smaller the product $\psi_a \psi_R$, involved in the theory of heterocoagulation (Figs.5 and 6), the smaller is the probability that the particles which had previously overcome the disjoining pressure of the double layer via the adhesional hydrodynamic force will break away. The greater the value of this product, the smaller the depth of the primary potential well, and the greater the probability that the particles will break away (particularly if the Hamaker constant is small). In other words, the condition for overcoming the disjoining pressure via the adhesional hydrodynamic force for sufficiently low values of the product $\psi_a \psi_R$ is necessary and sufficient for flotation. For higher values of this product, the above condition becomes only necessary.

The possibility of breaking away increases with increasing size and the rising velocity of the bubble. The mechanism of the stripping process can then be complicated by the deformation of the double layer on the mobile bubble surface, which can lead to an increase of the surface charge and hence of the electrostatic repulsion forces at the lower pole of the bubble. When the size of the bubble is not unduly small, its surface is mobile. Its upper part becomes extended as the bubble floats upwards while the lower part is compressed[3,4]. The new surface regions produced are filled with the adsorbable substance, while the contraction of the surface results in its desorption. On the upper half of the rising bubble, the degree of adsorption is lower than on a stationary surface (Γ_0), which ensures a continuous supply of the surfactant (or of adsorbable inorganic ions) from the bulk phase to the expanded surface. On the lower half of the rising bubble, the degree of adsorption is higher than Γ_0, which gives rise to the desorption of the surfactant. Thus the degree of adsorption $\Gamma(\theta)$ increases in the direction of the migration of the surface of the bubble, i.e. from the upper pole ($\theta = 0$) to the lower pole ($\theta = \pi$).

The supply of the surfactant to the upper half of the bubble and the removal to the bulk phase of the surfactant desorbed from the lower half take place owing to the existence near the surface of the so-called diffusion boundary layer. Its thickness is much smaller than the radius of the bubble R and is defined by the formula

$$\delta = R/\mathrm{Pe}^{1/3} \quad , \qquad (24)$$

where Pe is the Peclet number defined by the expression

$$\mathrm{Pe} = \frac{RU}{D} = \mathrm{Re}\,\frac{\nu}{D} \quad . \qquad (25)$$

Since the diffusion coefficient $D \cong 10^{-5}$ cm^2 s^{-1} and $\nu/D \cong 10^3$, in the relevant range of Reynolds numbers the quantity Pe should be large (~10^4–10^6); the surfactant concentration in the diffusion boundary layer on the upper half of the bubble is smaller than in the bulk phase and increases from the upper to the lower pole, as in the dynamic adsorption layer. For any specified angle θ, which is reckoned from the upper pole, equilibrium between the degrees of adsorption $\Gamma(\theta)$ and the volume concentration in the bulk of the diffusion layer directly at the surface $c(R, \theta)$ persists:

$$\frac{\Gamma(\theta)}{c(R, \theta)} = \frac{\Gamma_0}{c_0} \qquad (26)$$

where Γ_0 is the equilibrium degree of adsorption on the surface of a stationary bubble at a surfactant concentration in the bulk of the solution c_0.

Not only the movement of the bubble surface influences the formation of a dynamic adsorption layer; the opposite influence of the dynamic adsorption layer on the movement of the surface also obtains. The degree of adsorption increases in the direction of motion of the liquid, while the surface tension σ falls. This leads to the generation of forces directed in opposition to the stream of liquid and retarding the movement of the surface. Thus the theory of the dynamic layer must be based on the simultaneous

†During the preparation of this article for the press, we learnt of the communication by Anfruns and Kitchener[98], in which they described an experimental confirmation of the above considerations.

solution of the equation for diffusion, complicated by allowance for the influence of the movement of the surface on adsorption–desorption processes, and the hydrodynamic equations complicated by the influence of the adsorption layer on the movement of the interface between the liquid phases[68–71].

The simultaneous allowance for the influence of the hydrodynamic field on the distribution of adsorption and volume concentration and for the influence of dynamic adsorption on the velocity field for Pe $\gg$ 1 has been achieved in the limiting cases of weak (Re $\gg$ 1) and strong retardation of the surface (Re $\ll$ 1).

For weak retardation of the main section of the surface and for a moderate surface activity, i.e. when

$$\Gamma_0/c_0 \ll \delta \quad , \tag{27}$$

the change in the degree of adsorption is slight: $\Gamma_0 - \Gamma|_{\theta=0} \ll \Gamma_0$. The angular relation $\Gamma(\theta)$, obtained by Deryagin et al.[3], can be roughly approximated by a cosine, as assumed by Frumkin[69], only on the upper half of the bubble. A virtually uniform and weak retardation of the surface can be characterised by the retardation coefficient

$$\gamma = \frac{2}{3}\frac{\partial\sigma}{\partial c}\Gamma_0 \mathrm{Pe}^{-1/3} D^{-1} \tag{28}$$

and $\gamma \ll \eta$.

For weak retardation and a high surface activity, i.e. when

$$\Gamma_0/c_0 \gg \delta \quad , \tag{29}$$

the degree of adsorption on the main section of the bubble surface is much smaller than the equilibrium value and a very rapid growth of adsorption and a strong inhibition of the surface should be observed only for $\theta \to \pi$.[4]

In connection with the influence of the surface on the adsorption layer discussed above, the problem arises of the change in the structure of the electrical double layer along the mobile bubble surface. A characteristic feature of the structure of the equilibrium double layer at the air–water interface is that it is caused by the negative and not positive adsorption of ions. Numerous experimental studies, which have been reviewed[73,74], have established that the surface tension in solutions of inorganic electrolytes increases. According to the Gibbs formula, this indicates negative adsorption. The magnitude of the effect is frequently characterised by the thickness of the ion-free layer (h). This thickness is of the order of magnitude of the size of water molecules. The expulsion of ions from the surface layer is caused by their electrostatic interaction with the interface, which can be characterised in terms of electrostatic image forces.

In order to test the validity of condition (27), one can use the following estimate:

$$(\Gamma_0/c_0) \simeq h \simeq 10^{-7}\ \mathrm{cm} \ll \delta \quad . \tag{30}$$

Thus condition (27) is valid, which means that, under the conditions of negative adsorption, the double layer is hardly deformed on the mobile bubble surface.

On passing from the Stokes field of the bubble to the potential field, the stripping hydrodynamic force increases by a factor R/a, since the radial flow rate of the liquid at the distance of closest approach of the centre of the particle to the surface of the bubble (a) increases by the same factor. This difference between the Stokes and potential regimes in the treatment of the possibility of the breaking away of particles diminishes somewhat if account is taken of the retardation of the bubble surface. On the fully retarded section of the bubble surface, the radial component of the velocity of the liquid at a distance y from the surface of the bubble diminishes according to a quadratic law for $y \ll R$, as in the Stokes regime. On a partly retarded section of the surface, the charge proceeds in accordance with a linear law but with a coefficient which is comparable to the ratio of the local retardation coefficient to the viscosity of water. The higher the degree of retardation of the bubble surface, the smaller the possibility that the particles will break away in contact-free flotation. For this reason, the question of the degree of retardation of the surface is of great interest.

The literature data[54,75] presented in Fig.7 show that, for Re > 40, the velocity of the bubble is greater the lower the concentration of the surfactant introduced and that, for Re < 40, bubbles rise as solid spheres even when the water has been very carefully freed from impurities. The agreement of the rate at which the bubble rises with the value calculated for a solid sphere is regarded by many investigators as the criterion of the retardation of the entire surface of the bubble. In the light of theoretical studies of the retardation of the movement of the bubble surface, this condition is believed to be necessary but not sufficient. When a considerable proportion of the bubble surface is retarded, some of it, near the upper pole, can retain mobility[70]. There is also a possibility of a uniform, strong, but incomplete retardation of the entire surface[71,72]. In both cases the rate at which the bubble rises can be the same, within the limits of the error of the measurement, as that for a solid sphere. However, the degree of adsorption of the surfactant at the upper pole can then be much less than Γ_0.[71,72]

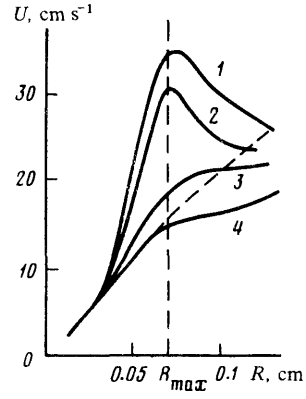

Figure 7. The rate of the rise of bubbles in aqueous solutions of sodium dodecyl sulphate: *1*) distilled water; *2*) 10^{-6} M; *3*) 1.2×10^{-5} M; *4*) 10^{-3}–10^{-4} M. The dashed curve corresponds to bubbles with a fully retarded surface in distilled water or a millimolar solution[54].

The hydrodynamic resistance, which determines the rate of the upward rise of the bubble, consists of the shape resistance, which depends on the position of the line at which the particle breaks away, and the viscous resistance, which depends on the degree of retardation of the entire surface. Since the contribution of the viscous resistance is not small, one must assume that, for Re < 40, the entire lower half of the bubble is retarded, since otherwise the velocity of the bubble would have differed significantly from

the velocity of the solid sphere owing to the contribution of the viscous resistance. Hence follows the important conclusion that, at Re < 40, the stripping force increases insignificantly compared with the Stokes regime.

The transitional regime (1 < Re < 40) can be optimal for reagent-free flotation. Its advantage over the Stokes regime consists in the fact that, when it obtains, the possibility of fixation at the primary energy minimum increases. A necessary condition for reagent-free flotation is sufficient depth of the primary energy minimum. If this condition does not hold, then ionogenic surfactants must be introduced to prevent the breaking away of the particles.

The agreement of experimental data for the rates at which bubbles rise with the calculated values[54], obtained on the assumption that the surface is unretarded implies that, at Re > 40, a considerable proportion of the lower half of the bubble is mobile, to which corresponds a sharp increase of the normal component of the velocity responsible for the breaking away of the particles. Therefore, on passing to the condition where Re > 40, contact-free flotation becomes hindered. Hence the introduction of an ionogenic surfactant is necessary even when the adhesional hydrodynamic force ensures the overcoming of the disjoining pressure, except in the case where the depth of the primary well is large or contact flotation obtains.

The introduction of a cationic surfactant (for a negative particle charge) leads to three effects ensuring flotation, namely the difficulty associated with the overcoming of the disjoining pressure in the deposition of particles on the bubble is eliminated, attraction forces (stronger under certain conditions than the van der Waals forces) preventing the breaking away of the particles are ensured and, as a result of the retardation of the movement of the lower half of the bubble surface, the stripping hydrodynamic force diminishes.

The consumption of the ionogenic surfactant should ensure the neutralisation of the bubble charge, which can be roughly estimated by specifying the surface potential ψ, as was done by Ekserova and Zakharieva[76]. It follows from the Gouy–Chapman theory that

$$\sigma = F\Gamma' = Fc_e\varkappa^{-1}\sinh(\Psi/2) \qquad (31)$$

where Γ' is the degree of adsorption of the cationic surfactant necessary for the neutralisation of the bubble charge at an electrolyte concentration c_e and $\varkappa^{-1}$ is the thickness of the diffuse component of the double layer. The consumption of the surfactant should ensure a fairly high degree of adsorption, i.e. the following relation should hold:

$$\Gamma > \Gamma' \simeq c_e\varkappa^{-1}. \qquad (32)$$

In the most important case where

$$\varkappa^{-1} \ll \delta \qquad (33)$$

conditon (32) can be ensured both for low and high surface activities. The use of surfactants with a very high surface activity, corresponding to condition (29), is undesirable since the adsorption layer is then displaced to the lower pole of the bubble. The introduction of such a surfactant does not facilitate the deposition of particles on the upper half of the bubble and does not prevent their breaking away from the lower half, since the surfactant is concentrated in the small region near the lower pole of the bubble and the particles can break away from any section of the surface near which the normal component of the velocity is directed into the bulk of the liquid. By increasing the concentration c_0, it is possible to expand the retarded zone. This question has been considered by Dukhin and Buikov[71,72], but these investigations do not answer the question whether the retardation of the entire lower half of the bubble is possible at a sufficiently high c_0.

The use of surfactants with a very low surface activity is inconvenient, since it is associated with an excess consumption of the reagent. The same necessary degree of adsorption Γ' can be ensured at a lower concentration c_0 the higher the ratio Γ_0/c_0 within the limits of the validity of condition (27). With increase of Γ_0/c_0, the retardation coefficient also increases [see Eqn.(28)] even for an equivalent decrease of c_0, which is also important for the prevention of the breaking away of the particle. One may therefore conclude that it is useful to employ surfactants with a surface activity such that $\Gamma_0/c_0 \cong \delta$. A surfactant concentration equal to

$$c_0 = \frac{c_e\varkappa^{-1}}{\delta} \qquad (34)$$

is then necessary to ensure condition (32). At this retardation concentration γ may be comparable to the viscosity, which shows that a certain section of the bubble surface is retarded, because the following relation holds:

$$\frac{\gamma}{\eta} = \frac{2}{3}\frac{\partial\sigma}{\partial c}\Gamma_0 \mathrm{Pe}^{-1/4}D^{-1}\eta^{-1} \simeq \frac{RT}{\eta U}\varkappa^{-1}c_e \ . \qquad (35)$$

VII. NON-EQUILIBRIUM SURFACE FORCES IN FLOTATION

A characteristic feature of the mechanism of the deformation of the thin double layer by various kinds of external influences is that equilibrium conditions, particularly the electroneutrality condition, hold for each section of the surface[3,77]. The degrees of adsorption (surface charge) and the concentration in the diffusion layer vary along the mobile surface of the bubble. Thus the thickness of the double layer varies along the surface of the bubble in accordance with the variation of the surface charge and the electrolyte concentration but on each section of the surface its three-dimensional double layer structure is described by the equilibrium theory. This justifies the consideration of the elementary step in flotation on the basis of the theory of heterocoagulation. However, qualitatively new effects also arise on formation of the double layer. Diffusion in an electrolyte is known to be usually coupled with the generation of an electric field. The vector lines of the electric field E_D coincide with the vector lines of the concentration gradient grad c. In a binary electrolyte solution the electric field strength is expressed in terms of the local concentration gradient by the familiar formula[3,78]

$$E_D = \frac{D^+ - D^-}{z^+D^+ + z^-D^-}\frac{RT}{F}\frac{\mathrm{grad}\,c}{c} \ , \qquad (36)$$

where D^+, D^-, z^+, and z^- are the diffusion coefficients and the electrovalences of the anions and cations and F is the Faraday. An electric field should therefore arise within the limits of the diffusion boundary layer coupled with the dynamic adsorption layer of the ionogenic surfactant. This is caused by the slight deviation from the electroneutrality condition. Like the grad c vector lines, the E_D vector lines begin at the upper boundary of the quasi-equilibrium double layer, are oriented approximately at right angles to the surface, and terminate at a point within the diffusion layer. However, the sources of electric field lines are known to be positive charges, while negative charges diminish the field. Hence it follows that charges of opposite sign, approximately cancelling out, are localised within the limits of the quasi-equilibrium double layer and

in the diffusion layer (Fig.8). These two layers of charges constitute a single system in the sense that the change in the distribution of charges of one layer is necessarily accompanied by redistribution of charges in the other layer.

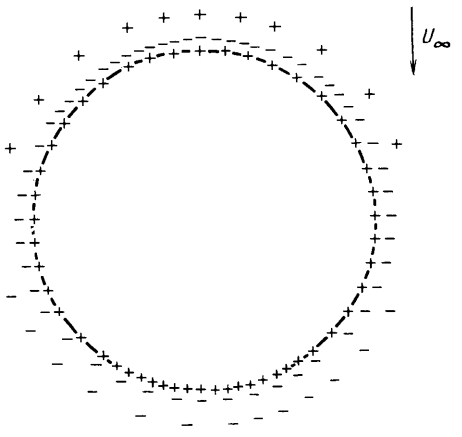

Figure 8. Distribution of the charge signs in the primary and secondary double layers for a substance with moderate surface activity[5].

This system of charges, arising on deformation of the equilibrium double layer, can be naturally called the secondary double layer[78-80]. Since the thickness of the secondary double layer exceeds that of the equilibrium double layer by several orders of magnitude (except at low electrolyte concentrations), the deposition of particles on the surface of the bubble can be controlled under certain conditions primarily by the stage in which the particles pass through the diffusion layer[81]. The consideration of this question simplifies if the particle size is less than δ, so that a particle passing through the diffusion layer can be regarded as subject to homogeneous electric and diffusion fields. Consequently a particle crossing the diffusion layer is subjected to electrophoresis and diffusiophoresis[82,83].

In a study of the deposition under gravitational forces of galenite particles of different size on the mobile surface of a fixed bubble from a vertical stream of liquid[9], it was observed that particles whose size is below a critical value a_{cr} do not reach the surface of the bubble. On the basis of the measured values of ζ, it was established that, for $a < a_{cr}$, the joint action of electrophoresis and diffusiophoresis is responsible for the force repelling the particles from the bubble, which exceeds the gravitational force. With increasing electrolyte concentration, the repulsion force weakens, which is revealed experimentally by a decrease of a_{cr}.

The thickness of the diffusion layer of a freely rising bubble is much smaller, in view of its high velocity, than in the experiments described. The effect can therefore appear only for particles which are so small that their thermal motion is significant. Electrophoresis and diffusiophoresis must be taken into account in the description of the Brownian diffusion of submicron particles to the mobile surface of a bubble and at a fairly low electrolyte concentration. It has been shown[84] that the concentration drop in the diffusion layer δc is very small when the surface of the bubble is fully mobile:

$$\frac{\delta c}{c} \simeq \frac{\mathrm{Pe}^{1/3}}{(\varkappa a)^2} \quad . \tag{37}$$

The mechanism of the action of non-equilibrium surface forces for particles whose size exceeds δc can be established fairly simply only when the same ionogenic surfactant is sorbed on the surfaces of the bubble and the particle. This mechanism is associated with the desorption of the reagent from the surface of the particle, diffusion through the film, and adsorption on the surface of the bubble. The diffusional transport of the adsorbate is caused by the decrease of the concentration of the reagent in the diffusion layer of the bubble, which extends over the upper half of the bubble and, when condition (29) holds, also over a considerable proportion of the lower half. The section of the bubble surface where adsorption takes place acquires an excess charge, whose sign is the same as that of the rapidly diffusing ion. An equal charge of the opposite sign arises on the section of the surface of the particle from which the reagent is desorbed. An estimate showed that an electric field of $\sim 10^3$ V cm arises under these conditions. The excess charges of the bubble are attracted to the excess charges of the particle, so that the interfacial film is as it were clamped between the plates of a condenser, as a result of which its thickness diminishes. The non-equilibrium surface forces decrease in the presence of an indifferent electrolyte if its concentration is much greater than that of the ions in the adsorption layer. For a quantitative estimate of this important factor, which reduces the non-equilibrium surface forces, it is necessary to extend the theory[8] developed in relation to a binary electrolyte to the case of three kinds of ions.

High electrolyte concentrations have only a weak influence on the non-equilibrium surface forces due to the dynamic adsorption layer of the non-ionogenic surfactant[85,86]. In the course of migration along the mobile surface of the bubble the surfactant concentration in the diffusion boundary layer in the vicinity of the particle increases continuously. Therefore in the centre of the interfacial film the concentration of the surfactant and the degree of adsorption are lower than on the periphery of the film, where the concentration increases continuously as a result of the migration of the particle along the diffusion layer. Since the degree of adsorption at the centre of the interfacial film is smaller than on its periphery, the surface tension at the centre of the film is higher. The increase of the surface tension towards the centre of the film from its periphery should be accompanied by surface flow from the periphery to the centre, involving the entire liquid of the film. The flow of liquid into the gap between the particle and the bubble prevents a decrease of the thickness of the film and rules out the possibility of flotation. This analogue of the Marangoni–Gibbs effect does not arise if the surface of the bubble is stationary and the degree of adsorption does not change along it.

The decrease of the collision efficiency due to this effect has been calculated[99] for spherical and disc-shaped particles under the conditions of a weak retardation of the surface and a moderate adsorbability of the surfactant, satisfying condition (27). For a disc-shaped particle, the collision efficiency can diminish by several orders of magnitude. For spherical particles, the diffusional exchange in the interfacial film between the centre of the latter and its periphery is more intense, which leads to a decrease of the drop in adsorption and surface tension, i.e. a weakening of the effect. However, the deposition of even a spherical

particle is possible only in the small region near the upper pole of the bubble.

The effect involving the stabilisation of the interfacial film discussed above can weaken if the surfactant is adsorbed not only by the bubble but also by the particle. There is then a possibility of the diffusional transfer of the surfactant from the surface of the particle to the surface of the bubble, which should lower the surface tension at the centre of the interfacial film, compensating to some extent its increase as a result of the tangentian movement of the particle.

Diffusional non-equilibrium surface forces have been observed experimentally[87,88]. A thin layer of soluble ionogenic surfactant was first deposited on a small section of an inclined surface of the solid. When water had flowed off the surface, the thickness of the inclined surface layer under stationary conditions was always constant except for the section coated by the surfactant. Over the surfactant-coated section, the film became appreciably thinner under the influence of the surfactant. Since the surface of the film in the attenuated region was significantly curved, the authors[87,88] reached the completely correct conclusion that appreciable forces, which must compensate for the capillary pressure due to the curvature of the surface of the film, act at right-angles to the water–air interface. A theory of this effect has been proposed[89], taking into account the electro-capillary effects, which were significant in both the experiments of Evans and Ewers[87,88] and in the application of ionogenic surfactants in the flotation of small particles.

By introducing ionogenic surfactants, it is possible to eliminate the hindrance of the flotation of small particles associated with the operation of equilibrium surface forces (neutralisation of the charge of the bubble and decrease of the electrostatic component of the disjoining pressure), but the effect of the stabilisation of the interfacial film can then be considerable, as a result of which flotation is impaired. The introduction of ionogenic surfactants in flotation by small bubbles therefore appears to be more reliable, since in the Stokes regime one may expect the complete retardation of the surface of the bubble and a sharp weakening of the non-equilibrium surface forces. This can also be achieved in the transitional regime by increasing the consumption of the reagent, ensuring thereby the retardation of the surface.

VIII. THE EFFICIENCY OF THE COLLISION AND FLOTATION KINETICS

Flotation is usually carried out with large volume fractions of bubbles, which leads to an appreciable deviation of the distribution of the velocities of the liquid in the vicinity of the bubbles compared with the case of a single bubble discussed above. As a result of allowance for the velocity distribution engendered by the system of bubbles[17], a formula was obtained for the capture efficiency. The efficiency depends not only on the bubble size but also on the fraction of dispersed gas[18]. The study of the flotation of monodisperse particles by a system of bubbles led to the formula

$$n(t)=n_0e^{-kt} \quad , \tag{38}$$

which had been obtained earlier in another study[90]. Here $n(t)$ and n_0 is the concentration of particles at time t and the initial concentration. Under these conditions, the following expression was obtained for k (in the case of monodisperse systems):

$$k=\frac{3qE}{4R} \tag{39}$$

where q is the rate of bubbling, equal to the volume of gas blown across a unit cross-sectional area of the flotation chamber per unit time. This formula was extended[17] to the case of polydisperse systems and it was found that under conditions of a nearly normal distribution of particles to the bubbles, one may use Eqn.(39) in which the statistical mean particle and bubble sizes are employed.

Thus the kinetic theory of the flotation of small particles described above makes it possible to relate the technologically most important parameter k to the measured characteristics of the flotation system. The parameter k can be related to E also when particles with sizes greater than a_{max} can break away after deposition. In the summation with respect to fractions of deposited particles [in the integration of $E(a)$] it is sufficient to use a_{max} as the upper integration limit.

IX. THE INFLUENCE OF THE AGGREGATION OF PARTICLES ON THE ELEMENTARY STEP IN NON-INERTIAL FLOTATION

The introduction of surfactants in order to reduce the electrokinetic potential [of the bubble?] can lead simultaneously to a decrease of the electrokinetic potential of the particles and hence to their aggregation. The influence of aggregation on the elementary step in flotation has been considered[20] on the assumption that the aggregate is rigid and spherical in shape and that its radius a^* is small compared with R. With these simplifying assumptions, the efficiency of the collision of the aggregate with the bubble E^* can be described by Eqns.(13) and (14) having replaced the particle radius a by the radius of the aggregate a^*. Then the following estimates can be obtained from Eqns.(13) and (14) for the intensity of the deposition of particles on the bubble as a result of aggregation in relation to the Stokes and potential regimes:

$$E_s^*/E_s \simeq (A/a)^2;\ (E_p^*/E_p) \simeq a^*/a \ . \tag{40}$$

Since under the conditions of the short-range hydrodynamic interaction, there is a possibility of the outflow of the liquid from the film separating the bubble and the aggregate into the pores within the aggregate, the attenuation of the film is faster and the ratio E^*/E may prove to be greater than that found by Eqns.(40).

The increase in the size of the aggregate plays a positive role in flotation only at the stage involving the formation of the aggregate–bubble system, since the probability that the aggregate will break away from the bubble increases simultaneously. Indeed, the greater the size of the aggregate or particle, the greater the radial component of the velocity at the centre of the aggregate, which is oriented outwards at right angles on the lower half of the surface of the bubble. Formulae have been obtained[20] for the stripping hydrodynamic force and the maximum radius of the bubble capable of flotation without the breaking away of aggregates of given radius. The derivation of the formulae was based on the solution[91,92] of the hydrodynamic problem of two spheres rising upwards along a common axis in the Stokes regime.

For a given bubble size, there is an optimum size of the aggregate ensuring the most intense flotation, since larger aggregates break away from the surface of the bubble and smaller aggregates are deposited on its surface at a lower frequency. It is inconvenient to increase appreciably the size of the bubble, since, under the conditions of a simultaneous decrease of the size of the aggregate, this leads to a sharp diminution of the ratio of the volumes of the aggregates undergoing flotation and of the gas bubbled

through the system. An appreciable decrease in the size of the bubble is also inconvenient, because the rate of transport of the aggregates by the bubbles decreases sharply at the same time. This means that there is an optimum bubble size for the flotation of aggregates of given dimensions. Unfortunately, it is difficult to estimate this optimum reliably. Firstly, it is difficult to estimate the number of aggregate particles in contact with the bubble, in proportion to which the force acting against the stripping force increases. This number depends on the deformation of the aggregate under the influence of the adhesional hydrodynamic force and the tangential stream of liquid. Secondly, the aggregate may break away owing to the rupture of the coagulation linkage between the particle adhering to the bubble and the neighbouring particles of the aggregate.

X. THE FLOTATION OF SUBMICRON PARTICLES

With decrease of the radius of the non-inertial particles and when the latter attain the region of submicron dimensions, they acquire the capacity for intense Brownian diffusion. In this case the electrostatic barrier impenetrable to comparatively large but non-inertial particles can be overcome by small "Brownian" particles owing to the energy of their thermal movement.

The efficiency of the capture of Brownian particles by the bubble can be determined by solving the equation for the convective diffusion of particles to a spherical obstacle in the field of the forces of interaction between the particles and the bubble. It is then possible to isolate two limiting cases. If the interaction force promotes rapid adhesion of the particles to the surface of the bubble, then the rate of deposition and hence the capture efficiency will be limited by the rate of diffusion of the particles to the surface of the bubble. It follows from the work of Ruckenstein and Prieve[93] and Spielman and Friedlander[94] that the efficiency of the capture of particles by a bubble rising under the conditions of small Reynolds numbers and having a fully retarded surface is then expressed by the formula

$$E_s = \frac{3}{2\Gamma(4/3)}\left(\frac{D_a^2\pi^2}{3R_s^2U_s^2}\right)^{1/3}, \qquad (41)$$

where Γ is the gamma-function and D_a the diffusion coefficient of the particles. On the other hand, if the bubble rises in the potential regime ($Re \gg 1$) and its surface is fully mobile then, as shown by Rulev[95], the capture efficiency is defined by the expression

$$E_p = \left(\frac{32D_a}{\pi U_p R_p}\right)^{1/2}. \qquad (42)$$

If the deposition of the particles on the surface of the bubble is hindered by their interaction (for example, electrostatic), then the capture efficiency will be limited solely by the rate of diffusion in the field of surface forces. In this case

$$E = \frac{4K}{U}, \qquad (43)$$

where K is the deposition rate constant which is determined by the energy of the interaction of the particle with the bubble. If we denote this energy by ϕ, then it follows from the work of Ruckenstein and Prieve[93] that the following expression is valid:

$$K = \frac{1}{D}\int_0^\infty \left\{\exp\frac{[\varphi(h)/kT]}{f(h/a)} - 1\right\} dh, \qquad (44)$$

$$f(H) = \begin{cases} \dfrac{H}{1+H} \text{ when } H = \dfrac{h}{a} \leqslant 1 \\ \dfrac{H - 1/8}{H+1} \text{ when } H \to \infty . \end{cases} \qquad (45)$$

Eqns.(41) and (42) show that, in contrast to the second case, in the first case the capture efficiency is determined exclusively by the diffusion coefficient, which is inversely proportional to the particle radius. Hence it follows that

$$E_s \propto a^{-2/3}, \; E_p \propto a^{-1/2}, \qquad (46)$$

i.e. the capture efficiency increases with decreasing particle radius in the submicron region, which has in fact been observed experimentally[55].

Thus, with decrease of the particle radius and on transition from the non-inertial deposition regime to the diffusional regime, a minimum in capture efficiency is observed in the region of $a \cong 0.1$ μm. The intensification of the flotation of particles of this size is particularly important and can be achieved by means of their aggregation.

If one excludes from consideration effects complicating the elementary step in flotation at a fairly low electrolyte concentration and for a fairly large bubble size, then the theory developed here, whose fundamental postulates have already been confirmed experimentally, indicates ways of optimising the purification of water by flotation. In the absence of non-electrostatic stability factors and at an electrolyte concentration above the threshold value, one must test the possibility of reagent-free flotation. On the other hand, if the level of the electrolyte concentration in the water to be purified is low or when a non-electrostatic stability factor is characteristic of the particles, then their fixation on the surface of the bubble must be ensured by introducing ionogenic surfactants.

The intensity of extraction in water purification by flotation and the possibility of increasing the productivity of flotation water purification plants without increasing their size can be achieved by employing bubbles of optimum dimensions and at the optimum concentration. In this connection one should note that the experience gained in water purification by flotation, although the latter has so far been developing solely on an empirical basis, is consistent with the hydrodynamic theory described. Indeed, in order to ensure an acceptable rate of extraction of disperse contaminations by flotation, one resorts to small bubbles, which corresponds to an increase in the efficiency of particle capture by the bubble as its size diminishes. Instead of flotation by large bubbles, formed on mechanical dispersion of air, in water purification one employs electroflotation, microflotation, flotation by bubbles evolved from supersaturated solutions of air in water, i.e. methods ensuring bubbles of small size. The observed intensification of flotation on passing to small bubbles (electroflotation, microflotation) can be associated with the weakening of the forces tending to strip the particles off the bubble. However, for maximum rates of extraction of disperse contaminations, one must use bubbles which are not simply small but have the optimum size.

Full control of the flotation of small particles can be achieved only by studying the entire set of problems associated with the hydrodynamics and stability of thin films which are and are not in equilibrium with surface forces.

Kinetics and Mechanism of the Oxidation of Aliphatic Amines

I.P.Gragerov, L.K.Skrunts, and B.A.Geller

Data on the kinetics and mechanism of the oxidation of aliphatic amines by various oxidants are surveyed and examined critically.
The bibliography includes 205 references

I. INTRODUCTION

Only that part of the extensive literature on the oxidation of aliphatic amines in which problems of the kinetics and mechanism of the oxidation reaction are considered is surveyed. These studies are of considerable and general interest to organic chemists as an example of the current approach to the problem of the mechanisms of complex reactions. They are of interest also to biochemists in view of the biological importance of aliphatic amines.

Our aim was to find common features in the oxidative reactions of aliphatic amines, to understand the causes of the differences between them, to examine the existing ideas about the mechanism, and to give a critical and general compilation of the entire set of the available data. We do not include studies on photochemical oxidation, electrochemical oxidation, and the interaction of amines with free radicals, since modern reviews of the literature on these problems are available[1-3].

II. INTERMEDIATE OXIDATION PRODUCTS

Non-aromatic ammonium radical-cations $RR'R''\dot{\overset{+}{N}}$ are formed in various reactions of amines, their derivatives, and certain other nitrogen-containing compounds. Their structure and properties have been thoroughly investigated (see the latest review on this problem[4]).

The simplest ammonium radical-cations have a planar structure. They are extremely unstable, but their stability can be made appreciable or increased for radical-cations corresponding to triethylenediamine or olefins with $N(CH_3)_2$ groups at the double bond. In weakly acid, neutral, or basic media the above species rapidly lose a proton at the α-carbon atom and give rise to α-amino-radicals;

$$\dot{\overset{+}{R}}CH_2\ddot{N}R'_2 \xrightarrow[-H^+]{} \dot{\overset{-}{R}}CH-\ddot{\overset{+}{N}}R'_2 \longleftrightarrow \dot{\overset{-}{R}}CH-\ddot{N}R'_2 \quad . \qquad (1)$$

This reaction is usually much faster than the abstraction of an $H^\cdot$ atom from the medium by the radical-cation; it is retarded in a strongly acid medium. Species of the type $RR'\dot{\overset{+}{N}}H$ are stronger acids by several orders of magnitude than $RR'\dot{\overset{+}{N}}H_2$.

The existence of α-amino-radicals has been demonstrated and their EPR spectra have been studied[5]. Their chemical properties have not been investigated by direct methods; all the available information about them is hypothetical and is based on indirect data obtained by studying the oxidation of amines in the intermediate stages of which the formation of α-amino-radicals is postulated. In the oxidation of amines α-amino-radicals can be obtained not only via reaction (1) but also as a result of the abstraction of $H^\cdot$ from the α-carbon atom in amines. Under oxidation conditions, the radicals undergo further rapid reactions, probably via two pathways—with electron transfer to the oxidant and the formation of immonium ions:

$$RCH_2\dot{C}H-\ddot{N}R'_2 + Ox \xrightarrow[-Ox^-]{} RCH_2\overset{+}{C}H-\ddot{N}R'_2 \longleftrightarrow RCH_2CH=\dot{\overset{+}{N}}R'_2$$

or by transition with the oxidation of a hydrogen atom and the formation of an enamine:

$$RCH_2\dot{C}H-\ddot{N}R'_2 + Ox \xrightarrow[-OxH]{} RCH=CH-\ddot{N}R'_2 \quad .$$

Enamines can be obtained also from immonium ions:

$$RCH_2\overset{+}{C}H-\ddot{N}R'_2 \longleftrightarrow RCH_2CH=\dot{\overset{+}{N}}R'_2 \xrightarrow[-H^+]{} RCH=CH-\ddot{N}R'_2 \quad .$$

Radicals of the type $R\dot{C}H-NHR'$ are also capable of disproportionating:

$$2R\dot{C}H-NHR' \rightarrow RCH=NR' + RCH_2NHR' \quad .$$

The radicals of the last type as well as $RCH_2\dot{N}H$ can give rise to imines also by losing $H^\cdot$ atoms as a result of oxidation.

Among the properties of the immonium ions $RR'C=\dot{\overset{+}{N}}R''_2$ and imines $RR'C=NR''$, we may mention their tendency to hydrolyse with formation of aldehydes or ketones and dealkylated initial amines. This tendency depends on the structure and the reaction conditions. Sometimes the hydrolysis is slow or does not occur at all and the imines are the main oxidation products. We may also mention the capacity of certain imines for polymerisation, which can lead to tarry products.

Carbinolamines $R_2NCH(OH)CH_2R'$ are formed when secondary amines interact with aldehydes. They are unstable and, as regards their properties, we shall mention their ability to hydrolyse in an acid medium with formation of the initial amine and an aldehyde and to undergo dehydration to the enamines $R_2NCH=CHR'$ (see, for example, Henbest and Stratford[6]).

A significant feature of the properties of enamines (vinylamines)[7] is that these compounds readily hydrolyse in an acid medium to carbonyl compounds and dealkylated initial amines and that enamines containing hydrogen at the nitrogen atom are in tautomeric equilibrium with imines:

$$RR'C=CR''-NHR''' \rightleftharpoons RR'CH-CR''=NR'''.$$

III. THE OXIDATION REACTIONS OF ALIPHATIC AMINES

1. Oxidation by Iodonium Salts

The interaction of iodonium salts $Ar_2I^+X^-$ with amines has been widely investigated[8-12] under various conditions. These reactions give rise to the salts of the initial amines, the

products of the reduction of the iodonium salts (iodoarenes), and the compounds ArH and Ar—Ar. In certain cases a nitrogen-containing resin is also obtained.

This composition of the products serves as an argument in support of a radical reaction mechanism. The latter has been confirmed by the formation of diphenylmercury in the interaction of $(C_6H_5)_2I^+BF_4^-$ with diethyl- or triethyl-amine in the presence of mercury[8,9]; the following reaction mechanism has been proposed:

$$Ar_2I^+X^- + NR_3 \rightleftharpoons [Ar_2I : NR_3]^+ X^- \rightarrow Ar_2\dot{I} + \overset{+}{N}R_3X^-$$
$$Ar_2\dot{I} \xrightarrow{-ArI} \dot{A}r \xrightarrow{+\dot{A}r} Ar-Ar$$
$$\overset{+}{N}R_3X^- + \dot{H} \rightarrow \overset{+}{N}HR_3X^- \ .$$

By analogy with aromatic amines[13] and spectroscopic data[9], it has been suggested that the first stage involves the formation of a donor—acceptor complex, whose homolytic decomposition leads to the products.

This mechanism does not reflect the entire complexity of the reactions of amines with iodonium salts (see below). We may also mention that its last stage requires revision, since ammonium radical-cations rapidly split off protons, particularly in basic media. One can therefore postulate that ammonium salts are formed via the reactions

$$R_2\overset{+}{N}HX^- + R_2NH \rightarrow R_2\dot{N} + R_2\overset{+}{N}H_2X^- \text{ (for primary and secondary amines);} \quad (2a)$$
$$R_3\overset{+}{N}CH_2R'X^- + R_3N \rightarrow R_2N\dot{C}HR' + R_3\overset{+}{N}HX^- \text{ (for tertiary amines).} \quad (2b)$$

Apparently the main pathway, leading to the formation of biaryls, consists in the addition of radicals Ar$^\cdot$ to the compounds ArH and the splitting off of H$^\cdot$ from the resulting cyclohexadienes.

An alternative reaction mechanism, possible only in an aqueous medium, namely homolytic decomposition of diaryliodonium hydroxide, has been rejected[11] on the grounds that the decomposition of $Ar_2I^+OH^-$ is slower than the interaction of iodonium salts with amines and gives rise to other products.

The formation of arylated amines (which are the main products according to some data, for example, those of Beringer et al.[14]) in the reactions considered has also been explained by a radical mechanism[10]):

$$Ar_2\dot{I} + \ddot{N}H_2R \xrightarrow{-ArI} ArNHR + \dot{H}$$

However, one cannot rule out the possibility that nucleophilic substitution of iodonium salts by amines takes place simultaneously with the homolytic reaction[14] and that the arylated amines are formed via this mechanism. We may note that the simultaneous occurrence of nucleophilic and radical reactions has been established in the interaction of iodonium salts with alkoxides[15].

An unambiguous proof of the involvement of radicals in the reactions of amines with iodonium salts has been obtained with the aid of chemically induced nuclear polarisation (CIDNP) and EPR. Chemically induced nuclear polarisation arises in radical pairs and is manifested by anomalies in the NMR spectra of the reaction products of the radicals in these pairs. The reaction kinetics can be inferred from the CIDNP kinetics[16]. In the case considered CIDNP was observed in the benzene obtained by the interaction of iodonium salts with *N,N'*-tetramethyl-*p*-phenylenediamine (TMPA) or triethylamine. At the same time the TMPA radical-cations were detected[17,18]. These data have been treated[17,18] as evidence proving electron transfer from the amine to the iodonium salt in the key stage of the reaction. However, kinetic studies have shown that the mechanism is much more complex.

The kinetics of the oxidation of amines by diphenyliodonium chloride have been investigated in several studies. Reactions with di-n-butylamine[19], ethanolamine[20], and triethylamine[21] proved to have a radical-chain mechanism. They have an inductive period the duration of which is increased by the addition of inhibitors of radical-chain processes. CIDNP in the resulting benzene and iodobenzene is observed under certain conditions. The kinetic equations for the reactions with ethanolamine and triethylamine have the same form (here Am = amine):

$$w = k[Ph_2I^+Cl^-][Am] \ . \quad (3)$$

However, this form changes for dibutylamine, for which the following equation is valid in the presence of an excess of the amine:

$$w = k[Ph_2I^+Cl^-]^2, \ w_0 = k_0[Ph_2I^+X^-] \ , \quad (4)$$

where w_0 and k_0 are the rate of initiation and the initiation rate constant†.

The following mechanism of the reaction with triethylamine corresponds to Eqn.(3).

$$(C_6H_5)_2I^+ + (C_2H_5)_3N \xrightarrow[S]{\text{fast}} [(C_6H_5)_2I : N(C_2H_5)_3]^+ \xrightarrow[S]{k_0} \rightarrow (C_6H_5)_2\dot{I}\overset{+}{N}(C_2H_5)_3 \xrightarrow{-C_6H_5I} C_6H_5\overset{+}{N}(C_2H_5)_3 \rightarrow \dot{C}_6H_5 + \dot{\overset{+}{N}}(C_2H_5)_3 \quad \text{(initiation)} \quad (5)$$

$$C_6\dot{H}_5 + (C_2H_5)_3N \xrightarrow[\text{slow}]{k_1} C_6H_6 + (C_2H_5)_2N-\dot{C}HCH_3$$
$$(C_6H_5)_2I^+ + CH_3\dot{C}H-N(C_2H_5)_3 \xrightarrow[-C_6H_5\cdot -C_6H_5I]{k_2}$$
$$\rightarrow CH_3\overset{+}{C}H-N(C_2H_5)_2 \longleftrightarrow CH_3CH=\overset{+}{N}(C_2H_5)_2$$
$$\downarrow$$
$$CH_2=CH-N(C_2H_5)_2 + H^+ \quad \text{(chain propagation)}$$

$$C_6\dot{H}_5 + \text{inhibitor} \xrightarrow{k_3} \text{inactive products (chain termination)}$$

Mechanism (5) explains the formation of benzene, biphenyl, and the triethylammonium salt on oxidation: it agrees with the formation of the compounds $RCH = \overset{+}{N}R_2$ or vinylamines, frequently observed in the oxidation of aliphatic amines (see below), and also with the formation of the radicals $CH_3\dot{C}HN.(C_2H_5)_2$ identified in the photochemical oxidation reaction[22].

The reaction with ethanolamine differs only by the fact that in the rate-limiting chain propagation stage the phenyl radical abstracts hydrogen not from a carbon atom of the amine but from the nitrogen atom to give the radical $\dot{N}HCH_2CH_2OH$, which participates in the chain propagation process.

On the other hand, the mechanism of the oxidation of dibutylamine differs significantly from mechanism (5)—the chain propagation is controlled by the second and not the first reaction:

$$C_6\dot{H}_5 + (C_4H_9)_2NH \xrightarrow{k_1} C_6H_6 + (C_4H_9)_2\dot{N} \ ;$$
$$(C_6H_5)_2I^+ + (C_4H_9)_2N^\cdot \xrightarrow[\text{slow}]{k_2} C_6\dot{H}_5 + PhI + (C_4H_9)_2\overset{+}{\dot{N}} \ . \quad (6)$$

This leads to the change in the kinetic equation already mentioned above.

The differences discussed are apparently caused by the fact that the radicals $(C_2H_5)_2N\dot{C}HCH_3$ and $\dot{N}HCH_2CH_2OH$ are less stable and are formed more slowly than the radicals

† The last equation was obtained from data for CIDNP kinetics in the benzene formed in the initiation stage. The addition of hydroquinone alters the form of the kinetic equation for the oxidation of dibutylamine; the mechanism of the effect of hydroquinone is obscure[19].

$(C_4H_9)_2\dot{N}$. On the other hand, it may be that the first two radicals give up their electrons to the iodonium cation more rapidly than $(C_4H_9)_2\dot{N}$, because the ionisation potential of the last radical is higher than those of the first two. This alters the ratio of the rates of the two chain propagation stages and the form of the kinetic equation.

The interaction of $(C_6H_5)_2I^+Cl^-$ with *N,N'*-tetramethyl-*p*-phenylenediamine (TMPA) [23] also obeys Eqn.(3) but differs radically from the three reactions considered. This is a radical and not a chain process. The CIDNP of the benzene formed is observed in the reaction, but there is no induction period and inhibitors of radical-chain reactions do not lead to its appearance and do not alter the rate of reaction. The reaction considered probably procceeds via a mechanism whose slow stage [and not the fast stage as in mechanism (5)] involves the formation of the complex

$$[(C_6H_5)_2I:N(CH_3)_2C_6H_4N(CH_3)_2]^+ \text{ (I) or CTC:}$$

$$(C_6H_5)_2I^+ + (CH_3)_2N{-}C_6H_4{-}N(CH_3)_2 \xrightarrow[\text{slow}]{} \text{(I) or CTC} \rightarrow$$

$$\rightarrow (C_6H_5)_2\dot{I}\,{}^{+}\left[(CH_3)_2N{-}C_6H_4{-}N(CH_3)_2\right] \xrightarrow{-C_6H_5I}$$

(II)

$$\xrightarrow{S} C_6\dot{H}_5\,{}^{+}\left[(CH_3)_2N{-}C_6H_4{-}N(CH_3)_2\right] \rightarrow C_6H_6 + \left[(CH_3)_2N{-}C_6H_4{-}N(CH_3)_2\right]^+ \quad (7)$$

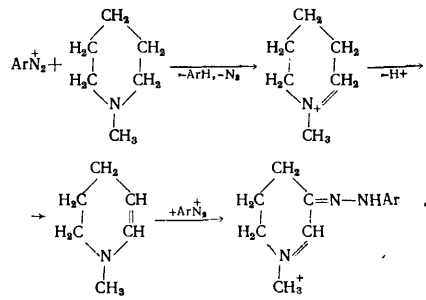
However, one cannot rule out the possibility that the complex or the charge-transfer complex (CTC) are formed reversibly and that the homolytic decomposition of the complex or electron transfer in the CTC with formation of the pair (II) take place in the slow stage.

Reaction (7) is analogous to the initiation stage in mechanism (5) but, in contrast to mechanism (5), it is followed by the chain propagation stage. This can be explained by the fact that the radicals

$$\dot{N}(CH_3)\text{-}C_6H_4\text{-}N(CH_3)_2 \quad \text{or} \quad (CH_3)_2N\text{-}C_6H_3(\dot{C}HPh)\text{-}N(CH_3)_2,$$

which are probably formed when phenyl radicals interact with TMPA and which may be expected to be very stable, are incapable of transferring electrons rapidly to the Ph_2I^+ ions. This is why the chain propagation process cannot compete with reaction (7) as regards rate.

Thus the non-chain mechanism of the reaction considered is determined by the properties of the radicals formed from TMPA. It is clear from the foregoing that the properties of the radicals corresponding to amines determine the characteristics of the kinetics and mechanisms also of the other reactions considered.



2. Oxidation by Diazonium Salts

The interaction of the salts $ArN_2^+BF_4^-$ with tertiary amines has been studied[25,26]. The reactions with tribenzylamine or benzyldimethylamine lead to the compounds ArH and immonium salts, which have been identified from the hydrolysis products. These results have been explained by the transfer of a hydride ion from the α-carbon atom to the ArN_2^+ ion:

$$ArN_2^+ + N(CH_2C_6H_5)_3 \xrightarrow[-ArH,-N_2]{} C_6H_5CH{=}\overset{+}{N}(CH_2C_6H_5)_2 \xrightarrow{+H_2O}$$

$$\rightarrow C_6H_5HO + (C_6H_5CH_2)_2NH + H^+ \quad .$$

N-Methyl- or *N*-benzyl-piperidine and *N*-benzylpyrrolidine react via a mechanism of the first type, which, however, is more complex

There are data in conflict with the above mechanism which indicate the involvement of radicals in the reactions. Thus the reaction induces the polymerisation of acrylonitrile[27] and is inhibited by oxygen and added bromotrichloromethane. A radical-chain mechanism was therefore proposed[28]:

$$ArN_2^+ + (RCH_2)_3N \rightarrow ArN{=}\dot{N} + (RCH_2)_3N^{\dot{+}};$$

$$ArN{=}\dot{N} \rightarrow A\dot{r} + N_2;$$

$$A\dot{r} + (RCH_2)_3N \rightarrow ArH + R\dot{C}HN(CH_2R)_2;$$

$$R\dot{C}HN(CH_2R)_2 + ArN_2^+ \rightarrow RCH{=}\overset{+}{N}(CH_2R)_2 + ArN{=}\dot{N}.$$

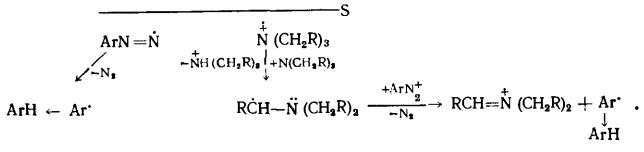
Unambiguous proof of the radical mechanism was obtained by Bilevich and coworkers[18,29-31]. They observed CIDNP in the benzene formed in the reactions of $PhN_2^+BF_4^-$ with aliphatic tertiary amines and the formation of the TMPA radical-cations and the polarisation of the protons of the substituted benzenes formed in the oxidation of TMPA by diazonium salts; the rate of the last reaction is proportional to the concentrations of both reactants. Substituents in the *para*-position in the ring of the salt alter by several orders of magnitude the rate of reaction (the oxidation is accelerated by the withdrawal of electrons by substitutents); the influence of the substituents obeys the Hammett equation ($\rho = 1.92$). The data presented served as the basis for the following mechanism of the slow stage:

$$ArN_2^+ + (CH_3)_2N{-}C_6H_4{-}N(CH_3)_2 \rightarrow ArN{=}\dot{N} + \left[(CH_3)_2N{-}C_6H_4{-}N(CH_3)_2\right]^{\dot{+}},$$

which includes electron transfer from the amine to the cation ArN_2^+.

The kinetics of the oxidation of trimethyl-, triethyl-, and tri-n-butyl-amines by the salts $p\text{-}XC_6H_4N_2^+BF_4^-$ have been investigated by Gragerov and coworkers[32,33] on the basis of the CIDNP kinetics in the compounds C_6H_5X formed. The reactions proved to be of the non-chain type and obeyed a first-order equation. Both electron-accepting and electron-donating substituents X accelerate the reaction by a factor of only 2–3 and the nature of the amine hardly affects its rate, although the basicities of the amines differ considerably.

The results differ sharply from those obtained by the oxidation of TMPA. To account for them, the authors assumed that the slow stage involves the decomposition into free radicals of the intermediate, possibly $Ar{-}N{=}N{-}\overset{+}{N}R_3$, formed via the mechanism



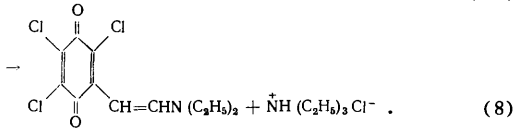
$$ArN_2^+ + R_3N \rightarrow Ar{-}N{=}N{-}\overset{+}{N}R_3 \quad .$$

This hypothesis is consistent with the first order of the reaction and explains the weak dependence of the reaction rate on the nature of X and the acceleration of the reaction by both electron-donating and electron-accepting substituents (these features are characteristic of many reactions involving decomposition into radicals—see, for example,

Walling[34]) and agrees with the independence of the rate of reaction of the nature of the amine.

The significant difference between the reactions of diazonium salts with TMPA and aliphatic tertiary amines is apparently caused by the stability of the TMPA radical-cations and the ease of electron transfer from TMPA. Thus, like the oxidation of amines by iodonium salts, it is caused by the nature of the radical species formed. The difference shows how unjustified can be a hypothesis concerning the details of the reaction mechanism arrived at by analogy.

The reactions of the radical pairs arising in the decomposition of the above intermediate can be represented schematically as follows:

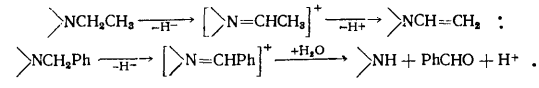


The presence of ammonium salts may be expected in the reaction products.

3. Oxidation by Quinonoid Compounds

The reactions of aliphatic tertiary amines with quinones have been investigated[35,36] and it has been found that, for example, triethylamine interacts with chloroanil in benzene via the mechanism

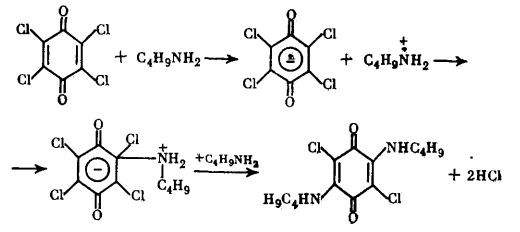
$$C_6O_2Cl_4 + (C_2H_5)_3N \rightarrow CH_2{=}CHN(C_2H_5)_2 + C_6H_2O_2Cl_2 \ .$$



$$C_6O_2Cl_4 + CH_2{=}CHN(C_2H_5)_2 + (C_2H_5)_3N \rightarrow \qquad \text{(III)}$$

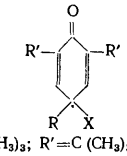
$$\qquad \text{(8)}$$

Other halogen-containing quinones react similarly, but the rate of reaction diminishes with decrease of the electron affinity of the quinone. Compounds of type (III) ("blue quinone") are formed only from amines containing the residue $\rangle NCH{-}CH_2{-}$. Amines with a different structure give rise to aldehydes among other products.



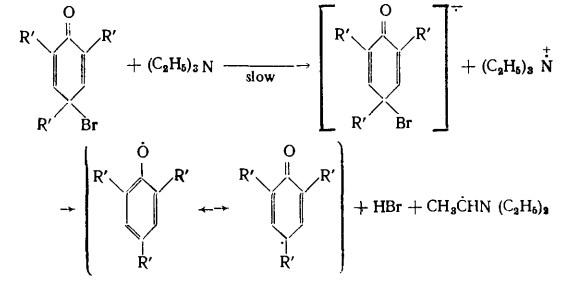
The authors[35,36] suggest that the key stage involves the transfer of a hydride ion from the amine to the quinone, which is followed rapidly by proton transfer from the β-position relative to the nitrogen atom. If there is no such proton in the molecule then the process stops at the stage involving the formation of immonium salts, whose hydrolysis gives rise to aldehydes:

A hydride ion is transferred in the CTC of quinones with amines. The existence of such complexes has been confirmed by spectroscopic data. The details of the hydride shift remain obscure.



The above mechanisms involve the formation of semiquinone radical-anions preceding the formation of the "blue quinone". This was demonstrated by spectroscopic methods for reaction (8) in solution in chloroform or acetonitrile and the rate and activation energy and entropy for the formation of the semiquinone and compound (III) were determined[38]. The kinetic and activation parameters have also been obtained for electron transfer from tri-isopropylamine and tri-n-butylamine to chloranil. In these cases the process stops at the semiquinone radical-ion formation stage. In methanol or ethanol reaction (8) leads to trichlorohydroquinone and not to the "blue quinone"; the reason for this change has not been elucidated.

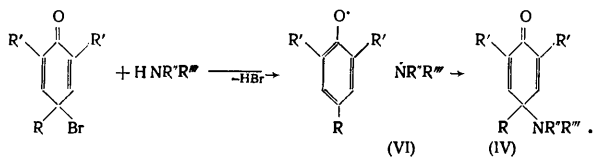
The formation of semiquinone radicals has been established in the interaction of quinones with amines of different structure. It is promoted by a low ionisation potential of the amine, a high electron affinity of the quinone, and a high solvent polarity[39]. These radicals proved to be intermediates in the nucleophilic substitution of quinones by amines[40]. In the first stages of the substitution reaction semiquinones accumulate and are then consumed as the products accumulate:



The reaction kinetics have been investigated.

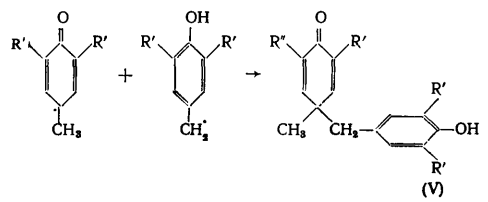
The reactions of amines with other compounds having a quinonoid structure were investigated in a number of studies. Thus it has been established[41] that the reactions of sterically hindered quinobromides or quinonitrols

R=CH_3 or $C(CH_3)_3$; R′=$C(CH_3)_3$; X=Br or NO_2



with triethylamine, piperidine, or pyridine give rise to phenoxy-radicals. The reaction in the presence of an excess of amines obeys a first-order kinetic equation; its rate and activation parameters have been found. It proceeds via the mechanism:

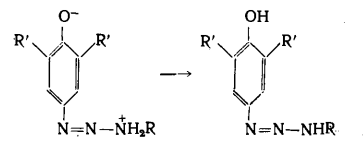
It has also been shown that the reaction of phenoxy-radicals with amines results in the formation of phenols.



The reactions of the above quinobromides with primary and secondary amines have been investigated[42,43] and it has also been concluded that phenoxy-radicals are formed as intermediates. Apart from phenols and ammonium salts, the main products include quinamines (IV) and quinol (V). The reactions obey a second order kinetic equation and their rates and activation parameters have been found. The authors

believe that electron transfer from the amine to the quinobromide is the key stage in the processes:

(VI) (IV)



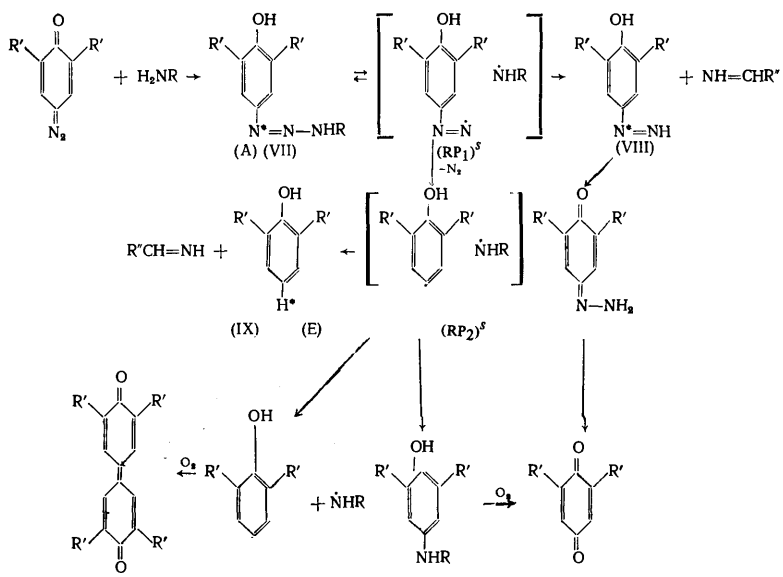
The formation of quinol (V) has been explained by the recombination of the phenoxy-radicals liberated from the pair (VI) with their isomerisation products[44]—hydroxybenzyl radicals:

(V)

The reactions of amines with *p*-benzoquinone diazides have been investigated. These reactions proceed rapidly with primary amines even at room temperature, giving rise to phenol, the quinone, and diphenoquinone corresponding to the quinone diazide used. The same products are obtained slowly in the reaction of quinone diazides with secondary amines or in the decomposition of the triazenes formed by the reaction of quinone diazides with secondary amines. Oxidation products are formed from amines, while with tertiary amines the reaction does not proceed.

The authors[45] suggest that triazenes are formed as intermediates. The triazenes corresponding to primary and secondary amines differ sharply in their stabilities. They are capable of decomposing into radicals (see, for example, Rozantsev and Sholle[46]). Radicals were indeed detected by EPR and with the aid of CIDNP. The CIDNP method made it possible to investigate their reaction pathways and thus to elucidate a series of details of the mechanisms of the processes[47,48]. The reaction mechanism taking into account all the data obtained is presented below in relation to the interaction of 2,6-di-t-butyl-*p*-benzoquinone diazide with primary amines (Scheme 1). Here the letters (A) and (E) denote positive and negative chemically induced nuclear polarisation, an asterisk represents a polarised atom, and (RP) is a radical pair (see below). The reaction begins with the addition of the electrophilic quinone diazide to the amine, which leads to the formation of a compound analogous to the product of the interaction of diazonium salts with tertiary amines (see above). Proton transfer to the oxygen results in the formation of a hydroxyphenyltriazene:

The nuclear polarisation in the latter indicates the reversibility of its decomposition and the sign of the polarisation in the azophenol (VIII) indicates its formation on disproportionation in $(RP_1)^S$. The sign of the polarisation shows that the main reaction product—the phenol (IX)—is formed mainly on disproportionation in $(RP_2)^S$.



4. Oxidation with Chlorine Dioxide and Hypochlorous Acid

The oxidation of amines with chlorine dioxide in aqueous solutions has been studied[49–52]. Under conditions where side reactions are suppressed, two moles of ClO_2 are consumed per mole of the amine in the presence of an excess of the latter and amine dealkylation products and aldehydes are formed, for example:

$$(C_2H_5)_3N + 2ClO_2 + H_2O \rightarrow CH_3CHO + (C_2H_5)_2NH + 2H^+ + 2ClO_2^-$$

The rate is proportional to the amine and ClO_2 concentrations. It decreases in the sequence $(C_2H_5)_3N > (CH_3)_3N > (C_2H_5)_2NH$; the rate falls very rapidly on passing from tertiary to secondary and primary amines. The rates are correlated with the values of $\Sigma\sigma^*$ for the substituents at the nitrogen atom; $\rho = -5.24$. The rate constants for *meta*- and *para*-substituted benzyldimethylamines are satisfactorily correlated with

Scheme 1

the pK_a of the amines (the Brønsted parameter $\alpha = 0.812$) and with the σ constants ($\rho = -0.924$). The dealkylation is relatively unselective: formaldehyde and benzaldehydes are formed in proportions of ~3 : 1. The formation of amine radical-cations in the oxidation of $[(CH_3)_2N-C_6H_4-]_3N$ or $(CH_3)_2-C_6H_4-N(CH_3)_2$ was established by EPR.

The authors[49-52] suggest that the rate-limiting stage involves electron transfer from the amine to the oxidant with formation of ammonium radical-cations and ClO_2^- ions and not the abstraction of a hydrogen atom. This is confirmed by the finding that the $\Sigma\sigma^*$ for the residues at the nitrogen atom in secondary or tertiary amines are correlated not only with the rate of oxidation but also with the half-wave potential for the polarographic oxidation of amines, for which a similar mechanism is valid.

However, this mechanism does not account for all the observed features of the reaction. It has been shown that the addition of ClO_2^- ions diminishes the rate of oxidation without altering the kinetic equation and electron transfer is thus reversible. The decrease of the rate is proportional to the amounts of added ClO_2^- for $(C_2H_5)_3N$, $(CH_3)_3N$, and $[(CH_3)_2CH]_2NH$, but its dependence on the concentration of additives is more complex in the case of $C_6H_5CH_2NH_2$, $(C_6H_5CH_2)_2NH$, and $C_6H_5CH_2NHC(CH_3)_3$. Analysis of these relations leads to the conclusion that the last three amines react simultaneously via two mechanisms: with reversible electron transfer in the rate-limiting stage and with irreversible transfer of H^- from the α-carbon atom to the oxidant molecule in the slow stage of the reaction. The contribution of the reaction via the second pathway is 31% (at 41 °C) for $C_6H_5CH_2NHC(CH_3)_3$, 35% for $(C_6H_5CH_2)_2NH$, and 73% (at 25 °C) for $C_6H_5CH_2NH_2$. It is considerable for the amines under consideration because the C–H bonds in the CH_2 groups are weakened by the interaction with the benzene ring, and increases with increasing ionisation potentials of the amines, which hinders the competitive electron transfer. The transfer of H· in the slow stage was confirmed by the observation of primary kinetic isotope effects in the oxidation of $C_6H_5CD_2NHC(CH_3)_3$ and $C_6H_5CD_2NH_2$.

Thus amines which do not contain a CH_2 group next to the benzene ring react with ClO_2 by electron transfer in the slow stage:

$$ClO_2 + RCH_2N(R')R' \underset{}{\overset{\text{slow}}{\rightleftharpoons}} ClO_2^- + RCH_2\overset{+}{N}(R')R' \quad ;$$

$$RCH_2\overset{+}{N}(R')R' \xrightarrow{\text{fast}} H^+ + RCH{\cdots}N(R')R' \quad ;$$

$$RCH{\cdots}N(R')R' + ClO_2 \xrightarrow{\text{fast}} RCH{=}\overset{+}{N}(R')R' + ClO_2^- \quad . \qquad (9)$$

The proton elimination stage cannot be excluded from this mechanism and the latter cannot be replaced by

$$ClO_2 + RCH_2N(R')R' \underset{}{\overset{\text{slow}}{\rightleftharpoons}} ClO_2^- + RCH_2\overset{+}{N}(R')R' \quad ;$$

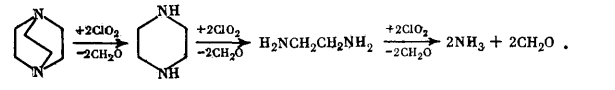
$$RCH_2\overset{+}{N}(R')R' + ClO_2 \xrightarrow{\text{fast}} HClO_2 + RCH{=}\overset{+}{N}(R')R' \quad ;$$

$$HClO_2 \rightleftarrows H^+ + ClO_2^- \quad ,$$

since analysis showed that the added ClO_2^- would infringe the first order of the reaction with respect to ClO_2 without the proton elimination stage, which is not observed.

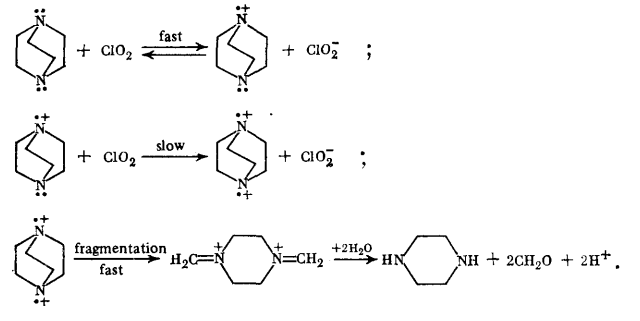
Amines containing CH_2 groups linked to the benzene ring react with ClO_2 both via mechanism (9) and with transfer of H· in the slow stage:

$$ClO_2 + RCH_2N(R')R' \xrightarrow{\text{slow}} RCH{\cdots}N(R')R' + HClO_2 \rightleftarrows H^+ + ClO_2^- \quad ;$$



$$RCH{\cdots}N(R')R' + ClO_2 \xrightarrow{\text{fast}} RCH{=}\overset{+}{N}(R')R' + ClO_2^- \qquad (10)$$

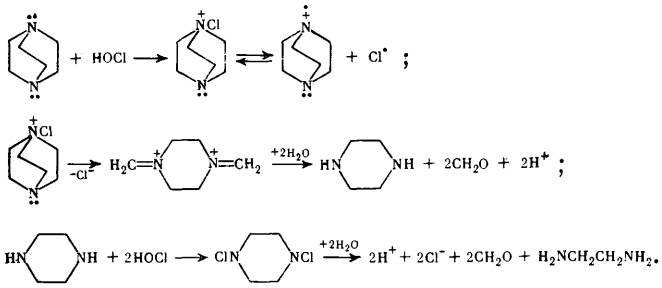
Hydrolysis of the immonium salts formed via both mechanisms leads to the observed reaction products—the aldehydes RCHO and the amines R'_2NH.



The results of Kudesia[53], who found that the replacement of water in the oxidation of benzylamine by D_2O (the replacement of $C_6H_5CH_2NH_2$ by $C_6H_5CH_2ND_2$) slows down the reaction by a factor of 5, are in conflict with the mechanisms described above and with experimental kinetic isotope effect data.

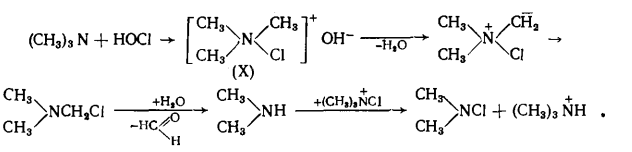
The amine dealkylation reactions under the influence of ClO_2 discussed above proceed with dissociation of C–N bonds. Reactions of another type, with dissociation of C–C bonds, are observed in the interaction of ClO_2 or HClO with β-amino-, β-hydroxy-, or β-oxo-amines, for example:

$$H_2NCH_2CH_2OH + 2ClO_2 \rightarrow NH_3 + 2CH_2O \quad ;$$



Such "oxidative fragmentation" has been studied[54-56] and the rate constants have been determined in many instances. The kinetics and mechanism of oxidative fragmentation have been investigated in relation to triethylenediamine. The reaction with this substance obeys a first-order kinetic equation with respect to the amine and a second-order equation with respect to the oxidant and is retarded by ClO_2^- ions in proportion to their concentration. The formation of triethylenediamine radical-cations in the course of the reaction has been demonstrated by EPR and the following mechanism has been proposed:

It involves the formation of the amine biradical-dication in the slow stage and not of a radical-cation as in mechanism (9). This difference is responsible for a change in the kinetic equation, which arises owing to the high stability of the triethylenediamine radical-cation. The triethylenediamine biradical-dication is unstable and rapidly fragments.

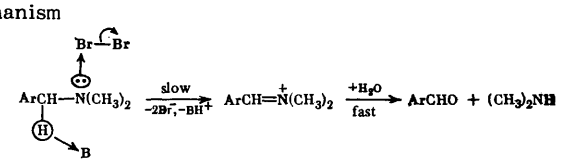


The oxidation of triethylenediamine by HOCl requires three moles of the acid per mole of the amine and probably obeys a first-order kinetic equation with respect to both the amine and the oxidant. Here too it was concluded that an ammonium radical-cation is formed in this reaction but the above investigators suggest that it is formed as a side product, since

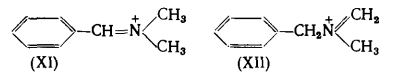
HOCl is a two-electron oxidant. The mechanism is different:

The products contain 1,4-dichloropiperazine, since its hydrolysis is slow.

The oxidation of trimethylamine with HOCl in aqueous solutions gives rise to dimethylchloroamine and formaldehyde[57]:

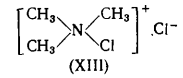


It proceeds via a mechanism analogous to mechanism (11). A proton is probably split off from compound (X) also in the reaction with the initial amine.

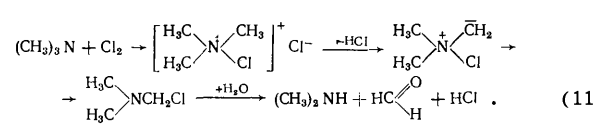


5. Oxidation with Bromine, Chlorine, and *N*-Halogenoamino-Compounds

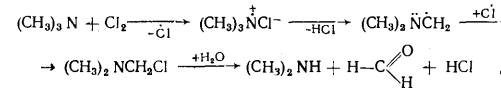
The oxidation of amines with an aqueous solution of bromine at pH 5–7 in the presence of an excess of the amine has been studied[58]. Under these conditions, amines lose one alkyl group. Secondary alkyl groups are split off in the form of ketones and the fate of primary alkyls depends on the structure of the initial amine. The rate of oxidation of tripropylamine is proportional to the concentrations of both reagents, depends on pH in a complex manner, and is independent of illumination. The Hammett relation between the rate and the σ constants of the ring substituents holds for substituted benzyldimethylamines; $\rho = -0.84$. The reaction mechanism can consist in the elimination of an α-hydrogen atom in the form of H^+ with simultaneous abstraction of the electron pair at the nitrogen atom by the bromine. However, this mechanism does not account for the differences between the reaction products of primary, secondary, and tertiary amines. It has been confirmed and specified in greater detail by studies of the kinetics of the oxidation of *para*- and *meta*-substituted benzyldimethylamines with a bromine solution in 50% aqueous acetic acid[59].



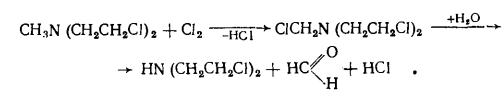
The reaction is of first order with respect to each reactant and its rate is correlated with the pK_a of the amines (the Brønsted parameter $\alpha = 0.67$) and obeys the Hammett relation ($\rho = -0.95$). The addition of sodium acetate or benzoate accelerates the oxidation; $C_6H_5CD_2N(CH_3)_2$ reacts more slowly than $C_6H_5CH_2N(CH_3)_2$. Irradiation with light does not affect the rate of reaction. The oxidation proceeds very selectively with formation of a high yield of benzaldehyde (in contrast to the radical oxidation of benzyldimethylamine with ClO_2). All these features of the reaction can be accounted for by the mechanism



(where B is a base). The selectivity of the oxidation is associated with the preferential formation in the limiting stage of the ions (XI), which, in contrast to the ions (XII), are stabilised by the conjugation of the C=N bond with the ring:



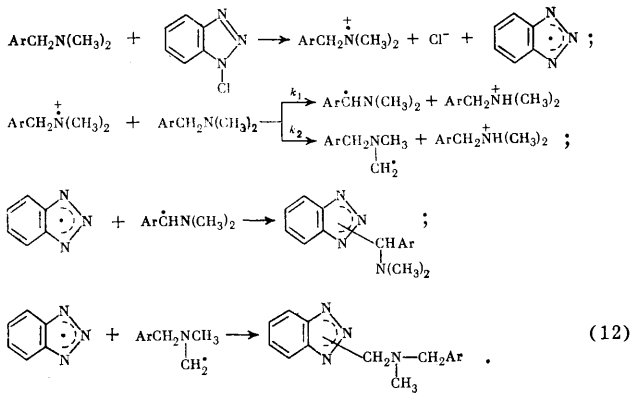
When trimethyl- or triethyl-amine interacts with an aqueous solution of an equimolar amount of chlorine, the hydrochloride of the corresponding secondary amine is formed. In solution in CCl_4, trimethylamine forms with chlorine a compound which probably has the following structure:



On hydrolysis, this compound is converted into the products formed on reaction of trimethylamine with an aqueous chlorine solution. On this basis, the following heterolytic mechanism has been proposed[60]:

However, it has been shown[61] that mechanism (11) is not consistent with the kinetic data and that compound (XIII) or the reaction mixture in the interaction of trimethylamine with chlorine cause the polymerisation of acrylonitrile. The authors[61] therefore propose the radical mechanism

The oxidation of amines of the type $RN(CH_2CH_2Cl)_2$ with chlorine and *N*-chloroimides, leading to the dealkylation of the amine, has been studied[62], for example:



The reaction mechanism was not investigated.

The oxidation of amines by 1-chlorobenzotriazole has been investigated[63]. In the case of *para*-substituted benzyldimethylamines the reaction leads to 1- and 2-aminoalkylbenzotriazoles, the hydrochlorides of the initial amines, and compounds containing active (positive) chlorine. The rate of formation of products, not containing active chlorine, in benzene is proportional to the concentrations of both reactants and is correlated with the pK_a of the amines (the Brønsted parameter $\alpha = 0.63$). The influence of substituents in the benzene rings of the amines is described by the Hammett equation ($\rho = -0.71$). An induction period is not observed in the reaction and its rate is independent of illumination and the presence of oxygen or radical-chain process inhibitors. $C_6H_5CH_2N(CH_3)_2$ is oxidised faster than $C_6H_5CD_2N.(CH_3)_2$. The reaction is accelerated by the addition of methanol. *para*-Substituted benzaldehydes, p-$XC_6H_4CH_2.NHCH_3$ and formaldehyde, formed from aminoalkylbenzotriazoles, were identified after acid hydrolysis.

The oxidation of triethylenediamine yields 1,4-bis(benzotriazolylmethyl)piperazine—the product of the oxidative fragmentation of the amine. It has been established by EPR

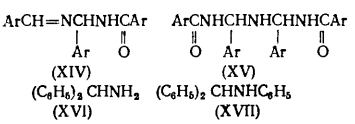
that ammonium radical-cations are formed in the reaction. The radical-cations have been identified also in the oxidation of *N,N'*-tetramethyl-*p*-phenylenediamine. Primary amines give rise to monochloroamines.

The formation of aminoalkylbenzotriazoles has been explained by a radical non-chain mechanism, which agrees with all the data described above:

(12)

The authors[63] rejected two variants of the ionic mechanism—with transfer of H^- or Cl^+—on the grounds of not very reliable criteria—the inconsistency of the values of ρ and the kinetic isotope effects with values usually observed for such mechanisms.

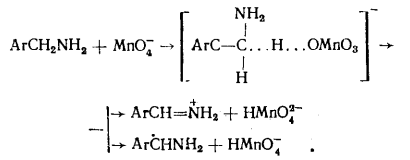
The ratio of the yields of the hydrolysis products of aminoalkylbenzotriazoles, namely substituted benzaldehydes and p-$XC_6H_4CH_2NHCH_3$, is determined by the rates of abstraction of H^+ from the CH_2 or CH_3 groups of the ammonium radical-cations and is equal to the ratio k_1/k_2 [see mechanism (12)]. This mechanism depends on the nature of X and decreases with increasing solvent polarity. For reactions in methanol, it is close to the statistical value, as in the oxidation of benzyldimethylamines by a solution of ClO_2 in water.



When tertiary amines are acted upon by *N*-bromosuccinimide, the C–N bonds are broken and secondary amines and aldehydes are formed (see, for example, Dunstan and Henvest[64] and Filler[65]). A radical mechanism has been proposed for the reaction on the basis of general considerations[66].

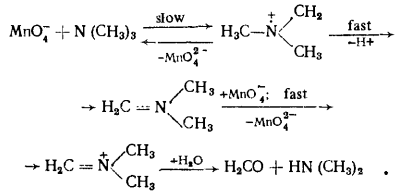
Studies on the oxidation of amines by "chloramine-T" ($CH_3C_6H_4SO_2NNaCl$) have been undertaken for synthetic purposes. The problems of the reaction mechanism have been investigated only in relation to diethanolamine[67] and monoethanolamine[68]. Both compounds undergo oxidative fragmentation with formation of formaldehyde, formic acid, and ammonia. The details of the mechanism are obscure.

6. Oxidation with Potassium Permanganate, Periodic Acid, and Chromic Acid



The mechanism of the oxidation of amines by potassium permanganate has not so far been thoroughly elucidated. A brief review of early studies has been published[69]; the investigations in recent years are considered below.

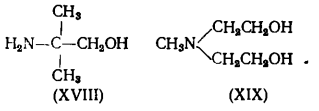
Substituted benzylamines give rise to compounds (XIV) and (XV) on oxidation with $KMnO_4$ in a 1 : 1 aqueous t-butyl alcohol in the presence of an excess of $CaSO_4$:



The reaction mechanism has not been established, but the aldimines ArCH=NH are probably formed in the initial stages; the initial amines then add to them, giving rise to products whose oxidation leads to compounds (XIV) and (XV).[72] The oxidation of compound (XVI), dibenzylamines, and compound (XVII) apparently proceeds similarly. Tertiary amines, incapable of being converted into aldimines, are oxidised differently. Thus tributylamine gives rise to dibutylamine, butyraldehyde, butyric acid, and the *N,N*-dibutylamide of butyric acid, which are products of subsequent interactions of the enamine $(C_4H_9)_2NCH{=}CHCH_2CH_3$ formed initially. Tribenzylamine is oxidised to benzaldehyde and benzoic acid; dibenzylamine is not formed. The mechanism of this reaction has not been established[70].

It has been observed[71] that in the reaction of substituted benzylamines with $KMnO_4$ in water, the amines and not their salts are oxidised. At pH 10 the rate of reaction is described by a first-order equation with respect to the amine and the oxidant. The rate is independent of the ionic strength of the solution. The activation energy and entropy are 10.4–11.7 kcal mol^{-1} and from −21.6 to −24.8 e.u. respectively. Benzylamine is oxidised seven times faster than $C_6H_5CD_2NH_2$ but at the same rate as $C_6H_5CH_2ND_2$. The influence of substituents is correlated with σ^+ ($\rho = -0.28$). At high pH yet another reaction takes place whose mechanism has not been established. The following mechanism has been proposed for the reaction in weakly alkaline media:

Here the activated complex decomposes with transfer of a hydride ion or H·. The radicals are then (after the loss of the proton) oxidised to benzaldimine.



It has been found[73] that the rate of oxidation of amines at pH 7.5–8 is proportional to the concentration of the oxidant and the substrate and decreases in the sequence $(C_2H_5)_3N$ > $(C_2H_5)_2NH$ > $C_2H_5NH_2$; it has also been found that $(CH_3)_3N$ is oxidised to formaldehyde 1.84 times faster than $(CD_3)_3N$. According to the authors[73], an electron is transferred in the slow stage of the oxidation of trimethylamine and the abstraction of hydrogen is not the main reaction pathway. The reaction proceeds preferentially via a mechanism analogous to that of the oxidation by ClO_2:

On passing to secondary or tertiary amines, the abstraction of hydrogen in the slow reaction stage assumes increasing importance, as in the oxidation by ClO_2.

The oxidation of $(CH_3)_3N$ and $(C_2H_5)_3N$ with aqueous $KMnO_4$ at pH 6–8 has been studied[74] and a mechanism has been proposed in which the ammonium radical-cations are formed when amines interact with manganese complexes. The latter are obtained in the first stages from complexes of the amines with manganese (VII) and manganese(V) compounds.

On treatment with periodic acid; ethanolamine, diethanolamine, triethanolamine, ethylenediamine, and the amines (XVIII) and (XIX) undergo oxidative fragmentation[75], the reactions with ethanolamine and ethylenediamine being quantitative[76].

(XVIII) (XIX)

The study of the kinetics of the oxidation of ethanolamine[77] and *N*-methylethanolamine[77,78] did not yield sufficient data for the determination of the reaction mechanism. It is not even clear whether ethanolamine or their protonated forms and which of the ions $H_4IO_6^-$ and $H_3IO_6^{2-}$, $H_2IO_5^-$, or HIO_5^{2-} are involved in the reaction.

The mechanism of the oxidation of amines with chromic acid has not been studied. Data on the kinetics of the oxidation of a number of amines to CO_2, H_2O, and NH_3 by $K_2Cr_2O_7$ in an acid medium have been published in only one communication[79].

7. Oxidation by $K_3Fe(CN)_6$, $Pb(OCOCH_3)_4$, Silver(II) Picolinate, and $AgNO_3$

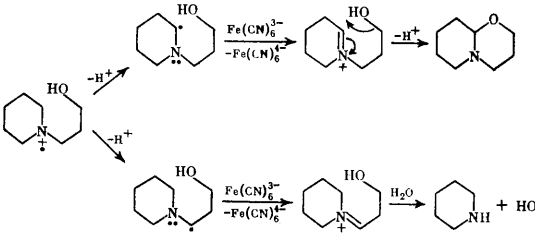
Smith and coworkers studied the oxidation of tertiary amines by $K_3Fe(CN)_6$ in aqueous solutions at pH > 12. In the presence of an excess of the substrate, two moles of the oxidant are consumed per mole of the amine and mainly oxidative dealkylation products are formed. The reaction obeys a first-order kinetic law with respect to the oxidant and the amine. Tertiary *N*-methyl- and *N*,*N*-dimethyl-amines are mainly demethylated[80]. The secondary amines formed are not oxidised further. The rate of reaction is correlated with the $\Sigma\sigma^*$ of the substituents at the nitrogen atom; $\rho^* = -5.45$ and is close to $\rho^* = -5.24$ found for the oxidation of amines by ClO_2, where an electron is transferred in the rate-limiting stage. The addition of $K_4Fe(CN)_6$ does not affect the rate of oxidation. The salt effect of cations is observed. All these data can be accounted for by a mechanism involving the irreversible transfer of an electron from the amine to the oxidant in the slow stage#:

$$RCH_2NR'_2 + Fe(CN)_6^{3-} \xrightarrow[-Fe(CN)_6^{4-}]{slow} RCH_2\overset{+}{N}R'_2 \xrightarrow{-H^+}$$

$$\rightarrow RCH{=}NR'_2 \xrightarrow[-Fe(CN)_6^{4-}]{+Fe(CN)_6^{3-}} RCH{=}\overset{+}{N}R'_2 \xrightarrow{+OH^-}$$

$$\rightarrow RCH(OH)NR'_2 \rightarrow RCHO + R'NH \quad . \qquad (13)$$

An alternative mechanism, in which the first two stages have been replaced by the concerted loss of an electron and an α-proton by the amine, i.e.



$$RCH_2NR'_2 + Fe(CN)_6^{3-} \rightarrow R\dot{C}HNR'_2 + Fe(CN)_6^{4-} + H^+ \ ,$$

is in poor agreement with the high value of ρ^* and the small kinetic isotope effect (see below). The possibility of the simultaneous occurrence of the reaction via both mechanisms is ruled out by the finding that a linear relation between $\delta\Delta H^{\neq}$ and $\delta\Delta S^{\neq}$ holds for a series of the amines investigated.

It has been found[82] that at pH 8.8 the rate of oxidation of triethylamine by $K_3Fe(CN)_6$ diminishes following the addition of $K_4Fe(CN)_6$ in proportion to the concentration of the additive. It was therefore concluded that the electron transfer in the slow stage is reversible. The discrepancy between these data and the findings described above was explained by differences in the pH.

The oxidation of *para*-substituted benzyldimethylamines[81] also proceeds via mechanism (13). The rate of reaction is correlated with the Hammett σ constants of the ring substituents, with the $\Sigma\sigma^*$ of the substituents at the nitrogen atom, and with the pK_a of the amines. The values of ρ, ρ*, and α (−0.989, −4.24, and 0.990 respectively) are close to those found for the oxidation of benzyldimethylamines by ClO_2. The ratio of the demethylation and debenzylation products (formed after the loss of H^+ from the CH_3 or CH_2 group in the amines) differs from the statistical ratio. According to mechanism (13), it is determined by the relative acidity of the *N*-methyl or *N*-benzyl hydrogen atoms and the number of these atoms.

Mechanism (13) has been confirmed in the oxidation of trialkylaminoalcohols and trialkylaminoamines[83]. Thus 3-piperidino-1-propanol gives rise to a cyclisation product and piperidine, which can be explained by the intermediate formation of a radical-cation and of immonium ions:

The electron transfer in the rate-limiting stage is confirmed by the low kinetic isotope effect in the oxidation of $CH_3N(C_4H_9)_2$ and $CD_3N(C_4H_9)_2$ ($k_H/k_D = 1.04$). The ratio of the demethylation and debutylation products changes greatly on isotope substitution—the isotope effect is 3.6.[84]

It has also been shown[84] that the characteristics of the rate of oxidation of tertiary amines with a nitrogen atom in the ring or bicyclic tertiary amines can be satisfactorily explained by mechanism (13). The radical-cations $R_3\overset{+}{N}$ have a planar structure and the transition state for their formation is a structure close to that of radical-cations. The rate of oxidation is therefore controlled by the changes in ring strain and the barriers to changes in conformation which arise when the molecules are converted into radical-cations. This treatment has been confirmed[85] in relation to trialkylaminoalcohols, their ethers, trialkylaminoamines, phenetylamines, and cyclic, bicyclic, and tricyclic amines.

In contrast to tertiary amines, diethanolamine undergoes oxidative fragmentation in oxidation by $K_3Fe(CN)_6$ in aqueous alkali[86–88]:

$$NH(CH_2CH_2OH)_2 + 4OH^- + 4Fe(CN)_6^{3-} \rightarrow 4HCHO + \\ + NH_3 + 4Fe(CN)_6^{4-} + 2H_2O \quad .$$

The process is analogous to the oxidation of β-hydroxyamines by ClO_2, but its mechanism has been studied inadequately. At low $K_3Fe(CN)_6$ concentrations the rate of oxidation is proportional to the concentrations of alkali, the substrate, and the oxidant, but the reaction order with respect to the oxidant decreases with increasing concentration of the latter and may become zero. The addition of salts, including $K_4Fe(CN)_6$, accelerates the reaction, while the addition of methanol retards it. The following mechanism has been proposed:

$$NH(CH_2CH_2OH)_2 + OH^- \underset{-H_2O}{\rightleftharpoons} HOCH_2CH_2NHCH_2CH_2O^- \xrightarrow{+Fe(CN)_6^{3-}}$$

$$\rightarrow complex \xrightarrow{+Fe(CN)_6^{3-}} 2Fe(CN)_6^{4-} + products.$$

At low oxidant concentrations the rate of reaction is limited

by the formation of a complex, which explains the third order of the reaction, while at high oxidant concentration it is limited by the ionisation of ethanolamine.

The oxidation of primary amines with a methylene group by $Pb(OCOCH_3)_4$ in boiling benzene[89,90] leads to the formation of nitriles in yields up to 60%. The reaction is believed to be a two-stage dehydrogenation process with the intermediate formation of aldimines. The mechanism has been confirmed by the formation of 2–4% of benzaldehyde in the oxidation of benzylamine and subsequent hydrolysis, since the aldehyde is probably formed from the aldimine $C_6H_5CH{=}NH$. Aliphatic aldehydes are not formed in the reaction, since their aldimines are unstable. They rapidly polymerise, which lowers the yield of nitriles and increases the yield of resins.

In specifying the details of the mechanism, the authors[89,90] postulated the intermediate formation of the products (XX) and (XXI) of the aminolysis of lead tetra-acetate [see mechanism (14)] and their homolytic decomposition. This is based on the analogy with the alcoholysis of $Pb(OAc)_4$ and the photochemical oxidation of benzylamine to benzonitrile by $Pb(OAc)_4$. The reaction mechanism is as follows:

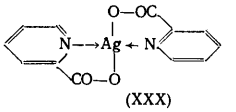
$$RCH_2NH_2 + Pb(OAc)_4 \overset{a}{\rightleftarrows} RCH_2NHPb(OAc)_3 + AcOH$$
$$\overset{c}{\downarrow} \qquad \overset{b}{\downarrow} \quad (XX)$$
$$RCH_2\dot{N}H + \dot{P}b(OAc)_3 \rightarrow RCH{=}NH + Pb(OAc)_2 + AcOH \ ;$$

$$RCH{=}NH + Pb(OAc)_4 \overset{a}{\rightleftarrows} RCH{=}NPb(OAc)_3 + AcOH$$
$$\overset{c}{\downarrow} \qquad \overset{b}{\downarrow} \quad (XXI)$$
$$RCH{=}\dot{N} + \dot{P}b(OAc)_3 \longrightarrow RC{\equiv}N + Pb(OAc)_2 + AcOH \ . \qquad (14)$$

Compounds (XX) and (XXI) are converted into an imine or a nitrile either directly (pathway *b*) or with the intermediate formation of radical pairs (pathway c). Mechanisms involving the formation of side products have also been proposed.

The oxidation of dibenzylamine gives rise to benzaldehyde, benzonitrile, benzylamine, and the compounds $C_6H_5CH_2N = CHC_6H_5$ (XXII) and $C_6H_5CH(COCH_3)NH = CHC_6H_5$ (XXIII). A reaction mechanism has been proposed in which compound (XXII) is formed in the first stage via a mechanism analogous to mechanism (14); its subsequent reactions explain the formation of the other products mentioned.

Triethylamine is very slowly oxidised by lead tetra-acetate in glacial acetic acid, while the amines (XXIV)–(XXVII) are rapidly oxidised. After hydrolysis, the amines (XXIV)–(XXVI) give high yields of diethylamine, while compound (XXVII) gives rise to piperidine. The hydroxylamines (XXVIII) and (XXIX) are oxidised much more slowly than compounds (XXIV)–(XXVII) but faster than the mixture of $(C_2H_5)_3N$ and 1-propanol, which is in its turn oxidised faster than triethylamine[91]. The oxidation of the amines (XXIV) and (XXVII) results in the formation of glyoxal.



$(C_2H_5)_2NCH_2CH_2OH$ (XXIV); $(C_2H_5)_2NCH_2CHCH_3$ (OH) (XXV); $(C_2H_5)_2NCH_2C(CH_3)_2$ (OH) (XXVI);

(XXVII); $(C_2H_5)_2NCH_2CH_2CH_2OH$ (XXVIII); $(C_2H_5)_2NCH_2CH_2CH_2CH_2OH$ (XXIX) .

The above data show that the C–N bonds are cleaved in the reaction. The authors quoted above proposed the following process mechanism:

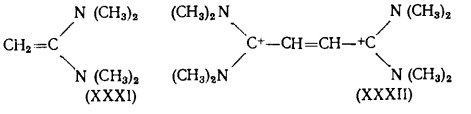
$$(C_2H_5)_2NCH_2CH_2OH \xrightarrow[-CH_3COOH]{+CH_3COO^-} (C_2H_5)_2N\dot{C}HCH_2OH \xrightarrow{+CH_3COO^-}$$
$$\rightarrow (C_2H_5)_2NCH(OCOCH_3)CH_2OH \xrightarrow{+H_2O} (C_2H_5)_2NH + CH_3COOH + O{=}CHCH_2OH$$

The oxidation of primary and secondary amines with an α-hydrogen atom by a suspension of silver(II) picolinate (XXX) in water or polar solvents[93] leads to the formation of aldehydes or ketones and apparently proceeds via an imine formation stage.

(XXX)

The imines were isolated in those instances of the oxidation of secondary amines where the imines were stable. Stable imines, corresponding to primary amines, are oxidised further to nitriles. The stoichiometry of the reaction is described by the equations

$$\rangle CHNH_2 + 2Ag^{2+} + H_2O \rightarrow \rangle CO + NH_3 + 2Ag^+ + 2H^+ \ ;$$
$$\rangle CHNHR + 2Ag^{2+} \rightarrow \left(\rangle C{=}NR + 2Ag^+ + 2H^+\right) \overset{H_2O}{\rightleftarrows} \rangle CO + RNH_2 + 2Ag^+ + 2H^+ \ .$$



The authors[93] suggest that the amines substitute picolinic acid in the complex (XXX), after which they give up an electron to silver(II). This is followed by the oxidation of the resulting radical by a second picolinate molecule, which leads to an imine either directly or via a hydroxyamine formation stage:

$$RCH_2NHR' \rightarrow Ag(I) + RCH_2\overset{+}{N}HR' \rightarrow R\dot{C}HNHR' + H^+ \ ;$$
$$\downarrow Ag(II)$$
$$Ag(II) + R\dot{C}HNHR' \begin{cases} \longrightarrow Ag(I) + H^+ + RCH{=}NR' \\ \xrightarrow{H_2O} Ag(I) + H^+ + RCH(OH)NHR' \rightleftarrows RCHO + R'NH_2 \ . \end{cases}$$

One cannot rule out the possibility that imines are formed in the disproportionation of α-amino radicals:

$$2R\dot{C}HNHR' \rightarrow RCH{=}NR' + RCH_2NHR' \ .$$

The interaction of vinylidenebisdialkylamines with silver nitrate in acetonitrile leads to oxidative dimerisation with formation of diamidinium salts[94,95]. Thus compound (XXXII) and metallic silver are formed from compound (XXXI).

(XXXI) (XXXII)

If the initial amine contains two double bonds, there is a possibility of the formation of cyclic or bicyclic products. It has been suggested that the reaction proceeds with participation of radical-cations. In certain cases their formation was established by EPR.

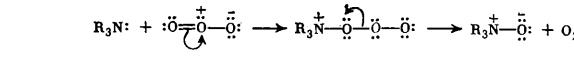
8. Oxidation with Molecular Oxygen and Ozone

When triethylamine is oxidised with oxgen in the gas phase at 200 °C,[96,97] mainly ethylamine, acetaldehyde, and diethylamine are formed. The diethylamine concentration initially increases, but rapidly attains a limiting value. It has been suggested that oxygen abstracts H˙ from the CH_2 group, after which another oxygen molecule adds to the resulting radical to form a peroxy-radical; ethylamine is formed in the intramolecular decomposition of this radical, while diethylamine arises in consequence of the decomposition of the hydroperoxide. The details of the mechanism have not been determined.

The kinetics of the radical-initiated liquid-phase oxidation of amines by oxygen have been studied[98–109]. These reactions proceed at a lower temperature than the gas-phase

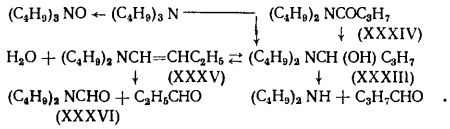
oxidation, but their products have not been investigated. In most cases the oxidation involves radical-chain processes and proceeds via the following mechanism with both primary and secondary amines:

$$\text{Initiator} \xrightarrow{+RH,+O_2} \dot{R} \xrightarrow{+O_2} R\dot{O}_2 \xrightarrow{+RH} ROOH + \dot{R} \quad ;$$
$$2R\dot{O}_2 \rightarrow O_2 + \text{molecular products.}$$



Here $\dot{R}$ = α-amino-radical. Tertiary amines are oxidised more readily than primary and secondary amines. The involvement of enamines in the reaction and in certain cases linear chain termination have been postulated[102].

The specific features of the reactions consist in the fact that α-aminoperoxy-radicals have not only oxidative but also reductive properties. They are capable of regenerating the inhibitors of radical-chain processes, which explains the observed high stoichiometric inhibition coefficients.



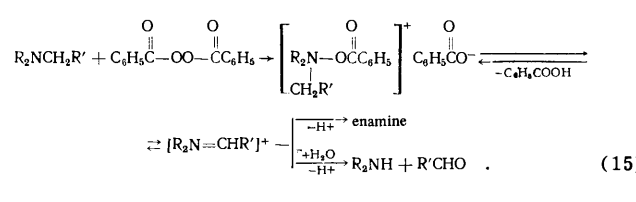
The liquid-phase autoxidation of enamines with a complex structure has been studied[110]. The reaction proceeds via a radical-chain mechanism. In the initiation stage the amine gives up an electron to the oxygen with formation of ammonium radical-cations. The Fe^{3+} and Cu^{2+} ions react similarly and greatly accelerate the autoxidation.

It has been found[111] that $RuCl_3$ catalyses the homogeneous liquid-phase oxidation of amines by oxygen. In toluene at 100 °C benzylamine is converted into benzonitrile and benzamide, while butyronitrile and butyramide are formed from n-butylamine. 2-Aminohexane gives rise to the corresponding ketone (formed in the hydrolysis of the imine) and the product of the condensation of the ketone with the initial amine. Variants of the mechanism involving ruthenium(III)—amide and ruthenium(III)—hydride complexes have been proposed.

In their interaction with ozone in chloroform at low temperatures, tertiary amines are converted with high yields into *N*-oxides[112]. The reaction probably proceeds via the mechanism[112,113]

The reaction has been studied in detail in relation to tri-n-butylamine[6,114]. Apart from its *N*-oxide, compounds (XXXIV) and (XXXVI) and dibutylamine are formed. The ratio of their yields is influenced by the nature of the solvent and temperature. In chloroform or methanol at −45 °C the main product is the *N*-oxide, while in hydrocarbons or 1-chlorobutane the products are dibutylamine at −45° or −78 °C and compound (XXVI) at +15 °C. It has also been shown that, for a tributylamine : ozone ratio of 1 : 1 at −78 °C in pentane, subsequent heating to 20 °C results in the formation of the enamine (XXXV), which is oxidised by ozone to compound (XXXVI). The following process mechanism has been proposed:

The formation of an *N*-oxide is apparently favoured by the tendency of the solvent to form hydrogen bonds; the carbinolamine (XXXIII) is obtained in solution in hydrocarbons or 1-chlorobutane. It is oxidised to compound (XXXIV), hydrolyses to butylamine and butyraldehyde, and is dehydrated to compound (XXXV) with subsequent ozonolysis at the double bond. Heating, which promotes dehydration, lowers the yield of dibutylamine and increases that of dibutylformamide. Hydrolysis of the carbinolamine, leading to dibutylamine and butyraldehyde, predominates in the oxidation of a suspension of tributylamine in water. The mechanism discussed does not, however, explain the formation of carbinolamine.

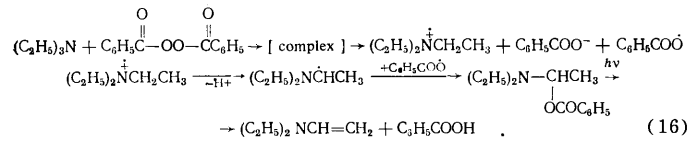


Primary amines are oxidised by ozone to nitro-compounds. At low temperatures the yields are 25–50%.[115] Alkylhydroxyamines and nitroso-compounds are probably formed initially, which is confirmed by the presence in the reaction mixture of alkylhydroxylamines when the oxidation is interrupted, after the introduction of one equivalent of ozone, by the conversion of alkylhydroxylamines into nitro-compounds under the influence of ozone and by the colour characteristic of nitroso-compounds appearing in the course of the reaction.

Since oximes are not converted into nitro-compounds on being oxidised with ozone, it is to be expected, in conformity with the mechanism discussed, that amines with tertiary hydrocarbon groups, which are converted into nitroso-compounds incapable of isomerising to oximes, would give rise to higher yields of nitro-compounds than amines with primary or secondary hydrocarbon groups. This prediction has been confirmed. However, it is noteworthy that the mechanism of the formation of alkylhydroxylamines and of their conversion into nitroso-compounds and then nitro-compounds remains obscure.

9. Oxidation by Peroxy-Compounds

The oxidation of amines by peroxy-compounds frequently depends on the nature of the solvent and the mechanism is often different for primary, secondary, and tertiary amines. These reactions apparently include both heterolytic and homolytic processes. The study of their kinetics is complicated by the inhibition or acceleration of the oxidation by reaction products, which is frequently encountered, and by the widespread occurrence of radical-chain processes. The oxidation mechanisms are by no means always satisfactorily justified and their details are frequently unknown.

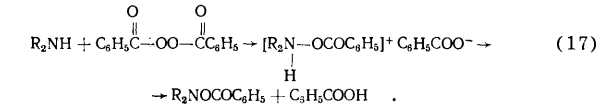


The interaction of benzoyl peroxide with tertiary amines has been investigated[116]. In benzene, in the presence of an excess of the amine, the stages involving the oxidation of amines with the $R_2NCH_2CH_2$ group yield enamines, which have been identified from the formation of compounds of the "blue quinone" type (see Section III, 2) when the reaction is carried out in the presence of quinones. The enamine $(C_2H_5)_2.NCH{=}CH_2$ has been isolated[117]. Amines of the type $(CH_3)_2.NCH_2Ar$, which are incapable of forming enamines, give rise to immonium salts, which hydrolyse to secondary amines and carbonyl compounds. These data can be accounted for by a mechanism analogous to that of the interaction of benzoyl peroxide with dimethylaniline[118]:

(15)

The first stage involves nucleophilic substitution with formation of a quaternary salt, corresponding to the ether of the substituted hydroxylamine. Mechansim (15) has been confirmed by the isolation of a compound of this type in the oxidation of triethylamine by acetyl peroxide[119]; however, it conflicts with the formation of radicals giving rise to polymerisation (see, for example, Margaritova and coworkers[120,121]).

The involvement of radicals in the stages where amines are oxidised by benzoyl peroxide, the intermediates, and the kinetics and mechanisms of the reactions have been investigated[122-128]. The authors used a method based on the chemiluminescence which arises in the course of the recombination of radicals: its appearance is a sign of a radical mechanism and the variation of its intensity makes it possible to infer the reaction kinetics. It has been established that the oxidation of triethylamine by benzoyl peroxide obeys a first-order kinetic equation with respect to each reactant and has a radical but not chain mechanism. Benzoic acid retards while pyridine accelerates the reaction as a result of the formation of complexes with the amines or the peroxide respectively. In the presence of an excess of the peroxide, chemiluminescence, corresponding to the oxidation of an intermediate, probably an enamine, is observed. On hydrolysis, the enamine gives rise to diethylamine and acetaldehyde. The following mechanism has been proposed:



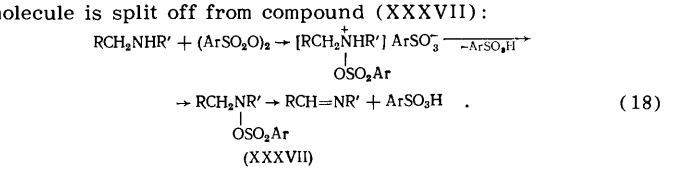
(16)

It is closer to Horner's mechanism of the oxidation of *N*,*N*-dialkylanilines (see, for example, Horner and Junkermann[129]). It may be that the intermediate complex is a quaternary salt, corresponding to an ether of the substituted hydroxylamine[130], which rapidly decomposes into radicals. It is also possible that the salt decomposes simultaneously via a non-radical mechanism (see, for example, Walling and Inductor[117]).

According to the authors of the studies quoted, the oxidation of aminoalcohols $R'R''NCH_2CH_2OH$ [123,128,131] proceeds via a mechanism analogous to mechanism (16). The oxidation of triethanolamine[132-134] is a radical-chain reaction.

The structure factors which determine the mode of dealkylation of tertiary amines have been studied[135].

The secondary amine oxidation reactions[122,126,127,133,136-140] are also usually second-order reactions. Radicals are probably not formed in these reactions or not in the initial stages, being produced in the oxidation of the intermediates [for example, of $(C_2H_5)_2NCH{=}CH_2$, obtained in the oxidation of diethylamine[143]]. The radical mechanisms proposed previously (see, for example, Horner and Kirmse[194]) are probably incorrect[142]. Apparently the cations of the quaternary salts obtained from hydroxylamine derivatives are formed in these reactions and then rapidly lose protons:

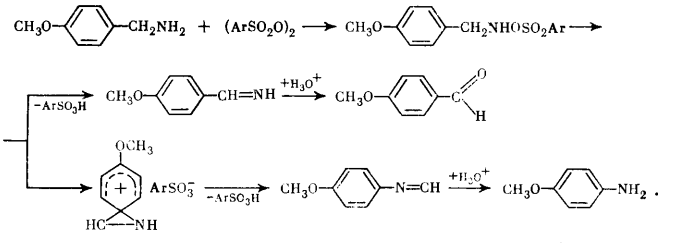


(17)

Nor can one rule out the possibility[139] that secondary amines react with an amine–peroxide complex rather than the peroxide itself.

The oxidation of primary amines by benzoyl peroxide has been investigated only in relation to propylamine[127], butylamine[140], and benzylamine[144-146]. The ideas concerning the mechanisms of these reactions have been only slightly elaborated.

When primary or secondary amines interact with *p*-nitrobenzenesulphonyl peroxide with subsequent hydrolysis, carbonyl compounds are obtained, frequently in good yields. Imines are formed in the intermediate oxidation stages and can sometimes be isolated. The process apparently begins with nucleophilic attack by the amine on the peroxide, analogous to reaction (17), and then yet another sulphonic acid molecule is split off from compound (XXXVII):



(18)

(XXXVII)

The electrophilic nature of the peroxide and its tendency to split off the $ArSO_3^-$ residue favour this two-electron mechanism.

The "anomalous" course of the reaction has been studied[148]. In the oxidation of, for example, *p*-methoxybenzylamine or diphenylmethylamine the products are *p*-methoxyaniline or benzaldehyde instead of *p*-methoxybenzaldehyde or benzophenone expected on the basis of mechanism (18). These results have been explained by the migration of the aryl residue from the carbon atom to the positively charged nitrogen atom arising on ionisation of a compound of type (XXXVII):

It has been shown[148] that the radical variants of the mechanism are less probable.

The oxidation of amines by dicyclohexyl peroxydicarbonate $(C_6H_{11}OCOO)_2$ has been investigated[141]. In the presence of an excess of the amine, the reactions with triethylamine, *N*-diethylethanolamine, and *N*-ethyldiethanolamine obey a second-order kinetic equation and are accompanied by chemiluminescence. A radical mechanism analogous to mechanism (16) has been proposed.

The oxidation of amines by potassium persulphate in water has been studied[149-156]. According to the characteristics of the rate and the reaction mechanism, the authors divided amines into two groups[149,150]. Primary and secondary amines were assigned to the first group. Their oxidation products have not been determined, but the rate obeys a second-order kinetic equation and is proportional to the KOH concentration. Primary amines are oxidised more slowly than secondary amines. The initial rates of oxidation of amines in this group are proportional to their pK_a, which has been explained by complex formation between the amine and the peroxide in the slow stage. The reaction mechanism has not been established, but it is probably of a non-radical type[149-152].

Tertiary amines and aminoalcohols were assigned to the second group. The oxidation of tertiary amines[149,150,153-156] results in the formation of secondary amines and carbonyl compounds. Diethylvinylamine, which gives rise to diethylamine and acetaldehyde on hydrolysis, was detected among the products of the reaction with triethylamine. The oxidation of tertiary and secondary aminoalcohols[149-150,152,154-166] leads to secondary or primary aminoalcohols and carbonyl compounds respectively. In the case of triethylamine, diethanolamine, and *N*-ethyldiethanolamine, formaldehyde is present among the products, i.e. oxidative fragmentation takes place. The kinetics of the above reactions are fairly complex; fractional reaction orders, the acceleration of the consumption of the oxidant by the reaction products, and the dependence of the rate of oxidation on the presence of radical chain process inhibitors are observed. The rate is not

simply related to the basicity of the amines; the addition of KOH has a different and more complex effect on the rate than for amines in the first group. These data can be accounted for by the involvement of radicals in the reaction, which is consistent with the finding that some of the reactions of this type induce radical polymerisation.

The mechanism of the oxidation of amines of the second group remains obscure. We believe that the proposed mechanisms[150,153,154,156,158,159] are inadequately founded and are unconvincing. They do not explain or only explain poorly the dependence of the rates of the reactions on the concentration of alkali, their orders, etc. and are not detailed.

The oxidation of amines by potassium persulphate is catalysed by variable-valence metals. These reactions with amines and aminoalcohols have been studied[167–173]. The catalytic effect of metal ions increases in the sequence Co^{2+} < Cu^{2+} < Ag^{+}.[170,172] In most cases the rate of oxidation falls with increasing basicity of the amines[167,172], which the authors explained by a decrease of the activity of the metal ions as a result of the increase of the stability of their complexes with the amines. A reaction mechanism involving the formation of a complex comprising the amine, Ag^+ ions, and persulphate, in which the metal ion behaves as an agent transferring an electron from the amine to the persulphate, has been proposed[170,172]. The reaction products were not determined in the above investigations.

The interaction of persulphate with primary amines in the presence of Ag^+ ions is of preparative value[174]. Amines of the type RCH_2NH_2 are converted into aldimines $RCH{=}NCH_2R$, amines of the type $RR'CHNH_2$ give rise to ketones, while the amines R_3CNH_2 are not oxidised. In contrast to the results of Bacon and Stewart[174], Babu et al.[175] isolated hydroxylamine derivatives and oximes as intermediates in the above reaction. In the presence of an excess of the amine (Am), the rate of reaction is proportional to the concentrations of persulphate and Ag^+, the order with respect to the amine falls with increasing Ag^+ concentration, and the reaction is of first order with respect to the amine in the absence of the catalyst. Neutral salts retard the reaction. These data have been explained by the fact that non-catalysed and catalysed reactions take place simultaneously. Ions of opposite sign react in the slow stage of the latter. The overall rate of the process is expressed by the equation

$$\frac{d[S_2O_8^{2-}]}{dt} = k_1[Am][S_2O_8^{2-}] + k_2[Ag^+][S_2O_8^{2-}] \quad .$$

At a high Ag^+ concentration the quantity $k_1[Am]$ becomes much smaller than $k_2[Ag^+]$ and the order of the reaction with respect to the amine becomes zero. The rate constant k_2 is higher the smaller the stability of the complexes of the amines with Ag^+. The catalysed reaction proceeds via the mechanism

$$S_2O_8^{2-} \rightleftarrows 2SO_4^{\cdot-} \quad ,$$

$$2SO_4^{\cdot-} + Ag^+ \xrightarrow[k_M]{\text{slow}} 2SO_4^{2-} + Ag^{3+} \quad ,$$

$$Ag^{3+} + RNH_2 + H_2O \rightarrow RNHOH + Ag^+ \quad , \qquad (19)$$

according to which $w = k_M[SO_4^{\cdot-}]^2[Ag^+]$. Bearing in mind that $[SO_4^{\cdot-}]^2 = K[S_2O_8^{2-}]$ (where K is the equilibrium constant of the reaction $S_2O_8^{2-} \rightleftharpoons 2SO_4^{\cdot-}$), then $w = k_M K[Ag^+][S_2O_8^{2-}]$ and $k_2 = k_M K$. We may note that the last stage in mechanism (19) is not specified in detail and that an analogous mechanism explains the formation of aldimines.

Secondary amines of the type $(RCH_2)_2NH$ react with persulphate and Ag^+ ions to form aldehydes, while those of the type $(RR'CH)_2NH$ give rise to ketones. Primary amines are formed simultaneously. α-Aminoacids give rise to aldehydes while *N*-methylpiperidine and *N*-methylpyridine are not oxidised. These reactions are more complex than the oxidation of primary amines[176].

In contrast to the data presented above, it has been found[177] that di-isopropylamine and the aminoalcohol $HN(CH_2CHOHCH_3)_2$ are oxidised to hydroxylamine derivatives; the mechanism of these reactions has not been established.

Among the reactions of dialkyl peroxides, only the interaction of di-t-butyl peroxide with tri-n-butylamine, di-isopropylamine, and 4-methyl-2-pentylamine has been investigated[178,179]. t-Butyl alcohol and compounds with $-C{=}N-$ bonds are formed almost quantitatively. The rate of reaction is determined by the stage involving the decomposition of the peroxide into radicals, which dehydrogenate the amine. Two variants of the mechanism have been proposed:

$$(CH_3)_3C\dot{O} + R_2CH{-}NHR' \xrightarrow[-(CH_3)_3COH]{} R_2\dot{C}{-}NHR' \xrightarrow{+(CH_3)_3C\dot{O}} \rightarrow (CH_3)_3COH + R_2C{=}NHR'$$

$$(CH_3)_3C\dot{O} + R_2CH{-}NHR' \rightarrow (CH_3)_3CO^- + R_2CH{-}\dot{\overset{+}{N}}R' \xrightarrow[-(CH_3)_3COH]{} R_2\dot{C}{-}\ddot{N}HR' \rightarrow$$

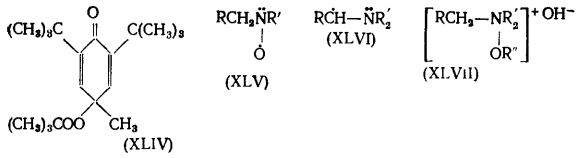
$$\xrightarrow{(CH_3)_3C\dot{O}} R_2C{=}\overset{+}{N}HR' + (CH_3)_3CO^- \rightarrow R_2C{=}NR' + (CH_3)_3COH \quad .$$

The interaction of hydroperoxides with amines has been studied more widely. It has been shown[180] that these reactions lead to satisfactory yields of the alcohols coresponding to the peroxides. Their mechanism has been studied[179] in relation to the reactions of t-butyl hydroperoxide with an excess of 4-methyl-2-pentylamine, di-isopropylamine, tri-n-propylamine, and 2,4,4-trimethyl-2-pentylamine. All these amines form hydrogen-bonded complexes with the hydroperoxide; t-butyl alcohol was detected among the products. The last of the above amines, which does not contain a hydrogen atom in the α-position relative to the amino-group, reacts at a higher temperature than the other amines and gives rise to 2,4,4-trimethyl-2-nitropentane and the products of the thermal decomposition of the hydroperoxide. The reaction mechanism is unknown. The first three amines are converted respectively into the ketimine (XXXVIII), ammonia, and water, into acetone, isopropylamine, water, and the ketimine (XXXIX), and into dipropylamine, propionaldehyde, and its aldol condensation products. Compounds (XL)–(XLIII) are probably formed in addition from tri-n-propylamine.

$(CH_3)_2CHCH_2C{=}NCHCH_2CH(CH_3)_2$ (XXXVIII)

$(CH_3)_2C{=}NCH(CH_3)_2$ (XXXIX)

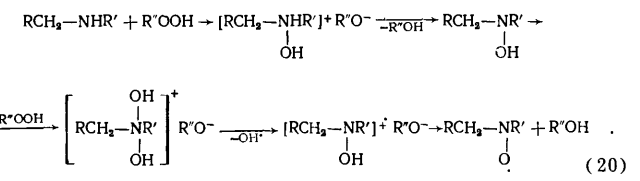
$C_3H_7NHCHCH_2CH_3$ (XL)
OC_4H_9



$(C_2H_7)_2NCHCH_2CH_3$ (XLI)
OC_1H_9

$C_3H_7NHCHCH_2CH_3$ (XLII)
$C_3H_7NHCHCH_2CH_3$

$(C_3H_7)_2NCHCH_2CH_3$ (XLIII)
$(C_3H_7)_2NCHCH_2CH_3$



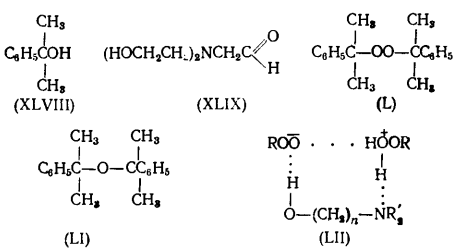
One may therefore assume that the first three amines give rise to dealkylation products and carbonyl compounds, which can be converted into imines by reacting with the initial amine or the amine formed in the reaction. The products (XL)–(XLIII) probably arise from intermediate radicals. The involvement of radicals is confirmed by the retardation of the reactions by radical chain process inhibitors, for example ionol. The formation of the radicals $(CH_3)_3C\dot{O}$ has been demonstrated by the isolation of compound (XLIV)—the product of their interaction with radicals corresponding to

ionol.

(XLIV) (XLV) (XLVI) (XLVII)

De La Mare[179] explained the set of results obtained in terms of a radical-chain mechanism. The radicals (XLV) or (XLVI) arise in the initiation stage. The formation of the radicals (XLV) in the oxidation of tertiary and secondary amines by t-butyl hydroperoxide has been demonstrated by EPR.[181] The mechanism of their formation is obscure in the case of tertiary amines and that in the reaction with secondary and primary amines is

(20)

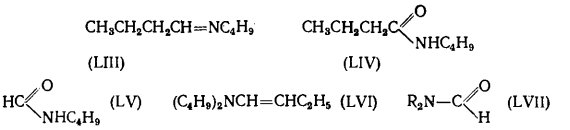


The radicals (XLVI) are obtained via the mechanism

(21)

possibly with the intermediate involvement of the quaternary ammonium salt (XLVII). The chain propagation and termination mechanisms proposed by De La Mare[179] easily explain the mechanisms of the formation of all the reaction products.

The interaction of amines with cumenyl hydroperoxides in water has been studied[182–185]. Two parallel reactions take place with triethanolamine. The rate of one of them is proportional to the concentrations of the amine and the hydroperoxide. The rate of the second reaction is proportional to the square of the concentration of the hydroperoxide and depends on the dielectric constant and the presence of neutral salts. The reaction products—the alcohol (XLVIII), the aldehyde (XLIX), the peroxide (L), oxygen, and possibly the ether (LI)—are believed to be formed on decomposition of complexes of the amine with the hydroperoxide or its dimer. The latter complex is formed only by aminoalcohols, which has been explained by the structure (LII).



(XLVIII) (XLIX) (L) (LI) (LII)

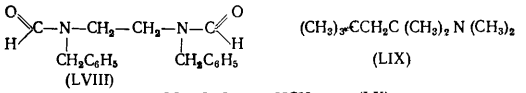
The mechanism of the decomposition of the complexes is unknown.

Metal compounds catalyse the oxidation of amines by hydroperoxides. Tertiary amines and aminoalcohols are converted into *N*-oxides in high yields, piperidine is converted into 2-piperidinone, and primary amines are converted into oximes. Vanadium, molybdenum, titanium, and tungsten compounds are particularly active. The reaction mechanism has not been established[186]. A study has been made of the kinetics of the reactions of triethylamine and morpholine with cumenyl hydroperoxide catalysed by metal ions[187].

The oxidation of amines by hydrogen peroxide has been little investigated. Only isolated data are available concerning its kinetics and mechanism. Thus it has been shown[188] that in acetonitrile the intermediate in the oxidation of n-butylamine is the aldimine (LIII), which is converted by the peroxide into the amides (LIV) and (LV).

(LIII) (LIV) (LV) (LVI) (LVII)

In addition the corresponding hydroxylamine and oxime are formed. The reaction with di-n-butylamine leads to dibutylhydroxylamine, the aldimine (LIII), and its oxidation products. Tri-n-butylamine gives rise to an amine oxide and the enamine (LVI), which hydrolyses to dibutylamine and butyraldehyde. It has been established[189] that the hydroxylamines formed in the oxidation of secondary amines on treatment with an aqueous H_2O_2 solution always contain an admixture of the corresponding *N*-formyldialkylamines (LVII) and a mechanism of their formation has been proposed. The kinetics of the oxidation of triethylamine by hydrogen peroxide have been investigated[190].



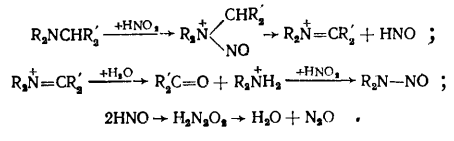
The characteristics of the catalytic oxidation of amines by hydrogen peroxide in the presence of $NaWO_4$ or $NaMoO_4$ have been studied[191,192]. The rate of reaction is proportional to the concentrations of the amine and the catalyst, decreasing on passing from tertiary to secondary amines and with increasing branching of the hydrocarbon residues at the nitrogen atom. It has been suggested that the primary products are amine oxides or amine oxide hydrates. Those obtained from ammonia and primary and secondary amines isomerise to hydroxylamines, which have been identified. Among other products, oximes and in certain cases carbonyl compounds have been detected. The formation of oxides from tertiary amines and of *N*,*N*-dialkylhydroxylamines from secondary amines on treatment with hydrogen peroxide in the presence of $NaWO_4$ has also been established in another study[193]. t-Butylamine is converted into a nitro-compound, while amines in which a primary or secondary carbon atom are linked to the NH_2 group give rise to aldoximes or ketoximes (isomerisation products of nitroso-compounds). It is believed that the above reactions involve electrophilic substitution at the nitrogen atom.

It is noteworthy that, despite the incompleteness of the data presented, one can postulate that radicals are involved in the reactions. It may be that radical processes take place simultaneously with electrophilic substitution. This is indicated by the formation of imines, enamines, and carbonyl compounds, usually obtained in the radical oxidation reactions of amines. One cannot rule out the possibility that radical reactions involving oxidation by hydrogen peroxide begin with reactions of types (20) and (21).

10. Other Oxidation Reactions

The oxidation of tri-n-alkylamines with $N-CH_2-CH_2$ residues by a suspension of hydrated manganese dioxide ($HOMnO_x$) in cyclohexane[114,195] leads to the formation of dialkylformamides. The hydrolysis of the reaction mixture gives rise also to dialkylamines. It has been suggested that the "$HOMnO_x$" surface generates HȮ radicals, which oxidise the adsorbed amines to carbinolamines. As in the reaction of amines with ozone, the latter hydrolyse to dialkylamines or are dehydrated to enamines, whose oxidation gives rise to dialkylformamides.

The formation of carbinolamines and their reactions account for the nature of the products of the reactions of various tertiary amines with "$HOMnO_x$". Thus benzaldehyde has been obtained from benzyldimethyl-, benzyldiethyl-, and tribenzyl-amines. 1,4-Dibenzylpiperazine gives rise to compound (LVIII). Cyclohexyldimethyl- and cyclohexyldiethylamines are converted into cyclohexanone, while the latter amines also give rise to acetaldehyde. Triethylenediamine and 1,2-dipiperidinoethane are converted into 1,4-diformylpiperazine and 1-formylpiperidine respectively. The amine (LIX) is converted into compound (LX).[195,196]

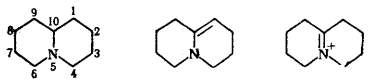


(LVIII)

$(CH_3)_3CCH_2C(CH_3)_2N(CH_3)_2$ (LIX)

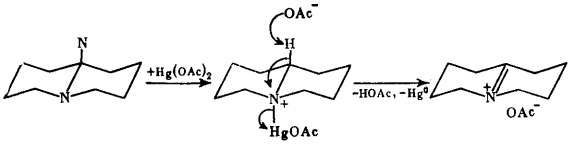
$(CH_3)_3CCH_2C(CH_3)_2NHCH_3$ (LX)

Nitrous acid in aqueous acetic acid reacts with tertiary amines via the mechanism $R_2NCHR'_2 + HNO_2 \rightarrow R_2N{-}NO + R'_2C{=}O$.



Nitrous oxide is present among the products. The introduction of substituents in the *meta*- or *para*-positions in one of the tribenzylamine rings influences the process: the fractions of unsubstituted benzaldehyde and substituted nitrosamine are given by the Hammett equation with a small negative value of ρ. The rate of reaction decreases with decrease of the basicity of the amines. Quinuclidine does not react. Substituents in one of the α-positions of tribenzylamine or benzyldiethylamine lead to the preferential formation of benzaldehyde or acetaldehyde regardless of the nature of the substituents. The amine $C_6H_5CD_2N(CH_2C_6H_5)_2$ is converted into deuterated and non-deuterated benzaldehyde in proportions of 1 : 8 ($k_H/k_D = 3.78$). The results have been explained by a heterolytic mechanism[197,198]:

It has been suggested that the elimination of HNO takes place intramolecularly in the reaction with a cyclic transition state. The mechanism involving the intermediate formation of ammonium radical-cations and nitric oxide as one of the reaction products[199] does not explain the formation of nitrous oxide, while the nucleophilic dealkylation mechanism[200] is inconsistent with the isotope effect. Nor can one rule out a mechanism in which NO^+ abstracts a hydride ion from the α-carbon atom of the amine[198].



In the oxidation of triethylamine by iron(III) complexes of phenanthroline derivatives or the molybdenum(V) octacyanide complex[80] an electron is transferred from the amine to the oxidant with formation of ammonium radical-cations.

The oxidation of cyclic tertiary amines by mercury(II) acetate has been investigated[92,201-205]. The reaction leads to the formation of enamines. For example, the enamine (LXII) is formed from quinolizidine (LXI) and is converted into a salt.

(LXI) (LXII) (LXIII)

The oxidation apparently proceeds via a heterocyclic mechanism involving structure (LXIII):

$Hg(OAc)_2 + Hg^0 \rightarrow Hg_2(OAc)_2$.

Quinolizidine-10-*d* is oxidised 2.3 times more slowly, so that the rate is limited by the decomposition and not the formation of the complex illustrated in the scheme above. The C–H bond involving the eliminated proton must be located in the *trans*-position relative to the N–Hg bond. A one-electron reaction mechanism is also not ruled out.

The data described above show that most of the reactions considered have radical or radical chain mechanisms. However, in only a few instances has direct evidence been obtained for the involvement of the radicals and their decisive role in the formation of the main reaction products established. We include in evidence of this type the observation of chemically induced nuclear polarisation in the products, the observation of EPR and optical spectra of the radicals or radical-cations involved in the formation of the products, the observation of the chemiluminescence of the reaction mixture and the initiation of polymerisation processes by the reaction mixture, and the presence of an induction period, which depends on the presence of inhibitors or initiators of radical chain reactions. Such evidence has been obtained for the oxidation of amines by diazonium and iodonium salts, ClO_2, quinonoid and peroxide compounds, etc., but in such cases there is no certainty that the main reaction products are obtained solely via the radical mechanism.

In other instances the radical mechanism has been justified indirectly. The relevant evidence has been obtained by considering kinetic data (in particular, the nature of the dependence of the rate of oxidation on the substituents in the substrate and the oxidant), the nature of the products formed, etc. Such combined indirect evidence constitutes a serious argument in support of the proposed mechanisms but cannot be regarded as their unambiguous confirmation.

The radical mechanisms examined can be classified in terms of the mode of generation and the nature of the radicals formed in the key stages. In most reactions the key role is due to the ammonium radical-cations, but direct evidence for their involvement in the reactions is available in only rare instances. These radicals can be obtained on electron transfer from the amines to the oxidants. If the transfer is reversible and limits the rate of oxidation, then the rates of reaction of a specified amine with a series of oxidants are correlated with their oxidation potentials E^0 and the rates of oxidation of different amines are correlated with the E^0 and the sum of the σ^* constants of the substituents at the nitrogen atom of the amine or with the E^0 and the photoionisation potentials of the amines[82]. The validity of these correlations may serve as a criterion of reversible electron transfer from the amine to the oxidant in the slow stage of the reaction. (Its other features were frequently discussed above.)

Yet another way of forming ammonium radical-cations consists in the decomposition of an intermediate compound or complex of the amine with the oxidant. The choice between this pathway and electron transfer is important for the understanding of the mechanism; however, frequently, such choice is based on indirect data in view of the lack of detailed information about the reaction kinetics. In only relatively

rare instances (see Section III, 2) has it been shown clearly that there is no direct electron transfer in the slow stage of the reaction.

In certain reactions (see, for example, Sections III, 4 and III, 6) the primary formation of α-amino radicals or the competitive formation of these radicals and ammonium radical-cations has been postulated. The rates of such reactions do not obey the above correlations. However, one should note that the involvement of α-amine radicals in the reactions, which can be regarded as likely on the basis of the available experimental data, has not been demonstrated directly. The observation of the primary isotope effect of deuterium cannot be regarded as direct evidence, since it can arise in the transfer of protons or hydride ions in the slow stage.

The formation of nitroxy-radicals has been established in the interaction of amines with t-butyl hydroperoxide. It is natural to postulate their key role in radical reactions of hydroperoxides and possibly of hydrogen peroxide with amines, particularly in those cases where compounds with nitrogen–oxygen bonds are formed.

As can be seen from the data presented above, the non-radical (molecular and ionic) amine oxidation mechanisms have been specified in less detail and are less well founded than the radical mechanisms. This applies particularly to mechanisms where the shift of a hydride ion is postulated. We may note that doubts have arisen in recent years as to whether the hydride ion shift is an elementary step and not consecutive transfer of an electron and a hydrogen atom or of two electrons and a proton[24,37].

We emphasise the importance of the results obtained in the study of the mechanism of the oxidation of amines with the aid of CIDNP. This method not only permits an unambiguous solution of the problem of the involvement of radicals in the formation of the reaction products but also allows one to derive information about the fine details of the mechanism, in particular to identify the radical pairs whose radicals are converted into the products (see Section III, 2 and Section III, 4).

In conclusion we may note that, despite the considerable advances in the study of individual amine oxidation reactions, this field has still not been adequately studied.

The Molecular Geometry of Nitro-compounds

N.I.Sadova and L.V.Vilkov

A systematic account is given of data on the molecular geometries of approximately 300 nitro-compounds obtained for the vapours by gas electron diffraction and microwave spectroscopy and for the crystalline phases by X-ray diffraction. Certain rules have been formulated for the variation of the geometrical parameters of the molecules in the principal classes of nitro-compounds: inorganic, aliphatic, alicyclic, and aromatic nitro-compounds, nitroamines, and salts and complexes of nitro-alkanes and aromatic nitro-compounds.
The bibliography includes 181 references.

IV. Conclusion 101

I. INTRODUCTION

Nitro-compounds constitute a class of compounds which is important for practical and theoretical chemistry. The nitrogen atom in the NO_2 group has a specific valence state. From the standpoint of the classical theory of chemical structures, the valence of the nitrogen atom in the nitro-group $-N\begin{matrix}=O\\ \\ =O\end{matrix}$ is five, but approximate quantum-chemical ideas do not allow an increase of the valence of the nitrogen atom above four. On the basis of the concept that the nitrogen atom is quadrivalent, pronounced electron-accepting properties of the nitro-group have been postulated.

Analysis of data on the geometrical structure of the molecules is particularly important for the determination of the relation between the chemical structure and physicochemical properties of nitro-compounds. Numerous studies on these compounds have now been made by different methods: by gas electron diffraction (GE) and microwave spectroscopy (MW) for the vapours of the substances and by X-ray diffraction (XD) and neutron diffraction (to a much lesser extent) for the crystalline phase. Unfortunately, the results are not uniformly distributed with respect to different classes of compounds. The majority of data refer to the structures of aromatic nitro-compounds in the crystalline phase; there have been few electron diffraction and microwave studies on the free molecules in the gas phase.

Table 1. Geometrical parameters of inorganic nitro-compounds in the gas phase.

Structural formula	Symmetry	Parameters of nitro-group			Other bonds and valence angles	Method	Parameter	References
		r(N=O), Å	∠ONO, deg	r(O...O), Å				
	C_{2v}	1.1934(10) 1.202(3)	134.07(1.0) 134.0(1.3)	2.198 2.213	—	MW GE	r_a r_a	[1] [2]
	C_s	NO(1) 1.202(6) NO(2) 1.217(7)	129.8(1.1)	2.190	r(NO(3))=1.142(4) Å r(NN)=1.864(7) Å ∠O(3)NN=105.1(0.1)° ∠NNO(1)=112.7(0.7)° ∠NNO(2)=117.5(0.4)°	MW	r_s	[4]
	D_{2h}	1.190(2)	135.4(0.6)	2.201	r(NN)=1.782(8) Å	GE	r_a	[5]
	—	1.21(1)	134(5)		r(NO′)=1.46(2) Å, ∠NO′N95(30)°	GE		[6]
	C_s	NO(1) 1.211(5) NO(2) 1.199(5)	130.2(0.5)	2.184	r(NO(3))=1.406(5) Å r(OH)=0.964(10) Å ∠O(1)NO(3)=115.9(0.5)° ∠O(2)NO(3)=113.9(0.5)°	MW	r_s	[7]
	C_{2v}	1.180(5)	136.0(1.5)	2.188	r(NF)=1.467(15) Å	MW	r_s	[8]
	C_{2v}	1.202(20)	130.6(2.0)	2.181	r(NCl)=1.840(20) Å	MW	r_0	[9]
	C_s	1.206	130.1(0.5)	2.185	r(NN)=1.427 (3) Å r(NH)=1.005(15) Å ∠HNH=115.2(3.0)° ∠Φ=51.8(1.5)°	MW	r_0	[10]

Note. The errors of the determination of the parameters, referring to the last significant figures, are given in brackets, for example 1.190(2) Å = 1.190 ± 0.002 Å and 130.2(0.5)° = 130.2 ± 0.5°. For the differences between the types of the parameters r_a, r_0, and r_s due to vibrational effects and usually amounting to <0.01 Å, see, for example, Vilkov et al.[3] The bond length r(N=O) = 1.206 Å in NH_2NO_2 was fixed and was not varied in refining the parameters; Φ is the angle between the NH_2 and NNO_2 planes.

The task of the analysis of the molecular structure consisted in the determination of the rules governing the variation of the geometries of the groups CNO_2 (*C*-nitro-compounds), NNO_2 (*N*-nitroamines), and ONO_2 (*O*-nitro-compounds) as a function of the class of compound and the nature of the atoms and groups of atoms linked to the above groups. On the other hand, it is necessary to elucidate the influence of the NO_2 group on the neighbouring groups of atoms in the molecules of nitro-compounds. The molecular confirmation and the nature of the internal rotation of the nitro-group are important.

The review includes literature data up to 1978 inclusive and the results of a few studies in 1979. Since virtually all the data for the crystal structures published up to 1971 have been included in handbooks, references to the latter are given.

II. GEOMETRICAL STRUCTURE OF THE MOLECULES OF NITRO-COMPOUNDS IN THE GAS PHASE

1. Inorganic Nitro-Compounds

The determination of gas-phase structural data for inorganic nitro-compounds such as nitrogen oxides, nitric acid, and nitryl halides is associated with considerable experimental difficulties. As apparatus and experimental techniques have improved, the molecular geometries of these compounds have been reinvestigated. The results of the latest electron diffraction and microwave studies are presented in Table 1.

The N=O bond length in the nitro-group is almost constant and amounts to 1.20 Å on average. The ONO valence angle varies within wide limits, from 130° to 136°. The smallest value of r(N=O) and the greatest value of ∠ONO have been found for the NO_2F molecule, which is attributed to the high electronegativity of the fluorine atom[8]. We may note that, despite certain differences in the N=O bond lengths and ONO valence angles, the distance between the oxygen atoms in the nitro-group remains constant to within 0.02 Å.

The N_2O_3 and N_2O_4 molecules are characterised by unusually low N–N bonds, whose length exceeds by 0.3 Å the lengths of the corresponding bonds in hydrazine and its derivatives[3]. The nature of the N–N bond in these molecules has been discussed, for example, in a review[11]. The N–F and N–Cl bond lengths in the NO_2F and NO_2Cl molecules are greater than these bond lengths in NF_3 (1.36 Å) and NCl_3 (1.77 Å).

The molecules of the compounds presented in Table 1 are planar with the exception of N_2O_5 and NH_2NO_2. The conformation of the N_2O_5 molecule has not been reliably determined owing to the rotational movement of the nitro-group. In nitramide the amino-nitrogen atom has a pyramidal configuration of the bonds. In the determination of the geometry of this compound from the microwave spectrum[10], the N=O bond length, which is an important parameter, was assumed†. It has been shown[12] that another set of parameters, in which r(N=O) = 1.232 Å and r(N–N) = 1.381 Å, is consistent with the moments of inertia obtained[10]; this is consistent with the corresponding parameters of nitroamines (see Table 4 below).

2. Organic Nitro-Compounds

The majority of the molecular structures of simple aliphatic and aromatic nitro-compounds as well as nitroamines were investigated in the gas phase for the first time in the course of the last decade. The earlier data for the molecular geometries of CH_3NO_2, CH_3ONO_2, and $C(NO_2)_4$ have also been

Table 2. Principal geometrical parameters of the molecules of aliphatic nitro-compounds in the gas phase (X = C, F, Cl, or Br).

Compound	r (N=O), Å	r (C–N), Å	r (C–X), Å	∠ONO, deg	∠XCN, deg	Conformation	Method	Parameter	Refs.
CH_3NO_2	1.224 (5)	1.489 (5)	—	125.3(0.5)	—	free rot.	MW	r_a	[13]

$C_2H_5NO_2$	1.213 (3)	1.505 (3)	[1.540]	[134]	—	C_s	MW	r_0	[19]
$CH_2{=}CHNO_2$	1.220 (6), 1.234 (4)	1.471 (3)	1.322 (5)	126.0 (0.3)	121.2 (0.2)	C_s, planar	MW	r_s	[20]
▷—NO_2	1.213 (21)	1.488 (20)	[1.511]	[130]	—	C_s, bisector type	MW	r_0	[21]
$CCl_2(NO_2)_2$	1.224 (4)	1.506 (12)	1.757 (8)	124.9 (1.1)	109.7 (0.7)	C_2; φ=74(3)°	GE	r_a	[22]
$CH(NO_2)_3$	1.219 (3)	1.505 (5)	—	128.6 (1.0)	—	C_3; φ=26(1)°	GE	r_a	[23]
$CCl(NO_2)_3$	1.213 (3)	1.513 (3)	1.712 (4)	128.3 (0.6)	112.1 (0.5)	C_3; φ=49(1)°	GE	r_a	[23]
$CBr(NO_2)_3$	1.214 (3)	1.514 (6)	1.885 (9)	132.5 (2.0)	111.3 (1.0)	C_3; φ=49(1)°	GE	r_a	[23]
$C(NO_2)_4$	1.218 (2)	1.526 (6)	—	129.3 (1.0)	—	S_4; φ=47(4)°	GE	r_a	[24]

Note. The assumed values of the parameters are given in square brackets; φ is the angle of rotation of the NO_2 group about the C–N bond; φ = 0° for the coplanar disposition of the nitro-groups in $CCl_2(NO_2)_2$ and $C(NO_2)_4$ (D_{2d}) and for the planar arrangement of the XCNO atoms in $CX(NO_2)_3$.

† Here and henceforth the term "assumed" implies that the parameter was fixed and was not varied in the minimisation process whereby the parameters were refined.

revised. The principal structural parameters are presented in Table 2. A fairly detailed discussion of the molecular structures of organic nitro-compounds in the gas phase can be found in a book[3] and in a review[25]. We shall therefore confine ourselves to only a brief consideration of the principal characteristics of their geometrical structures.

The study of the molecular structures of aliphatic nitro-compounds (Table 2) has shown that the parameters of the nitro-group depend little on the substituent. In particular, the mutual influence of several nitro-groups in polynitroalkanes is weakly reflected in the geometry of these groups. The constancy of the N=O bond length (the average value is 1.22 Å) is particularly characteristic. The ONO angle is on average 129° with a maximum deviation of ±4° (we may note that angles exceeding 130° are quoted with large errors). The minimum value ∠ONO = 125° has been found for nitromethane and dichlorodinitromethane.

The C–N bond lengths in nitroalkanes are in the range 1.49–1.53 Å. Halogenopicrins, whose structure is discussed below, are an exception. There is a tendency towards an increase of r(C–N) with increase of the number of nitro-groups:

Compound	CH_3NO_2	$CH(NO_2)_3$	$C(NO_2)_4$
r(C–N), Å	1.489 (5)	1.505 (5)	1.526 (6) . #

A characteristic geometrical feature of the CNO_2 group is its planar structure[13,16,19,20].

Under the influence of nitro-groups, the lengths of the C–Cl and C–Br bonds adjoining them diminish, which is particularly notable in trinitro-compounds. The bond lengths r(C–Cl) = 1.712(4) Å in $CCl(NO_2)_3$ and r(C–Br) = 1.885(9) Å in $CBr(NO_2)_3$ are the shortest for bonds of the type $\geq$C–X (X = Cl or Br) and are virtually identical with the corresponding bond lengths in the vinyl derivatives.

Halogenopicrins CX_3NO_2 (X = F, Cl, or Br), the electron diffraction data for which conflict with the results of microwave studies on CH_3NO_2 [13,27] and CF_3NO_2,[16] occupy a special place among the mononitroalkanes presented in Table 2. Electron diffraction study of halogenopicrin molecules yielded unusually high C–N bond lengths (up to 1.59 Å), demonstrated hindered rotation about this bond with a barrier of approximately 3 kcal mol^{-1}, and revealed a slight deviation from the planar structure of the CNO_2 groups, leading to a preferred staggered conformation. According to microwave data for CF_3NO_2 (and also CH_3NO_2), the C–N bond length is 1.49 Å, the rotation about this bond is free, and the CNO_2 group is planar. Analysis of electron diffraction data, carried out by the compilers of a handbook[28], led them to the conclusion that these had been obtained with a lower accuracy than indicated by the authors[17,18] [for example, the real error of the determination of r(C–N) is 0.06 Å] and that the barrier to rotation is probably too high. Thus the problem of the molecular structure of halogenopicrins cannot be regarded as ultimately solved.

The molecules of nitroethane, nitroethylene, and nitrocyclopropane have the C_S symmetry. The NO_2 group in nitroethane is in the same plane as the C–N and C–C bonds, and the four hydrogen atoms are arranged symmetrically above and below this plane. The nitroethylene molecule is also planar. Only a bisectorial conformer has been found for nitrocyclopropane in which the plane of the nitro-group is at right angles to the plane of the three-membered ring. The barrier to rotation about the C–N bond in the nitrocyclopropane molecule has been estimated as 1100 ± 500 cm^{-1} or 3.3 ± 1.5 kcal mol^{-1}.

A characteristic feature of the conformation of polynitroalkane molecules in the gas phase is that the angles of rotation of the nitro-groups relative to the N–C–X plane (X = H, Cl, Br, or N) differ from 0° (Table 2). The non-bonded O...Hal and N...O distances are reduced compared with the sum of the van der Waals radii, while the O...O distances are normal. Theoretical calculations of the molecular conformations of trinitro-compounds[29] and tetranitromethane[30] on the basis of a mechanical model agree satisfactorily with experiment; such agreement has not been obtained for dichlorodinitromethane[29].

The geometrical parameters of aromatic nitro-compounds are presented in Table 3. Comparison of the C–N bond lengths and ONO angles in aromatic and aliphatic nitro-compounds shows that as a rule both these parameters are smaller for benzene derivatives than for saturated aliphatic compounds. On the other hand, the equality of the r(C–N) in aliphatic and aromatic nitro-compounds has been noted in a number of monographs (see, for example, Feuer[36]) on the basis of old experimental data, which is difficult to reconcile with the ideas concerning their electronic structure.

The principal conclusion which follows from the study of the molecular structures of aromatic nitro-compounds in the gas phase is that the geometry of their benzene ring is altered. Thus the average C...C bond length§ in $C_6H_5NO_2$, *sym*-$C_6H_3(NO)_3$, *p*-$C_6H_4(NO_2)_2$, and *p*-$ClC_6H_4NO_2$ is smaller than in benzene [r_g = 1.399(1) Å] [3] and is almost independent of the number of nitro-groups. The $CC_{NO_2}C$ valence angle at the carbon atom linked to the nitro-group is greater than 120° in all the compounds listed in Table 3 except *o*-$C_6H_4(NO_2)_2$.

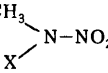
It has been shown in relation to *p*-nitroaniline and *p*-chloronitrobenzene that the nitro-group shortens the C–X (X = Cl or NH_2) bonds, while the CC_XC valence angle hardly changes:

Compound	$C_6H_5NH_2$ [3]	$NH_2C_6H_4NO_2$ [35]	C_6H_5Cl [37]	$ClC_6H_4NO_2$ [34]
r(C–X), Å	1,402 (2)	1,367 (17)	1,737 (5)	1,707 (4)
$\angle CC_XC$, deg	119,5 (2)	119,8 (1,7)	121,7 (0.6)	120,5 (0,6)

Note. The numbers in square brackets denote references (Ed. of Translation).

The *o*-dinitrobenzene molecule, in which there is appreciable steric hindrance, is non-planar and its conformation is characterised not only by the rotation of the nitro-group but also by the deviation of the C–N bonds by 3.6° from the direction of the bisector and by their displacement from the plane of the ring (by approximately 1°) (which fully agrees with a conformational calculation[38]). The non-planar conformations of the other compounds in Table 3, determined by electron diffraction, is associated with the torsional vibrations of the nitro-groups. Allowance for these vibrations leads to a planar equilibrium model with a barrier to rotation $V_2 \cong 5$ kcal mol^{-1}.[39]

In analysing the structural data for *N*-nitroamines (Table 4), it is important to elucidate the dependence of the change in the N–N bond length and in the molecular configuration on



The value r(C–N) = 1.47 Å was quoted in an early electron diffraction study[26]. The difference of 0.05 Å from the result of a reinvestigation[24] presented here can be associated with the inaccuracy of the earlier visual method.

§ The bond lengths in the benzene rings of the molecules investigated were not found to be unequal, although models with different bond lengths have been considered in structural analysis.

Table 3. Principal geometrical parameters of aromatic nitro-compounds in the gas phase.

Compound	r(N=O), Å	r(C–N), Å	r(C...C), Å	∠ONO, deg	∠$CCNO_2$C, deg	φ_{NO_2}, deg	References

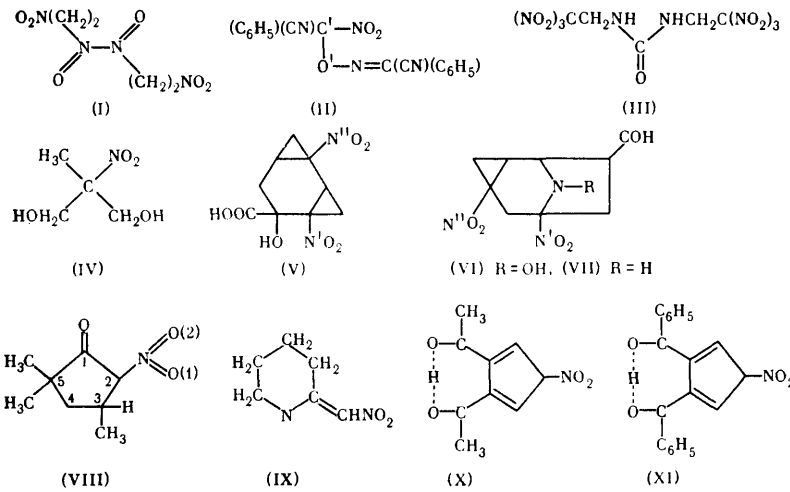
the substituents at the amino-nitrogen atom. It was found that the replacement of the CH_3 group or a hydrogen atom in methylamines by a chlorine atom or the NO_2 group leads to a marked increase of the N–N length (by approximately 0.1 Å). A planar configuration of the bonds involving the amino-nitrogen atom is observed only in the $(CH_3)_2NNO_2$ and $(CH_2Cl)CH_3NNO_2$ molecules. Moreover, whereas the dimethylnitramine molecule is planar overall†, the nitro-group in the *N*-chloromethyl-*N*-methylnitroamine molecule has been rotated by 35°. In other *N*-substituted nitroamines and nitramide (Table 1) the amino-nitrogen atom has a pyramidal configuration of the bonds. This leads to the conclusion that the configuration of the amino-nitrogen bonds depends only on the atoms and groups of atoms linked directly to the nitrogen atom. Overall, greater differences between the structural parameters are observed for *N*-nitroamines than for *C*-nitro-compounds. The complex geometrical relations for nitroamines require further study.



† Here and henceforth the term "assumed" implies that the parameter was fixed and was not varied in the minimisation process whereby the parameters were refined.

The molecular structures of *O*-nitro-compounds have been hardly investigated in the gas phase. Fairly reliable structural data have been obtained only for methyl nitrate[43]. The  molecule has the C_s symmetry and a planar skeleton with the following parameters: r(N–O) = 1.205(5) Å, r(N–O′) = 1.402(5) Å, r(C–O′) = 1.437(5) Å, ∠O′NO = 118.1(0.3)° (*cis*), ∠O′NO = 112.4(0.3)° (*trans*), and ∠CO′N = 112.7(0.3)°. Thus the parameters of the nitro-group are close to the corresponding parameters of aliphatic nitro-compounds and nitroamines.

III. THE GEOMETRICAL STRUCTURE OF THE MOLECULES OF NITRO-COMPOUNDS IN THE CRYSTAL

1. Aliphatic and Alicyclic *C*-Nitro-compounds

There have been only a few studies of aliphatic and alicyclic nitro-compounds by X-ray diffraction and their accuracy has been low in a number of instances. The structures whose parameters have been obtained with satisfactory accuracy, are presented in Table 5.

Owing to the scatter of the bond lengths and valence angles, it is difficult to compare them with the analogous compounds in the gas phase. Averaging of the geometrical parameters of the CNO_2 groups yields the following values: $r(N=O)$ = 1.21 Å, $r(C-N)$ = 1.50 Å, and ∠ONO = 124°. The average N=O and C–N internuclear distances obtained agree, within the limits of the errors, with the average values of the same distances in the compounds investigated in the gas phase; the ONO angle is somewhat smaller.

Table 5. Geometrical parameters of the CNO_2 group in a series of aliphatic and alicyclic nitro-compounds in the crystalline phase.

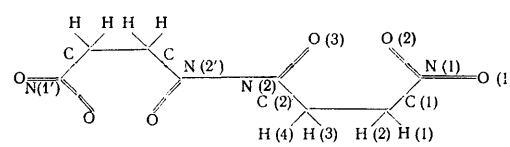
Note. The values of $r(N=O)$ in the NO_2 group are given as independent parameters which can differ both within the same group and in different groups. When the differences are small, the average value is quoted; different nitro-groups are designated by primes.



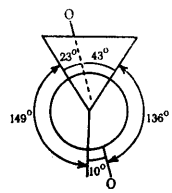
*$r(N=O)$ = 1.262(4) Å in the nitroso-group; $r(C-N_{nitroso})$ = 1.470(5) Å.

**The $N_{NO_2}CN_{NO_2}$ are 107.2(0.8)°, 107.1(0.8)°, and 104.8(0.8)°.

***The parameters of compounds (VI) and (VII) agree within the limits of the errors and average values are quoted here.

In two instances there are considerable deviations of the C–N bond lengths from the mean. An unusually long $C-NO_2$ bond [1.617(6) Å, cf. CX_3NO_2] has been found in the *o*-(phenylcyanonitromethyl)benzoylcyanoxime molecule[45], which led the authors to the conclusion that the $C-NO_2$ bond is weakened, which was confirmed by mass-spectrometric data. The $C-NO_2$ bond in 2-(nitromethylene)piperidine[51], where the nitro-group is linked to a carbon atom of the type $=C\diagup$, is shortened to 1.362(8) Å, which is smaller by 0.1 Å than in aromatic nitro-compounds. The ONO angle also is unusually small [117.7(0.6)° (the deviations of the parameters of the CNO_2 groups are not discussed by Kokkou and Rentzeperis[45])]. The nitro-group is in the *cis*-position relative to the nitrogen atom of the ring.

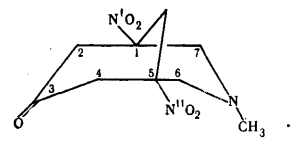
We shall consider certain conformational features of the compounds investigated. The dimer of 2-nitronitrosoethane[44]



has the *trans*-configuration with the centre of symmetry in the middle of the N–N bond. In the monomeric fragments a staggered conformation is observed with projection of the C(1)–N(1) bond approximately on the bisector of the H(4)C(2)N(2) bond. This conformation is stabilised (according to Ref.44) by intramolecular interactions between the negatively charged oxygen atom O(2) of the nitro-group and the positively charged nitrogen atom (2) and by similar interactions between N(1) and O(3). The N(2)...O(2), N(1)...O(3), O(1)...O(3), and N(1)...N(2) distances are greater than the sums of the van der Waals radii. The N–N bond length [1.304(4) Å] agrees with the value found for other nitroso-compounds, for example, *cis*-nitrosomethane (1.31 Å),[54] *p*-bromonitrosobenzene (1.31 Å),[56] and potassium dinitrososulphite (1.30 Å).[56]

The plane of the NO_2 group in *O*-(phenylcyanonitromethyl)-benzenecyanoxime[45] makes a dihedral angle of 83° with the plane of the main atomic chain C′–O′–N=C and a 75° angle with the plane of the benzene ring attached to the C′ atom.

The conformations of the $C-C(NO_2)_3$ fragments in compounds such as *N*,*N*′-bis(β,β,β-trinitroethylurea[46] and *N*-(2,2,2-trinitroisopropyl)amides of chloro- and bromoacetic acids[53] are on the whole similar to the conformations



of the trinitro-compounds investigated in the gas phase. Thus the nitro-groups in the $CH_2XC(O)NHC(CH_3)C(NO_2)_3$ molecules[53] form a propeller" configuration. A relative disposition of the nitro-groups in the $OC[NHCH_2C(NO_2)_3]_2$ molecule has been indicated such that the three N...O distances between the nitrogen and oxygen atoms of neighbouring nitro-groups are reduced to 2.56 Å compared with the sum of the van der Waals radii (2.80 Å). Other N...O and O...O distances are equal to or greater than the sum of the van der Waals radii.

For alicyclic nitro-compounds, it is important to elucidate the disposition of the nitro-group relative to the ring. The determination of the conformation of the nitrocyclopropane fragment in the 6-hydroxymethylene-1,3-dinitro-*N*-oxy-3,4-methanonortropane molecule[49] yielded the results illustrated below on a Newman projection:

The same conformation of the nitrocyclopropane fragment has been found in 6,6-dibromo-2,3 : 4,5-dimethano-2,4-dinitrocyclohexanone[54].

The relative orientations of the nitro-group and the five-membered ring in the 3,5,5-trimethyl-2-nitrocyclopentanone molecule[50] are determined by the CCNO dihedral angles, which are approximately 60°. Accordingly, the angle between the planes of the ring and of the nitro-group is 95°, i.e. the nitro-group is almost perpendicular to the cyclopentane ring. The ring has the form of a slightly twisted "half-chair" with C_1 symmetry. The nitro-group and the nearest CH_3 group are in the *trans*-positions. Different orientations of the nitro-groups relative to the bicyclononane skeleton have been observed in 1,5-dinitro-3-azabicyclo[3,3,1]nonan-7-one,[55] for which two modifications have been investigated—A (space group $P2_1/c$) and B (space group $Pccn$).

The $N'O_2$ group virtually eclipses the C(1)–C(2) bond in A and B, while the other nitro-group is perpendicular to the C(5)–C(4) bond in A and eclipses the C(5)–C(6) bond in B. Thus the molecules of modifications A and B are conformational isomers.

Table 5 also presents data for the molecules of two derivatives of 5-nitrocyclopentadiene[52]. The $C-NO_2$ bond lengths in these molecules (1.43 Å) are somewhat smaller than in nitrobenzenes (1.47 Å); the remaining parameters of the CNO_2 group are closer to the parameters of aromatic rather than aliphatic nitro-compounds. In the five-membered ring the C(3)–C(4) bond length (1.446 Å) is similar to that of the $=C-C=$ bond in cyclo-octatetraene[3], while the remaining bond lengths are the same within the limits of the errors (the average bond length is 1.396 Å). The enolic hydrogen atom is midway between the two oxygen atoms and forms a short symmetrical intramolecular O...H...O bond, the O...O distance being 2.43–2.45 Å. A fairly complex picture is observed for the anions of aliphatic nitro-compounds. The structure of mononitrocarbanions has been investigated[56–58]. The parameters of the CNO_2 group in these compounds, i.e. $r(N=O)$ = 1.25–1.32 Å, $r(C-N)$ = 1.37–1.39 Å, and $\angle ONO$ = 117–121°, are significantly altered compared with the values found for neutral nitro-compounds, which can be attributed to the distribution of the charge of the anion[57].

The nitroacetate dianion $[OOC-CH-NO_2]^{2-}$ has a planar structure[56]. The atoms of the phenylnitroacetonitrile anion[57]

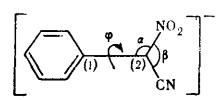


Table 6. Structural parameters of certain carbanions of the type $[R-C(NO_2)_2]$.

Note. The average values of the bond lengths (Å) and valence angles (degrees) in the $C(NO_2)_2$ group are quoted; ϕ are the angles of rotation of the nitro-group; τ is the angle of rotation of planar $C(NO_2)_2$ groups about the C–C(N) bond. The accuracy of the determination of the bond lengths is to within not more than 0.02 Å and that of the angles is to within not more than 2°; the data for a series of salts, obtained with a lower accuracy, are not included in the Table. In the salt of *N*-methyl-α,α-nitroacetamide (R = $CONH_2$) one nitro-group is coplanar with the amide group, while the other forms an angle of 53° relative to the latter[63].

are located in virtually two planes—those of the cyanonitromethyl fragment and of the benzene ring. The angle of rotation of the benzene ring relative to the $O_2N-C-CN$ plane is 17°. The angle α is increased to 130(3)°, while the angle is compressed to 111(3)°. The O...C(1) distance (2.87 Å) is then reduced compared with the sum of the van der Waals radii. It has been noted[58] that the geometry of the anion $[O_2NC(CN)_2]^-$ is very sensitive to the environment (in the present instance owing to the coordination to the Ag^+ ions).

The structure of the salts of polynitro-compounds containing a carbanion of the type $[R-C(NO_2)_2]^-$, including the trinitromethyl anion $[C(NO_2)_3]^-$ (R = NO_2), has been studied in greatest detail (Table 6). The parameters of the $C(NO_2)_2$ group in the carbanion differ significantly from those for the usual aliphatic nitro-compounds. Thus the C–N bond length is smaller by approximately 0.1 Å than the usual value and the CNC angle is unusually large (>120°). Appreciable differences have been observed for r(N=O) and ∠CNO. In many instance the N=O bond lengths were found to be unequal within the same nitro-group (by up to 0.06 Å).

As a rule, the $C(NO_2)$ group is almost planar and the rotations of the NO_2 groups relative to the plane are small (up to approximately 10°). The shortest O...O distance between neighbouring nitro-groups is approximately 2.6 Å. The increase of the "inner" CNO angles compared with the "outer" angles by approximately 6° is consistent with the hypothesis that the oxygen atoms of the two nitro-groups repel one another. The influence of the bulky substituent $(CH_3)_2CCN$, incapable of conjugation, on the deviation of the nitro-groups from coplanarity has been examined in relation to the anion of 2,2-dimethyl-1,1-dinitropropionitrile[64]. One of the nitro-groups has been rotated by the angle $\phi = 30°$ relative to the C–N bond, which the authors[64] attributed to the mutual repulsion of the oxygen atoms of this nitro-group and the atoms of the methyl group.

Studies of the salts $X[C(NO_2)_3]$ (X = N_2H_5,[46] K,[67] Rb,[61] or Cs [68]) have shown that the nitro-groups of the trinitromethyl anion are non-equivalent, two being located in virtually the same plane, while the third forms an angle relative to this plane.

General analysis of structural data for the anions of aliphatic nitro-compounds leads to the conclusion that the structure of the anion in the crystalline state is determined by a number of factors, among which crystal packing, intermolecular steric interactions, coordination, etc. play a significant role. It is noteworthy that unfortunately the accuracy of many studies of the salts of nitro-compounds has been low.

2. Aromatic Nitro-Compounds

Aromatic nitro-compounds constitute the largest group of nitro-compounds whose structure is now known (Table 7). It has been noted that, under the influence of the nitro-group, the geometry of the benzene ring changes, namely the inner angle at the carbon atom, to which the nitro-group is attached, as a rule exceeds 120°. This has been accounted for by the electron-accepting properties of the NO_2 group, which alter the hybridisation of the carbon atom[107]. The influence of various functional groups, including the nitro-group, on the geometry of the benzene ring has been most thoroughly examined by Domenicano et al.[108] and by Zvonkova[109] on the basis of a statistical analysis of extensive experimental data.

The method involving the statistical treatment of experimental data has been applied also by the authors of the present review to the analysis of parameters of aromatic nitro-compounds such as $r(C\cdots C)$ and $\angle CC_{NO_2}C$ in the benzene ring and the parameters of the CNO_2 group, i.e. r(N=O), $r(C-NO_2)$, and ∠ONO.[110] When the number of structural data is large, this approach can reveal the fundamental characteristics of the geometrical structure of the class of compounds under consideration.

In connection with the problem of the mutual influence of atoms and groups of atoms in molecules, nitro-compounds containing the amino-group or a chlorine atom as substituents, the data for which are more numerous than those for other substituted nitro-compounds, have been of special interest. Accordingly statistical analysis has been performed for three groups of compounds: group I—compounds which do not contain the NH_2 group or a Cl atom as substituents; group II—nitro-compounds with one or several amino-groups; group III—nitro-compounds with one or several chlorine atoms. The results of the statistical treatment, presented in Table 7, have led to the following findings.

Table 7. The weighted-mean geometrical parameters of aromatic nitro-compounds.

a	$r(C\cdots C)$, Å	$r(C-NO_2)$, Å	$r(C-X)$, Å	r(N=O), Å	$\angle CC_{NO_2}C$,°	$\angle CC_XC$,°	∠ONO,°

Group III—chloronitrobenzenes							
1	1.388 (4)	1.452 (2)	1.744 (7)	1.219 (4)	122.0 (0.3)	121.4 (0.5)	122.6 (1.1)
2	1.385 (7)	1.466 (6)	1.721 (7)	1.215 (8)	122.9 (0.2)	122.0 (0.4)	123.7 (0.3)
3	1.376 (3)	1.471 (2)	1.708 (3)	1.400 (4)	121.9 (0.3)	117.0 (0.2)	120.3 (0.3)
Mean	1.380 (2)	1.468 (2)	—	1.212 (4)	122.3 (0.2)	120.3 (0.8)	124 1 (0.3)

In compounds of group I the average $C\cdots C$ bond length is 1.384 Å and is independent of the number n of nitro-groups. A similar value $r(C\cdots C)$ = 1.380 Å has been observed for compounds of group III. The results of X-ray diffraction analysis do not permit a reliable conclusion concerning variation of the $C\cdots C$ bond in the benzene ring and the influence of nitro-groups, since the values of $r(C\cdots C)$ in crystalline benzene are subject to a considerable scatter: 1.378(3) Å without allowance for thermal corrections and 1.392(10) Å when the latter are taken into account[56]. Comparison with neutron diffraction data [$r(C\cdots C)$ = 1.393(7) Å] [54] indicates a slight shortening of the $C\cdots C$ bond under the influence of the nitro-groups. This conclusion follows more distinctly from the above electron-diffraction data for $C_6H_3(NO_2)_3$ in the gas phase.

It has been noted[111] that the average length of the $C\cdots C$ bonds adjoining the NO_2 group is smaller and that of the bonds adjoining the NH_2 groups is larger than in benzene. However, the average $C\cdots C$ bond length in aromatic nitroamines (group II) is the same as in benzene in the gas phase (1.399 Å).

The above observation—the increase of the inner angles in the benzene ring at the nitro-group—has been confirmed for compounds of all three groups. The angles in the benzene ring at the amino-group are less than 120° and those at

the chlorine atom are the same as in benzene within the limits of the errors.

Comparison of geometrical parameters such as $r(N=O)$, $r(C-NO_2)$, and ∠ONO shows that $r(C-NO_2)$ in compounds of group I is greater than in those of groups II and III; $r(N=O)$ and ∠ONO are similar for groups I and III and differ from the corresponding parameters for group II and in aromatic nitroamines there is a tendency towards an increase of the N=O bond length and a decrease of the ONO angle. There have been a number of studies where the authors attempted

Table 8. Geometrical parameters of the simplest derivatives of nitrobenzene, dinitrobenzene, and trinitrobenzene in the crystalline state.

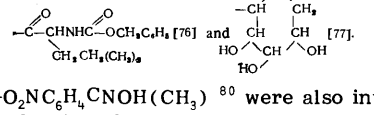
[a] There are also structural data for nitromesitylene[56] and pentamethylnitrobenzene[70].



[b] The methyl ester of o-nitrobenzenesulphonic acid $O_2NC_6H_4SOCH_3$ was investigated[54].

[c] The structure of 4-chloro-2-nitrophenol was investigated[72,73].

[d] Monoclinic modification containing two independent molecules A and B in the unit cell. Their parameters do not differ within the limits of the errors. The average values are quoted here.

[e] Here α and β represent the stable and metastable modifications respectively.

[f] The p-nitrophenyl ethers $O_2NC_6H_4OR$ were investigated with the following groups R:

[g] The structures of $O_2NC_6H_4CClNOH$ [79] and p-$O_2NC_6H_4CNOH(CH_3)$ [80] were also investigated.

[h] The unit cell contains two independent molecules A and B and the average values of their bond lengths and valence angles are given.

[i] For structural data concerning 2-chloro-5-nitrobenzoic acid, see the relevant handbook[54].

[j] The structures of o- and p-nitroperoxybenzoic acids $O_2NC_6H_4C(O)OOH$ are given in handbooks[46,54].

[k] There are data for the structures of other nitrobenzoate esters of the type $O_2NC_6H_4C(O)OR$ with more complex groups R.[68,86-89]

[l] For data on o-, m-, and p-nitroanilines and their derivatives, see Table 9.

[m] For the structures of 1-chloro(bromo)-2,4-nitrobenzenes, see the relevant handbook[54].

[n] The chloro- and bromo-derivatives were investigated[94,95].

[o] Here and henceforth the angles of rotation of different nitro-groups are given; they are the same in m- and p-$C_6H_4(NO_2)_2$.

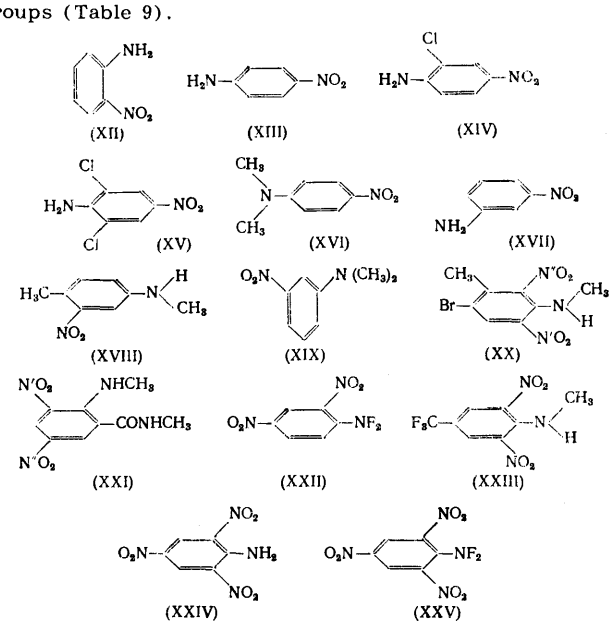
[p] The structures of several 3,5-dinitrobenzoate esters were investigated—derivatives of bicyclo-octane[46], calciferol[98,99], and toxisterol[100,101].

[q] The structure of 1,3-dichloro-2,4,6-trinitrobenzene is given in a handbook[67].

[r] I—centrosymmetric form, II—non-centrosymmetric form.

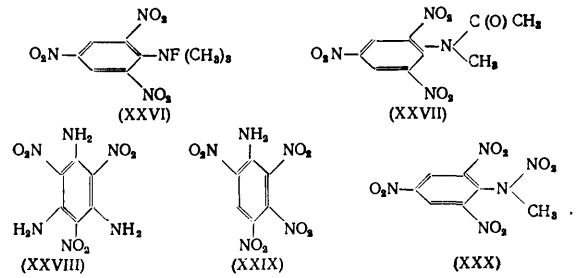
to analyse the relation between the geometrical parameters of the CNO_2 group in aromatic nitro-compounds[113–115].

It follows from Table 7 that, with increase in the number of nitro-groups in aromatic nitroamines and chloronitrobenzenes, the C–NH_2 and C–Cl bond lengths decrease.



Analysis of the conformations of aromatic nitro-compounds in the crystal leads to the conclusion that the CNO_2 groups in the majority of compounds are planar or deviate insignificantly from the plane. The average CNO valence angle in the CNO_2 group is 118°, although in many cases the two angles at the same nitrogen atom have different values, apparently due to crystal field effects.

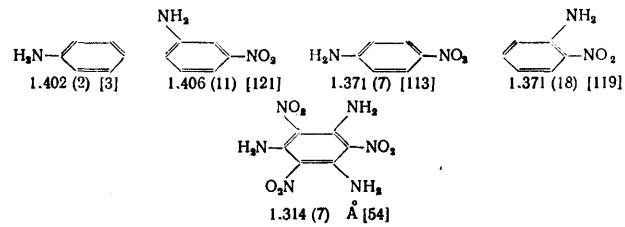
Aromatic nitro-compounds in which there are no bulky substituents next to the nitro-group have a planar or nearly planar conformation of the fragment  . Such a conformation is characteristic of *meta*- and *para*-substituted nitrobenzenes[111–116] (Table 8). In the presence of bulky *ortho*-substituents next to the nitro-group the latter rotates about the C–N bonds†. The average angles of rotation of the NO_2 groups in the absence and presence of one and two *ortho*-substituents have been calculated[116], 6°, 40°, and 63° being obtained respectively.



The question of the dependence of the C–NO_2 bond length on the angle of rotation of the nitro-groups has been discussed in the literature for a long time[117,118]. Such a dependence does not follow from the analysis of numerous experimental data[111]. Admittedly, the shortest C–NO_2 bonds refer to the CNO_2 groups having small angles of rotation, but the converse conclusion is not valid.

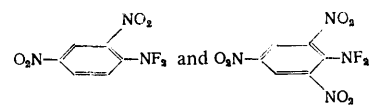
From the standpoint of the problem of the mutual influence of atoms and groups of atoms in molecules and when account is taken of the conformational characteristics, is is necessary to examine separately the structures of aromatic nitroamines, *o*-nitrophenols, polynuclear nitro-compounds, and also π-complexes of trinitrobenzene and its substituted derivatives.

The structural characteristics of aromatic nitroamines are associated with the mutual influence of the nitro- and amino-groups (Table 9).



† Primary amines and phenols, in which there is a hydrogen bond, are an exception (see below).

Analysis of data for primary aromatic amines led the authors[129] to conclude that aromatic amines without the nitro-group have the longest C–NH_2 bond lengths, amines with *para*-nitro-groups have bonds of medium length, and those with *ortho*-nitro-groups have the shortest bonds.

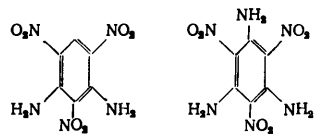


A recent X-ray diffraction study of the γ-modification of *o*-nitroaniline[119] showed that the C–NH_2 bond length in this compound is the same as in *p*-nitroaniline. An appreciable shortening of the C–Namine bonds has been observed in polynitroanilines:

Note. Here and in the other formulae the numbers in square brackets denote references (Ed.of Translation).

The shortening of the C–N_{amine} bonds is a consequence of the influence of nitro-groups in the *o*- or *p*-positions relative to the amino-group.

The substitution of the hydrogen atoms in the NH_2 group by the more electronegative fluorine atoms leads to an appreciable lengthening of the C–N_{amine} bond to 1.46 Å, as shown by a study of



The parameters of the CNO_2 group, i.e. r(C–N), r(N=O), and ∠ONO, change less than r(C–N_{amine}), which leads to the conclusion that the effect of the interaction of the NH_2 and NO_2 groups is manifested to the greatest extent by a change in the length of the C–N_{amine} bond and is small for the CNO_2 group.

The deformations of the benzene ring caused by substituents are particularly pronounced in aromatic nitroamines[108]. The $CC_{NO_2}C$ valence angle is as a rule increased, while ∠$CC_{NH_2}C$ is reduced on average by 2–3° compared with benzene. In polynitroamines the deviations of the $CC_{NH_2}C$ angles from 120° reach 5°. In *p*-nitroaniline the C⋯C bonds in the benzene ring were found to be non-equivalent, with formation of the quinonoid structure  , the $CC_{NO_2}C$ angle is 121.4(0.4)°, and the $CC_{NH_2}C$ angle is 118.9(0.4)°.

A planar configuration of the bonds involving the amino-nitrogen atom is characteristic of *m*- and *p*-nitroanilines and their derivatives. In the absence of other substituents, the

m- and *p*-nitroaniline molecules are on the whole planar. A planar structure has also been observed for the molecule of *p*-nitroaniline and polynitroamines containing adjoining nitro- and unsubstituted amino-groups, for example;

This is associated with the formation of hydrogen bonds of the type $NH_2 \ldots O_2N$.

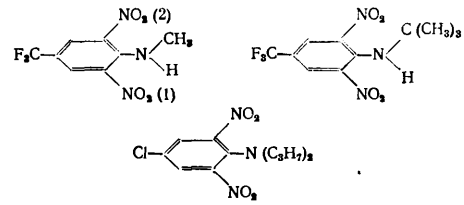
[a] For structural data on 2,6-dichloro-*N*,*N*-dimethyl-4-nitroaniline, see Ref. 54.

[b] The structure of *p*-bromo-*N*-methyl-*m*-nitroaniline is also described.

[c] Here and henceforth the average values of $r(C-NO_2)$ are given.

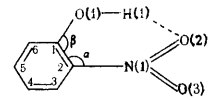


[d] The structure of Cl–C(NO₂)(N(C₃H₇)₂)(NO₂) [127] and F₃C–C(NO₂)(NHC(CH₃)₃)(NO₂) [128] were also investigated.

[e] There exist data of low accuracy (σ_r = 0.02 Å, $\sigma_\angle$ = 2°) for the 1,3-diamino-2,4,6-trinitrobenzene[67].

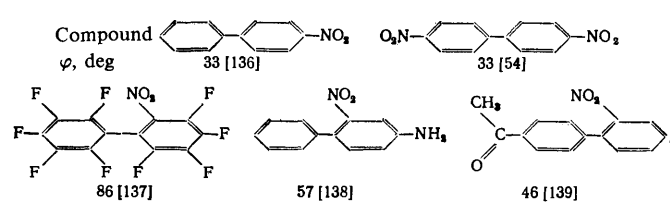
[f] The geometrical parameters of the $N(NO_2)CH_3$ group are $r(N-NO_2)$ = 1.348(4) Å, $r(N-CH_3)$ = 1.466(9) Å, and $\angle NNCH_3$ = 118.8(0.3)°; the angle of rotation of this group about the $C_{ph}-N$ bond is 65°.

[g] There are also data for β,β,β-trifluoroethyl-2,4,6-tetranitroaniline[44].



The substitution of hydrogen atoms in the amino-group by more bulky groups infringes the planarity of the molecules, as has been shown in a series of studies[126–128] of aliphatic *N*-substituted derivatives of 2,6-dinitroanilines:

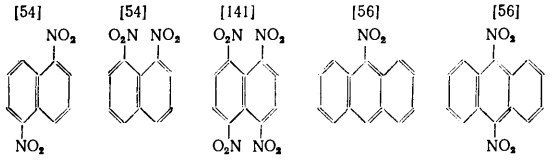
The crystals of $CF_3C_6H_2(NO_2)_2NHCH_3$ contain two types of molecules whose conformations are identical: the nitro-group (1) is almost coplanar with the ring, while the nitro-group (2), closest to the methyl group, has been rotated by approximately 50°. A similar conformation has been observed in $CF_3C_6H_2(NO_2)_2NHC(CH_3)_3$. Both nitro-groups in $ClC_6H_2 \cdot (NO_2)_2N(C_3H_7)_2$ have been rotated by approximately 52° out of plane of the ring and their planes form an angle of 83° relative to one another.



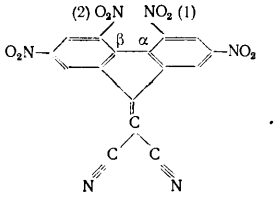
The planar configuration of the bonds involving the nitrogen atom changes to a significantly pyramidal configuration when a hydrogen atom in the NH_2 group is replaced by fluorine, i.e. in the compounds $(NO_2)_2C_6H_3NF_2$ and $(NO_2)_3 \cdot C_6H_2NF_2$. In the molecules of these compounds the nitro-groups have been appreciably rotated relative to the plane of the benzene ring.

A characteristic feature of the structure of *o*-nitrophenols (Table 8) is the formation of an intramolecular hydrogen bond between the OH and NO_2 groups. The geometry of these groups of bonds

is characterised by the following features[133]: (1) short O(1)...O(2) (2.55–2.60 Å) and H...O(2) contacts; (2) small (∠14°) angles of twist τ for rotation about the O(1)–C(1) and C–N bonds; (3) large NCC(α) and CCO(β) angles. As a rule, the N=O bonds of the nitro-group adjoining the OH group are also found to be non-equivalent: the N(1)=O(3) bond is shorter than the N(1)=O(2) bond involved in the formation of a hydrogen bond. A detailed analysis of the bond lengths in *o*-nitrophenols and nitrophenoxides has been carried out[134].



Polynuclear aromatic nitro-compounds—derivatives of biphenyl and condensed aromatic hydrocarbons—have a number of conformational characteristics. According to numerous structural data, the most significant conformational distortion of the molecules of biphenyl and its derivatives consists in the rotation (by an angle φ) of one benzene ring relative to the other about the $C_{benz}-C_{benz}$ bond[135]. The following data are available for crystalline nitrobiphenyl derivatives:

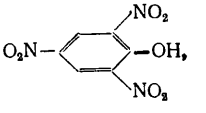


These show that the maximum angle of rotation of the ring

ϕ_{C-C} is observed in 2-nitrononafluorobiphenyl[137]#. The angle of rotation of the nitro-group in the same compound is also large (56°). A virtually coplanar disposition of the nitro-groups and the benzene ring has been noted in compounds with *p*-nitro-groups, i.e. the conformation is the same as for *p*-substituted benzene derivatives. For example, the angle of rotation of the NO_2 group in 4-nitrobiphenyl is 2°, while those in 4,4'-dinitrobiphenyl are 0° and 11°. The length of the $C_{benz}\cdots C_{benz}$ central bond in nitrobiphenyl derivatives is the same as in biphenyl (1.49 Å).

The steric hindrance in the molecules of nitro-compounds with condensed benzene rings

leads to larger angles of rotation of the nitro-groups relative to the plane of the ring and to deformations of the outer valence angles[135]. For example, the nitro-groups in 1,5-dinitronaphthalene have been rotated by 49°, those in 9,10-dinitroanthracene have been rotated by 64°, etc. The steric hindrance in 1,8-dinitronaphthalene causes the rotation of the nitro-groups by 43° relative to the plane of the ring, the displacement of the nitrogen atoms from this plane by 0.4 Å, and the deformation of the NCC valence angles by approximately 3°. The proximity of nitro-groups (1) and (2) in the 9-dicyanomethylene-2,4,5,7-tetranitrofluorene molecule[142] leads to the rotation of these groups by 35° and to an increase of the angles α and β to 123° and 134° respectively:

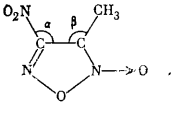


Thus in the analysis of the molecular structure of polynuclear nitro-compounds it is necessary to take into account steric factors, which frequently play a decisive role in the geometry of compounds of this class.

Unsubstituted and substituted polynitro-compounds form a series of complexes with aromatic hydrocarbons, quinhydrone, and aromatic iodo-hydrocarbons[143]. The crystal chemistry of molecular donor–acceptor π-complexes, including those of *sym*-trinitrobenzene, has been reviewed[144]. According to X-ray diffraction data, complex formation does not alter or hardly alters the molecular geometry of the donor and acceptor. In all the π-complexes of *sym*-trinitrobenzene its benzene ring is planar within the limits of experimental error, but in certain complexes, for example in the complex with acepleiadylene[68], there are slight deviations of two carbon atoms from the average plane of the benzene ring. The nitrogen atoms are also virtually in the plane of the ring. The nitro-groups are as a rule rotated by small angles (on average by 4°, at most by 18°), the angles being determined by steric effects, the packing requirements, the interaction of the donor and acceptor, etc.

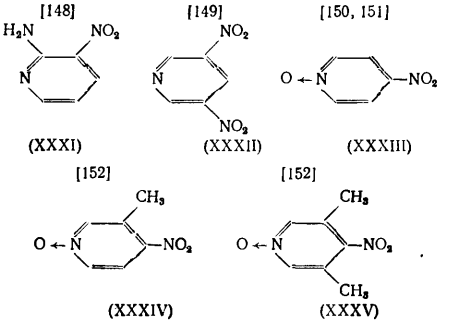
The principal geometrical parameters of *sym*-trinitrobenzene in the complexes, such as *r*(C–N), *r*(C$\cdots$C), ∠ONO, and ∠CCC (according to the most accurate experimental data)[54], do not vary as a function of the donor. The significant scatter of the values of *r*(N=O) may be associated with the appreciable thermal vibrations of the nitro-group.

For the complexes of substituted trinitrobenzene derivatives, the above factors influencing the rotation of the nitro-group relative to the plane of the benzene ring are supplemented by the influence of the substituent and, as a rule, the angle of rotation of the nitro-groups in the *o*-positions relative to the substituent is much greater than for the nitro-groups in the *p*-positions.



The characteristics of the structure of picric acid

which are analogous to those observed for *o*-nitrophenols and are due to the formation of an intramolecular hydrogen bond, persist in its π-complexes. The donors in these complexes are anthracene[145], pyridine[146], and 2-amino-1-bromonaphthalene[61].

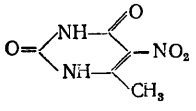


3. Heterocyclic and Organoelemental Nitro-Compounds

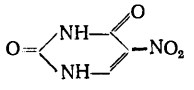
The heterocyclic nitro-compounds investigated are fairly varied. The nitro-group in 3-methyl-4-nitrofuroxan[147] is linked directly to the five-membered ring:

The close proximity of the NO_2 and CH_3 groups leads to conformational distortions: α = 125.7°, β = 135.3°, and ϕ_{NO_2} = 17°. The heterocyclic ring is planar with distorted valence angles. The parameters of the CNO_2 group are the same as in aromatic nitro-compounds.

The structures of derivatives of nitropyridine have been studied in greatest detail:



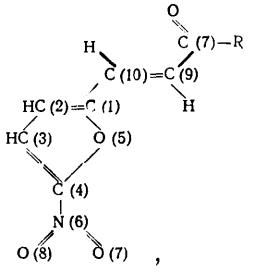
In the 2-amino-3-nitropyridine (XXXI) molecule, where the nitro-group adjoins the amino-group, one may note a decrease of *r*(C–NH_2) to 1.336 Å, similar to that observed for aromatic



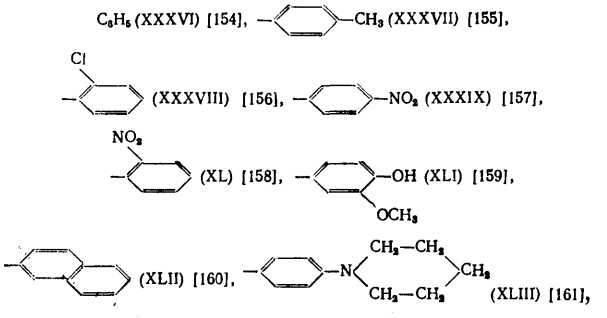
In 6,6'-dinitrophenyl-2,2'-dicarboxylic acid, which has been recently investigated[140], the angle of rotation of the rings is 71° and the angle of rotation of the *o*-nitro-groups is 30°.

nitroamines, and a slight shortening of the C–NO_2 bond to 1.440 Å. The $C_{NH_2} \cdots C_{NO_2}$ bond in the pyridine ring (1.412 Å) is somewhat longer than the other bonds in the ring (1.33–1.39 Å), while the amino-group is planar. There is an intramolecular NH...ON hydrogen bond and in the crystal the molecules are linked by NH...N_{ring} hydrogen bonds.

The molecules of 3,5-dinitropyridine (XXXII) and 4-nitropyridine *N*-oxide (XXXIII) are planar. In contrast to compound (XXXIII), the molecules of derivatives of 4-nitropyridine oxide (XXXIV) and (XXXV) are non-planar. In compound (XXXIV) the rotation of the nitro-group adjoining the CH_3 group is slight (approximately 17°). In compound (XXXV) two methyl groups are in the *ortho*-positions relative to the NO_2 group, and the angle ϕ_{NO_2} has increased to approximately 50°. It is of interest that the introduction of only one methyl group next to the nitro-group in 6-methyl-5-nitrouracil[153]



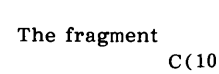
leads to the rotation of the latter by approximately 40°. The molecule of 5-nitrouracil[67]



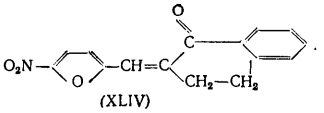
is planar.

Thus the influence of the heterocycle in the heterocyclic nitro-compounds examined hardly affects the parameters of the CNO_2 group: they are the same as for aromatic nitro-compounds.

The structure of nitrofuranylpropenes having the general formula

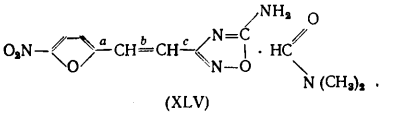


where R is



has been studied in a series of investigations[154–161].

The $C-NO_2$ bond in the CNO_2 group linked to the furan ring is shorter (1.42 Å) than in aromatic nitro-compounds on average by 0.05 Å. A slight non-equivalence of the CNO angles has been noted, but it does exceed the experimental error, the angle C(4)N(6)O(7) being greater than the angle C(4)N(6)O(8) by 2–3°. The outer angles which the nitro-group makes with the furan ring, namely ∠C(3)C(4)N(6) and ∠O(5)C(4)N(6), are respectively 130° and 117°. On the whole, the parameters of the furan ring in the compounds considered differ only slightly from those found for the furan molecule in the gas phase[3], but the ring symmetry C_2 is altered.

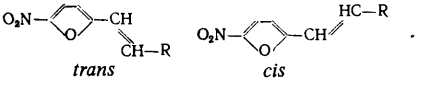


The fragment  has a cisoid configuration in the majority of compounds. The molecules of compounds (XXXVI), (XXXVII), (XXXIX), and (XLII) are planar. The non-planarity of the molecules of compounds (XXXVIII), (XL), (XLI), and (XLIII) arises only as regards the substituent R.

The series of studies examined above includes also an investigation of the molecule of compound (XLIV):[162]

(XLIV)

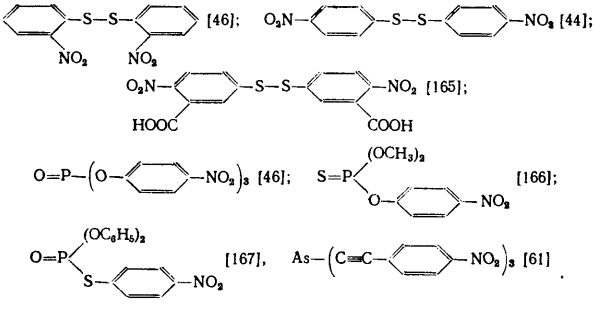
and of the complex (XLV)[163]



(XLV)

The parameters of the nitrofuran fragment in compounds (XLIV) and (XLV) are analogous to those discussed above. The bonds *a*, *b*, and *c* in the planar molecule of *trans*-5-amino-3-[2-(4-nitro-2-furyl)vinyl]-1,2,4-oxadiazole in complex (XLV) have the *trans*-configuration.

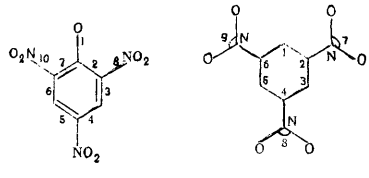
The structure of derivatives of 5-nitro-2-vinylfuran



where R = $SO_2C_6H_4Cl$, $SO_2C_6H_4CH_3$, or $N(CH_3)_2$, has been investigated[164]. It has been noted that the conformation of these compounds depends on the nature of the substituent R: the *trans*-structure is preferred for compounds with electron-accepting substituents and the *cis*-structure is preferred for those with electron-donating substituents.

trans *cis*

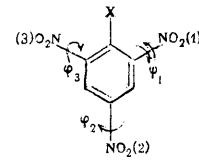
The available structural data for organoelemental nitro-compounds are limited. The following nitro-derivatives of sulphur, phosphorus, and arsenic compounds have been studied:



No significant deviations from the general rules governing the structure of aromatic nitro-compounds have been observed in the aromatic nitro-component.

4. Anions of Aromatic Nitro-Compounds

Changes in the geometrical parameters of the aromatic nitro-fragment have been observed in aromatic nitro-anions compared with the neutral molecules. Thus the N=O bond lengths are greater and the ONO angles are reduced to less than 120° in a series of anions. The shortening of the $C-NO_2$ bond by 0.05–0.07 Å has been noted in picrates, phenoxides, Meisenheimer salts, and certain other anions. It is believed[168] that the decrease of the length of this bond depends on the stronger interaction between the NO_2 group and the ring. The $CC_{NO_2}C$ angles in the aromatic rings of 4-hydroxy-5,7-dinitrofurazan anions[168] and in the corresponding Meisenheimer salt involving one of the nitro-groups are not increased, as is usually the case, but are actually reduced to 118.5°, which is probably associated with the influence of the furazan ring[169]. In these compounds both nitro-groups are virtually coplanar with the ring, despite the presence of the *ortho*-substituent.



The bond lengths and valence angles in nitrophenoxides and picrates have been analysed[134] and a significant alteration of the geometry of the benzene ring in the anion has been demonstrated: bonds 2 and 7 of the C···C type have been lengthened to 1.45 Å, the CCC angle between these bonds has been reduced to 112°, and the bond lengths $r(C-O)$ and $r(C-NO_2)$ have also been altered (Table 10).

Table 10. The weighted-mean values of the parameters of nitrophenoxides and picrates (averaged with respect to 12 molecules).

Type of bond	r, Å	Type of angle	Angle, deg	Type of bond	r, Å	Type of angle	Angle, deg
1	1.248	1	111.8	6	1.370	6	124.1
2	1.451	2	123.8	7	1.444	7	121.6
3	1.373	3	119.6	8	1.452	8	122.6
4	1.380	4	121.2	9	1.445	9	120.7
5	1.384	5	119.3	10	1.443		

An interesting conformational feature has been noted on comparing the angles of rotation of the nitro-groups in picryl halides and their complexes as well as picrates[170]. It was found that in some of the compounds indicated, particularly in potassium and ammonium picrates, the nitro-groups (1) and (3) rotate in the same direction and the molecules have the C_2 symmetry with $\phi_1 = \phi_3$. In other compounds, for example, in complexes of picryl bromide with fluoranthene and pyrene, the nitro-groups (1) and (3) rotate in opposite directions and the molecular symmetry is C_S.

Comparison of the anions of aliphatic and aromatic nitro-compounds shows that the geometry of the anions of aliphatic nitro-compounds is on the whole altered less relative to neutral molecules.

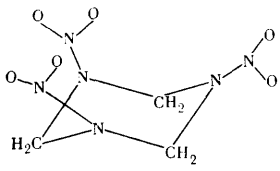


Table 11. The bond lengths (Å) and the valence angles (deg) in the nitroamino-groups in the molecules of cyclic nitro-amines*.

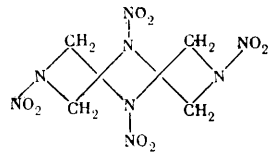
*Each row in the Table corresponds to one of the $CNNO_2$ groups.

5. *N*-Nitro- and *O*-Nitro-Compounds

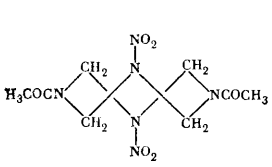


A series of *N*-nitro- and *O*-nitro-compounds, among which cyclic nitroamines occupy the principal place (Table 11), have been studied in the crystalline state.

(XLVI)

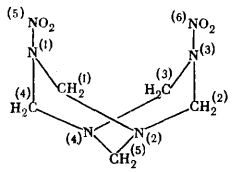
(XLVIIa)

(XLVIIб)



The six-membered ring of the molecule of hexogen (XLVI) has the chair conformation with two N–N bonds (1.41 Å) almost parallel with one another and approximately perpendicular to the average plane of the ring atoms; the third N–N bond (1.35 Å) is located in this plane. The molecular symmetry is C_1. The angle by which the N–N bonds are displaced from the C–N–C plane are 21.5°, 33.0°, and 32.4°. We may note that in solution the hexogen molecule has the C_3 symmetry ($\gamma = 0°$).[176]

Four crystalline modifications (α, β, γ, and δ) of octogen (XLVII) are known. The structures of α-, β-, and γ-octogens have now been determined. The crown conformation has now been established for the molecule of α-octogen (XLVIIa). Two nitroamino-groups have the equatorial conformation, while two others have the axial conformation. The planes of the neighbouring nitroamino-groups are almost perpendicular to one another. The dihedral CNNO angles are 4° and 10°.



The crystal structure of β-octogen (XLVIIb) was first investigated by X-ray diffraction in 1955 [56] and was revised in 1963.[54] In 1970 the crystal structure of β-octogen was investigated by neutron diffraction[46] and it was established that the eight-membered ring of this compound has the twisted chair configuration. The $CNNO_2$ fragments of the molecule are almost planar (the dihedral CNNO angles are 0° and 10°). The angles by which the N–N bonds are displaced from the CNC planes are 4° and 17°. The two neighbouring nitroamino-groups are located in mutually perpendicular planes. In the methylene groups the HCH plane is perpendicular to the NCN plane. All the hydrogen atoms are close to the neighbouring oxygen atoms and some of them form intramolecular and intermolecular hydrogen bonds of the type CH...O.

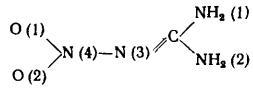
The δ-octogen molecule resembles that of α-octogen. The $C_2N–NO_2$ groups are almost planar; the four carbon atoms of the ring lie in the same plane; the axis perpendicular to this plane is a twofold axis (we may note that the α-octogen molecule has a C_2 crystallographic symmetry). The study of the complex of octogen with dimethylformamide (DMF) [174] showed that its octogen molecule has a C_2 crystallographic symmetry and is similar in form to the molecules of the α- and δ-modifications. It is characterised by parameters which are comparable to those found for α-, β-, and δ-octogens. The nitroamino-groups are almost planar.

The structure of 1,5-diacetyl-3,7-dinitro-1,3,5,7-tetra-azacyclo-octane (XLVIII) has been determined[175].

(XLVIII)

(XLIX)

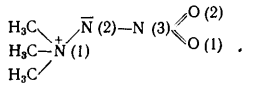
As for β-octogen, the same C_1 molecular symmetry and twisted chair conformation have been established. The C and O atoms of the $COCH_3$ group and the NO_2 group are located in the same plane with the nitrogen atoms to which they are attached. The bond lengths and valence angles in the molecule of compound (XLIII) are close to those found for α-, β-, and δ-octogens.



The cyclic nitroamine 3,7-dinitro-1,3,5,7-tetra-azabicyclo-[3,3,1]nonane (XLIX) [176] is an intermediate in the synthesis of octogen and hexogen. The molecule of this compound contains the eight-membered C,N-ring of octogen and the six-membered C,N-ring of hexogen. The two NNO_2 groups are planar. The dihedral angles between the NNO_2 and CNN planes are 26° and 34°. The molecule has an approximate plane of symmetry passing through the N(5), N(1), C(5), N(3), and N(6) atoms. The molecule is structurally more similar to hexogen than to octogen. Table 11 shows that the C–N bonds in the nitroamino-groups of compound (XLIX) are longer by 0.02–0.05 Å than in octogen and hexogen. The CNC angles, which are on average 115.6°, are much smaller than the corresponding angles in octogen, but agree with the angles in hexogen.

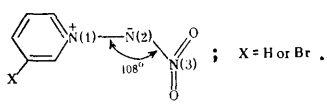
There are a number of structural data for open-chain nitroamines: NH_2NO_2;[56] $(CH_3)_2NNO_2$,[56] and $O_2NNHCH_2CH_2.NHNO_2$.[61] The structures of nitroamine and dimethylnitroamine have been investigated with a low accuracy. The NH_2NO_2 molecule is planar in the crystal, in contrast to the gas phase. In the crystalline state dimethylnitroamine has the same planar molecular configuration as in the gas phase, but the N–N bond length is greatly reduced [1.25(5) Å]. $CNHNO_2$ groups in the *N,N'*-dinitroethylenediamine molecule are planar, but the molecule as a whole is non-planar with a dihedral angle of 84° between the CCN and CNN planes. The N–N bond length is 1.301(4) Å.

A planar configuration of the amino–nitrogen bonds is characteristic of two *N*-substituted derivatives of tetranitroaniline (Table 9). The N–N bond length in *N*-methyl-*N*,2,4,6-tetranitroaniline (tetryl)[67] is 1.35 Å and the $N\begin{smallmatrix}NO_2\\CH_3\end{smallmatrix}$ group has been rotated relative to the plane of the benzene ring by 65°. The N–N bond in *N*,*N*-(β,β,β-trifluoroethyl)-*N*,2,4,6-tetranitroaniline[44] is longer than in tetryl (1.41 Å) and the angle of rotation of the group $-N\begin{smallmatrix}NO_2\\CH_2CF_2\end{smallmatrix}$ relative to the plane of the ring is 86°.



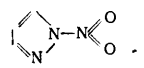
The planarity of the $-C\begin{smallmatrix}\diagup\\\diagdown\end{smallmatrix}N–NO_2\begin{smallmatrix}\diagdown\\\diagup\end{smallmatrix}C-$ group with $r(N–N)$ = 1.357(5) Å in 2,2'-dinitratoethylenenitroamine $O_2NN(CH_2CH_2.ONO_2)_2$ [177] has been established by X-ray diffraction. Other parameters of this molecule are discussed below.

The structures of a number of *N*-nitro-compounds which do not belong to the class of nitro-amines have also been studied. The nitroguanidine molecule[56]



is planar with an N–N bond length of 1.35(1) Å. The steric hindrance arising between the N(1) and O(1) atoms increases the O(1)N(4)N(3) and N(1)CN(3) valence angles to 124° and 129° respectively. The remaining angles do not deviate from the usual values.

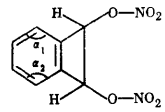
The structure of trimethylammonium nitroamidate, which is an ylid, has been investigated[178]. The N(1)–N(2) bond length [1.47(1) Å] in this molecule is close to that found in hydrazine (1.45 Å), i.e. it is a single bond.



On the other hand, the bond lengths in the N–NO_2 fragment have unusual values: r(N–NO_2) = 1.32(1) Å [longer than the N=N double bond (1.25 Å) but shorter than the N–N bonds in nitroamines]; the N=O bond length [1.26(1) Å] exceeds somewhat the values usual for the NO_2 group. The authors[178] believe that this occurs owing to the considerable delocalisation in the charge in the nitro-group. The N(1)N(2)N(3)O(1) dihedral angle is approximately 0°.

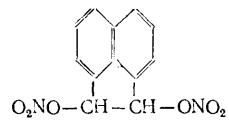
In 1974 a large group of investigators published structural data for two representatives of heterocyclic *N*-nitroimides–pyridine 1-nitroimide and its bromo-derivative[179].

In these compounds the $\overset{+}{N}-\overset{-}{N}-NO_2$ system is almost planar and the dihedral angle relative to the plane of the ring is 72° for unsubstituted pyridine 1-nitroimide and 78° for its bromo-derivative. The bond lengths r(Å) are 1.42, 1.34, and 1.25 for N(1)–N(2), N(2)–N(3), and N=O respectively. Compared with the $(CH_3)_3\overset{+}{N}-\overset{-}{N}-NO_2$ system, the N(1)–N(2) bond is considerably shorter, the N(3)–N(4) bond is lengthened, and the NNN angle is reduced. We may note that the N(2)–N(3) bond length in this compound is close to r(N–N) in cyclic nitroamines. *N*-Nitropyrazole[180] also belongs to the class of compounds containing the N–NO_2 bond.



The molecule is planar and the N–NO_2 bond length (1.399 Å) and the ONO angle (128.5°) are somewhat increased relative to the average values of these parameters in crystalline nitroamines. The N–C (1.364 Å), N=C (1.315 Å), C=C (1.341 Å), and C–C (1.407 Å) bond lengths in the pyrazole ring differ from the corresponding bond lengths in unsubstituted pyrazole[3] by 0.01–0.03 Å.

Few X-ray diffraction data are available for *O*-nitro-compounds. The compound $O_2NN(CH_2CH_2ONO_2)_2$, which has been investigated[177], contains both the N–NO_2 and O–NO_2 groups with bond lengths of 1.357(5) and 1.399(6) Å respectively. The O=N=O angle in the nitroxy group (approximately 130°) is much greater than in the nitroamino-group (125°). The atoms of the molecule are located in three planes: one plane contains the atoms of the nitroamino-group $O_2N-N\begin{matrix}C\\C\end{matrix}$ and the other two planes contain the atoms of the $CONO_2$ groups.



Two crystalline modifications of pentaerythritol tetranitrate $C(CH_2ONO_2)_4$ have been investigated—the low-temperature[54] and high-temperature[181] modifications. The geometrical parameters of the $CONO_2$ groups in both forms are close to the corresponding parameters of the CH_3ONO_2 molecule.

X-Ray diffraction analysis confirmed that the high-boiling isomer of benzocyclobutene 1,2-dinitrate[146] has the *cis*-configuration:

An interesting feature of the structure of this compound is the reduction of two angles in the benzene ring (α_1 and α_2) to 115°. Similar deformations of the angles have also been noted for other benzocyclobutene compounds. The bond common to the two rings (1.363 Å) has been shortened by approximately 0.02 Å relative to the average $(C\cdots C)_{benz}$ bond length, which is 1.383 Å. The length of the C(1)–C(2) bond in the cyclobutene ring is 1.561(5) Å. The nitrate groups are planar and have been rotated relative to the plane of the ring by 53° and 71°.

The dinitrate of *cis*-acenaphthene-1,2-diol

has a similar structure. The planar nitroxy-groups in this compound are inclined to the plane of the carbocyclic ring at angles of 62° and 72°.

In conclusion of this section we should note that in the cyclic nitroamines investigated the configuration of the bonds involving the nitrogen atom is planar or nearly planar. The average parameters are presented below (r in Å; the angles are expressed in degrees):

r(N=O)	r(N–N)	r(N–C)	∠CNO	∠CNC
1.221	1.367	1.463	124.9	119.3

In nitric acid esters the nitrate groups C–O(1)–N$\begin{matrix}O(2)\\O(3)\end{matrix}$ are as a rule planar with the following parameters:

r(N=O)	r(N–O(1))	r(C–O)	∠O(2)NO(3)	∠O(1)NO(2)	∠O(1)NO(3)
1.20	1.40	1.45	130	117	112

The differences between the O(1)N=O angles, which are outside the limit of the experimental error, have been explained by the steric repulsion of the C and O(2) atoms.

IV. CONCLUSION

Inspection of the combined data on nitro-compounds shows that there are distinct differences in the geometries of the NO_2 group in molecules of compounds of different classes. The N=O bond lengths vary in the range 1.20–1.24 Å with an average of 1.22 Å and the ONO valence angles vary in the range 123–133° with an average of approximately 128°. The minimum ONO angles are observed in molecules of aromatic nitro-compounds and nitroamines, while the maximum values are observed in molecules of aliphatic and alicyclic nitro-compounds. This is apparently associated with the fact that in aromatic nitro-compounds and nitroamines carbon atoms or amino-nitrogen atoms with a planar bond system are linked to the NO_2 group. The tendency towards an overall planar configuration of the NO_2 group and the groups linked to it in these molecules gives rise to a steric strain, which leads to a decrease in the ONO angle.

Analysis of structural data on aliphatic and aromatic nitro-compounds leads to the conclusion that the C–N bond lengths in the molecules of aliphatic compounds (average

1.51 Å) are greater by 0.03–0.04 Å than in the molecules of the aromatic compounds (average 1.47 Å). Similar variations are observed also in the C–C(=O)R bond lengths. The lengths of the >C–C(=O)R bonds are greater than those of >C–C(=O)R (or >C–C(=O)R) bonds by 0.03 Å.

Previously, when only a limited amount of data on the structure of nitro-compounds was available, it was noted that the lengths of different types of >C–NO_2 and >C–NO_2 bonds are equal[36]. Nowadays this conclusion must be regarded as erroneous.

Statistical analysis of the C–N bond lengths and ONO valence angles indicates a correlation between these quantities. With increase of the ONO valence angle, the C–N bond length as a rule also increases.

The planar conformation of nitroamines and aromatic nitro-compounds, in which there are no appreciable steric interactions, confirms the idea that the nitro-group is conjugated with the amino- and phenyl-groups. This is also confirmed by the finding that the amino-nitrogen atom has a planar bond configuration in contrast to the pyramidal bond configuration in the simplest amines. The effects due to the transmission of influences through the benzene ring to the *para*-position have also been observed in aromatic nitro-compounds. Steric interactions lead to the breakdown of the planar conformation of the >N–N(=O)=O and >C–N(=O)=O fragments. It is noteworthy that the >C–N(=O)=O bond length has not yet been found to vary with the angle of rotation about the C–N bond.

In aliphatic compounds the NO_2 group also influences the neighbouring bonds, but is nature is somewhat different. The conformations of the molecules of aliphatic nitro-compounds depend to a large extent on the type of groups attached to the carbon atom and on the number of nitro-groups. For a deeper understanding of the characteristics of the geometrical structure of the molecules of nitro-compounds, systematic studies are necessary.

The Charge-transfer Complexes of Neutral Donors with Organic Cations as Acceptors

V.E.Kampar

The principal results of studies on charge-transfer π-complexes (CTC) with an organic cation (carbonium, heteroaromatic, and hetero-onium) as the acceptor are examined and problems of the classification of the CTC on the basis of the structures of the ground and excited states are discussed. The thermodynamic and spectroscopic data for the type of CTC considered are analysed. The results of the determination of the electron affinities of the acceptor cations are examined and surveyed. Ideas concerning the photochemical properties of the CTC or arenediazonium ions, which are of interest as materials for the recording of information, are described.
The bibliography includes 101 references.

I. INTRODUCTION

The chemistry and physics of charge-transfer complexes (CTC) now constitute in many respects an independent field, which is closely related to a number of other fundamental scientific disciplines as well as practical applications[1]. Despite the fairly large number of reviews and books on this field[2-12], some types of the CTC have been described extremely superficially. These include also the CTC formed by a neutral electron donor and an acceptor cation. Although the specific conductances of crystalline CTC of this type[13-15] are fairly low, one cannot claim that their interaction is of no practical interest. It is known that many acceptor cations are directly involved in important biological processes[4] or exhibit a pronounced biological activity[12,13,16,17]. Charge-transfer complexes with a nitronium cation are considered as intermediates in the nitration of aromatic compounds[18,19] and the CTC of diazonium salts are believed to be a possible means of improving the light sensitivity of photographic materials[20,21]. From this, it follows that the comparatively little investigated type of CTC formed between a neutral π-donor and an acceptor cation is fairly interesting also from the practical point of view.

The aim of the present review is to examine the general characteristics of the formation of the CTC of this type; particular attention has been devoted to the electron affinities of the acceptor cations and the photochemical properties of the CTC of diazonium salts. The complexes between aromatic hydrocarbons and metal cations are not considered

here; the readers interested in this problem are recommended to refer to the interesting monograph of Mulliken and Person[5].

II. THE ENERGY LEVEL SCHEMES AND THE CLASSIFICATION OF THE CHARGE-TRANSFER COMPLEXES

The formation of CTC is usually accompanied by the appearance of one or several new bands in the electronic absorption spectrum. These bands are referred to as the charge-transfer (CT) bands and are due to the intermolecular electronic transition on excitation of the CTC. Despite the fact that the presence of CT bands in the spectrum is not in general proof of the formation of a thermodynamically stable CTC and their absence does not rule out the formation of such a complex, nevertheless CT bands are the most characteristic feature of the absorption spectra of CTC. The charge-transfer energy depends on the ionisation potential of the donor $IP(D)$, the electron affinity of the acceptor $EA(A)$, and the stabilisation energies of the ground and excited states of the CTC.[5] The electronic transitions for different components of the CTC can be represented schematically as follows:

$$D, A \xrightarrow{h\nu_{CT}} D^{+}, A^{-} \qquad (I)$$

$$D, A^{+} \xrightarrow{h\nu_{CT}} D^{+}, A^{\cdot}. \qquad (II)$$

The fundamental differences between the stabilisation energies of the CTC formed by two neutral molecules [reaction (I)] or an ion and a neutral molecule [reaction (II)] follow from this approximate scheme. In the first place the excited state is stabilised by the strong Coulombic interaction of the oppositely charged species, while in the second case this does not occur. The different structures of the ground and excited states of the above CTC make it possible to refer them to two separate types of CTC.[22] The energy levels arising on their formation are presented in Fig.1. Weak CTC, in the formation of which the contribution of the CT forces is insignificant, are considered in both cases.

The CT energies for CTC of both types in the gas phase are expressed by the following equations:

$$h\nu_{CT}(D, A) = IP(D) - EA(A) + (W_0 - E_c) + (R_N + R_E), \qquad (1)$$

$$h\nu_{CT}(D, A^{+}) = IP(D) - EA(A^{+}) + (W_0' - W_1) + (R'_N + R'_E), \qquad (2)$$

where W_0, W'_0, W_1 are the stabilisation energies of the ground and excited states as a consequence of all the types of interaction with the exception of the interaction via the charge-transfer pathway, E_C is the Coulombic interaction energy of the oppositely charged species, and R_N, R_E, R'_N, and R'_E are the energies of stabilisation or destabilisation as a consequence of the interaction of the configurations without charge transfer and with complete charge transfer in the ground (N) and excited (E) states respectively. Assuming that for a weak CTC the sums $R_N + R_E$ and $R'_N + R'_E$ are small and approximately equal, we conclude that the constant terms in Eqns.(1) and (2) are largely determined by the differences $W_0 - E_C$ and $W'_0 - W_1$ respectively. The upper limit to the quantity W_0 is set by the experimental ΔH, which do not exceed 0.5 eV for the CTC of tetracyanoethylene with methylbenzenes and naphthalene in the gas phase[10]. According to theoretical estimates[5], the quantity E_C exceeds somewhat 3 eV. Thus $W_0 - E_C \cong -3$ eV and we obtain from Eqn.(1)

$$h\nu_{CT} \simeq IP(D) - EA(A) - 3 \ \text{(eV)},$$

which agrees fairly well with experiment[23]. When a CTC is formed between an ion and a neutral molecule, one can assume that $W_0 \geq W_1$ and the CT energy in the gas phase is approximately expressed by the equation

$$h\nu_{CT} \simeq IP(D) - EA(A^{+}) + E_{II}, \qquad (3)$$

where $E_{II} \geq 0$. According to the Franck–Condon principle, the energy is higher in solutions (Fig.1).

Thus the $h\nu_{CT}$ in the two cases examined differ greatly, the difference seeming more appreciable than the changes arising as a consequence of the difference between the types of the interacting boundary orbitals of the components (m, σ, π, etc.) for both types of CTC considered. The distinctive features of the CTC having different ground and excited states are also manifested directly in the experiment. For example, it has been established[24] that the CT energy and the formation constants of CTC vary differently with increasing pressure depending on whether the CTC are formed by neutral molecules, a neutral molecule and an ion, or two oppositely charged ions.

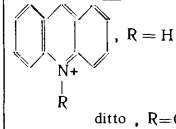
Because of the reasons described above, we believe it useful to classify the CTC beginning with the structures of the ground and excited states having specified three main types: (1) CTC between neutral molecules (D, A); (2) CTC between an ion and a neutral molecule (D^{-}, A and D^{+}, A); (3) CTC between oppositely charged ions (D^{-}, A^{+}). Within the limits of these types, further classification can be achieved in conformity with the type of interacting orbitals[5] and, within the limits of the resulting subtypes, also in terms of the classes of the compounds.

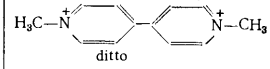
III. GENERAL INFORMATION ABOUT THE SPECTROSCOPIC AND THERMODYNAMIC PROPERTIES OF THE CHARGE-TRANSFER COMPLEXES BETWEEN A NEUTRAL π-DONOR AND AN ORGANIC CATION AS AN ACCEPTOR

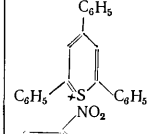
During the period since the publication of the first studies on the CTC of the type considered[25], a comparatively small amount of experimental data has accumulated. However, the date are sufficient to reach a number of conclusions, which is facilitated by the availability of the results of analysis of extensive experimental data on the CTC between neutral species[1–12].

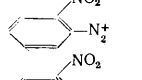
It has been observed that organic cations of different classes of compounds are capable of forming CTC with neutral π-donors. The cations include carbonium ions (tropylium, triphenylmethyl, and diphenylmethyl cations), heteroaromatic ions (protonated and alkylated N-heterocycles, derivatives of pyrylium and thiopyrylium), and hetero-onium ions (diaryliodonium and arenediazonium ions). So far it is not altogether clear what causes the complex-forming capacity of diaryliodonium ions, since only the formation of their CTC with aromatic amines[26], which are capable of utilising their l orbitals for the interaction, has been reported. For the remaining cations, the CTC with pure π-donors have also been studied.

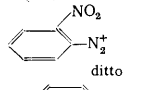
The complex-formation constants K of CTC in solution are usually low and vary in the range 1–10 litre mol^{-1} depending on the properties of the CTC components and the solvent (Table 1). The individual instances where the constants K are much greater than 10 litre mol^{-1} are either associated with specific conditions promoting complex formation or can be accounted for by experimental difficulties in their correct determination[10].











In most cases the constants K for neutral donor–cationic acceptor CTC are similar to those for weak $\pi-\pi$ CTC of neutral molecules. As for the latter, there is a tendency towards an increase of K with decrease of the ionisation potential of the donor and with increase of the electron affinity of the acceptor (see Nos.1–4 and 17–25 in Table 1).

However, this tendency does not constitute proof of the predominant contribution of the CT forces[5,10] and there are at present no grounds for the belief that CT forces are the main ones in complex formation. It is most likely that the degree of charge transfer in the ground state is slight and complex formation is determined to a larger extent by the forces of universal intermolecular interactions than by CT forces. Nevertheless the question of the contribution of the CT forces to the formation of CTC of the given type must be regarded as open in view of the inadequacy of the experimental data. The problem of whether CTC of the given type are contact or thermodynamically stable complexes has been studied more widely. The CTC of the given type are thermodynamically stable, since the enthalpies of complex formation ΔH are negative (Table 1). The absolute value of ΔH does not exceed 6 kcal mol^{-1}, which is characteristic of weak $\pi-\pi$ complexes of neutral molecules[5,10]. Like the latter, the CTC between a neutral donor and a cationic acceptor can be obtained in a crystalline state[13-15,27,31,32,35].

In most cases a more or less distinct CT band is observed in the electronic spectrum of the CTC. The CT energy is usually determined from the maximum of the CT band, which in the general does not correspond to the 0–0 transition. Determination of the CT energies for the 0–0 transition has shown[36] that the latter vary approximately in parallel with the CT energies determined from the CT band maxima but are smaller by 0.35–0.4 eV. Therefore the observed dependence of $h\nu_{CT}$ on the characteristics of the components remains unaltered regardless of the way in which the CT energy has been determined.

The study of the CTC formed by identical acceptors with different donors has shown that the CT energy usually varies linearly with IP(D); this is also characteristic of CTC of other types[5,10]. The slope of the $h\nu_{CT}$–IP(D) straight lines is close to unity: for the CTC of aromatic hydrocarbons with the tropylium cation, it is 0.98 in methylene chloride[27] and 1.0 in acetonitrile[37]; it is 0.87 for the CTC of 4-cyano-*N*-methylpyridinium with polyalkylbenzenes in 96% ethanol[29] and 0.96 for the complexes with aromatic hydrocarbons in chloroform containing 8 vol.% of ethanol[38]; for the CTC of aromatic hydrocarbons with benzenediazonium cations in nitromethane, the slope is 0.92.[39,40] Such relations can be regarded as satisfactory evidence that the new absorption bands appearing in the spectrum are indeed CT bands. The slope of the above straight lines depends little on the properties of the solvent, so that the different values obtained in different studies are largely due to the different nature of the donors and their ionisation potentials.

*The compounds are *l*-donors and coordination involves both the nitrogen atom and the residual π-system.

The influence of the solvent on the CT energy has been studied in a number of investigations[28,29,36,41,42]. According to the energy level scheme in Fig.1, the CT energy in the gas phase is expressed by Eqn.(2), while in solution a more complex relation obtains:

$$h\nu_{CT}(D, A^+)_{solv} = IP(D) - EA(A^+) + \\ + (W_0' - W_1) + (R_N' + R_E') + [E_{solv}(D, A^+) - E_{solv}(D^+, A^-)] + E_{FC} \quad (4)$$

Since it can be assumed with adequate approximation that the solvation energy $E_{solv}(D, A^+) \cong E_{solv}(D^+, A^-)$, the frequency shift on transition from the gas phase to the solution and also when the solvent is altered should be determined mainly by the quantity E_{FC}, i.e. $\Delta h\nu_{CT}(D, A^+) \cong \Delta E_{FC}$. In this case a comparatively slight hypsochromic shift is to be expected on passing from the gas phase to the solution as well as a comparatively weak solvatochromism in different solvents. The latter hypothesis has been confirmed experimentally (Table 2). Nevertheless there is no reason to believe that the solvent virtually does not influence the CT energy[36]. The shift of the CT band in a series of 14 solvents presented in Table 2 is approximately 2000 cm^{-1} for the majority of CTC. This quantity is small compared with the corresponding shift of the CT band for the CTC formed by oppositely charged ions (approximately 7000 cm^{-1}), but is too large to neglect the influence of the solvent. The influence of the properties of the solvent on the CT energy is confirmed also by experimental data on the solvatochromism of substances with an analogous intramolecular transition[44,45].

Table 2. The influence of the solvent on the position of the CT band maximum ($10^{-3}\nu$, cm^{-1}).

There is a satisfactory linear relation between the energy shifts of the CT bands for all six CTC in Table 2. Consequently, apart from the individual instances of the specific interaction of the components or of the CTC itself with the solvent, these data contain information about the influence of

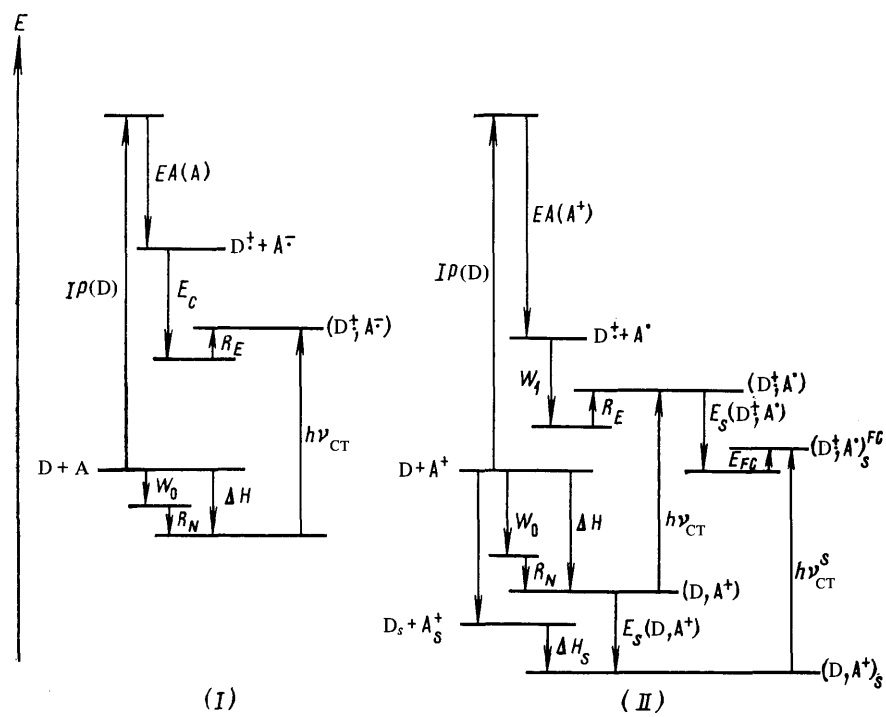

Figure 1. Schematic arrangement of the energy levels for CTC between neutral molecules (I) and a neutral molecule and an ion (II); E_C = Coulombic interaction energy; R_N, R_E = stabilisation or destabilisation energies as a consequence of the interaction of the configurations without and with complete charge transfer in the ground and excited states respectively; W_0, W_1 = stabilisation energies of the ground and excited states as a consequence of all types of interactions with the exception of CT forces; ΔH, ΔH_S = enthalpies of complex formation in the gas phase and in solution; $h\nu_{CT}$ = CT energy; $E_S(X)$ = solvation energy of the corresponding structure X; E_{FC} = destabilisation energy of the non-equilibrium excited state relative to the equilibrium state (the Franck–Condon state).

the solvent on the CTC of this class as a whole. The changes in the CT energies when the solvent is altered are not correlated with empirical parameters of the solvent such as the values of Z and E_T.[29,41,42] Nor does one observe their dependence on the polarisability of the solvent expressed in the form $(n^2 - 1)/(2n^2 + 2)$, where n is the refractive index. A quantitative description of the dependence of the CT energy on the properties of the solvent is probably possible in this case only with the aid of a multiparameter equation[43]. In broad outline, the state of the problem is very similar to that in the case of neutral $\pi-\pi$ complexes[45,46,47], although there is no correlation between the frequency shifts for the CTC of the two types. The structure of the so-called cybotactic region probably plays the most important role in both cases[4].

IV. THE ELECTRON AFFINITY OF ACCEPTOR CATIONS

The electron affinity EA is defined as the energy evolved (+) or absorbed (−) when a given species (atom, molecule, ion, radical, or radical-ion) captures an electron in the gas phase. If the species is a positive ion, then the vertical and adiabatic electron capture processes can be illustrated by the following equations:

$$A^+(r_{A^+}) + e \xrightarrow{EA_v(A^+)} A^{\cdot}(r_{A^+}), \quad (5)$$

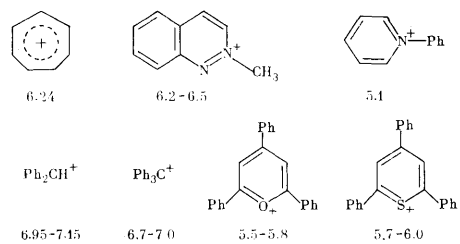
$$A^+(r_{A^+}) + e \xrightarrow{EA_{ad}(A^+)} A^{\cdot}(r_{A^{\cdot}}), \quad (6)$$

where $EA_v(A^+)$ and $EA_{ad}(A^+)$ are the vertical and adiabatic electron affinities of the cation A^+ and r_{A^+} and $r_{A^{\cdot}}$ denote the equilibrium geometries of the ion and radical respectively.

The majority of methods used to determine the EA for neutral species[48] are inapplicable to the determination of the EA for positive ions and the only way in which the latter can be found directly involves the study of the energy characteristics of the reverse process—the ionisation of the conjugate radicals:

$$A^{\cdot}(r_{A^{\cdot}}) \xrightarrow{IP_v(A^{\cdot})} A^+(r_{A^{\cdot}}) + e, \quad (7)$$

$$A^{\cdot}(r_{A^{\cdot}}) \xrightarrow{IP_{ad}(A^{\cdot})} A^+(r_{A^+}) + e, \quad (8)$$



where $IP_v(A^{\cdot})$ and $IP_{ad}(A^{\cdot})$ are the vertical and adiabatic ionisation potentials of the conjugate radical $A^{\cdot}$.

Since only Eqns.(6) and (8) reflect the transition between identical energy levels, the determination of $IP_{ad}(A^{\cdot})$ makes it possible to determine simultaneously also $EA_{ad}(A^+)$, while the $IP_v(A^{\cdot})$ will in general differ from both $EA_v(A^+)$ and $EA_{ad}(A^+)$.

In view of the purely experimental difficulties in the determination of $IP(A^{\cdot})$, only a few ionisation potentials of radicals whose ionisation leads to cations forming stable CTC are at present known. One of these is the tropylium radical, whose $IP(A^{\cdot})$ is 6.24 eV [49,50] (obtained from Rydberg spectra). The electron impact method leads to a higher value (6.6 eV).[51] These differences can be largely caused by the method of measurement itself, since it is known that, without special modification of the measuring apparatus, the latter method yields unduly high results[52]. For benzene, whose values of IP_{ad} and IP_v are equal, the ionisation potential obtained by Tajima and Tsuchiya[52] is higher by 0.3 eV than the value of IP obtained from photoelectron spectroscopy. One must therefore assume that the true adiabatic ionisation potential of the tropylium radical is close to 6.24 eV. The ionisation potential of the N-methylcinnolinyl radical, amounting to 6.5 eV [53] (electron impact method), is also known. In the light of the foregoing, it is to be expected that the true ionisation potential of this radical is in the range 6.2–6.5 eV.

The photoelectron spectroscopic data mentioned by Kosower et al.[54], according to which the values of IP_v and IP_{ad} for the 1-ethyl-4-methoxycarbonylpyridyl radical are 7.2 and 6.8 eV respectively, must be regarded as erroneous. In all probability these ionisation potentials do not correspond to the ionisation of the pyridyl radical. The ionisation potential of the 1-phenylpyridyl radical, determined by the mass-spectrometric method and estimated from the IP of the corresponding 1,4-dihydropyridine, is 5.1 eV.[55] The IP for the triphenylmethyl radical can also be estimated approximately. According to the results of a study of the CTC of the diphenylmethyl and triphenylmethyl radicals with neutral π-acceptors[56], the value of IP for the latter is lower by ~0.2 eV. Assuming that the transition from the benzyl to the diphenylmethyl radical is associated with the same change in IP and using the value of IP_{ad} for the benzyl radical, which is 7.2–7.3 eV,[57,58] we find that IP_{ad} for the triphenylmethyl radical should be in the range 6.7–7.0 eV. Using mass-spectrometric data for pyrylium salts[59], one can estimate the IP also for the 2,4,6-triphenylpyrylium and 2,4,6-triphenylthiopyrylium radicals. Their values are most probably 5.5–5.8 and 5.7–6.0 eV respectively.

All the results described above make possible a direct estimate of the $EA(A^+)$ for acceptors which are listed below together with their structural formulae:

The results of quantum-chemical calculations also permit, in principle, the estimation of the EA for acceptor cations. The approximate nature of the versions of the calculations which are simplest in practice nevertheless makes it necessary to treat with caution the absolute values obtained, while the relative changes in the EA in individual series of compounds can be obtained with a fairly high accuracy.

At least three approaches can be used to calculate the EA. These involve the calculation of the $IP(A^{\cdot})$ and $EA(A^+)$ as the orbital energies in terms of the approximation of Koopmans theorem and the calculation of $EA(A^+)$ as the difference between the total energies of the radical and the ion. Calculation of the $IP(A^{\cdot})$ for tropyl, 1-methylpyridyl, 3-cyano-1-methylpyridyl, and 2-methoxycarbonyl-1-methylpyridyl radicals led to the following values: 8.85; 7.83; 7.96; and 8.73 eV respectively[60]. Despite the fact that all the results are much too high, the difference between the IP for tropyl and 1-methylpyridyl radicals agrees fairly well with experiment, which gives rise to hope for progress in this field when computational methods have been improved[61,62].

Calculations have been made in a number of studies for acceptor cations[63–67]. The most satisfactory agreement with the above experimental data has been obtained taking into account all the valence electrons. As an example, we shall present data obtained in the calculation for the N-methylpyridinium cation. According to the CNDO/2 method, the energy of the lowest vacant molecular orbital is 4.74 eV,[64] while a non-empirical calculation yielded[67] 5.23 eV.

The spectroscopy of the CTC and electrochemical reduction are indirect methods for the determination of the EA. According to Eqns.(3) and (4), the CT energy in both the

gas phase and in solution can be approximately expressed by the following relation:

$$h\nu_{CT} = IP(D) - EA(A^+) + E, \quad (9)$$

where E is a quantity which varies somewhat as a function of the conditions of the investigation. For known values of $h\nu_{CT}$, $IP(D)$, and $EA(A^+)$, it is possible to determine E and to estimate $EA(A^+)$ for other acceptor cations. This approach was first used by Feldman and Winstein[37], who established, on the basis of the results of a study of the CTC of the tropylium cation [$EA(A^+) = 6.24$ eV] that E in solution is close to 1.2 eV. This value agrees well with the expectation based on the analysis of the energy levels of the CTC of the given type, but differs markedly from that for the CTC between a neutral π-donor and a π-acceptor.

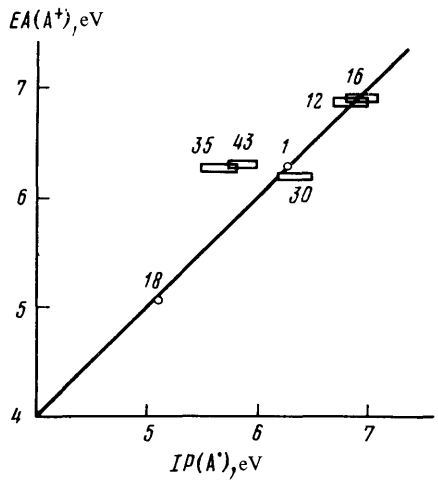


Figure 2. Dependence of the electron affinities of acceptor cations, determined by the method involving the study of CTC, on the ionisation potentials of the conjugate radicals. The points are numberd as in Table 3. In the case of the acceptor No.18 the value of $IP(A^·)$ for the N-phenylpyridyl radical was used; it is assumed that $IP(A^·)$ for acceptor No.16 is lower than $IP(A^·)$ for the diphenylmethyl radical (the difference may be 0.1–0.3 eV).

There is no reason to doubt that, in the study of different CTC under identical conditions, the value of E can be regarded as a constant to a satisfactory approximation under identical conditions in the vast majority of cases. The changes in E following the alteration of the solvent can be taken into account by studying a standard system (the CTC of the tropylium cation) in different solvents (Table 3).

It is noteworthy that certain complications arise because the CT band is associated with the vertical transition and the CT energy depends on $IP_v(D)$ and $EA_v(A^+)$. In this respect the parametrisation of Eqn.(5) relative to the EA_{ad} for the tropylium cation is justified only when $EA_v(A^+) = EA_{ad}(A^+)$ for this cation. Unfortunately measurements of the absolute values of these quantities have not been made for any acceptor cations and the increase in the complexity of the parametrisation produced by introducing any assumptions is at present unjustified. The satisfactory agreement between the values of $IP(A^·)$ and $EA(A^+)$ obtained by the method involving the study of the CTC (Fig.2) suggests that an equation of type (5) can be used to estimate $EA(A^+)$. Nevertheless one must bear in mind that the values of $EA(A^+)$ obtained in this way should vary in proportion to $EA_v(A^+)$ and can therefore differ from the values of $EA_{ad}(A^+)$ obtained by other methods. The difference should be particularly marked in the study of cations A^+ whose equilibrium geometry differs strongly from that of A (for example, arenediazonium salts).

Polarography is a second indirect method which is used fairly frequently to estimate EA.[48,76] It is most likely that the electrochemical reduction process carries information about the adiabatic addition of an electron and hence about the $EA_{ad}(A^+)$.

The half-wave potential for the reversible one electron reduction ($E_{1/2}$) can be expressed by the following equation with a satisfactory degree of approximation[77]:

$$E_{1/2} = EA + \Delta E_{solv} + Z, \quad (10)$$

where E_{solv} is the difference between the solvation energies of the reduced and oxidised forms and Z is a constant characterising the free energy of the electron in the standard electrode relative to that *in vacuo*.

The quantity ΔE_{solv} is virtually determined by the solvation energy of the charged species, since the solvation energies of neutral species are insignificant. The solvation energies of organic ions with a markedly delocalised charge in a series of polar solvents are ~2.0 eV [78] and vary comparatively little (by ±0.2 eV) when their structure is altered. The quantity Z for the saturated calomel electrode (s.c.e.) in acetonitrile solution is 4.38 eV.[78] When cations are reduced, the highly solvated species is the oxidised form and not the reduced form as happed in the reduction of neutral species. ΔE_{solv} therefore enters into Eqn.(10) with the opposite sign and $E_{1/2}$ in acetonitrile relative to the s.c.e. is expressed by the equation

$$E_{1/2}(V) = EA(A^+) - 6.38 \pm 0.2 \text{ (eV)}. \quad (11)$$

Using the literature data for the electrochemical reduction of acceptor cations[15,53,64,68,71,79–83], it is possible to test the validity of Eqn.(11). It follows from Eqn.(3) that in most cases there is an entirely satisfactory agreement between the $E_{1/2}$ and $EA(A^+)$. This agreement can actually be regarded as satisfactory, since the values of $E_{1/2}$ have been obtained in different solvents using different supporting electrolytes, which, together with the possible adsorption on the surface of mercury, can appreciably alter $E_{1/2}$.[84,85]

The data for acceptors Nos.41, 44–46, and 49 deviate from the overall relation (Fig.3). Whereas in the case of dibenzopyrylium (No.41) this can be associated with inaccurate experimental data, for benzenediazonium acceptor cations[40] the problem can be complicated by the appreciable difference between $EA_v(A^+)$ and $EA_{ad}(A^+)$. In this case one can assume that the experimental $EA(A^+$, CTC) are insufficiently high for Eqn.(11) to be observed and that the deviations of the experimental points vary with the substituent. Since this does actually occur, presumably the difference between $EA_{ad}(A^+)$ and $EA_v(A^+)$ for benzenediazonium ions reaches ~1 eV. For heteroaromatic and also carbonium ions, there is no reason to believe that the difference between the adiabatic and vertical electron affinities exceeds 0.2–0.3 eV. It should also be assumed that the parametrisation of Eqn.(5) has been carried out correctly and that the data in Table 3 reflect the true vertical values of EA for acceptor cations, which, with the exception of hetero-onium ions, are close to the adiabatic values.

**Here and henceforth the values of E_{II} have been adopted on the basis of the results for the CTC of the tropylium cation and the average value of $EA(A^+)$ has been rounded off to 0.05 eV.

Despite the limited number of studies whose results permit a direct estimation of the absolute values of $EA(A^+)$ in the gas phase, there is no doubt that the latter greatly exceed the values for neutral electron acceptors[48]. For example, *EA* for one of the weakest acceptor cations (*N*-methylpyridinium) is ~5.05 eV, while *EA* for one of the strongest neutral electron acceptors (tetracyanoquinodimethane) is ~2.8 eV. On the other hand, if one considers the entire set of possible acceptors, one may conclude that the CTC with clearly detectable CT bands are formed by neutral acceptors whose *EA* are in the range 0.5–3.0 eV and acceptor cations for which the *EA* are 4.5–7.0 eV. In fact these limits of the *EA* lie in both cases in an intermediate region between the values reflecting a weak CTC type interaction and those characteristic of one-electron transfer. Therefore another conclusion is also valid, namely in a condensed phase a neutral acceptor and an acceptor cation manifest approximately the same electron-accepting properties, provided that the *EA* (in the gas phase) for the latter exceeds ~4 eV. This difference is due to the effects of solvation or polarisation of the medium, which are clearly shown on comparing the photoelectron spectra of solutions and gases comprising neutral substances and ions[85–87]. The external ionisation potential for solutions of neutral molecules is lower by 1–2 eV and for solutions of ions is higher by 2–3 eV than the corresponding characteristics in the gas phase[88]. On this basis, we arrive at the analogous conclusion that a neutral molecule and an ion have approximately the same electron-donating or electron-accepting properties in solution, provided that their values of *IP* and *EA* in the gas phase differ on average by 4 eV.

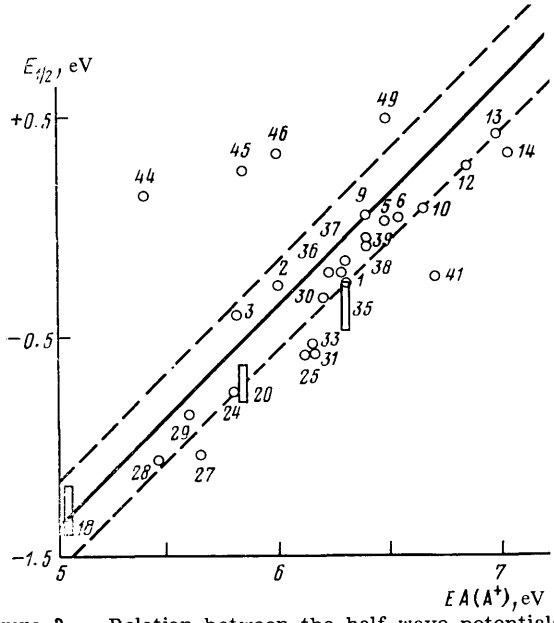

Figure 3. Relation between the half-wave potentials of the polarographic reduction of A^+ and $EA(A^+)$ obtained from the study of CTC. The acceptors are numbered as in Table 3. The straight lines have been drawn on the basis of Eqn.(11).

V. THE PHOTOCHEMICAL PROPERTIES OF THE CHARGE-TRANSFER COMPLEXES OF ARENEDIAZONIUM IONS

The ability of arenediazonium ions to decompose under the influence of light constitutes the basis of many non-silver photographic materials and photoresistors[20,21,89–93]. Many of these contain a substituted benzenediazonium cation as the light-sensitive substance. As a rule, a disadvantage of these materials is a comparatively low overall and not especially favourable spectral sensitivity. On formation of CTC with neutral π-donors, new absorption bands appear, which in principle can lead to the expansion of the spectral sensitivity and an increase of the overall light sensitivity of such materials[20,21,94]. Indeed, depending on the donor and arenediazonium salt employed, CT bands can occur up to 750 nm (see Table 3) which, in the case of photodecomposition on irradiation with light corresponding to the given band, should naturally lead to an appreciable expansion of spectral sensitivity. The photodecomposition on irradiation with light corresponding to the CT band can be regarded as a special case of the familiar radical mechanism of photodecomposition[20,21,95]. In the general case benzenediazonium salts can decompose via both ionic and radical mechanisms[20,21,94], which in isolated instances can be complicated by other processes[96]:

$$ArN_2^+ \longrightarrow N_2 + Ar^+ \xrightarrow{R^1OH} ArOR^1$$

$$ArN_2^+ \longrightarrow ArN_2^{\cdot} \rightarrow Ar^{\cdot} + N_2 \xrightarrow{R^2R^3CHOH} \rightarrow ArH + R^2R^3\dot{C}{-}OH \xrightarrow{ArN_2^+} \text{chain propagation.}$$

Photodecomposition via an ionic mechanism can be regarded as a consequence of intramolecular electron transfer to the diazonium group and leads to nucleophilic substitution products. This pathway cannot be achieved with a quantum yield ϕ exceeding unity. Photodecomposition via a radical mechanism can be regarded as a consequence of intermolecular electron transfer and leads to reduction products. Despite the fact that in the given instance the primary photoprocess cannot be achieved with $\phi > 1$, the overall quantum yield can exceed unity owing to the occurrence of chain reactions with participation of the solvent or the polymer matrix[21,34,97–100]. For example, in alcoholic solutions chain propagation can proceed via the following mechanism:

$$ArN_2^+ + R_2\dot{C}{-}OH \rightarrow ArN_2^{\cdot} + R_2C{=}O + H^+,$$

$$ArN_2^{\cdot} \rightarrow Ar^{\cdot} + N_2 .$$

The solvent, the corresponding anion, or a neutral electron donor can serve as a source of the external electron necessary for the first stage[21,34]. This process is limited thermodynamically by the energy necessary for electron transfer and the free energy of activation is expressed by the following equation[21,34]:

$$\Delta G^{\neq} = E_{1/2}^{oxy}(D) - h\nu_{00} - E_{1/2}^{red}(A^+),$$

where $E_{1/2}^{oxy}(D)$ is the half-wave potential for the anodic oxidation of the donor and $h\nu_{00}$ is the energy of the 0–0 transition on excitation of the donor, acceptor, or the CTC (for a thermal process, $h\nu_{00} = 0$).

Simple ideas about orbital symmetry in photochemical reactions confirm the occurrence of the adiabatic transition from the excited CT state to the aryldiazo-radical[101] and the experimental results for solutions[21,34,94,100,101] demonstrate the validity of the ideas described above. Irradiation with

light corresponding to the CT band leads to the decomposition of the arenediazonium ion[34] and the photolysis of the CTC of the *p*-chlorobenzenediazonium ion with pyrene results in 100% formation of chlorobenzene. An analogous increase of the amount of the products of the photodecomposition via the radical mechanism has been observed also in other instances[34, 100,101]. The operation of the radical mechanism is also indicated by the influence of various inhibitors of similar reactions on the process[34,100,101].

The quantum yield of the photodecomposition by light corresponding to the CT band depends on a number of factors[34]. It increase on enhancement of the electron-donating, properties of the donor D and the electron-accepting properties of the acceptor A^+ and with increase of the concentration of the H-donor solvent and diminishes in the presence of oxygen and other radical traps and also with increase of the donor concentration. When the CTC of pyrene with the 4-chlorobenzenediazonium ion was irradiated with light at $\lambda = 405$ nm in an atmosphere of nitrogen in a mixed solvent (dioxan : acetonitrile = 4 : 1), the yield ϕ exceeded 10 for certain concentration ratios[34]. In an atmosphere of oxygen the quantum yield of the photodecomposition was ~0.1.

Consequently, despite the fact that the use of CTC of arenediazonium ions with neutral electron donors does in principle make it possible to eliminate the significant disadvantages of the photographic materials based on diazonium salts used nowadays, their practical application constitutes an extremely complex problem. In a polymer matrix it is complicated still further by the restriction of diffusion which prevents the release of the primary radical pair from the cage.

Influence of Ring Size on Properties and Reactivity of Cyclic Systems

V.G.Granik

Results obtained during 1960-1979 on the effect of the size of a saturated or partly hydrogenated carbo- or hetero-cycle on the physicochemical (spectral, polarographic, ionisation) and chemical properties of cyclic compounds are summarised. Attention is paid mainly to the usual (C_5-C_7) cyclic systems. Results are interpreted in terms of classical strain theory, the *I*-strain concept, and the Finnegan-Streitwieser rehybridisation model. A list of 173 references is included.

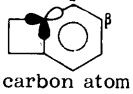
I. INTRODUCTION

The influence of the size of a saturated or partly hydrogenated ring on the properties and the reactivity of a cyclic system is now well known and continually subject to close attention by organic chemists. This problem is dealt with in some way or another in all the many monographs and reviews[1-10] concerned with aspects of the stereochemistry of cyclic compounds. However, the ever increasing information on this topic has not been subjected to detailed analysis since publication of the 1960 review[9]. The present survey is intended in some measure to fill this gap. Nevertheless, it is not possible to cover all aspects of the problem, and this Review will be confined mainly to the "usual" (C_5-C_7) and to a less extent small (C_3, C_4) rings. Information on rings larger than seven-membered has not been specially systematised (reviews have appeared[11,12]), and is considered only when necessary to ensure completeness of exposition.

Although the data given below are largely determined by the strain in the rings, it seems useful to include appropriate thermodynamic parameters, which have been summarised in detail in the above monographs and reviews[1-3,9]. Results published during recent years[13-15] do not change fundamentally existing information on the relative stabilities of cyclic systems. It must be noted only that the strain sequence known for carbocyclic derivatives is on the whole maintained in saturated heterocyclic compounds[15].



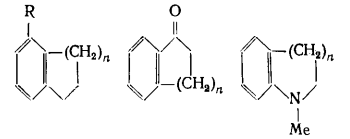
The premises on which experimental results obtained to establish a correlation between properties and ring size can be interpreted have now been quite well developed. They involve primarily the types of strain inherent in the systems† and the changes they undergo on passing from the ground to the transition state (or final state in the case of equilibrium).

† These comprise mainly Baeyer or angular strain involving distortion of bond angles; Pitzer or torsional strain, due to the "striving" of substitutents attached to adjacent atoms to avoid an unfavourable eclipsed conformation and to occupy the energetically most favourable relative positions; transannular interaction (across the ring); *F*-strain, i.e. increase in steric strain on formation of a bond between two atoms, due to spatial interaction of substituents attached to these atoms; and finally *I*-strain—change in the internal strain of the cyclic system due to changes in angles and conformation accompanying change in the coordination number of a ring atom during reaction[9].

An important supplement to such a treatment, especially in connection with the concept of *I*-strain, is that differences in reactivity between compounds depending on ring size are determined, under otherwise similar conditions, also by how far along the reaction coordinate the transition state was formed (i.e. whether the latter was "initial-like" or "final-like"). If achievement of the transition state involves rehybridisation of a ring atom, the influence of ring size will be considerably less marked in the former than in the latter case[16].

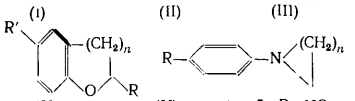
Even the most rigorous examination possible of all types of strain and their variation during a reaction in no way exhausts all aspects of the problem and relates mostly to reactions involving a ring atom. Simple angular strain clearly cannot provide an interpretation of the overall effect of a fused ring on the reactive behaviour of a molecule, e.g. the Mills-Nixon effect. Results on effects of this type were generalised[17,18] with an explanation that has now been confirmed by many spectral and kinetic investigations[19,20].

According to this generalisation aryl positions attached to a strained fused ring (α-positions) exhibit diminished reactivity towards electrophilic reagents. The reason is enhancement of the *p*-character of those orbitals (shown solid)



that are directed from a carbon atom of the benzene ring towards the strained ring with consequent enhancement of the *s*-character of the orbitals (shown open) directed towards the α-position of the benzene ring. Such increase in *s*-character clearly improves the electron-accepting properties of the orbital and hence lowers the reactivity of the α-position towards electrophilic reagents with greater acidity of the corresponding carbon-hydrogen bonds. These conditions provide a good explanation of the Mills-Nixon effect[21], i.e. why in indane derivatives (which contain a strained five-membered ring), in contrast to tetrahydronaphthalene derivatives, electrophilic substitution is oriented predominantly at a β-position.

II. PHYSICOCHEMICAL PROPERTIES OF CYCLIC SYSTEMS



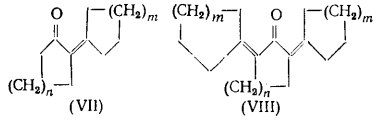
1. Spectral Properties

Spectral methods, in particular electron spectroscopy, have been widely used to elucidate reasons for the differences in reactivity between cyclic systems varying in ring

size. Mention must first be made of several early papers on bicyclic derivatives, not covered in existing reviews. Examination of the ultraviolet spectra of benzocycloalkanes (I),[22] benzocycloalkanones (II),[23] and heterobicyclic compounds (III) and (IV)[24–26] indicated that maximum conjugation was present in the almost planar five-membered ring:

(I) (II) (III)

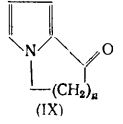
(IV) (V): $n = 1-5$, R=NO_2; (VI): $n = 1-4$, R=H



Study of the ultraviolet spectra of the *N*-arylazacycloalkanes (V) and (VI) has revealed[27] for the aziridine derivative (V: $n = 1$) a strong hypsochromic displacement of the absorption maximum and a decrease in the extinction coefficient relative to the other compounds of this series. Some fall in intensity and shift in the absorption maximum to shorter wavelengths is observed also with the *N*-arylpiperidine (V: $n = 4$). The conclusion[27] that sp^3-hybridisation of the nitrogen atom occurs in the former compound and inhibition of conjugation in the latter, six-membered compound is confirmed by the nuclear magnetic resonance spectra (down-field shift in the signals from *ortho*-protons of the benzene ring) and by measurements of the ionisation constants (subsection 2).

Other workers[28] who studied the ultraviolet spectra of *N*-phenylazacycloalkanes (VI: $n = 1-4$) assumed that the nitrogen atom has an sp^3-configuration in all the compounds, but the degree of conjugation decreases according to ring size in the sequence

$$C_5 > C_4 > NN\text{-dimethylaniline} > C_6 > C_3$$

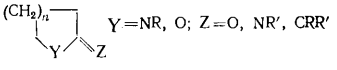


which is consistent with the exaltation of molecular refraction. In this case the degree of conjugation is determined by the angle ϕ between the direction of the orbital bearing the lone pair of electrons of the nitrogen atom and the normal to the plane of the benzene ring, with increase in ϕ leading to a weakening of absorption. From an analysis of molecular models it was concluded[28] that for a five-membered ring $\phi = 0$, whereas for a six-membered ring $\phi > 0$ owing to interaction of α-protons of the piperidine ring with *ortho*-protons of the benzene ring.

A study[29] of the electronic spectra of the cycloalkylidene ketones

(VII) (VIII)

also showed that five-membered compounds absorb in the ultraviolet at longer wavelengths than do six-membered compounds. Analysis of the spectra of the fused pyrroles



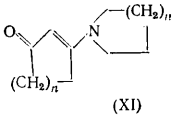
(IX)

($n = 1-3$) also indicated[30] that conjugation of the carbonyl with the pyrrole ring is best in the five-membered compound ($n = 1$). The infrared spectra of the pyrroles (IX) were also examined, and found to be closely similar for the six- and seven-membered compounds (ν_{CO} respectively 1650 and 1645 cm^{-1}) but appreciably different for five-membered compounds (1700 cm^{-1}). The increase in the carbonyl frequency in the spectrum of (IX: $n = 1$) was attributed[30] to enhancement of the *s*-character of the orbital directed towards the oxygen atom.

Analogous results were obtained from the infrared spectra of cycloalkanones, lactams, lactones, cyclic ureas, imides, urethanes, and other compounds of similar type[31]. The carbonyl frequencies were regarded[31] in all cases as indicating not ring-strain by hybridisation of the orbital directed towards the oxygen atom: enchancement of the *s*-character of this orbital, which increases on passing from seven- and six-membered to five- and four-membered rings, is the reason for the higher ν_{CO} frequency in compounds having strained rings.

Hypotheses of this type are consistent with a very good correlation[32] between the acetolysis rate constants of toluene-*p*-sulphonates $RR'CHOSO_2Ar$ and the carbonyl frequencies of the corresponding ketones. From this it can be concluded that the two parameters are equally sensitive to angular strain and to hybridisation. The correlation does not apply to compounds whose hydrolysis is sterically accelerated, as e.g. the pair cyclopentyl toluene-*p*-sulphonate and cyclopentanone.

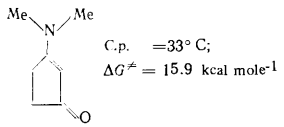
The above views on the correlation between carbonyl frequency and the *s*-character of the hybride orbital are apparently quite valid for non-conjugated systems[33]. For systems in which the carbonyl is conjugated with other groups Y, as in lactams, lactones, etc.



Y=NR, O; Z=O, NR', CRR'

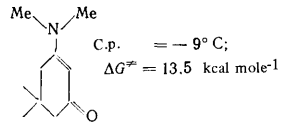
(this applies also to other types of compounds having a conjugated exocyclic double bond—enamines and amidines), however, it must also be borne in mind that such conjugation is best realised in a six-membered ring[34,35], and the increase in the carbonyl (or C : C or C : N) frequency for five-membered compounds must be partly attributed to inhibition of conjugation in them#.

Enhancement of the *s*-character of the C–O orbital in strained cycloalkanones affects also their capacity for hydrogen bonding (determined from the infrared spectra). Depending on ring size the strength of the hydrogen bond diminishes in the sequence $C_5 < C_6 < C_7$.[37] For cyclic imines[38] and ethers[39] it has been shown earlier that hydrogen bonding is stronger in five- than in six-membered compounds. For lactones[39], on the other hand, the situation is similar to that observed for cyclic ketones, and valerolactone forms a stronger hydrogen bond with methanol than does butyrolactone. Comparison of the behaviour of lactones and cyclic ethers indicated[30] that in the former the carbonyl oxygen is involved in hydrogen bonding.



Several comparisons have been made of ^1H n.m.r. spectra as a function of ring size[40–42]. The chemical shifts of signals from vinyl protons of enamines, e.g. of type

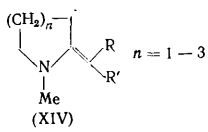
(XI)



The increase in carbonyl frequency in five-membered rings in a series of benzolactams has been explained in terms of diminished conjugation between carbonyl and imino-groups[36].

indicate that delocalisation of the electron pair of the nitrogen atom is more strongly marked in five- than in six-membered compounds[40,41]. These results are confirmed by infrared and ultraviolet spectra and also by the greater restriction of rotation about the carbon–nitrogen bond in the five-membered enamino-ketone (XII) than in its six-membered analogue (XIII)§:

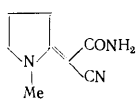
C.p. =33° C;
$\Delta G^{\neq} = 15.9$ kcal mole^{-1}



(XII)

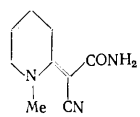
C.p. = — 9° C;
$\Delta G^{\neq} = 13.5$ kcal mole^{-1}

(XIII)



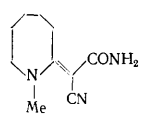
In a detailed analysis of the influence of ring size on the barrier to rotation about the carbon–carbon double bond in enamines of the type

$n = 1 - 3$



(XIV)

it was established[42] by ^{1}H n.m.r. spectroscopy that restricted rotation occurs with a comparatively low energy barrier, with activation free energies of *cis–trans* isomerisation lowest for six-membered and highest for five-membered compounds. A characteristic example is[42]

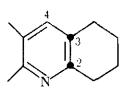


C.p. °C 71°

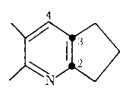
$\Delta G^{\neq}$ kcal mole^{-1} 19.1; 17.4

—14°

13.1; 13.7



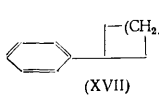
45°



16.0; 16.3

Interpretation of these results was based on the conclusion that the energy of the transition state is significantly higher for five- than for six-membered compounds owing to the unsuitability for the former of transformation of the exocyclic into an endocyclic double bond.

Annelated pyridines have recently been studied[20] by ^{13}C n.m.r. spectroscopy. On passing from six-membered (XV) to five-membered (XVI) analogues



(XV)

(XVI)

the signals from carbon atoms 2 and 3 undergo down-field shifts of ~8–9 and 4.8–5 ppm respectively, which agrees well with the stronger electron-accepting effect of a strained five-membered ring (Section I). Thus annelation with a strained ring enhances the electronegativity of the nitrogen atom and carbon atom 4, with consequent deshielding of the carbon atoms at positions 2 and 3.

Study of the fragmentation under electron bombardment of the compounds

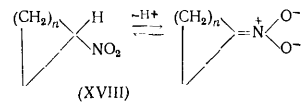
(XVII)

n	1	2	3
E_a, kcal mole^{-1}	34.5±4.8	53.5±4.8	62.5±4.8

has established[43] a parallelism between stability of the ring and resistance to electron impact: i.e. the activation energy of fragmentation E_a increases on passing from the strained cyclobutane and cyclopentane rings to the unstrained cyclohexane ring.

2. Ionisation Constants

Most research on the dependence of physicochemical properties on ring size has been based on the measurement of ionisation constants and interpretation of the results[44–73]. Firstly we must note that the kinetic acidity of cycloalkanes varies[44] in the sequence¶

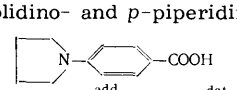


$$C_3 \gg C_4 > C_5 > C_6 \approx C_9 > C_7 \approx C_{10} > C_8 \approx C_{11} > C_{12} > C_{14}.$$

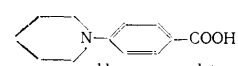
The divergence of these results from those for the rates of solvolysis of the corresponding toluene-*p*-sulphonates led to the conclusion[44] that the conformations of initial and final states (cycloalkane and cycloalkyl anion) are closely similar, and the differences in acidity are determined solely by the degree of *s*-character of the C–H orbital. These workers[44] regarded this conclusion as supported by the good correlation of kinetic acidities with the $J(^{13}C–H)$ values characterising hybridisation.

The action of n-butylsodium on mixtures of cyclopentene and cyclohexene showed[46] that the carbon–hydrogen bond in the former cycloalkene possesses the more acidic properties. On the other hand, measurement of the basicity of unsaturated ketones —cyclopent-2-enone and cyclohex-2-enone—revealed no effect of ring size[47]. The acidity of a series of nitrocycloalkanes

$$C_8 > C_7 > C_5 > C_6 > C_4 \gg C_3$$



diminishes with ring size in the sequence[48]



(XVIII)

The greater acidity of seven- and five-membered than of six-membered compounds agrees well with the change from sp^3 to sp^2 hybridisation of the cyclic carbon atom accompanying formation of an anion, i.e. with the concept of *I*-strain.

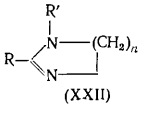
Considerably more research in this field has been done on heterocyclic compounds. It has been shown[27] for *N*-aryl-azacycloalkanes that five-membered compounds are least basic, which is due to steric inhibition of conjugation of the nitrogen lone pair with the benzene ring (subsection 1)†. Basicity and acidity constants had been determined[50] for *p*-pyrrolidino- and *p*-piperidino-benzoic acids:

(XIX), $pK_a^{add} = 0.39$; $pK_a^{det} = 6.07$

(XX), $pK_a^{add} = 2.67$; $pK_a^{det} = 5.75$

where pK_a^{add} and pK_a^{det} correspond to addition and detachment of a proton respectively. Comparison with the acidity constants of corresponding acyclic compounds (e.g. for *p*-dimethylaminobenzoic acid (XXI) $pK_a^{det} = 6.0$) shows[50] that (XX) is characterised by considerable steric inhibition

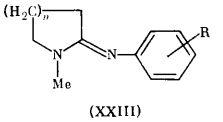
§ Here and subsequently C.p. = coalescence temperature (point).



¶ Different relations apparently occur among chlorofluoroalkenes[45].

† Similar results had been obtained earlier for *N*-phenylpyrrolidine and -piperidine[49].

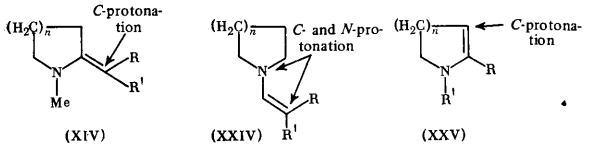
of resonance interaction, due to overlapping of the orbitals of α-protons of the piperidine ring with those of *o*-protons of the benzene ring.



The very low basicity of (XIX) in comparison with not only (XX) but also (XXI) ($pK_a^{det} = 1.40$) was attributed[50] to non-bonded interactions occurring on protonation of the pyrrolidine nitrogen atom, accompanied by a change in its configuration from sp^2 to sp^3. The Reviewer regards such an explanation as entirely logical; from these results the hypothesis of an sp^3 configuration for the nitrogen atom in all *N*-phenylazacycloalkanes (subsection 1) can be considered improbable. Basicity measurements on oxacycloalkanes[51] gave the same sequence depending on ring size $C_5 > C_7 > C_6$ as for cyclic imines#. The effect of *F*-strain during protonation was regarded as insignificant (application of this concept would have given the different sequence $C_5 > C_6 > C_7$), and the results were explained in terms of the so called electronic correlation effect. This explanation presupposes that repulsion of the lone pair of the oxygen atom from the α–C–H group accompanying protonation at the oxygen would be more greatly diminished for five- and seven-membered rings (where shielding is present) than for a six-membered ring. It was supposed that this would relieve a certain proportion of the strain on the protonation of oxygen in a five-membered (and to a less extent seven-membered) ring. Since shielding is absent from a six-membered ring, this effect plays no part; hence an additional gain in energy accompanies protonation of five- and seven-membered compounds, so that they are more basic than the pyran derivative.

Among cyclic amidines

(XXII)

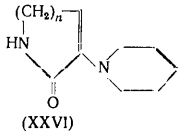


the most basic are hydrogenated pyrimidine derivatives, which are followed by seven- and eight-membered compounds, the least basic being imidazolines (XXII: $n = 1$).[53] The same sequence $C_6 > C_7 > C_5$ is maintained[35] in amidines of the different type

(XXIII)

The explanation of such variation in basicity is that the best conditions for conjugation of the lone pair of the cyclic nitrogen atom with the exocyclic double bond occur in the six-membered ring§. Correlation analysis showed[35] that rotation of the benzene ring relative to the plane of the C : N bond depends little on ring size.

Several studies have been made of the basicity of tertiary enamines

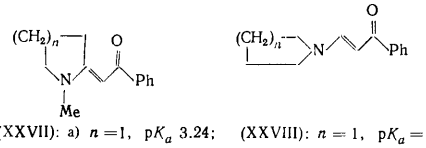


(XIV) (XXIV) (XXV)

The same sequence had previously been obtained[52] for cyclic ethers, but a different sequence for lactones ($C_6 > C_5 > C_4$) and cycloalkanones ($C_7 > C_6 > C_5 > C_4$), which indicates a change in the site of protonation (at the carbonyl oxygen) for these compounds.

§ Such an explanation had earlier been advanced[34] in connection with the basicity of lactams.

For the compounds of type (XIV) the sequence $C_6 > C_7 > C_5$ has been established[54–56] for the variation of basicity with ring size¶. Study of restricted rotation about ethylenic bonds in these enamines (subsection 1) indicates[56] that migration of such a bond from an exocyclic to an endocyclic position (on protonation at the β-carbon atom) is energetically most favourable for six-membered and unfavourable for five-membered rings. For enamines of type (XXIV) it is assumed[57] that, in contrast to (XIV), they are protonated not at the β-carbon atom but mainly at the nitrogen atom, owing to steric hindrance to conjugation. From the concept of *I*-strain it would be expected that the six-membered compound would be more basic. Actually, however, the opposite situation is observed[57]: pK_a is respectively 8.71 and 8.34 according as n has the value 1 or 2 in (XXIV)†. A possible reason is that in the former case steric hindrance to conjugation is smaller and the contribution of *C*-protonation to the effective ionisation constant larger: hence the enhanced basicity of the five-membered enamine. The above view is confirmed by study of the protonation of enamines of this type[58]. Five-membered are more basic than six-membered enamines of type (XXV) also[59], apparently owing to diminished angular stress accompanying *C*-protonation of the former. A marked change in basicity with ring size is observed[60] also for enamines of a fourth type:



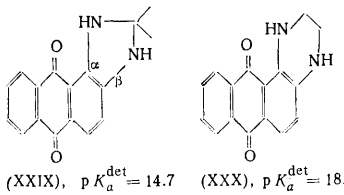
(XXVI)

$n=2$, $\Delta pK_a(MeNO_2) = 3.93$;
$n=3$, $\Delta pK_a(MeNO_2) = 1.6$

The lower the basicity of the six- than of the seven-membered enamine is due to a smaller contribution of *C*-protonation to the ionisation constant of the former compound.

Unusual results have been obtained[61] in a study of the basicity of the enamino-ketones (XXVII) and (XXVIII):

(XXVII): a) $n = 1$, pK_a 3.24; b) $n = 2$, pK_a 5.22; c) $n = 3$, pK_a 4.3

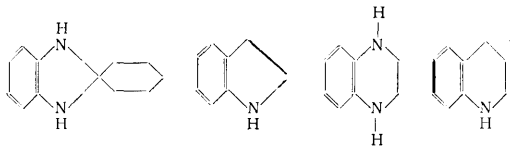


(XXVIII): $n = 1$, $pK_a = 2.08$; $n = 2$, $pK_a = 2.11$; $n = 3$, $pK_a = 1.83$

The dependence on ring size in the series (XXVII) is the same as for the enamines (XIV), but that in (XXVIII) is considerably smaller. These facts, as well as the sharp fall in basicity on passing from (XXVII) to (XXVIII), have been explained by studying the protonation of these compounds: the former undergo *C*-protonation, but the latter *N*- and *O*-protonation[61].

We have been considering research on heteromonocyclic compounds, but several studies have been made of the ionisation constants of fused heterocycles. An interesting investigation of the properties of tetracyclic derivatives containing an anthraquinone fragment has revealed[62] a considerable difference in acidity between the compounds

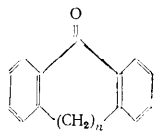
¶ The same sequence is maintained for other compounds (amidines, lactams[34,35]) which, like the enamines (XIV), are protonated at an exocyclic atom.



† These differences were not discussed[57].

(XXIX), $pK_a^{det} = 14.7$ (XXX), $pK_a^{det} = 18.9$

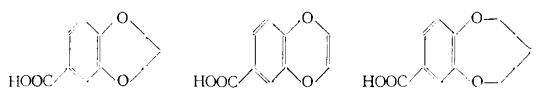
the former, containing a strained five-membered ring, is a stronger acid than its six-membered analogue (XXX) by a factor of ~10^4. This is explained[62] in terms of the enhanced *p*-character[17,18] of the orbitals of atoms α and β forming the strained ring: hence the N : H orbital of (XXIX) has an enhanced *s*-character, which is responsible for the increased acidity of this compound.



Among other examples of nitrogen heterocycles the five-membered compounds (XXXI) and (XXXII) are stronger acids than their six-membered analogues (XXXIII) and (XXXIV) [63]:

	(XXXI)	(XXXII)	(XXXIII)	(XXXIV)
pK_a^{det}	29.3	30.5	32.1	32.1

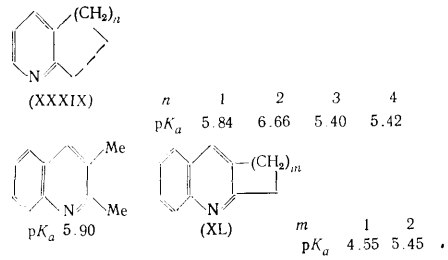
In explaining such effects we must also bear in mind that the better conditions of solvation of the anion of a five-membered ring may play an important part.



In contrast to basicity measurements on unsaturated[47] (above) and saturated ketones, in which the influence of ring size is insignificant, the fused cycloalkanones

(XXXV)

show a decrease in basicity with ring size[64] in the sequence $C_6 > C_7 \cong C_8 > C_5$.

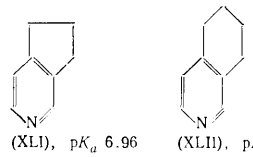


Measurements on a series of oxygen-containing bicyclic compounds showed[65] that the seven-membered is the strongest acid, and the five-membered the weakest:

	(XXXVI)	(XXXVII)	(XXXVIII)
pK_a	4.50	4.35	4.23

This was attributed to two effects—conjugation of the lone pair of the oxygen atom *para* to the carboxyl and the negative inductive effect of the second oxygen atom on the first—both of which are largest for the five-membered ring and smallest for the seven-membered ring. The former effect produces a decrease in acidity with ring size in the sequence $C_7 > C_8 > C_5$, and the latter effect in the sequence $C_5 > C_6 > C_7$. Superposition of these effects gave[65] the experimental situation $C_7 > C_6 > C_5$, with a relatively small influence of ring size on acidity (the need to consider both effects follows from results for hydrolysis of the ethers (XXXVI)–(XXXVIII), which will be discussed in section III, 3).

The greater electron-accepting influence of a small, strained ring on an adjacent position in a fused aromatic ring agrees well with basicity data for annelated pyridines (XXXIX) [66] and quinolines (XL) [67]:



(XXXIX)

n	1	2	3	4
pK_a	5.84	6.66	5.40	5.42

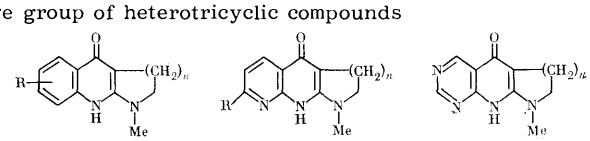
pK_a 5.90 (XL)

m	1	2
pK_a	4.55	5.45

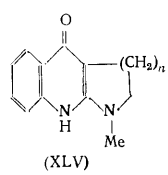
Comparison of similar data with ^{13}C n.m.r. spectra reveals[20] the interesting fact that, when the fused ring is attached at positions 3 and 4 instead of 2 and 3 of the pyridine ring, the five-membered are more basic than the six-membered compounds:

(XLI), pK_a 6.96 (XLII), pK_a 6.83 .

It is suggested[20] that atoms located β to the strained ring are enriched with electrons. In other words, the *p*-character of orbitals in this position is assumed to be enhanced (this is not mentioned in Ref. 20). Although these considerations seem to be consistent with the ^{13}C n.m.r. data, considerably more experimental results will be required to confirm them.



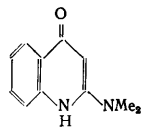
Measurement of the ionisation constants of series of hydrogenated furo- and pyrano-[2,3-*b*]pyridine derivatives has shown[68] that for the *N*-unsubstituted compounds (XLIII) and (XLIV) the five-membered system is much more strongly acid than the six-membered, but they are equally basic:



(XLIII), pK_a^{det} 8.92; pK_a^{add} 1.95 (XLIV), pK_a^{det} 10.17; pK_a^{add} 1.94 ,

The former effect is apparently due to the influence of the strained five-membered ring on the adjacent position (NH) of the aromatic ring, and the latter to protonation at the exocyclic oxygen atom. The same explanation applies to the closely similar basicities of the *N*-methyl derivatives contrasted with the less basic five-membered than six-membered methoxy-derivative (pK_a respectively 1.84 and 3.04).

Finally, a recent study of the ionisation constants of a large group of heterotricyclic compounds

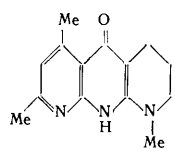


has shown fairly weak basic and acidic properties with protonation occurring at the oxygen atom[69,70]. An example is provided by the data obtained[69] for the quinoline derivatives

(XLV)

n	1	2	3
pK_a^{add}	5.60	5.31	4.97
pK_a^{det}	12.55	12.65	12.70

which fit well into the above schemes: the basicity is maximal, since electrons of the nitrogen atom in the five-membered ring are conjugated best, while the maximum acidity of the compound containing a five-membered ring is explained by Streitwieser rehybridisation of the orbitals, as has already been discussed several times. However, comparison of these data with pK_a measurements for 2-dimethylaminoquinol-4-one



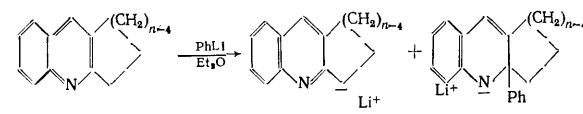
(XLVI)

pK_a^{add} 5.60;
pK_a^{det} 11.92,

reveals that the results cannot be explained in terms of the Finnegan-Streitwieser concept (the pattern is preserved for compounds containing a substituent such as chloro or nitro at position 6 in the benzene ring). Indeed, on this view compounds containing a fused five-membered ring should be far stronger acids than bicyclic compounds of type (XLVI). With regard to basicity, too, the ultraviolet spectra would suggest that the six-membered compound (XLVI) would be more basic, whereas for compounds of type (XLV) (and their chloro-derivatives) and (XLVI) the opposite pattern is in fact observed.

In order to interpret these results it was suggested[69,70] that an important (if not leading) role is played by the ability of the solvent to solvate cations and anions on protonation and deprotonation respectively. On this hypothesis acid and basic strengths in this series of compounds are determined by steric hindrance to solvation, such hindrance being least for five-membered rings on protonation, but on deprotonation for compounds devoid of a third, fused ring (XLVI).

To confirm these views, basicity and acidity measurements were made[70] on the 1,8-naphthyridine derivative

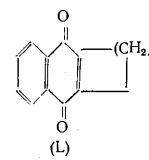


(XLVII)

pK_a^{det} 12.86; pK_a^{add} 4.61

containing methyl groups at positions 2 and 4 of the pyridine ring. As was to be expected, this compound proved to be less basic than the benzene analogue (XLV: $n = 2$) (pK_a 5.31), owing to the stronger electron-accepting influence of the annelated dimethylpyridine than of the benzene ring. Introduction of methyl groups at α and γ positions of the pyridine ring does not affect solvation of the protonated form, where the chief role belongs to solvation of the positive charge concentrated mainly on the nitrogen atom of the middle pyridone ring. On the other hand, solvation of the negative charge on the pyridone oxygen atom is the main factor for the anion, and the vicinity of a bulky methyl group should have an appreciable effect. These conclusions and hypotheses agree well with experimental results: the acidity of (XLVII) is even lower (despite the electron-accepting effect of the pyridine ring) than that of the benzene analogue (XLV: $n = 2$) (pK_a 12.65).

In concluding this subsection we consider the reaction of fused quinolines (XLVIII) with phenyl-lithium, which indicates the acidity of the corresponding α-methylene groups[71]:

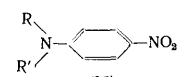


(XLVIII) (XLIX)

n	Yield, %	
1	97	< 1
2	96	< 1
3	61	31
4	33	48

It is assumed[70] that the acidity of the methylene groups is much lower for seven- and eight-membered rings, owing to steric inhibition of resonance in the resulting anion. A competitive process involving formation of the compounds (XLIX) is therefore observed with these rings.

3. Polargraphy



The polarographic reduction of C_5–C_{16} bromocycloalkanes gives a curve[74] similar to that obtained earlier for S_N2 solvolytic reactions. The five-membered compound is reduced most readily, and the six-membered compound with greatest difficulty (bromocycloheptanone occupies an intermediate position)[74], in good agreement with the concept of *I*-strain. For the fused cyclic compounds

(L)

n	1	2	3
$-E_{1/2}$, V	0.695	0.748	0.854

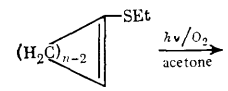
the variation in ease of polarographic reduction agrees well[75] with the Finnegan–Streitwieser concept. In the case of nitrobenzenes containing *p*-diethylamino, *p*-pyrrolidino, or *p*-piperidino

(LI)

a) R = R′ = Et, $E_{1/2}$ = −0.625 V;
b) RR′ = $(CH_2)_4$, $E_{1/2}$ = −0.619 V;
c) RR′ = $(CH_2)_5$, $E_{1/2}$ = −0.599 V.

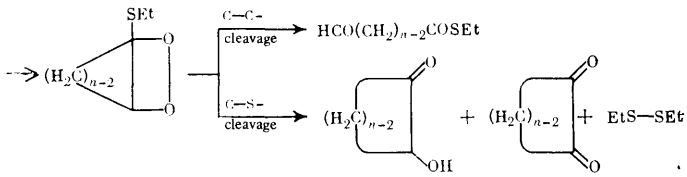
on the other hand, the six-membered compound is reduced more readily, since the pyrrolidine ring conjugates better with the benzene ring, i.e. is a stronger electron donor[50].

The polarographic behaviour of enamines (XIV: $n = 1$–3) shows[76] small but definite differences in half-wave potentials depending on ring size, with six-membered most readily reduced, and five-membered enamines with the greatest difficulty. This is explained[76] in terms of *I*-strain on the hypothesis that reduction to the radical-anion involves enhancement of the *p*-character of the radical centre. It was shown in the same and a subsequent paper[77] that this is apparently a general rule and can be used to indicate the site of reduction of an enamine (i.e. whether a ring atom or a side-chain is attacked by the electron) and the structure of the radical-anion.



III. RING SIZE AND REACTIVITY

1. Oxidation and Reduction

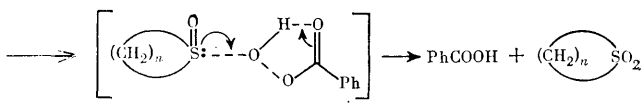


Rates of oxidation of cycloalkanes[78] and their derivatives by various reagents decrease with ring size in the sequence $C_8 > C_7 > C_5 > C_6$, which on the whole is consistent with the concept of *I*-strain[79]. However, the differences in rates of oxidation are far smaller than those in rates of solvolysis,

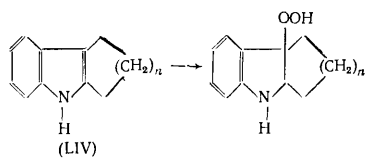
from which it was concluded that oxidation involves not formation of a carbonium ion but homolytic fission of a carbon-carbon bond[78].

Among cycloalkenes cyclohexene undergoes more rapid autoxidation than does cycloheptene, while cyclopentene is the most difficult to oxidise[80]. In contrast, rates of ozonolysis of cycloalkenes diminish in the sequence cyclopentene > cycloheptene > cyclohexene[81]: i.e. on the assumption that the reaction involves an $sp^2 \rightarrow sp^3$ change in configuration of the cyclic carbon atoms, this sequence is the opposite to that to be expected on the basis of *I*-strain. The direction of the photo-oxidation of cyclic vinyl sulphides (LII) depends considerably on ring size[82]:

(LII)



Carbon–carbon cleavage takes place almost quantitatively in unstrained six-membered and little strained twelve-membered rings[82].

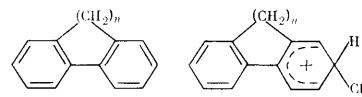


The rate of oxidation of cyclic tertiary amines, with slow intermediate formation of a planar radical-cation, decreases[83] in the sequence *N*-methylhexamethyleneimine > *N*-methylpyrrolidine > *N*-methylpiperidine. The oxidation of cyclic sulphoxides in acid and alkaline media

(LIII), $n = 3$–5

diminishes with ring size[84] in the sequences $C_6 > C_4 > C_5$ (pH 3.2–3.6) and $C_6 \cong C_4 > C_5$ (pH 11.85), the differences in rate being small. Finally, the dependence of rate of oxidation of polymethyleneindoles

(LIV)



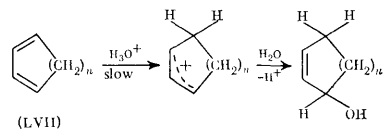
on ring size agrees well with the concept of *I*-strain[85].

Several studies have been made of the dependence of rate of reduction on ring size. Reduction of cycloalkenes by various methods gives a sequence of variation in rate (cycloheptene > cyclopentene > cyclohexene) the direct reverse of what might be expected on the basis of *I*-strain. It was supposed[86] that the main factor here is not change in hybridisation of the cyclic atoms but change in torsional and angular strains and the effect of α-substitutents. The dependence of rate of hydrogenation of cycloalkanones on ring size ($C_6 > C_5 > C_7$) suggests[87] change in hybridisation $sp^2 \rightarrow sp^3$ of the carbonyl carbon atom at slow stage. Other workers[88,89] have obtained similar results for the hydrogenation of cycloalkanones.

Among the compounds (LIa–c) the six-membered derivative is reduced far more rapidly[50], because of the difference in conjugation of pyrrolidine and piperidine rings with the benzene ring (Section II,3). The reduction of cyclic sulphoxides[90], which probably has an S_N2 mechanism, gives the expected dependence $C_5 > C_7 > C_6$ of rate on ring size. The negative entropy of activation increases as the ring becomes larger[90], because small and five-membered rings are quite rigid in the ground state, and the degree of order in the activated complex does not increase so substantially as in six- and seven-membered rings.

2. Reactions with Electrophilic Reagents

Bromination[91], nitration[91,92], and isotope exchange[93] in indane and tetralin show that, when a strained fused ring is present, electrophilic substitution occurs to a considerably greater extent at a β- than at an α-position, in good agreement with the above Finnegan–Streitwieser concept. This effect does not operate[94] in the chlorination of tricyclic compounds (LV)



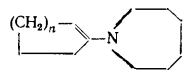
(LV) (LVI)

where the ability of the second benzene ring to stabilise a transition state of type (LVI) is the most important factor. Values for (LV) of the angle θ of the twisting of the second benzene ring from the plane of the first and the relative rates of chlorination

n	1	2	3	4
θ	0	16	49	67
k_{rel}	300	26.6	1.3	0.84

demonstrate[94] the importance of coplanarity of the two aromatic rings in reactions of this type.

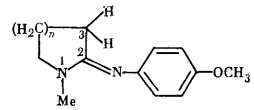
Protodesilylation of benzocyclobutane, indane, and tetralin derivatives also gives the expected results[95]: the presence of a strained fused ring directs electrophilic addition of a proton (the rate-determining stage) mainly at a β-position (Section I). The main factor in the addition of various reagents at the double bond in cycloalkenes is apparently (as in reduction) not the change in hybridisation but the overall change in strain in the rings: in such cases addition to cyclopentene is more rapid than that to cyclohexene[96]. On the other hand, the highest rate of hydration of dienes in acid medium is observed with the six-membered compound[97]:



(LVII)

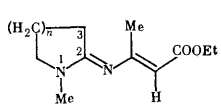
n	1	2	3	4
k_{rel}	200	2000	4	1

These workers remark[97] that a model of *I*-strain fits nucleophilic substitution better than electrophilic substitution: differences in the dependence on ring size are substantially smaller in the latter case. This is attributed[97] to a smaller



degree of rehybridisation in the transition state involved in electrophilic substitution.

Several studies[98-100] of the alkylation of cyclic enamines have shown in all cases that attack at a cyclic carbon atom (*C*-alkylation) occurs more readily with five-membered compounds, owing to the stronger conjugation of the lone pair of the pyrrolidine nitrogen atom with the enamine double bond. The rate of deuterium exchange K^D_{rel} of a vinyl proton in enamines also depends on ring size[101]:

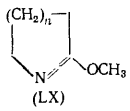


n	1	3
k^D_{rel}	5.95	1.98

Dependence of rate of deuterium exchange of protons in perdeuteromethanol at position 3 on the size of a saturated nitrogen heterocycle has been observed also in series of amidines and enamidines[102,103]:

(LVIII)

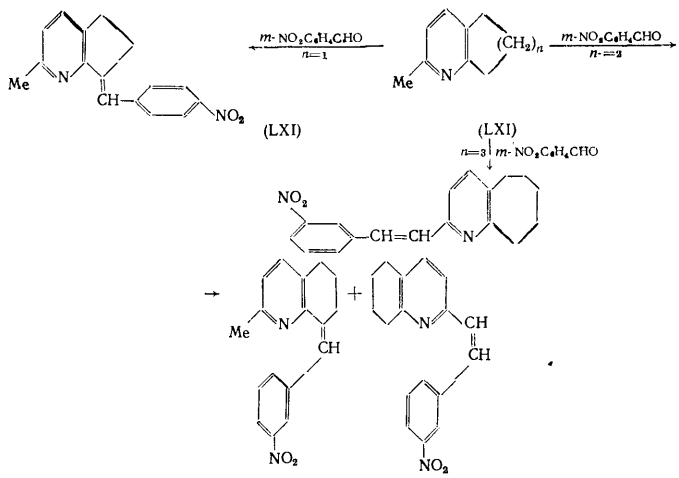
n	1	2	3
10^5k, s^{-1}	13.02	51.69	6.48



(LIX)

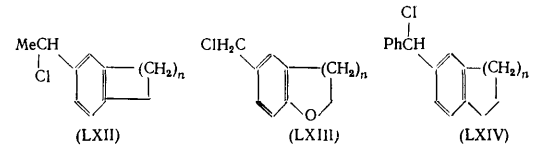
n	1	2	3
10^5k, s^{-1}	1.44	3.77	0,25

On the assumption that the reaction involves tautomeric enamines with the double bond at position 2 or 3, rehybridisation of carbon atom 3 takes place in the rate-determining stage, and the resulting series corresponds to the variation in *I*-strain.



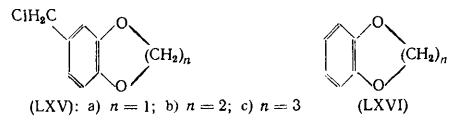
Small but definite differences have been observed[104] in the alkylation of lactim ethers with dimethyl sulphate:

(LX)



n	1	2	3
k_{rel}	1.36	1.13	1

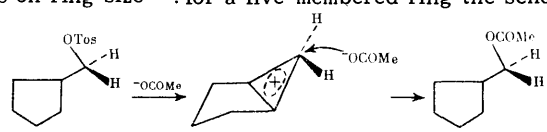
Rehybridisation does not occur, and *F*-strain is apparently responsible for the variation in rate. The action of aldehydes on 2,3-polymethylenepyridines (LXI) depends[105,106] on the length of the polymethylene chain:



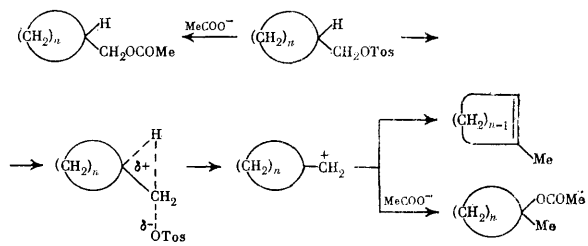
3. Reactions with Nucleophilic Reagents

Most of the work concerned with the problem covered in this Review has been devoted to reactions of cyclic compounds with nucleophilic reagents[107-131], and most of these investigations have studied various types of solvolytic reactions. Thus the rate of solvolysis of the chlorine atom in (LXII)

(LXII) (LXIII) (LXIV)

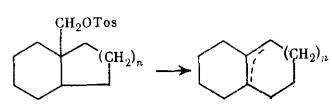


decreases in the sequence $C_5 > C_4 > C_6$.[92] The same rules for five- and six-membered rings had been observed earlier in oxygen-containing bicycles (LXIII)[25] and the compounds (LXIV)[107]; in the latter case the effect was explained in terms of hyperconjugation. For the bicyclic compounds (LXVa-c)



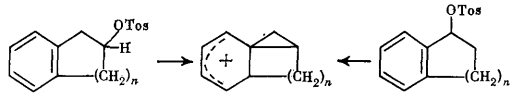
(LXV): a) $n = 1$; b) $n = 2$; c) $n = 3$ (LXVI)

the relative rates of solvolysis were 10 : 6 : 1.[108] What these workers[108] regarded as the two main effects in this system (conjugation of the lone pair of the oxygen atom with the cationic centre and the inductive effect of the second oxygen atom) have already been discussed in detail (Section II,2). These same effects determine the relative rates of hydrolysis of the complex ethers (LXVI).[65] The solvolysis of cycloalkyl bromides (as well as their reaction with the iodide anion) is fully consistent with the concept of *I*-strain[109].



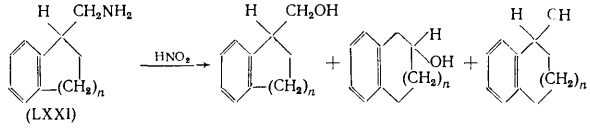
The solvolysis of cycloalkylmethyl toluene-*p*-sulphonates depends on ring size[110]: for a five-membered ring the scheme

has been suggested; and for larger rings



It is evident that in all cases a planar configuration of the cyclic carbon atom should arise at an intermediate stage, so that the rate of solvolysis varies with the *I*-strain: $C_5 > C_7 > C_6$. The solvolysis of toluene-*p*-sulphonates (or *p*-nitrobenzoates) in the different type of system (LXVII) is also appreciably more rapid in the five-membered compound[111]:

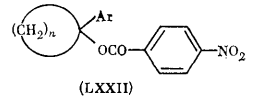
(LXVII)



n	1	2
k_{rel}	1500	3.9

An interesting comparison has been made of the solvolysis of the toluene-p-sulphonates (LXVIII) and (LXIX), in which the same mechanism with intermediate formation of a phenonium ion (LXX) is involved[112]:

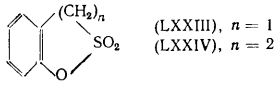
(LXVIII) (LXX) (LXIX)



The rate constants (10^5k, s^{-1}) of formolysis of (LXVIII) are 27.3 (6), 152 (7), 2250 (8) (ring size in parentheses). Such successive increase in rates was attributed[112] to decrease in the angular strain in the cation (LXX). However, a different variation in rate applies to the process (LXIX) → (LXX): 2.51 (5), 6.80 (6), 1.80 (7), 0.18 (8). These results were interpreted[112] on the basis of molecular models: only axial isomers can be converted into (LXX), but because of conformational factors the existence of such isomers is unfavourable for seven- and especially eight-membered compounds. The same conformational effects determine the composition of the products in the deamination of amines (LXXI)[113]:

(LXXI)

n		Yield, %	
1	—	85	15
2	38	62	—
3	—	45	53
4	—	<5	54

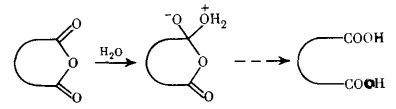


A closely related investigation of the hydrolysis of *p*-nitrobenzoates (LXXII)[114] has given results agreeing well with the concept of *I*-strain:

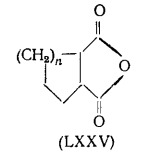
(LXXII)

n	3	4	5	6	7
k_{rel}	0.426	178	1	51.5	515

An attempt has been made[115] to relate rates of hydrolysis of lactones and cyclic toluene-*p*-sulphonates with the strain in the rings. However, a correlation has been observed only for the pair



(LXXIII), $n = 1$
(LXXIV), $n = 2$

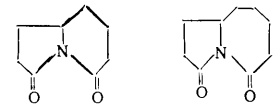


the five-membered ring is more stressed by ~100 kJ mole^{-1}, and is hydrolysed more rapidly by a factor of 10^4.

In aqueous ethanol five-membered anhydrides are hydrolysed rather more rapidly than the six-membered compounds, whereas in an alkaline medium glutaric anhydride is hydrolysed slightly more rapidly[116]. In contrast to this closeness of the rates of hydrolysis of anhydrides the differences for lactams and especially lactones and thiolactones are incomparably larger[116], and agreement with Brown's views (*I*-strain) is better. Various degrees of change in hybridisation in the transition state were assumed[116] to be possible, and these changes determined the relative rate constants of six- and five-membered compounds. The rate of the reverse reaction—cyclisation of acid esters into anhydrides—is much higher for the five-membered ring, apparently because of the entropy factor, consisting in better steric conditions for closure of such a ring[116].

Rates of hydrolysis of succinic and glutaric anhydrides at pH 5.2 and 20 °C are almost equal[117]. This is interpreted in terms of *I*-strain, with respect to which the situation in the transition state is more favourable of the six-membered ring:

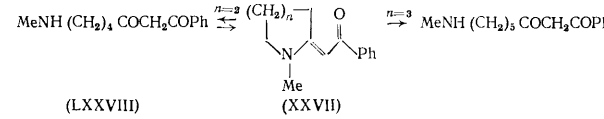
On the other hand, succinic anhydride is characterised by an extremely strained ground state (three sp^2-carbon atoms), which facilitates addition of water. The superposition of these effects gives almost the same rate constants for the five- and six-membered rings. Results in the same paper[117] for the effect of the size of the fused ring on the rate of hydrolysis of anhydrides



(LXXV)

n	1	2	3
k, min^{-1}	1.13	0.381	0.185

show that the effect is due to steric hindrance (by the methylene groups) to attach by water in seven- and six-membered in comparison with five-membered anhydrides.

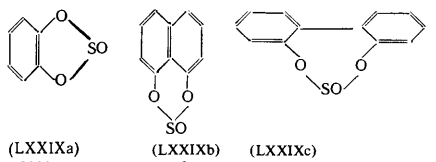


For *N*-methyl-succinimide, -glutarimide, and -adipimide rates of hydrolysis fall in the sequence $C_6 > C_7 > C_5$, with not very large differences ($k_6 : k_7 : k_5 = 2.6 : 1.5 : 1$).[118] Hydrolysis of the bicyclic imides

(LXXVI); 85.7% (LXXVII); 66.1%

in an alkaline medium occurs preferentially at the six- and seven-membered rings (degrees of hydrolysis given for 20 °C).[118]

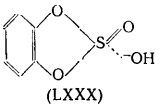
Among enamines, compounds containing a six-membered ring are hydrolysed appreciably more rapidly in the pH range in which addition of water ($sp^2 \rightarrow sp^3$ transition for the β-carbon atom) limits the rate[119,120]. Rates of hydrolysis of the enamines (XXVI) depend significantly on ring size[60, 121], owing to the difference in the site of their protonation in strongly acid media. Detailed polarographic study[122] of the hydrolysis of the enamino-ketones (XXVII) has established that in 0.1*N* hydrochloric acid only the seven-membered (XXVIIc) is hydrolysed quantitatively, the equilibrium (XXVIIb) ⇋ (LXXVIII) being established for the six-membered compound:



(LXXVIII) (XXVII)

the five-membered (XXVIIa) is not hydrolysed. Such differences are explained by acceleration of the reverse reaction on passing from the seven- to the six- and then the five-membered ring as a consequence of the entropy factor. The rate constant of the forward reaction (hydrolysis) for the six-membered ring (9×10^{-4} s^{-1}) is about double that for the seven-membered ring. Heating (XXVIIa and b) in an acetate buffer results in acid cleavage (with formation of benzoic acid), the rate of which is lower for the five- than for the six-membered ring (10^4k respectively 1.63 ± 0.37 and 6.2 ± 1.9 s^{-1}). Heating (XXVIIa–c) in 0.1*N* sodium hydroxide yields acetophenone, the rate decreasing in the sequence $C_6 > C_7 > C_5$.

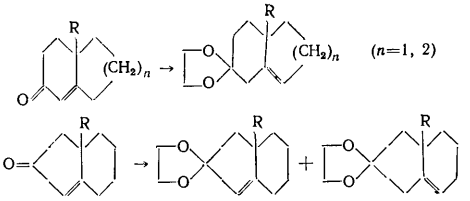
The kinetics of the alkaline hydrolysis of amidines[53] is not consistent with the concept of *I*-strain: the rate of hydrolysis falls in the sequence $C_5 > C_6 \gg C_7 > C_8$. In the



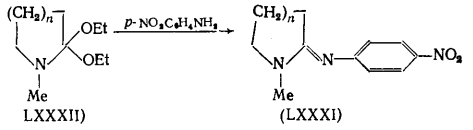
alkaline hydrolysis of cyclic sulphites the five-membered compound is hydrolysed most rapidly, and the seven-membered compound most slowly[123]:

(LXXIXa) (LXXIXb) (LXXIXc)

$10^6\ k,\ s^{-1}$	2000	16	2.9



The explanation given[53] for these results is that attainment of a transition state of type

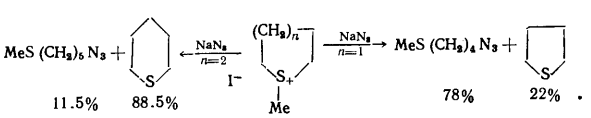


(LXXX)

is more favourbale for the planar five-membered ring. An alternative explanation can be based on repulsion of the hydroxide anion and the lone pair of the oxygen atom (as already discussed for lactones)[124], which diminishes in the sequence $C_7 > C_6 > C_5$.

Results[125,126] on the formation of hemiacetals and acetals of cyclic ketones agree well with concept of *I*-strain. An extremely interesting investigation[127] on migration of a double bond during acetalisation as a function of ring size has shown that, if the carbonyl group is present in a six-membered ring, 100% migration into the other ring takes place, whereas in a five-membered ring a mixture is formed:

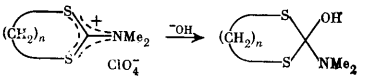
It has been established[128] by a method of competing reactions that the rate of formation of amidines (LXXXI) by the action of primary amines on lactam acetals (LXXXII) depends on ring size, varying in the sequence $C_5 > C_7 > C_6$:



LXXXII) (LXXXI)

n	1	2	3
k_{rel}	28	1	8.3

The reaction mechanism was not studied specially, but the above relation corresponds to a change in hybridisation of the cyclic carbon from sp^3 to sp^2.

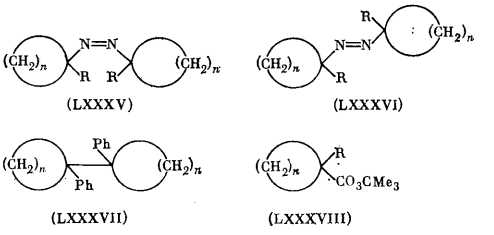


In the action of sodium azide on onium salts, e.g. (LXXXIII), the five-membered ring undergoes cleavage, wheras a six-membered ring is preserved:

(LXXXIII)

It was assumed[129] that the cleavage of an unstrained five-membered ring is more favourable than that of an unstrained six-membered ring, and that attack on the unshielded carbon atom 2 in the saturated ring is more favourable for the five-membered ring. Six-membered compounds are characterised by attack at the exocyclic methyl group.

Maximum and minimum rates of reaction of dithiolonium salts

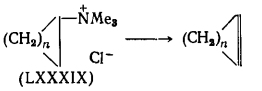


(LXXXIV), $n = 2-4$

are exhibited by seven- and five-membered compounds respectively, which is regarded[130], as corresponding to an increase in stability of the ground state in this sequence ($C_5 > C_6 > C_7$).

4. Radical Reactions

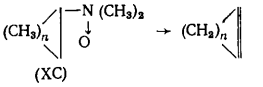
Capture of a hydrogen atom by various radicals (butoxy, bromine, chlorine, phenyl, etc.) on reaction with cycloalkanes gives a sequence of diminishing reaction velocity $C_5 \cong C_7 > C_6 > C_8 > C_9$ corresponding well to formation of a planar (sp^2) radical centre[132]. Similar results have been obtained for the detachment of a bromine radical from cycloalkyl bromides[133]. A series of studies[134,135] of the formation of radicals by the thermolysis or photolysis of *cis*- and *trans*-azo-compounds (LXXXV) and (LXXXVI), biscycloalkanes (LXXXVII), and peroxides (LXXXVIII)



(LXXXV) (LXXXVI)

(LXXXVII) (LXXXVIII)

has established that, although the concept of *I*-strain applies well to (LXXXVI) and (LXXXVII), with (LXXXVIII) the dependence of rate on ring size is quite insignificant, but for (LXXXV) the rate increases monotonically. The explanation is that the variation in rate depends on the extent to which hybridisation of the reaction centre has changed in the transition state, i.e. whether the latter resembles the initial or the final state. It is necessary[135] to take into account *F*-strain as well as *I*-strain.

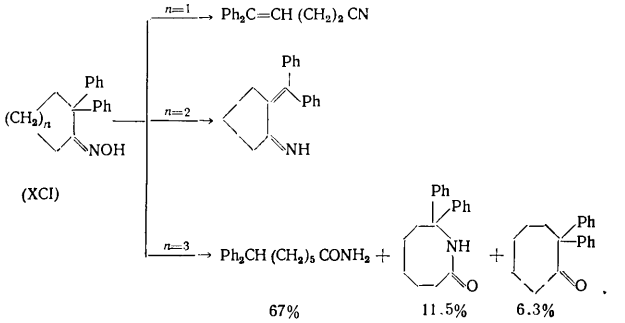


5. Elimination Reactions

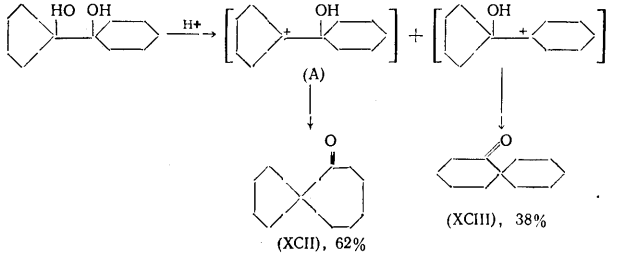
Relatively few investigations have been made on the influence of ring size on rate of elimination. In that of trimethylamine from salts

(LXXXIX)

the rate varies in the sequences $C_5 > C_7 > C_6$ and $C_7 > C_5 > C_6$ in the presence of potassium t-butoxide and ethoxide respectively[136,137]. The suggested reaction mechanism involves formation of a planar activated complex, which is energetically unfavourable for six-membered and favourable for five- and seven-membered compounds. Similar results (with the same interpretation) have been obtained for the formation of cycloalkenes from *N*-oxides[138]



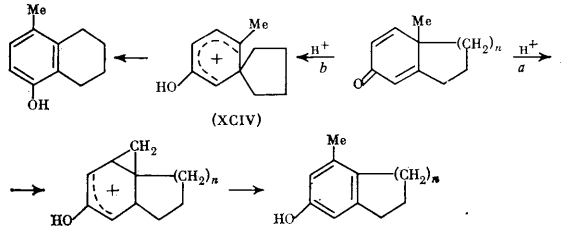
(XC)



and also in the dehydration of cycloalkanols and the dehydrochlorination of cycloalkyl chlorides[139].

6. Rearrangements

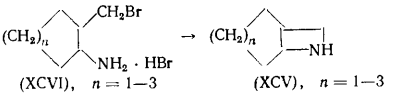
It was shown in several studies[140-143] that the rate of the Beckmann rearrangement falls in the aqueous cyclohexanone > cycloheptanone > cyclo-octanone > cyclopentanone. If the rate determining stage is assumed to involve conversion of an exocyclic into an endocyclic carbon-nitrogen double bond, these results are consistent with Brown's generalisation that five-membered rings are especially likely to retain double bonds in an exocyclic position[42]. When oximes (XCI) are heated under the conditions of the rearrangement, considerable differences are observed[144] in the dependence on ring size, with preferential opening of strained five- and seven-membered rings:



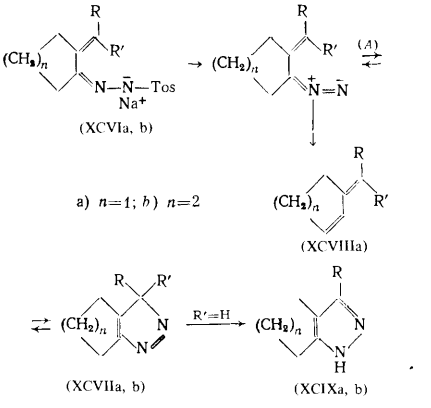
Important results have been obtained for the pinacoline rearrangement, clearly showing[145] that the first direction predominates when the carbonium centre is located in a five- or six-membered ring:

From our point of view formation of the cation (A) is still more favourable than would follow from the relative yields of reaction products (XCII) and (XCIII), since the entropy factor promotes closure of a six-membered (XCIII), not a seven-membered (XCII), ring. This factor must be taken into account in other cases as well (e.g. in the rearrangement of a compound containing five- and seven-membered rings), but the conclusion from the above work seems to be valid—that a carbocation centre is more readily localised on cyclic atoms of five- and seven-membered than of a six-membered ring.

The dienone–phenol rearrangement also depends on ring size:

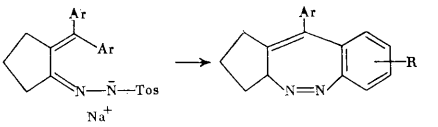


Only reaction path (*a*) is followed by the five-membered ring, since a four-membered spiro-compound of type (XCIV) is apparently unstable[146].

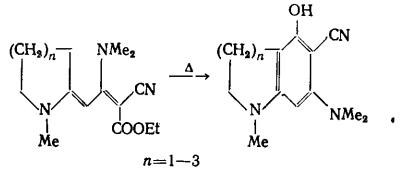


The rate of rearrangement of toluene-*p*-sulphonates of 1-hydroxymethyl-1-phenylcycloalkanes (into benzylcycloalkenes and benzylidenecycloalkanes) accompanying acetolysis decreases in the sequence $C_6 > C_5 > C_3 > C_4$.[147] The rate of isomerisation of methylenecycloalkanes into cycloalkenes[148,149] diminishes with ring size in the sequence $C_4 > C_5 >$ acylic cpd. $> C_6$. The slow stage is apparently formation of an anion with rehybridisation of the corresponding orbital.

7. Heterocyclisation

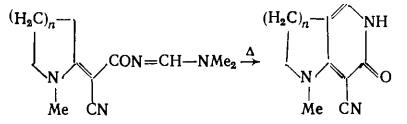


Formation of fused azetidines

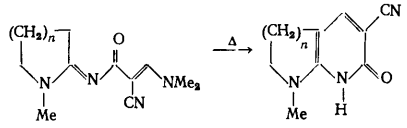


is most rapid for the seven-membered and slowest for the six-membered compound[150]. The increased rate of closure of (XCVI: $n = 3$) is attributed to greater conformational mobility of the seven-membered ring. Distinct differences are observed[151] in the cyclisation of toluene-*p*-sulphonylhydrazones (XCVIa, b):

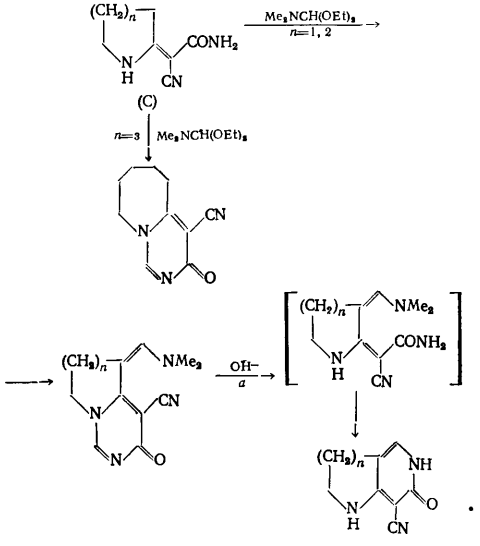
If R, R′ ≠ H, cyclisation of (XCVIa) yields only dienes, but that of (XCVIb) gives pyrazoles, since (XCVIIIa) is then unstable, equilibrium (*A*) is displaced to the left, and stabilisation is achieved with formation of the dienes (XCVIIIa). When R′ = H, stable pyrazoles (XCIXa, b) are formed. With R = R′ = Ar the direction of reaction is unchanged for six-membered compounds, but fused diazepines are formed from five-membered rings:



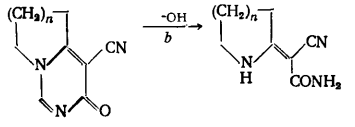
It has been established polarographically that in the formation of fused phenols from dienediamines six-membered compounds are cyclised most rapidly, and five-membered least rapidly[152]:



n=1–3

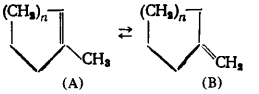


It has been shown by the same method that the rate of formation of fused pyrid-2-ones diminishes in the sequence $C_6 > C_7 > C_5$ [77]:



n	1	2	3
k_{rel}	1	249	28.6

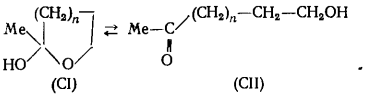
Such variation in rate is due to rehybridisation of cyclic carbon from sp^2 to sp^3 on formation of the transition state (it is supposed that tautomers having a $C_{(2)}:C_{(3)}$ endocyclic double bond undergo cyclisation). In the reaction between enaminoamides (C) and dimethylformamide acetal different compounds are formed depending on ring size[153–155]:



The ready cleavage of the pyrimidine ring observed in alkaline medium, with or without subsequent recyclisation (path *a* or *b*)

also depends on ring size, the rate varying in the sequence $C_5 \cong C_6 > C_7$.

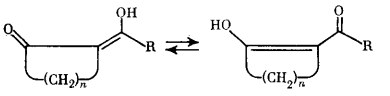
IV. RING SIZE AND EQUILIBRIA



Investigation of the equilibrium between methylenecycloalkanes and methylcycloalkenes indicated that, in contrast to Brown's conclusion[5], the *endo/exo* ratio was higher for five- than for six-membered rings. The earlier assumption[158] was adopted[156,157] that the "greater substitution" of the double bond in tautomer (A) than in (B) is important:

(A) (B)

It is significant that the position of equilibrium is very largely determined by solvation, and in the gas phase the above ratio is close to unity.

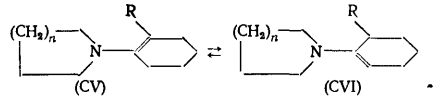


The leading role in the ring–chain equilibrium aminoketone ⇋ aminomethanol belongs to the entropy factor, and the cyclic form is observed only on formation of a five-membered ring[159]. When on cyclisation a larger number eclipsed interactions arise (in five-membered compounds), the situation levels off even for the equilibrium[160]

(CI) (CII)

Extremely contradictory results have been obtained for keto–enol tautomerism. Thus comparison of 2-benzoylindan-1-one with tetrahydronaphthalen-1-one reveals a much higher enol content in the five-membered compound[161], whereas in cycloalkanones and in acyl-lactones, -thiolactones, and -lactams[162–164] the quantity of the enolic tautomer diminishes on passing from the six- to the five-membered compounds. In 2-benzoylcycloalkanones[165], in contrast, the enol content decreases in the sequence $C_5 > C_7 > C_6$; in the enolic form the benzene ring is completely conjugated with carbonyl only in the five-membered compound.

Examination of the influence of ring size on the equilibrium

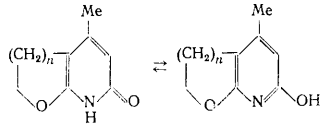


(CIII) (CIV)

shows[166,167] that tautomers having an endocylic double bond predominate in the six-membered compounds, followed by derivatives of cycloheptanone and cyclopentanone#.

The sequence $C_6 > C_8 > C_5 > C_7 > C_4$ in the rate of acid enolisation was explained[162] by the energetic advantage of formation of an endocylic double bond. However, the rate of basic enolisation of cycloalkanones varies in the different sequence $C_4 > C_5 > C_6 > C_7$, and it was correctly stated[162] that neither the advantage or disadvantage of formation of such a bond nor the concept of *I*-strain would explain such a sequence of decrease in rate of basic enoslisation. The explanation advanced[162] was that on passing from a seven- to a four-membered ring the s-character of the C–H orbital increases and ionisation of the C–H bond is facilitated, the latter being the rate-determining process in enolisation.

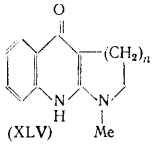
Similar relations have been observed[168] for the tautomerism of 2-acylcycloalkanethiones and 2-thioacylcycloalkanones.



On the whole the view that exocyclic double bonds predominate with five-membered rings, and endocylic double bonds with six-membered rings[5], has now become fundamental in the interpretation of results for enamine–enamine tautomerism of the type[169,170]

(CV) (CVI)

With a substituent R capable of conjugation (COOAlK, $COCH_3$, COC_6H_5, etc.) the tautometer (CV) predominates with the five-membered ring, whereas the ratio of tautomers for the six-membered ring is close to unity. This was attributed[169,170] to a greater degree of conjugation of the former ring (associated with greater favourability of the resonance structure having an exocyclic N:C bond) and less steric hindrance to such conjugation (involving steric interaction of methylene protons of the pyrrolidine or piperidine ring with R). However, as has already been pointed out repeatedly[9], Brown's "exo–endo" generalisation[5] is not rigorous and is by no means always observed. For hydrazone–enehydrazine tautomerism in *NN*-dimethylhydrazones of ethyl 2-oxocycloalkanecarboxylates[171] the quantity of the latter tautomer (having an endocyclic double bond) increases in the sequence $C_7 < C_6 < C_5$, perhaps because conditions for intramolecular hydrogen bonding are best in a cyclopentenylhydrazine derivative.



Lactim–lactam tautomerism

(XLIII), $n = 1$ (CVII)
(XLIV), $n = 2$

is another type exhibiting a distinct dependence of the position of equilibrium on ring size. Replacement of a dihydrofuran by a tetrahydropyran ring, both fused to a pyridone, leads to an appreciable decrease in the content of the lactim tautomer: the ratio of lactim to lactam decreases by factors of 15–20.[68] This was explained[68] by the Mills-Nixon-Brown effect (in the pyridone tautomer the double bond is localised in greater measure between the rings, which creates a more unfavourable situation for the five-membered ring: i.e. an endocyclic double bond is present) and by the electron-accepting influence of the strained ring, which increases the acidity of the nitrogen–hydrogen bond in (XLIII). Some uncertainty arises concerning the electron-accepting influence of five-membered compounds in the case of fused oxa- and aza-rings, since the degree of conjugation of the lone pair, in such case with the pyridone ring (electron-donor effect), is apparently highest also for these rings.

In another approach to the dependence of the position of lactim–lactam equilibrium the decrease in the content of lactim tautomers of the tricycles

(XLV)

n	1	2	3
Lactim, %	89	49	31

in the sequence $C_5 > C_6 > C_7$ has been attributed[172] to an accompanying diminution in the solvation of this tautomer, since hypothetical rehybridisation does not explain the differences between the six- and seven-membered rings. We can also try on this view to explain results for the equilibrium (XLIII), (XLIV) ⇆ (CVII). The orbital of the second pair of electrons of the oxygen atom (that of the first pair is perpendicular to the plane of the pyridine ring) is parallel to the nitrogen–hydrogen bond, and unfavourable shielding occurs with increase in the bulk of the substituent attached to the nitrogen atom (i.e. on solvation). For a six-membered ring, for which conjugation is less, the degree of shielding is also smaller, the lactam tautomer is better solvated, and the lactim content is appreciably diminished.

Finally, yet another equilibrium also characterised by dependence on ring size is the intermolecular association of lactams in non-polar solvents[173]: depending on the solvent the degree of association of lactams varies in the sequence $C_7 > C_5 > C_6$ (in tetrachloromethane, cyclohexane) or $C_5 > C_7 > C_6$ (benzene).

---oOo---

From the above survey several considerations arise of which, in the Reviewer's opinion, insufficient account is taken in interpreting experimental results, especially when the concept of *I*-strain is used. Thus in processes involving $sp^2 \rightarrow sp^3$ rehybridisation very much depends on the size of α-substitutents in the ring and that of the attacking species. Steric hindrance to attack at a ring atom increases in the sequence $C_5 < C_6 < C_7$, which differs from the rate sequence $C_5 < C_7 < C_6$ to be expected from a model based on *I*-strain: i.e. inversion of rates for five- and seven-, six- and seven-, and even five- and six-membered compounds is by no means excluded. In reactions of the reverse type (change in hybridisation $sp^3 \rightarrow sp^2$), in which the sequence $C_5 > C_7 > C_6$ is to be expected, the presence of bulky substituents at the reaction centre may lead to unexpected acceleration of reactions with six- and especially seven-membered compounds.

It must also be stressed that the tendency of a reaction centre to be solvated has likewise only occasionally been discussed as a function of ring size, although in several cases solvation may exert an appreciable (and perhaps decisive) influence on the relative rates of processes. It is clearly an extremely complicated task to separate these effects.

In conclusion it must be noted that, despite the complexity of the questions and the hitherto inadequate predictive power of existing theoretical approaches, efforts aimed at solving the problem of the relation between ring size and the properties and reactivity of compounds have proved extremely fruitful and have enriched significantly both theoretical and synthetic organic chemistry.

Phosphorylated and Thiophosphorylated Aminoheterocycles

L.V.Razvodovskaya, A.F.Grapov, and N.N.Mel'nikov

The review is devoted to the methods of synthesis, chemical reactions, reactivities, and transformations of phosphoryl- and thiophosphoryl-aminoheterocycles in living organisms and in the surrounding medium. Many of these substances are biologically active and are used in the national economy.
The bibliography includes 170 references.

CONTENTS

I. Introduction 135
II. Methods of synthesis of phosphorylated aminoheterocycles 135
III. Reactions of phosphorylated and thiophosphorylated aminoheterocycles 142

I. INTRODUCTION

Many derivatives of aminoheterocycles are used in various branches of the national ecomony; particular mention should be made of the use of sulphamidoheterocycles as medicinal drugs.. Phosphorylated and thiophosphorylated aminoheterocycles of similar structure also exhibit a varied biological activity. The nature of the activity is influenced significantly both by the nature of the heterocycle and by the structure of the phosphorus-containing residue. Phosphorylated and thiophosphorylated aminothiadiazoles[1], aminotriazoles[2-8], and aminothiazoles[1] have been patented as fungicides. Diethyleneaminophosphoryl-derivatives of 2- and 4-aminopyrimidines[9-12], aminopurine[13-15], 3-aminopyridazine[16], and 2-amino-1,3,4-thiadiazole[17-19] exhibit a carcinolytic activity against various strains of leukaemia and sarcoma. Data exist on the herbicidal and growth regulating activity of phosphorylaminothiazoles[20], phosphorylaminotriazoles[21], and phosphorylaminotriazines[22-27]; derivatives of 4-phosphazopyridazine also possess a herbicidal activity[28]. The weaker bactericidal activity of derivatives of phosphorylaminopyridine has been noted[29].

However, most phosphorylaminoheterocycles exhibit insecticidal and acaricidal activities. Derivatives of aminopyran[30], aminothietan[31-34], aminodithiolan[35-37], aminooxazole and amino-oxazoline[38-41], aminothiazole and aminothiazoline[38,41-48], amino-oxazine[41], aminotriazole[2,4,5,8,21], amino-1,3,4-thiadiazole and amino-1,2,4-thiadiazole[49,50], aminotriazine[51], and aminophenothiazine[52] have been described as insecticides and acaricides.

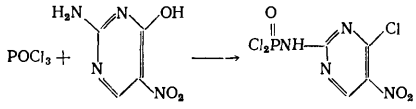
Some of the phosphoryl- and thiophosphoryl-aminoheterocycles have found practical applications as chemical plant protecting agents and medicinal drugs. 2-Diethoxythiophosphorylamino-1,3-dithiolan and 2-diethoxythiophosphorylamino-4-methyl-1,3-dithiolan under the commercial names "Cyolan" (dithiolene) and "Dithiolan" [53] are used as broad-spectrum insecticides against a group of pests on the cotton plant. 5-Amino-3-phenyl-1H-1,2-triazol-1-yl, *N*,*N*-dimethylphosphoramidate (triamiphos, vepsin) has been employed on a small scale as a systemic fungicide against powder mildew[53-57]. 4-Bromo-2-phenyl-5-(trimethoxyphosphazo)pyridazin-2-one (SGA 18796 preparation) has been tested as an experimental herbicide against weeds in sugar beet plantations[53]. Diaziridinyl 2-pyrimidinyl phosphoramidate (phosphamide) has been used in medical practice for the treatment of hypodermiasis[11]. The antitumour preparation 6-diaziridinylphosphorylamino-2-dimethylamino-7-methylpurine (fopurine) is effective against various forms of leukaemia in laboratory animals[58,59].

Bearing in mind the increasing importance of phosphorylated and thiophosphorylated aminoheterocycles for practical applications in the national economy, we thought it timely to compile this review of the literature data concerning the methods of synthesis and the chemical and physical properties of compounds of this class. The review covers the literature up to the middle of 1980.

II. METHODS OF SYNTHESIS OF PHOSPHORYLATED AMINOHETEROCYCLES

The commonest method of synthesising phosphoryl- and thiophosphoryl-aminoheterocycles is the reaction involving the phosphorylation of aminoheterocycles. Phosphoryl chloride, the chlorides and isothiocyanides of phosphorus acids, diphosphadithietans, acid phosphites, phosphorus pentachloride, etc. can be used as phosphorylating agents.

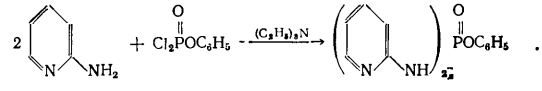
1. Phosphorylation with Chlorides of Tetracoordinate Phosphorus Acids



When phosphoryl chloride interacts with aminoheterocycles, the corresponding dichlorides of phosphoramidic acids are formed (Het is the residue of the heterocycle):

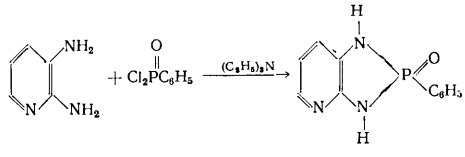
$$POCl_3 + H_2N\text{—}Het \xrightarrow[-HCl]{} Cl_2\overset{\overset{O}{\|}}{P}NH\text{—}Het \quad .$$

2-, 3-, and 4-Aminopyridines[10,60], 2- and 4-aminopyrimidines[10,12,61-65], 2-aminothiadiazoles[17,19,60,66], 2-aminobenzothiazole[67], 3-aminoindole[68], aminopurines[14,69], 3-aminopyridazine[70], creatinine[71], and sydnone imine[72] have been used as the initial aminoheterocycles. These reactions are usually carried out with refluxing in an excess of phosphoryl chloride for several hours and sometimes with heating in an organic solvent, for example, in benzene[64] or dichloromethane[72,73].



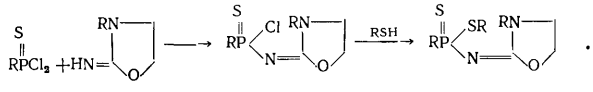
The reactions with secondary heterocyclic amines such as 2-alkylamino-1,3,4-thiadiazoles[18,19], 2-alkylamino-*sym*-triazines[24,73], and 2- and 4-alkylaminopyridines[74-76] proceed analogously. We may note that, when 6-chloro-2,4-bis-ethylamino-*sym*-triazine is refluxed with phosphoryl chloride for several hours, the products of the phosphorylation of only one amino-group are formed[23,25].

In the reaction with 2-amino-4-hydroxy-5-nitropyrimidine, phosphoryl chloride behaves not only as a phosphorylating agent but also as a chlorinating agent[77,78]:



This method has been used to synthesise labelled compounds[15].

When phosphorus acids dichlorides were allowed to react with aminoheterocycles in the presence of tertiary amines, the corresponding phosphorus acid diamides were isolated[29,79,80]. *N*,*N*-di-(2-pyridyl)- and *N*,*N*-di-(2-pyrimidinyl)-*p*-nitrophenylphosphonodiamidates have been obtained in yields of 43 and 7% respectively by refluxing in dioxan 1 mole of *p*-nitrophenylphosphonic acid dichloride with 4 moles of the aminoheterocycle. Aryl *N*,*N*-di-(2-pyridyl)phosphorodiamidates have been obtained under similar conditions[29]:



It is of interest to note that 2,4-diaminopyridine and the dichloride of phenylphosphonic acid react on heating in bromobenzene at 90–100 °C in the presence of an excess of a tertiary amine[81] to form a bicyclic condensation product:

4,5-Diaminopyrimidine does not enter into a similar reaction[81].

In many instances it is possible to achieve a controlled substitution of only one chlorine atom in the dichlorides of phosphonothionic acids by an aminoheterocycle residue and in such reactions the acid monochlorides are as a rule treated with nucleophiles without isolation in a pure form and the corresponding amidoesters of phosphonothionic acids are obtained. For example, the dithiophosphoryl derivatives of imino-oxazolidine are obtained by the reaction of the dichlorides of phosphonothionic acids with imino-oxazolidine and subsequent treatment with a thiol in the presence of sodium hydroxide[38,82]:

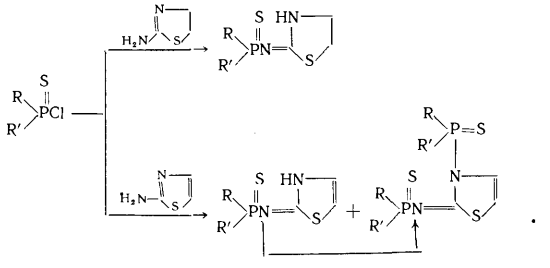
The reaction of the dichloride of chlorobutylphosphonic acid with 2-aminopyridine and subsequent hydrolysis with water in the presence of triethylamine yielded the acid ester of the corresponding pyridylphosphonamidic acid[83].

The reactions with the monochloride, ester, amide, and ester-amide derivatives of phosphorus acids with 2-, 3-, and 4-aminopyridines[29,84–88], 2- and 4-aminopyrimidines[85,89,90], 2-aminodithiolan and its salt[36], 2-iminodithiole and its salt[91], derivatives of 4-aminopyrazole[92], 2-aminoimidazoline[79], 2-aminothiazole[79,85,93,94], 3-alkyl-2-iminothiazolines[43,44,95], 2-aminothiazoline[79], 3-alkyl-2-iminothiazolidines[38,41,82,96–97], 2-imino-oxazolidines[38,41,82,96–98], 2-imino-1,3,4-thiadiazole[49], 3-alkyl-2-iminoperhydro-oxazines[38,41,97], 2-aminoquinoline[86], 2-aminobenzimidazole[99], 2-imino-1,3-dimethylbenzimidazoline[99], 2-aminobenzothiazole[85,99], 3-alkyl-2-iminobenzothiazoline[85,99], 2-aminobenzoxazole[99], 3-alkyl-2-iminobenzoxazoline[99], and 2-aminophenothiazine[52] have been investigated.

The reaction is carried out by heating a mixture of the phosphorus acid chloride with the aminoheterocycle or its salt in an organic solvent in the presence of a tertiary base and a double excess of the aminoheterocycle or an inorganic base, and also in a water–organic solvent two-phase system in the presence of alkali. The reaction and the yield of final products are influenced significantly by the structure of the phosphorus acid chloride, the basicity of the initial aminoheterocycle, and the nature of the solvent.

As a rule, the chlorides of oxygen-containing phosphorus acids react smoothly with aminoheterocycles in the presence of tertiary bases in non-polar and polar solvents and give rise to the corresponding amides in high yields. However, dialkyl phosphorochloridates do not react with 2-aminoquinoline in benzene; phosphorylation products have been obtained in 35% yield when the process was carried out in dioxan at 100 °C.[86] On reaction with dialkylphosphorochloridates, 2-aminopyridine *N*-oxide is converted into the corresponding hydrochloride[87].

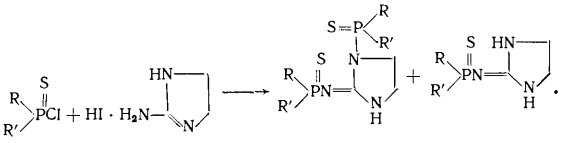
It is noteworthy that dialkyl phosphorochloridates sometimes act as alkylating and not phosphorylating agents. Dimethyl phosphorochloridate reacts vigorously with 2-aminopyridine, the process being accompanied by a spontaneous temperature rise to 230 °C. *N*-Methylpyridone imine was isolated from the reaction products[100].



When 2-aminoquinoline *N*-oxide reacts with dialkyl phosphorochloridates, the products of its alkylation at the exocyclic nitrogen atom are formed[86].

The decrease of reactivity on passing from diaryl phosphorochloridates and diaryl phosphorochloridothioates to the chloride of dimethylphosphinothionic acid, caused by the decrease of electron density at the phosphorus atom, can be followed in relation to the reaction of 2-aminopyridine with phosphorus acid chlorides. For example, 2-aminopyridine reacts smoothly with diaryl phosphorochloridates and phosphorochloridothioates in benzene or toluene in the presence of tertiary bases[29]; the yields reach 60%. Aryl *N*-(2-pyridyl)methylphosphonoamidates and *N*-(2-pyridyl)-methylphosphonoamidothioates have been obtained in 40–70% yield on refluxing of the components in benzene for several hours[84]. Under these conditions, ethyl methylphosphonothioate was isolated in a yield less than 20%,[84] and, when the reaction of the chloride of dimethylphosphinothionic acid with 2-aminopyrimidine was carried out in moist benzene, only tetramethyl pyrophosphinodithioate was isolated[85]. However, when anhydrous pyridine is used as the solvent, thiophosphorylation of 2-aminopyridine (and also 2-aminopyrimidine, 2-aminothiazole, and 2-aminobenzothiazole) leads to dimethylthiophosphorylaminoheterocycles in yields of 60–70%.[85]

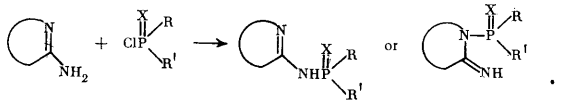
In the general case highly basic aromatic aminoheterocycles and heterocyclic imino-compounds substitute chlorine relatively readily in the chlorides of phosphoric, phosphonic, and phosphinic acids and also their thio-analogues when the reactions are carried out in both non-polar and polar solvents. Heteroaromatic compounds of the type of 2-aminopyridine and 2-aminopyrimidine react poorly or not at all in the required manner. The transition from non-polar to polar solvents sometimes leads to an increase of the reactivity of the initial components and the formation of phosphoryl- or thiophosphoryl-aminoheterocycles[85,86].



In the study of the reactions of aminoheterocycles containing the amidine system with the chlorides of oxygen- and sulphur-containing phosphorus acids it was noted that, depending on the phosphorylating agent, mono- or diphosphorylated products are formed[79]. The reactions with the chlorides of phosphonic acids result in the formation of

only 2 phosphorylamino-derivatives in all cases. The reactions with the chlorides of the sulphur-containing phosphorus acids proceed specifically as a function of the nature of the amine. 2-Aminothiazoline reacts with the chlorides of phosphonothioic acids to form the products of thiophosphorylation at the exocyclic nitrogen atom, while the reaction with 2-aminothiazole yields a mixture of products of thiophosphorylation at the exocyclic nitrogen atom alone and at both nitrogen atoms:

The diphosphorylation product is apparently obtained as a result of the stepwise substitution of the hydrogen atoms of the amino-groups by the phosphonothioic acid residue.



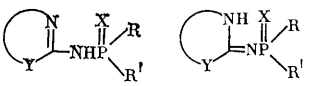
The reaction of equimolar amounts of 2-aminoimidazoline hydriodide with the chlorides of phosphonothioic acids in the presence of 2 moles of triethylamine led to the isolation of the products of diphosphorylation of 2-aminoimidazoline in 20% yield. The reaction of 3 moles of phenyl methylphosphonochloridothioate with 1 mole of 2-aminoimidazoline hydriodide leads to a mixture of di- and mono-phosphorylation products[79]:

The difference between the thiophosphorylation reactions is a consequence of the decrease of the nucleophilicity of the ring nitrogen atom in the series of thiophosphorylated 2-aminoimidazoline, 2-aminothiazole, and 2-aminothiazoline[79]. The absence of diphosphorylation products in the series of phosphonic acids can be explained not only by the decrease of the electron density at the endocyclic nitrogen atom in phosphorylaminoheterocycles compared with their thiophosphoryl analogues, as a consequence of the greater electron-accepting influence of the phosphoryl group, but also by the presence of a strong intramolecular bond between the phosphoryl oxygen and the hydrogen atom at the ring nitrogen atom.

The reaction of 3,5-diamino-1,2,4-thiadiazole or its salt with the chlorides of phosphorus acids leads to the formation of the products of the phosphorylation of only one amino-group[49].

Aminoheterocycles containing the amidine fragment N = C–N, in which one of the nitrogen atoms is exocyclic, can be phosphorylated at both endocyclic and exocyclic nitrogen atoms:

Furthermore, 2-phosphoryl(thiophosphoryl)amino-1-azaheterocycles can exist in the amino- or imino-forms:



amino imino

In the determination of the structures of phosphoryl-(thiophosphoryl)aminoheterocycles, various spectroscopic methods were used for each group of compounds: ultraviolet and infrared spectroscopy and ^1H and ^{13}C NMR.[79,84,89,99,105]. Compounds with a fixed structure were used as standards. ^{31}P NMR could not be used for these purposes because of the complex dependence of the chemical shifts of the signals and their form on the immediate environment of the phosphorus atom[101]. It follows from the results that in all the cases investigated the phosphorylation (thiophosphorylation) of 2-amino-1-azaheterocycles involves the exocyclic nitrogen atom[79,84,89,99], except for derivatives of 3-amino-1,2,4-triazole[102–104].

The existence of a phosphorylated (thiophosphorylated) heterocyclic amine in the amino- or imino-form depends significantly on both the nature of the heterocycle and on the electron-accepting properties of the phosphorus-containing residue. Phosphorylated and thiophosphorylated aromatic aminoheterocycles, namely pyridine[84] and pyrimidine[89], exist exclusively in the amino-form regardless of the nature of the solvent and the phosphorus-containing residue. For derivatives of 2-aminobenzimidazoles and 2-aminobenzothiazole[99], whose aromaticity is lower, the influence of the phosphorus-containing residue is decisive. Phosphoryl derivatives exist in the imino-form, while thiophosphoryl derivatives exist in the amino-form. 2-Aminobenzoxazole[99], 2-amino-1-methylbenzimidazole[99], and 2-aminothiazole[79] are still less aromatic and their derivatives have the imino-structure. Phosphorylated 2-aminoaza-heterocycles, whose rings are not stabilised to some extent as a result of aromaticity, exist only in the imino-form[79] (see Table).

The structure of phosphorylated and thiophosphorylated 2-amino-1-azaheterocycles.

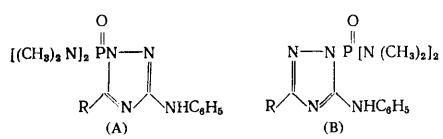
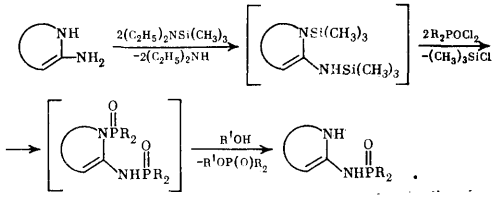
Prototropic tautomerism in these compounds has not so far been observed. We may also mention an NMR study of the diastereoisomers of phosphorylimino-oxazolidines[106].

The phosphorylation of 5-substituted 3-amino-1,2,4-triazole with phosphorus acid chlorides of different structure (including phosphoryl chloride) involves the nitrogen atom of the heterocycle in the 2-position[2-4,7,8,21,102-104,107-111]:



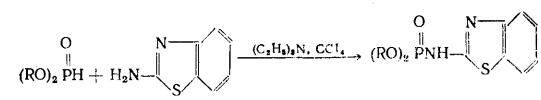
The structure of 1-phosphorylamino-derivatives, attributed by some workers to the phosphorylation products of 2-aminobenzimidazole[109], 5-aminotetrazole[110], and 4-amino-3,5-dimethylpyrazole, is either correct (cf. Grapov et al.[99]) or is insufficiently well founded.

According to quantum-mechanical calculations, the electron density maximum in heterocyclic amines containing the N = C–NH_2 group is located at the endocyclic nitrogen atom[112,113]. To account for the phosphorylation of the majority of such amines at the exocyclic nitrogen atom, one can postulate, in conformity with Katritzky's ideas[113], that heterocyclic amines react with acid halides in the tautomeric imino-form at the "hard" exocyclic nitrogen atom. The hypothesis that the polarisability of the aminoheterocycle molecule has an influence appears more probable. Under the influence of the phosphinyl (phosphinothionyl) group, the aminoheterocycle molecule is polarised and the electron could undergo a redistribution, which leads to an increase of electron density at the exocyclic nitrogen atom, which is then attacked by the phosphorus atom[99]:

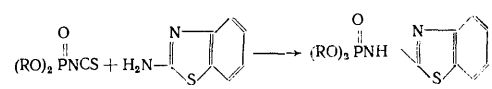


However, one cannot rule out the possibility of the initial attack by the phosphorus atom on the endocyclic nitrogen atom and subsequent migration of the phosphoryl group to the exocyclic nitrogen atom (cf. Simonov and Anisimova[114]).

Only isolated data are available for the reactions of 2-alkylamino- and 2-arylamino-heterocycles with phosphorus acid chlorides. When 2-methylaminobenzothiazole was allowed to react with phenyl methylphosphonochloridothioate, the product of thiophosphorylation at the exocyclic nitrogen atom was obtained[99]. 5-Alkyl-3-anilino-1,2,4-triazoles react with *N,N*-dimethylphosphoramidochloridate to form products of phosphorylation at the nitrogen atoms in both 2- and 1-positions, the product ratio being A : B = 2 : 13.[111]



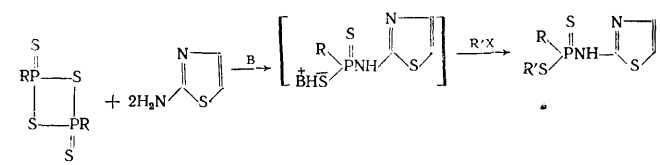
The method of phosphorylating 2-aminobenzimidazole, 3-amino-1,2,4-triazole, 2-aminobenzothiazole, and 2-aminopyrimidine with phosphorus acid chlorides using the trimethylsilyl protecting group is of interest[115]. When aminoheterocycles are treated with two equivalents of trimethylsilyldiethylamine, 1-trimethylsilyl-2-trimethylsilylaminoheterocycles are formed (except for 2-aminobenzothiazole, which reacts with only one equivalent of silylamine). When the reaction mass is treated with 2 moles of the acid chloride, the subsequent decomposition of the resulting 1-phosphoryl-2-phosphorylaminoheterocycles with alcohol results in the formation of 2-phosphorylaminoheterocycles:



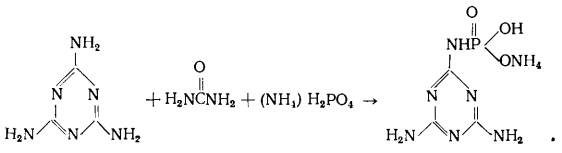
Although this method does provide for the consumption of twice the amount of the acid chloride, it makes it possible to obtain products which are known to be phosphorylated at the exocyclic nitrogen atom, including 3-phosphorylamino-1,2,4-triazoles, which cannot be obtained by the direct phosphorylation of 3-amino-1,2,4-triazole with phosphorus acid chlorides; however, we believe that this requires additional evidence.

2. Phosphorylation by Various Tetracoordinate Phosphorus Derivatives

A convenient method of synthesising phosphorylated aminoheterocycles is provided by the Todd–Atherton reaction. When acid phosphites or phosphonites were allowed to react with 2-aminobenzothiazole[116], 2-aminothiazole, and 2-aminothiazoline[79], the corresponding phosphorylated derivatives were obtained:



The isothiocyanates of phosphorus acids can also be used as phosphorylating agents. Levchenko and Sheinkman[117] showed for the first time that the reaction of diethyl and diphenyl phosphoroisothiocyanatidates with 2-aminobenzothiazole results in the formation of the corresponding 2-phosphorylaminobenzothiazoles:

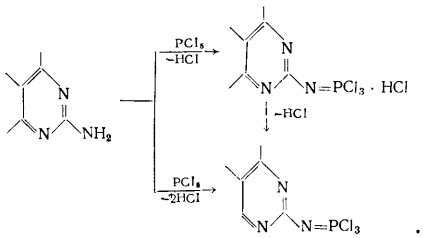


Methylphosphonoisothiocyanatidothioates react analogously with 2-aminothiazole and 2-aminothiazoline[79]. The isothiocyanate group then reacts as a pseudohalogen.

Dithiophosphorylaminothiazoles and aminopyridines have been obtained by the phosphorylation of the corresponding aminoheterocycles with dithioanhydrides of phosphonic acid, or more precisely with diphosphadithietans, and subsequent alkylation[42,45,118]:

Phosphate salts can also be used as phosphorylating agents. The monoammonium salt of 4,6-diamino-2-dihydroxyphosphorylamino-*sym*-triazine has been obtained by heating a mixture of ammonium dihydrogen phosphate, urea, and

melamine at 170–200 °C:[51]

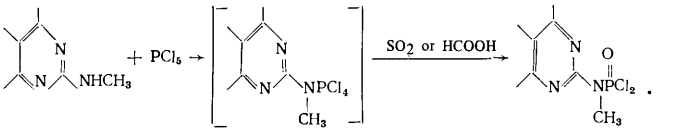


3. Phosphorylation with Phosphorus Pentachloride

One of the general methods of synthesising phosphorylated aminoheterocycles is the Kirsanov or phosphazo-reaction, an interaction of primary amines, in the given instance aminoheterocycles, with phosphorus pentachloride of halogenophosphoranes. 2-Aminopyridines[119], 4-aminopyridines[120], 2-aminopyrimidines[9,11,61,74,76,121], 4-aminopyrimidines[75,122], aminopurines[13], 3-aminobenzoisothiazole 1,1-dioxide[123], and aminotriazines[124,125] have been made to undergo this reaction.

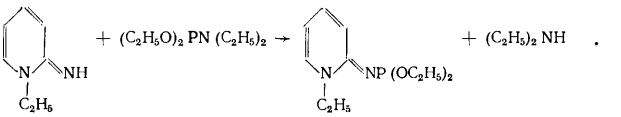
The reactions of aminoheterocycles with phosphorus pentachloride are usually carried out in a boiling solvent (benzene, dichloroethane, and chlorobenzene).

It has been shown for 2- and 4-aminopyrimidines that, when the basicity of the initial aminopyrimidine is relatively low ($pK_a \leq 3.62$ for substituted 2-aminopyrimidines[76] and $pK_a \leq 3.7$ for 4-aminopyrimidines[75]), then two equivalents of hydrogen chloride are evolved in the reaction[75] and monomeric phosphazo-compounds are formed.



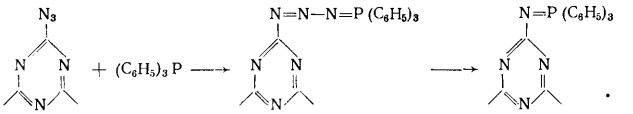
If the pK_a of the initial aminopyrimidines are greater than 3.62 for the 2-amino-derivatives and greater than 5.19 for the 4-amino-derivatives, then only one equivalent of hydrogen chloride is evolved and the hydrochlorides of phosphazopyrimidines are formed (the structure of pyrimidylaminophosphorus tetrachlorides was attributed to them previously[121]); on refluxing in chlorobenzene, one equivalent of hydrogen chloride is split off and the hydrochlorides are converted into monomeric phosphazo-compounds[75]. In contrast to heteroarylaminophosphorus tetrachloride derivatives, the hydrochlorides of phosphazoheterocycles do not react with anhydrous sulphur dioxide[75,76].

[^{32}P]Phosphazopyrimidines can be obtained by the same method[11].



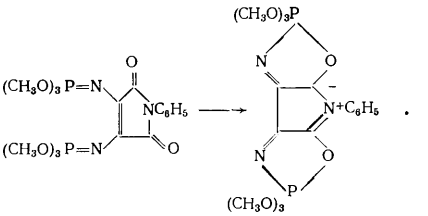
With increase of the number of amino-groups in amino-*sym*-triazines, the rate of the phosphazo-reaction diminishes[124]. The reaction of 2-amino-4,6-dichlorotriazine with 1 mole of PCl_5 terminates after 30 min and that of 2,4-diamino-6-chlorotriazine with 2 moles of PCl_5 terminates after 2–3 h, while the reaction of melamine with 3 moles of PCl_5 terminates after 5 h in dichloroethane and after 3–4 h in phosphoryl chloride.

On treatment with phosphorus pentachloride, 2- and 4-methylaminopyrimidines are converted into *N*-methyl-*N*-pyrimidinylaminophosphorus tetrachlorides, whose structure has been established by conversion into the corresponding acid dichlorides on treatment with sulphur dioxide or formic acid[74–76]:



4. Phosphorylation with Tervalent Phosphorus Derivatives

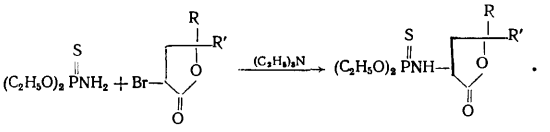
When aminoheterocycles are phosphorylated with tervalent phosphorus derivatives, the reaction can proceed both without a change in valence and with formation of derivatives of tetracoordinate phosphorus. The transamidation of diethyl *N*,*N*-diethylphosphoramidite with 1-ethyl-2-pyridone imine yielded the corresponding phosphoramidite[126]:



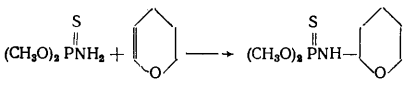
When heterocyclic azides are treated with tertiary phosphines or fully esterified phosphites, phosphazo-compounds are formed in high yields; in many instances it is possible to isolate the intermediate phosphazines. 4-Azido-5-chloro-1-phenyl-1*H*-pyridazin-6-one[127], 4-azidopyrrolin-2-ones[128], azido-*sym*-triazines[129,130], 9-azido-1,2,3,4-tetrafluoroacridine[131], 4-azido-5*H*-furan-2-ones[128], diazidopyrroline-2,5-dione[132], 2-azido-3-ethylbenzothiazolinium fluoroborate[126], and 3-azido-1-ethylpyridinium fluoroborate[126] have been made to undergo this reaction. The reaction is carried out by allowing the azides of the heterocycles to interact with triphenylphosphine in an organic solvent (methylene chloride, ether):

In the reaction of azidotriazines with trialkylphosphites at 5–10 °C it was possible to isolate the intermediate phosphazidotriazines, which split off a nitrogen molecule on heating and are converted into phosphazotriazines[129].

3,4-Diazidopyrroline-2,5-dione reacts with 2 moles of trimethyl phosphite to form the stable 3,4-bisphosphazopyrroline-2,5-dione. The authors explain its stability[132] by the fact that it exists in the form of a dipolar ion:

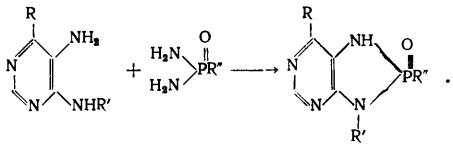


5. Phosphorylamidation Reactions

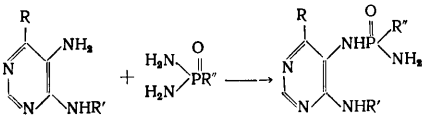


Whereas the methods for the phosphorylation of aminoheterocycles are general for the synthesis of various derivatives of this class, the phosphorylamidation and cyclisation methods are to a large extent specific and can

be used only for the synthesis of a small group of compounds of similar structure.

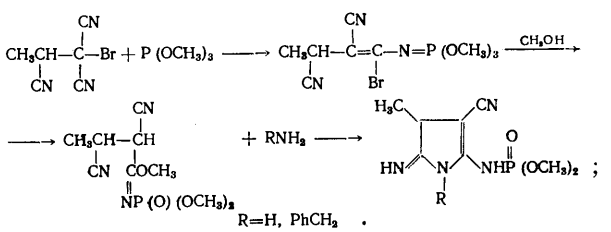


A small group of methods for the synthesis of phosphorylaminoheterocycles is based on the reaction of phosphorus acid amides with different derivatives of the heterocycles. When 3-halogenolactones are heated with diethyl phosphoramidothioate in the presence of triethylamine, the corresponding derivative of 3-aminohydrofuran-2-one is formed[133]:

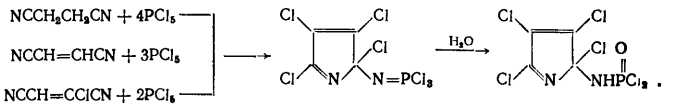


O,O-Dimethyl and *O,S*-dimethyl phosphoramidothioates add to dihydropyran in the presence of catalytic amounts of toluene-*p*-sulphonic acid[30]:

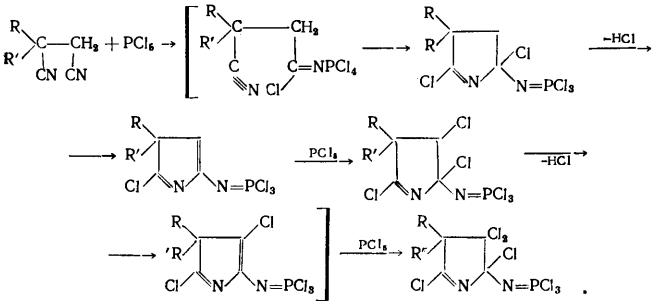
The condensation of phosphonodiamidates with 4,5-diaminopyrimidines usually results in the formation of 1,3-diaza-1,3-dihydro-2-phospholo[4,5-*d*]pyrimidines[134,135]:



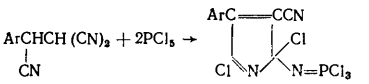
In certain cases only one amino-group, in the 5-position, is involved in the reaction and 4-amino-5-phosphorylaminopyrimidines are formed[135]:



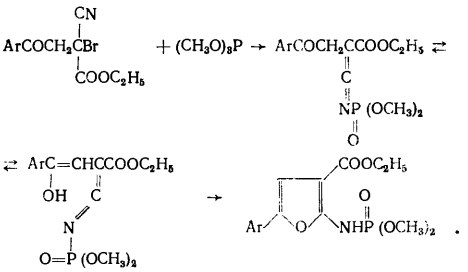
6. Cyclisation Reactions



(*a*) *Derivatives of five-membered aminoheterocycles with one heteroatom.* The phosphorylated derivatives of aminopyrroline are obtained from di- and tri-nitriles. When α-bromo-α,α,β-tricyanopropane is treated with trimethyl phosphite, the corresponding iminotrimethoxyphosphorane is obtained and on treatment with methanol is converted into an *N*-methylenephosphonamidate. On treatment with benzylamine or ammonia, the latter is converted into a substituted 2-dimethoxyphosphorylamino-Δ^2-pyrroline[136]:

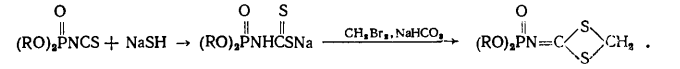


The dinitriles of unsubstituted, monosubstituted, and disubstituted succinic acid as well as the dinitriles of maleic, fumaric, and chloromaleic acids react with phosphorus pentachloride to form 2-trichlorophosphazopolyhalogenopyrrolenines. On controlled hydrolysis, the latter are readily converted into dichlorophosphorylaminopolyhalogenopyrrolenines[137–140]:

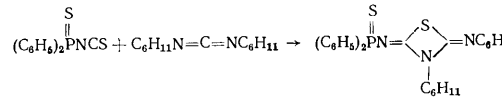


The presence of substituents in the α-position in the dinitriles of succinic acid does not prevent their cyclisation. Since nitriles not containing a hydrogen atom in the α-position do not react with phosphorus pentachloride, the following mechanism of the cyclisation reaction has been proposed[139]:

The reaction begins with the addition of phosphorus pentachloride to the cyano-group at the primary carbon atom. 2-Aryl-1,1,2-tricyanoethanes react via a similar mechanism[141]:

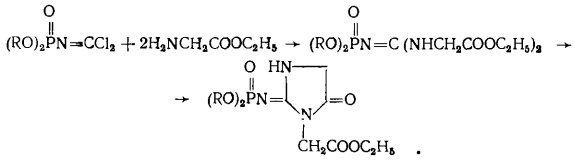


Substituted aminofurans are formed when ethyl α-bromo-α-cyano-β-benzoylpropionate is treated with trimethyl phosphite[142]:

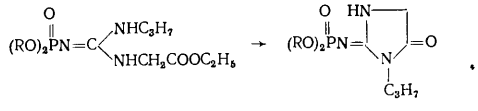


The authors[142] postulated the formation of a keten imine as an intermediate.

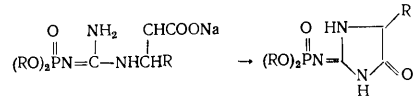
(*b*) *Derivatives of four- and five-membered aminoheterocycles with two heteroatoms.* *N*-Phosphorylated 2-amino-1,3-dithietans are obtained by the cyclisation of the sodium salts of *N*-phosphoryldithiocarbamic acids, which are formed when sodium hydrogen sulphide reacts with phosphoroisothiocyanatidates; the cyclisation takes place on treatment with methylene bromide in the presence of sodium dicarbonate[31–34]:



When diphenylphosphinothionyl isothiocyanate is heated with dicyclohexylcarbodi-imide, a 1,2-cycloaddition reaction takes place and a 1,3-thia-azetidine derivative is formed[143]:

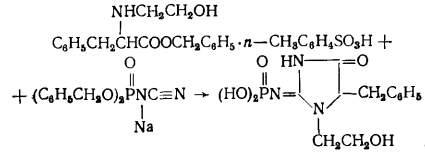


Thus it has been shown that the cycloaddition of isothiocyanates with electron-accepting groups to carbodi-imides takes place at the C–S- and not the C = N bond.

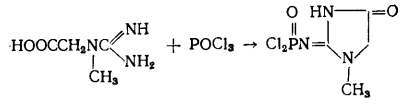


The method of synthesis of phosphorylated imino-imidazolidinones from dichloro-methyleneamides of phosphorus acids is of interest[144]. The reaction of *N*-dichloromethylene-phosphoramidate with ethyl glycinate results in the formation of the corresponding substituted guanidine, which splits off an alcohol molecule on distillation and is converted into a derivative of phosphoryliminoimidazolidinone:

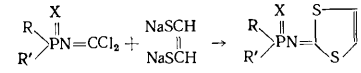
Phosphorylated 1-alkyl-2-iminoimidazolidinones are synthesised via an analogous mechanism involving the thermal decomposition (*in vacuo* at 80–120 °C) of *N*-ethoxycarbonyl-methyl-*N'*-propyl-*N''*-diethoxyphosphinylguanidine[145,146]:



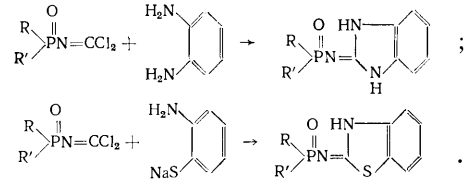
Yet another method of synthesis of phosphorylated imidazolidines consists in the cyclisation of derivatives of *N*-α-carboxyalkyl-*N'*-phosphorylguanidine. The latter are obtained by heating phosphoryl-*N*-methylisothiourea with mercury(II) oxide and subsequent treatment with aminoacids or their derivatives[147,148]:



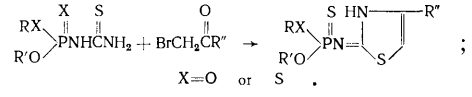
When the disodium salt of *N*-(1,2-dicarboxyethyl)-*N'*-phosphorylguanidine is reduced with hydrogen (on the Pd/C catalyst), 5-ethyl-2-phosphoryliminoimidazolidin-4-one is obtained[147].



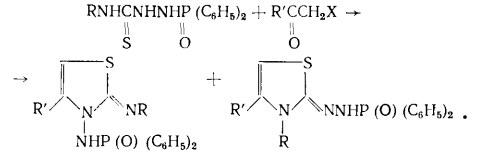
The condensation of the tosylates of the esters of *N*-β-hydroxyalkylaminoacids with salts of phosphorylated cyanamides followed by hydrolysis results in the formation of 1-(β-hydroxyethyl)-2-phosphoryliminoimidazolidin-4-ones[149]:



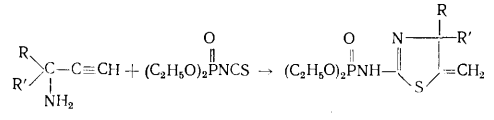
When creatine is refluxed with an excess of phosphoryl chloride, dichlorophosphorylcreatinine is formed[150]:



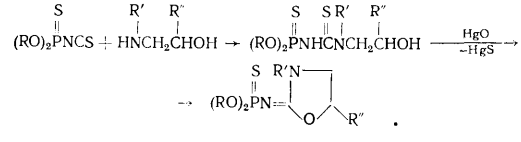
Derivatives of iminodithiole are obtained by the reaction of dialkyl *N*-dihalogenomethylenephosphoramidates with the disodium salt of *cis*-1,2-dimercaptoethylene[91]:



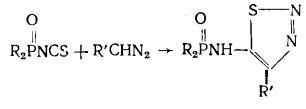
Derivatives of phosphorylaminobenzimidazole and phosphoryl-aminobenzothiazole have been obtained analogously from *N*-dichloromethylenephosphoramidates or *N*-dichloromethylene-phosphonamidates and a diamine of the sodium salt of *o*-aminothiophenol[99]:



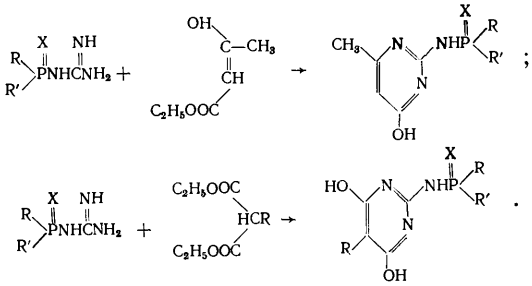
A method of synthesis of aminothiazoline derivatives, consisting in the reaction of thio- or dithio-phosphoryl-thioureas with α-halogenoketones, has been developed[48]:



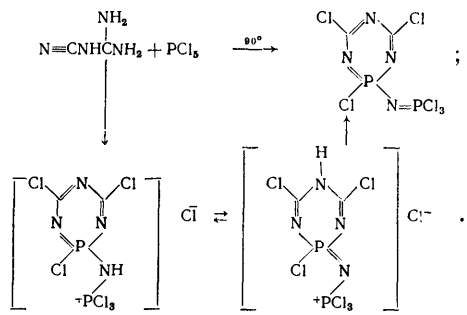
When α-halogenoketones were allowed to react with diphenylphosphorylthiosemicarbazide, mixtures containing 2-alkylimino-3-phosphorylamino-1,3-thiazolines and phosphorylated 2-hydrazino-1,3-thiazolines were obtained[151]:



The reaction of diethyl phosphoroisothiocyanatidates with α-aminoacetylenic derivatives takes place vigorously and results in the formation of diethoxyphosphorylamino-thiazoline having a methylene substituent in the 5-position[152]:



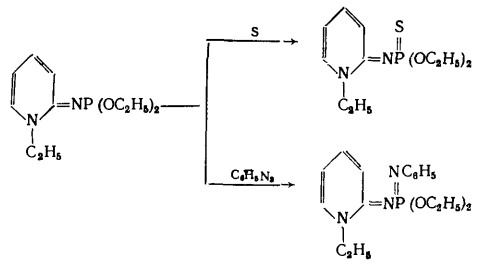
Phosphorylated 2-imino-oxazolidines are obtained by the reaction of the isothiocyanates of phosphorus thioacids with *N*-alkylethanolamines followed by the elimination of hydrogen sulphide from the resulting phosphorylated urea under the influence of mercury(II) oxide[38,40,41,82,96,153]:



Phosphinyl isothiocyanates react with aliphatic diazo-compounds via the 1,3-dipolar cycloaddition mechanism and form 5-phosphorylamino-1,2,3-thiadiazoles[154]:

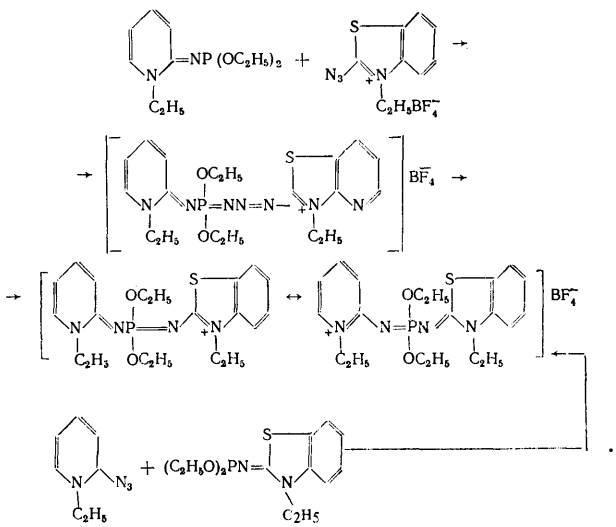
(*c*) *Derivatives of six-membered aminoheterocycles.* One of the possible ways of synthesising phosphorylated 2-aminopyrimidin-4-ones and 2-aminopyrimidine-2,6-diones may be the condensation of guanidinophosphoric acid with β-carbonyl compounds, for example with acetoacetic or malonic esters[89,155]:

The reaction of dicyanodiamide with phosphorus pentachloride leads to two compounds depending on the conditions[156]. When a 1:2 mixture of the components is heated at 90 °C for 4–5 h, 1,3,5-trichloro-1-trichlorophosphazo-1-phospha-2,4,6-triazine is formed. On the other hand, if the reaction is carried out in dichloroethane at 35 °C, it is possible to detect the formation of an intermediate salt-like product which splits off hydrogen chloride on being refluxed in dichloroethane and is converted into a phosphazo-compound:



III. REACTIONS OF PHOSPHORYLATED AND THIOPHOSPHORYLATED AMINOHETEROCYCLES

Phosphorus-containing aminoheterocycles, obtained by the methods described in the previous sections, can undergo in many instances addition, substitution, oxidation, reduction, etc. reactions, forming new derivatives of phosphorylaminoheterocycles with a different environment at the phosphorus atom or with new substituents in the heterocyclic ring.

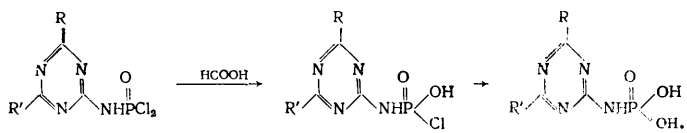


1. Reactions of Tervalent Phosphorus Derivatives

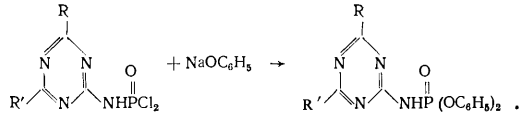
Phosphorylated aminoheterocycles, containing a tervalent phosphorus atom, enter into reactions characteristic also of other tervalent phosphorus derivatives.

Diethyl *N*-(1-ethyl-1,2-dihydropyridylidene)phosphoramidite readily combines with sulphur or phenyl azide and forms the corresponding phosphoramidothionate or iminophosphorane[126]:

The phosphorus analogues of carbocyanines have been obtained by the same procedure[126]. When diethyl imidophosphite *N*-(1-ethyl-1,2-dihydro-2-pyridylidene)-phosphonamidite reacts with 2-azido-1-ethylbenzothiazolium fluoroborate in chloroform at 20 °C, the product is a phosphatriazene, which decomposes on heating in chlorobenzene to form a phosphacyanine. The same phosphacyanine has been obtained by the reaction of 2-azido-1-ethylpyridinium fluoroborate with the corresponding phosphoramidite:

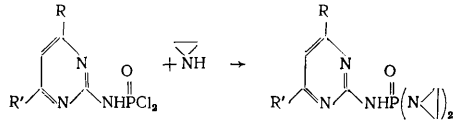


The results show that the positive charge is delocalised over the terminal nitrogen atoms in the phosphacyanine formed.

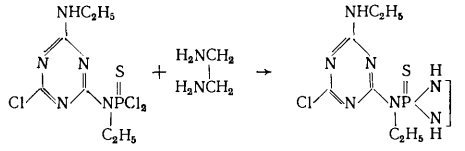


2. Reactions of Tetracoordinate Phosphorus Derivatives

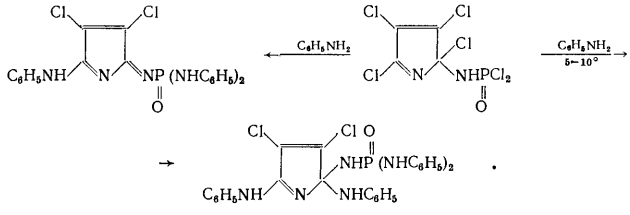
Phosphorylaminoheterocycles can undergo reactions accompanied by a change in the environment at the phosphorus atom or in the heterocyclic ring and also with the dissociation of the nitrogen–phosphorus bond.



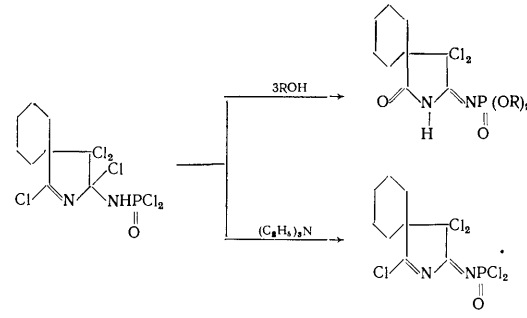
(*a*) *Nucleophilic substitution reactions of dichlorophosphorylaminoheterocycles.* Dichlorophosphorylaminoheterocycles readily react with various nucleophiles: water, acids, alcohols, phenols, and amines. Controlled hydrolysis of dichlorophosphorylaminotriazines has been achieved[124] by treatment with anhydrous formic acid:



Dichlorophosphorylaminoheterocycles readily react with alcohols[157] and phenoxides[120,123,157], forming the corresponding ester-amides:

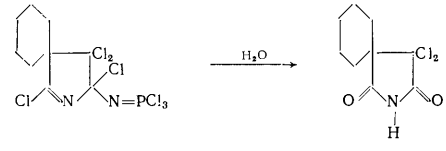


They also readily react with ammonia[23,25,73,78], primary[123] and secondary[103] aliphatic amines, anilines[123,157], piperidine[76], and morpholine[61,76]. This method has acquired particular importance for the synthesis of aziridinyl phosphates with carcinolytic activity[9,11–19,60–66,68,69,158,159]:



The hydrochloride of dichlorophosphorylaminopyrimidine can also be introduced into the reaction[75]. When 6-chloro-2-(*N*-dichlorothiophosphoryl-*N*-ethylamino)-4-ethylamino-*sym*-triazine reacted with ethylenediamine, the corresponding triazinylaminodiazaphospholane was obtained[26]:

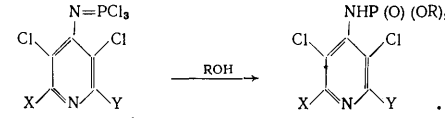
The aminolysis and alcoholysis of dichlorophosphorylaminoperchloropyrrolenines and pyrrolines do not proceed via the standard mechanism. When the dichloride of *N*-perchloropyrroleninylphosphoramidic acid is treated with aniline in boiling benzene, hydrogen chloride is split off and at the same time both the chlorine atoms of the acid chloride groups and that in the 2-position are substituted; the reaction with aniline at 5–10 °C results in the substitution of four chlorine atoms[139]:



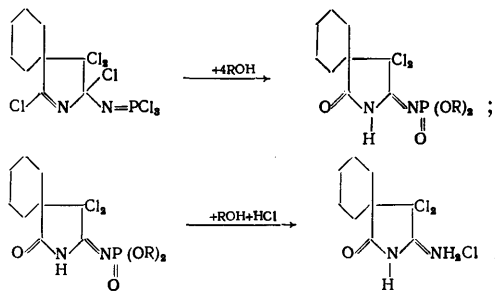
When the dichloride of 2,4,4,5-tetrachloro-3,3-pentamethylene-5-pyrrolinylphosphoramidic acid interacts with three equivalents of alcohol the chlorine atoms in the 2- and 5-positions in the pyrroline ring react, apart from the chlorine atoms attached to the phosphorus atoms[138,139,160]. When the same dichloride was treated with triethylamine, the 2,4,4-trichloro-derivative was obtained[139]:

(*b*) *Nucleophilic substitution reactions of trichlorophosphazoheterocycles.* Trichlorophosphazoheterocycles also readily react with various nucleophiles. They rapidly hydrolyse under the influence of atmospheric moisture and cold water with cleavage of the nitrogen–phosphorus bond and the formation of hydrogen chloride, phosphoric acid, and the initial aminoheterocycles[123,139–141].

2,4,4,5-Tetrachloro-5-trichlorophosphazo-3,3-pentamethylenepyrroline is hydrolysed by water to the corresponding succinic acid amide[139]:

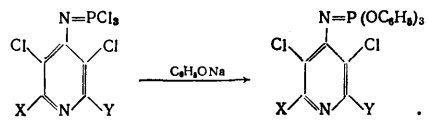


The acidolysis of trichlorophosphazoheterocycles by formic[74,75,120–122,124,141,146] or acetic[11,75,122,123,139,140] acids results in the formation of dichlorophosphorylaminoheterocycles:

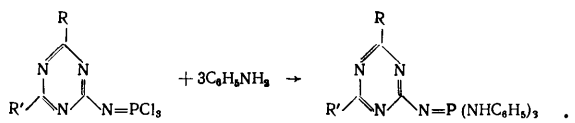


4-Trichlorophosphazopyrimidine reacts with glacial acetic acid to form dichlorophosphorylaminopyrimidine, while the reaction with anhydrous formic acid results in the corresponding hydrochloride[75].

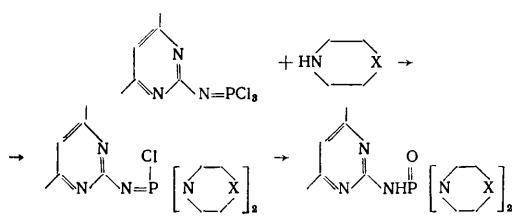
On treatment with alcohols, not only are chlorine atoms substituted but also a rearrangement of the type of the second stage of the Arbuzov reactions takes place and the diesters of *N*-heterylphosphoramidic acid are formed[120,140,157]:



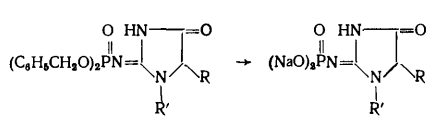
The interaction of 2,4,4,5-tetrachloro-2-trichlorophosphazopyrroline with four moles of alcohol in benzene at 80 °C or in carbon tetrachloride for 20–30 min involves not only the chlorine atoms of the phosphazo-group but also the chlorine atoms in the 2- and 5-positions of the pyrroline ring with formation of the esters of 3,3-dichloro-5-oxo-2-pyrrolidinylidenephosphonamidic acid[138,139,160]. If this reaction is carried out in a large excess of boiling alcohol without a solvent but in the presence of hydrochloric acid,



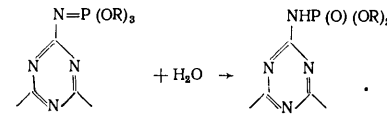
the P–N bond is ruptured[138,139,160]:



Trichlorophosphazo-derivatives also readily react with alkali metal phenoxides to form the corresponding triphenoxyiminophosphoranes[120,125,127]:

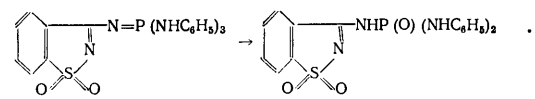


When phosphazoheterocycles are treated with amines, three chlorine atoms are as a rule substituted with formation of triaminoiminophosphoranes[125,140]:

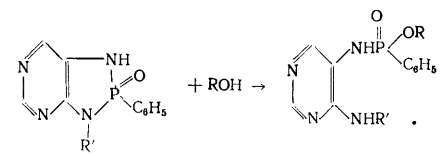


However, the reaction of 2- and 4-trichlorophosphazopyrimidines with morpholine and piperidine proceeds with substitution of only two chlorine atoms and the formation of diaminochloroiminophosphoranes[75,76,119,146], which are converted into phosphorotriamides on heating with 96% alcohol. The hydrochlorides of 2- and 4-trichlorophosphazopyrimidines react analogously[75,76].

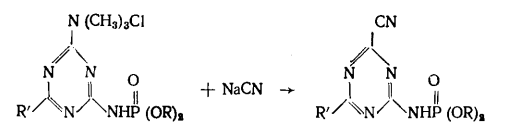
(c) *Nucleophilic substitution reactions of other phosphorylaminoheterocycles.* The acid hydrolysis of phosphorylaminoheterocycles results in the rupture of the nitrogen-phosphorus bond and the liberation of the initial heterocycles[159]. The alkaline hydrolysis of dibenzyl *N*-heterylidenephosphoramidates involves the dissociation of the P–O bonds and the formation of alkali metal salts of *N*-heterylidenephosphoramidic acids[147,149,161]:



The kinetics of the hydrolysis of the dialkyl esters of phosphoryliminohydantoins have been studied[162]. The hydrolysis of triphenoxy- and trialkoxy-*N*-heterylidenephosphoranes results in the formation of the corresponding esters of phosphoramidic acid[29,120,125,129,157]:



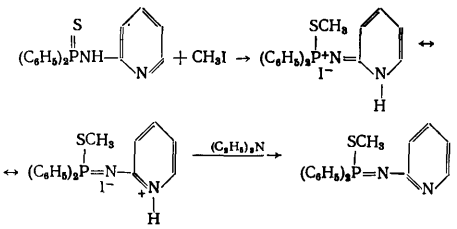
Under these conditions, triphenoxy-*N*-triazinyliminophosphoranes are stable—they do not hydrolyse on being refluxed with 1 *N* hydrochloric acid[130].



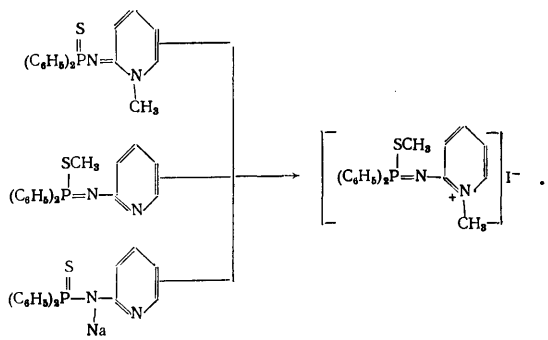
The trianilino-derivatives hydrolyse even on being refluxed in 96% alcohol and give rise to dianilinophosphorylaminoheterocycles[123]:

The diazaphosphole ring in 1,3-diaza-1,3-dihydro-2-phospholo[4,5-*d*]pyrimidine 2-oxide is readily cleaved at the P–N bond on treatment with water or alcohol; derivatives of 4-amino-5-phosphorylaminopyrimidine are formed[135]:

N-Phosphorylated derivatives of aminotriazines[22,27,163,164], aminopyrimidines[159], and aminoacridines[165], containing labile atoms or groups in the heterocyclic ring, readily exchange them under the influence of various nucleophiles. For example, (2-phosphorylamino-4-*sym*-triazinyl)trimethylammonium chloride is converted into the corresponding 4-cyano- or 4-azido-derivative under the influence of sodium cyanide[22]:

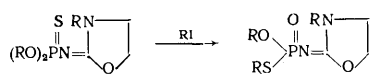


Polyfluoro-9-acridinyliminotriphenylphosphoranes react with alkoxides, phenoxides, and primary and secondary amines with substitution of only one fluorine atom[165].



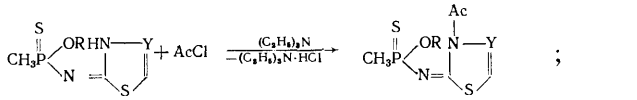
(d) *Electrophilic substitution reactions.* Interesting data have been obtained in the study of electrophilic substitution reactions involving phosphorylated and thiophosphorylated aminoheterocycles containing the amidine system.

Phosphorylaminoheterocycles do not undergo the electrophilic substitution reaction[166]. 2-Dimethylthiophosphorylamino-derivatives of pyridine, pyrimidine, and triazole are readily methylated by methyl iodide at the sulphur atom with dissociation of the P–S bond and are converted into phosphonium salts stabilised by resonance with the iminophosphorane structure[167]. 2-Diphenylaminothiophosphorylaminopyrimidine reacts with methyl iodide to form an adduct of a phosphonium salt with methyl iodide, from which a stable adduct of the phosphonium salt and benzene was obtained on treatment with an excess of benzene. The latter adduct is converted into the corresponding imino-

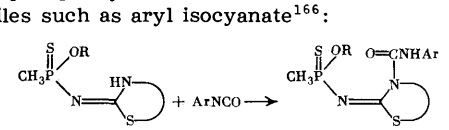


phosphorane on treatment with ammonia or triethylamine:

On being refluxed in benzene, the iminophosphorane isomerises to methyl *N*-(1,2-dihydro-2-pyridylidene)diphenylphosphinamidothiolate[167]. Its methylation as well as the methylation of methylthiodiphenyl-*N*-(2-pyridyl)iminophosphorane and the sodium salt of *N*-(2-pyridyl)diphenylphosphinamidothioate with methyl iodide in nitromethane leads to the same product:

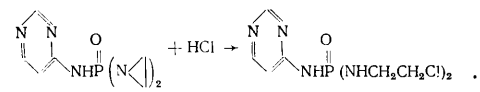


The attempts to methylate dialkoxyphosphoryl- and aryloxymethylthiophosphorylamino-derivatives of thiazoles, thiazolines, and thiadiazoles were unsuccessful[166]. On treatment with alkyl iodides, dialkoxythiophosphoryliminothiazolidines and the corresponding oxazolidines isomerise via the Pishchimuka reaction and give rise to the corresponding phosphoramidothiolates[38,153]:



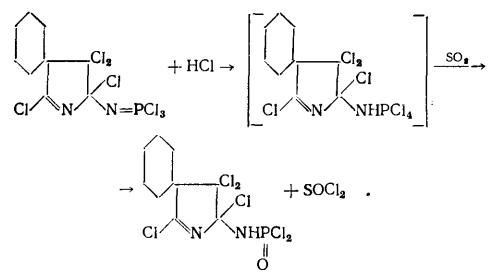
As a rule, 2-phosphorylaminoazaheterocycles are not protonated and do not form salts with acids. The picrates and nitroindandionates of phosphorylated 2-aminopyrimidines have been described[86].

Thiophosphorylated derivatives of 2-aminothiazole and 2-amino-1,3,4-thiadiazole react with the chlorides of phosphorus thioacids and benzenesulphonyl chloride to form products of substitution at the endocyclic nitrogen atom[166]:



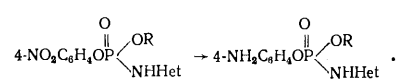
Y=N or CH; Ac=CH_3 (RO) P (S), or $C_6H_5SO_2$.

Under analogous conditions, thiophosphoryliminothiazolidines do not react. However, not only thiophosphorylated 2-aminothiazoles and 2-aminothiadiazoles, but also 2-thiophosphorylaminothiazolines react with hard electrophiles such as aryl isocyanate[166]:



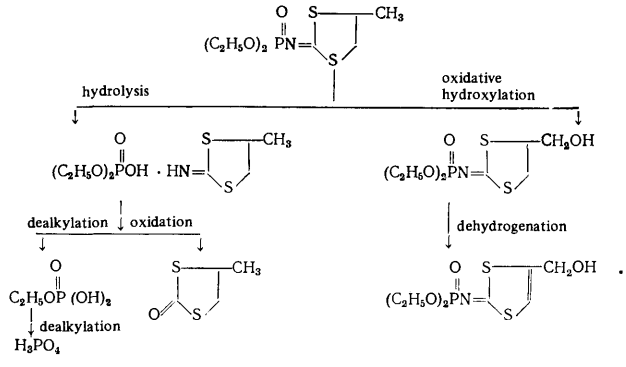
The greater ease of electrophilic substitution reactions for thiophosphorylated derivatives of aminothiazole and aminothiadiazole compared with the derivatives of aminothiazoline can be explained by the more pronounced nucleophilic properties of the endocyclic nitrogen atom in the thiophosphoryliminoheterocycles as a consequence of the electron-donating influence of the neighbouring π-bond.

(*e*) *Other reactions.* In many instances diaziridinoheteryl-aminophosphine oxides are converted by anhydrous hydrogen chloride into the corresponding bis(β-chloroethylamino)-derivatives in high yields[10,62]:

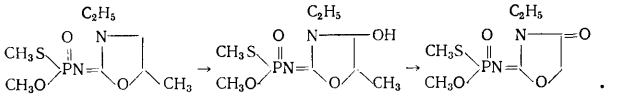


It has been noted[159] that, when diaziridino(4-chloropyrimidinyl-2-morpholinylamino)phosphine oxide is refluxed in dilute hydrochloric acid, a mixture of the hydrochloride of the initial pyrimidine and *N*,*N*'-bis(2-chloroethylamino)-pyrimidinylphosphonamidate is formed.

Trichlorophosphazoheterocycles readily combine with anhydrous hydrogen chloride at the P = N double bond and give rise to phosphorus tetrachloride derivatives. The latter are unstable and are converted under the influence of sulphur dioxide into the corresponding dichlorophosphorylated derivatives[139-141]:



The amides of *p*-nitrophenylphosphonic acid, containing the heterocyclic residue at the nitrogen atom, are reduced with hydrogen in the presence of Raney nickel to the corresponding derivatives of *p*-aminophenylphosphonic acid[80,168]:



(*f*) *Reactions of phosphorylaminoheterocycles in the environment and in living organisms.* In connection with the high biological activity of certain phosphorylaminoheterocycles and their use as plant protecting agents, their photolysis and behaviour in living organisms have been investigated.

After the exposure of aqueous solutions of 2-diethoxyphosphorylimino-4-methyl-1,3-dithiolan to sunlight, its hydrolysis products were isolated: diethylphosphoric acid, monoethylphosphoric acid (in small amounts), and 2-imino-4-methyldithiolan[169]. The preparation decomposes via the same mechanism in paddy rice plants[170]. When a 2% aqueous solution of acetone was used as the solvent in the study of the photolysis of 2-diethoxyphosphorylimino-4-methyl-1,3-dithiolan, the main decomposition product was *S*,*S*-1,2-propylene dithiocarbonate[169].

The main process determining the metabolism of 2-diethoxyphosphorylimino-4-methyl-1,3-dithiolan in the cotton plant is oxidative hydroxylation of the methyl group in the 4-position with partial dehydrogenation of the molecule:

3-Ethyl-2-methoxymethylthiophosphorylimino-5-methyl-1,3-oxazolidine also undergoes oxidative phosphorylation in the cotton plant, in the organisms of house flies, and in enzymatic and model oxidation systems; the 4-hydroxy derivative is readily converted into the 4-oxo-derivatives[39]:

* * *

In conclusion one may note that, as shown by the data presented above, this interesting branch of chemistry, related, on the one hand, to the chemistry of organoelemental compounds and, on the other hand, to the chemistry of heterocycles, has been developing vigorously in recent years. The results permit one to hope that new physiologically active compounds of this class will be found in the immediate future and experimental data of theoretical value will be obtained.

Polyphosphazens

V.V.Kireev, G.I.Mitropol'skaya, and Z.K.Zinovich

The main features of the catalytic and thermal polymerisation of chlorocylophosphazens are examined, with a possible mechanism of rearrangement of rings in the thermal polymerisation of mixtures of cyclic chlorophosphazens. Research on the influence of side-groups on the chemical and physicochemical properties of polyorganophosphazens (polydialkoxyphosphazens, polydiaminophosphazens) is discussed, as well as aspects of the vulcanisation and stabilisation of these polymers. The chemical properties, structure, molecular-mass characteristics, and thermal stability of polyphosphazens are surveyed, and also the application of these polymers in the national economy. A list of 151 references is included.

I. INTRODUCTION

Interest in polyphosphazens has increased considerably during recent years, as a consequence of the undoubted practical value of this interesting class of hetero-organic polymers. The large quantity of experimental results and the many original investigations following publication of Allcock's monograph[1] and a review[2] have made it necessary to summarise some of the most important aspects of the chemistry of polyphosphazens. We have now attempted to systematise work appearing during recent years on the synthesis and properties of linear homopolyphosphazens, a most interesting and industrially important type of phosphazen polymers. The survey of published data has taken into account recent reviews[3-10], most of which cover only part of the field or are essentially advertising material.

II. POLYHALOGENOPHOSPHAZENS

The only method for synthesising linear macromolecular polyphosphazens has been to replace halogen atoms in polydihalogenophosphazens by various groups. Since polydichlorophosphazen is most often used for this purpose, establishment of the laws and mechanism of its formation in the polymerisation of chlorocyclophosphazens is a most urgent problem of phosphazen chemistry.

The polymerisation of cyclic chlorophosphazens

$$(PNCl_2)_n \xrightarrow{200-300^\circ} -\left[\begin{array}{c} Cl \\ | \\ -P=N- \\ | \\ Cl \end{array}\right]_x -$$

$n=3-8,\ x \lesssim 15\,000$

known long ago from the work of Stokes[11], can be accomplished either thermally or catalytically. Research during recent years on the catalytic polymerisation of hexachlorocyclotriphosphazen has determined the most effective range of catalysts for subsequent investigation. Alkali-metal phenoxides and alkoxides[12], inorganic acids, and hetero-organic Lewis acids (e.g. ethylaluminium halides)[13] enable the temperature to be lowered to 200 °C. Use of 1 mass % of phosphoric acid[17] also permits the above chlorocyclophosphazen to be polymerised in a solvent (1,2,4-trichlorobenzene) at this temperature; the resulting polydichlorophosphazen has a lower molecular mass and a broader distribution thereof than has that obtained purely thermally[7,14].

The use of metal chlorides[15], known some time ago for the splitting of chlorocyclophosphazens[16,17], enables the temperature of polymerisation to be lowered to 175–200 °C, but also leads to a decrease in molecular mass that is larger the greater the quantity of catalyst.

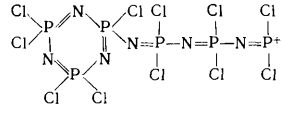
Ring opening occurs in hexachlorocyclotriphosphazen under mild conditions in the presence of phenylmagnesium bromide[18] or diphenylmagnesium[19], and especially readily (at 20 °C) on treatment with phenyl-lithium[20]. In the last case the first stage involves formation of a linear product $C_6H_5PCl_2NPCl_2$. $.NPCl_2NLi$, which undergoes further phenylation by excess of phenyl-lithium (mainly from the end), but in the presence of a deficiency of this compound branched structures are formed owing to interaction with other similar molecules, the resulting oligomer having molecular mass up to 2000 and relative composition

$$(C_6H_5)_3P : (C_6H_5)_2P : PCl_2 = 5 : 2 : 22.$$

Low-temperature opening of phosphazen rings is fundamentally possible[18-20], but the catalysts used must be inert towards phosphorus–chlorine bonds.

Since effective catalysts for the polymerisation of chlorocyclophosphazens have not yet been found, thermal polymerisation mainly of a cyclic trimer remains the chief method for obtaining polydichlorophosphazen. Despite the large amount of research on thermal polymerisation[1,2] methods are not yet available for conducting the process under controlled conditions, which would yield reproducible results; nor can the yield, solubility, and molecular-mass characteristics of the products be controlled.

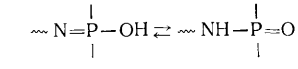
It now seems highly likely that the usual thermal polymerisation of hexachlorocyclotriphosphazen and other chlorocyclophosphazens is not a truly thermal process, but is determined in considerable measure by the presence of impurities in the initial cyclic compound and on the walls of the reaction vessels. Thus hexachlorocyclotriphosphazen that has been thoroughly purified by successive recrystallisation, boiling with barium oxide in a stream of nitrogen at 130 °C, passage of the vapour over phosphorus pentoxide, and vacuum sublimation does not polymerise below 300 °C,[21] but rapid polymerisation begins after the introduction of oxygen. The reason for this and the nature of the active centres were not discussed[21]. An effective method for purifying the trimer is first to heat it under polymerisation conditions (200–250 °C) for 15–180 min and then distil[22]: polymerisation of the purified product gives a higher yield



of soluble polydichlorophosphazen, but the rate of the process is lowered.

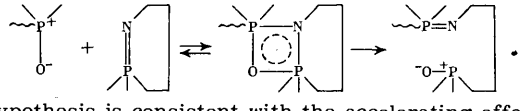
The now preferred ionisation mechanism of the thermal polymerisation of hexachlorocyclotriphosphazen[23-25] involves as initial stage heterolysis of a phosphorus–chlorine bond with formation of a cyclic azophosphonium cation

$$P_3N_3Cl_6 \rightleftarrows P_3N_3Cl_5^+ + Cl^-$$



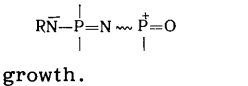
that initiates chain growth. It was confirmed in later work[26,27], and agrees well with conductivity measurements on the trimer and on polydichlorophosphazen[28].

Examination of the effects of pH at the surface of the glass ampoules, temperature, and duration[29], indicating an increase in the rate of polymerisation of hexachlorocyclotriphosphazen with increase in acidity of the glass, suggested in terms of the ionisation mechanism[26] that chain growth begins with protonation of a trimer molecule. The cation $P_3N_3Cl_6H^+$ then reacts with a second trimer molecule to eliminate hydrogen chloride and form the cyclolinear cation



which is responsible for further chain growth, as in the usual ionisation polymerisation[26].

However, the hydrogen chloride not only does not catalyse polymerisation but is even capable of inhibiting it slightly[30]. Phosphorus pentachloride is a stronger inhibitor of this process, and also acts as a telogen[30,32]. The accelerating effect of small additions of water (10^{-5}–10^{-1} mole mole^{-1} trimer) also indicates that the main role in initiating polymerisation is played by acid centres of the type



formed at the same time as hydrogen chloride[30,31]. Allcock's results[30] indicate that chain growth in the polymerisation of chlorocyclophosphazens is effected not only by an azophosphonium cation but also by a terminal phosphoryl group:

(1)

This hypothesis is consistent with the accelerating effect of phosphoric acid[17] and alkoxy-derivatives of the trimer[12] on its polymerisation; it is assumed in the latter case that phosphazen–phosphazan rearrangement takes place, and the resulting phosphazan is converted into a zwitterion

which initiates chain growth.

Although formation of cationic centres seems to be generally accepted as initiating chain growth in the thermal polymerisation of hexachlorocyclotriphosphazen, information on the laws of chain growth and termination has hitherto been almost completely lacking, and the reasons for the wide molecular-mass distribution in particular have remained obscure.

Interesting results have been obtained from investigation of the copolymerisation of hexachlorocyclotriphosphazen with other chlorocyclophosphazens. Although a patent report[33] that the rate and the yield of soluble polydichlorophosphazen in the polymerisation of this trimer are increased by the presence of 5–25% of octachlorocyclotetraphosphazen has not been confirmed[34], and additions of other higher chlorocyclophosphazens only slightly raise the yield of soluble product[35], study of the thermal copolymerisation of the trimer with its higher cyclic homologues has revealed the phenomenon of ring rearrangement, mostly involving increases in the proportion of tetramer and other homologues in the initial stages of polymerisation[36,37] (Table 1). This was first detected by Allen et al.[75], who synthesised polydichlorophosphazen by the thermal polymerisation (at 250 °C) of the trimer containing 2.9% of the tetramer, and found that increasing the duration of the process from 20 to 62 h not only raised the yield but also increased the content of higher homologues—especially pentamers and hexamers—in the mixture that had not reacted. However, at the time due attention was not paid to this interesting observation.

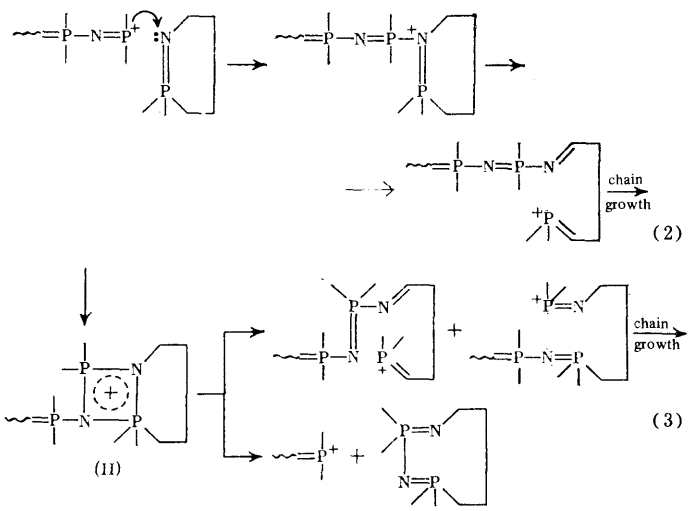
**Total quantity of pentamer and heptamer.

Interconversions of rings have in general been known in phosphazen chemistry for a comparatively long time. Thus as early as 1960 Korshak et al.[38] observed the conversion of octaphenylcyclotetraphosphazen at 320–500 °C into a mixture of tri-, tetra-, penta-, and hexa-mers; hexakisheptafluorobutoxycyclotriphosphazen when boiled at 340 °C for 50 h is 50% converted into a tetramer[39]; and the reverse conversion of a tetrameric into a trimeric ring takes place when octachlorocyclotetraphosphazen is phenylated with phenylmagnesium bromide[40]. Interconversions of mixtures of cyclic chlorophosphazen homologues from trimer to heptamer during their vacuum distillation and in certain low-temperature (20–80 °C) nucleophilic substitutions have been reported recently[41], and also those of trimeric into tetrameric dimethylcyclophosphazens over the range 200–350 °C.[42] However, a distinguishing feature of this work[38-42] is that interconversions of chlorocyclophosphazens at 20–500 °C are not accompanied by polymer formation (except in the vacuum distillation of mixtures[41]).

In addition to the above work[36,37] formation of higher cyclic homologues from trimeric phosphazens has been observed by Allcock et al.[43] in a study of the thermal polymerisation of trifluoroethoxychlorocyclotriphosphazens $P_3N_3Cl_n(OCH_2CF_3)_{6-n}$ and the copolymerisation of hexachlorocyclotriphosphazen with the hexakistrifluoroethoxycyclotriphosphazen (I) (Table 2). Among the most important aspects of this work[43] pure (I) does not polymerise below 300 °C, but when heated at 275 °C for > 46 h, small quantities of the corresponding



tetramer and pentamer are formed; copolymerisation of hexachlorocyclotriphosphazen and (I) takes place at 200 °C, at which temperature neither of the pure individual compounds polymerises; among partly substituted trifluoroethoxychlorocyclotriphosphazens only those having $n = 5-3$ undergo polymerisation; above 230 °C polycondensation takes place with the evolution of 2-chloro-1,1,1-trifluoroethane; and the molecular masses of the products of the above copolymerisation are lower than those resulting from the polymerisation of pure hexachlorocyclotriphosphazen.

Table 2. Copolymerisation of equimolecular quantities of hexakistrifluoroethoxycyclotriphosphazen (I) and hexachlorocyclotriphosphazen (III) at 200 °C[43]*.

The considerable increase in the content of higher chlorocyclophosphazens accompanying formation of polydichlorophosphazens in the initial stage of their copolymerisation with hexachlorocyclotriphosphazen has been explained[37] by specific interaction of the growing macrocation with cyclophosphazen molecules. The usual interaction (2) leading to further chain growth may be accompanied by an anomalous reaction involving formation of a cyclic transition state (II):

Localisation of the positive charge on either phosphorus atom of the four-membered ring (II) will entail its cleavage with increase in the length of the macrocation by the number of units of the initial ring. In view of the great stability of four-membered cyclic systems in phosphazen chemistry[44], however, it may be postulated that the transition state (II) can also break down at an exocyclic phosphorus–nitrogen bond (3). The additional structural units expanding the chlorophosphazen rings are thus provided by growing macrocations, which as a consequence of specific interaction with cyclic molecules (3) become one unit shorter, and this unit is incorporated into the ring under attack, which becomes larger.

Reaction (3) can evidently take place also with $-N=P<$ units of linear macromolecules that have already been formed, and the proportion of such interaction will increase with the degree of conversion. It may provide one reason for the observed wide molecular-mass distribution of polydichlorophosphazen. Determination of the proportions of reactions (2) and (3) in an actual process must obviously take into account both structural and thermodynamic factors. The strain in a ring, which governs the energy of its vapour-phase polymerisation, may differ substantially for different conformers[45]. For example, the difference in strain between crenulated planar and buckled C_2 forms of the cyclic pentamer, which characterise crystalline and liquid states respectively, is 18.75 kJ mole^{-1}.

The presence of ring substituents other than chlorine atoms will also influence the probability of formation of transition state (II), so that the capacity of partly substituted chlorocyclophosphazens for thermal polymerisation becomes significant. Even before the appearance of Allcock's work[43] it had been reported[46,47] that fluoroalkoxychlorocyclotriphosphazens can polymerise at 200 °C. The process occurred only when $R_FO : Cl \leq 2 : 1$ (Table 3). When mixtures of hexachlorocyclotriphosphazen with hexakisperfluoroalkoxycyclotriphosphazen or other mixtures satisfying the above ratio are used, polymerisation is apparently preceded by exchange of substituents[48], which is not excluded by Allcock et al.[43]

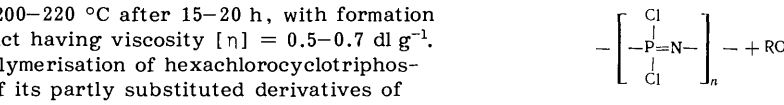
In the polymerisation of fluoroalkoxychlorocyclotriphosphazens, however, the proportion of polycondensation processes accompanied by separation of a fluoroalkyl chloride increases with rise in temperature[43]. Such processes take place at lower temperatures with non-fluorinated alkoxyphosphazens—e.g. at 150–170 °C with butoxychlorocyclotriphosphazens[49]—although polycondensation of the latter with separation of butyl chloride and formation of polymers containing P–O–P links between phosphazen rings is also accompanied[50] by polymerisation with ring opening.

It is therefore more interesting, from the point of view of capacity for polymerisation, to investigate alkylchlorocyclotriphosphazens containing the more stable phosphorus–carbon bonds. Trimethyltrichlorocyclotriphosphazen, tetramethyltetrachlorocyclotetraphosphazen, and their mixtures are polymerised[51] at 200–220 °C after 15–20 h, with formation of a rubberlike product having viscosity $[\eta] = 0.5–0.7$ dl g^{-1}. Use in the thermal polymerisation of hexachlorocyclotriphosphazen of additions of its partly substituted derivatives of general formula $R_xP_3N_3Cl_{6-x}$ (R = CH_3, CF_3CH_2O, or other fluoroalkoxyl; $x \leq 1.5$) not only shortens the process but also raises the yield of soluble polydichlorophosphazen[52].

In an investigation of the thermal polymerisation of a series of phenylhalogenocyclotriphosphazens Allcock and Moore established[53] that only the phenylpentafluoro-compound is capable of homopolymerisation at 300 °C: geminal and non-geminal compounds $(C_6H_5)_nP_3N_3Cl_{6-n}$ having $n = 2–6$ do not polymerise at this temperature, although at 250 °C homologues in which $n = 2$, 3 copolymerise with an equimolecular proportion of hexachlorocyclotriphosphazen, but products in which $n = 4–6$ inhibit polymerisation of the latter. The copolymers have a considerably lower molecular mass than has the polydichlorophosphazen obtained by its homopolymerisation. Results[47,53] are fully consistent with the above mechanism of chain growth (schemes 2 and 3). Attempts to effect the catalytic polymerisation of hexaphenyl- and hexaphenoxy-cyclotriphosphazens in the presence of strong acids gave only a low yield of oligomeric products, whose formation involves intermediate detachment of side-groups[54–56]. Yet a report appeared on the thermal polymerisation of an aryloxypentachlorocyclotriphosphazen[57], essentially by a modification of the method of Ref.12.

Among other methods for obtaining polydichlorophosphazen is its synthesis from linear oligomers $Cl_3P{:}N.[PCl_2{:}N]_n.PCl_4$ ($n = 3–15$) by prolonged heating at 240–260 °C. The process is accompanied by separation of phosphorus pentachloride, obviously by the reaction of terminal groups[58]:

Thermal degradation of polydichlorophosphazen is a first-order reaction having activation energy 92.11 kJ mole^{-1} and yielding a large number of oligomeric linear and cyclic homologues[59]. It is assumed to involve ionic terminal groups, which is consistent with the known[1,2] equilibrium character of the polymerisation of chlorocyclophosphazens.



X-Ray examination of polydifluorophosphazen–the phosphazen polymer having the smallest of known side-groups–has yielded interesting results[60]. This polyphosphazen can be present as two conformers: conformer A exists between −36 and +25 °C, and has a repeat distance of 6.49 Å; conformer B is observed at around −56 °C, and has repeat distance 4.86 Å (for polydichlorophosphazen 4.96 Å). The latter conformer has a *cis–trans* planar chain conformation with P–N–P and P–F bond lengths 1.52 and 1.47 Å, and PNP, NPN, and FPF angles 136°, 119°, and 95° respectively. The density of polydifluorophosphazen at 25 °C is 1.84 g cm^{-3}.[60]

III. POLYORGANOPHOSPHAZENS

Interest in the synthesis of macromolecular linear polyphosphazens has grown considerably during recent years[61–63] in connection with the problem of producing thermostable and non-flammable rubbers having good resistance to cold.

1. Polydialkoxyphosphazens

These polyphosphazens are obtained by replacing chlorine atoms in polydichlorophosphazen by alcohol or phenol residues:

where R = Alk, Ar and M = alkali metal. The main trends in research during recent years have been the synthesis of polyperfluoroalkoxyphosphazens as potential fire-resistant and thermostable rubbers having high chemical stability and resistance to cold, investigation of the effect of the nature of side-groups on the chemical and physicochemical properties of such polymers, study of the possibilities of using polydialkoxyphosphazens for biomedical purposes, and a search for methods of vulcanisation and stabilisation.

It had been shown earlier[1] that polyphosphazens having identical lower perfluoroalkoxy-groups in the side-chain are in most cases crystalline. In order to obtain elastomeric products, therefore, the synthesis of polymers containing various groups–perfluoroalkyl[65–70] or mixed alkoxy-substituents[71,73,79–83]–has been investigated.

* Macromolecules may contain doubly and singly substituted phosphorus atoms.

** T_{decomp} = temperature at which decomposition begins.

Polyperfluoroalkoxyphosphazen copolymers are most often obtained from mixtures of trifluoroethoxides with fluorinated higher alkoxides[65–69] and also with phenoxides[65,81,105]. Sodium alkoxides are usually employed, although in some cases the lithium compounds are more effective[74]. Substitutions are conducted predominantly in oxolan, dioxan, diglyme, and their mixtures with benzene; the last is usually employed to dissolve polydichlorophosphazen. In order to increase the conversion the concluding stages are carried out at high temperatures, especially when aryloxy-groups are introduced[70,75–77]. Almost complete replacement of chlorine can thus be achieved, although this is influenced by various uncontrollable factors, assumed[78] to be connected mainly with the stage of polymerisation of hexachlorocyclotriphosphazen in the synthesis of polydichlorophosphazen.

By varying the nature and the proportions of side-groups it is possible to change within wide limits such properties of polydialkoxyphosphazens as solubility, glass temperature,

molecular mass and molecular-mass distribution, thermal stability, processability by various methods, etc.[78-85,89,91,92]. For this purpose substitution is effected with mixtures of alcohols and phenols[65,70,81,89], fluorinated C_{4-12} alcohols[79], and mixtures of phenols[80,83]. The properties of homoaryloxyphosphazens can be controlled by varying the nature and the position of constituents in the initial phenol[76,77,82]. Table 4 lists some of the properties of polyalkoxyphosphazen copolymers, among the most interesting of which are those of trifluoroethoxy- and octafluoropentyloxy-phosphazens. Thus a copolymer containing 65 mole % of CF_3CH_2O groups and 35 mole % of $H[CF_2]_4CH_2O$ groups has a glass point of −68 °C and does not swell in hydrocarbons; 86% of this copolymer comprises a macromolecular fraction having $\bar{M}_n$ = 1370600 and $\bar{M}_{wt}$ = 4085800 (M_{wt}/M_n = 3), whereas corresponding values for the unfractionated copolymer are 123700 and 3514500 (28.4).[92] The high polydispersity is evidently due to the presence of a considerable proportion of fractions of low molecular weight. For this copolymer the viscosity $[\eta] = 0.00488\bar{7}M_n$.[1,47]

Even with equimolecular proportions of the initial substituting reagents the resulting copolymers contain three types of units—two paired, NPR_2 and NPR'_2, and the mixed NPRR′—in quantities determined by (apart from the proportions of the initial reactants) the dimensions and the inductive properties of the new substituents. The presence in various combinations of three types of monomer units in the macromolecules of polyalkoxyphosphazen copolymers is responsible for their hyperelastic properties over a wide temperature range.

The low glass point of polyfluoroalkoxyphosphazens is due to the high thermodynamic flexibility of the main chain and the absence of side-group interactions. Introduction of bulky aromatic groups in the place of chlorine, however, raises the glass point, which is especially clearly shown[70] by the polyphosphazen copolymers $-[N{:}P(OCH_2CF_3)_{2-x}.(OC_6H_4C_6H_5\text{-}p)_x]-$. These copolymers are obtained by treating a solution of polydichlorophosphazen in benzene successively with a phenoxide and an alkoxide in oxolan, and are purified by reprecipitation from oxolan solution into water. In oxolan at 25 °C the copolymers have viscosities in the range $[\eta]$ = 1.06–2.20 dl g^{-1}, which fall with decrease in x; their molecular mass $\bar{M}_n = (0.9–3.3) \times 10^5$ (measured osmometrically in cyclohexanone). Fractionation showed the copolymers to be inhomogeneous with respect to composition: thus for a product having x = 0.15 this parameter is 0.32 for the fraction of high molecular weight, and 0.08 for that of low molecular weight. Heating the copolymers in air at 150 °C for 12 h lowers their viscosity $[\eta]$ by factors of 4–5. X-Ray examination shows the copolymers to be relatively disordered, with crystallites formed by the crystallisation of microblocks comprising $-N{:}P(OCH_2CF_3)_2-$ units, the presence of which is confirmed by the fluorine-19 nuclear magnetic resonance spectra[70].

A convenient method for the synthesis of polydialkoxyphosphazen copolymers is the transetherification of alkoxylated polymers with higher alcohols; alkoxides of the latter are used to obtain polyperfluoroalkoxyphosphazens[73,85]. Besides the alkoxide–phenoxide method an acceptor method is also available for the synthesis of polyalkoxyphosphazens[86,90,106,107]. Thus, when trifluoroethanol in oxolan at 60 °C is used to replace chlorine atoms in polydichlorophosphazen, the degree of substitution reaches 65% after 5 h, and a limiting value of 85% after 100 h; introduction of lithium chloride into the reaction mixture increases this to 90%. However, substitution is accompanied by side-reactions of polydichlorophosphazen with triethylamine and other processes, so that the heterounit character of the resulting polymer reaches 6.8%.[86] Nevertheless, the acceptor method of substitution in polydichlorophosphazen is more convenient for preparative purposes[50,106,107].

Several polyaryloxyphosphazens having identical side-groups have been synthesised and characterised[75-77]. These polymers are soluble in dimethylformamide and oxolan, have viscosities $[\eta]$ = 0.8–12 dl g^{-1} (Table 5), and are shown by X-ray examination to be only slightly ordered with glass points between −40 and +50 °C. Polydialkoxyphosphazens $\{[P(OR)_2{:}N]_2.P(OR)(OR'){:}N-\}_n$ with regularly alternating (every two phosphorus atoms) R′ groups are obtained by the action of alkoxides or phenoxides on linear polymerisation products of monoaryloxypentachlorocyclotriphosphazens $R'OP_3N_3Cl_5$.[12,133]

2. Polydiaminophosphazens

Polydiaminophosphazens are obtained by replacing chlorine atoms in polydichlorophosphazen with residues of primary or secondary amines:

Either the initial amine or a specially added tertiary amine can act as acceptor of the hydrogen chloride formed[87,88,94-96].

Polybisarylaminophosphazens have higher glass points (Table 6) than have polydiaryloxyphosphazens, as a consequence of the greater rigidity of chains due to hydrogen bonding in the former[87,88]; a similar pattern is observed on comparing corresponding polydialkoxyphosphazens[1,9] and polybisalkylaminophosphazens[94-96]. The latter differ from the former in possessing an ordered structure (Table 7), although their formation is accompanied by degradative processes, as is indicated by the considerably lower molecular mass in comparison with the initial polydichlorophosphazen or corresponding polydialkoxyphosphazens[96]. This may be due to the reaction [87]

When primary amines are used as substituting reagents, however, the molecular mass may be increased by partial cross-linking[96]

Polyaminophosphazens are chemically stable. The use of alkyl esters of amino-acids[97,98], however, entails not only increase in the proportion of degradative processes in main chains and decrease in degree of substitution with bulky ligands but also diminished chemical stability of the polyphosphazens, which begin to decompose even at room temperature.

When sterically hindered nucleophiles, e.g. *p*-phenylazoaniline[99], derivatives of other colorants or steroids[100], are used for the preparation of polyphosphazens, at most one chlorine atom can be substituted at each phosphorus atom in polydichlorophosphazen, and the activity of the remaining chlorine atoms is sharply diminished even towards such highly active reagents as sodium trifluoroethoxide and methylamine[100].

An original method for synthesising polybistrifluoroethoxyphosphazen[101] consists in heating tristrifluoroethoxy-*N*-trimethylsilylphosphazen at 200 °C. Trifluoroethoxytrimethylsilane separates and a polymer of molecular mass 4000–10000 is formed.

3. Polyalkylphosphazens

Since alkylated cyclophosphazens cannot be polymerised, polyphosphazens containing organic groups attached by a carbon–phosphorus bond are obtained by the action of various organometallic compounds on polyhalogenophosphazens. Thus boiling polydichlorophosphazen in benzene with a double excess of phenyl-lithium gives a 22% yield of polydiphenylphosphazen[102]. Polydifluorophosphazen reacts more readily with phenyl-lithium, and also with diethyl- and dibutyl-magnesium[103], although in this case, too, only one halogen atom on each phosphorus atom is replaced preferentially. Thus an attempt to replace all the fluorine atoms in polydifluorophosphazen enabled only 80–90% substitution to be attained, with considerable degradation of macromolecules[103,104].

IV. PROPERTIES OF POLYPHOSPHAZENS

Molecular-mass Characteristics

These characteristics of polyphosphazens have been the subject of lively discussion, primarily because of the unusually wide molecular-mass distribution noted by many workers[1,76-78,87,88,95,96]. Thus the polydispersity coefficient of polyaryloxyphosphazens may reach 30,[76] and amounts to 5–10 even for individual fractions; in most cases gas-absorption chromatography indicates a bimodal distribution for these polymers[70,78], the origin of which is still obscure. Nor has the reason been ascertained why radii of inertia of

macromolecules found from light scattering considerably exceed the calculated values: $\langle S^2\rangle^{\frac{1}{2}} = 546$ or 638 nm[76,77] for polydi-p-chlorophenoxyphosphazen, but 600–1300 nm[78] for the corresponding *m*-chlorophenoxy-derivative. The calculated value for phosphazen chains having $M = 10^6$ is $\langle S^2\rangle^{\frac{1}{2}} = 40$–50 nm. Such a substantial divergence is assumed[76,78] to be due to a wide molecular-mass distribution or a branched character of the macromolecules.

Similar anomalies are observed with polybisarylaminophosphazens (Table 8). The identical character of molecular-mass characteristics for polyphosphazens having different types of side-groups indicates that the distributions are "prescribed" during formation of the initial polydichlorophosphazen. This hypothesis is confirmed by results[114] showing a significant difference between the molecular-mass distributions of polyphosphazens prepared from polydichlorophosphazen and those obtained by the polymerisation of hexachlorocyclotriphosphazen in the mass and in solution.

Structure of Polyphosphazens

Little work has yet been done on structure, although definite progress has been noted in recent years. Thus two transition points have been observed[8,108–112] in certain partly crystalline polyphosphazens, the difference between which may reach 150–250 deg. The first T_1 corresponds to a transition from an ordered three-dimensional to a mesomorphous state. In polybischlorophenoxyphosphazens the latter is characterised by a pseudohexagonal structure with two-dimensional order in the packing of parallel oriented chains[108]. Study of polybistrifluoroethoxyphosphazen by optical microscopy, nuclear magnetic resonance, X-ray diffraction, and differential scanning calorimetry[109,110] has revealed spherulitic morphology remaining unchanged on passage through the first transition point, although this is accompanied by disruption of ordered orientation of macromolecular axes and a transition to structures with hexagonal packing. These transition temperatures and melting points are given for several polyphosphazens in Table 9.

Table 9. Transition and decomposition temperatures of polyphosphazens $-[PN(OR)_2]-$[8].

R	T_{gl}, °C	Transition temp., °C		T_{decomp}, °C**
		T_1^*	m.p.

m-ClC_6H_4	−24	66	370	380
p-ClC_6H_4	4	167	365	410
C_6H_5 + *p*-ClC_6H_4 (1 : 1)	5	77, 94	—	—

* T_1 = temperature of transition to liquid-crystalline state.
** From dynamic thermogravimetric analysis in air.

The mesomorphous transitions in polyphosphazens are characterised by considerable enthalpy changes, exceeding those for a transition into the isotropic melt by factors of 10 and > 50 in polybistrifluoroethoxyphosphazen and polydi-*p*-chlorophenoxyphosphazen respectively[109] (Table 10). This feature is more characteristic of liquid-crystalline systems of low molecular weight[113]. The discrepancies in transition points and melting points given by different workers (Tables 9 and 10) are apparently due to the dependence of these temperatures on the preliminary annealing conditions. Thus the former polymer exhibits a significant dependence of the transition point on the conditions of crystallisation, the temperature, and the duration of the anneal (Fig.1).[109] The highest value (T_1 = 91.5 °C) and the maximum heat of transition are achieved after the polymer has been preheated in the range 240–255 °C.[109]

Table 10. Transitions in polyphosphazens and other compounds[109]*.

* ΔH = change in enthalpy; ΔV = volume change, %.

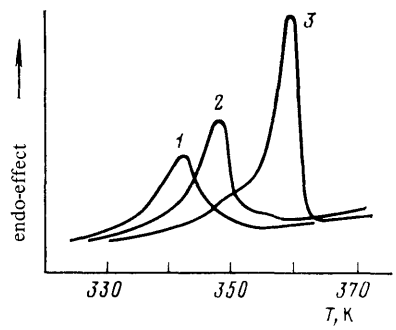

Figure 1. Effect of heat-treatment on the endotherms for the transition of polybistrifluoroethoxyphosphazen from the crystalline to the mesomorphous state: 1) specimen obtained from melt by moulding (T_1 = 79.5 °C); 2) as (1) after recrystallisation by cooling from 112 °C at 20 deg min^{-1} (80.5 °C); 3) specimen preheated at 240–255 °C (91.5 °C).

Dynamic mechanical tests on polybistrifluoroethoxyphosphazen have shown[76,112] a sharp decrease in modulus of elasticity at the transition point, at or slightly above which the polymer can already be moulded under pressure into strong flexible films. Despite considerable interest in the mesomorphous state of polyphosphazens, it is not yet clear what type of structure it possesses—whether smectic, nematic, or plastic crystalline.

Amorphous polyphosphazens can be assumed to have a globular structure in view of the great flexibility of the macromolecules[1] and by analogy with amorphous polysiloxanes. This hypothesis is consistent with the closely similar permeabilities of these two groups of polymers to water vapour and diffusion coefficients of the vapour in them[114, 115]. Mixtures of partly crystalline homopolymers differ from the corresponding phosphazen copolymers in having a single glass point and several transition points T_1, which indicates

compatibility of the amorphous phases and absence of such compatibility from crystalline regions[116].

Like polydichlorophosphazen[28] its isothiocyanato- and alkylamino-derivatives[117,118], in contrast to corresponding cyclic analogues, exhibit predominantly electronic conduction.

Chemical Properties

The chemical properties of polyphosphazens are determined in considerable measure by the nature of the side-groups. The completely substituted compounds containing inert aliphatic and aromatic groups attached to phosphorus atoms of the main chain directly through oxygen or nitrogen atoms resist the action of atmospheric moisture and weak acids and bases[1,8]. Thus polydiphenylphosphazen remains unchanged after being boiled in 1 *N* nitric acid and 1 *N* aqueous potassium hydroxide for 48 h.[102] Polymers containing residues of amino-acids in the side-chain, however, readily undergo spontaneous decomposition when stored under normal conditions[97].

Thermal Stability

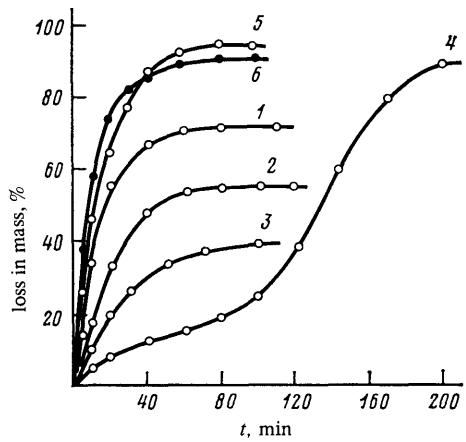
Polyphosphazens containing organic substituents are considerably less stable than the original polydichlorophosphazen, which begins to depolymerise only above 350 °C,[1,8] a first-order reaction having activation energy 98 ± 8 kJ mole^{-1}.[119,126] The temperatures given in Tables 5, 6, and 9 for the start of decomposition of various polyphosphazens were obtained by dynamic thermogravimetric analysis. However, viscosimetric measurements indicate that macromolecules of most of the organically substituted polyphosphazens begin to break down over the range 100–200 °C.[78,119–121]

Polybisalkylaminophosphazens are thermally the most stable, like their cyclic analogues beginning to undergo deaminolysis above 100–150 °C.[1,8,122] Polydialkoxyphosphazens are somewhat more stable, although both polydiphenoxy- and polydi-*m*-chlorophenoxy-phosphazens[119,78] exhibit a decrease in molecular mass over the range 130–160 °C. In contrast to the results of dynamic thermogravimetric analysis (Table 9), polybistrifluoroethoxyphosphazen is relatively thermostable under conditions of isothermal heating and resembles most other polyperfluoroalkoxyphosphazens in decomposing under equilibrium and non-equilibrium conditions with the formation of cyclic homologues[120,121].

Experimental results at present available indicate that the thermal stability of polyphosphazens is determined by the factors—thermal stability of side-groups, presence of weak, defective chain units resulting from incomplete substitution and other causes, steric interactions of side-substituents facilitating breakdown of the main chain, and degradation governed by the influence of terminal groups.

The influence of the nature of side-groups on the thermal stability of polyphosphazens is illustrated by polybisalkylaminophosphazens (Table 6)[37,88,122]. The presence of defective units is apparently responsible for cases of regular increase in molecular mass of polydiaryloxyphosphazens at 130–170 °C.[78,119] This is indicated by the formation of a small quantity of 2-chloro-1,1,1-trifluoroethane in the degradation of polybistrifluoroethoxyphosphazen[120]. Instability due to steric interactions of bulky side-groups has been examined in detail by Allcock[1,127,128].

With small and thermally stable side-groups (e.g. trifluoroethoxy) and with a sufficiently high degree of substitution, however, terminal groups begin to play an important part in the thermal stability of polyphosphazens. Thus it was shown[123] for polydibutoxyphosphazens that, as the molecular mass decreases and the concentration of terminal P:O and P.OH groups increases, the rate of degradation in a vacuum (0.133 Pa) at 200 °C rises, while the character of the weight-loss curves changes owing to depolymerisation with formation of cyclic butoxyphosphazens (Fig. 2). At higher temperatures (220–250 °C) the molecular mass of the polymer has hardly any effect on the character of degradation: under these conditions instability of side-groups obviously becomes the dominant factor. As decomposition diminishes (residual pressure 266 Pa), dibutyl ether and tributyl phosphate appear among the volatile degradation products[123].



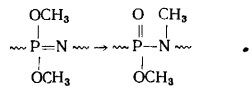


Figure 2. Thermal degradation of polydibutoxyphosphazens in a vacuum (0.133 Pa) at (°C) (molecular mass): 1) 200 (1340); 2) 200 (3100); 3) 200 (5400); 4) 200 (750000); 5) 220 (750000); 6) 250 (750000).

Establishment of the influence of the nature and concentration of terminal groups in polydialkoxyphosphazens on their thermal degradation has enabled coordinated polyphosphazens of chelate type to be obtained from analogous linear oligomers[124]. The thermal stability of polyphosphazens can be enhanced by the chemical blocking of terminal groups and also groups responsible for initiating the thermal breakdown of other weak bonds in macromolecules. Thus thiocarbonate derivatives of zinc and lead[129], oxides, hydroxides, and carbonates of alkali and alkaline-earth metals, quinolinol complexes of transition metals[130], a zinc derivative of mercaptobenzothiazole[131], and zinc hippurate[132] are used to stabilise polyphosphazens.

Among other thermal reactions of polyphosphazens mention must be made of the phosphazen–phosphazan rearrangement, which takes place in polydimethoxyphosphazen at 130 °C[125]:

After 6 h the degree of conversion into a polymeric phosphazan is 34.7%.

Vulcanisation of Polyphosphazens

Vulcanisation is acquiring increasing importance in view of the great practical value of these polymers. Traditionally, unsaturated groups are introduced into side-chains, and

vulcanisation is effected with peroxides[134,135]. In the case of polyaryloxyphosphazens, polymers containing unsaturated groups—mostly allyl[136,137] or alkenyl[90]—in the aryloxy-radicals are used. These polymers can be hardened also by heating with sulphur or by the action of ionising radiations[137,138,143].

In order to lower the temperature of the vulcanisation of polyphosphazens primary and secondary amino-groups[139] or hydroxyalkyl radicals[140] are introduced in their side-chains; such polymers can be cross-linked at moderate temperatures by the action of diazocyanates, polyanhydrides, and diepoxides. Polyphosphazens containing unsaturated bonds in side-chains can be vulcanised at room temperature by means of oligomeric siloxanes containing silicon–hydrogen bonds, the process being accomplished in the presence of catalysts containing platinum[141]. It has been suggested[73,142] that polyperfluoroalkoxyphosphazens could be cross-linked by treatment with alkoxides of perfluoroglycols.

V. APPLICATIONS

The main trends in the application of macromolecular polyphosphazens have been[6-10] the production of elastomers and hence articles able to withstand low temperatures and aggressive media, the preparation of non-flammable and incombustible materials, and biomedical uses. The most promising elastomers have been obtained from polyperfluoroalkoxyphosphazen copolymers, e.g. $\{(CF_3CH_2O)_x(H[CF_2]_4.CH_2O)_{2-x}PN\}$, and also polymers containing other perfluorinated alcohol residues[7,8,67,145].

Table 11. Fire resistance of polymers[7,148].

R = *p*-Cl	44	455
R = *p*-Br	65	—
R = *p*-OCH_3	26	120
R = H, C_2H_5 (copolymer)	43**	40

* Obtained on testing in a smoke chamber.
** Copolymer filled with 50 mass % of aluminium hydroxide; the unfilled copolymer has O.i. = 28.

Elastomers are obtained by adding to the initial polyperfluoroalkoxyphosphazens 30–40 mass % of reinforcing fillers (carbon black, Aerosil, clay, aluminium hydroxide, etc.) and also vulcanising and stabilising agents. Those resulting from the vulcanisation of such mixtures have good low-temperature properties, modulus of elasticity at 100% elongation 3.5–10.5 MPa, tensile strength 7.0–14.0 MPa, and elongation at break 100–200%. They resist the action of oils, liquid fuels, and hydraulic fluids, and can operate at temperatures up to 175 °C for a long time[7,145]. Such elastomers are used to make flange seals, airtight and damping packing, glands, fuel hoses, and other components employed in aviation and other branches of technology[144,146,147].

Polyphosphazens have been widely used to obtain fire-resistant and non-flammable polymeric materials. Table 11 compares oxygen indices (O.i.) and specific optical densities of smoke D_{sm} for the combustion of several industrial polymers and polyphosphazens. The latter are either incombustible (O.i. > 30) or self-extinguishing (> 25). Polyphosphazens have the advantage over difficultly combustible or self-extinguishing organic polymers (polyvinyl chloride, polycarbonates) of forming less toxic products on combustion or thermal decomposition[149,150]. The presence of halogens in organic side-chains improves considerably the fire-resistance of polyphosphazens[7,148,149].

An interesting field of application of polydialkoxyphosphazen homopolymers and copolymers is the production of elastic and semi-rigid foams[149,151].

The Dilatancy of Colloidal Structures and Polymer Solutions

I.F.Efremov

The dilatant regime in the flow of dispersions under the constrained conditions of the interaction of colloidal particles resistant to aggregation is discussed. In this case the system behaves as a dilatant periodic colloidal structure of the second type with a limited volume of the medium (PCS_2) in which a positive disjoining pressure $\pi_2 > 0$ operates. The similarity in the dilatant behaviour of dispersed systems and structured solutions of surfactants and polymers is demonstrated. With increased concentration of ions (and also of particle size), the dilatant regime passes into an anomalously viscous (thixotropic regime), i.e. under these conditions the dilatant PCS_2 is converted into a thixotropic PCS_1 (of the first type) in which $\pi_1 < 0$.
The bibliography includes 254 references.

I. INTRODUCTION

The unusual rheological properties of colloidal structures, which usually exhibit a non-Newtonian viscosity, have already been investigated for a long time. However, until recently most interest was shown in the behaviour of dispersions, whose shear deformation is accompanied by an appreciable decrease of the effective viscosity as a consequence of the breakdown of the colloidal structure under the influence of gradient fluxes in the liquid medium†.

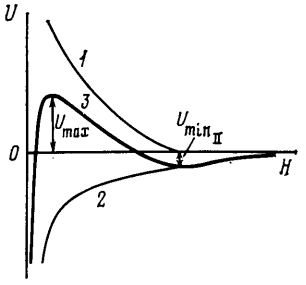

Figure 1. Potential curves for the interaction of two disperse particles: 1) repulsive curve; 2) attractive curve; 3) resultant curve in the presence of a repulsion barrier U_{max} and a secondary minimum with a depth $U_{min\,II}$ (U is the potential energy of the interaction of the particles and H the distance between them).

†A change in viscosity is also possible as a consequence of the orientation of the anisometric micro-objects in the stream, but these effects are comparatively small and will not be considered here[1-4].

The magnitude of the anomaly in the viscosity is determined by the change in the stability of the structure in the deformation process. The stability of a thixotropic system depends in its turn on the binding energy between its constituent elements and correspondingly on the depth of the secondary minimum on the potential interaction curves (Figs.1 and 2).[5]

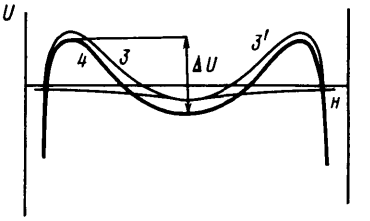

Figure 2. Potential curve for the interaction of a single test particle with two neighbouring particles (curve 4) in the presence of an energy minimum ΔU. Curves 3 and 3' are the resultant pair interaction curves.

The systems arising as a result of the fixation of micro-objects at the secondary minimum constitute periodic colloidal structures of the first type (PCS_1) with thixotropic properties. As a rule the PCS_1 are of a local character, i.e. they are not formed throughout the bulk of the system (under certain conditions and at a sufficiently high concentration in the solid phase, complete immobilisation of the dispersion is possible) and consist of ordered micro-regions (tactoids) alternating with individual "amorphous" sections with a lower density[6]. Such a tactoid structure, which is known for dispersions of many substances, particularly argillaceous minerals[7-10], is responsible for the possibility of the appearance of anomalies in viscosity, whose magnitude $\eta_0 - \eta_m$

(η_0 and η_m are the viscosities of the virtually undisrupted structure and the structure disrupted to the maximum extent) naturally depends on the depth of the potential minimum $U_{min\ II}$ (Fig.3)[1,11,12].

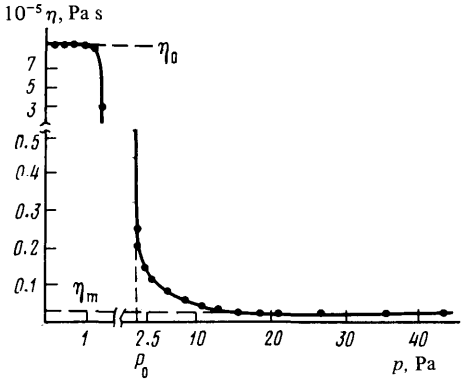

Figure 3. Dependence of the viscosity on the shear stress in a 10% aqueous (wt.%) dispersion of bentonite[11].

At the same time the authors of a number of studies[13-15] drew attention to the fact that the magnitude of the anomaly in viscosity does not determine the capacity of the system for thixotropic recovery and is not an unambiguous characteristic of thixotropic properties: thixotropy is defined as the isothermal and reversible sol ⇌ gel transformation[16,17]. One should bear in mind that many colloidal structures decompose irreversibly (partially or completely); complete reversibility is a rare case arising as a consequence of syneresis and other possible processes#. Fully irreversible PCS are not strictly speaking thixotropic systems. However, the origin, structure, and many properties, for example peptisability, are similar for reversible and irreversible PCS. Furthermore, both types of PCS undergo syneresis, which can be sharply accelerated due to external influences leading to the breakdown of the structure and can occur with partial or complete precipitation of the phase. However, there is a possibility of a microrecovery to some extent, which can be inferred solely on the basis of special studies.

Despite the large number of studies on thixotropy[1,5,6,11-27], little is known about the mechanism of the recovery processes, their energetics, and kinetics. Thus it is not clear which dispersions can recover their structure, to what extent, and over what period. One of the causes of this situation is apparently insufficient investigation of the structural transformations at the microlevel with determination of quantitative rules governing the interaction of micro-objects in external force fields. In a number of studies an attempt has been made at a quantitative interpretation of the thixotropic recovery on the basis of general equations, which are usually empirical (or semiempirical) (see, for example, Refs.23, 24, and 28-31). The results of the analysis of thixotropic multicomponent mixtures with allowance for the kinetics of the breakdown and recovery of the structural elements have been published[12,26]. A model of a thixotropic system, developed using the methods of hydrodynamics, rheology, and information theory as well as the mathematical apparatus of Markovian processes has been proposed[32]. The phenomenon of thixotropy has also been considered on the basis of the thermodynamics of irreversible processes[33,34].

It has been noted[14,35] that thixotropy can be of two kinds: based on stability and characterising the breakdown and recovery of the structural network, and based on viscosity and reflecting the breakdown and recovery of individual aggregates of colloidal particles.

Dilatancy, usually expressed by an increase of viscosity over a certain medium range of deformations, is, in addition to thixotropy, also a characteristic rheological property of colloidal dispersions (Fig.4). Dilatancy frequently plays an important role in industrial and natural processes. Dilatant effects frequently hinder the technology and transport of dispersions and limit the intensification of deformation processes[6,36-41]. Dilatant rocks (various types of earth, soil, etc.), whose rheology is of interest to many specialists, are widely distributed in nature; dilatancy has a major influence on the behaviour of these rocks (for example, in different instances of "stabilisation" of clay ground[42], in the treatment of soils[43], in different rheological processes, etc.). At the same time the causes of the onset of the dilatant flow regime have been inadequately determined and the existing explanations are not unique[5,6,15,36,44-46].

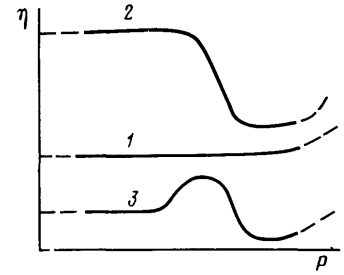

Figure 4. Dependence of the viscosity on the shear stress for different systems: 1) pseudoplastic (Bingham); 2) structural-viscous (thixotropic); 3) dilatant.

II. THE PROBLEM OF THE DILATANCY OF DISPERSIONS WITH MODERATE AND LOW CONCENTRATIONS OF THE SOLID PHASE

According to the literature[47-49], dilatancy (dilatation) is defined as a homogeneous deformation involving the volume expansion of highly concentrated dispersed systems. The expansion of such dispersions is caused by the fact that, with increase in the rate of shear, the particles pass into a less close-packed state generating pores which suck in the liquid: the volume of the system then increases and the dissipation of energy is enhanced. This is observed particularly clearly in pastes where the dispersed particles are almost close-packed. On deformation, the particles move away from one another (some approach one another), which

#Various binding mixtures, in which solidification processes take place, increasing the stability and the possibility of its restoration after the breakdown of the structure of the mixture, are frequently classified as reversible systems. In this case the term "reversibility" naturally has a limited significance.

leads to an increase of volume[6,21,50-52]. The volume of many disperse systems with close-packed particles changes on deformation regardless of whether the gaps between the particles are filled with water or air[51]. The viscosity and volume of certain concentrated dispersions increase as the rate of shear is altered, although there is in all probability no direct contact between their colloidal particles[53,54].

However, dilatant phenomena are more varied than would follow from the concept of dilatancy as deformation of volume expansion[48-50]. From the standpoint of these ideas, it is difficult to explain rheological data such as the absence of expansion in the dilatant deformation regime, for example, in starch pastes[52]; some workers believe that an increase of volume in dilatancy is altogether non-obligatory[21]. Furthermore, dilatancy has been observed in many dispersions containing the solid phase in an amount much smaller than would correspond to close-packing.

The range of compositions of dilatant dispersions is very wide. Thus, starting from systems concentrated to the limiting extent, for example, hydro-dispersions of silica or quartz glass (with a volume fraction of the solid phase $\phi = 0.85-0.87$),[55,56] the following systems are dilatant: dispersions of alumina in water (0.60) [56] and of iron in carbon tetrachloride (0.46),[57] aqueous clay strata (0.40–0.47),[58] quartz (0.41–0.45),[59] and starch (0.38–0.48),[56,59] dispersions in liquids of different kinds, latices (0.30–0.50),[44,45,60-62] titanium dioxide (0.30–0.43),[63,64] barium sulphate and carbonate (0.30),[65] latex PCS (0.12–0.40),[66-68] etc.

The above features—dilatancy of colloidal structures with a low content of the disperse phase and the absence of expansion on shear—led to the postulation of various mechanisms of dilatancy (more precisely of the increase of viscosity on shear) in dispersions with high and low concentrations[15,44,45,51,53,61,69-71]. Different terms have been proposed for the deformation of the latter systems: "quasi-dilatancy"[44,61], "pseudo-dilatancy"[72], "antithixotropy"[73], "negative thixotropy"[74,75], etc., the term "dilatancy" being retained for processes consistent with the definition given above[47-50]. However, this terminology has not gained wide currency.

The complexity of the problem under discussion arises from the fact that the increase of viscosity on shear or, in other words, the increase of the resistance offered by the system to external influences may be a consequence of the occurrence of different (one or several simultaneous) comparatively little investigated processes (many of which are reversible), rather than of the absence of a unified terminology; this greatly hinders the determination of the real mechanism responsible for the behaviour of the system under deformation conditions. We may note the following processes.

1. Reversible deformation of a highly concentrated dispersion accompanied by an increase of the viscosity and volume of the system (the Reynolds and Reiner dilatation[47-49]).

2. Reversible deformation of dispersions at moderate and low concentrations accompanied by an increase in viscosity at constant volume (quasi-dilatancy as defined by Krasheninnikov and coworkers[44,61]).

3. Rheopey—acceleration of the restoration of the thixotropic structure disrupted beforehand (as defined by Freundlich and Yuliusburger[76]).

4. Long-range aggregation (long-range coagulation) with fixation of micro-objects at the secondary potential minimum as well as short-range coagulation (fixation at the primary minimum) induced by the flow (Fig.5).[5,77-85] The statistical theory of aggregation under the conditions of steady-state flow has been developed[86].

5. Stabilisation of the dispersion as a result of unidirectional and periodic deformations and their superposition[14,87-89] as well as vibro-treatment[90-92]. It has been noted[89] that, depending on the rate of shear or the frequency of sinusoidal vibrations of a kaolin hydrodispersion, either thixotropic or dilatant effects arise in the latter. An increase of the rate of shear with the same stress under the conditions of the superposition of two types of deformation can arise in flow through tubes as a consequence of the appearance of random sources of vibrations. It has been concluded[92] that the capacity for thixotropic transformations of a dispersion compacted by vibro-treatment increases with increasing density of the medium. However, the increase of viscosity with increasing density of the medium greatly exceeds its decrease due to the thixotropic breakdown. The characteristics of the formation and breakdown of dispersed structures under the conditions of the joint action of vibration and surfactant additives have been discussed[93].

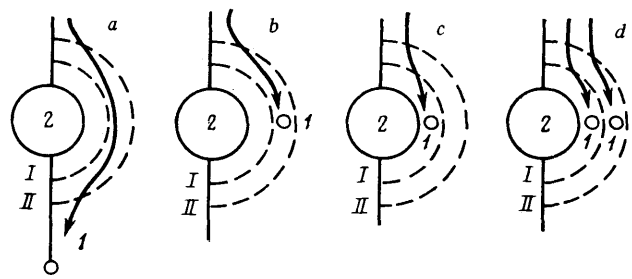

Figure 5. Schematic illustration of the interaction of micro-objects in a flow: *a*) no bond formed between particles *1* and *2*; *b*) particle *1* fixed at the secondary (II) minimum; *c*) particle *1* fixed at the primary (I) minimum; *d*) particles *1* fixed at the primary and secondary minima[80].

Figure 6. Electron micrograph of the aggregation of rod-shaped sepiolite particles having electrical dipole moments[94].

6. Stabilisation of the colloidal structure as a result of its rearrangement under the influence of the flow. For example, the structure comprising non-uniformly arranged particles can become stabilised after the particles have been more uniformly distributed, or the strength of the bonds between anisometric particles—rods and plates with permanent electric dipole moments—can increase under the influence

of hydrodynamic forces which is apparently characteristic of dispersions of argillaceous minerals (Fig.6).[5,81,94-99]

7. The fluidity of a dispersion can diminish following the onset of turbulence, which can be interpreted as an increase of viscosity[100-103]; this is by no means always easy to observe, particularly for an anomalously microturbulent regime and also in the presence of aggregation processes[104].

Furthermore, considerations have been put forward concerning the possibility of other processes leading to the stabilisation of the system. It has been suggested[105] that the elasticity of dispersions of gas carbon black in a mineral oil is determined by the breakdown of the network of carbon black particles with formation of chain fragments; the formation of the coagulation network and the rearrangement of its structure in dilatancy has been indicated in a number of studies. Many investigators have noted the need to take account of the interaction forces, the solvation effects, and other factors which can influence the flow regime. Despite the importance of such explanations, they are nevertheless largely hypothetical and are usually one-sided.

The determination of the mechanisms of processes occurring in disperse systems subjected to external force fields is an extremely complex problem whose solution solely with the aid of rheological methods, without a detailed description of the system, as a rule involves considerable difficulties. As a result of failure to take into account this factor adequately, a heterogeneous rheological terminology has arisen[14,15,70,88,90]; there have been frequent instances of the incorrect employment of different terms, which has been discussed in a number of studies[13-15,70,99,106], as well as others. Thus the term "rheopexy"[107,108] has apparently been used (in conflict with the definition of Freundlich and Yuliusburger[76]) to denote a dilatant increase in the viscosity of the dispersion§; the increase of the viscosity of a surfactant solution with a simultaneous alteration of pH has been called a rheopectic increase[109]. The changes in the viscosity of a polymer solution under the influence of shear deformation are frequently referred to as thixotropic (Refs.110, 111, etc.), which cannot be regarded as correct.

Processes in which the stability or viscosity of the system decreases are frequently classified as thixotropic, although in terms of their mechanisms they can be very remote from thixotropy[106]. As an example, one may quote the decrease of the elastic properties of a polymer solution following the rupture of the three-dimensional network arising as a consequence of the chemical "cross-linking" of the chain, as well as the disruption of gel monolith (swollen fibre, hydrated sorbent, etc.). A different significance is frequently imparted to the concept of colloidal structures in rheological studies; attention has been drawn[71,81] to the insufficiently clear-cut nature of the term "coagulation structures", which does not reflect the entire wide variety of different types of dispersions[5,81,99,112,113].

The inadequate investigation of dilatancy phenomena precludes a sufficiently complete explanation of the fundamental experimental data. For example, it is not clear what determines the difference between the volume of a close-packed disperse phase and its volume under conditions where dilatant flow begins; this difference can be small in some cases[56,114], while in others it can be very significant[57,65-68,115]. Furthermore, the question arises why dilatancy is manifested in poly(vinyl chloride) plastisols ($\phi = 0.5$) for particles of one size, while in the presence of particles of two sizes there is no dilatancy[116]; the dilatancy of paint and varnish systems based on TiO_2 disappears at 50 °C,[64] while in the case of quartz glass dispersions it disappears at 80 °C.[117]

Studies have been published recently on the rheological properties of PCS. It was found that PCS_2 (with a limited volume of the medium) at moderate and low concentrations are of the dilatant type under certain conditions in contrast to PCS_1 which are pseudoplastics. A detailed quantitative characterisation of these dispersions permitted an interpretation, somewhat different to the previous one, of the deformation processes and the establishment of the overall factors which determine the onset of a dilatant regime in various systems.

III. DILATANT-THIXOTROPIC TRANSFORMATIONS OF PERIODIC COLLOIDAL STRUCTURES

The differences between the PCS of different types are determined by the nature and forces of the interaction between micro-objects[5,81]. The PCS_1, which have arisen as a consequence of the predominance of attraction forces over long distances, are thixotropic systems which are both reversible and partly or completely irreversible. A second type of periodic colloidal structures (PCS_2), with a limited volume of the dispersion medium, is characterised by the predominance of repulsion forces over attraction forces, i.e. in the PCS_2 the dispersed particles interact under "constrained" conditions, which determines the large-scale nature of the order. Therefore, the PCS_2 fill almost the entire volume and their quasi-crystallinity is frequently readily indicated by their rainbow colour[118]. The constrained conditions play an important role in the behaviour of dispersions: ease of peptisation, liquefaction following the addition of a small amount of electrolyte, and conversion into thixotropic PCS_1 on addition of a further amount of the electrolyte (Fig.7) are characteristic of PCS_2.[5] The PCS_2—dispersions stabilised by the presence of double ionic layers (DIL) or adsorption-solvate layers (ASL)—have dilatant properties [this has been established in a study of aqueous dispersions of polyacrylonitrile (PAN) [66-68,119] and Al_2O_3 (Refs.120–123 and others)].

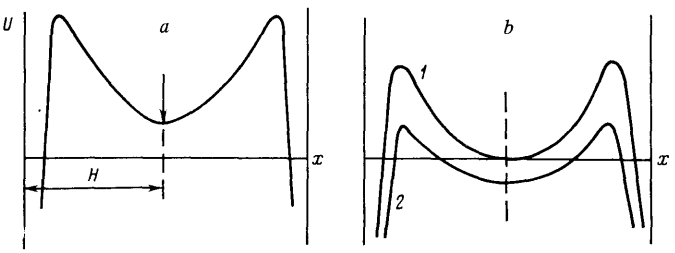

Figure 7, Potential curves for the interaction of particles: *a*) in the presence of a low content of electrolyte—in PCS_2; *b*) with increase of the content of electrolyte—in PCS of an intermediate type (curve *1*) and in PCS_1 (curve *2*).

§ It has been suggested[15,70] that the anomalous increase of viscosity on shear deformation without an increase in the volume of the system be called kinepexy (instead of quasi- or pseudo-dilatancy, antithixotropy, etc.).

PAN dispersions ($a \approx 150$ nm; ξ-potential of 40–52 mV), which are dilatant at low NaCl concentrations (0.004–0.024 M) and thixotropic at moderate concentrations (0.024–0.035 M), belong to stable ion-stabilised systems in terms of the nature

of the sedimentation and the magnitude of the charge (Fig.8). Figs.9 and 10 present plots of the function $I/\tau = f(P)$, where τ is the time of the movement of the sphere in the cylinder of the viscometer and P is the applied load. Evidently, with decrease of the NaCl content or with increase of the PAN concentration, the dilatant section begins at lower flow rates and for higher loads. This is due to the increase of the specific effective volume (fraction) of the disperse phase ϕ_e, which includes its real volume ϕ and the volume of the surface layers ϕ_S (immobilised as a consequence of the formation of DIL or ASL on the surface of the particles). An increase of ϕ_e leads to a decrease of the effective free or vacant volume ϕ_V:

$$\varphi_v = 1 - \varphi_e = 1 - (\varphi + \varphi_s) \quad (1)$$

or

$$\varphi_v = \varphi_0 - \varphi_s , \quad (2)$$

where $\phi_0 = 1 - \phi = \phi_V + \phi_S$ is the volume fraction of the liquid medium including the volume of the surface layers (DIL or ASL). The decrease of ϕ_V (as a consequence of the increase of ϕ_S due to the decrease of c_{NaCl} and the expansion of the DIL or the increase of ϕ with increase of the PAN content) leads to a greater constraint on the movement of the particles, which hinders the relaxation of the stresses arising in the system. Therefore the smaller the value of ϕ_V, the lower the rates at which dilatancy begins and at the same time a greater force is required for deformation (other conditions being equal).

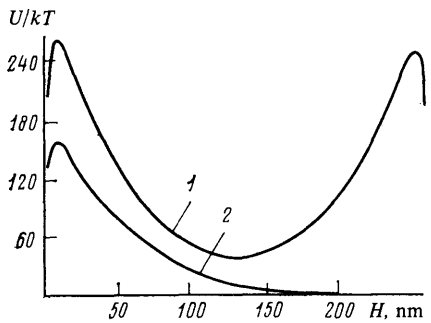

Figure 8. Potential curves for the interaction of PAN particles (for a volume concentration of the disperse phase $\phi = 0.25$) involving three particles with $\zeta = 52$ mV (curve *1*); for two particles with $\zeta = 41$ mV (curve *2*).

The fraction of "free" critical volume corresponding to the onset of the dilatant regime can be designated by $\phi_{V,cr}$. Then

$$\varphi_{v,cr} = 1 - \varphi_{e,cr} = 1 - (\varphi_{cr} + \varphi_{s,cr}) \quad (3)$$

or

$$\varphi_{v,cr} = \varphi_{0,cr} - \varphi_{s,cr} , \quad (4)$$

The above components of the volume fractions are illustrated in the schemes for model PCS_2 (Fig.11). Evidently the quantity $\phi_{e,cr} = 1 - \phi_{V,cr}$ should be approximately equal to the degree of saturation of the volume of the system by the solid phase for close-packed disperse particles in the absence of ionic and solvation layers, i.e. when $\phi_S = 0$ and

$$\varphi_{v,cr} = \varphi_{0,cr} = 1 - \varphi_{cr} . \quad (5)$$

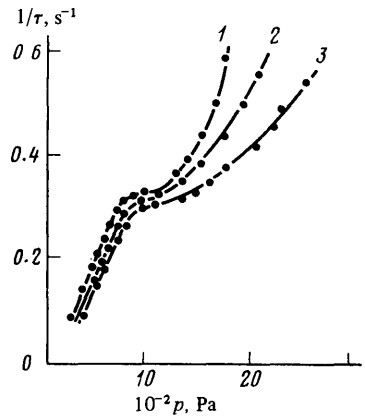

Figure 9. Dependence of the rate of deformation on the shear stress in aqueous PAN dispersions ($\phi = 0.165$) at 18 °C and different NaCl concentrations (M): 1) 0.020; 2) 0.014; 3) 0.004.

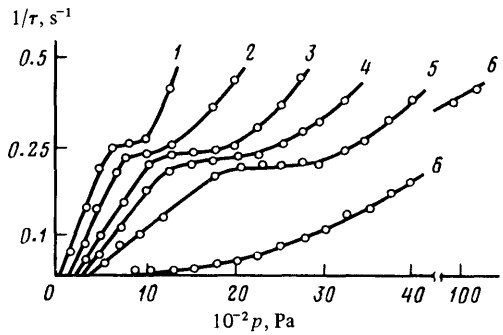

Figure 10. Dependence of the rate of deformation on the shear stress in aqueous PAN dispersions at 18 °C and different NaCl concentrations [1)–3) 0.024 M; 4) and 5) 0.005 M] and for different PAN volume fractions [1) 0.127; 2) 0.196; 3) 0.224; 4) 0.351; 5) 0.387; 6) 0.455].

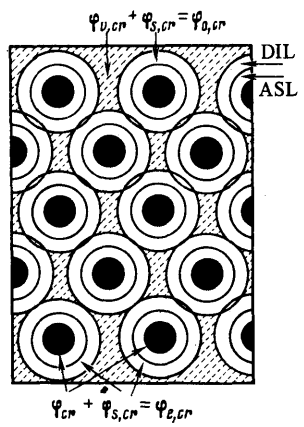

Figure 11. The periodic colloidal structure (PCS_2) stabilised by a double ionic layer. The effective volume (fraction) of the disperse phase and the "free" volume have critical values.

It follows from the above relations between the volume fractions [Eqns.(1)–(5)] that the differences between the critical concentrations of the disperse phase in different instances of deformation are caused mainly by the influence of the DIL and ASL, whose volume fraction $\phi_{s,cr}$ increases the volume fraction of the solid phase ϕ_{cr} to $\phi_{e,cr}$—the effective degree of volume saturation in "close" packing. In this case

$$\varphi_{e,cr} \simeq \varphi_{cr} + \varphi_{s,cr} . \qquad (6)$$

Thus the critical effective volume $\phi_{e,cr}$ is equivalent to the volume of the close-packed solid phase corresponding to the appearance of dilatancy; the quantity $\phi_{e,cr}$ then represents the sum of the critical volumes of the solid phase (ϕ_{cr}) and the protective layers ($\phi_{s,cr}$)(ASL and DIL) or, in other words, $\phi_{e,cr}$ is the effective hydrodynamic volume of the disperse phase.

The value of $\phi_{e,cr}$ for an ion-stabilised dispersion (Fig.11) can be determined with some approximation by plotting potential curves by the method of Efremov and coworkers[5,124] or analytically[125,126]. However, in order to obtain the true value of $\phi_{e,cr}$ for which the dilatant regime is established, it is necessary to take into account the relaxation times of the DIL and the entire disperse system, which is difficult. The DIL relaxation is known to be comparatively rapid[127]¶, but this applies also to DIL in the absence of structured boundary liquid layers, which can determine to a large extent the characteristic features of the rheological behaviour of concentrated dispersions—their structural-viscous properties.

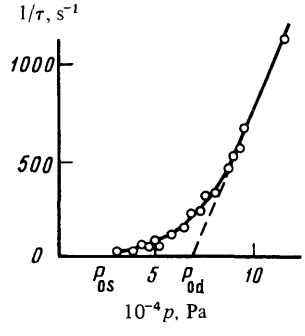

Figure 12. Dependence of the rate of deformation on the shear stress in an aqueous PAN dispersion (ϕ = 0.485) at an NaCl concentration of 0.005 M; P_{0S} = static limiting shear stress; P_{0d} = dynamic limiting shear stress.

The upper concentration limit, corresponding to the disappearance of dilatancy and the onset of structural-viscous flow (Fig.12), is therefore apparently determined by the long relaxation times of the system as a consequence of the decrease in the thickness of the liquid layers ($\phi_v \to$ min when $\phi \to$ max), the overlap of the compressed DIL, and the decrease of the depth of the energy well (Fig.13), which intensifies the aggregation and coagulation processes. The rupture of the bonds between particles undergoing rearrangement on deformation requires the application of appreciable loads. The system then behaves like thixotropic highly viscous PCS_1, which corresponds to the curve in Fig.12.

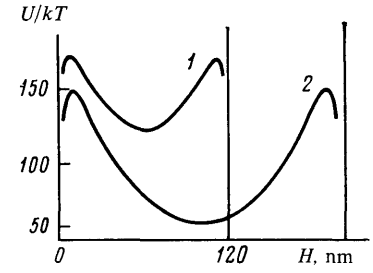

Figure 13. Potential curves for the interaction of the particles of aqueous PAN dispersions: 1) ϕ = 0.415 (distance between the surfaces $H_1 \cong$ 60 nm); 2) ϕ = 0.30 ($H_2 \cong$ 100 nm).[119]

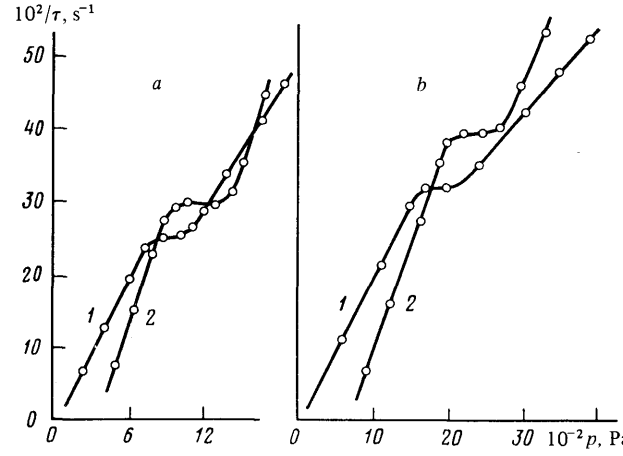

Figure 14. Dependence of the rate of deformation on the shear stress in aqueous PAN dispersions for c_{NaCl} = 0.22 M: *a*) ϕ_1 = 0.15 at 20 °C (curve *1*) and 68 °C (curve *2*); *b*) ϕ_2 = 0.25 at 10 °C (curve *1*) and 50 °C (curve *2*).[46]

With increase of temperature, the dilatant sections of the rheological curves for PAN dispersions shift to the region of higher rates of shear and a greater applied load (Fig.14). It is evident that (a), at a comparatively high temperature (68 °C) and a low PAN concentration (ϕ_1 = 0.15), the dilatant regime is shown fairly clearly as a consequence of the characteristics of the ionic stabilisation (a greater DIL thickness in the presence of a low content of ions and the retention of ionic stabilisation at elevated temperatures) and that (b) an increase of the PAN content shifts the dilatant section (like an increase of temperature) to the region of high rates of shear and a greater applied load.

¶ The DIL relaxation time θ is a function of the system parameters. Under the usual conditions, θ for a given solvent and electrolyte depends only on the concentration c_{el}. Thus, for an aqueous solution at the usual temperature $\theta \cong 10^{-10}/c_{el}$; when $c_{el} = 10^{-3}$ *N*, we have $\theta \cong 10^{-7}$ s.[127]

Interesting results have been obtained[120–123] in the study of aqueous dispersions of two fractions, I and II, of Al_2O_3 (with effective particle diameters of 4 and 40 μm and a nearly ellipsodal particle shape with an axial ratio of 1 : 3). The dispersion medium was a solution of sodium carboxymethylcellulose (0.1 wt.%); at pH 9.5 the particles had a ξ-potential of approximately −140 mV. Plots of potential curves for the interaction of the particles of the highly disperse Al_2O_3 system with $\phi \cong 0.50$ showed that it is a PCS_2 system in which repulsive forces predominate between the particles (separated by an average distance of 35 nm). The dispersion of large Al_2O_3 particles, fixed at the secondary potential minimum, is a thixotropic PCS_1. The study of the rheological properties of these systems reveals the following features.

1. The highly disperse PCS_2 (fraction I) has dilatant properties (Fig.15, curve *1*) due to the constrained conditions in the interaction of the particles.

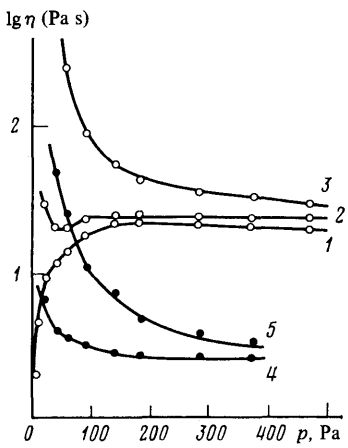

Figure 15. Rheological curves for Al_2O_3 dispersions characterising the change in the type of PCS as a function of the degree of dispersion of the solid phase and the KCl concentration (M): 1) 0; 2) 0.08; 3) 0.25 (fraction I); 4) 0; 5) 0.25 (fraction II).[122]

2. When small amounts of KCl are introduced into the PCS_2, the dilatant properties degenerate and the deformation regime becomes close to a Newtonian regime. A further addition of the electrolyte causes (in conformity with Fig.7) the conversion of the PCS_2 into the thixotropic PCS_1 (Fig.15, curves *2* and *3*).

3. When an electrolyte is introduced into the thixotropic PCS_1, formed by fraction II, with a low degree of dispersion, the latter is stabilised as a consequence of the increase in the depth of the minimum (Fig.15, curves *4* and *5*).

4. The dilatant regime in the deformation of the PCS_2 passes to a structural-viscous (thixotropic) regime when the disperse composition of the system is altered by adding to the latter fraction II, with a low degree of dispersion, instead of the same mass of fraction I (Fig.16). The transition $PCS_2 \rightarrow PCS_1$ then takes place and complex higher-order structures are formed (Fig.17);[99,128] in the latter the interaction of the large central particle with small particles can be illustrated by the periodic potential curve (Fig.18).[129] The breakdown of these complex aggregates under an external influence determines the structural-viscous deformation regime.

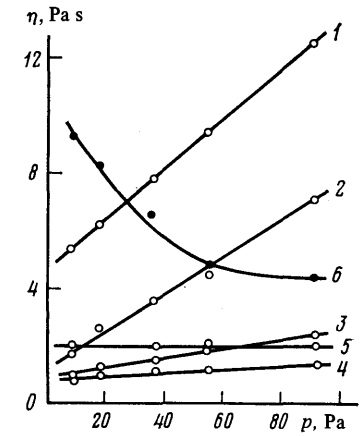

Figure 16. Flow curves for Al_2O_3 dispersions ($\phi \cong 0.50$) corresponding to different weight ratios of the fractions (I/II): 1) 80/20; 2) 70/30; 3) 50/50; 4) 40/60; 5) 20/80; 6) 10/90.[121]

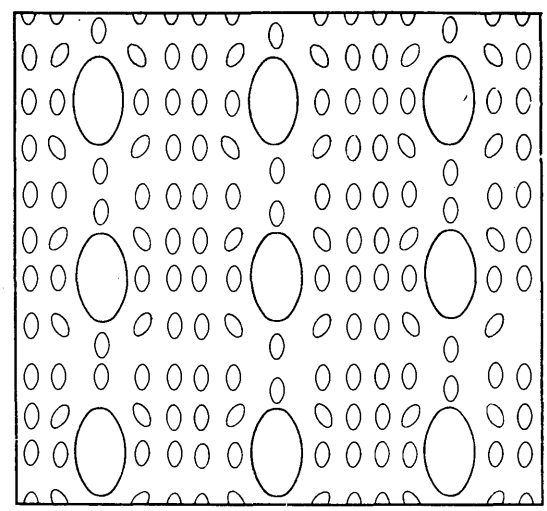

Figure 17. An element of a complex periodic colloidal structure consisting of large and small particles.

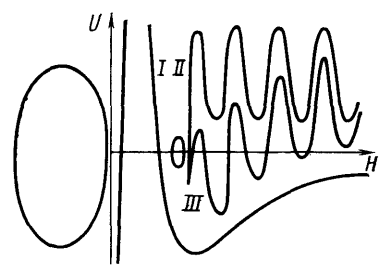

Figure 18. Potential curves characterising the interaction of small ellipsoidal particles with a large ellipsoidal particle: I) curve for the pair interaction of the particles; II) periodic curve for the interaction of several small particles in the absence of a large particle; III) overall curve for the interaction of heterogeneous particles.

5. The dilatant deformation regime in PCS_2 also passes to the structural-viscous regime after the introduction into the system of 1–2 wt.% of Latnensk clay (or a modified aerosil) instead of the corresponding amount of Al_2O_3 (Fig.19).[121] The considerable stabilisation of the dispersion after the introduction of the clay may be a consequence of the aggregation of heterogeneous particles, particularly when account is taken of the possibility that the clay particles have a permanent electric dipole moment[5,99]. The breakdown of these aggregates can lead to the structural-viscous deformation regime.

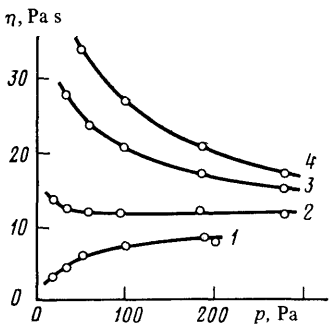

Figure 19. The influence of added Latnensk clay (instead of the corresponding amount of Al_2O_3) on the flow of Al_2O_3 dispersions (fraction I); percentage of clay (%): 1) 0; 2) 1.0; 3) 1.5; 4) 2.0.[121]

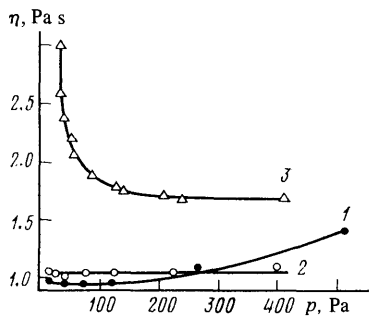

Figure 20. Dependence of the viscosity of aluminium hydroxide dispersions on the shear stress at different aluminium oxide nitrate concentrations (g litre^{-1}): 1) 16; 2) 60; 3) 100.[130]

Tikhonov and coworkers[121–123] showed for the first time that the rheology of dispersions is determined by their stability and hence by the conditions and the nature of the interaction forces between micro-objects: dilatant properties are manifested primarily in systems resistant to aggregation, under constrained conditions, while structural-viscous plastic properties are characteristic of less stable thixotropic dispersions.

The results of the study of dispersions of aluminium hydroxide in aqueous solutions of aluminium oxide nitrate have been published[130]. The content of the solid phase was 64% (ϕ = 0.64) in dispersions (1) and (3) and 62% (ϕ = 0.62) in dispersion (2). The shape of the colloidal particles (average diameter ~1 μm) was nearly spherical. In the presence of a low content of aluminium oxynitrate, the $Al(OH)_3$ dispersions are resistant to aggregation and exhibit dilatancy (Fig.20, curve *1*); with increase of the content of ions, there is a transition from the dilatant flow regime to the Newtonian regime and further to the structural-viscous regime, i.e. the $PCS_2 \rightarrow PCS_1$ transformation takes place (Fig.20, curves *2* and *3*). An increase of temperature causes the liquefaction of the system (as for PAN dispersions).

A transition of dilatant dispersions (ϕ = 0.48) of poly(methyl methacrylate) (PMMA) in dibutyl phthalate (DBP) to thixotropic structural-viscous systems on successive replacement of DBP by dioctyl sebacate (DOS) has been demonstrated[131] (Fig.21). The authors[131] explained this by the difference between the solvating properties of DBP and DOS, with which one can in the main agree, although the question of the role of the double ionic layers (DIL), which can significantly affect (together with solvation) the behaviour of dispersions, particularly in the region of high DOS concentrations, remains open. However, there can be hardly any doubt that the $PCS_2 \rightarrow PCS_1$ transition occurs in this instance.

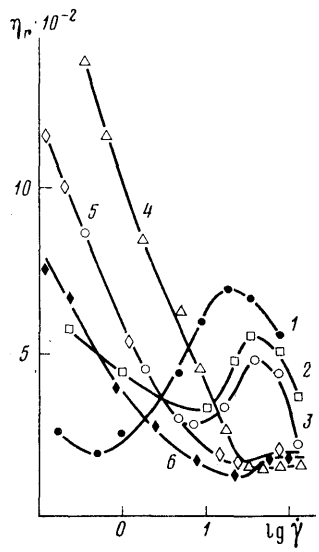

Figure 21. Dependence of the relative viscosity of a PMMA dispersion in DBP, DOS, and their mixtures on the rate of shear. DOS content (vol.%): 1) 0; 2) 10; 3) 20; 4) 40; 5) 70; 6) 100.[131]

IV. FACTORS DETERMINING THE DILATANT DEFORMATION REGIME

In the introduction it was noted that many investigators have pointed out various factors which in their view are responsible for the appearance of dilatancy on deformation of various dispersions. Consideration of these factors leads to the conclusion, that despite the significant differences in the nature and type of their influence, their action reduces ultimately to a decrease of the "free" volume ϕ_v of the system and to a greater retardation of the relaxation processes. It is then found that the results obtained in

the study of PCS, which were described in the preceding section, are of general significance and their use in rheological research is of definite interest. We shall consider the principal factors to which the majority of investigators refer when they explain the mechanism of the appearance of dilatant flow conditions.

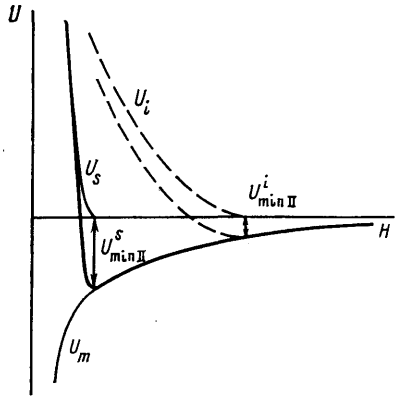

Figure 22. Potential pair interaction curves; $U^S_{min\ II}$—secondary minimum due to the presence of solvate layers on the surface; $U_S(H)$—repulsion energy curve for these layers; $U^i_{min\ II}$—secondary minimum due to the predominance of the attraction energy over long distances [$U_m(H)$ curve] over the double ionic layer repulsion energy [the $U_i(H)$ curve][99].

1. Adsorption-solvate Layers

It has been established[69] that dispersions (ϕ = 0.48) of the acrylonitrile–methacrylate copolymer in 1-propanol, 2-nitro-1-propyl acetate, and 2-nitro-1-butyl acetate are viscoplastic, while dispersions of the same copolymer in 2-nitro-1-propanol and 2-nitro-1-butanol are dilatant. The authors[69] explain the dilatancy by solvation and by the unusual behaviour of hydrogen bonds; at the same time they also postulate that the breakdown of the aggregates of the disperse particles formed at rest and the formation of coagulation structures should likewise give rise to dilatancy. Naturally, in viscoplastic dispersions the lower degree of solvation may be responsible for their structure being analogous to that of PCS_1. On the other hand, the more stable solvate layers, which might have been influenced by hydrogen bonds, can (when their thickness h is sufficiently great) lead to constrained conditions—a decrease of ϕ_V and the formation of dilatant PCS_2. This agrees with the fact that boundary liquid layers with retarded relaxation can impart a high viscosity to a system under constrained conditions. However, a final conclusion requires the experimental detection of these layers and the determination of the role of DIL, which should exist on the surface of the polymer particles and should also exert a stabilising effect and correspondingly diminish ϕ_V.

The rheology of PMMA dispersions in dilute poly(vinyl chloride) solutions and in dialkyl phthalates has been investigated[132,133]. It was shown that thixotropic behaviour is characteristic of dispersions with weak solvation and adsorption effects; on the other hand, the onset of dilatancy is associated with a fairly pronounced manifestation of these effects and also depends to some extent on the viscosity of the dispersion medium. A dilatant latex dispersion at rest has been considered[45] as a system of non-interacting swollen micro-objects separated by a structural-mechanical barrier. For fairly large shear stresses, capable of deforming layers of the swollen polymer and of overcoming the repulsion forces, a structural network arises, being deformed after the cessation of external influences. It has been concluded that, with increasing degree of lyophilicity, polymer dispersions pass from the thixotropic to the dilatant state (in other words, the $PCS_1 \rightarrow PCS_2$ transformation takes place). Thus, by altering the interaction at the polymer–plasticiser interface and by creating the optimum structure of the swollen layer on the surface of the polymer particles, it is possible to impart dilatant properties to the system. The decisive importance of solvation and adsorption in the dilatancy of dispersions has also been discussed in a number of other studies[63,64,134–137].

It has been established[63,64] that TiO_2 dispersions (ϕ = 30–42%) in white spirit possess thixotropic or dilatant properties depending on the content of alkyd resins: the dispersions are thixotropic for c_{SA} = 2–5% and dilatant for c_{SA} = 7.5%, where c_{SA} is the concentration of the surfactant. Thus the comparatively thin adsorption layer of the surfactant apparently determines the interaction of the TiO_2 particles over a long distance with formation of PCS_1 (Fig.22);[99] thicker and highly viscous layers lead to constrained conditions and PCS_2, whose electrical conductivity is smaller by several orders of magnitude than that of PCS_1. The fact that dilatancy disappears at temperature up to 50 °C or with increase in the solvent power of the solvent constitutes an important confirmation of the validity of the postulate that the ASL play a decisive role in imparting dilatant properties to TiO_2 dispersions; ion-stabilised PCS_2 retain dilatancy at relatively higher temperatures[138]. A sharp decrease of the dilatancy of starch dispersions (ϕ = 0.48) with increase of temperature has been observed[117,139], while the dilatancy of an aqueous dispersion of quartz glass (ϕ = 0.77) disappears only at 80 °C. The ζ-potential is ~|30| mV for quartz particles in an aqueous medium at pH 5.0;[134] consequently the dispersion was in all probability an ion-stabilised PCS_2.

The influence of the adsorption layer of the surfactant on the effective volume fraction of the disperse phase for a small thickness of the layer h, i.e. $h/a \ll 1$,[140,141] has been taken into account with the aid of the following expression:

$$\varphi_e \approx \varphi(1+3\,h/a)\,, \qquad (7)$$

where ϕ is the volume fraction of the solid phase, h the thickness of the surfactant layer, and a the radius of the particles.

2. Double Ionic Layers

In view of their wide occurrence, DIL frequency exert a decisive influence on the onset of the dilatant deformation regime. This has been confirmed in the studies quoted in the previous section as well as a number of others. Thus the influence of the concentration of the dilute electrolyte, the nature and pH of the liquid medium, and the size and concentration of the disperse SiO_2 particles on the nature of the deformation of the system, has been studied in detail[134]. The determination of the sedimentation volumes and of the ζ-potential made it possible to describe the stabilisation of the particles and to find the effective volume of the disperse phase ϕ_e and its ionic-electrostatic and solvation constituents.

This resulted in an explanation of the deviation of the rheology of SiO_2 dispersions from Newtonian behaviour corresponding to the Einstein equation

$$\eta=\eta_0(1+2.5\varphi), \quad (8)$$

where η and η_0 are the viscosities of the dispersion and of the dispersion medium and ϕ is the volume fraction of the disperse phase.

Depending on the system parameters and the flow regime, SiO_2 dispersions had thixotropic or dilatant properties, which was explained by the electroviscous effect, i.e. by the influence of the DIL on the deformation process, and also by the presence on the surface of the particles of a solvate layer with a thickness h. The value of h was found graphically[134] using Eqn.(8) in the form

$$\eta_{sp}=2.5\ \varphi_e=k\varphi\ . \quad (9)$$

From Eqn.(9), it is possible to obtain the expression†

$$\frac{k}{2.5}=\frac{\varphi_e}{\varphi}=\frac{\pi(a+h)^3}{\pi a^3}=\left(1+\frac{h}{a}\right)^3, \quad (10)$$

where a is the radius of the disperse particles. As mentioned by Greenberg and Chang[134], the values of h were somewhat too low (1.5–1.7 nm).

The study of the viscous changes in a latex during dialysis led to the discovery of the so-called electroviscous effect, which consists in the fact that the viscosity of the latex increases by a factor of several hundreds as a result of dialysis and returns to its initial value after the addition of an electrolyte[142,143]. This reversible sol ⇌ gel transformation indicates the occurrence of the $PCS_2 \rightleftharpoons PCS_1$ transition, which takes place in the ion-stabilised latex as the concentration of ions is varied. It has been shown[144] that the density of the electric charge on the surface of latex particles and the ionic strength of the liquid medium have a significant influence on the rheology of dispersions as a consequence of the increase of the effective volume of the particles, which increases their hydrodynamic volume; the relation between the increment of the radius of the particles and the Debye parameter κ has been discussed.

Thus ASL and DIL are the main factors in dilatancy; their role reduces to increasing the effective volume of the disperse phase $\phi_e = \phi + \phi_S$ or, in other words, to decreasing the free volume of the system $\phi_V = 1 - \phi e$. When these layers are fairly large, constrained conditions appear even in dilute dispersions, in conformity with Eqn.(3).

The mechanism of the influence of ASL and DIL consists in the fact that, under constrained conditions, the displacement of the particles relative to one another on shear leads to the overlap of the layers and thei mutual repulsion, which gives rise to a stress whose relaxation depends on many system parameters. The ideas developed in relation to these phenomena have been confirmed by numerous experimental data and considerations put forward by various investigators. Thus a relation has been pointed out between dilatancy and (a) the free volume of the dispersion[56,62,145–151], (b) solvation and adsorption[36,40,45,63,64,131–137], (c) the double ionic layer, the ζ-potential, and the stability of colloidal particles[67,68,119,134,143–146,152–155], (d) the interaction of the particles and the formation of a bond[40,42,59,62,98,121–123,130,134–136,138,143,156–158], and (e) the superposition and repulsion of the ASL and DIL [63,64,121–123,135]; dilatancy has been explained in a number of studies by the dominant effect of repulsion forces[6,45,67,68,119,122,123,138,146,159]. Ideas concerning entropic repulsion have been envoked[45] (although apparently it would be more correct to employ the concept of osmotic pressure[160,161] or, in the general case, the concept of the disjoining pressure[5,81]).

The above principal results of studies designed to determine the factors governing dilatancy, which are by no means complete, are in good agreement with conclusions reached in numerous experimental and theoretical studies of the general characteristics of the rheological behaviour of colloidal structures under different conditions. In addition to the series of studies quoted above (for example Refs.54, 79, 80, 83, 134, 146, 152, etc.), we may also mention investigations[162–168] in which quantitative relations between the rheological and energetic parameters of dispersions have been discussed.

3. Peptisation

The peptisation of aggregates to individual disperse particles has the following consequences: (1) protective surface layers (ASL and DIL) arise on the fresh surfaces; (2) the thickness of liquid layers between the particles diminishes and the distribution of particles becomes more uniform; (3) the overall surface area of the particles increases; (4) the free volume of the dispersion ϕ_V diminishes. The deformation of dispersions unstable as regards aggregation can therefore entail the peptisation of the aggregates under the influence of shear forces[78] with formation of ASL and DIL of definite thickness, which should reduce sharply the values of ϕ_V. Thus peptisation is an important auxiliary factor in dilatancy. On the other hand, the main factors remain ASL and DIL in this case also, since only their formation diminishes the free volume and gives rise to constrained conditions. Naturally, in dispersions which are stable as regards aggregation, there will be either no peptisation at all or, under the influence of the flow, a reversible aggregation and deaggregation process may occur, which will be less pronounced the more stable the system[77–79].

The important role of peptisation and of the uniform distribution of particles in the manifestation of dilatancy in the deformation of various dispersions has been indicated[14,63,71,169–171]. It has been established[172] that weakly disperse suspensions of aggregates and individual PMMA latex particles (ϕ = 0.5) in DBP are dilatant (Fig.23), which has been explained tentatively by the orientation of the particles in the stream and by the formation of a new additional coagulation structure. One should apparently agree with the authors' claim[172] that the peptisation of aggregates of PMMA particles leads to the formation of PCS_2 (of an additional "coagulation" structure# according to Bubis et al.[172]), a decrease of ϕ_V, and the onset of dilatancy.

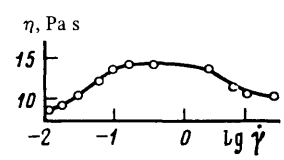

Figure 23. Dependence of the viscosity of a PMMA dispersion in DBP (ϕ = 0.50) on the shear velocity gradient[172].

†Series expansion of the cube of the sum and retention of only the first two terms for $h/a \ll 1$ yields Eqn.(7).

#It is erroneous to refer to colloidal structures of the PCS_2 as coagulation structures. The formation of PCS_2 is a forced process accompanied by an increase in the energy of the system[119].

At the same time the explanation of dilatancy is frequently restricted to a general postulate concerning "changes in the packing of coagulation structures"—network, chain, etc. structures. Thus it has been assumed[153] that the dispersion investigated consists of individual floccules in which colloidal particles form chains. In a shear flow the floccules combine with displacement of the particles from their equilibrium positions. A change in the packing of the particles on dilatancy with formation of a less ordered structure has been noted[145]. The authors of other investigations also believe that dilatancy results in the formation of various "coagulation structures", etc.

One cannot reject the possibility of aggregation and deaggregation processes in a flow[77-80,86], but the hypothesis of such processes must be adequately justified in each specific instance, which is as a rule difficult when rheological data alone are used. Therefore many investigators have endeavoured to employ various modern methods of physics and physical chemistry in rheological research. Here one must note the attempts at a quantitative description of the interparticle interaction forces[67,68,119-123,134,142,145,149], thermodynamic properties[33,34,83,86,137], and physicochemical characteristics[63,79,80,152,164,173] in systems undergoing deformation.

At the same time the modification and improvement of rheological methods are being continued. Methods based on unidirectional and periodic deformations and their superposition have been used[14,88,170,171] in the study of the structures of aerosil dispersions in organic and organosilicon liquids and also of aluminium naphthenate gels. It has been established that, under certain deformation conditions, the dependence of the dynamic modulus of shear G^{I} (the real component of the complex modulus $G^{\times} = G^{I} + iG^{II}$) on the extent of periodic deformation (on the sinusoidal regime) is characterised by a marked maximum; the increase in the stability of the system in this instance is explained by the transition of the coagulation structure as a result of peptisation to a more ordered state (i.e. by the $PCS_1 \rightarrow PCS_2$ transition). Similarly it has been observed[89] that 70% hydrodispersions of kaolin are thixotropic at low frequencies of sinusoidal oscillations and dilatant at high frequencies ($PCS_1 \rightarrow PCS_2$).

It was noted previously that dilatancy degenerates with increase of temperature. However, the results of different investigators have shown that, to a first approximation, there are two temperature ranges in which a dilatant regime passes to a Newtonian or structural-viscous regime. The first range (40–50 °C) corresponds to an appreciable breakdown and rearrangement of the ASL. Thus it has been established[63] that dilatancy of SiO_2 dispersions in solutions of alkyd resins in white spirit disappears below 50 °C as a consequence of the increasing solvent power of the solvent and the decreasing degree of adsorption of the resins. The second range (75–90 °C) corresponds to a sharp increase of the rate of relaxation of the DIL and of the stresses which have arisen as a result of the operation of external forces. The dilatant properties of concentrated aqueous dispersions of SiO_2 [117] and iron oxides[174] as well as, apparently, dilute ion-stabilised PAN latexes[67,68] disappear in this region. Naturally, other variants are also possible. It has been observed[175] that the relative viscosities of dilute bentonite suspensions depend little on temperature, while at high concentrations the viscosity increases appreciably and depends markedly on temperature, which has been explained by structure formation.

An attempt has been made[145,176] to devise a quantitative theory of the dilatant behaviour of dispersions by taking into account the van der Waals attraction forces, the DIL repulsion forces, and the external forces giving rise to shear deformation. A careful analysis of the dimensionless geometrical, energetic, and mechanical parameters of a dispersion undergoing deformation ($\phi = 0.65$) has been carried out[149]; equations describing the rheological properties of disperse systems which thicken and liquefy under the influence of shear deformations have been put forward. Rheological equations for thixotropic-dilatant structures have also been proposed[156,177]. The dependence of the relative viscosities of dispersions of spherical non-interacting particles on the volume fraction has been expressed[178] by the single-parameter equation

$$\eta = \left[1 + \frac{1.25\varphi}{1 - (\varphi/\varphi_{max})}\right]^2, \qquad (11)$$

where ϕ_{max} is the value of ϕ corresponding to close packing. In the presence of ASL or DIL on the surface, ϕ_e replaces ϕ and an equation of type (10) or, when the thickness of these layers is small, Eqn.(7) is used[178].

The following equation is employed for concentrated dispersions of glass spheres ($d \cong 27-118$ μm) in low-molecular-weight polyisobutylene[179]:

$$\eta_r = \left[1 + 0{,}75\left(\frac{\varphi/\varphi_{cr}}{1 - \varphi/\varphi_{cr}}\right)\right]^2. \qquad (12)$$

For monodisperse systems, $\phi_{cr} \cong 0.6$§ and for bimodal systems the dependence of the viscosity on the content of the smallest particles (at a constant overall concentration) passes through a minimum, which is related directly to the thixotropic and dilatant properties of the dispersions. An analogous relation has been observed in Refs.121, 180, 181, etc.

V. DILATANCY OF MICELLAR SOLUTIONS OF SURFACTANTS, SOAP GELS, AND SURFACE MONOLAYERS

Micellar solutions are known to be systems in thermodynamic equilibrium. The micelles have different shapes—usually spherical, cylindrical, or lamellar. The surface of cylindrical micelles is non-isotropic (has no circular symmetry), which can be accounted for by the unusual orientation of the dipolar molecules on the surface[113,182]. The micelles present in solution at not unduly high surfactant concentrations consist of hydrated surfactant molecules; there are comparatively thick liquid layers between the micelles[183].

The results of a study of the viscous properties of 1–15% aqueous solutions of dioctyl sulphosuccinate have been published[108]. At a concentration of 5% and above, the solutions prepared using distilled water are thixotropic (i.e. constitute a PCS_1). On the other hand, when inorganic electrolytes are present ($c_{el} = 1$ *N*), the viscosity of the system diminishes at low rates of deformation and increases at high rates. These rheological anomalies have been explained[138] by taking into account the salting-out effect of ions, which results in the formation of comparatively large micelles separated by hydrate layers (PCS_1), and the breakdown of large micelles into small ones at high rates of deformation, which leads to constrained conditions and the appearance of PCS_2. Thus the transition from the thixotropic to the dilatant flow regime observed in these solutions can be explained satisfactorily by the $PCS_1 \rightarrow PCS_2$ transition (Fig.24). Furthermore, under the conditions of salting-out in surfactant solutions, there is also a possibility of the preferential formation of extended instead of spherical micelles, which enhances the viscoelastic properties[184-186].

§ The value $\phi_{cr} \cong 0.6$ does not correspond to the close packing of monodisperse spheres ($\phi \cong 0.74$). This discrepancy is apparently due to the presence of ASL or DIL on the surfaces of the glass spheres [see Eqn.(6)].

The mechanism of the dilatant increase of viscosity in dilute solutions of hexadecyltrimethylammonium bromide in methylnaphthlene has been explained[187] by the appearance of a network of rod-shaped micelles under the influence of the flow. It has been suggested[138] that the network is formed from the very beginning of the deformation, but at low rates the rupture of the bonds between the micelles predominates (thixotropic liquefaction), while at higher rates the micelles themselves break down, which leads to constrained conditions and the formation of a PCS_2. These solutions have anomalous rheological properties at 22 °C, while at higher temperatures they become Newtonian liquids.

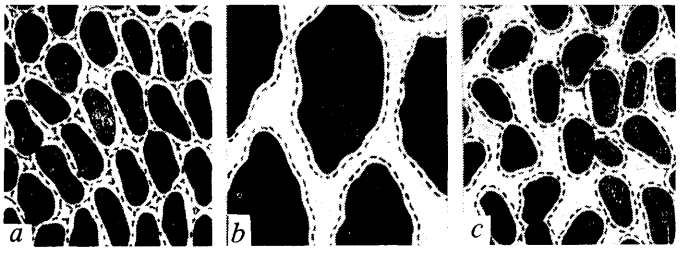

Figure 24. Schematic illustration of the changes in the micellar structure of surfactant solutions after the addition of an electrolyte ($a \rightarrow b$) and with increase of the rate of shear deformation ($b \rightarrow c$).

(a) Dilatancy of Soap Gels

Dilatant thickening has been observed in ammonium oleate[188] and organo-aluminium salt[17,74] gels. An increase in the stability of aluminium naphthenate gels (6%) (both pure and filled with aerosil) in medicinal liquid paraffin as a result of the superposition of harmonic oscillations at a constant rate of shear has been demonstrated[169,189]. It has been noted[190] that the measurement of the dynamic moduli of soap gels itself causes some disruption of the structure. A considerable increase in the stability of hydrocarbon gels of ammonium abietate under the conditions of shear has been observed[191].

In discussing these instances of dilatancy, it is necessary to take into account the microheterogeneous nature of surfactant gels. Presumably, at sufficiently high rates of shear the elements of the gel lattice—floccules consisting of associated surfactant and solvent molecules (ions)—have insufficient time to relax and therefore decompose, which leads to constrained conditions and the formation of structures analogous to PCS_2. This explanation is consistent with the results of a number of studies. Thus a study[192] of the rheological properties of plastic calcium greases, consisting of soap–oil gels, established that (a) the size and shape of the particles of the disperse phase (soap fibres) have a decisive influence on the properties of the grease and (b) a decrease in the size of these particles is accomapnied by an increase of viscosity and stability and also by an increase of the colloidal stability of the system. The common features in the mechanism of the influences of the degree of dispersion, the distribution of grain sizes, and peptisation on the structural-mechanical properties of PCS of various types can be readily seen. Incidentally, calcium greases are optically anisotropic, which shows that the structure is ordered[193].

The results of the investigation of "filled" systems, which are of great theoretical and practical importance, have been published in a number of communications[169,170,189,190,194,195]. The phenomenon of the breakdown of the aluminium naphthenate gel structure in liquid paraffin filled with aerosil has been investigated[170] with periodic deformations and with stabilisation of the structure in unidirectional deformation. It has been established[194] that aqueous bentonite gels, to which a small amount (a fraction %) of non-ionic surfactants has been added, are thixotropic systems; in the presence of ionic surfactants (anionic or cationic) these gels exhibit dilatant properties. It is significant that surfactants, or more correctly the DIL arising on the surface of adsorption layers, are responsible for the change in the properties of bentonite gels¶. On the other hand, the clay particles themselves, being "encapsulated", play an auxiliary role in this process. Such systems can be regarded as intermediate between typical hydrophobic dispersions and micellar solutions. On the other hand, it has been shown[196] that low-tar bitumens with a high content of asphaltenes behave like typical disperse systems, while high-tar bitumens with a low content of asphaltenes have rheological properties similar to those of concentrated polymer solutions. Bitumens with transitional properties are located between these extreme structural-rheological types.

(b) Dilatational Surface Viscosity of Monolayers

A method has been proposed[197] for the determination of the surface viscosities of surfactant monolayers based on the joint dynamic study of the surface pressure and the surface potential; the results of the investigation of the dynamic properties of insoluble elastic and highly elastic monolayers, which permit the determination of the role of the dilatational viscosity in the behaviour of these monolayers, have been published. The behaviour of a liquid drop in another liquid phase has been analysed[198]; it was shown that the period of circulation in the equatorial plane of the drop can be used to calculate the quantity $3k + 2\varepsilon$, where k is the dilatational surface viscosity and ε is the surface shear viscosity. A method for the determination of k has also been proposed in another study[199]†.

VI. DILATANCY OF SOLUTIONS OF HIGH-MOLECULAR-WEIGHT COMPOUNDS

Polymeric molecules frequently form aggregates or associated complexes in solution, such behaviour being usually quite pronounced in solutions of polar polymers and polyelectrolytes. As a result of the interaction of the aggregates, ordered structures may arise, which are analogous, on the one hand, to PCS, and, on the other hand, to liquid crystals[201–208]; this can be accounted for by the common features of the operation of ionic-electrostatic and molecular forces in disperse systems and in polyelectrolyte solutions[99].

¶ In contrast to this, the non-ionic hydroxyethylated octyl alcohol adsorbed on particles of phthalocyanine pigments sharply decreases the thixotropy of the dispersion as a consequence of the formation of fairly extensive ASL.[195]

†The dilatational viscoelastic properties of a thick film with a single soluble surfactant have been analysed quantitatively[200].

In a number of recent studies it has been shown that solutions of many polymers are structured. Thus the presence of involved ordered complexes—globular associated species and microgels (the authors[213] believe that these formations can be compared with colloidal particles)—has been demonstrated[209-212] in aqueous solutions of poly(vinyl alcohol) (PVA). It has been observed[214] by thermal, rheological, and morphological methods that very large aggregates of hydrated macromolecules exist in aqueous solutions of polyvinylpyrrolidinone, hydroxyethyl-starch, poly(vinyl alcohol), and poly(ethylene glycol). The aggregation of macromolecules in solutions of different polymers has also been discussed in a series of other studies[215-217]. Rheological studies of a solution of polyisobutylene in liquid paraffin have led to the conclusion[218] that structures made up of polymer chains exist in this solution.

Structured solutions of many polymers have dilatant (antithixotropic) properties[110,111,218-231]. Various factors determining the onset of the dilatant deformation regime have been described in the literature. Some investigators point to the orientation of the structural elements of the polymer, their aggregation and crystallisation, caused by the gradient flux, as well as mixing as fundamental factors in dilatancy[221, 232-237]. Ordered aggregates of macromolecules, strongly interacting with the solvent, constitute a kind of hydrates oriented in the flow[209-212,238-242]. Freshly formed gel fibres have an analogous structure[243]; the crystalline nature of fibrils containing the solvent has been noted[240,244-246]. It has been claimed in a number of studies that the principal condition for the occurrence of dilatancy is low solubility of the polymer and the consequent presence of associated complexes and aggregates of molecular chains (see Refs. 226, 230, 232, etc.). It has been shown[247] that the existence of a fluctuation network in solutions of methyl methacrylate–methacrylic acid copolymers is responsible for antithixotropy both under the conditions of simple shear and in complex (predominantly longitudinal) flow deformations.

The data presented permit the conclusion that the increased viscosity of polymer solutions under the conditions of shear is a consequence of the peptisation of the associated chain species and chain aggregates and of the appearance of constrained conditions, under which deaggregated formations—partly decomposed aggregates and individual macromolecules as well as their separate units—interact. When the degree of structure formation in the solution is low, complex and structure formation intensify in the first deformation stage[224]. At higher rates there is also a possibility of the peptisation of more stable complexes, leading to constrained conditions in dilatancy[138].

The ideas developed here are consistent with experimental data and with the conclusions of other investigators. Thus the formation of a second structure under the conditions of shear deformations after the partial breakdown of the first structure in polymer solutions has been discussed[218]. Evidently the second structure arises as a result of the peptisation of the first structure with formation of uniformly distributed solvated microfibrils under constrained conditions. The increase of viscosity in the initial state of the deformation of solutions of a number of polymers has been explained[248-250] by orientational effects. The observed relative expansion of fibrous polymer gels in the extension process has been attributed[248] to a rearrangement of their structure.

The peptisation of aggregates and microgel particles in polymer solutions can be illustrated by an example from the technology of paper manufacture. The grinding of a freely flowing paper mass by a roller reduces mainly to the dispersion of large fibrous particles until very fine hydrated fibres (fibrils) are obtained. For a high degree of grinding (for "fat" or "slimy" grinding), the mass becomes gel-like with an increased viscosity, which is due to the increase of the overall surface area of the fibrils and the decrease of ϕ_v.[251] In this case the freely disperse system is converted into PCS_2 as a result of peptisation. To complete the analogy, one can imagine that after fat grinding the fibrilled mass undergoes further dispersion up to "molecular" peptisation with formation of a "structured solution" possessing dilatant properties and resembling the usual dilatant polymer solutions[5].

---o0o---

The common features in the rheological behaviour of PCS and polymer solutions, determined by the following common characteristics of the interaction of micro-objects, may be noted.

1. PCS_2 are dilatant as a consequence of the dominant operation of repulsion forces in the system, or, in other words, the manifestation of the positive disjoining pressure $\Pi_2 > 0$; PCS_1 are thixotropic and are characterised by a negative disjoining pressure $\Pi_1 < 0$.

2. In polymer solutions the peptisation or deaggregation of structural elements (complexes, associated species) under conditions involving the stabilisation of the ASL or DIL deaggregation products leads to a decrease of ϕ_v, a more uniform distribution of the polymer, and constrained conditions. This is possible when the polymer particles are adequately solvated or protected by ionic layers and the repulsion forces predominate, i.e. $\Pi_2^1 > 0$, which is responsible for dilatancy. If the deaggregation products in solution are not resistant to mutual adhesion, i.e. $\Pi_1^1 < 0$, then in the breakdown process the deformation of structures of one kind will be accompanied by the appearance of those of another, denser kind; the "network continuity" will then be infringed and the viscosity will correspondingly diminish.

The phenomenon of dilatancy has been considered in this review in the simplest form where the increase of the resistance to shear is determined mainly by the properties of the liquid layers separating the micro-objects. However, it is frequently complicated by various concomitant aggregation processes of different kinds, which have been enumerated in the second section. Furthermore, regardless of external influences, syneresis takes place spontaneously in disperse systems, while various processes involving the deaggregation of dissolved polymers, which may be intensified on deformation, occur in solutions of high-molecular-weight compounds[218, 252-254]. As a result of this, the processes occurring in the flow can be of a complex type whose determination is the next primary task of rheology. In particular, in view of the large particle size (of sand or other substances) and close packing, which hinders the movement of the particles during shear, classical dilatancy is a limiting if not an exceptional case. Here too the operation of common factors (ASL and DIL) is manifested, but under conditions of major constraint determined by the low value of ϕ_v (or by the ratio of the volume concentration of the disperse phase to the maximum attainable close packing, approaching unity[56]).

Consideration of the mechanism of the dilatancy of colloidal structures raises the question of the invariance of the rheological characteristics of non-Newtonian liquids. It is found that the flow parameters, determining the onset of the dilatant flow regime, depend on the deformation conditions[146,179]. Bearing this factor in mind, Strivens[146] notes that the dilatant effect observed on deformation is a kind of instrumental artifact. Further study of the energetic and kinetic aspects of the interaction of micro-objects will make it possible to establish the relation between the microparameters of the dispersion and its integral characteristics, which constitutes the basis of the development of methods for the

rational regulation of the structural-mechanical properties of dispersions and will also permit the construction of a quantitative theory of dilatant-thixotropic transformations in colloidal structures.

Advances and Prospects in the Chemistry of Nucleoaminoacids and Nucleopeptides

Yu.P.Shvachkin, G.P.Mishin, and G.A.Korshunova

The present state of research into the development of methods of synthesis and into properties of aminoacids containing a natural nucleic acid base in the side chain (nucleoaminoacids) as well as the peptides formed from nucleoaminoacids (nucleopeptides) is examined. Attention is concentrated on the description of naturally-occurring representatives of these classes of compounds and on the analysis of prospects for their further investigation and use.
The bibliography includes 64 references.

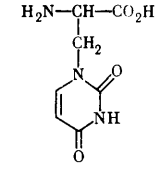
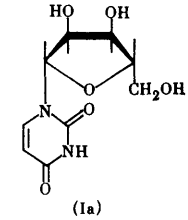
I. INTRODUCTION

Pyrimidine and purine bases are widely distributed in nature and play an important role in vital processes. They are obligatory structural components of all nucleic acids without exception. Many coenzymes, vitamins, and antibiotics are purine- or pyrimidine derivatives; the pyrimidine ring is the basis of many most important natural condensed systems (pteridines, isoalloxazines, etc.). α-Aminoacids, which constitute the elementary structural units of peptides and proteins and occupy one of the central positions among known natural products, are no less important and are just as widely distributed in biological systems.



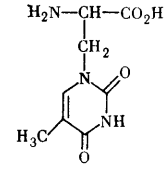
One may claim that pyrimidine and purine derivatives as well as α-aminoacids belong to chemical structures which permeate the entire spectrum of life, starting from viruses and extending to higher animals and man.

The chemical research into the above heterocyclic compounds, on the one side, and α-aminoacids and peptides, on the other, was prosecuted for a long time in isolation and such investigations did not as a rule overlap. Nevertheless, biochemical and molecular biological data undoubtedly indicate the occurrence in biological systems of very intimate interactions, combining these classes of natural products. This has been manifested not only in the study of metabolic pathways involving these structures but also in the detection in nature of various aminoacids (and recently also peptides) derived from pyrimidine and purines.

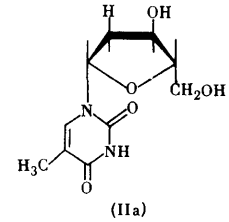


Among the wide variety of pyrimidinyl- and purinyl-aminoacids, *nucleoaminoacids* are of special interest[1]. Here and henceforth this term will be used to designate α-amino-carboxylic acids with pyrimidine or purine nucleic acid bases in the side chain, attached to the aminoacid fragment via the N^1 (pyrimidine) or N^9 (purine) atom.

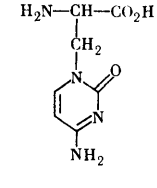
In conformity with the above definition, the structure of nucleoaminoacids follows unambiguously from the structures of the known nucleic acid bases. If we disregard for the moment the minor nucleic acid bases and confine ourselves to the principal nucleic acid bases (uracil, thymine, cytosine, adenine, and guanine) and if among all the aminoacid fragments only the α-alanine fragment is considered, then typical examples of the class of nucleoaminoacids are β-(N^1-uracilyl)-α-alanine (I), β-(N^1-thyminyl)-α-alanine (II), β-(N^1-cytosinyl)-α-alanine (III), β-(N^9-adeninyl)-α-alanine (IV), and β-(N^9-guaninyl)-α-alanine (V). The three-letter abbreviations for these nucleoaminoacid residues are Ual, Tal, Cal, Aal, and Gal respectively.



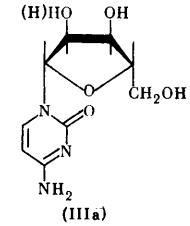
Comparison of the structure of nucleoaminoacids with that of the corresponding nucleosides of the pyrimidine and purine series shows readily that nucleoaminoacids are aminoacid analogues of the natural nucleosides (Ia)–(Va), differing from the latter by the substitution of the pentose (ribose or deoxyribose) residue by the aminoacid fragment:



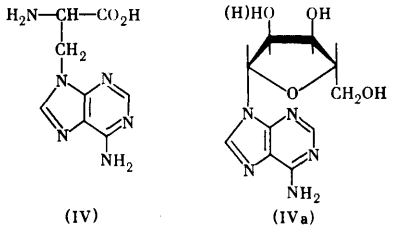
(I)



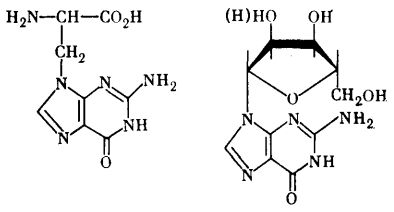
(Ia)



(II)



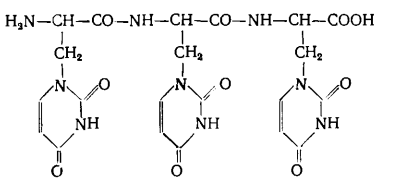
(IIa)



(III)

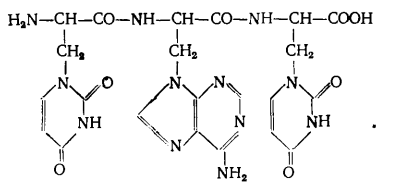
(IIIa)

(IV) (IVa)



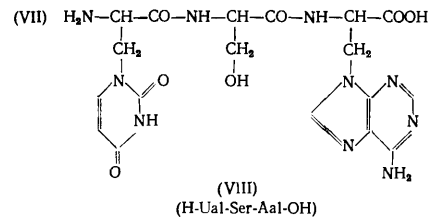
(V) (Va)

When nucleoaminoacid residues are linked together by peptide bonds, *nucleopeptides* are formed[1]. Here and henceforth this term will be used to designate peptides containing nucleoaminoacid residues. Whereas nucleic acid bases in oligonucleotides are attached to the pentose phosphate skeleton, in nucleopeptides the bases form a framework around the peptide chain.



Depending on the qualitative composition, nucleopeptides can in general be divided into three main types: (1) homonucleopeptides; (2) heteronucleopeptides; (3) mixonucleopeptides.

Homonucleopeptides. These are nucleopeptides made up of repeating units of the same nucleoaminoacid. The tripeptide (VI), made up exclusively of β-(N^1-uracilyl)-α-alanine residues, is an example of a homonucleopeptide (the structure of this tripeptide is formulated in an abbreviated form in brackets underneath the formula below):



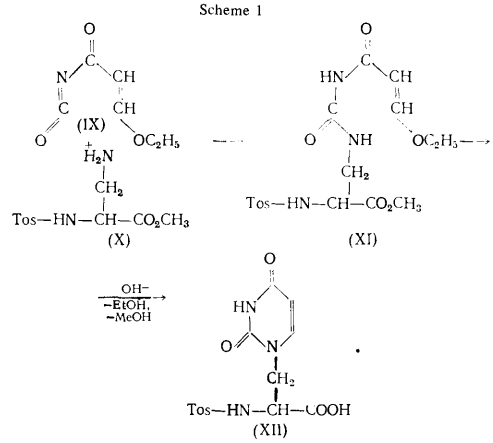
(VI) (H-Ual-Ual-Ual-OH)

Heteronucleopeptides. These are nucleopeptides made up of different nucleoaminoacid residues. The tripeptide (VII), whose composition includes two β-(N^1-uracilyl)-α-alanine residues and one β-(N^9-adeninyl)-α-alanine residue, is a typical example of heteronucleopeptides:

(VII)
(H-Ual-Aal-Ual-OH)

Mixonucleopeptides (synonym—nucleopeptides of the mixed type). These are peptides containing, together with nucleoaminoacid residues, also the residues of other aminoacids (in particular protein aminoacids). The tripeptide (VIII), whose composition includes the residues of β-(N^1-uracilyl)-α-alanine, serine (a protein aminoacid), and β-(N^9-adeninyl)-α-alanine, may serve as an example of a mixonucleopeptide:

(VIII)
(H-Ual-Ser-Aal-OH)



The methods of synthesis and the reactions of nucleoaminoacids are considered below, the methods of synthesis and properties of nucleopeptides are described, and the prospects for the further study and utilisation of nucleopeptides and nucleoaminoacids are discussed.

II. SYNTHESIS OF NUCLEOAMINOACIDS

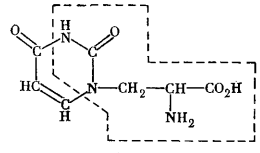
All the methods of synthesis of nucleoaminoacids known at the present time can be divided by convention into two main groups: (1) methods of synthesis based on reactions in which the pyrimidine or purine ring is formed during the synthesis of the compound: (2) methods of synthesis in which a substituent is introduced into a complete hydropyrimidine or purine.

A typical example of the first group of methods of synthesis of nucleoaminoacids is the synthesis of the N^{α}-tosyl derivative of β-(N^1-uracilyl)-α-alanine [compound (XII)] by Kjaer et al.[2], which is based on the intramolecular cyclisation of the asymmetrically substituted urea (XI), formed on condensation of β-ethoxyacryloyl isocyanate (IX) with methyl α-tosylamino-β-DL-aminopropionate (X) via Scheme 1.

Scheme 1

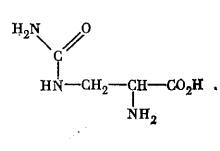
(X) (XI) (XII)

It must be emphasised that initially the interest of investigators in the development of methods of synthesis of nucleoaminoacids was to a large extent stimulated by the detection of individual representatives of the class of nucleoaminoacids in nature. The first report of the possible presence of naturally-occurring nucleoaminoacids, by the German biochemist Gmelin[3], appeared at the end of 1959. In his study of extracts from the seeds of *Acacia willardiana*, Gmelin detected in them a new aminoacid, which he called "willardiine".



Subsequently Gmelin was able to isolate this aminoacid on a preparative scale and to show that its composition corresponds to the overall formula $C_7H_9N_3O_4.H_2O$. One of the remarkable properties of the new aminoacid was its capacity to absorb ultraviolet light intensely. The study of the ultraviolet absorption spectra of willardiine at different pH showed that they are extremely similar to the corresponding spectra in the near ultraviolet of compounds such as uridine and 1-methyluracil. Investigation of the infrared spectra of willardiine also revealed the presence of characteristic frequencies corresponding to the uracil ring; furthermore, it was concluded that the infrared spectra of willardiine contain absorption bands characteristic of the alanine fragment.

The hypothesis that willardiine may constitute a structure in which the alanine residue is linked to one of the oxygen atoms in the uracil molecule was abandoned when it was established[3] that the new aminoacid is extremely stable and, in particular, does not change on prolonged refluxing with 28% hydrobromic acid. If the alanine residue were linked to one of the oxygen atoms of the uracil molecule, then serine would have been inevitably formed under these conditions, which was not observed.



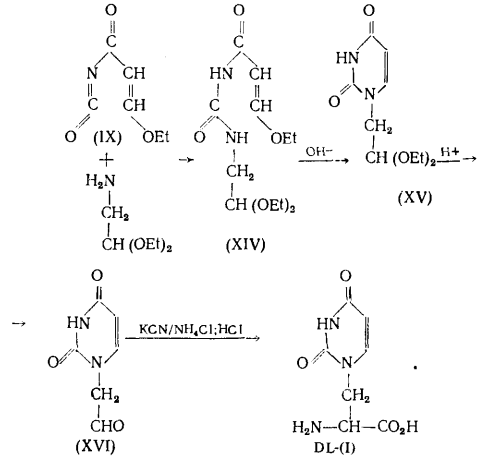
A more detailed study of the ultraviolet absorption spectra of willardiine[3] made it possible subsequently to eliminate from consideration variants of the structure which involved the addition of the alanine residue to the uracil ring via its carbon atoms in the 5- or 6-position and also via the nitrogen heteroatom in the 3-position. The last variant was rejected on the grounds that the ultraviolet spectra of willardiine, recorded at different pH, did not exhibit a bathochromic shift of λ_{max} with increasing alkalinity of the medium, which is known to be a characteristic property of 3-substituted uracils and is not observed in the spectra of 1-substituted uracils[4-6].

As a result of his investigations, Gmelin[3] concluded that willardiine apparently has a structure in which the alanine fragment is linked to the uracil ring and that the most probable point of addition of the alanine chain is the nitrogen heteroatom in the 1-position in the uracil ring. In other words, Gmelin suggested that the new natural aminoacid which he isolated has the structure of L-β-(N^1-uracilyl)-α-alanine (I).[3]

The fact that, long before the discovery of willardiine, a hitherto also unknown acyclic aminoacid was detected in plants of the family of Mimosaceae and was called "albizziine" [7,8] is noteworthy. It was subsequently shown unambiguously to have the structure of L-α-amino-β-ureidopropionic acid (XIII):[9,10]

(I)

(XIII)



Gmelin was able to demonstrate that albizziine is present together with willardiine in the seeds of *Acacia willardiana*, *Acacia millefolia*, *Acacia lemmoni*, and *Mimosa asperata*.[3] This observation and the evident analogy between the molecular structures of (I) and (XIII) constituted additional arguments in support of structure (I) proposed for willardiine. Furthermore, on the basis of the above observation, Gmelin put forward the hypothesis that albizziine (XIII) can be a bioprecursor of willardiine[3].

All these ideas agree satisfactorily with one another and are consistent with a logical general scheme. However, one must not forget that at that time there was no final and rigorous proof that willardiine does indeed have structure (I). The question of the possible existence of nucleoaminoacids in nature therefore remained open.

The resulting situation was finally clarified when structure (I) of willardiine was demonstrated rigorously in 1961 by unambiguous chemical syntheses of this substance carried out almost simultaneously and independently by two groups of chemists—in Denmark[2] and in England[11,12].

The English investigators initially reported the synthesis of DL-β-(N^1-uracilyl)-α-alanine[11] from β-ethoxyacryloyl isocyanate (IX) which they had obtained previously[13,14]. Treatment of compound (IX) with the diethyl acetal of aminoacetaldehyde led to the formation of the disubstituted urea (XIV), which underwent intramolecular cyclisation on being heated in an aqueous solution of sodium hydroxide, accompanied by the elimination of an ethanol molecule and the formation of N^1-(2′,2′-diethoxyethyl)uracil (XV). Acid hydrolysis of the latter then yielded N^1-uracilylacetaldehyde (XVI), which was introduced into the cyanohydrin synthesis reaction, ensuring the unambiguous formation of DL-β-(N^1-uracilyl)-α-alanine via Scheme 2.

Scheme 2

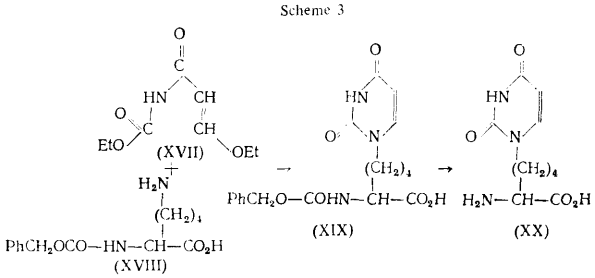
As was to be expected, apart from the positive response to the ninhydrin test, the compound was able to absorb ultraviolet light intensely. Comparison of the ultraviolet spectra and other characteristics of the synthetic compound (I) and natural willardiine led to the conclusion that the chemical structures of these substances are identical.

Later the English investigators reported the separation of the racemic aminoacid (I) into its optical isomers[12]. For this purpose, the N^{α}-formyl derivative was obtained from the racemic aminoacid (I) and was treated with the dextrorotatory isomer of methylphenylaminomethane. The resulting mixture of diastereoisomeric salts was subjected to fractional crystallisation, which led to the isolation of the laevorotatory isomer of β-(N^1-uracilyl)-α-alanine, whose properties, including the magnitude and sign of the specific optical rotation, proved to be identical with those of natural willardiine[12].

Although these studies did not solve the problem of the absolute configuration of willardiine, they did not leave any doubt about the natural aminoacid being a nucleoaminoacid whose structure is identical with that of compound (I).

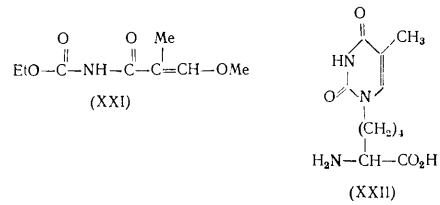
The fact that Dewar and Shaw[12] were unable to convert N^1-uracilyl-acetaldehyde (XVI) into compound (I) by the hydantoin method of synthesis[15,16] instead of the cyanohydrin method is noteworthy. This attempt led to the formation of the corresponding 1-hydantoinylmethyluracil; however, this compound proved to be extremely stable and did not hydrolyse even after prolonged heating at 150 °C with 10 *N* hydrochloric acid in a sealed tube[12].

Danish investigators[2] carried out an unambiguous synthesis of β-(N^1-uracilyl)-α-alanine (I) by the somewhat different procedure illustrated in Scheme 1 (see above). They obtained N^{α}-tosyl-DL-β-(N^1-uracilyl)-α-alanine (XII) in an analytically pure state. Further studies showed that this compound is chromatographically identical with the substance obtained on tosylation of natural willardiine[2]. This constituted independent proof that the new natural amino-acid has the structure of β-(N^1-uracilyl)-α-alanine.



Kjaer et al.[2] studied the possibility of detosylating compound (XII) in order to obtain synthetic DL-β-(N^1-uracilyl)-α-alanine. However, they found that treatment of compound (XII) with sodium in liquid ammonia entails the breakdown of the uracil ring and the appearance of a whole "family" of aminoacids which did not absorb in the ultra-violet, one of which was identified as α,β-diaminopropionic acid. Treatment of the N^{α}-tosyl derivative of willardiine with a solution of hydrogen bromide in glacial acetic acid (for 3 h at 70 °C [17]) results in the complete removal of the protecting tosyl group; however, according to the above author's data[2], this involves extensive racemisation of the free aminoacid formed. When the duration of the detosylation process was reduced to 1 h, the Danish chemists were able to obtain from compound (XII) a substance whose infrared spectrum and specific optical rotation did not differ from those of natural willardiine. However, the yield of the optically active nucleoaminoacid (I) prepared in this way was extremely low (2%).

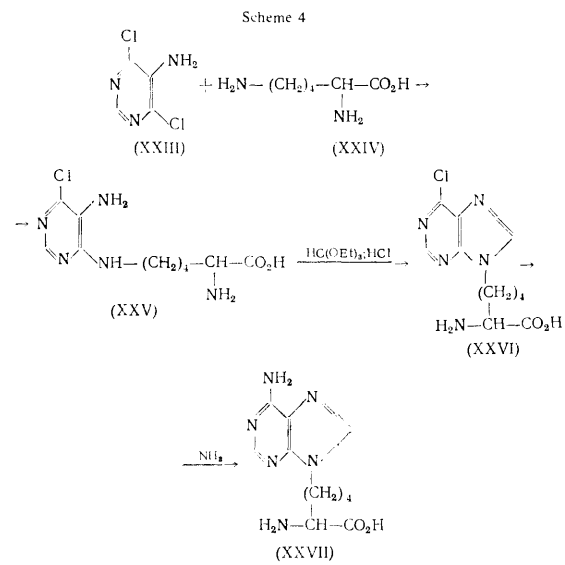
Thus the above method of preparing β-(N^1-uracilyl)-α-alanine, which solves in principle the problem of the complete chemical synthesis of this naturai nucleoaminoacid, does not permit its preparative synthesis in appreciable amounts.



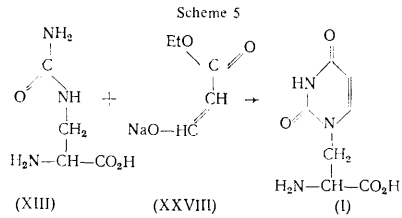
In this connection we should note that the method of synthesis of compound (I) proposed by the English investigators[12] also fails to solve the problem of the preparative synthesis of the nucleoaminoacid β-ethoxyacryloyl isocyanate, which they used as the starting material, is itself difficult to obtain[13,14]. Examination of the entire synthetic pathway leading to compound (IX) from ethyl bromoacetate shows that the yield of the diethyl acetal of N^1-uracilyl-acetaldehyde (XV), which is the key compound in this method of synthesis of β-(N^1-uracilyl)-α-alanine, is only 4% of theoretical.

In 1971 De Koning and Pandit[18] described the synthesis of α-amino-ε-(N^1-uracilyl)-caproic acid (XX) via Scheme 3, which provides for the condensation of 3-ethoxy-*N*-ethoxy-carbonylacrylamide (XVII) with N^{α}-benzyloxycarbonyl-lysine (XVIII). α-Amino-N^{α}-benzyloxycarbonyl-ε-(N^1-uracilyl)-caproic acid (XIX) is an intermediate in this synthesis.

Scheme 3

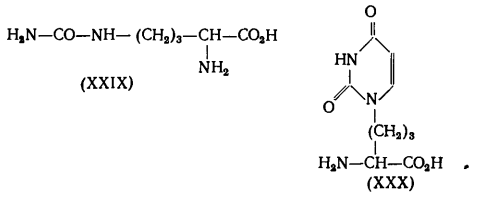


When *N*-ethoxycarbonyl-3-methoxy-2-methylacrylamide (XXI) was used in the condensation stage instead of compound (XVII), α-amino-ε-(N^1-thyminyl)-caproic acid (XXII) was obtained via an analogous scheme. The yield of the racemic nucleoaminoacids (XX) and (XXII) was approximately 40%.



The first group of methods of synthesis also includes that of the synthesis of α-amino-ε-(6-chloro-N^9-purinyl)-caproic acid (XXVI). Compound (XXVI) is the key substance in the synthesis of ε-(N^9-adeninyl)-α-aminocaproic acid (XXVII).[19] A characteristic feature of the synthesis of compound (XXVI) is the formation of the purine ring as a result of the closure of the imidazole ring in the course of the synthesis via Scheme 4. The initial compounds are 5-amino-4,6-dichloro-pyrimidine (XXIII) and lysine (XXIV), while the pyrimidinyl-aminoacid (XXV) is an intermediate.

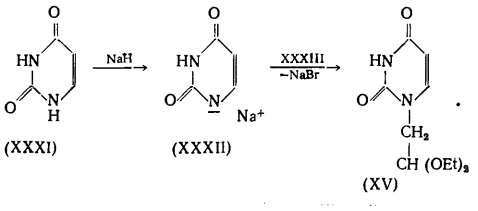
Scheme 4



The method of synthesis of compound (I) by the condensation of α-amino-β-ureidopropionic acid (albizziine) with formylacetic ester also belongs to this group[20,21]. The ester is used in the form of the sodio-derivative (XXVIII) and condensation proceeds via Scheme 5.

Scheme 5

If citrulline (α-amino-δ-ureidovaleric acid (XXIX) is used in the analogous condensation instead of albizziine, then α-amino-δ-(N^1-uracilyl)valeric acid (XXX) can be



obtained[22]:

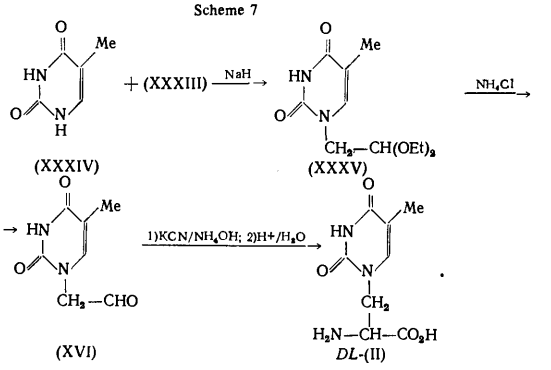
(XXIX) (XXX)

A new direct synthesis from uracil (XXXI) of compound (XV), i.e. N^1-(2′,2′-diethoxyethyl)uracil (the diethyl acetal of N^1-uracilylacetaldehyde), already mentioned above (see Scheme 2), was described in 1965.[23] According to these data[23], when compound (XXXI) is treated with sodium hydride in dimethylformamide, the sodio-derivative of uracil (XXXII) is formed initially and, on subsequent heating with 2-bromo-1,1-diethoxyethane (XXXIII), is smoothly converted into N^1-(2′,2′-diethoxyethyl)uracil (XV):

Scheme 6

(XXXI) (XXXII) (XV)

The yield of compound (XV), which is the key substance in the synthesis of nucleoaminoacids, is approximately 40%.

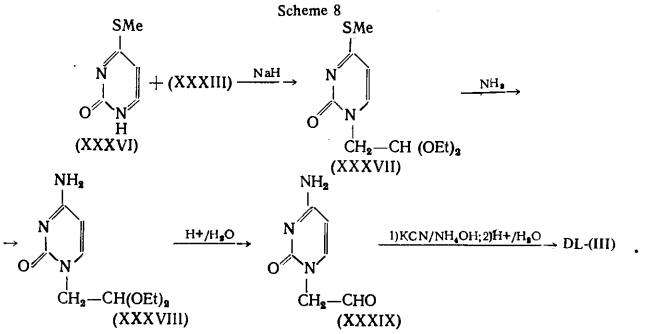


The formation of the N^1,N^3-disubstituted product (XXXV) takes place simultaneously (yield approximately 13%), but this substance can be separated comparatively readily from the desired compound (XV).

In contrast to Shaw and Dewar[11], who used acid hydrolysis, American investigators[23] suggested that the diethyl acetal of N^1-uracilyl-acetaldehyde be converted into free N^1-uracilyl-acetaldehyde by a milder process involving the heating of compound (XV) with an aqueous solution of ammonium chloride. Under these conditions, the yield of compound (XVI) was increased from 40 to 83%. The subsequent introduction of compound (XVI) into the cyanohydrin synthesis reaction makes it possible to obtain readily the racemic nucleoaminoacid (I) on a preparative scale by the scheme already described (Scheme 2).

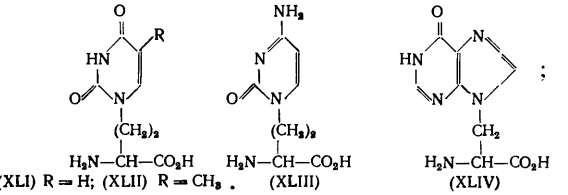
The above method of synthesis of DL-β-(N^1-uracilyl)-α-alanine (I) was extended to other nucleoaminoacids. In particular, DL-β-(N^1-thyminyl)-α-alanine and DL-β-(N^1-cytosinyl)-α-alanine can be synthesised by this method[24,25].

The synthesis of DL-β-(N^1-thyminyl)-α-alanine is based on thymine (XXXIV) as the starting material and proceeds via the following scheme:



Scheme 7

(XXXIV) (XXXV) (XVI) DL-(II)

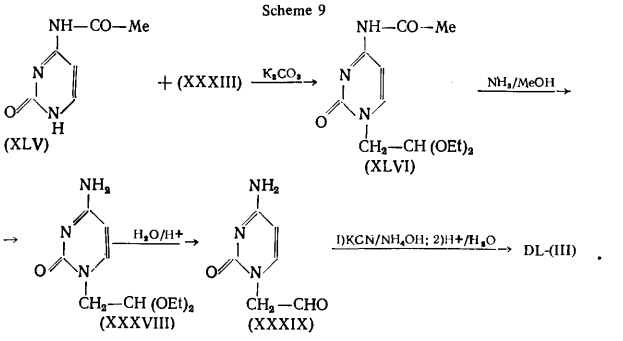


In the synthesis of DL-β-(N^1-cytosinyl)-α-alanine (III) the starting material is 4-methylthio-2-oxodihydropyrimidine (XXXVI):

Scheme 8

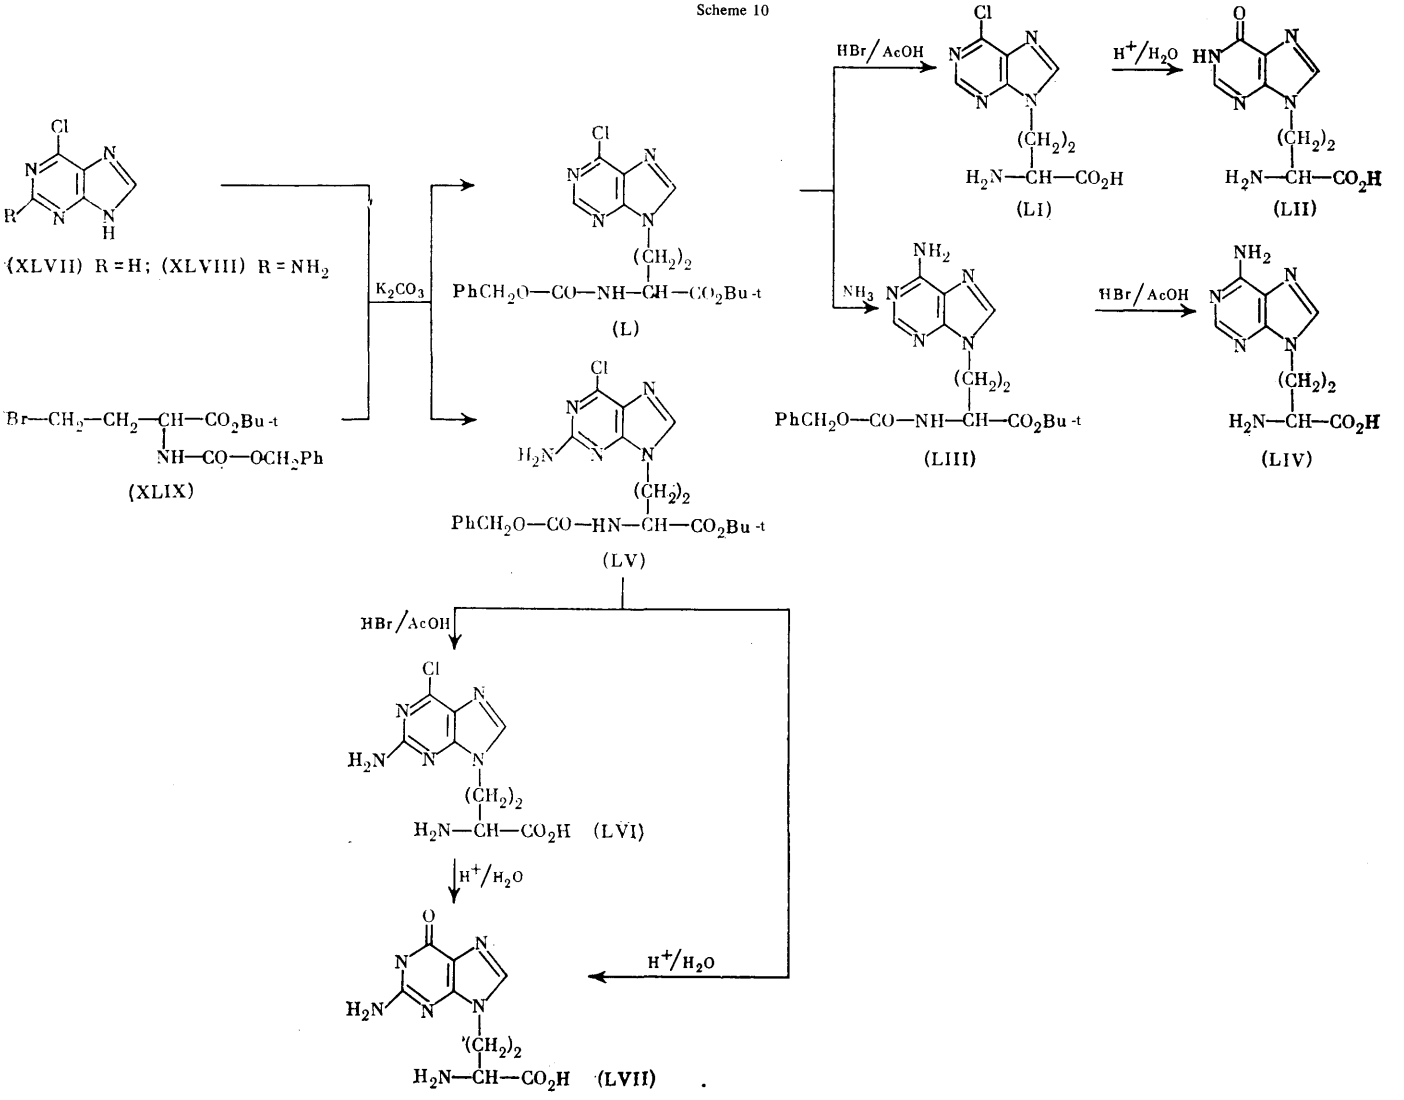
(XXXVI) (XXXVII) (XXXVIII) (XXXIX) DL-(III)

The interaction of uracil (XXXI), thymine (XXXIV), and 4-methylthio-2-oxodihydropyrimidine (XXXVI) with the diethyl acetal of γ-chloropropionaldehyde (XL) has also been investigated[25]. It was established that uracil and thymine give rise to both N^1- and N^3-derivatives, which can be readily separated by crystallisation. On the other hand, the exclusive formation of the N^1-isomer was noted in the case of 4-methylthio-2-oxodihydropyrimidine (XXXVI). These investigations led to the synthesis of α-amino-γ-(N^1-uracilyl)-butyric acid (XLI), α-amino-γ-(N^1-thyminyl)-butyric acid (XLII), and α-amino-γ-(N^1-cytosinyl)-butyric acid (XLIII):[25]



(XLI) R = H; (XLII) R = CH_3. (XLIII) (XLIV)

The reaction of heterocyclic bases with 2-bromo-1,1-diethoxyethane (XXXIII) was extended to the synthesis of a number of aminoacids of the purine series, including β-(N^9-adeninyl)-α-alanine and β-(N^9-hypoxanthinyl)-α-alanine (XLIV).[26,27] A series of β-(amino-N^9-purinyl)-α-alanines, including β-(N^9-guaninyl)-α-alanine, were synthesised with the aid of this reaction[28].

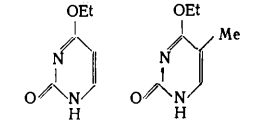


A further improvement of the method of synthesis of nucleoaminoacids based on the reaction of acetals of halogenoaldehydes with heterocyclic bases of the pyrimidine and purine series involved the use of potassium carbonate, proposed by Doel et al.[29], instead of sodium hydride in the alkylation stage. This change significantly simplified the method of synthesis, and, what is particularly important, made it possible to increase the yield of nucleoaminoacids to 50–60%.

Various nucleoaminoacids, including β-(N^1-thyminyl)-α-alanine and β-(N^9-adeninyl)-α-alanine, were synthesised by this modified method. In the synthesis of β-(N^1-cytosinyl)-α-alanine by this procedure, the starting material can be 4-*N*-acetylcytosine (XLV) and the intermediates in this instance are the diethyl acetal of 4-*N*-acetyl-N^1-cytosinylacetaldehyde (XLVI), the diethyl acetal of N^1-cytosinylacetaldehyde (XXXVIII) and, directly, N^1-cytosinylacetaldehyde (XXXIX):

Scheme 9

Scheme 10

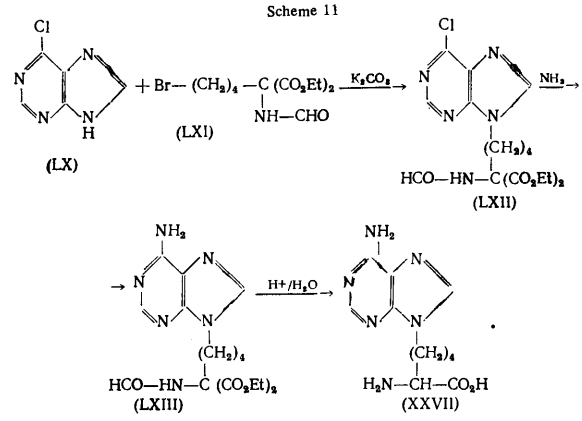


This method is most frequently used nowadays for the synthesis of various nucleoaminoacids, particularly nucleoalanines.

A variant of this method is the synthesis of nucleoaminoacids by the alkylation of pyrimidine or purine bases with the corresponding halogeno-derivatives of protected aliphatic aminoacids. For example, Nollet et al.[30] described the synthesis of a series of nucleoaminoacids of the purine series via Scheme 10, which provides for the use of various 6-chloropurines and potassium carbonate as the starting materials and of t-butyl γ-benzyloxycarbonylamino-α-bromobutyric acid (XLIX) as the alkylating agent. α-Amino-γ-(N^9-hypoxanthinyl)-butyric acid (LII), γ-(N^9-adeninyl)-α-aminobutyric acid (LIV), and α-amino-γ-(N^9-guaninyl)butyric acid (LVII) have been synthesised using this compound[30].

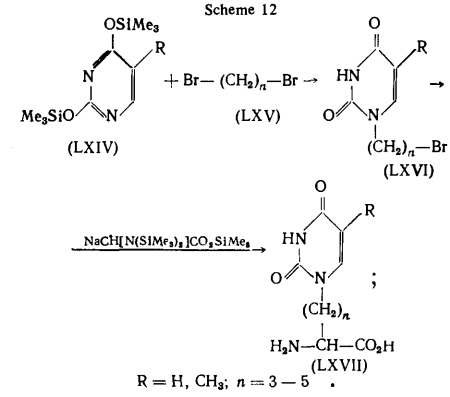
The alkylation reactions proceed with high yields (70 to 88%) in these syntheses and lead to the preferential formation of the N^9-derivatives. Admixtures of the isomeric N^7-derivatives did not exceed 10–11% in all cases and could be readily separated by chromatography on alumina.

Nollet and Pandit[31] also described the synthesis via an analogous scheme of α-amino-γ-(N^1-uracilyl)butyric acid (XLI), α-amino-γ-(N^1-cytosinyl)butyric acid (XLIII), and α-amino-γ-(N^1-thyminyl)butyric acid (XLII).



The nucleoaminoacids (XLI) and (XLII) were synthesised from 4-ethoxy-2-oxodihydropyrimidine (LVIII); on the other hand, in the synthesis of the nucleoaminoacid (XLII) the starting material was 4-ethoxy-5-methyl-2-oxodihydropyrimidine (LIX). The alkylation stages in these syntheses were carried out using sodium hydride.

(LVIII) (LIX)

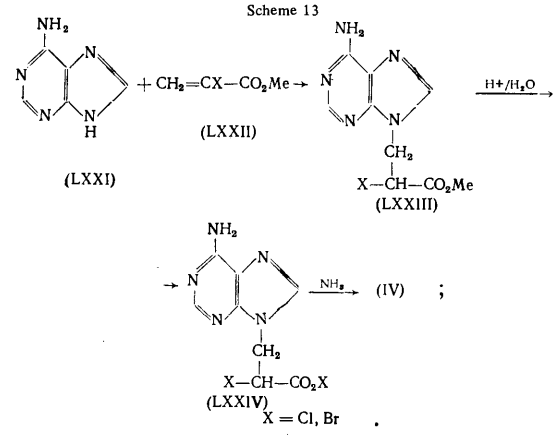


De Koning and Pandit[18] also used halogenoacylaminomalonic esters for the alkylation of heterocyclic bases. In particular, they obtained α-(4-bromobutyl)-α-formylaminomalonic ester (LXI) by the reaction of 1,4-dibromobutane with formylaminomalonic ester and then used it as the alkylating agent in the synthesis of ε-(N^9-adeninyl)-α-aminocaproic acid via the following scheme:

Scheme 11

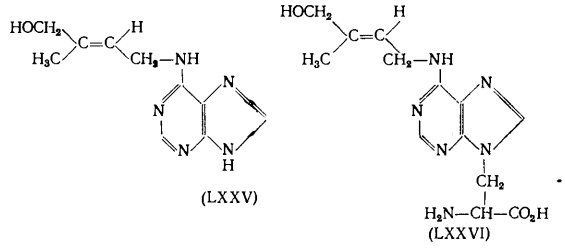
Another sequence of reactions ensuring the formation of nucleoaminoacids by the alkylation of complete heterocyclic structures has been proposed[32].

Scheme 12



The principle of the method is that the heterocyclic structure is initially treated with an α,ω-dihalogenoalkane and the resulting ω-halogenoalkyl derivative of the pyrimidine or purine series is then converted into the corresponding nucleoaminoacid. The specific stages of this method are indicated in Scheme 12. α-Amino-ε-(N^1-uracilyl)caproic acid (XX) and α-amino-ε-(N^1-thyminyl)caproic acid (XXII), as well as the previously unknown α-amino-δ-(N^1-thyminyl)-valeric acid (LXVIII), α-amino-ω-(N^1-uracilyl)oenanthic acid (LXIX), and α-amino-ω-(N^1-thyminyl)oenanthic acid (LXX) have been synthesised by this method.

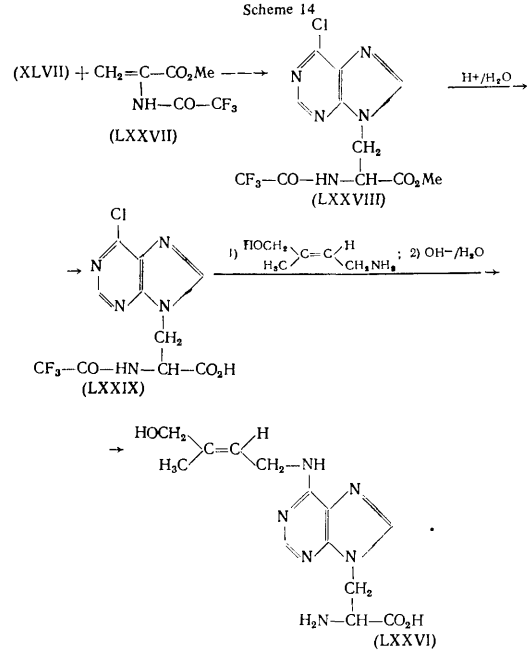
Japanese investigators[33] recently reported the synthesis via the alkylation reactions of a special group of nucleoaminoacids in which the pyrimidine or purine ring is linked directly to the α-carbon atom of the aminoacid residue.



Instead of the alkylation of heterocyclic derivatives, one can use in the synthesis of nucleoaminoacids the reaction involving the addition of the corresponding nucleic acid bases to unsaturated compounds with an activated double bond. The preparation of β-(N^9-adeninyl)-α-alanine via Scheme 13, in which adenine (LXXI) and methyl α-halogenoacrylate (LXXII) are used as the starting materials[34], can serve as an example of such synthesis:

Scheme 13

The methyl ester of the corresponding β-(N^9-adeninyl)-α-halogenopropionic acid (LXXIII) and free β-(N^9-adeninyl)-α-halogenopropionic acid (LXXIV) are intermediates in this synthesis. The addition of adenine to methyl α-halogenoacrylate takes place with 80–85% yield, which ensures a fairly high overall yield of the nucleoaminoacid.



An analogous scheme can be used successfully also in the synthesis of other nucleoaminoacids of the purine series. Thus the method has been employed[35] to synthesise lupinic acid (LXXVI), which is a natural purine nucleoaminoacid. Lupinic acid was first isolated by Australian investigators[35,36] from prickly lupin (*Lupinus angustifolius*) and can be regarded as the N^9-alanine derivative of the familiar phytohormone zeatin (LXXV):

(LXXV) (LXXVI)

Lupinic acid can be regarded just as reasonably as a derivative of the nucleoaminoacid (IV) with the substituent in the exocyclic 6-aminogroup. Racemic lupinic acid has been synthesised via the following scheme[35]:

Scheme 14

The overall yield of compound (LXXVI) was approximately 5% (relative to the initial 6-chloropurine).

III. PROPERTIES OF NUCLEOAMINOACIDS

All the nucleoaminoacids known at present are colourless crystalline substances in a free state with high melting points. The solubilities of nucleoaminoacids in water are various and depend both on the nature of the nucleic acid base and on the length of the hydrocarbon chain linking the nucleic acid base to the α-carbon atom of the nucleoaminoacid. Nucleoaminoacids are almost insoluble in non-polar organic solvents. As typical amphoteric compounds, nucleoaminoacids are as a rule readily soluble in acid and alkaline aqueous solutions.

The ultraviolet spectroscopy occupies a special place in the study of the structures and physical properties of nucleoaminoacids (both naturally-occurring and synthetic). In many instances this technique makes it possible to solve convincingly and unambiguously the important problem of the cycloaddition of the aminoacid fragment to the nucleic acid base. Thus in the case of substituted uracils and analogous compounds of the pyrimidine series the large bathochromic shift of λ_{max} in the ultraviolet spectra of alkaline solutions of the test substances is characteristic of N^3-substituted derivatives. On the other hand, there is virtually no bathochromic shift in the spectra of the isomeric N^1-substituted derivatives in alkaline media[4-6,22].

NMR,[37,38] infrared spectroscopy[2,12,39], and mass spectrometry[35,36] are also useful in the solution of structural problems in the chemistry of nucleoaminoacids.

All the nucleoaminoacids give a positive response to tests with ninhydrin and other reagents forming characteristic coloured products on interaction with α-aminoacids. The chemical reactions of nucleoaminoacids can be divided into those involving the α-amino-group, the α-carboxy-group, and the nucleic acid base. The reactions of the first two types have now been particularly widely investigated. Methods of synthesis of N^{α}-protected nucleoaminoacids, in particular N^{α}-benzyloxycarbonyl-[40,41] and N^{α}-t-butoxycarbonyl-nucleoaminoacids[42-44] as well as nucleoaminoacid esters (including methyl, ethyl, and t-butyl esters[30,31,43,45]), amides[46], and hydrazides[45] have been developed on the basis of these studies. The synthesis of various activated esters of N^{α}-protected nucleoaminoacids (in particular, *p*-nitrophenyl, pentachlorophenyl, pentafluorophenyl, *N*-hydroxysuccinimido, and other esters) has also been achieved[45-47].

Takemoto et al.[48] obtained in a high yield and characterised the *N*-carboxyanhydride of β-(N^1-uracilyl)-α-alanine. The formyl[12], tosyl[2], *o*-nitrobenzenesulphenyl[44], 2,4-dinitrophenyl[45], and acetyl[49] derivatives of nucleoaminoacids have also been described in the literature.

The bromination and chlorination of certain nucleoaminoacids of the pyrimidine series in the 5-position in the pyrimidine ring by bromine and *N*-chlorosuccinimide respectively have also been studied[24].

Microbiological transformations as well as the chemical nature of the resulting products have been studied for certain nucleoaminoacids[52]. In particular, it has been established that a strain of *Microbacterium sp.* can utilise only the L-forms of compounds (I) and (II) as well as certain other nucleoaminoacids. This involves in the first place the oxidative deamination of the nucleoaminoacids and then the cleavage of the bond between the nitrogen atom in the 1-position in the pyrimidine ring and the β-carbon atom of the alanine fragment. Uracil, thymine, as well as the corresponding α-ketoacids of the pyrimidine series, which are apparently the precursors of the free nucleic acid bases formed, have been found among the microbiological transformation products of nucleoaminoacids.

IV. SYNTHESIS OF NUCLEOPEPTIDES

The reactions of peptide synthesis in solution, the methods of synthesis of peptides on insoluble polymeric carriers, as well as polycondensation reactions of carboxyl-activated derivatives of nucleoaminoacids can be used to synthesise nucleopeptides.

The synthesis of nucleopeptides in solution requires the preliminary solution of many special problems due to the

specific features of the chemical structures of nucleoaminoacids. The direct transfer to the synthesis of nucleopeptides of the traditional methods of the usual peptide synthesis, disregarding the characteristic features of the structure and reactivity of nucleoaminoacids, is in most cases relatively ineffective. At the same time there is much in common between the synthesis of nucleopeptides in solution and the usual peptide synthesis. In particular, as in the synthesis of normal peptides, made up of protein aminoacid residues, in the synthesis of nucleopeptides one must have at one's disposal the corresponding protected and activated derivatives of nucleoaminoacids, as well as reliable methods for the formation of peptide bonds between individual nucleoaminoacid residues.

The benzyloxycarbonyl and t-butoxycarbonyl groups are most often used in the synthesis of nucleopeptides in solution for the temporary protection of the α-aminogroup. In order to protect the carboxy-group, the nucleoaminoacids are first converted into esters (the methyl and ethyl esters are most often employed).

The carboxyl of the *N*-protected nucleoaminoacid used as the carboxy-component in nucleopeptide synthesis can be activated by the mixed anhydride or activated ester method as well as the azide and carbodi-imide methods.

Using the above protecting groups and methods of activation, a series of nucleopeptides incorporating the β-(N^1-uracilyl)-α-alanine residue have been synthesised[40,41]. The simplest representative of the family of homonucleopeptides—β-(N^1-uracilyl)-α-alanyl-β-(N^1-uracilyl)-α-alanine (LXXX)—was also obtained for the first time by this procedure. The syntheses of a series of oligonucleopeptides containing the α-amino-ε-(N^1-uracilyl)caproic acid (XX) and α-amino-ε-(N^1-thyminyl)caproic acid (XXII) residues[50], as well as other nucleoaminoacid residues of the pyrimidine and purine series[43,44,53,54] have been achieved analogously.

An example of the synthesis of nucleopeptides using insoluble polymeric carriers is provided by the synthesis of an oligonucleopeptide containing a monotonic block comprising nine repeating residues of compound (I).[55] The chloromethylated styrene–1% divinylbenzene copolymer was used as the insoluble carrier and the condensing agent was *N*,*N*′-dicyclohexylcarbodi-imide.

The nucleopeptide was separated from the polymeric carrier by hydrazinolysis. An oligonucleopeptide containing a monotonic block of repeating residues of compound (IV) has been synthesised via a similar scheme[56].

It is noteworthy that the synthesis of nucleopeptides on insoluble polymeric carriers involves many difficulties characteristic of the solid-phase synthesis of the usual peptides made up of protein α-aminoacid residues[57,58].

The polycondensation reactions of carboxyl-activated derivatives of nucleoaminoacids can be used to synthesise both homo- and hetero-nucleopeptides.

Homonucleopeptides containing the residues of nucleoaminoacids (I) or (II) have been synthesised by the polycondensation of the *p*-nitrophenyl esters of the nucleoaminoacids[59]. The molecular weight of the homonucleopeptides obtained is approximately 2000 according to sedimentation analysis and gel filtration data. Homonucleopeptides containing repeating units of nucleoaminoacids (XXII) or (XXVII) have been synthesised analogously[50]. Their yields were 85–90% and the molecular weight of the homonucleotide made up repeating nucleoaminoacid (XX) residues reached 5%.

Together with the polycondensation of *p*-nitrophenyl esters of nucleoaminoacids, the analogous reaction using the pentachlorophenyl esters of nucleoaminoacids has also been studied[46]. Compared with the *p*-nitrophenyl esters, the pentachlorophenyl esters of nucleoaminoacids are more reactive and make it possible to obtain longer homonucleopeptide chains.

Takemoto et al.[48] reported the synthesis of homonucleopeptides containing repeating residues of β-(N^1-uracilyl)-α-alanine from the *N*-carboxyanhydride of the same nucleoaminoacid. Aliphatic amines (in particular, mono-, di-, and tributylamines) were used as the initiators of the polycondensation reaction[48]. The same workers also reported the synthesis of mixonucleopeptides containing the residues of β-(N^1-uracilyl)-α-alanine and γ-benzylglutamic acid[48].

An important new stage in the study of nucleopeptides has been the development of methods of synthesis of hitherto unknown stereoregular nucleopeptides made up of optically pure, and not racemic, enantiomeric nucleoaminoacids. A necessary condition for the synthesis of stereoregular nucleopeptides was the development of preparative methods of synthesising the optical isomers of nucleoaminoacids.

The first attempts to obtain L-β-(N^1-uracilyl)-α-alanine were made by Kjaer and Knudsen[2] and Dewar ahd Shaw[12]. Kjaer and Knudsen[2] started with the optically active derivative of α,β-diaminopropionic acid. However, as already mentioned above, the difficulties arising in the stage involving the removal of the N^{α}-protecting groups prevented these investigators from obtaining L-β-(N^1-uracilyl)-α-alanine in preparative amounts. Dewar and Shaw[12] attempted to separate racemic β-(N^1-uracilyl)-α-alanine into optical isomers by forming diastereoisomeric salts with optically active bases. The latter consisted of the dextrorotatory enantiomer of α-methylphenylamine and natural laevorotatory brucine. However, these attempts were also unsuccessful as regards the preparative scale of the synthesis of optical isomers of nucleoaminoacids.

It was not until 1975–1976 that preparative methods for the synthesis of nucleoaminoacid enantiomers were developed. A special series of studies established that nucleoaminoacid racemates can be separated into optical isomers with the aid of the stereoselective enzymatic hydrolysis of the N^{α}-acyl derivatives of D,L-nucleoaminoacids by pig kidney acylase (I) [49] or plant acylase[51]. The possibility of using chymotrypsin for the stereoselective hydrolysis of racemic nucleoaminoacid esters was also demonstrated.

The use of the above methods made it possible for the first time to obtain the optical isomers of various nucleoaminoacids on a preparative scale. Using individual enantiomers of nucleoaminoacids, methods were then developed for the synthesis of protected and carboxyl-activated derivatives of optically active nucleoaminoacids, which led to the possibility of synthesising also stereoregular nucleopeptides. For example, the corresponding N^{α}-t-butoxycarbonyl derivatives and pentachlorophenyl esters have been synthesised from the L- and D-isomers of the nucleoaminoacid (I). They were made to undergo the polycondensation reaction, which yielded stereoisomeric homonucleotides made up of repeating L- (I) or D- (I) residues[60].

Various stereoisomeric mixonucleopeptides—in particular water-soluble stereoregular nucleopeptides of the mixed type made up of regularly alternating residues of compound L- (I)—have also been synthesised by an analogous procedure[61].

An important recent discovery has been the detection of naturally-occurring nucleopeptides of a mixed type. The isolation of two new willardiine peptides from the seeds of *Fagus silvaticus* has been reported[62,63]. The structures of γ-L-glutamyl-L-β-(N^1-uracilyl)-α-alanine (LXXXI) and γ-glutamylphenylalanyl-β-(N^1-uracilyl)-α-alanine (LXXXII) respectively have been proposed for the above peptides on the basis of a study of their chemical and spectroscopic

properties[62]. In view of the very limited amount of the second compound, the authors were unable to determine the stereochemical configuration of the aminoacid residues in this nucleotripeptide. The question of the synthesis of these new natural products also remained open.

Both problems were subsequently solved. Firstly, the total synthesis of the nucleopeptide (LXXXI) was carried out[64]. Secondly, authentic γ-L-glutamyl-L-phenylalanyl-L-β-(N^1-uracilyl)-α-alanine was synthesised. The natural nucleopeptides proved to be identical with the synthetic specimens[64]. Thus it can be regarded as proved that all three aminoacid residues in the nucleotripeptide (LXXXII) have the L-configuration.

V. PROPERTIES OF NUCLEOPEPTIDES

In a free state nucleopeptides are colourless crystalline or amorphous substances with high and as a rule non-characteristic melting points. The solubility of nucleopeptides in water varies within wide limits and depends on the nature of the aminoacid residues and on the length of the nucleopeptide chain. There is an overall tendency towards a decrease of the solubility of nucleopeptides in water with increase of the length of the nucleopeptide chains. Free nucleopeptides are almost insoluble in non-polar salts. Comparatively short nucleopeptides dissolve satisfactorily in aqueous solutions of acids and alkalies. The solubility of nucleopeptides of the mixed type can be regulated within wide limits by introducing "solubilising inserts" into the nucleopeptide chain. Thus water-soluble nucleopeptides of a mixed type can be obtained by introducing the residues of hydrophilic α-aminoacids (in particular serine, lysine, glutamic acid, etc.) into the nucleopeptide chain. The properties of long nucleopeptide chains have so far been inadequately investigated.

Short nucleopeptides can be used to prepare longer nucleopeptide chains either by the stepwise growing of the chain or by employing fragment polycondensation methods. At the same time short nucleopeptides are not only important intermediates but are also of independent interest, because these compounds can exhibit certain general properties characteristic of nucleopeptide structures.

One of these general properties is the interaction of the side groups in nucleopeptides. In nucleopeptides made up exclusively of nucleoaminoacid residues there is a possibility of observing the interaction between the corresponding nucleic acid bases. On the other hand, in nucleopeptides of the mixed type, incorporating various protein and non-proteinogenic aminoacid residues, together with those of nucleoaminoacids, the interaction of the nucleic acid bases with the side chains of aromatic and heterocyclic aminoacids merits attention.

Comparative study of the ultraviolet and ^{1}H NMR spectra of aqueous solutions of oligonucleopeptides incorporating the residues of nucleoaminoacid (I) as well as the residues of this nucleoaminoacid and phenylalanine showed[38] that secondary structures, stabilised by intramolecular hydrophobic stacking interactions, are formed in such nucleopeptides.

VI. PROSPECTS FOR THE STUDY OF NUCLEOAMINOACIDS AND NUCLEOPEPTIDES

The synthesis and investigation of nucleoaminoacids and nucleopeptides are of undoubted interest. Nucleoaminoacids are necessary for the synthesis of nucleopeptides. The latter can have unique properties, the unusual nature of which is determined by the combination, within the framework of a single molecule, of the peptide skeleton characteristic of proteins and of heterocyclic bases characteristic of nucleic acids.

Interesting effects can be expected as a result of the superposition and interaction of the system of hydrogen bonds characteristic of the polypeptide chain and the system of hydrogen bonds characteristic of nucleic acids and bases. An important structural factor, namely the hydrophobic stacking interaction between the heterocyclic bases, should also be added to the structure-forming factors playing a cardinal role in biopolymers.

In nucleopeptides the nucleic acid bases are attached to the nitrogen atom of the peptide skeleton in the 1- and 9-positions (in the pyrimidine and purine bases respectively). These are the positions at which the nucleic acid bases are attached to the pentose phosphate skeleton in polynucleotides. Thus the nucleic acid bases in nucleopeptides retain in an unchanged form all the structural elements necessary for the formation of specific mutually complementary hydrogen bonds between the complementary bases.

The distances between neighbouring nucleic acid bases in regular nucleopeptides are identical and equal to the translation along the chain by one nucleoaminoacid residue.

The combination of the above structural features of nucleopeptides creates the necessary and sufficient conditions for the occurrence of numerous intermolecular cooperative contacts between the nucleopeptide chains. These contacts must be similar to those which arise in the interaction of the corresponding polynucleotide chains. As a result of the cooperative nature of the process, each interaction of the pair of complementary bases increases the probability of subsequent contacts. Ultimately one may foresee the possibility of complementary interactions between different nucleopeptide chains, carrying complementary nucleic acid bases, corresponding to the canonical nucleoaminoacid pairs Aal-Tal (Aal-Ual), Gal-Cal, etc.

Complementary interactions of the above type can also take place intramolecularly, i.e. between different sections of the same nucleopeptide chain if the sequence of the alternating nucleoaminoacid residues in these sections of the nucleopeptide chain ensures the possibility of the formation of complementary pairs of nucleic acid bases.

The possibility of the occurrence of the analogous complementary interactions between nucleopeptide and polynucleotide chains and also between nucleopeptides and oligonucleotides is of especial interest. Complementary interactions can also take place when polynucleotides come into contact with nucleoaminoacids and short nucleopeptides.

All these factors suggest that it may become possible to employ nucleopeptide structures for the specific interference with nucleic acid–protein interactions, which play the most important role in vital phenomena.

The Present State of Research into Organosulphur Compounds in Petroleum

N.K.Lyapina

Data on the compositions, structures, and properties of organosulphur compounds forming part of various petroleum distillates are examined. Attention is concentrated on the organosulphur compounds in high-boiling petroleum distillates. The results of studies on the individual and structural-group compositions of mercaptans, sulphides, and thiophens in various distillates of typical petroleums of the USSR are presented. Certain chemical properties of the organosulphur compounds of petroleum and the problems of their utilisation in the national economy are discussed.
The bibliography includes 114 references.

I. INTRODUCTION

Organosulphur compounds, which have found extensive applications both in large-scale technical chemical processes and in fine organic synthesis, have been vigorously and comprehensively investigated in recent years. Natural organosulphur compounds (OSC) of petroleum origin, which consist of sulphides, thiophens, and mercaptans of different structure and molecular weight, have a wide spectrum of specific properties and can serve as starting materials for the synthesis of polyfunctional, bi- and poly-dentate compounds with still more interesting properties. It is sufficient to mention that sulphides from petroleum can be used as effective extractants for noble metals and that the sulphoxides obtained from them are highly selective extractants of many heavy metals and lanthanide elements.

However, in modern processes for the purification of petroleum products the OSC are either converted into hydrocarbons and hydrogen sulphide, or they are transformed into acid resins, or they remain in the petroleum products; in all these instances they are lost for specific applications. One of the main factors hindering the wide-scale employment of the OSC in the national economy is inadequate knowledge of their structure and properties. The interest in these compounds, which has arisen since the discovery of sulphurous petroleums, has been growing and expanding; the methods for the isolation and study of the composition of the sulphides and thiophens in individual petroleum distillates as well as data on their structure have been surveyed in reviews and monographs[1-3].

The studies in recent years (since 1975) are characterised by a combined approach to the investigation of the composition and properties of the OSC in petroleums and by an endeavour to determine the structure of the OSC of the entire distillate component of petroleum and to extend the practical applications of the OSC. Much attention has been devoted to the study of the OSC in high-boiling distillates, because the main bulk of the petroleum OSC is concentrated in the latter. These results are of considerable theoretical and practical interest for both petroleum chemistry and for the improvement of the technology of the processing of petroleum in order to increase the yield of light petroleum products. The study of the structure and properties of the OSC not only makes it possible to find applications for these substances and their derivatives but also stimulates the search for methods of synthesising them.

This review deals with studies in recent years of the structural-group compositions of the sulphides, thiophens, and mercaptans in the distillate components of typical petroleums, studies of the chemical reactions and the possible applications of the petroleum OSC discussed, and the existing schemes for the isolation of the OSC from petroleum distillates are analysed.

II. METHODS FOR THE ISOLATION AND DIFFERENTIATION OF ORGANOSULPHUR COMPOUNDS IN PETROLEUM DISTILLATES

Almost all petroleums contain between 0.01 and 10% of sulphur (S_{tot}).[4] Sulphurous ($0.5 < S_{tot} \leq 1.9\%$) and highly sulphurous ($S_{tot} > 1.9\%$) petroleums, whose contribution to the world production is ~60%, are of greatest interest. The OSC content in the petrol (40–200 °C), kerosene (150–250 °C), and gas-oil (190–450 °C) distillates is usually not more than 1.5, 5, and 10 wt.% respectively and the study of the structures and compositions of the OSC requires their preliminary concentration. Petroleum distillates are multicomponent mixtures of isomers of paraffinic, naphthenic, and aromatic hydrocarbons as well as sulphur, nitrogen, and oxygen compounds, for the isolation and separation of which complex multistage schemes involving the application of physical and physicochemical methods of differentiation are used. As physicochemical methods for the analysis and separation of organosulphur compounds have developed and improved, the schemes for their isolation have been modified. Three principal schemes for the extraction of organosulphur compounds from petroleum distillates are known (Fig.1).

The first scheme is based on the application of the adsorption method for the concentration of organosulphur compounds from petroleum distillates. The composition of the organosulphur compounds present mainly in petrol distillates (40–200 °C) has been studied by this scheme[5]. Elution chromatography on silica gel or alumina is usually employed[5-7]. When the adsorption-chromatographic method of concentration is used, the process conditions and the nature of the

sorbent and eluents can be varied within wide limits. The sulphur content in the resulting concentrates varies from 5 to 11%; the paraffinic-naphthenic hydrocarbons are then most completely separated, while organosulphur compounds—sulphides, thiophens, and mercaptans—are concentrated together with aromatic hydrocarbons. These concentrates are then subjected to further differentiation by complex formation with mercury acetate[5], low-temperature extraction (HI,[8] H_2SO_4 [9]), the formation of adducts with 1,3,5-trinitrobenzene,[8,10] gel permeation chromatography[11–15], fractionation, etc.

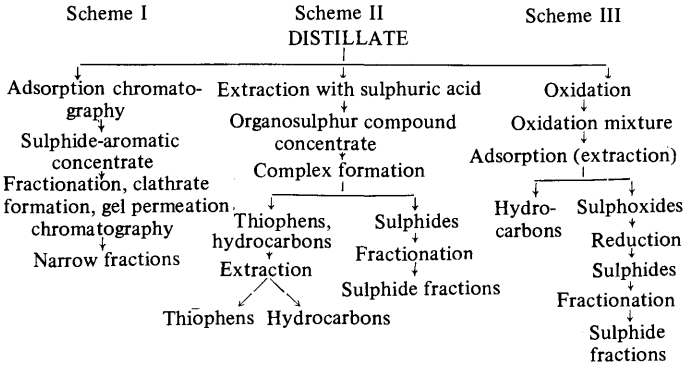

Figure 1. Schemes for the isolation and separation of organosulphur compounds in petroleum distillates.

Selective extraction is used for the preferential removal of sulphides from petroleum fractions (40–360 °C) by scheme II.[16,17] This method makes it possible to isolate from the distillate up to 70% of the sulphides, whose content in the concentrates is ≤60% in sulphuric acid extraction[16] and 40–50% in extraction by organic solvents[17]. Together with sulphides, hydrocarbons and thiophen derivatives are coextracted into the concentrates; the concentrates obtained with the aid of organic solvents are distinguished by an enhanced content of aromatic hydrocarbons. The OSC content in the sulphuric acid concentrates can be raised to 95–97% by means of re-extraction with sulphuric acid[18] or a countercurrent using another solvent[19]. For the selective extraction of sulphides from distillates and sulphuric acid concentrates of OSC, complex formation with silver nitrate is used[20], whereby one can obtain sulphides which are virtually free from thiophens and hydrocarbons. Titanium tetrachloride[21] and aluminium chloride[22] are also used as complex-forming agents; the degree of extraction of sulphur from the distillates is then low (39%), since oxygen and organonitrogen compounds are extracted together with the OSC.

Scheme II has been used[5] to identify the organosulphur compounds in petrol distillates (40–190 °C) and to establish the structural-group composition of organosulphur compounds from the middle distillates (15–360 °C) of a series of petroleums[23–25]. However, this scheme is apparently relatively inapplicable to the fraction of heavy high-tar petroleums owing to the marked charring in the sulphuric acid extraction stage and the low yield of complexes with silver nitrate.

The technology of the preparation of concentrates of organosulphur compounds from middle petroleum distillates on an experimental industrial scale has been developed on the basis of this method[26,27]. The large batches of concentrates of organosulphur petroleum compounds obtained were tested for the first time on an industrial scale in various branches of the national economy[28,29].

Scheme III, proposed[30] for the isolation and investigation of sulphides in petroleum distillates, is based on the chemical method of isolation. The authors[30] developed conditions for the selective oxidation of sulphides in a mixture with thiophens and hydrocarbons. The sulphoxides isolated are either desulphurised or reduced and the composition of the resulting hydrocarbons or sulphides is investigated; it is then possible to characterise up to 80% of the sulphides (relative to their initial content). The method is applicable to the light and middle distillates and has been used successfully for the industrial preparation of sulphoxides[31].

This scheme has been used in the investigation of the sulphides in the Romashki petroleum[32], the accumulated South Uzbekistan petroleum[33], the Khaudag and Kyzyl-Tumshuk petroleums[34], and the organosulphur compounds in the deparaffinated distillate of the Kuwait petroleum[35].

Apart from the adsorption methods for the isolation of mercaptans from petroleum distillates, methods involving extraction with 40% alkali[36], sodium aminoethoxide in anhydrous ethylenediamine[37], and the metal oxides and salts[38] are widely used. The degree of extraction of mercaptans is low (up to 40%) when mercury chloride, mercury acetate, cadmium acetate, and silver nitrate are used[38], about 60% for extraction with an ethanol solution of 40% KOH,[36] 68% for extraction with sodium aminoethoxide[37], and up to 96% for extraction with iron dodecarbonyl[39]. Mercaptans are regenerated from the mercaptides or disulphides obtained by these methods in order to investigate their structural-group composition. After demercaptanisation, the residual OSC in the distillates are isolated in accordance with schemes I and II (Fig. 1).

Sometimes the order of treatment can be altered. Thus, in the study of mercaptan-containing distillates, adsorption is carried out initially and then alkaline extraction, etc.[8] It is noteworthy that repeated treatment with reagents is usually necessary. Depending on the aim, fractionation, molecular distillation[8], thermal diffusion separation[40], etc. are used in various stages.

Concentrates of thiophens, sulphides, and mercaptans or narrow fractions are investigated by a set of various physical methods of analysis, including infrared and ultraviolet spectroscopy, ^{1}H NMR, mass spectrometry, hydrodesulphurisation on Raney nickel, gas–liquid chromatography, chemical reactions, and elemental and functional analyses in order to identify the components and determine the structural-group composition.

III. INVESTIGATION OF THE COMPOSITIONS OF CONCENTRATES OF ORGANOSULPHUR COMPOUNDS IN PETROLEUM DISTILLATES

The study of the composition of the OSC has been developing in three main directions: (1) group analysis of the OSC in petroleums and petroleum products; (2) identification of the OSC, which is characteristic of studies of the OSC in the petrol–ligroin distillates (40–240 °C); (3) determination of the structural-group composition of the OSC, which is most widely used in the study of the kerosene–gas-oil distillates (150–535 °C).

1. The Group Composition of Petroleum OSC

The analysis of the group composition of the OSC in petroleums and distillates involves the determination of elemental (S_S), hydrogen sulphide (S_{H_2S}), mercaptan (S_{merc}), disulphide (S_{RSSR}), and sulphide (S_{sulph}) sulphur. The unidentified component is usually referred to as the

residual or thiophen sulphur (S_{res}); it usually constitutes a large fraction, owing to the difficulties arising in the analysis and the study of the composition and structure of the petroleum OSC. The residual sulphur includes (apart from that in thiophens) the sulphur in diaryl and alkyl aryl sulphides, but only a small amount of these compounds has been found in petroleums[13].

Hitherto systematic studies have been made of the group compositions of the OSC present in the distillates (40–300 °C) for the majority of the petroleums in the USSR (250 specimens of petroleums and distillates boiling up to 300 °C),[43] America, and the Near East[4]. These data are necessary for the technological characterisation of sulphurous and highly sulphurous petroleums. However, the existing methods for the analysis of the group composition of the OSC have been developed for the low-boiling and middle distillates and are inapplicable to the high-boiling distillates (above 360 °C), a characteristic feature of which is the similarity and averaging of the properties of the components.

The results of the study of the group composition of the OSC of certain petroleums are presented in Table 1. Depending on the group composition of the OSC contained in the distillates, petroleums can be divided by convention into three types: thiophen petroleums (type I), which contain mainly thiophen sulphur and not more than 10% of sulphide sulphur, while the remaining groups are absent; sulphide petroleums (type II) containing thiophens and sulphides, while the content of mercaptans is not more than 5%; mercaptan petroleums (type III), which contain comparable amounts of sulphides, thiophens, and mercaptans and there is also a possibility of the presence of disulphides, hydrogen sulphide, and elemental sulphur (see Table 1). Since the content of hydrogen sulphide in petroleum is variable and depends on the sampling, storage, and transport conditions, its amount in petroleum is usually not determined. Petroleums of the first and third types are encountered in nature much more rarely than those of the second type.

Table 1. The group compositions of the organosulphur compounds in certain world petroleums (relative content, %).

Each of the above types of petroleum is not characterised solely in terms of differences between their group compositions. The thermal stability of the petroleum OSC is an important technological characteristic[43], decreasing on passing from petroleums of type I to those of type III, which must be taken into account in the study of the composition and structure of the OSC. The content of sulphur in all the consecutively boiling fractions of petroleums of types I and II is higher the higher its content in the petroleum. The sulphur content in the low-boiling distillates of petroleums of type III can be higher than in the high-boiling distillates and depends mainly on the thermal stability of the OSC. The group compositions of straight-run distillates (particularly petrol distillates) of petroleums of various types therefore differ greatly (Table 2). With increase of the boiling point of the distillate, the difference is smoothed out.

Table 2. The proportions of organosulphur compounds in the distillates of certain petroleums.

Sulphur	Boiling range of distillate, °C		
	40–200	200–360	360–410

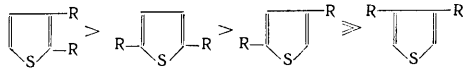
B	29.9	16.1	

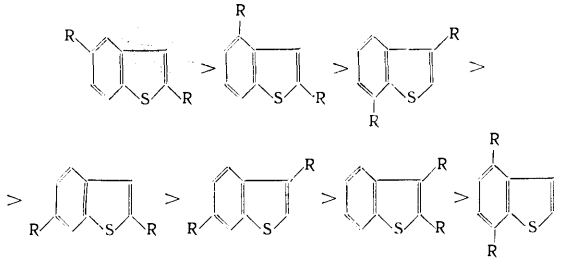
*Mercaptan sulphur, % of total sulphur in distillate.

It is noteworthy that active sulphur compounds (S, H_2S, RSH, RSSR) are mainly concentrated in the low-boiling distillates.



2. Identification of Petroleum OSC

The identification of the OSC in petroleum distillates is a fairly complex problem, as a result of which only 200 organosulphur compounds have been identified in the course of 90 years[5,8]. The results of the identification permit the conclusion that, in the petrol distillates (40–200 °C) of type I petroleums, the OSC consist of alkylthiophens and their derivatives, those in type II petroleums are mainly cyclic sulphides, and those in type III petroleums are aliphatic and cyclic mercaptans and sulphides. All the potential isomers of the sulphides and mercaptans, ranging from C_3 to C_7 (with the exception of unstable compounds containing less than 4 carbon atoms in the ring), are present in these distillates of petroleums of the first and second types. The majority of monocyclic sulphides in petroleums consist of alkylthiacyclopentanes and alkylthiacyclohexanes, the amount of the latter



being smaller by a factor of ~2 (which follows from the analysis of the literature data[47-50]). *gem*-Substituted, α,β-disubstituted (in five- and six-membered sulphides), and α,β,γ-trisubstituted (in six-membered sulphides) are more rarely encountered among cyclic sulphides.

The main bulk of the branched aliphatic sulphides and mercaptans as well as paraffins isolated from the distillates consist of isomers with a single branch in the hydrocarbon group[47,48]. Compounds with groups located in the α- and β-positions relative to the sulphur atom are usually encountered. The number of isomers with two branches in the group is much smaller and those with three and more branches have not so far been detected[47-51].

Among the identified C_4–C_7 alkylthiophens[50,51] and C_8–C_{11} benzothiophens[7,8,52-57], the α-derivatives are usually encountered, the isomers of the disubstituted thiophens forming the following sequence in terms of their relative contents in petroleum:

while disubstituted benzothiophens give rise to the sequence

Eighteen C_8–C_{11} alkylthiaindans, mainly with methyl and ethyl substituents, have been identified. The substituents are usually located in the 2- and 3-positions relative to the sulphur atom[6].

Identification made it possible to characterise the OSC in the low-boiling petroleum distillates and to deduce the most likely structures of the compounds in the high-boiling distillates. However, one should note that it is at present impossible to carry out an exhaustive identification of the OSC in the kerosene–gas-oil distillates (150–450 °C). Qualitative identification of certain successfully isolated components from the distillates does not allow inferences about the composition and properties of the mixture of OSC in the concentrates. Therefore the study of the quantitative structural-group composition of the OSC is the most valuable procedure and the only one available procedure for kerosene–gas-oil distillates.

3. The Structural-Group Composition of the Petroleum OSC

The structural-group composition of the OSC has been determined for the 150–250°, 190–360°, 360–450°, and 370 to 535 °C distillates of various petroleums of the USSR,[23,41-46] America, and the Near East.[8,11-15] The majority of the petroleums investigated belong to the second type, whose OSC consist mainly of sulphides and thiophens.

(a) The structural-group composition of the OSC of the distillates of type I petroleums. The typical structures of the OSC found in petroleums of this type are given below:

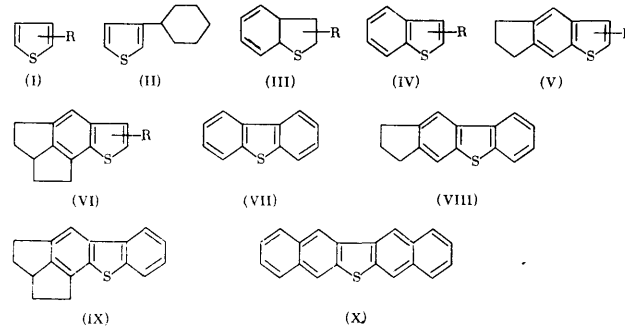


Table 3. The structural-group composition of the OSC in the high-boiling distillates of type I petroleums (relative content, %).

Type of structure	Yaregsk (Ref.42), 280–400°	Usinsk (Ref.41), 200–410°	Recluse (Ref.8)*, 370–535°	Swan Hills (Ref.8)*, 370–535°
(I)	6.4	7.0	—	—
(II)	—	0.6	—	—
(III)	5.9	12.8	—	—
(IV)	24.4	23.1	14.4**	18.6**
(V)	16.2	10.7	21.1	12.3
(VI)	10.2	9.9	—	6.1
(VII)	15.4	17.7	6.7	5.2
(VIII)	20.6	9.1	10.0	12.3
(IX)	0.5	7.4	7.8	4.9
(X)	0.4	1.7	6.7	2.3

*The sum of the high-molecular-weight thiophens is 33.3 and 38.3% for the Recluse and Swan Hills petroleums respectively.
**Calculated from the data of Rall et al.[8]

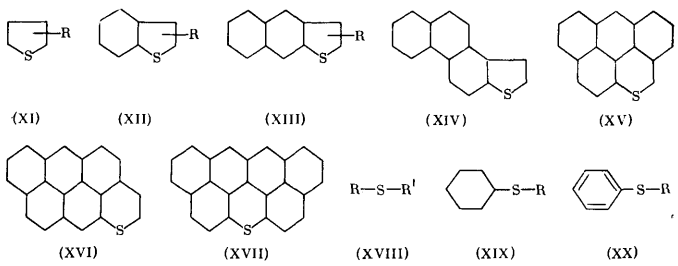

Table 3 shows that the structural-group compositions of the OSC of the 200–410 °C distillates of type I petroleums are fairly close[41,42]. Alkylbenzothiophens (IV) constitute one-fourth of the OSC. Cycloalkano- and bicycloalkano-derivatives of benzothiophens [(V) and (VI)] and dibenzothiophens [(VIII) and (IX)] constitute an appreciable fraction. Thus the content of the tricyclic and polycyclic structures (V)–(X) in these distillates is 55–65%. The contents of dibenzothiophens (VII) and their derivatives (VIII)–(X) are particularly high in the heavy Yareg petroleum[42]. A low content of alkylthiophens (I) (4–6%) and thiaindans (III) (8–10%) is characteristic of petroleums of type I.

The distillates of type I petroleums do not contain compounds with the sulphide structure probably owing to the catalytic transformations of the petroleum OSC under the influence of the petroleum-bearing rocks and the increased radioactivity of petroleum waters[42].

The content of thiophen structures increases with increasing boiling point of the distillate, the quantitative content of benzothiophens, dibenzothiophens, and cycloalkanodibenzothiophens increasing faster than that of alkylthiophens and cycloalkano- and bicycloalkano-benzothiophens. These data, characterised by an increased content of aromatic OSC, agree with the hydrocarbon composition of the distillates,

which are distinguished by a higher content of naphthalene and phenanthrene hydrocarbons.

(b) The structural group composition of the OSC in the distillates of type II petroleums. The typical structures of the sulphides detected in these petroleums are as follows:

With increase of the boiling points of the distillates, the content of sulphides in the OSC diminishes (Table 2). The sulphide component of the OSC in the petrol distillates (40–190 °C) of the Weatern Surgut petroleum consists of almost 90% of thiacycloalkanes. The fraction of thiamonocycloalkanes (XI) is 80%, while the content of thiabicycloalkanes (XII), thiaindans (III), and dialkyl sulphides (XVIII) does not exceed 5–7%.[58]

Thiamonocycloalkanes also predominate (45–55%) in the diesel distillate (190–360 °C) of this petroleum, but their relative content is smaller by ~20–30% than in the petrol distillate. The number of rings in the thiacycloalkane molecules in this distillate increases to 4–5. The content of dialkyl sulphides is reduced by a factor of ~2, while the content of thiaindans remains unchanged[44].

Thiamonocycloalkanes predominate in the 360–410 °C distillate, while the content of thiabicycloalkanes is fairly high[59]; the latter predominate in the 410–450 °C distillate[60]. These data show that the number of rings in the OSC molecules increases with increasing boiling point of the distillate.

Thus the relative content of thiamonocycloalkanes and dialkylsulphides falls on going from a low-boiling to a high-boiling distillate, the content of thiaindans changes little, and that of thiapolycycloalkanes increases.

The absolute content of all types of sulphides in the distillate as a rule increases with increase of the boiling point (Fig.2).[61] The absolute content of thiamonocycloalkanes is a maximum in the 360–410 °C distillate and that of acyclic sulphides is a maximum in the 190–360 °C distillate. The curve representing the proportions of thiamonocycloalkanes as a function of the boiling point of the distillate has a lower slope than the corresponding curves for thiabi-, thiatri-, thiatetra-cycloalkanes, which means that the increase in the number of rings in the molecules of the organosulphur compounds is faster than the increase in the size of the molecules with increase of the length of the alkyl group in the alkylcycloalkane.

Polynuclear OSC with a long side chain or with a naphthene ring as substituents have not been discovered in the 190° to 360 °C distillates. This may be evidence that the increase in molecular weight is to a large extent associated with the increase of the degree of substitution.

In contrast to sulphides, the content of thiophens increases and becomes dominant in the high-boiling distillates. For example, alkylthiophens (100%), constituting 2–4% of the total content of the OSC, have been found in the petrol distillate (40–200 °C) of the Western Surgut petroleum. The dominant structural group in the thiophen component of the 190–360 °C distillate[44] is alkylbenzothiophens (60–80%), while alkylthiophens constitute not more than 5–7%. The thiophen components of the 360–410° and 410–450 °C distillates[59,60] contain mainly alkylbenzothiophens (~40%) and cycloalkanobenzothiophens (16%). The absolute content of alkylthiophens is a maximum in the 360–410 °C distillate: on passing to the high-boiling distillate, the content of cycloalkanobenzothiophens and dibenzothiophens increases most sharply; the amount of the remaining structural groups of thiophens increases uniformly (Fig.3).[61]

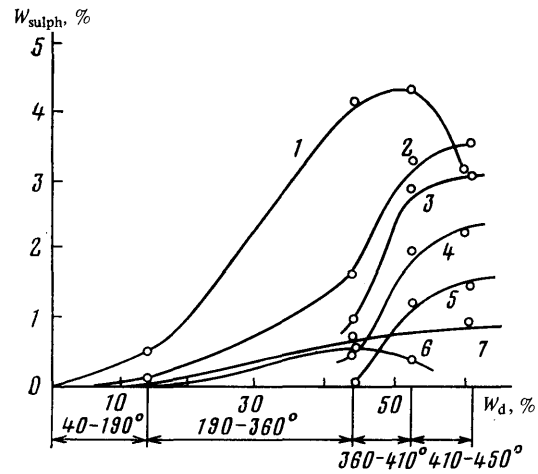

Figure 2. The proportions of thiamonocycloalkanes (curve *1*), thiabicycloalkanes (curve *2*), thiatricycloalkanes (curve *3*), thiatetracycloalkanes (curve *4*), thiapentacycloalkanes (curve *5*), dialkyl sulphides (curve *6*), and thiaindans (curve *7*) in the 40–190°, 190–360°, 360–410°, and 410–450° distillates of the Western Surgut petroleum (W_d = yield of distillate, wt.% of petroleum; W_{sulph} = content of sulphides, wt.% of the corresponding distillate).

The quantitative contents of the structural groups of sulphides and thiophens in the high-boiling distillates of various type II petroleums are compared in Table 4. It is noteworthy that the compositions of thiacycloalkanes are similar, the differences between the relative contents of alkylthiabi-, alkylthiatri-, and alkylthiatetra-cycloalkanes being particularly small. The increased content of thiamonocycloalkanes and the reduced content of thiapolycycloalkanes in the Wester Surgut petroleum, compared with the other petroleums quoted, is consistent with the differences between the boiling points of their distillates. Compared with the sulphide component of the OSC, the structural-group compositions of the thiophen components of these petroleums differ to a greater extent.

The results of the estimates of the overall contents of the individual structural groups in straight-run distillates (40–450 °C) are presented in Fig.4. Evidently the structural groups present in greatest amounts comprise alkylbenzothiophens and thiamono-, thiabi-, and thiatri-cycloalkanes; the sum of the acyclic sulphides is 5%.[61] The relative content of compounds with increasing numbers of rings in their molecules diminishes uniformly for thiacycloalkanes and non-uniformly for thiophens. The diagram shows that the content of alkylbenzothiophens greatly exceeds that

of all the remaining thiophen groups. This can apparently be accounted for by the higher stability of alkylbenzothiophens and the possibility of the presence of a large amount of isomers. Some of the alkylbenzothiophens are probably the products of the thermal degradation of the more condensed thiophen-containing polynuclear structures.

(c) The structural-group composition of the OSC of type III petroleums. A considerable amount of OSC (S_{tot} = 0.53) has been found in the low-boiling distillates of petroleums of this type, exceeding by an order of magnitude that in the analogous distillates of type I and II petroleums.

*Calculated from the data of Rall et al.[8]
**410–450 °C distillate.
***A = sum of high-molecular-weight thiophens.

With increase of the boiling point of the distillate, the content of mercaptans and sulphides falls, while that of thiophens increases (Table 2). The content of mercaptans decreases more than that of the sulphides. The absolute content of mercaptans is a maximum in the 200–360 °C distillate. The mercaptans in the low-boiling distillates are mainly primary or secondary. The 200–360 °C distillate contains a very large amount of cyclic mercaptans[62].

The sulphides consist mainly of thiamonocycloalkanes and acyclic sulphides (Fig.5). It is noteworthy that, in contrast to the corresponding distillates of type II petroleums, these distillates contain a considerable amount of dialkyl sulphides and alkyl cycloalkyl sulphides[46]. Among thiophens, dibenzothiophens predominate, particularly in the 200–360 and 360–410 °C distillates. The content of alkylthiophens is slight[62]. The curves illustrating the relative contents of dibenzothiophens as well as cycloalkano- and bicycloalkanobenzothiophens in the distillates become steeper with increase of the boiling points of the latter than the corresponding curves for benzothiophen and particularly alkylthiophen derivatives. These results show that the amount of condensed OSC molecules increases sharply with increase of the boiling point of the distillate. Thus type III petroleums are similar to type I petroleums in terms of the structural-group composition of the thiophens and the nature of their distribution among the distillates and can serve as the starting material for the preparation of benzo- and dibenzo-thiophens.

4. Certain Generalisation Concerning the Individual and Structural-Group Compositions of the OSC of World Petroleums

On the basis of the results of the identification [of components] and the study of the structural group-composition of the OSC of the petrol, kerosene, and gas-oil distillates, it is possible to make certain comparisons and generalisations. The principal components of the 40–535 °C distillates are benzo- and dibenzo-thiophens in petroleums of the thiophen type, thiacycloalkanes and benzothiophens in petroleums of the sulphide type, and dibenzothiophens, thiacycloalkanes, acyclic sulphides, and mercaptans in petroleums of the mercaptan type.

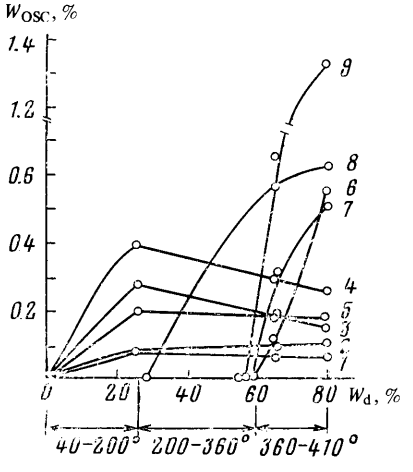

Figure 5. The proportions of alkyl cycloalkyl sulphides (curve *1*), thiaindans (curve *2*), dialkyl sulphides (curve *3*), thiamonocycloalkanes (curve *4*), alkylthiophens (curve *5*), cycloalkanobenzothiophens (curve *6*), bicycloalkanobenzothiophens (curve *7*), benzothiophens (curve *8*), and dibenzothiophens (curve *9*) in the 40–200°, 200–360°, and 360° to 410 °C distillates of the Orenburg petroleum (W_d = yield of distillate, wt.% of petroleum; W_{OSC} = OSC content, wt.% of the corresponding distillate).

The thiacycloalkanes consist mainly of five- and six-membered isomers. The number of rings increases with increasing boiling point of the fraction. The maximum content of isomers with the greatest number of substituents is characteristic of thiamonocycloalkanes, the substituents being linked to different carbon atoms. The kerosene distillate (150–250 °C) contains 25% of α,α'-dialkylthiamonocycloalkanes with substituents having the straight-chain structure only, while the diesel distillate (190–360 °C) contains ~5% of similar structures relative to the total amount of thiamonocycloalkanes[23].

A detailed comparison of the structural-group compositions of the sulphides isolated from diesel distillates (190–360 °C) with petroleums of the sulphide type shows that they are qualitatively similar (Table 5). The quantitative contents of the individual structural groups in the distillates of highly sulphurous petroleums (for example the Arlansk and Western Surgut petroleums) are approximately the same; the corresponding structural groups are present in a smaller amount in the distillates of sulphurous petroleums (the Samotlor petroleum). However, the relative contents of analogous structures are fairly similar in distillates of petroleums of the same type. Thus the contents of the principal components (thiamono- and thiabi-cycloalkanes) differ by not more than 15–20%. This result is important for the practical utilisation of petroleum sulphides.

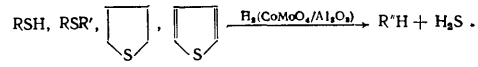
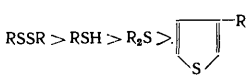
*Calculated from data in Refs.33 and 34.

Comparison of the quantitative contents of the individual structural groups of thiophens in different petroleums revealed certain characteristic features. Benzothiophens predominate in the distillates of highly sulphurous type II petroleums[9]. Both thiophens and benzothiophens and naphthenobenzothiophens have been found in approximately equal amounts in the distillates of sulphurous petroleums of this type[45]. Condensed derivatives of benzo- and dibenzothiophens greatly predominate in the distillates of type I and III petroleums.



It follows from the data presented above that the relative contents of the individual and structural groups of OSC within the limits of each class (sulphides, thiophens, benzothiophens, and naphthenobenzothiophens) are approximately of the same order of magnitude for different petroleums, as in the case of hydrocarbons[63]; the contents of each class of compounds in different petroleums are different.

The data presented permit the conclusion that certain petroleum distillates can serve as a realistic source of natural mercaptans, thiacycloalkanes, benzothiophens, dibenzothiophens, etc.



IV. CHEMICAL PROPERTIES OF THE MERCAPTANS, SULPHIDES, AND THIOPHENS IN PETROLEUM

The petroleum OSC consist of a mixture of isotypical structures of different molecular weights, the functionality of the molecules decreasing as a rule with increasing molecular weight. One can therefore postulate that only those reactions which exhibit a low selectivity within the homologous series and are at the same time highly sensitive to the functional characteristics of the molecules can be used successfully in the chemistry of petroleum OSC. This is why only a few of the known reactions of individual mercaptans, sulphides, and thiophens have been applied to petroleum systems.

The reaction most thoroughly investigated in this sense is that of hydrogenolysis—one of the most effective methods for the desulphurisation of all the groups of OSC:

The catalysts for the hydrodesulphurisation of the OSC are cobalt, molybdenum, tungsten, nickel, and iron oxides or sulphides or their mixtures on alumina. The process is carried out under a hydrogen pressure from 4 to 70 atm at 300–425 °C (depending on the composition of the OSC and their content in the petroleum products)[64]. In terms of their capacity to undergo hydrodesulphurisation, the OSC can be arranged in the sequence

Depending on the conditions, the process can be carried out with a quantitative conversion of the OSC. More severe conditions are required in the hydrodesulphurisation of compounds with a high molecular weight and a large number of rings in their molecules and with a high degree of condensation. Hydrogenolysis has been widely used in industrial large-scale processes involving the removal of sulphur from petroleum products and also in analytical practice.

The reactions characteristic of specific groups of OSC are examined below.

1. Reactions of Petroleum Mercaptans

Mercaptans are the most reactive compounds among the OSC; they exhibit acidic properties and react fairly readily with alkalies:

The reaction is reversible and mercaptans can be regenerated by hydrolysis and for this reason the degree of conversion is low even for low-boiling mercaptans. Aliphatic mercaptans react more readily the shorter their hydrocarbon chain and the lower the degree of branching of the latter. The addition of the so-called "solutisers" increases the degree of conversion. The solutisers tested have included *m*- and *p*-cresols, phenol, ethanol, and methanol[65,66]. The use of the latter makes it possible to achieve a virtually theoretical conversion of mercaptans (90–95%). However, after regeneration the yield of mercaptans does not exceed 60%,[66] because they are readily oxidised by atmospheric oxygen to disulphides. A high degree of extraction of petroleum mercaptans (40–60%) is observed when they are treated with a KOH solution containing monoethanolamine[36]. The subsequent oxidation of the resulting mercaptans to disulphides takes place in the presence of catalysts—copper(I) chloride or the sodium salt of cobalt-disulphophthalocyanine ($C_{32}H_{14}O_6N_8S_2CoNa_2$):

The method makes it possible to remove mercaptan sulphur almost completely from petrols[66], light hydrocarbon fractions, and gas condensates[67].

Disulphides can be formed in acetic acid solution in the presence of lead tetra-acetate[3] and in concentrated sulphuric acid. Mercaptans are capable of substituting the carbonyl groups in iron carbonyl complexes[68]:

The relative reactivities of the OSC form the sequence (in proportions of 14 : 9 : 1)

Mercaptans react most fully with iron dodecarbonyl, forming iron tricarbonyl mercaptides. When dry hydrogen chloride is passed through iron tricarbonyl mercaptides in solution in dodecane at elevated temperatures, the corresponding mercaptans are formed. Treatment of this solution with copper(II) chloride makes it possible to obtain the disulphides. Oxidation with concentrated nitric acid leads to a quantitative yield of the corresponding alkanesulphonic acid (isolated as the sodium salt)[68]. The sodium salts of sulphonic acids can be obtained by the oxidative chlorination of petroleum mercaptans followed by hydrolysis with alkali[69].

Petroleum mercaptans react with heavy metal oxides and salts. The reactions with silver nitrate[38], cadmium acetate and chloride[65], and mercury acetate[66] have been investigated; in all cases the degree of conversion of the mercaptans is low (~60–70%). In the reaction with mercury acetate the tertiary mercaptans decompose with dissociation of the C–S bond. The reaction with sodium aminoethoxide in anhydrous ethylenediamine is less sensitive to the structural features of mercaptans[37]:

The degree of conversion of the mercaptans is almost quantitative.

Bis-sulphides have been obtained by the reaction of petroleum mercaptans with 1,2-dibromoethane:

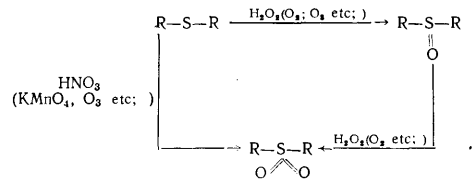
The reaction proceeds in an alcoholic solution of alkali and the yield of bis-sulphides is 75–85%,[70] the products being effective stabilisers in the thermo-oxidative degradation of poly(methyl methacrylate).

Petroleum mercaptans constitute a readily available starting material for the synthesis of vinyl sulphides[71];

The reaction is quantitative and the products can be used as insecticides, flotation agents, and as a base for varnishes. The condensation of mercaptans in the petrol and kerosene distillates with ethylene chlorohydrin followed by oxidation and dehydration makes it possible to obtain alkyl vinyl sulphones, which are effective herbicides[72]:

Petroleum mercaptans react fairly completely with olefins[73,74]:

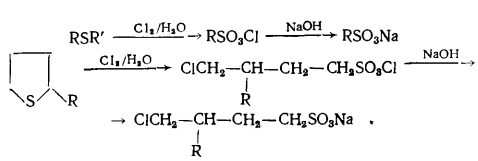
The C–C bonds in olefins were thi-ylated with the mercaptans of the low-boiling fraction (40–200 °C) of the Orenburg petroleum containing 0.22 wt.% of mercaptan sulphur and 0.25 wt.% of sulphide sulphur[62]. The catalysts used were benzoyl peroxide, aluminium chloride, ethylenealuminium dichloride, and an aluminium-containing catalytic complex. The results indicate a fairly high degree of conversion of the petroleum mercaptans (70–80%). Among the olefins investigated, best results were obtained for 2-methylpent-1-ene, containing an active carbonium ion attached to the double bond, and the best catalysts were ethylenealuminium dichloride and the active aluminium-containing complex. Analysis of the group composition of the product agreed satisfactorily with the results of the physicochemical study of the sulphide concentrate isolated from this fraction by extraction with



sulphuric acid. Comparison of the structural-group compositions of the sulphides present in the petrol distillate and obtained from the petroleum mercaptans shows that the main bulk of the former sulphides have a lower molecular weight than those obtained from the mercaptans[62].

A lower degree of conversion is characteristic of the interaction with olefins of the mercaptan concentrate obtained from the higher-boiling distillate (200–360 °C) in which the content of mercaptan sulphur is 8.25%.[62] This can apparently be accounted for by the lower thi-ylating activity of cyclic mercaptans, ~30% of which were detected in the given concentrate relative to the total OSC content. Among the olefins tested, low-molecular-weight olefins, namely isoprene and 2-methylpent-1-ene, proved to be the most reactive in the reaction with mercaptans[62,74]. Investigations have shown that aliphatic mercaptans can be converted almost quantitatively into sulphides, which can be more conveniently isolated and their structural-group composition investigated, because, as shown above, mercaptans are oxidised during isolation and intense corrosion of the detector is observed in analysis by gas–liquid chromatography (GLC).

The possibility of the catalytic conversion of petroleum mercaptans into sulphides makes it possible to regard mercaptan-containing petroleums and gas condensates as additional sources of raw materials for the preparation of sulphides.

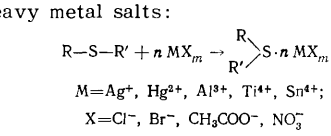


2. Reactions of Petroleum Sulphides

Reactions involving the oxidation of petroleum sulphides to sulphoxides and sulphones have been vigorously investigated in the last 10–15 years:

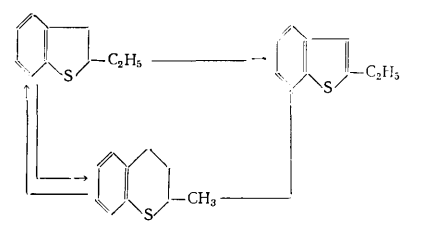
The oxidants used in these reactions are hydrogen peroxide[2,75], atmospheric oxygen in the presence of transition metals and their oxides and sulphides[76], heteropolyacids[77], organic hydroperoxides, etc. The highest selectivity and highest degree of conversion are attained when the reaction is carried out at 70–80 °C in the presence of catalytic amounts of H_2SO_4. The yield of sulphoxides is 70–80%.[2] Depending on the conditions, the oxidation can be continued until the formation of sulphones in 90–100% yields. Sulphides with a higher molecular weight are oxidised under more severe conditions. This reaction is very important for the preparation of substances with biological activity[78] and complex-forming capacity[79], i.e. substances with more valuable properties than the initial petroleum sulphides.

Different fractions of sulphides isolated from distillates of highly sulphurous petroleums readily undergo oxidative chlorination. Subsequent hydrolysis of the reaction products yields the sodium salts of sulphonic acids[80]:



Sulphuric acid has been used for a long time for the removal of OSC from petroleum products. It has been established that the interaction of petroleum sulphides with sulphuric acid is exothermic[18,81] and results in the formation of a protonated complex:

The degree of protonation depends on the molecular weight and structure of the sulphide, the sulphuric acid concentration, and the extraction temperature. With increase of the molecular weight of the sulphide, protonation takes place at a lower temperature and with more concentrated acid[9,82].

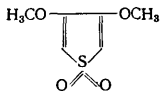


Apart from sulphuric acid, HI,[83] HF,[55] and copper sulphate dihydrochloride[84] have been tested as protonating agents: the first two reagents have not found extensive application owing to the occurrence of side reactions (the dissociation of the C–S bond in sulphides with a tertiary carbon atom in the α-position relative to the sulphur atom, coextraction of aromatic hydrocarbons, and the predominance of the reaction with aromatic hydrocarbons) and the difficulty of regenerating the extracted sulphides. Copper sulphate dihydrochloride is a milder protonating agent, which is active in reactions with low-molecular-weight sulphides.

Petroleum sulphides undergo fairly readily addition reactions with heavy metal salts:

It has been established that, with increase of molecular weight and with decrease of the symmetry of the sulphides, their reactivity falls[85]. Mercury derivatives have therefore been obtained mainly for the sulphides in the petrol–ligroin distillates[5]. Titanium[86] and aluminium[87] salts proved to be less selective complex-forming agents, since they react vigorously also with other hetero-organic compounds containing nitrogen and oxygen.

The catalytic dehydrogenation and isomerisation of thia-heterocycloalkanes of different structure are promising reactions:

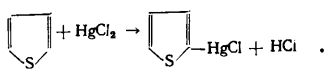


It has been shown[88] that the reaction proceeds via an ionic mechanism involving the successive elimination of a hydride ion and a proton. It has been found that the reactions are effective in the presence of quinoline-treated ASK-Na or ASK catalysts.

3. The Reactions of Petroleum Thiophens

Despite the considerable content of thiophens of different structure in petroleums, their compositions and properties have been less thoroughly investigated than those of sulphides and mercaptans. This is probably due to the difficulty of isolating them from a mixture with aromatic hydrocarbons and other sulphur compounds and the fact that their

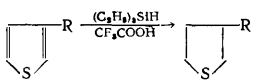
main bulk is present in the relatively little studied high-boiling petroleum distillates.



Thiophens are more resistant to oxidation than sulphides. The introduction of electron-donating substituents into the thiophen molecule promotes its oxidation to the sulphone[89]. Stable sulphones are formed in the presence of two symmetrically located substituents:

On treatment with strong oxidants, the side chains are converted into carboxy-groups. As regards the degree of oxidation of petroleum thiophens, the available literature data do not permit a clear-cut analysis, because the oxidised products have been characterised only by their molecular weights and boiling points and the sulphones derived from petroleum thiophens have not been isolated[3,90,91].

Electrophilic substitution reactions are characteristic of thiophens, which is associated with the enhanced electron density in the α-position due to the presence of the sulphur atom. The sulphonation method has been used[92] for the isolation of a mixture of thiophens from petroleum distillates; the degree of their extraction did not exceed 45%.



In reactions with bivalent mercury salts thiophens form organometallic derivatives:

However, the regeneration of thiophens from the mercurated products involves considerable losses[93]. The reaction has not therefore found extensive practical applications.

In a series of analytical studies[94–96] of middle and high-boiling distillates the method involving the dealkylation of thiophens free from other groups of OSC was used. It may be that the dealkylation reaction will be of practical importance for the analysis of fairly thoroughly purified concentrates of petroleum thiophens.

Ionic hydrogenation[97] with trifluoroacetic acid and triethylsilane can be used successfully to convert petroleum thiophens into the corresponding sulphides[97]:

The results of experiments on the hydrogenation of thiophen concentrates of different composition have shown that more severe conditions (a longer reaction time and a greater excess of trifluoroacetic acid) are required to attain a 70–86% degree of conversion of a mixture of thiophens than in the hydrogenation of individual thiophens[98]. The study of the structural-group composition of the products showed that the main compounds are monothiacycloalkanes and thiaindans; apparently derivatives of thiophens and benzothiophens were hydrogenated and in the case of the latter only the thiophen ring was hydrogenated.

Sulphuric acid concentrates of OSC obtained after the ionic hydrogenation reaction contain up to 70% of thiacycloalkanes and 20% of thiaindans, the overall sulphide content being 96%. Thus the application of the ionic hydrogenation method makes it possible to increase by 15–20% the content of sulphides in the sulphuric acid concentrates[23].

Since aromatic hydrocarbons (benzene, naphthalene, and their homologues) do not enter into the ionic hydrogenation reaction even under severe conditions, the method can be used to hydrogenate the thiophens in aromatic sulphur compound concentrates, particularly since they can be obtained (see Section II) on treatment with any solvents which extract aromatic hydrocarbons selectively. Further separation of the aromatic and organosulphur compounds can be achieved by sulphuric acid extraction[16,18]. Two products of practical importance can be obtained by this procedure: sulphide concentrates and aromatic hydrocarbons.

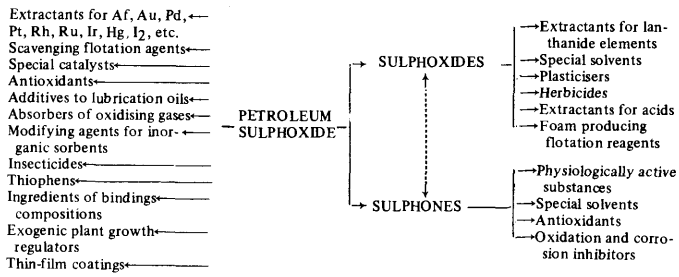


Figure 6. The applications of the sulphides in petroleum distillates; continuous arrows—tested on semi-industrial scale; dashed arrows—tested in the laboratory.

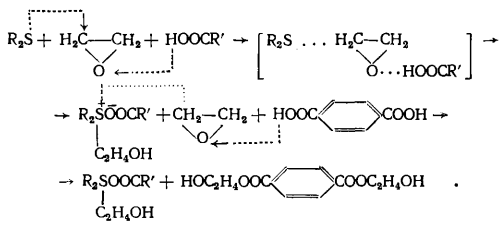
The ionic hydrogenation method is also promising for the conversion of thiophens directly in the distillates into the corresponding thiacycloalkanes, which are then extracted; this is particularly valuable in the study of the composition of the OSC in high-boiling petroleum distillates.

V. THE USE OF ORGANOSULPHUR COMPOUNDS OF PETROLEUM IN THE NATIONAL ECONOMY



Studies of the compositions and properties of petroleum sulphides led to the discovery of their practical applications; in many instances large-scale industrial tests have been made (Fig.6). The oxidation of petroleum sulphides to sulphoxides and sulphones is of great practical importance; the preparation and properties of the latter have been examined in detail in a review[79]. It has been shown that sulphoxides can find extensive applications in hydrometallurgy and non-ferrous metallurgy as extractants and flotation agents. Studies in recent years have established that sulphoxides can be employed also in the chemical and petrochemical industry as effective solvents for phenols, resorcinol, catechol, hydroquinone[99], aromatic hydrocarbons[100], and acid oxides (SO_2, NO_2) contained in the waste gases released into the environment[101], and also as the starting materials for the synthesis of sulphones.

An extraction method has been developed for the elimination of monochloroacetic acid from sulphuric[102] and acetic[103] acids with the aid of sulphoxides. Sulphoxides have been tested successfully for the extraction of lower monocarboxylic acids from sewage[104] and of sulphur dioxide from industrial waste released into the atmosphere[105].

Some of the direct applications of petroleum sulphides are examined below.

1. Sulphides as Catalysts of the Oxidation of Terephthalic Acid

Individual OSC, for example thiacyclohexane[106], are known to be effective catalysts of the hydroxyethylation of terephthalic acid.

It has been shown[107] that petroleum OSC as well as thiacyclohexane are converted into a sulphonium salt by reaction with epoxyethane and terephthalic acid. The active complex obtained exhibits a high selectivity in the formation of bis-β-hydroxyethyl terephthalate.

OSC concentrates and purified sulphides isolated from petroleum distillates have been tested[23]. It has been found that an increase of the concentration of sulphide sulphur from 10.6 to 22.4% has a significant effect on the catalytic activity of sulphide concentrates, which is associated with the decrease of their content of thiophen derivatives. It has been noted that it is useful to obtain the sulphonium salts beforehand from OSC concentrates, epoxyethane, and terephthalic acid and then use them as catalysts.

A combined study has shown that the use of OSC concentrates (with $S_{sulph} \geq 20\%$) in the stage involving the hydroxyethylation of terephthalic acid makes it possible to obtain poly(ethylene terephthalate) with satisfactory physicomechanical parameters.

2. Petroleum Sulphides as Highly Effective Extractants for Noble Metals

The complex formation reaction between the sulphides and various metal salts is of enormous practical importance for the concentration and separation of silver[108,109] and platinum-group metals[29]. The results of studies on the extraction of silver by petroleum sulphides of different structure have been published[108] and a virtually quantitative isolation of silver of high purity has been achieved.

The extraction of platinum metals by petroleum sulphides in the presence of cumenyl and pentyl hydroperoxide has been investigated and it has been shown that all platinum metals are extracted from hydrochloric acid solutions (0.5 to 5.0 M) with a high partition coefficient[29]. The dependence of the rate of extraction of platinum metals on the nature of the diluent has been established. The possibility of the selective separation of a mixture of noble metals in the regeneration stage has been demonstrated[29].

3. Petroleum Sulphides as Effective Flotation Agents

The possibility of using petroleum sulphides as scavenging reagents and foaming agents in the flotation of copper-nickel and copper-molybdenum sulphide ores has been studied[110-112]. The scavenging and foam-forming properties of sulphides have been compared with those of reagents widely used in flotation such as potassium butylxanthate and the T-66 foaming agent. It has been shown that the scavenging capacity of the sulphides approaches that of the xanthate and their foam-forming capacity is greater than that of the T-66 foaming agent. The boiling points of the sulphide fractions, i.e. their molecular weights, have little influence on the results of flotation. A decrease of the foam-forming capacity of sulphides with increasing boiling point has been observed. It has been shown that the use of petroleum sulphides for the enrichment of polymetallic sulphide ores increases the degree of extraction of non-ferrous and noble metals and greatly reduces the cost of flotation agents.

4. Petroleum Sulphides as Exogenic Regulators of the Growth of Gramineous Plants

Studies have shown a high effectiveness of sulphides as a non-root feed for rye and wheat[113]. It follows from the experimental data that sulphides have a positive influence on the assimilation of nitrogen by plants and also promote a more intense formation of proteins. Spraying of spring wheat and winter rye with a solution of sulphides increases the crop and the quality of the grain as well as the yield of protein per hectare. Supplementary feeding with petroleum sulphides increases the crop of certain varieties of wheat by 13.5%.

5. OSC Concentrates as Binding Additives to Soils

Organosulphur compounds exhibit an effective adhesion and it is therefore of interest to test them as additives to soils. Between 0.9 and 1.1% of the OSC concentrate was added to a composition of binding substances consisting of crude petroleum and cement. The results of tests showed that, when the amount of binding material containing added OSC is 9.1–11.15% of the mass of dry soil, the stability of the latter increases by 30–50% and the water-stability coefficient increases by 11–15% compared with soils stabilised with petroleum containing added cement[114]. Thus dusty sands stabilised by the binding material have effective physicomechanical properties.

---o0o---

In conclusion it must be emphasised that the study of the structural-group composition of the OSC of petroleum distillates is laborious and complicated. However, these investigations not only expand our ideas about the principal components of petroleums but, in combination with the development of industrial methods for their isolation, make it possible to create a scientific basis for the rational utilisation of the very rich store of organosulphur compounds which are of practical interest and are difficult to synthesise; they also permit the development, on the basis of studies of the chemical reactions of OSC, of methods of preparation of a wide variety of bifunctional and polyfunctional compounds of practical importance.

Some Problems of the Kinetics of Radical Reactions in Solid Polymers

N.M.Emanuel', V.A.Roginskii, and A.L.Buchachenko

The kinetics of radical reactions in solid polymers have a number of features which are examined in the present review in relation to the destruction of macroradicals, the reactions of macroradicals with macromolecules, and also the reactions involving low-molecular-weight substances. The mechanism and kinetics of the migration of the free valence in solid polymeric matrices are discussed in detail. Attention is concentrated on the relation between molecular mobility and the kinetics of radical reactions in solid polymers.
The bibliography includes 154 references.

I. INTRODUCTION

Interest in theoretical problems of the kinetics of radical reactions in solid polymeric matrices arose in the period between the 1950's and 1960's in connection with the development of the radiation chemistry of polymers and later in connection with roblems of the stabilisation and modification of polymers and the micromechanics of their decomposition.

The first studies already showed that the kinetics of radical reactions in solid polymers are distinguished by a number of features: they depend to a greater extent than in the liquid phase on the physical properties of the medium, primarily on the molecular mobility; the main ideas about chemical kinetics, developed for reactions in the gas and liquid phases, namely the Law of Mass Action and the Arrhenius equation, in many instances do not hold formally, etc. This makes it necessary to regard the kinetics of radical reactions in solid polymers as an independent branch of chemical kinetics. The problems of the kinetics of radical processes in solid organic low-molecular-weight matrices are related to this field. The results of these studies have been surveyed in a series of reviews and monographs[1-11].

Unusual phenomena have been recently observed in this field, which entailed the creation of new theoretical models; the amount of quantitative kinetic information has increased. The aim of this review is to analyse the present state of the experimental and theoretical studies (primarily those of recent years) on the kinetics of radical reactions in solid polymers, to discover the main characteristics of these processes, and to formulate the main ideas and key problems. At the same time the review does not claim to cover fully the extensive experimental and theoretical data available.

II. KINETICS OF RADICAL REACTIONS IN SOLID POLYMERS

The kinetics of radical reactions in solid polymers are distinguished by a number of phenomenological features.

1. The transition from the liquid phase to solid polymers is frequently accompanied by the replacement of simple kinetic laws by complex laws specific to the solid phase. The most striking example is provided by the so-called stepwise kinetics—the decrease of the reaction rate long before the complete consumption of the reactants ("kinetic arrest"). It is observed in the recombination of radicals and radical pairs, in the addition of oxygen to macroradicals, in radical substitution, etc. The theory of stepwise kinetics has been described[2,10-13]. It is assumed that the observation of stepwise kinetics shows that the reacting species have a range of rate constants†. Therefore, in contrast to the usual kinetics, describing the reaction with the aid of a single "monchromatic" constant, the stepwise kinetics are frequently also referred to as "polychromatic".

2. In most cases the experimental Arrhenius parameters of the rate constants for bimolecular reactions in solid polymers (the effective activation energies and pre-exponential factors) are much higher than the "normal" values characteristic of gas-phase and liquid-phase reactions; they are frequently linked by the compensation relation [the compensation effect (CEF)]:

$$\lg (k_0)_{\text{eff}} = a + bE_{\text{eff}} \quad . \qquad (1)$$

The CEF is common in both chemical kinetics and in the kinetics of certain physical processes (diffusion, viscous flow, molecular mobility, etc.) and has been discussed in a number of studies[1,7,14-18]. In the vast majority of cases the CEF does not have a real physical significance and is merely a consequence of the incorrect application of the Arrhenius equation. The most general idea concerning the origin of the CEF has been put forward by Lebedev et al.[15] If the true activation energy varies with temperature for any reason, then the Arrhenius equation is strictly speaking inapplicable to the analysis of experimental results. However, if the temperature variation of the activation energy ($\partial E/\partial T$) is not too great, then the experimental data can be described formally by the Arrhenius equation within a comparatively narrow temperature range, but the effective values of E_{eff} and $(k_0)_{\text{eff}}$ then obtained differ from the true values:

$$E_{\text{eff}} = E - T(\partial E/\partial T) \quad ,$$
$$(k_0)_{\text{eff}} = k_0 \exp\left(-\frac{1}{R}\frac{\partial E}{\partial T}\right) \quad ,$$

and are linked by the compensation relation (1). If, for example, E = 10 kcal mol^{-1} and $\partial E/\partial T = -0.05$ kcal mol^{-1} K^{-1}, then at 300 K we obtain E_{eff} = 25 kcal mol^{-1}, i.e. 2.5 times greater than the true value. This is compensated by the apparent increase of the pre-exponential factor by a factor of 10^{11}.

†A recent study of the kinetics of the reaction $\dot{C}_2H_5 + O_2 \rightarrow C_2H_5\dot{O}_2$ in solid methanol[14] has shown that this conclusion is not ambiguous. If the stepwise kinetics are due to a range of rate constants, then the decrease of the concentration of $\dot{C}_2H_5$ can be described by the expression

$$[\dot{C}_2H_5] = [\dot{C}_2H_5]_0 \sum g_i \exp(-k_i[O_2]t) \quad ,$$

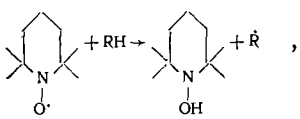
where g_i is the statistical weight of the rate constant k_i. The $\lg\{[\dot{C}_2H_5]/[C_2H_5]_0\} - [O_2]_t$ kinetic curves obtained for different values of $[O_2]\{[O_2] \gg [C_2H_5]_0\}$ should merge, which is not observed.

Another cause of the appearance of the CEF may be associated with the "polychromaticity" of the reaction kinetics in the solid phase. If the presence of a range of rate constants for the reacting species is caused by the presence of the corresponding range of activation energies, then the compensation effect automatically arises[16,17]. One must note that the CEF can obtain also for a fairly narrow range of rate constants when the "stepwise nature" of the kinetics is not yet observed directly.

3. The absolute values of the rate constants for reactions in solid polymers are in most cases much lower than the rate constants for the analogous reactions in the gas and liquid phases. This applies not only to rapid reactions, whose rates are limited in polymeric matrices by the rate of encounters of the reactants (this is quite natural), but also to the comparatively slow processes occurring under kinetic conditions.

4. As shown below, the kinetics of reactions in solid polymers are associated with the kinetics of molecular movement. In principle, there are two "channels" via which the molecular dynamics of the polymer can influence the kinetics of chemical reactions: (1) the change in the rate constant for the encounters as a result of a change in the coefficients of the translational diffusion of low-molecular-weight reactants as well as macroradicals and macromolecules (in the latter case as a consequence of the change in the frequencies and amplitudes of segmental movements); (2) the influence on the interaction of reacting species in the vapour and in the cage, i.e. on the chemical step proper. The first "channel", transmitting the influence of molecular mobility on the kinetics, is fairly trivial. On the other hand, the direct influence of molecular mobility on the chemical step is of great interest—it is specific to reactions in solid polymers and so far has no analogy in the liquid phase.

Apart from the fundamental characteristics of the kinetics of reactions in solid polymers indicated above, one may also mention a series of other less significant features—the clear kinetic non-equivalence of different regions of the polymer and the non-uniformity of the distribution of the reactants in the specimen (particularly in amorphous-crystalline polymers), which is frequently encountered. These anomalies are associated mainly with the structural-physical inhomogeneity (microheterophase nature) of many polymers and a fairly extensive "freezing" of the diffusion of the reacting species.



With increase of temperature, the intensity of molecular movement in the polymer increases, while at the same time the typical "solid-phase" stepwise kinetics approach increasingly closely the usual "liquid phase" kinetics. The glass point T_g constitutes the boundary, although the latter is not always sharp. On transition through T_g, a change in the kinetic laws governing the destruction of macroradicals[10], the isomerisation of low-molecular-weight substances in polymeric matrices[19-21], and complex processes such as oxidation[22] and graft polymerisation[23], is observed; there is also a change in the nature of the influence of the external pressure on the kinetics of the recombination of macroradicals[22-25]. At the temperature T_g a break is sometimes observed in the curves for the temperature variation of the rate of decomposition of radical initiators[26] and for the destruction of macroradicals[27,28], as well as for the diffusion coefficients of gases and vapours[29].

The stepwise solid-phase kinetics, which obtain under the conditions where molecular movements are extensively frozen below T_g, have been frequently discussed[1-4,10-13]. On the other hand, the kinetics of reactions in "softer" polymeric matrices, which are of great practical interest, have begun

to be studied extensively only in recent years. In the present review attention will be concentrated on the latter case.

Before considering the kinetics of specific radical reactions in solid polymers, it is necessary to answer the question whether the above kinetic anomalies are due to the high molecular weight of the reacting species or whether they are associated with the phase state of the polymer as a solid. Many factors support the second hypothesis.

1. The rate constants for the reactions of a stable nitroxy-radical, i.e.

with fused polyethylene and its low-temperature analogues (n-heptane and n-hexadecane) are identical at 175–220 °C.[30]

2. The rate constants for the reactions of the t-butoxy-radical with polypropylene, polystyrene, and their low-molecular-weight analogues in solution at 125 °C also hardly differ[31]. At a low temperature (45 °C) certain differences do appear, but they are probably caused by the presence under these conditions of a specific conformation of the macromolecules (coil) which decreases the accessibility of many sections of the macromolecules and is equivalent to a decrease of the effective concentration of the polymer.

3. The rate constants for the destruction of peroxy-macroradicals of polystyrene in solution at 25 °C (1.6×10^5 litre mol^{-1} s^{-1} [32]) and their low-molecular-weight analogues—the peroxy-radicals derived from isopropyl-benzene (10^4–10^5 litre mol^{-1} s^{-1} [33,34])—are very similar.

On the other hand, many kinetic features of the radical reactions in solid polymers are observed also in those cases where both reactants are low-molecular-weight substances (see Section III below) and also for reactions in solid low-molecular-weight matrices[1–3,8]. Thus the main cause of the kinetic anomalies of reactions in solid polymeric matrices is associated with the characteristics of the phase state of the above systems, mainly with the restriction of the molecular movement.

III. REACTIONS INVOLVING LOW-MOLECULAR-WEIGHT SUBSTANCES

The characteristic features of these reactions consist in the fact that at least one of the reactants migrates comparatively readily in the polymer via physical diffusion and the rate of the process is limited by the encounters of the reactants only for fairly rapid reactions. However, since the diffusion coefficients of low-molecular-weight substances in solid polymers are nevertheless lower than in liquids, the boundary at which the kinetics change to the diffusion-dependent type shifts to the region of slower reactions. For the majority of processes involving low-molecular-weight substances, the problem of their chemical nature does not arise and the kinetic information obtained can be referred to a specific elementary reaction.

The theory of diffusion-controlled reactions in solid matrices (including polymeric matrices) has been considered in a number of studies[2,7,10,35,36] and in the most general form by Whaite[37]. For a bimolecular reaction between A and B, where B is a low-molecular-weight substance, it is possible to distinguish three stages:

(1) the macrodiffusional stage in which the reactants are non-uniformly distributed in the given volume and B diffuses as a consequence of its concentration gradient;

(2) the microdiffusional stage—there is no concentration gradient and the rate of the process is determined by the rate of encounters of A and B, the encounters resulting in the formation of the pair [A...B];

(3) the kinetic stage—chemical interaction in the pair.

The case where there is no concentration gradient is of greater interest. According to the simplest model[35], chemical interaction takes place when A and B enter a single cage with a volume v^* (of the order of magnitude of the molecular volume). In the quasi-stationary approximation, we obtain the following expression for the concentration of the pairs [A...B]:

$$-d[A]/dt = -d[B]/dt = k_{eff}[A][B] \quad ,$$

$$k_{eff} = \frac{k_d k_x}{k_d + k_x} v^* \quad , \qquad (2)$$

where k_d and k_x are the rate constants for the microdiffusional and chemical stages. If $k_d \ll k_x$, then $k_{eff} \cong k_d v^*$ (stage 2 is rate-limiting); on the other hand, if $k_d \gg k_x$, then $k_{eff} \cong k_x v^*$ (stage 3 is rate-limiting). In the general case k_d and k_x are combined in accordance with the law of kinetic resistances [Eqn.(2)].

Although there are extensive experimental data on reactions with participation of low-molecular-weight substances, a large proportion of these are either qualitative or the kinetics have been studied under specific conditions (mechanodegradation, low temperature#), which preclude a sufficiently rigorous comparison of the rate constants obtained with the corresponding parameters of the liquid-phase reactions.

Fairly numerous studies have been made on the addition of oxygen to macroradicals. This process is of interest for the kinetics of the oxidation of polymers. The rate constants for the interaction of O_3 with alkyl radicals in the liquid phase are large (~10^8 litre mol^{-1} s^{-1} [33]) and therefore in solid polymers, where the diffusion coefficients of O_2 are significantly lower than in a liquid, this reaction usually proceeds under diffusion-dependent conditions[36,40–42]. Thus in polystyrene the rate of addition of O_2 is independent of the nature of the radicals[40]. The diffusion coefficients of O_2, obtained on the basis of the kinetics of the reaction $\dot{R} + O_2 \rightarrow R\dot{O}_2$, are close to the values found by independent methods. For example, D_{O_2}, obtained on the basis of the kinetics of the oxidation of allyl macroradicals in the amorphous phase of γ-irradiated polyethylene, is 1×10^{-10} cm^2 s^{-1} at 190 K,[41] while direct measurements of D_{O_2} [43] yielded 5×10^{-11} cm^{-2} s^{-1} (extrapolation to 190 K). The stepwise kinetics of the oxidation of macroradicals are observed at low temperatures[40,42], which agrees with the "stepwise" nature of the diffusion of oxygen itself[44]. However, according to Bresler and Kazbekov's data[3], the interaction of O_2 with the macroradicals of poly(methyl methacrylate), polystyrene, and poly(vinylacetate), obtained in the mechanodegradation of polymers, takes place under kinetic conditions and the observed rate constants are clearly lower than the diffusion-dependent values.

#At low temperatures tunnel effects can be significant[38,39].

Table 1. The rate constants for the reactions of low-molecular-weight substances in solid polymers and in the liquid phase (at 25 °C).

***R = $-COC_6H_5$.

Under diffusional conditions, the phenoxy-radicals apparently recombine with the macroradicals. In the liquid phase the rate constants for the reaction

(here and henceforth R′ = t-Bu in structural formulae) are close to 10^8 litre mol^{-1} s^{-1};[45] in solid polypropylene this quantity is significantly reduced: $k = 6 \times 10^6$ litre mol^{-1} s^{-1} for X = $C(CH_3)_3$ at 80 °C.[46] The diffusion coefficient of the 2,4,6-tri-t-butylphenoxy-radical estimated from these data (2.5×10^{-8} cm^2 s^{-1} at 80 °C) agrees with the diffusion coefficient of ionol, which has a similar molecular weight, measured directly in this polymer[47].

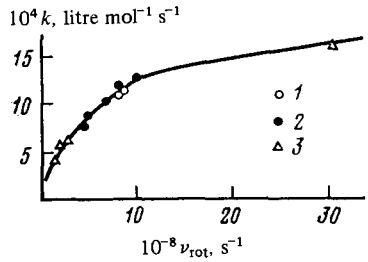
The reactions occurring under kinetic conditions are of much greater interest for the theory of radical reactions in solid polymers (Table 1). The data presented in Table 1 must be treated with extremely great caution. One of the reasons for this is that one cannot always eliminate from the polymer the residual amount of the solvents usually employed for the introduction of low-molecular-weight substances into the polymer. As will be shown below, sometimes even traces of the solvent are capable of greatly increasing the rates of reaction in solid polymers. For this reason, the measured rate constants[52,53,55,56] must be regarded as merely the upper limits of the true rate constants in solid polymeric matrices.

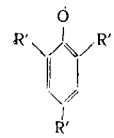
The first feature to which attention is drawn in the analysis of the data in Table 1 is a significant decrease (by a factor up to ~10^4) of the rate constants for reactions in solid polymers compared with the liquid phase. In most cases this is caused by the increase of the activation energy (the CEF is then usually observed); on the other hand, for reactions of hydrogen atoms, this is caused by the decrease of the pre-exponential factor§. We emphasise yet again that the decrease of the rate constants on transition to solid polymers, noted above, is in no way associated with diffusion-dependent obstacles—in certain cases (for example, in reactions of the methyl radical with polymers, of phenoxy-radicals with polymeric hydroperoxides, and of nitroxy-radicals with phenols) the rate constants for the encounters of the reactants, estimated from the diffusion coefficients of the corresponding low-molecular-weight substances exceed the experimental constants by 5–10 orders of magnitude.

Another characteristic feature of reactions involving low-molecular-weight substances, which was first observed by Karpukhin et al.[57], is some levelling of the reactivities of reactants having similar structures. Thus the rate constants for the reactions of peroxy-macroradicals with oxidation inhibitors (phenols, aromatic amines) in the solid polymers differ much less than in the liquid phase[46,50,57,59]. This phenomenon can hardly be explained by the fact that the above reactions proceed under diffusional conditions. This is particularly evident for reactions in the comparatively "soft" polypropylene at high temperatures, where the calculated rate constants for the encounters of the inhibitors with peroxy-radicals exceed the experimental reaction rate constants by a factor of 10^2–10^3.

§We may note that the rate constants for the reactions of hydrogen atoms have been measured at a low temperature where the tunnel mechanism frequently operates[38,39] and low pre-exponential factors are in fact characteristic of the tunnel mechanism.

The influence of molecular mobility on the rates of reactions involving low-molecular-weight radicals is extremely interesting. The rate constants for the reactions of phenoxy-radicals with polyolefin hydroperoxides[52,53] and of the nitroxy-radical with phenolic compounds[55] and methylenequinone[56] increase appreciably (the pre-exponential factors and activation energies diminish) after the addition of small amounts of chemically inert aromatic solvents and gradually approach the "liquid-phase" values (Table 2). The role of solvents, plasticising the polymer, evidently reduces to increasing the molecular mobility. Indeed the increase of the rate constants is correlated with the increase of the rotational frequency of the paramagnetic probe[52,55,56], characterising the intensity of the segmental movements in the polymer (Fig. 1). Since the above reactions are known to occur under kinetic conditions, one must consider the influence of molecular mobility directly on the chemical step. Presumably the decrease of the rate constants for the other reactions in Table 1, on passing from the liquid phase to the solid polymer, is also associated mainly with the decrease of molecular mobility.





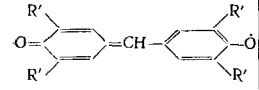


Figure 1. Dependence of the rate constant for the reaction of the 4-benzoyl-2,2,6,6-tetramethylpiperidinyloxy-radical with 2,4-di-t-butylphenol at 60 °C in polymer matrices [*1*) polyethylene; *2*) polypropylene; *3*) polystyrene] on the rotation frequency of the nitroxy-radical ν_{rot} (according to the data of Griva et al.[55]).

IV. DESTRUCTION OF MACRORADICALS

Although the number of studies devoted to the kinetics of the destruction of radicals in solid polymers is very large (they have been surveyed in a number of reviews[4,6-8,10-12]), only comparatively few of them define sufficiently clearly the experimental conditions: the nature of the radicals, their location and spatial distribution (the latter is particularly significant when the radicals are generated by ionising radiation), the concentration of low-molecular-weight substances, which can significantly influence the kinetics of the destruction process, as will be shown below, etc. We were therefore forced to approach very cautiously the discussion of the extensive experimental data, preference being given to studies in which the experimental conditions have been defined sufficiently unambiguously.

At temperatures below T_g the rate of destruction of radicals is usually low and is frequently described by stepwise kinetics. Above T_g, the usual bimolecular kinetics are as a rule observed¶, but the rate constants for the destruction of microradicals (k_t) are almost always lower than the corresponding constants in the liquid phase†, the effective activation energies are high, sometimes reaching 30–40 kcal mol^{-1}, and the CEF is usually observed. The kinetics of the destruction process are strongly influenced by factors which alter the intensity of the molecular movements in the polymer–orientation, mechanical deformation, external pressure, plasticisation, etc. (for further details, see below).

Table 2. The influence of benzene on the rate constants for the reactions of phenoxy-radicals with polypropylene hydroperoxide at 25 °C.

Phenoxy-radical	$[C_6H_6]$, %	k_0, litre mol^{-1} s^{-1}	E, kcal mol^{-1}	k, litre mol^{-1}	References
	0	$9.7\cdot10^{15}$	26.6	$3.1\cdot10^{-4}$	[46]

	100	$1.6\cdot10^{5}$	10.0	$6.8\cdot10^{-3}$	[54]

*For the reaction with t-butyl hydroperoxide.

In solid polymers the rate of destruction of macroradicals is usually limited by the rate of their encounters and the problem of the kinetics of the destruction process thus reduces to the problem of the mechanism and kinetics of the processes leading to the encounters. For this reason, the study of the destruction of macroradicals yields information about the physical and chemical processes resulting in the migration of the free valence in the solid polymer rather than about the nature of the elementary step. One can imagine two fundamental mechanisms of such migration—physical diffusion of macroradicals and chemical migration of the free valence (relay process, "chemical" diffusion), which takes place as a result of the alternation of chemical reactions.

The rate constant k_e for the encounter of the radicals $\dot{R}_A$ and $\dot{R}_B$ is related to their diffusion coefficients (physical or "chemical" diffusion) D_A and D_B (cm^2 s^{-1}) by the

¶Faster initial sections are frequently noted, which is characteristic of diffusion-controlled processes[10,37].

†In the liquid phase the recombination (disproportionation) rate constants are usually 10^8–10^9 litre mol^{-1} s^{-1}, while the activation energies are close to zero. Peroxy-radicals are an exception; the rate constants for their destruction are significantly lower, particularly for tertiary peroxy-radicals (10^3–10^5 litre mol^{-1} s^{-1}, activation energies up to 8–10 kcal mol^{-1}).[33,59].

Smoluchowski equation:

$$k_e = 4\pi a(D_A + D_B)6\cdot 10^{20} \quad \text{(litre mol}^{-1}\text{ s}^{-1}\text{)},$$

where a is the effective distance (cm) over which the radicals interact chemically. If $D_A = D_B = D$, then

$$k_e \simeq 1.5\cdot 10^{22} aD \quad \text{(litre mol}^{-1}\text{ s}^{-1}\text{)}.$$

In the chemical migration the physical significance of the quantity D depends on the specific migration mechanism (see below), but in any case D is an effective parameter characterising the rate of migration of the free valence. As in the liquid phase, the quantity a is close to the kinetic diameter of small molecules (3–5 Å)#. The possible mechanisms of the encounters are examined below.

1. Physical Diffusion

At temperatures above T_g the intensity of small-scale molecular movements in polymers is fairly high and does not differ in principle from that in viscous liquids. For example, the rotation of stable nitroxy-radicals (the paramagnetic probe), controlled by the low-amplitude movements of elements of the macromolecules, takes place at a frequency in excess of 10^9 s^{-1} in polypropylene and polyethylene at temperatures in excess of 60 °C.[71–73]. According to high-resolution neutron spectroscopic data[74], the hydrogen atoms in the C–H bonds in the amorphous phase of polyethylene execute random movements about the equilibrium position with an amplitude of 2.5 Å and a frequency of $5 \times 10^{12} \exp(-4500/RT)$ ($\sim 5 \times 10^9$ s^{-1} at 60 °C), which is close to the rotation frequency of the paramagnetic probe. However, with the exception of radical pairs, the average distance between the radicals almost always significantly exceeds 3–5 Å and movements with this amplitude cannot therefore by themselves ensure the encounter of the radicals.

The movements of segments of the macromolecules are characterised by a much greater amplitude (up to 30 Å), but the diffusion coefficients corresponding to this type of molecular mobility are usually fairly low even at temperatures above T_g. Thus $D \cong 10^{-21}$ cm^2 s^{-1} near T_g in polystyrene[65]. In the comparatively "soft" polyethylene at 60 °C (higher by 60–80 °C than T_g) we have $D \cong 10^{-18}$ cm^2 s^{-1},[60] which corresponds to a rate constant for the encounters (for a = 5 Å) $k_e \cong 10^{-3}$ litre mol^{-1} s^{-1}; on the other hand, the experimental value of k_t for the destruction of peroxy-radicals under the same conditions is greater by 7 orders of magnitude[61]. This constitutes a further reason why there is no point in considering the diffusional mechanism of the encounters of macroradicals in the crystalline phase or in the amorphous phase at temperatures T_g, because the intensity of the segmental movements is then negligible. One must note that in many instances of practical importance (for example, in the oxidation of polyolefins[75]) the average distance between the radicals amounts to hundreds of angstroms and their encounters cannot be ensured by physical diffusion alone even in principle.

#According to Butyagin[70], the quantity a reaches 75 Å in polymers. Such high values of a, which evidently have no physical significance, are apparently obtained as a result of the not entirely correct application of Waite's diffusional model[37] to the analysis of experimental data for the kinetics of the destruction of macroradicals.

The absence of a dependence of the rate of destruction of macroradicals on their nature is a virtually unambiguous criterion of the diffusional mechanism of the encounters. This case apparently obtains above T_g in isobutylene and in the ethylene–propene copolymer, where the rate constants for the destruction of alkyl and peroxy-radicals are similar and the frequencies of the diffusional jumps calculated from the kinetic data for the destruction process are of the same order of magnitude as the frequencies of the segmental movements determined by independent methods[10]. On the other hand, the rate constants for the destruction of macroradicals usually depend greatly on their nature (Table 3) and this phenomenon cannot be accounted for by a change in the probability of reaction on encounter, because the peroxy-radicals, for which the destruction rate constants in the liquid phase are significantly lower than for other active radicals, are in fact destroyed at the highest rate[33]. A diffusional mechanism of the encounters can be postulated for radicals with a low reactivity (for example, the allyl radicals in polyethylene[60]), whose chemical migration is unlikely.

Table 3. The rate constants for the destruction of certain macroradicals (at 60 °C).

Analysis of experimental data suggests that the diffusional mechanism of the destruction of macroradicals in solid polymers is more an exception than the rule, and that in most cases neither the amplitude nor the intensity of the molecular movements can ensure the encounter of the radicals. From the standpoint of the diffusional mechanism of the migration of the free valence, the acceleration of the destruction of macroradicals in the presence of low

concentrations of chemically active low-molecular-weight substances (H_2, O_2, Cl_2, cumenyl hydroperoxide, monomers, etc.) is completely inexplicable. There is no doubt that the main mechanism ensuring the encounter of macroradicals in solid polymers at not unduly high temperatures is "chemical" diffusion.

2. The Relay Migration of the Free Valence with Participation of Macroradicals Alone

This version of "chemical" diffusion has been most widely discussed in the literature. The migration of free valence can be achieved as a result of a sequence of identical-transfer reactions, for example, for alkyl radicals in polyethylene:

$$\sim CH_2\dot{C}HCH_2 \sim + \sim CH_2CH_2CH_2 \sim \rightarrow \sim CH_2CH_2CH_2 \sim + \sim CH_2\dot{C}HCH_2 \sim \quad (3)$$

or the repetition of a cycle of reactions, for example for the destruction of peroxy-radicals:

$$R\dot{O}_2 + RH \rightarrow \dot{R} + ROOH \quad , \quad (4)$$

$$\dot{R} + O_2 \xrightarrow{fast} R\dot{O}_2 \quad . \quad (5)$$

We shall refer to this type of migration mechanism as trivial relay; it has been proposed by Dole et al.[76] and Koritskii et al.[77] and subsequently developed[7,65,78]. The effective diffusion coefficient, characterising the trivial relay, is defined by the expression

$$D_r = \frac{\lambda_r^2 k_p [RH]}{6} \quad ,$$

where λ_r is the average distance over which the free valence migrates during a single "step" (of the order of magnitude of the length of a chemical bond), k_p is the rate constant for the rate-limiting reaction in the relay process [for example, reaction (3) or (4)] and [RH] is the concentration of the monomeric unit; the product k_p[RH] has the significance of the jump frequency. The rate constant for encounters is given by the following expression:

$$k_e = \frac{8\pi a \lambda_r^2 k_p [RH]}{6} 6 \cdot 10^{20} \simeq 2.5 \cdot 10^{21} a \lambda_r^2 k_p [RH] \text{ (litre mol}^{-1}\text{ s}^{-1}\text{)}. \quad (6)$$

The principal argument in support of the trivial relay is the sharp increase of the constant k_t in the series of radicals allyl < alkyl < peroxy,[8] in qualitative agreement with the variation of k_p in the same sequence[33].

The most significant experimental confirmation of this mechanism of the migration of the free valence is available for peroxy-radicals. The destruction of peroxy-macroradicals is accompanied by the chain process involving the absorption of O_2 and the formation of a hydroperoxide[7,79,80]. In fact the chain oxidation of polymers is itself a process involving the relay migration of the free valence.

Oxygen in many instances accelerates the destruction of alkyl macroradicals even when the concentration of peroxy-radicals is too low to be detected by EPR.[81-83]. This is possible if the rate of reaction (5) is comparatively low and the chain propagation reaction (4) is in fact very effective. Analysis of this situation shows[81,82] that the kinetics of the destruction of alkyl radicals should obey a bimolecular law and the effective rate constant should be proportional to the oxygen concentration, which agrees with experiments[81].

Comparison of the experimental values of k_t and k_e, calculated by Eqn.(6), is possible only in rare instances, since accurate values of the rate constant k_p in solid polymers, necessary for the calculation of k_e, are usually unknown.

Sufficiently reliable values of k_t and k_p are available for peroxy-radicals in amorphous atactic polypropylene[64] and in the amorphous phase of isotactic polypropylene[62,80,84]. It has been shown[62,85] that at 60 °C $k_t = 6 \times 10^2$ litre mol^{-1} s^{-1} and $k_p = 1.5 \times 10^{-2}$ litre mol^{-1} s^{-1}. Assuming that $\lambda_r = 3 \times 10^{-8}$ cm, $a = 5 \times 10^{-8}$ cm, and [RH] = 22 M, we find $k_e = 3.7 \times 10^{-2}$ litre mol^{-1} s^{-1} from Eqn.(6), i.e. lower by 4 orders of magnitude than the experimental value of k_t. A similar result has been obtained also for atactic polypropylene. In order to achieve agreement between k_e and k_t, it is necessary to assume that, under the given conditions, the "step" of the relay is $\lambda_r \cong 400$ Å, which is naturally unrealistic within the framework of the trivial relay.

An unusual version of the relay mechanism of the migration of the free valence obtains under the conditions of graft polymerisation. When the monomer M is brought into contact with a polymer containing stabilised macroradicals $\dot{R}_p$, a chain polymerisation process develops:

$$\dot{R}_p + M \rightarrow [\dot{R}_M]_1$$
$$\cdots\cdots\cdots$$
$$[R_M]_i + M \xrightarrow{k_{po}} [\dot{R}_M]_{i+1} \quad .$$

This process is accompanied by an appreciable acceleration of the destruction of macroradicals.

One chain propagation step leads to the migration of the free valence over a distance λ_{po}, equal to two chemical bond lengths (~2–3 Å); the jump frequency is evidently k_{po}[M]. Then the effective diffusion coefficient for the migration of the free valence is $D_{po} = \lambda_{po}^2 k_{po}$[M]/6 while the bimolecular rate constant for the encounters of the radicals is

$$k_e = 2.5 \cdot 10^{21} a \lambda_{po}^2 k_p [M] \quad .$$

This mechanism of the migration of the free valence is in essence similar to that of migration with participation of macroradicals alone. The difference is that the slow stage of the relay

$$\dot{R}\ (R\dot{O}_2) + RH \xrightarrow{k_p} RH\ (ROOH) + \dot{R}$$

is replaced by the much faster polymerisation chain propagation reaction. The ratio of the rate constants for the encounters determined by chain polymerisation and the trivial relay mechanism, which amounts to k_{po}[M]/k_p[RH], can be fairly large even for [M] << [RH], because the ratio k_{po}/k_p for vinyl monomers reaches 10^3–10^5.[33]

The results of the study of the kinetics of the destruction of macroradicals in the postpolymerisation of tetrafluoroethylene on γ-irradiated Teflon[87] agree satisfactorily with the analysis presented above.

3. The Relay-Diffusion Mechanism of the Migration of the Free Valence

As shown in the preceding section, the simplest variant of "chemical" diffusion—the trivial relay—is usually unsatisfactory. Firstly, the trivial relay does not explain the fairly large "step" in the relay, reaching sometimes hundreds of angstroms, and the high absolute rates of migration of the free valence observed in many cases. Secondly, in this variant of "chemical" diffusion, purely physical stages of the migration of the free valence are in essence ignored, which, as a rule, prevents a quantitative explanation of the clear relation between the kinetics of the destruction of radicals and molecular mobility. The idea that mobility influences the chemical step proper in the valence transfer reaction does not always help. The calculation of the rate constants for encounters by Eqn.(6), even

when "liquid-phase" rate constants for the transfer of valence k_p (which is apparently the upper limit of this quantity in solid polymers[88]) are used, leads to values of k_e which are in many instances lower by several orders of magnitude than the experimental k_t.

We shall consider the relay-diffusion model of the migration of the free valence in which the chemical relay is combined with the diffusional migration of segments (Fig.2). As an example, we shall consider reaction (3). As a result of the thermal movement of the segments, both the radical centre $-\dot{C}H-$ (black circle) and the $-CH_2-$reaction group (open circle) are capable of migrating within a sphere having a radius λ_s of the order of magnitude of the size of the segment. This single reaction step can result in the transfer of the free valence over a distance up to $2\lambda_s$. Depending on the ratio of the frequencies of segmental movements (ν_s) and relay transfer steps {k_p[RH]}, the followng extreme situations are possible. If $\lambda_s \ll k_p$[RH] (molecular mobility is greatly reduced), then the segmental movements should not contribute much to the migration process and this case will not differ from the trivial relay considered in the previous section. If the segmental mobility is high {$\nu_s \gg k_p$[RH]}, then during a period $1/k_p$[RH] between two elementary steps in the transfer of the free valence, the reaction centres have sufficient time to move around the entire sphere with a radius λ_s and during a single "step" of the relay the free valence migrates not over a distance λ_r but over a much larger distance in the range $\lambda_r < \overline{\lambda}_s \leq 2\lambda_s$. Thus the chemical relay takes place with a step close to the characteristic amplitude of the segmental movements. The analytical expression for the rate constant for encounters is analogous to the Eqn.(6), it being only necessary to replace λ_r by $\overline{\lambda}_s$. If the frequencies of the segmental movements and of the relay are comparable, then k_e has an intermediate value.

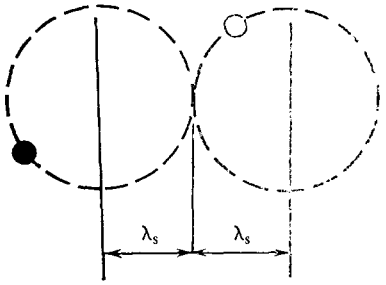

Figure 2. Illustration of the relay-diffusional model of the destruction of macroradicals in solid polymers.

It must be emphasised that in the mechanism of the transfer of the free valence considered here the decisive factor remains the chemical relay, the segmental mobility ensuring only a much larger step in the relay. The relay-diffusion mechanism agrees with the idea that diffusion-controlled stages are present in this process—the stages comprising the movements of the segments are of this kind. In very "rigid" polymers, where even a limited segmental mobility is virtually absent, the step of the relay is $\lambda \cong 1.5$–3 Å and the migration of valence is ensured solely by the chemical reaction (trivial relay). In "soft" polymers the amplitude of segmental movements is large ($\overline{\lambda}_s$ up to 60 Å), which, in principle, can ensure fairly high rates of migration.

Since the effective diffusion coefficient of the free valence is proportional to λ^2, even a comparatively small increase of the parameter λ leads to an appreciable increase in the rate of migration of the free valence compared with the trivial relay—in the limit by a factor $(2\lambda_s/\lambda_r)^2$. This can evidently still prove to be inadequate to explain the very rapid macroradical destruction processes. For example, in the case of the destruction of peroxy-radicals in polypropylene at 60 °C considered in the previous section {$k_p = 1.5 \times 10^{-2}$ litre mol^{-1} s^{-1}, [RH] = 22 M, $a = 5 \times 10^{-8}$ cm}, k_e is only 15 litre mol^{-1} s^{-1} even for $\lambda_r = 2\lambda_s = 60$ Å, which is lower by a factor of 40 than the experimental value $k_t = 6 \times 10^2$ litre mol^{-1} s^{-1}.

4. Migration of the Free Valence with Participation of Low-Molecular-Weight Radicals (Kinetic Analysis)

The constant k_e can increase sharply if low-molecular-weight radicals, with a much greater mobility than macroradicals and therefore capable of migrating over comparatively long distances in the solid polymer, participate in the migration processes. The analytical expressions for D_r and k_e depend on the mechanism of the formation of light radicals. We shall consider three versions: chain transfer to the low-molecular-weight admixture, the dissociation of macroradicals, and the formation of light radicals in the decomposition of the initiator.

The case of the transfer of the free valence to a low-molecular-weight admixture rH as a result of the reaction

$$\dot{R} + rH \xrightarrow{k_1} RH + \dot{r} \qquad (7)$$

has already been considered[89]. If $\dot{r}$ disappears mainly in the reverse free valence transfer reaction

$$\dot{r} + RH \xrightarrow{k_2} rH + \dot{R} \quad , \qquad (8)$$

then its lifetime between elementary steps of reactions (7) and (8) is $\tau = 1/k_2$[RH]. During the time τ, the radical $\dot{r}$ (its diffusion coefficient is D_0) makes a jump over a distance

$$\lambda = \sqrt{6D_0\tau} = \sqrt{6D_0/k_2[RH]}$$

and the frequency of these jumps is evidently $\nu = k_1$[RH]. For the effective diffusion coefficient of the free valence, one can write

$$D_r = \lambda^2\nu/6 = k_1D_0[rH]/k_2[RH] \quad .$$

The corresponding expression for the rate constant for encounters is

$$k_e = \frac{4\pi a 2D_0k_1[rH]}{k_2[RH]} 6 \cdot 10^{20} \simeq 1.5 \cdot 10^{22} \frac{aD_0k_1[rH]}{k_2[RH]} \quad . \qquad (9)$$

The derivation of Eqn.(9) can be approached in a different way. Since usually $[\dot{r}] \ll [\dot{R}]$, the reaction

$$\dot{r} + \dot{R} \xrightarrow{k_3} \text{products} \qquad (10)$$

can be regarded as virtually the only one in which the total number of radicals diminishes. The kinetic mechanism incorporating reactions (7), (8), and (10) is described by the system of differential equations

$$d[\dot{r}]/dt = k_1[\dot{R}][rH] - k_2[\dot{r}][RH] - k_3[\dot{r}][\dot{R}] \quad ,$$

$$d[\dot{R}]/dt = -k_1[\dot{R}][rH] + k_2[\dot{r}][RH] - k_3[\dot{r}][\dot{R}] \quad .$$

When the concentration of $\dot{R}$ is high and $k_3[\dot{R}] \gg k_2[RH]$, we obtain for the rate of destruction of macroradicals

$$-d[\dot{R}]/dt \simeq 2k_1[rH][\dot{R}] \ .$$

On the other hand, usually $k_3[\dot{R}] \ll k_2[RH]$, which implies that the encounter of the free valences is preceded by several cycles of reactions (7) and (8) or, in other words, the distance over which $\dot{r}$ migrates during its lifetime is significantly shorter than the overall migration path of the free valence before destruction. Then

$$-d[\dot{R}]/dt \simeq \frac{2k_1k_3[rH]}{k_2[RH]}[\dot{R}]^2 \ ,$$

i.e. the destruction of macroradicals is described by a second-order equation with respect to the radical with the effective constant

$$k_{eff} = 2k_1k_3[rH]/k_2[RH] \ . \qquad (11)$$

We shall assume that reaction (10) is controlled by diffusion with D_0, whereupon we obtain

$$k_3 = 4\pi aD_0 \times 6 \times 10^{20} \ . \qquad (12)$$

On substituting Eqn.(12) in Eqn.(11), we obtain Eqn.(9). If the low-molecular-weight radicals are formed in the dissociation of macroradicals or in the decomposition of the initiator Y, reaction (7) must be replaced by reactions (13) and (14) respectively:

$$R \xrightarrow{k_4} \dot{r} + \text{products} \quad ; \qquad (13)$$

$$Y \xrightarrow{w_0} \dot{r} \ . \qquad (14)$$

Table 4. Kinetics of the destruction of macroradicals as a result of the migration of the free valence with participation of light radicals.

No. of radical r formation reaction	Rate of destruction of macroradicals		k_e for $k_3[\dot{R}] \ll k_2[RH]$
	for $k_3[\dot{R}] \gg k_2[RH]$	for $k_3[\dot{R}] \ll k_2[RH]$	
(7)	$2k_1[rH][\dot{R}]$	$\frac{2k_1k_3[rH][\dot{R}]^2}{k_2[RH]}$	$1.5 \cdot 10^{20}\frac{aD_0k_1[rH]}{k_2[RH]}$ (9)
(13)	$2k_4[\dot{R}]$	$\frac{2k_3k_4[\dot{R}]^2}{k_2[RH]}$	$1.5 \cdot 10^{20}\frac{aD_0k_4}{k_2[RH]}$ (9a)
(14)	w_0	$-w_0$	—

The expressions for the rate of destruction of macroradicals and the rate constant for the encounter of the free valences, obtained in terms of an approximation analogous to that used in the previous case, are presented in Table 4.

The above analysis shows that the bimolecular law governing the destruction of macroradicals with participation of light radicals, which is most frequently observed experimentally, can be realised if the source of light radicals is reaction (7) or (13), while $k_3[\dot{R}] \ll k_2[RH]$. If, on the other hand, the low-molecular-weight radicals are formed in the decomposition of the initiator, then the bimolecular law governing the destruction of macroradicals should not be observed for any values of $[\dot{R}]$.

We shall compare the bimolecular rate constants for encounters in the migration of the free valence with participation of light radicals (k_{e_1}) and as a result of the trivial relay (k_{e_2}), having assumed that the distance a over which the radicals react chemically is in both cases the same. When $\dot{r}$ is formed via reactions (7), the ratio k_{e_1}/k_{e_2} can be obtained on dividing Eqn.(9) by Eqn.(6):

$$k_{e1}/k_{e2} = 6D_0k_1[rH]/\lambda_r^2k_2k_p[RH]^2 \ .$$

Assuming that $\lambda_r = 3 \times 10^{-8}$ cm, $k_2 = k_p = 10^{-1}$ litre mol^{-1} s^{-1}, [RH] = 10 M, and $D_0 = 10^{-10}$ cm^2 s^{-1}, we find $k_{e_1}/k_{e_2} \cong 7 \times 10^5k_1[rH]$. The ratio $k_{e_1}/k_{e_2} \gg 1$ holds subject to the condition that $k_1[rH] \gg 1.5 \times 10^{-6}$ s^{-1}, which obtains readily even for comparatively low values of [rH]. If $\dot{r}$ is formed in the dissociation of macroradicals, the ratio k_{e_1}/k_{e_2} is obtained on dividing Eqn.(9a) by Eqn.(6):

$$k_{e1}/k_{e2} = 6D_0k_4/\lambda_r^2k_2k_p[RH]^2 \ .$$

Using the same values of λ_r, k_2, $k_p[RH]$, and D_0 as in the previous case, we find that $k_{e_1}/k_{e_2} \gg 1$, provided that $k_4 \gg 1.5 \times 10^{-6}$ s^{-1}, which is frequently also readily obtainable.

Thus the involvement of light radicals can ensure a more effective migration of the free valence than the trivial relay and the relay-diffusional mechanism of migration. It is then possible to attain fairly high absolute values of k_e. For example, an estimate[89] for the destruction of peroxy-radicals in polypropylene undergoing oxidation at 130 °C, based on the assumption that the free valence is transferred to low-molecular-weight products of thermo-oxidative degradation, leads to $k_e \cong 10^5$–10^6 litre mol^{-1} s^{-1}, which is fairly close to the experimental values of k_t.[62,90] The mechanism of migration with participation of light radicals also agrees well with the idea that diffusion-controlled stages are present in the migration process; in the present instance the diffusion of light radicals is such a stage.

Table 4 shows that the two mechanisms of the formation of low-molecular-weight radicals [reaction (7) and (13)] cannot be distinguished solely on the basis of data for the kinetics of the destruction of macroradicals. The low-molecular-weight chain transferring agents rH in reaction (7) can be both specially introduced additives and random admixtures as well as polymer degradation products (in particular a high yield of low-molecular-weight products is observed in thermo-oxidative degradation). The latter case has been discussed[89].

We shall now consider a more universal mechanism of the formation of light radicals—the dissociation of macroradicals. Radicals tend to dissociate to a greater extent than the corresponding molecules, and the commonest dissociation mechanism involves the dissociation of the β-bond (the so-called β-decomposition). Radical recombination and disproportionation processes compete with the dissociation reaction. Since the lifetime τ_1 of active radicals in the liquid and gas phases is usually short and rarely exceeds 1 s, it is possible to observe only comparatively rapid dissociation processes under these conditions§. The situation changes in solid polymers where τ_1 is significantly greater and sometimes reaches many hours.

---

§In the bimolecular mechanism of the destruction of radicals $\tau_1 = 1/\sqrt{w_0k_t}$; the usual value of k_t for active radicals in the liquid phase is 10^9 litre mol^{-1} s^{-1},[33] while the rate of initiation w_0 in kinetic experiments is rarely below 10^{-9} mol litre^{-1} s^{-1}. Hence $\tau_1 \leq 1$ s. The probability of the dissociation of the radical is 10% subject to the condition that $k_4 = 0.1/\tau_1 \geq 0.1$ s^{-1}; thus in the liquid phase it is virtually impossible to detect dissociation processes with $k_4 < 0.1$ s^{-1}.

One can therefore expect that macroradical dissociation processes play a considerably greater role than the analogous reactions of low-molecular-weight radicals in the liquid and gas phases¶.

5. Migration of the Free Valence with Participation of Low-Molecular-Weight Radicals (Experimental Data)

We shall now consider experimental facts indicating the involvement of light radicals in free valence migration processes in solid polymers.

1. When chlorine is brought into contact with γ-irradiated polyethylene containing stable alkyl radicals, the polymer undergoes chain chlorination, which is accompanied by a decrease of the concentration of macroradicals at a rate several orders of magnitude greater than in the absence of molecular chlorine[96]. The high rate of destruction of alkyl radicals is ensured by the participation in the migration process of $\dot{C}l$ atoms formed by the reaction

$$\dot{R} + Cl_2 \rightarrow RCl + \dot{C}l$$

and capable of traversing comparatively long distances before recombining with $\dot{R}$ or before the reverse chain transfer reaction step:

$$RH + \dot{C}l \rightarrow \dot{R} + HCl \quad .$$

In this case chlorine plays the role of a kind of catalyst of the destruction of macroradicals.

2. Catalysis of the migration of the free valence by hydrogen is observed in γ-irradiated polyethylene[97-100]. The rate of migration can be inferred from the kinetics of not only the destruction of alkyl radicals ($\dot{R}_{alk}$) but also of the conversion of $\dot{R}_{alk}$ into allyl radicals ($\dot{R}_{all}$) (the rate of the latter process is apparently limited by the rate of encounters of the free valence with a double bond). Both processes are significantly accelerated by hydrogen (by a factor of ~15 for p_{H_2} = 400 mmHg at 24 °C in the transition $\dot{R}_{alk} \rightarrow \dot{R}_{all}$) and to a lesser extent by deuterium, the magnitude of the effect being proportional to the H_2 of D_2 pressure.

In the absence of hydrogen, the migration of the free valence in the polymer apparently takes place as a result of the reaction

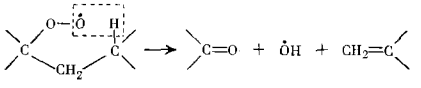
$$\dot{R}_{alk} + RH \xrightarrow{k_6} RH + \dot{R}_{alk} \quad . \qquad (15)$$

In a hydrogen atmosphere migration can take place as a consequence of the repetition of the reaction cycle:

$$\begin{aligned} &\dot{R}_{alk} + H_2 \xrightarrow{k_7} \dot{H} + RH \quad , \\ &\dot{H} + RH \rightarrow H_2 + \dot{R}_{alk.} \end{aligned} \qquad (16)$$

The occurrence of deuterium isotope exchange in such a system[97] confirms the above mechanism. Reaction (16) can be more effective than reaction (15) from the standpoint of the migration of the free valence in the polymer, although $k_7 \ll k_6$. This is associated with the exceptionally high mobility of H atoms†.

3. The rate of the chain oxidation of polyolefins decreases in the presence of the low-molecular-weight hydroperoxide $C_6H_5C(CH_3)_2OOH$.[102] The effect is evidently also caused by the increase of the effective termination rate constant as a result of the involvement in this process of light radicals arising in the reaction



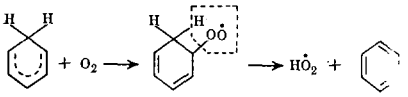
$$R\dot{O}_2 + C_6H_5C(CH_3)_2\dot{O}OH \rightarrow ROOH + C_6H_5C(CH_3)_2O\dot{O}.$$

This mechanism has been confirmed directly in a study[75] where the increase of the rate of destruction of peroxy-radicals in polypropylene in the presence of a low-molecular-weight hydroperoxide {by a factor of ~7 for $[C_6H_5C(CH_3)_2.OOH] = 0.12$ M at 25 °C} was observed directly by EPR. However, the effect is comparatively small, which implies that an extremely effective migration mechanism, possibly involving low-molecular-weight radicals (see below), obtains in solid polypropylene even without the addition of a low-molecular-weight hydroperoxide.

4. In poly(methyl methacrylate), polystyrene, and poly(vinyl acetate) at temperatures below T_g, i.e. under the conditions of highly limited mobility of the polymer molecules, the destruction of macroradicals proceeds at a measurable rate (Table 3) and is accompanied by the formation of considerable amounts of low-molecular-weight products[67,103]. The authors[67,103] concluded that the high rates of destruction of radicals are ensured by the involvement in the free valence migration processes of low-molecular-weight radicals arising on dissociation of the macroradicals. A new confirmation of this migration mechanism in polystyrene has been recently obtained[104]. The destruction of the peroxy-macroradicals in the presence of an alkyl radical acceptor—a stable nitroxy-radical $R_2\dot{N}O$—is accompanied by the formation of the ether R_2NOr, which is not "attached" to the polymer. This evidently implies that low-molecular-weight alkyl radicals arise in some way in processes leading to the destruction of macroradicals.

5. Light radicals apparently play a significant role also in processes involving the destruction of peroxy-macroradicals in polypropylene and polyethylene. The thermal oxidation of polyolefins is accompanied by the formation of volatile products[7] and of low-molecular-weight as well as polymeric hydroperoxides[105]. These data indicate an intense decomposition of the macroradicals, in which the decomposition products can include low-molecular-weight radicals. The latter have been detected directly by EPR in the thermal decomposition of solid polypropylene hydroperoxides[106]. It was assumed earlier that the dissociation is undergone mainly by alkoxy- and terminal alkyl radicals. However, recent studies have shown that one of the main processes responsible for the degradation of polyethylene[107] and polypropylene[108,109] is the decomposition of peroxy-macroradicals#.

A specific mechanism of the decomposition of RO_2 has been proposed[112,113]:



¶This also applies to low-molecular-weight sterically hindered radicals, which cannot compete or disproportionate with one another even in the liquid phase owing to steric hindrance. The range of such radicals has greatly expanded in recent years[91-95]. Many of these are destroyed at a low rate as a result of the β-decomposition followed by the recombination of the fragment radical with the initial radical.

†In solid polymers hydrogen atoms diffuse over distances up to ~10^{-6} cm without reacting with macroradicals[101].

#Data indicating the dissociation of peroxy-radicals in polytetrafluoroethylene have been published[22,110,111].

However, the ȮH radicals formed in this process are very reactive and for this reason can hardly traverse long distances in the polymer. Another mechanism of the decomposition of $\dot{R}O_2$ can be associated with the ejection of the considerably less active $H\dot{O}_2$ radical. Processes of this kind are known in the liquid phase close to room temperature for peroxy-radicals derived from hydroxy-compounds[114,115] and certain unsaturated hydrocarbons[116], for example, in the oxidation of cyclohexa-1,4-diene:

This mechanism has been invoked to account for the sharp increase of the rate of destruction of macroradicals of the cyclohexadienyl type in polycarbonate in the presence of O_2.[117] One cannot rule out the possibility that the decomposition of $R\dot{O}_2$ with ejection of $H\dot{O}_2$ takes place also in polyolefins and other polymers.

The bimolecular rate constant for the destruction of peroxy-radicals in polypropylene subjected to preliminary oxidation decreases with increase of the concentration of the polymeric hydroperoxide in accordance with the law[75,80]

$$k_t = \frac{a}{b + c[\mathrm{ROOH}]} \quad , \qquad (17)$$

where a, b, and c are constants. This dependence of k_t on [ROOH] can be accounted for most naturally within the framework of the mechanism of migration with participation of low-molecular-weight radicals. The polymeric hydroperoxide plays in this case the role of a trap for light radicals. As a result of the reaction

$$\dot{r} + \mathrm{ROOH} \xrightarrow{k_1} rH + R\dot{O}_2 \quad ,$$

the latter are replaced by polymeric peroxy-radicals, which reduces the effective rate of migration. The expression for the rate constants for the encounters of the free valences will differ from those quoted in Table 4 by the fact that the term k_1[ROOH] appears in the denominator. For example, if the light radicals arise in the dissociation of the macroradical $R\dot{O}_2$, the following expression is obtained:

$$k_e = 1{,}5 \cdot 10^{28} \frac{aD_0 k_t}{k_2[\mathrm{RH}] + k_1[\mathrm{ROOH}]} \quad ,$$

the form of which does not differ from that of Eqn.(17). Of the two possible mechanisms of the formation of light radicals participating in the migration of the free valence—chain transfer to a low-molecular-weight impurity and the dissociation of the macroradical—the second mechanism is more probable in the given instance[75].

6. The Influence of Molecular Mobility on the Kinetics of the Destruction of Macroradicals

Many facts are known indicating a relation between the kinetics of the destruction of macroradicals in solid polymers and molecular mobility—the decrease of the rate of destruction on passing from an amorphous to a crystalline phase[8,15,63,118–119], a lower value of k_t in oriented specimens compared with non-oriented specimens[65,120], the increase under these conditions of the effective activation energy for the destruction process[68], the increase of the stability of macroradicals when the polymer is cross-linked[121,122], the identity in many instances of the activation energy for the destruction of macroradicals and the activation energy for the segmental movements in the polymer measured by NMR (see the references in the review of Pudov and Buchachenko[7]) §, the increase in the rate of destruction of macroradicals in three-dimensional polymers with increase of the length of the oligomer block[123], etc.

Two methodological procedures, whereby the mobility can be subjected to a controlled variation within wide limits, based on the change of the external pressure and the plasticisation of the polymer by chemically inert solvents, have been used recently in the study of the influence of molecular mobility on the kinetics of the destruction of macroradicals.

In amorphous polymers—polystyrene[24], poly(vinyl acetate),[124] poly(methyl methacrylate),[125] polyamides[126], and polycarbonate[127]—the constant k_t decreases with increasing pressure at temperatures in excess of T_g (in some cases by a factor of 10^2–10^3 at $p \cong 10^4$ atm). Below T_g, the influence of p on k_t is comparatively small. The nature of the dependence of k_t on p is such (Fig.3) that the greatest effect is observed at comparatively low pressures p; at each temperature above T_g there is a critical pressure p_{cr}, above which k_t depends only slightly on p. At $p < p_{cr}$ the dependence of k_t on p is described by the relation[129]

$$k_t = A_0 \exp[-(E + pV^*)/RT] \quad , \qquad (18)$$

where V^* is the activation volume and E sometimes changes as the pressure is altered[25,129].

Although the specific cause of the influence of p on k_t in each case is not known exactly, a common factor is apparently the fact that the pressure affects the kinetics of the destruction of macroradicals via molecular mobility. With increase of pressure, the density of the polymer also increases, which lowers the intensity of molecular movements, this being manifested particularly by an increase of T_g [for example, in poly(methyl methacrylate) $dT_g/dp = 2 \times 10^{-2}$ K atm^{-1} [129]], a decrease of the free volume, a decrease of the rotation frequency of a paramagnetic probe[133], etc. Eqn.(18) shows that an increase of p affects k_t in the same way as a decrease of temperature. Presumably the glass point is attained at $p = p_{cr}$.

The variation of the external pressure constitutes an extremely promising instrument for investigating the mechanisms of processes involving the destruction of macroradicals (and apparently also other radical reactions in solid polymers), particularly in a simultaneous study of molecular mobility. For example, in the basis of the data of Szocs and Plack[25], Szocz and Rostasova[129] concluded that there are two mechanisms of the destruction of terminal radicals in poly(methyl methacrylate). In the region of low pressures and high temperatures (high mobility) the destruction process is characterised by $E = 29$ kcal mol^{-1} and $V^* = 70$ Å^3 and the destruction apparently takes place as a result of physical diffusion; in the region of high pressures and low temperatures (low mobility) $E = 17$ kcal mol^{-1}, $V^* = 7.5$ Å^3, and the free valence most probably migrates with participation of the light radicals formed on dissociation of the macroradicals. The study of the influence of pressure on the kinetics of the destruction of the radicals can also yield information about the localisation of the radicals in amorphous-crystalline polymers. Since pressure alters the molecular mobility virtually only in the

§This agreement between the activation energies should, incidentally, be treated with much caution, because radicals are sometimes localised in the crystalline phase of the polymer, while data for the mobility refer to the amorphous phase.

amorphous phase, the weak dependence of k_t on p at temperatures above T_g indicates the localisation of the radicals in the crystallites[129].

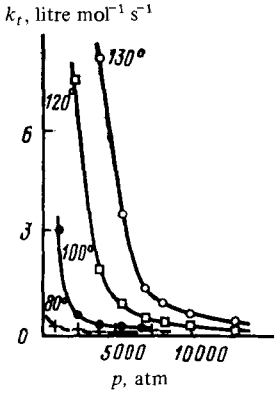


Figure 3. Dependence of k_t for terminal macroradicals in poly(methyl methacrylate) on pressure at different temperatures[125].

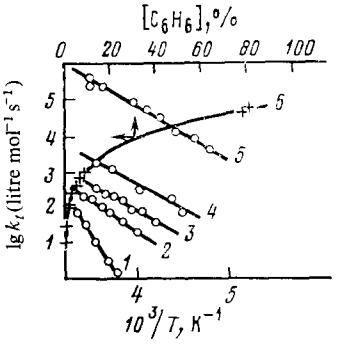

Figure 4. Temperature dependence of k_t for peroxy-radicals in polystyrene for different contents of benzene (%): *1*) 0; *2*) 2; *3*) 5; *4*) 12; *5*) 90; *6*) dependence of k_t on the benzene content at 270 K.[66]

The plasticisation of the polymers exerts a significant influence on the kinetics of the destruction of macroradicals. Thus the destruction of peroxy-radicals in polystyrene[66] (Fig. 4) and polypropylene[62,132] is greatly accelerated by the addition of comparatively small amounts of aromatic solvents, while the destruction of macroradicals in cellulose is accelerated by the addition of water[133]. The accelerating effect can be explained solely by an increase of molecular mobility. The variation of k_t in solid polypropylene in the presence of *o*-dichlorobenzene is correlated with the rotation frequency of the paramagnetic probe[132]. Table 5 shows that the increase of k_t is accompanied by a decrease of the activation energy and the pre-exponential factor; at fairly high concentrations of the additive these quantities approach the liquid-phase values.

The results of the consideration of the kinetics of the destruction of macroradicals are presented in Table 6. The operation of one of the mechanisms for the migration of the free valence in a specific system, discussed above, depends on the ratio of two factors: the intensity of the molecular movements in the polymer and the reactivity of the macroradicals. If the reactivity of the macroradicals is low and the intensity of the segmental movements is very great, the free valence will migrate mainly as a result of physical diffusion. This situation apparently obtains in elastomers above T_g and in highly plasticised polymers. In other cases physical diffusion leads to a very slow migration and cannot as a rule compete with "chemical" diffusion. When the free valence transfer reaction is fairly effective (high values of k_p), one may expect that the migration will take place via a relay-diffusional mechanism or, in the specific instance where the mobility is frozen to a large extent, via the trivial relay mechanism. If, finally, the macroradicals tend to dissociate or low-molecular-weight chain transferring agents are present in the system, the dominant mechanism of the migration will involve processes with participation of light radicals. Such migration mechanism ensures, in principle, the highest absolute rates of destruction of macroradicals.

Table 5. The influence of added aromatic solvents on the kinetics of the destruction of peroxy-macroradicals in solid polyolefins.

Low-molecular-weight additive	$(k_t)_0$, litre mol^{-1} s^{-1}	E, kcal mol^{-1}	k_t^*, litre mol^{-1} s^{-1}	Refs.
	Polypropylene			
—	$3.2\cdot10^{21}$	28.5	4	[62]
~2.5 M benzene	$5.6\cdot10^{13}$	14.5	$1.2\cdot10^3$	[62]
0.8 M *o*-dichlorobenzene	—	—	45	[132]
	Polystyrene

0.6 M benzene	$3.2\cdot10^7$	6.3	$8\cdot10^2$	[66]

*The values of k_t at 25 °C are quoted.

Table 6. Characteristics of the valence migration processes in a solid polymer.

Migration mechanisms	Factors determining migration mechanism: segmental mobility (D, λ_r)	k_p	presence of low-molecular-weight chain transferring agents (k_1[rH])	tendency of macroradical to dissociate (k_s)	Parameter determining rate of migration	Factor influenced by molecular mobility
Physical diffusion	high	low	absent	low	D_2	D
Trivial relay	low	high	absent	low	$k_p\lambda_s^2$	k_p
Relay-diffusion mechanism	high	high	absent	low	$k_p\lambda_c^2$	k_p, $\bar{\lambda}_c$
With participation of light radicals:						
(a) chain transfer to low-molecular-weight admixture	comparatively low	low	present	low	k_1[rH] D_0	k_1, D_0
(b) dissociation of macroradicals	comparatively low	low	absent	high	$k_s D_0$	D_0

It is clear from the foregoing that the mechanism of the migration of the free valence is actually determined not only by the nature of the polymer and temperature but also by the type of macroradical, the localisation of the radicals in the amorphous or crystalline phases of the polymer, the presence of low-molecular-weight admixtures (plasticisers or chain transferring agents), etc.

The last column of Table 6 shows the parameters through which molecular mobility influences the kinetics of the destruction of macroradicals as a function of the migration mechanism. Furthermore, in each specific instance it is as a rule impossible to specify the "channel" for the exertion of the influence, because, as we have seen, it is fairly difficult to establish reliably the migration mechanism.

V. REACTIONS OF MACRORADICALS WITH MACROMOLECULES: $\dot{R}_1 + R_2H \rightarrow R_1H + \dot{R}_2$

Since both reactants are in a single "cage", the reactions of this type always proceed under kinetic conditions. At low temperatures (as a rule below T_g), where the destruction of radicals is still inappreciable, the reactions of macroradicals with macromolecules can be investigated directly, by following the concentrations of $\dot{R}_1$ and $\dot{R}_2$ by EPR. The reactions of terminal radicals in polyethylene[134]

$$\sim CH_2\dot{C}H_2 + \sim CH_2CH_2CH_2 \sim \rightarrow \sim CH_2CH_3 + \sim CH_2\dot{C}HCH_2 \sim$$

and the reactions of peroxy-radicals (chain propagation in oxidation)

$$R\dot{O}_2 + RH \rightarrow \dot{R} + ROOH \qquad (19)$$

in polyethylene, polypropylene[135], polyethylene–urea complexes[136], polystyrene[67,88], poly(methyl methacrylate)[10,67], polycaproamide, and polyacrylonitrile[67] have been investigated in this way. The $R\dot{O}_2 \rightarrow \dot{R}$ transition at low temperatures is as a rule described in terms of stepwise kinetics.

The quantity k_p for $R\dot{O}_2$ can also be obtained from the kinetics of the chain oxidation. The rate of oxidation w_{O_2} is given by the following expression on the assumption of fairly long chains:

$$w_{O_2} = \frac{k_p}{\sqrt{k_t}}[RH]\sqrt{w_0} \quad . \qquad (20)$$

If the rate of initiation w_0 is known, then it is possible to find the parameter $k_p/\sqrt{k_t}$ with the aid of Eqn.(20). Independent measurements of the termination rate constant k_t are necessary for the determination of k_p. The relevant data are presented in Table 7.

The most detailed information has been obtained for polypropylene. The quantities $k_p/\sqrt{k_t}$, measured at different temperatures and using different initiators, are fairly similar. The discrepancies between the k_p are very significant owing to the considerable discrepancies between the k_t in different studies.

In principle, k_p can be calculated from k_t for the destruction of macroradicals subject to the condition that the migration of the free valence is caused by "chemical" diffusion. However, even if the migration mechanism has been established reliably (which can be done, as already stated above, in comparatively rare instances), the calculation of k_p involves large errors, because the necessary parameters [for example, the elementary jump $\bar{\lambda}_s$ for the relay-diffusional mechanism of the migration of the free valence—see Eqn.(6)] are usually estimated very approximately.

Thus the information about the rate constants for reactions of macroradicals with macromolecules is so far fairly limited and refers virtually only to the reactions of peroxy-radicals.

We shall consider the influence of molecular mobility on the kinetics of reaction (19). Since both reactants are always in direct contact, one may consider here the influence of mobility solely on their interaction in the cage.

In the crystalline regions of isotactic polypropylene the radicals $R\dot{O}_2$ are destroyed ~10^4 times more slowly than in the amorphous regions and the transition $R\dot{O}_2 \rightarrow \dot{R}$ hardly occurs[53], although the rate constant for reaction (19) in the amorphous phase is extremely large[84]. Thus at 80 °C $k_p = 1.5 \times 10^{-1}$ litre mol^{-1} s^{-1}, which corresponds to an average reaction time $1/k_p[RH] \cong 0.3$ s. Apparently the only cause of the enormous difference between the reactivities of $R\dot{O}_2$ in the crystalline and amorphous phases is the difference between the intensities of the molecular movements.

It has been shown[143,144] that the rate of oxidation of polypropylene diminishes and the relative decrease of stability after oxidation in the presence of the same amount of absorbed oxygen is smaller when the system is oriented. This apparently implies that the chain propagation rate constant k_p for strained polymer chains with a limited mobility is significantly lower than for the unstrained chains.

The results of the study of reaction (19) in amorphous polystyrene in an inert atmosphere below T_g are even clearer[88]. At 210–293 K the process is described in terms of stepwise kinetics with a hyperbolic initial distribution of peroxy-radicals with respect to rate constants. Thus peroxy-radicals of identical chemical nature differ greatly in their reactivities. Analysis of the stepwise kinetics makes it possible to find the limits of the distribution of $(k_p)_{max}$ and $(k_p)_{min}$ and of the corresponding activation energies (Table 7). It is of interest that the quantity $(k_p)_{max}$ is fairly close to the rate constant for the reaction of a low-molecular-weight analogue of polystyrene (cumene) with its peroxy-radical in the liquid phase[33].

The physical significance of the stepwise kinetics in the given instance is that at a given temperature the more active radicals are "burnt off" more rapidly with k_p close to $(k_p)_{max}$; as a result, the distribution curve shifts towards radicals with $(k_p)_{min}$ (Fig.5) and the overall rate of the process is sharply retarded. An analogous phenomenon is observed in poly(methyl methacrylate).[10] Evidently any influences on the polymer promoting the restoration of the initial distribution will "restore" the initial rate of reaction. This has been achieved[88] by a brief dispersion of the specimen, in which the active radicals have been "burnt off", at 77 K¶.[12] The dispersion results in relative migrations of macroradicals and macromolecules and in a change of the local environment of the radical and of molecular mobility in the vicinity of the radical; in other words, the distribution functions with respect to k_p are mixed, which results in the restoration of favourable relative orientations of the radical and the surrounding macromolecules from the standpoint of reaction (19). When reaction (19) is carried out in an atmosphere of O_2, "chemical" mixing of the distribution function takes place[10,88] as a result of the generation of new peroxy-radicals in the

¶At 77 K reaction (19) does not proceed even under dispersion conditions owing to the presence of a large activation barrier.

reaction

$$\dot{R} + O_2 \rightarrow R\dot{O}_2 \quad .$$

"Thermal" mixing of the distribution functions is also possible.

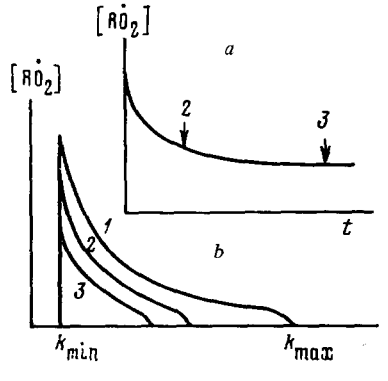

Figure 5. *a*) Kinetics of the reaction $R\dot{O}_2$ → $\dot{R}$ in polystyrene; *b*) changes in the curve illustrating the range of rate constants for $R\dot{O}_2$ reactions in the course of the kinetic experiment (according to Radtsig's data[10]).

Molecular mobility influences the rate of reaction (19) also in "softer" polymer matrices where the stepwise kinetics are not as yet observed. Thus k_p increases significantly in the oxidation of solid polypropylene at 25 °C in the presence of the chemically inert *o*-dichlorobenzene, the growth of k_p being correlated with the increase of the rotation frequency of the paramagnetic probe characterising molecular mobility[132].

VI. PHYSICAL MECHANISMS OF THE INFLUENCE OF MOLECULAR MOBILITY ON REACTIVITY

As shown in the previous sections, one of the characteristic features of radical reactions in solid polymers is that their rate is frequently related to the kinetics of molecular movements even under kinetic conditions. This is manifested both in reactions of macroradicals and macromolecules and in processes involving low-molecular-weight substances. If the treatment is confined to processes whose rates are not limited by the encounters of the reactants, it is possible in principle to set up two physical models relating the kinetics of chemical reactions in polymers to molecular mobility.

In the first model, which can be called the *delayed rehybridisation model*[146], it is assumed that the macrorelaxation time in polymers is long compared with the duration of the chemical step. For example, in the abstraction of a hydrogen atom from an sp^3-carbon atom in the polymer chain the hybridisation should change to sp^2, this being accompanied by a change in valence angles (from 109° to

120°) and bond lengths; the latter requires structural relaxation. In the liquid and gas phases both steps—the abstraction of a hydrogen atom and rehybridisation—take place sychronously, while in a polymer matrix they are separated in time. As a result of the low rate of structural relaxation in polymers, the energetically most favourable activated complex cannot be formed during the reaction step. The process therefore follows a higher profile of the potential energy surface compared with the liquid (gas) phase, which leads in its turn to an increase of the activation energy and a decrease of the reaction rate constants. With increase of mobility, structural relaxation is facilitated and the delay of rehybridisation is correspondingly diminished; as a result, the activation energy falls and the rate constant increases, approaching the liquid-phase values.

There is no direct evidence for the reality of the delayed rehybridisation model, which remains hypothetical. Although many kinetic features of radical reactions in solid polymers can be accounted for in the framework of this model, some of its consequences are not fulfilled. In particular the model predicts a significant decrease in the rate constants for radical substitution reactions only in processes involving the atoms in the main chain of the macromolecule, whereas it has been observed, as shown above, that the rate constants for reactions involving the side groups of macromolecules as well as low-molecular-weight substances are lower than in the liquid phase.

We shall now consider the second model. For the chemical reaction to occur, a rigorously defined orientation of the reacting species and their elements (for example, the unpaired electron orbital and the chemical bond) is necessary. Thus the abstraction of a hydrogen atom by a free radical requires that the bond undergoing association should be arranged coaxially with the unpaired electron at a distance of 1.5–2.0 Å. In other words, it is necessary that the state preceding the reaction (the prestart state) should be located on the reaction coordinate. To attain this state, a reorientation of the reacting species, as a result of translational and rotational diffusion, is necessary. This model (we shall call it the *structural-orientational correspondence model*) can in principle explain also the marked dependence of the reaction rate on the molecular dynamics of the polymer and its microstructure.

Many characteristic features of the kinetics of radical reactions in solid polymers can be naturally explained within the framework of this model: the sensitivity of the kinetics to the structure and morphology of the polymers, the decrease of the rate constants and the increase of the activation energies compared with the liquid phase, and the relation between the kinetics and molecular mobility. Solid polymers are structurally inhomogeneous systems with a broad distribution with respect to the frequencies and amplitudes of molecular movements. Such frequency-amplitude "polychromaticity" leads to a kinetic "polychromaticity"—a wide range of rate constants and activation energies for the reactants.

With increase of temperature, the molecular movements are gradually "unfrozen"; as the temperature increases, movements on a larger scale are "unfrozen". As a result of this, the effective activation energy (or the range of activation energies) depends on the temperature. A kinetic consequence of this change is the compensation effect and the anomalously high activation energies and pre-exponential factors, which lack physical significance. This also applies to the rotational[131] and translational[147] diffusion of low-molecular-weight substances, which are likewise controlled by the molecular dynamics of the polymer. It is striking that, if the Arrhenius parameters of the chemical reaction[65] or the rotational diffusion of the paramagnetic probe[131] in solid polymers have been obtained under the conditions of a constant intensity of the molecular movements of the polymer, then the activation energies and pre-exponential factors approach the "normal" liquid-phase values.

However, when specific versions of the structural-orientational correspondence model are considered, considerable difficulties are encountered.

(1) In the model of "black spot" spheres[56,148–151] it is assumed that the reacting species exhibit a marked anisotropy in their reactivity. In other words the reaction centre occupies only a small proportion (the "black spot") of the surface of the species. In order that contact between the species in the cage should be accompanied by reaction, their mutual orientation involving the coincidence of the "black spots" is necessary. Analysis of the results of studies[148,150] in which the above model has been considered most rigorously shows that the dependence of the effective rate constant for a bimolecular reaction on the rotation frequency of the reactants can be observed in those cases where the rate of reaction is limited by the encounters of the reactants, i.e. occurs under diffusional conditions. However, as already stated, such dependence is observed experimentally also for reactions which clearly take place under kinetic conditions.

A similar dependence is to be expected also when the required orientation (contact between the "black spots") cannot be realised, in principle, during the existence of the pair†. This situation is in its turn possible if the rotation frequency of the reacting species in the pair is significantly lower than the frequency of their translational migrations (the latter determines the frequency of the decomposition of the pair) or if the fraction of the required orientations is low (this is equivalent to a low pre-exponential factor).

Comparison of the rotation frequencies of stable nitroxy-radicals with the frequencies of their translational jumps in solid polymers[152] shows that the first case apparently does not occur. The second case can occur, according to the data of Griva et al.[56] for the reaction involving the addition of a nitroxy-radical to methylenequinone in the matrices of solid polyolefins: the pre-exponential factor in the expression for the rate constant for this reaction in the liquid phase is only ~10^2 litre mol^{-1} s^{-1}; however, it must be admitted that the reactions with such low pre-exponential factors are nevertheless encountered fairly rarely.

Thus the versions of the "black spot" model considered cannot as a rule explain the experimental relation between the rate constants for bimolecular reactions in solid polymers and the molecular mobility.

(2) The *stepwise orientation model* can be represented by the following scheme:

$$A + B \underset{\nu_t}{\rightarrow} [A \ldots B]_1 \underset{\nu_r}{\rightarrow} [A \ldots B]_2 \underset{\nu_r}{\rightarrow} [A \ldots B]_n \xrightarrow{k} \text{products}.$$
$$\uparrow \qquad\qquad |\nu_t \qquad\qquad |\nu_t \qquad\qquad |\nu_t$$

The pair $[A \ldots B]_1$ formed can either dissociate as a result of the translational jump of one of the reactants at a frequency ν_t or can be converted into another pair $[A \ldots B]_2$ with a different orientation of the reactants, etc. The rotational movement of the partners in the pair at a frequency ν_r "sorts through" the orientational states of the pair until the latter is in the "starting" state $[A \ldots B]_n$ with the orientation of the reactants favourable for reaction. The

†Otherwise the pair of reacting species is able to pass through all the possible orientational states and the rate of chemical reaction no longer depends on the rotation frequencies.

effective rate constant for a bimolecular reaction is

$$k_{\text{eff}} = \frac{k\nu_t}{k+\nu_t}\left(\frac{\nu_r}{\nu_r+\nu_t}\right)^n ,$$

where n is the average number of orientational states preceding the "starting" state $[A...B]_n$. The dependence of k_{eff} on the intensity of molecular movements involves mainly the numerator $[\nu_r/(\nu_r + \nu_t)]^n$.

(3) The "*rigid cage*" model[151,153] postulates that the orientation of the partners in the cage favourable for reaction has a statistically low probability, since it requires that a potential barrier be overcome. In fact one assumes here that the species in the cage are in thermodynamically favourable orientations, but the reaction takes place in other thermodynamically unfavourable states. It is postulated that, when molecular movements are "unfrozen", the statistical weight of the favourable orientations increases. This model is in essence similar to the previous one, the difference consisting in the fact that it involves a statistical thermodynamic and not a kinetic treatment.

The "rigid cage" and "stepwise orientation" models, as well as the "black spot" model discussed above, can operate under conditions where the rate-limiting stage of the process is the attainment of a favourable relative orientation of the reacting species in the cage as a result of their rotational diffusion. As already stated, this is apparently improbable.

The situation might be saved by the fact that the rotation of the species in the polymer matrix is in general anisotropic, i.e. the rotation frequencies relative to different molecular axes are different. One might assume that the rotation about an axis which requires the overcoming of a comparatively large potential barrier and is therefore slow is important for the attainment of a favourable orientation of the reactants in the cage and not rotation in general (which, as already stated, takes place at a higher frequency in solid polymers than translation). In other words, it is necessary to assume that the activation energies for rotation about different axes are different, i.e. that the anisotropy of the rotation depends on temperature.

An experimental test[154] did not confirm the latter hypothesis. It was found that the rotation of the nitroxy-radicals in polymer matrices is indeed anisotropic (incidentally the rotation frequencies about different axes differ by not more than an order of magnitude even for non-spherical radicals), but the anisotropy is independent of temperature and hence the activation energies for rotation about different axes are the same. Thus even allowance for the anisotropy of the rotation in the structural-orientational correspondence model does not eliminate its difficulties.

(4) Finally mention must be made of the *free volume model*[155]. It postulates that the reaction takes place only in certain local microregions of the polymer in which the free volume fluctuates and for this reason the local molecular movements are "unfrozen". This model is partly phenomenological; it does not deal in detail with the kinetics of the elementary reaction step, but relates the effective rate constants to physical parameters of the polymer such as compressibility, coefficient of thermal expansion, etc. An impression is created that the free volume model can explain the dependence of the rate of reaction on mobility only under the conditions of a low intensity of the molecular movements at temperatures below T_g, while the greatest difficulty arises in explaining this dependence in "soft" polymer matrices at temperatures significantly above T_g.

Thus the problem of the physical causes of the relation between the chemical kinetics and the molecular dynamics in solid polymers for reactions under kinetic conditions in essence remains open.

* * *

The problems considered in the review, namely the relation between the kinetics of radical reactions and the molecular dynamics of the polymer, the kinetics and mechanisms of the migration of the free valence, and the physical models of radical reactions, are fundamental key problems, on the solution of which further development of the given field of chemical kinetics, i.e. the kinetics of radical reactions in solid polymers, largely depends.

In assessing the general state of this field, one must recognise that, despite extremely extensive experimental data, the majority of the problems can be discussed at the present time mainly at the phenomenological level. The most important tasks are a detailed investigation of molecular dynamics in polymers and its relations with chemical kinetics, the elucidation of the true mechanism of radical processes, and an increase of the accuracy and reliability of kinetic information. All these require much effort and in particular the development of new research techniques and new experimental approaches.

Quantitative Analysis of Influence of Structure on Reactivity of Four-coordinated Phosphorus Compounds

B.I.Istomin (deceased) and V.A.Baranskii

A survey of the systematic application of correlation analysis to structural effects in organic compounds of four-coordinated quinquevalent phosphorus showed that the axiomatics of modern analysis (including possible types of intramolecular interaction between fragments of organic molecules and mathematical models of such interaction) will provide an adequate description of the effects of substituents attached to the phosphorus atom. Quantitative resolution into individual components of the structural effects governing the strengths of organophosphorus acids indicates that the widely used σ^{ph} constants are complicated in nature, comprising contributions by inductive, steric, and resonance interactions of substituents with the phosphorus atom. A list of 104 references is included.

I. INTRODUCTION

The intensive development of the chemistry of organophosphorus compounds is due to their widespread use in industry, medicine, agriculture, and other fields. Identification of the properties of practical importance and especially problems involved in the planned synthesis of such compounds make necessary further broadening and deepening of theoretical research in organophosphorus chemistry. One fundamental problem common to the whole of organic chemistry—the search for quantitative relations describing the effects of various factors on the reactivity and the physical and physicochemical properties of compounds—has now been satisfactorily solved in terms of correlation analysis[1-3]. Correlation equations are widely employed also in the chemistry of organophosphorus compounds. As early as 1953 Jaffe et al. showed that the Hammett equation will give a good description of the pK_a of aromatic phosphonic acids[4]. Later Kabanchik[5] found that this equation is applicable to the most diverse organic acids of phosphorus, provided that special constants σ^{ph} are used for *P*-substituents. These constants and their resolution into inductive and resonance components[6] have provided satisfactory descriptions of many types of reactions occurring both at the phosphorus atom and in a side-chain, and also of various physical and physicochemical properties of organophosphorus compounds[7,8]. Since, like the Hammett σ-constants, these are empirical constants, simple equations containing a single parameter can be employed, which has proved convenient for solving many problems of organophosphorus chemistry. However, their use automatically excludes the possibility of comparing, on the basis of correlation analysis and the corresponding equations, reaction series of organophosphorus compounds with those involving other organic or hetero-organic compounds.

Qualitative ideas on possible universal types of interaction (and their mechanisms) between fragments of organic molecules were formulated in theoretical organic chemistry long ago[9]. Correlation analysis, having established a list of possible interactions, conferred a quantitative form on these ideas[1,10] (mathematical models of individual types of interaction), by regarding any interaction as a departure from additivity[11-13] and introducing measures of the ability of substituents (molecular fragments) to undergo various types of interaction. Inspection of a large quantity of factual information on the effect of substituent structure on reactivity of organic compounds led to the formulation of axioms of correlation analysis, which reduced essentially to the following postulates.

1. Three types of intramolecular interactions—inductive, steric, and resonance—are possible between uncharged fragments (substituents) in organic molecules.
2. The change in free energy accompanying reaction or activation can be represented quite accurately as the sum of contributions by these interactions (Taft's first postulate[10]).
3. The principle of linearity of free energies applies to each of these contributions (Taft's second postulate[10]).
4. The contribution by any interaction between two structural fragments is proportional to the product of the corresponding constants characterising the ability of the fragments to undergo the given type of interaction (the Hine–Pal'm postulate[11-15]).
5. In addition to the above types of interaction, charged fragments can also have electrostatic interaction, described by an appropriate mathematical model[1,16] and inversely proportional to the macroscopic dielectric constant of the medium (Palm's postulate).

The scales of the ability of various substituents to undergo the above types of interaction (measured by the constants σ^*, E_S, σ^0, σ^+, etc.) have been calculated from experimental data for different series with variation in substituents mainly at a carbon atom. However, it has now been firmly established that these axioms and also the corresponding measures of the capacity of substituents for various types of interaction can be satisfactorily applied to the quantitative description of diverse kinetic and equilibrium series in which substituents are varied at atoms other than carbon—sulphur, nitrogen, oxygen, silicon, etc.—as is indicated by ample

practice of correlation analysis[1-3,17,18]. Special investigations[1,19-26] have been made on problems associated with the limits of applicability of these axioms (completeness of the list of interactions, universality of the corresponding measures (constants), etc.).

Systematic application, to the enthalpies of formation of diverse organic compounds in the gas phase, of the principle of polylinearity[11,27] together with the above postulates not only has enabled a fundamentally new and accurate scheme of calculation to be constructed for these most important standard thermodynamic characteristics of compounds but also has shown that the mathematical models of correlation analysis for individual types of interaction agree well with the corresponding contributions to heats of formation[19-23].

Nor have accurate measurements of the acidity and basicity of various classes of organic compounds in the gas phase necessitated a fundamental revision of the main concepts of correlation analysis (if the problem of the nature of the influence of alkyl groups is disregarded), since a good correlation usually exists between structural effects on dissociation in the gas phase and in solution[28-34], indicating that structural effects on the strengths of acids and bases in the gas phase and on the capacity of their neutral and ionic forms for solvation are of the same type. It would have been difficult to expect a different result in these terms, since correlation equations provide an adequate description of the influence of structural factors on the strengths of organic acids and bases in the most diverse pure media and their mixtures which vary markedly in dielectric properties, polarisability, and capacity for various types of specific solvation[18,25,26,35]. The nature of the influence of alkyl groups, however, has long been a matter of controversy in the correlation analysis of structural effects in the liquid phase[1,2,15,19,20,36-39], as also the physical nature of the inductive (polar) effect. But there is no doubt about the actual existence of such effects.

The satisfactory correlation of the properties of organophosphorus compounds with the σ^{pH} constants indicates that the principle of the linearity of free energies can be widely applied to describe the influence of *P*-substituents on the reactivity of these compounds. Isolated studies have shown also that certain of their properties can be described in terms of correlation relations based on the "carbon" constants of the substituents[4,40-44]. However, the fundamental applicability of the entire axiomatics of correlation analysis to the structural effects of *P*-substituents has remained an open question until recently, as also the limits of applicability of the axiomatics in organophosphorus chemistry. Other nontrivial questions that have not been settled are whether (i) the list of possible types of interaction and (ii) the mathematical models for individual types are adequate to describe the effects of such substituents.

Attempts by Pal'm[45] and by Charton[46] to solve these problems did not give unambiguous results[8]. The aim of the present Review consists in setting out the main results of investigations[47-55] which the Reviewers regard as providing answers to the above questions and leading to some unexpected but logically self-evident conclusions. In view of the great diversity of the valency and coordination states of the phosphorus atom in various organophosphorus compounds, only the effects of substituents attached to a four-coordinated quinquevalent phosphorus atom of the type $\gtrdot$PO have been considered, since such compounds have been most widely investigated in terms of their reactivity and various physicochemical properties, and the correlation of these properties with structure has also been studied. Furthermore, analogies for processes occurring at such a group can be found in classical organic chemistry, in particular among those taking place at a carbonyl group[56-62].

Because of the wide applicability of σ^{ph} constants in organophosphorus chemistry an analysis has been made of them[47-55] and also of the dissociation of various acids of general formula XYPOOH, the standard reaction series for their determination. Furthermore, a systematic comparison has been made of the influence of substituents on reaction centres containing carbonyl and phosphoryl to reveal specific structural effects characteristic of the phosphorus atom alone; the combined influence of substituents attached to a four-coordinated phosphorus atom has been examined.

II. EQUATION FOR pK_a OF ACIDS XYPOOH

On the above postulates the difference $\Delta\Delta G^0$ between the changes in free energy $\Delta G^0(XY)$ and $\Delta G^0(X_0Y_0)$ accompanying dissociation of the acids XYPOOH and X_0Y_0POOH can be written as the sum

$$\Delta\Delta G^0 = \Delta G^0(XY) - \Delta G^0(X_0Y_0) = \Delta\Delta G^0_{ind} + \Delta\Delta G^0_{ster} + \Delta\Delta G^0_{res}, \quad (1)$$

of contributions $\Delta\Delta G^0_{ind}$, $\Delta\Delta G^0_{ster}$, and $\Delta\Delta G^0_{res}$ by inductive, steric, and resonance interactions of the substituents X (X_0) and Y (Y_0) with the reaction centre and between themselves X and Y or X_0 and Y_0. The quantity $\Delta\Delta G^0$ corresponds to the change in free energy in the equilibrium proton transfer

$$XYP(O)OH + X_0Y_0P(O)O^- \rightleftharpoons XYP(O)O^- + X_0Y_0P(O)OH.$$

The quantities

$$\Delta\Delta G^0_{ind} = \Delta G^0_{ind}(XY) - \Delta G^0_{ind}(X_0Y_0), \quad \Delta\Delta G^0_{ster} = \Delta G^0_{ster}(XY) - \Delta G^0_{ster}(X_0Y_0), \quad \Delta\Delta G^0_{res} = \Delta G^0_{res}(XY) - \Delta G^0_{res}(X_0Y_0)$$

are the differences between the contributions by the corresponding interactions to the changes in free energy accompanying detachment of a proton from the acids XYPOOH and X_0Y_0POOH. In conformity with the practice of correlation analysis we adopt as standard substituent the methyl group: i.e. $X_0 = Y_0 = CH_3$.

In terms of the principle of polylinearity[1,27] and the homogeneity of inductive interaction[1]

$$\Delta\Delta G^0_{ind} = \Delta G^0_{ind}(XY) - \Delta G^0_{ind}(X_0Y_0) = -\alpha^*\Delta\sigma^*_{rc}\sum\sigma^* - \alpha^*\Delta Z^*\sigma^*_X\sigma^*_Y \quad (2)$$

where α^* is the universal constant[25] of inductive interaction,

$$\Delta\sigma^*_{rc} = \sigma^*(CH_3POOH) - \sigma^*(CH_3POO^-)$$

is the difference between the inductive constants of the reaction centre in initial and final states, and

$$\Delta Z^* = Z^*(\gtrdot POOH) - Z^*(\gtrdot POO^-)$$

is the difference between the conductivities of inductive interaction between X and Y through the reaction centre in its initial and final states. The first term in Eqn.(2) is the contribution to $\Delta\Delta G^0$ by inductive interaction of X and Y with the reaction centre†, and the second term by inductive interaction between X and Y through the reaction centre.

If the acid and its anion have a tetrahedral structure[63,64], it is obvious from symmetry considerations that the contribution

$$\Delta\Delta G^0_{ster} = \Delta G^0_{ster}(XY) - \Delta G^0_{ster}(X_0Y_0) = -\Delta a\sum E_s \quad (3)$$

† Here and subsequently. $\sum\sigma^*\left(\sum E_s\right) = \sigma^*_X + \sigma^*_Y\left(E_{sX} + E_{sY}\right)$.

where

$$\Delta a = a(CH_3POOH) - a(CH_3POO^-)$$

is the difference in sensitivity of the reaction centre, in initial and final states, to steric interaction with substituents#. Equation (3) contains no cross terms: i.e. contributions by steric interactions between substituents X and Y in the acid and in its anion are assumed to be similar (or equal) in magnitude, a hypothesis which has been confirmed[47].

Substitution of Eqns.(2) and (3) in (1) followed by conversion to pK_a values yields

$$pK_a(XYP(O)OH) = pK_a(Me_2P(O)OH) - \rho^* \sum \sigma^* - \gamma\sigma_X^*\sigma_Y^* - \delta \sum E_s + \Delta\Delta G^0_{res}/2.303RT \quad (4)$$

where

$$\rho^* = \alpha^* \Delta\sigma^-_{ph}/2.303RT;\ \gamma = \alpha^* \Delta Z^*/-2.303RT;\ \delta = \Delta a/2.303RT.$$

Hence, provided that all the above postulates are valid, the pK_a values of XYPOOH acids, in which X and Y are uncharged substituents, should be given by Eqn.(4).[47] With regard to experimental verification of this equation, the question of resonance interaction merits the special comment that, since hyperconjugation plays no great part[1,19] in the ground state of organic compounds, it was accepted[47-55] that aryl groups, αβ-unsaturated substituents, and substituents whose first atom is a heteroatom having a lone pair of electrons are capable of conjugating with an electron-deficient reaction centre of $-C$ type: all other substituents—alkyl groups, $X^1X^2X^3M[CH_2]_m$, $X^1X^2CH[CH_2]_m$, and $XCH_2[CH_2]_m$ (the X are various electronegative groups, and $m = 0, 1, 2, \ldots$)—were regarded as incapable of conjugation[19,47].

III. ANALYSIS OF σ^{ph} CONSTANTS

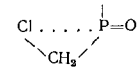
The dissociation of XYPOOH acids was chosen[5] as standard series for deducing σ^{ph} constants, and the hydrogen atom was adopted as standard substituent:

$$pK_a(XYP(O)OH) = pK_a(H_2P(O)OH) - \sum \sigma^{ph} \quad (5)$$

It follows from Eqns.(4) and (5) that the σ^{ph} constants of substituents incapable of conjugation with the reaction centre should be given by[47]

$$\sigma^{ph} = \sigma^{ph}(Me) + \rho^*\sigma^* + 0.5\gamma(\sigma^*)^2 + \delta E_s \quad (6)$$

The regression dependence



$$\sigma^* = -(0.938 \pm 0.036) + (1.151 \pm 0.076)\sigma^* - (0.199 \pm 0.031)(\sigma^*)^2 + (0.149 \pm 0.030)E_s$$

$$n = 25;\ R = 0.987;\ S_0 = 0.11 \quad (7)$$

has been found[47] for 25 such substituents. Here and subsequently n is the number of experimental points described by a given equation, $r(R)$ the (multiple) correlation coefficient, and $s_0(S_0)$ the (multiple) regression standard. All coefficients in the relation (7) are statistically significant, and from (6) the independent term is identical with $\sigma^*(CH_3)$.[7]

The reproducibility of pK_a values determined by potentiometric titration has been estimated[66,67] as 0.04–0.05 logarithmic unit. The pK_a values used[7] in calculating σ^{pH} have been measured at 20–25 °C, in which temperature range the divergence in estimates of pK_a for organic acids of phosphorus may reach estimates of pK_a for organic acids of phosphorus may reach ±0.03 lg unit[68]. In virtue of the law of the accumulation of errors the uncertainty in the calculation of σ^{ph} is thus at least ±0.09 lg unit. Furthermore, the σ^{ph} constants recommended[7] for use had been averaged over many reaction series, and such averaging replaces[17] the apparent reliability by considerable uncertainty in the constants. Consequently the regression (7) is close to adequacy.

In the resolution of σ^{ph} constants into inductive and resonance components σ^{ph}_{ind} and σ^{ph}_{res} non-zero resonance constants were ascribed[6,7] to many substituents and were not αβ-unsaturated and had no n-electrons on the α-atom. The especially high σ^{ph}_{res} values for mono-, di-, and tri-halogenomethyl groups were attributed[7,69] to a contribution by a transannular dative bond of type

However, such a bond was not detected[70] in the chlorine-35, bromine-79, and iodine-127 nuclear quadrupole resonance spectra of the compounds $(ClCH_2)_3PO$, $(ClCH_2)_2CH_3PO$, $(ICH_2)_3PO$, $(ICH_2)_2CH_3PO$, and $(BrCH_2)_2CH_3PO$. In terms of the regression (7) the resonance constants σ^{ph}_{res} for such substituents should be a combination of inductive and steric components (owing to incorrect resolution[6,7] of the σ^{ph} constants). In fact, for substituents described by regression (7) the relation

$$\sigma^{ph}_R = (0.059 \pm 0.046) - (1.202 \pm 0.042)\sigma^* + (0.237 \pm 0.050)E_s$$

$$n = 24;\ R = 0.9902;\ S_0 = 0.138$$

was found[47], from which only the point for cyanoethyl departs significantly.

Table 1. Values of $\overline{\Delta\sigma^{ph}}$ averaged over individual structural types of substituents*[48].

Type of substituent	m	$\overline{\Delta\sigma^{ph}}$
R_2N(R — Alk)	2	—0.79±0.06
PhO	1	—0.65
RO(R—H, Alk)	10	—0.62±0.02
RS(R — Alk)	4	—0.18±0.03
XC_6H_4(X—H, Alk, electroneg. subst.)	24	—0.07±0.01

*Here m is the number of substituents of the given structural type for which $\Delta\sigma^{ph}$ have been calculated.

Values of σ^{ph}_{calc} calculated by means of Eqn.(7) for substituents capable of conjugation are usually more positive than the experimental values σ^{ph}_{exp}: i.e. such substituents are characterised not only by inductive and steric effects but also by an additional effect that lowers the acidity of the compounds. This may be solely due to conjugation of the substituents with the reaction centre. On this basis the differences $\Delta\sigma^{ph} = \sigma^{ph}_{exp} - \sigma^{ph}_{calc}$ for these substituents were adopted as measures of their resonance capacity. For substituents of the same structural type calculated differences

Steric interaction is inhomogeneous[1,13,65], and therefore cannot be described by a mathematical model similar to that used for inductive interaction.

$\Delta\sigma^{ph}$ do not exceed the experimental uncertainty in the constants σ^{ph}_{exp}:[48] i.e. the ability of, for example, substituents RO, RS, and R_2N to conjugate is to a first approximation independent of R. Therefore average values $\overline{\Delta\sigma^{ph}}$ (Table 1) were taken[48] as the estimated capacities of such substituents for conjugation. An obvious correlation exists (Fig.1) between the $\Delta\sigma^{ph}$ values and the σ^{+}_{res} constants[24] representing the ability of the substituents to conjugate with a $-C$ type of reaction centre.

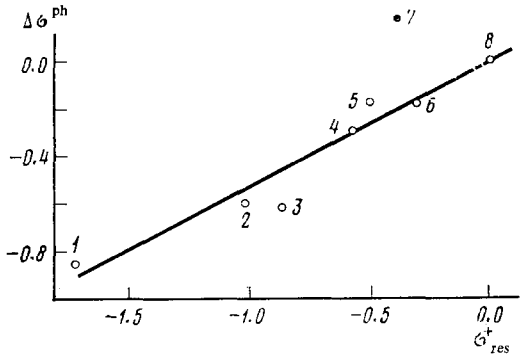


Figure 1. Correlation[48] between deviations $\Delta\sigma^{ph} = \sigma^{ph}_{exp} - \sigma^{ph}_{calc}$ and resonance constants σ^{+}_{res} for the substituents: 1) $(CH_3)_2N$; 2) CH_3O; 3) C_6H_5O; 4) F; 5) CH_3S; 6) C_6H_5; 7) Cl; 8) H.

The whole set of σ^{ph} constants (see compilation in Ref.48) is adequately described by the equation[48]

$$\sigma^{ph} = -(0.956 \pm 0.015) + (1.129 \pm 0.030)\,\sigma^{*} - (0.187 \pm 0.011)\,(\sigma^{*})^2 + (0.166 \pm 0.014)\,E_s - (0.952 \pm 0.44)\,\overline{\Delta\sigma^{ph}}$$
$$n=71;\ R=0.992;\ S_0=0.073\ . \qquad (8)$$

The estimated coefficients obtained in this regression, of the sensitivity of substituents to inductive and steric effects, coincide within the limits of their errors with the corresponding quantities in regression (7). The independent term, as Eqn.(6) requires, is identical with the $\sigma^{ph}(CH_3)$ constant. The coefficient accompanying the resonance contribution should be unity if $\overline{\Delta\sigma^{ph}}$ values have been introduced: the estimate of this coefficient in regression (8) is indeed close to unity.

Thus the above results[47,48] indicate that the σ^{ph} constants for *P*-substituents comprise inductive, steric, and resonance contributions that are adequately described in terms of the usual "carbon" constants σ^{*} and E_S and by means of $\Delta\sigma^{ph}$ values linearly related to the σ^{+}_{res} constants.

IV. INFLUENCE OF STRUCTURAL FACTORS ON STRENGTHS OF ACIDS XYPOOH

It has been shown above that the pK_a values of XYPOOH acids should be described by Eqn.(4), which itself should be defined by the pK_a of phosphinic acids, the pK_{a_1} and pK_{a_2} of phosphonic acids, and also all three pK_a of phosphoric acid if the fragment O^- is regarded as a substituent. In order to take into account the electrostatic interaction between two O^- substituents the electrostatic correction $\Delta pK_{el} = 1.2$ was calculated[49] from the equation suggested in Ref.16 and the geometry of the anion of phosphoric acid[63]. This correction was assumed to be constant for all phosphonic acids. The fundamental possibility of describing pK_{a_1}, pK_{a_2}, and pK_{a_3} by means of a single equation can be illustrated by the simple relation

$$pK_{a_3}(H_3PO_4) = 2pK_{a_2}(MeP(O)(OH)_2) - pK_a(Me_2P(O)OH) + \lg 3 - \lg 2$$

which follows from (4) and takes into account statistical corrections. This gives for $pK_{a_3}(H_3PO_4)$ an estimated 12.3, while the experimental value is 12.0–12.3.[71]

Table 2. Analysis of pK_a values (in water at 20–25 °C) by means of Eqn.(9).[49]

Coeff. or statistical criterion	Regression

*Calculated disregarding compounds in which X and (or) Y = Ar.
**Calculated disregarding both compounds in which X and (or) Y = Ar and also the electrostatic correction.
***Calculated for the complete set of pK_a values (see compilation in Ref.49).

Table 2 lists results of an analysis[49] of pK_a values of XYPOOH acids given with statistical and electrostatic corrections by the equation

$$pK_a(XYP(O)OH) = a_0 + a_1\sum\sigma^{*} + a_2\sigma^{\bullet}_X\sigma^{\bullet}_Y + a_3\sum E_s + a_4 n_{RO} + a_5 n_{Ar} + a_6 n_{O^-} + a_7 n_{ArO} \qquad (9)$$

in which a_0–a_7 are the unknown coefficients (a_0–a_3 should include analogous coefficients in Eqn.(4) and a_4–a_7 are resonance contributions by the corresponding substituents) and n_{RO}, n_{Ar}, n_{O^-}, and n_{ArO} are the numbers of substituents RO (R = H, Alk), *p*- or *m*-XC_6H_4, O^-, and *p*-XC_6H_4O respectively. Such allowance for the resonance component is based on the hypothesis, made in analysing the σ^{ph} constants[48], that substituents capable of conjugation and of the same structural type make a constant resonance contribution§.

It was assumed[49] for all *p*- or *m*-XC_6H_4 groups that $E_S = 0$. Since this postulate is arbitrary[72], the inclusion of arylphosphinic and arylphosphonic acids in the general set with other

§ This procedure for isolating the resonance contribution was adopted also because experimental data[71] for phosphinic acids containing substituents incapable of conjugation were insufficient for the construction of a reliable regression.

acids may lead to errors in the estimated regression of coefficients. Consequently regression No.1 must be regarded as basic in Table 2. The agreement between the estimated coefficients in regressions 1 and 3 and the quite high statistical indices of the latter indicate that the postulated equality of the steric constants of methyl and aryl groups produces no appreciable errors. Disregard of the electrostatic correction increases the resonance contribution of the O^- substituent by this amount, while the remaining regression coefficients remain unchanged (cf. regressions 1 and 2).

Thus use of the constants σ^* and E_s respectively to characterise inductive and steric effects of substituents enables Eqn.(9) to provide a good description of pK_a values for phosphinic acids, pK_{a1} and pK_{a2} for phosphonic acids, and the three values for phosphoric acid. The range of variation in acid strength covered by this equation is 12 lg units: i.e. the relative precision of the description $S = 1.4\%$. The results in Table 2 indicate that substituents destabilise by an inductive mechanism ($a_1 < 0$), and stabilise by a conjugation mechanism ($a_4 - a_7 > 0$), the initial state in the dissociation of organic acids of phosphorus. The difference $\Delta\sigma^*_{rc}$ (Section II) calculated from $a_1 = -\alpha^*\Delta\sigma^*_{rc}/2.303RT$ (see Eqn.4) is 0.66. The corresponding value for the dissociation of aliphatic carboxylic acids (in water at 25 °C) is 0.77.[25] Since $\sigma^*(CH_3POOH) = 1.47$, we obtain $\sigma^*(CH_3POO^-) = 0.81$, whereas $\sigma^*(COOH) = 1.7$ and $\sigma^*(COO^-) = 0.93$.[25] Hence for the dissociation of organic acids of phosphorus and of aliphatic carboxylic acids not only are the $\Delta\sigma^*_{rc}$ values closely similar but also the inductive constants of initial and final states respectively of their reaction centres.

The statistical significance of the coefficient a_3 in Eqn.(9) indicates different intensities of steric interaction of the substituents X, Y with the fragment $\rangle$POOH and with the corresponding anion. The sign of a_3 shows that the acid becomes weaker as the steric effects of the substituents become greater. This can be explained by steric hindrance to solvation stabilisation of the anion by X and Y, as occurs in the dissociation of carboxylic acids containing bulky substituents[73-75]. Significant steric influence of substituents on the strengths of XYPOOH acids is demonstrated by the regression[54]

$$pK_{a_2}(XP(O)(OH)_2) = (7.987 \pm 0.048) - (1.345 \pm 0.037)\sigma^* - (0.210 \pm 0.046)E_s$$
$$n=6;\ R=0.9987;\ S_0=0.073 \qquad (10)$$

obtained for very accurate measurements[76] of pK_{a2} for six phosphonic acids containing substituents incapable of conjugation. The independent term coincides with the experimental value[76] of $pK_{a2}(CH_3PO(OH)_2)$, and estimates of the coefficients for inductive and steric contributions agree well with the corresponding estimates in the regression in Table 2. Exclusion of the steric contribution from regression (10) produces a sharp impairment of its statistical indices[54] (for example, the standard deviation is doubled).

V. NON-ADDITIVITY OF EFFECTS OF SUBSTITUENTS ATTACHED TO A FOUR-COORDINATED PHOSPHORUS ATOM

Equation (4) contains a cross term, a contribution proportional to the product of the inductive constants of the substituents. The presence of cross terms is implied by the general form of polylinear equations[1,27], and is interpreted as a change in the intensity of the effect of one factor under the influence of another factor. These non-additive effects are closely connected with the phenomenon of isoparametricity[1,77,78], and have now been shown for various pairs of factors (medium and structure, pressure and structure, reactant and substrate structures, etc.) in many organic reactions[1,77-89]. A well known example of such non-additivity is the dependence of activation energy on reactant structure[1,12,77,89]. The character of the combined influence of different factors is obviously determined by the detailed mechanism of the chemical process[1,27,77].

The statistical significance of a_2 in the regressions in Table 2 presupposes non-additivity of the inductive effects of substituents X and Y on the dissociation of XYPOOH acids. However, exclusion of the cross term from these regressions neither impairs appreciably the quality of the description nor changes the estimated coefficients a_0, a_1, and a_3–a_7.[49] The variables $\Sigma\sigma^*$, $\sigma^*_X\sigma^*_Y$, and ΣE_s in the regressions are strongly interdependent (non-orthogonal). Because of the many-sided interrelationship the estimate of one coefficient (e.g. a_2) may be shifted relative to its true value without appreciably displacing the estimates of other coefficients.

The non-orthogonality of the scales of constants representing the abilities of substituents (or solvents) to undergo various types of interaction is a common weak point in multidimensional correlation analysis, to which many investigators do not pay due attention. A frequent consequence of such non-orthogonality is that the absolute estimates of regression coefficients obtained by least squares lose their physical content and in general cannot be compared either within a single regression or with corresponding parameters in analogous equations for other processes.

There are in principle two possible escapes from such a situation—(i) rejection of the convenient method of least squares and (ii) preliminary factorisation of the variables—both unattractive for correlation analysis[90]. The latter procedure, which is widely used in experiment design, leads to variables losing their concrete meaning (physical or quasi-physical), and furthermore does not permit the construction of invariant scales of constants for substituents (or solvents). In the Reviewers' opinion, therefore, the most acceptable way at present is first to deduce various equations based on some *a priori* considerations (theoretical or formal), followed by logical analysis of the parameters in regression corresponding to these equations, in terms of the meaning that had been implied *a priori* in these parameters. In some cases a model calculation may prove very useful: coefficients therein are specified that are close to those in the regression obtained, values of the function to be correlated are then calculated from these coefficients and the corresponding set of variables, and these values are "coarsened" (errors close to those in the experimental data are introduced). After this the coefficients in the regression are found from the resulting values of the function and the original set of variables. Comparison of the results with the specified coefficients will indicate whether the correctibility of the variables will lead in a given case to displacement of the estimated coefficients.

A model calculation[49] made to test the displaceability of the estimated coefficient a_2 in the regressions in Table 2 indicates that with a given set of variables, even when the cross term is *a priori* significant, its exclusion leads to no significant deterioration in the quality of the description and to no displacement of the estimates of other coefficients in the regression. Thus there is no direct confirmation of the presence of a cross term in Eqn.(4).

Little information is available on non-additive effects of substituents attached to four-coordinated phosphorus. Thus non-additivity was shown[91] in the influence of two alkoxy-groups X and Y on the alkaline hydrolysis of the esters $XYPOOC_6H_4NO_2$-*p*, but a recent analysis[92] of a larger number of results has indicated complete additivity. This example illustrates how changing the set of substituents and using

experimental results from different sources can influence the apparent character of the combined effects of substituents in a reaction series. In the Reviewers' opinion a solution to this problem should be based in each particular case on detailed analysis of the parameters of the correlation model for the given process, and it is desirable that self-consistent data should be used to deduce this model.

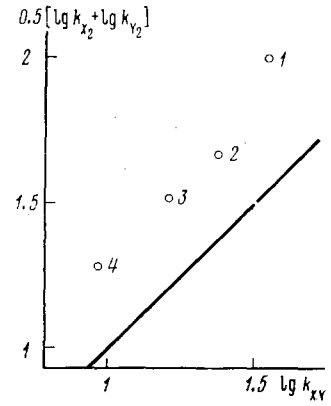

Figure 2. Non-observance[55] of additivity test for effects of substituents in alkaline hydrolysis of X(C_2H_5)POF, with X: 1) CH_3O; 2) C_2H_5O; 3) n-C_3H_7O; 4) iso-C_3H_7O.

*The compounds used are given in Ref.53.

A clear example of non-additivity of the effects of *P*-substituents is alkaline hydrolysis of the acid fluorides XYPOF, for which the criterion of additivity[55] is not observed: i.e. experimental points for the plot of lg k(XYPOF) against 0.5[lg k(X_2POF) + lg k(Y_2POF)] do not lie on a straight line of unit slope passing through the origin (Fig.2). The rate of this reaction (in water at 25 °C) [93] is well described (Table 3) by the non-additive equation[53]

$$\lg k(\mathrm{XYP(O)F}) = a_0 + a_1 \sum \sigma^* + a_2 \sigma^*_X \sigma^*_Y + a_3 \sum E_s + a_4 n_{RO} \qquad (11)$$

in which a_4 is the resonance contribution by the RO substituents and n_{RO} the number of such substituents in the molecule. Omission of the cross term $a_2\sigma^*_X\sigma^*_Y$ impairs the quality of the description (regression 2 in Table 3).

The contribution by non-additive interaction of the substituents is small when X and Y are alkyl, and amounts to 0.3 to 0.4 lg unit when they are alkoxyl groups. Alkaline hydrolysis of the acid fluorides XYPOF is obviously greatly hindered by the resonance effect of the alkoxy-groups, which stabilises the initial state. It is curious that this resonance effect in this reaction series is largely balanced by the inductive effect of these groups. Omission of the contribution $a_3\Sigma E_S$ also somewhat impairs the quality of the description: i.e. reactivity in the series is influenced by spatial factors, for steric effects of substituents X and Y hinder the reaction, by destabilising the transition state. Despite the smallness of the coefficient a_3 (Table 3), the steric contribution to lg k may be considerable: thus for the compound (iso-$C_3H_7O)_2$POF it is 0.33 lg unit, but the corresponding value when X = Y = t-C_4H_9O should be 0.61.

Confirmation of the non-additive character of the influence of substituents on the rate of substitution of fluorine in the compounds XYPOF can be obtained also by direct application of the principle of polylinearity[1], according to which the rate should be given by

$$\lg k(\mathrm{XYP(O)F}) = a_0 + X' + a_1 Y' + a_2 X'Y', \qquad (12)$$

if the effects are defined as

$$X' = \lg k(\mathrm{X_tY_0P(O)F}) - \lg k(\mathrm{X_0Y_0P(O)F});$$
$$Y' = \lg k(\mathrm{X_0Y_tP(O)F}) - \lg k(\mathrm{X_0Y_0P(O)F}),$$

where lg k(X_0Y_0POF) relates to the compound containing substituents X_0 and Y_0 chosen as standard. The principle imposes on the coefficients in (12) the limitations[1,27] a_0 = lg k(X_0Y_0POF) and a_1 = 1. The use of such scales to analyse the real significance of the coefficient a_2 in Eqn.(12) is extremely convenient, since mathematical expectancies are available for all the other coefficients. This prevents the appearance of a significant cross term because of shifts in the estimates of a_0 and a_1, e.g. owing to non-orthogonality of the variables X', Y', and $X'Y'$, in cases in which the effects of the factors are actually additive. Furthermore, use of the X' and Y' scales enables the presence to be revealed of small cross terms, whose omission does not affect significantly the statistical indices but leads to displaced estimates of a_0 and a_1. Choice of X_0 = Y_0 = C_2H_5 and calculation of X' and Y' for various groups X and Y gave[53] values of lg k for alkaline hydrolysis of compounds XYPOF well described by Eqn.(12) with a statistically significant cross term $a_2X'Y'$, exhibiting good convergence of estimates of a_0 and a_1 with the theoretical coefficients.

The structural effects of the departing aryloxy-group and the nucleophile on the rate of reaction of 2-aryloxy-2-oxo-1,3,2-dioxaphosphorinans with various nucleophilic reagents are also significantly non-additive[83]. A bimolecular mechanism of direct substitution S_N2(P) is involved[83], so that departing group and attacking nucleophile should interact strongly in the transition state. Thus the effects of two substituents attached to a phosphorus atom may indeed be non-additive. Such non-additivity has been confirmed in a study of alkaline hydrolysis of the esters XYPSOC_6H_4X-*p*(*m*).[94]

VI. COMPARISON OF INFLUENCE OF STRUCTURAL FACTORS ON DISSOCIATION OF XYPOOH AND XCOOH ACIDS

It is generally accepted in organophosphorus chemistry[95,96] that the electronic effects of substituents on reaction centres involving phosphorus and carbon atoms—including phosphinico and carboxyl—are different in nature. It has been shown above that substituents X and Y influence the strengths of

XYPOOH acids mainly by inductive and resonance mechanisms. The constant of sensitivity to the inductive effect for this series $\rho_P^* = 1.358 \pm 0.040$ (Table 2) is close to the corresponding value $\rho_C^* = 1.809 \pm 0.028$ for the dissociation of XCOOH acids[25].

Table 4. Resonance contributions ΔpK_P and ΔpK_C by substituents to pK_a (in water at 25 °C) of XYPOOH and XCOOH.[51]

X	ΔpK_P^* (F) **	ΔpK_C
OH	1.221±0.084 (51)	1.74
O^-	3.160±0.041 (40)	3.98
O^-	4.486±0.041 (40)	5.25***
Ph	0.256±0.041 (20)	0.57
R****	0.00	0.00

*Values taken from regressions in Table 2.
**F = number of degrees of freedom.
***Without electrostatic correction.
****Here R = CH_3 and other substituents incapable of conjugation.

Table 4 lists the resonance contributions ΔpK_P made by phenyl, hydroxyl, and oxide substituents (with and without the electrostatic correction) to the pK_a values of XYPOOH acids and the corresponding contributions ΔpK_C made by them¶ to the pK_a values of XCOOH acids, the latter calculated by means of the equation[1]

$$\Delta pK_C = pK_a(XCOOH) - 4.748 + 1.809\sigma^*.$$

Comparison was impossible withother substituents capable of conjugation, for either experimental data for such carboxylic acids were lacking or the pK_a values available for the corresponding organic acids of phosphorus were unreliable. Fig.3 shows a linear relation between ΔpK_C and ΔpK_P. The corresponding regression[51]

$$\Delta pK_C = (1.29 \pm 0.05)\Delta pK_P;\ r = 0.9976;\ s_0 = 0.18$$

passes through the origin, i.e. through the point X = Y = CH_3. Such a relation indicates that the effects of these substituents on the pK_a values of phosphororganic and carboxylic acids are identical in nature. The ratio of ΔpK_C to ΔpK_P is given by the slope of the straight line in Fig.3, which coincides with the ratio $\rho_C^*/\rho_P^* = 1.37 \pm 0.04$: i.e. the ratio of the resonance contributions in the dissociation of XCOOH and XYPOOH acids is equal to that of the corresponding inductive contributions. Hence it follows by proportion that the ratio of inductive and resonance contributions to the overall effect of a substituent is the same in the series under comparison.

The reaction centres COOH and POOH are of the $-C$ type, so that a correlation should be observed between the conjugation contributions ΔpK_C (ΔpK_P) and the constants $\sigma_{res}^+ = \sigma^+ - \sigma^0$ for the $+C$-type substituents C_6H_5, OH, and O^-. A very good linear relation does indeed exist[51] between ΔpK_C and σ_{res}^+, passing through the origin, i.e. through the point for the methyl substituent (Fig.4):

$$\Delta pK_C = (-2.209 \pm 0.003)\sigma_{res}^+;\ r = 0.9999;\ s_0 = 0.005.$$

The point for the resonance contribution of the substituent O^- without the electrostatic correction does not lie on the line. This demonstrates unambiguously the necessity for such correction in the case of charged substituents capable of conjugating with the reaction centre†.

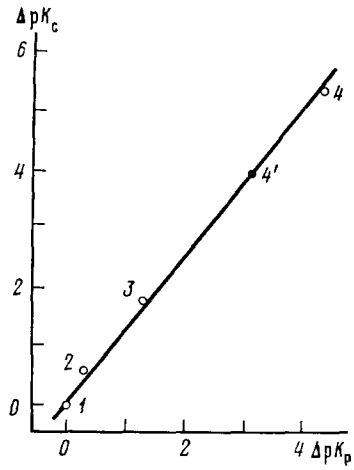

Figure 3. Relation[51] between resonance contributions to pK_a of carboxylic and organophosphorus acids (ΔpK_C and ΔpK_P) by the substituents: 1) CH_3; 2) C_6H_5; 3) HO; 4) O^-; 4') as (4) with electrostatic correction.

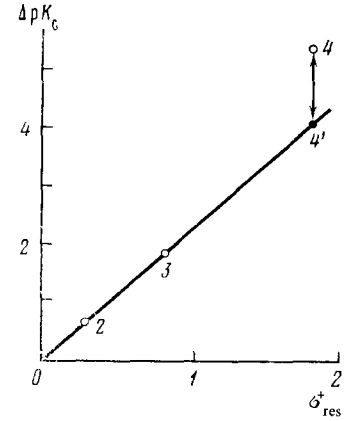

Figure 4. Correlation[51] between resonance contributions ΔpK_C and σ_{res}^+ constants: numbering as in Fig.3.

¶ The electrostatic correction ΔpK_{a1} for pK_{a2} of carbonic acid was calculated[51] from the geometry of the carbonate anion CO_3^{2-}, by a procedure similar to that adopted for phosphonic acids and phosphoric acid.

† The need to allow for electrostatic interaction has been shown[1,25] for charged substituents incapable of conjugation with the reaction centre.

Thus the electrostatically and statistically corrected pK_a values of XYPOOH acids are described by the equation[51]

$$pK_a(XYP(O)OH) = pK_a(Me_2P(O)OH) + \rho_P^* \sum \sigma^* + a_1\sigma_X^*\sigma_Y^* + \rho_{res\,P}^+ \sum \sigma_{res}^+ \quad (13)$$

and the pK_a values of XCOOH acids by[51]

$$pK_a(XCOOH) = pK_a(MeCOOH) + \rho_C^*\sigma^* + \rho_{res\,C}^+\sigma_{res}^+ \quad (14)$$

where $\sigma_{res,P}^+ = -1.709$ and $\sigma_{res,C}^+ = -2.209$ are the sensitivities of the series to the resonance influence of substituents. In these equations the ratio of the inductive contributions by substituents is equal to that of their resonance contributions:

$$\rho_P^*/\rho_C^* = \rho_{res\,P}^+/\rho_{res\,C}^+ = \alpha = 0.760 \pm 0.028. \quad (15)$$

From this formula together with Eqns.(13) and (14) it necessarily follows for the pK_a of XYPOOH acids in which Y remains unchanged that

$$pK_a(XYP(O)OH) = A_Y + \alpha pK_a(XCOOH) + a\sigma_X^*\sigma_Y^* + \delta_P E_{s,X} \quad (16)$$

where

$$A_Y = pK_a(MeYP(O)OH) - \alpha pK_a(MeCOOH).$$

Hence with any substituent X and any given substituent Y the experimental pK_a values should obey (16) with statistically significant contributions $\delta_P E_{s,X}$ and $a\sigma_X^*\sigma_Y^*$.

Conformity to Eqn.(16) has been verified[52] for the pK_{a_1} and pK_{a_2} values (Y respectively OH and O^-) of substituted phosphonic acids, for which this equation becomes

$$pK_{a_1}(XP(O)(OH)_2) = A_{OH} + \alpha pK_a(XCOOH) + a\sigma_{OH}^*\sigma_X^* + \delta_P E_s \quad (16a)$$

$$pK_{a_2}(XP(O)(OH)_2) = A_{O^-} + \alpha pK_a(XCOOH) + \delta_P E_{s,X}. \quad (16b)$$

The contribution $a\sigma_X^*\sigma_{O^-}^*$ is absent from the latter formula, since $\sigma_{O^-}^* = 0$.[26,49] Mathematical expectancies are known for all the coefficients in (16a) and (16b): δ_P and a should not differ significantly from -0.230 ± 0.027 and 0.161 ± 0.042 respectively (Table 2); from experimental values of pK_{a_1}. $.(CH_3PO(OH)_2)$, $pK_{a_2}(CH_3PO(OH)_2)$, and $pK_a(CH_3COOH)$ it has been found[52] that $A_{OH} = -0.93 \pm 0.147$ and $A_{O^-} = 2.71 \pm 0.147$, while $\alpha = 0.760 \pm 0.028$.

Checking the validity of Eqns.(16a) and (16b) reveals poor statistical indices (Table 5) only for the dependence of pK_{a_1} and pK_{a_2} (regressions 1 and 3 respectively) of phosphonic acids on the pK_a of the corresponding carboxylic acids.

Inclusion of the terms $a\sigma_{OH}^*\sigma_X^*$ and $\delta_P E_S$ in pK_{a_1} and of $\delta_P E_S$ in pK_{a_2} (regressions 2 and 4) sharply improves the quality of the description. The estimates of A_{OH}, A_{O^-}, and α agree well with the values expected mathematically; the estimates of δ_P and a have the required signs and also agree satisfactorily with their theoretical values (above). Consequently the pK_a of corresponding phosphonic and carboxylic acids are indeed represented by the above relations.

It is evident also from formulae (16a) and (16b) and the corresponding regressions that the pK_{a_1} and pK_{a_2} values of phosphonic acids should be given by the single equation[52]

$$pK_{a_{1(2)}}(XP(O)(OH)_2) = A_{OH} + \beta T + \alpha pK_a(XCOOH) + a\sigma_{OH}^*\sigma_X^* + \delta_P E_s \quad (17)$$

in which T is respectively 0 and 1. Here $\beta = -3.64 \pm 0.071$ is the difference between the independent terms in regressions 2 and 4 (Table 5).

The graphical illustration of Eqn.(17) in Fig.5 shows that the large majority of points lie close to a straight line of slope α. It is interesting that the pK_{a_2} values for trifluoro- and trichloro-methylphosphonic acids are located closest to the regression line if negative pK_a values are used for the corresponding carboxylic acids[72], whereas points corresponding to the pK_{a_1} of the above acids depart considerably from the straight line whatever the pK_a values of trifluoro- and trichloro-acetic acids. The pK_{a_1} values of the two phosphonic acids deviate also from the regressions in Table 2, apparently because they had been determined incorrectly.

Equation (17) corresponds to regression 5 in Table 5, covering 41 pK_a values for 22 phosphonic acids. All its coefficients agree well with the corresponding coefficients of regressions 2 and 4 and with their theoretical values. The statistical indices of the regression are good.

Thus the good adherence to relations (16a), (16b), and (17) for acids containing diverse substituents X, including charged groups (O^-) and those capable of conjugation with reaction centres, finally confirms the correctness of Eqns. (13)–(15). This indicates that the structural effects of substituents on the strengths of XYPOOH and XCOOH acids are entirely of the same type.

VII. CONCLUSION

Among the results covered in the Review the most unexpected to the Reviewers is the good linear relationship between the contributions by the conjugation of substituents with POOH and COOH reaction centres, as well as the closely similar relations between inductive and resonance contributions to the overall effect of substituents for dissociation of the two series of acids XYPOOH and XCOOH. However, an analogous conclusion follows logically from the good correlation observed in 1953 [4] between the pK_a values of arylphosphonic acids and the Hammett σ-constants. The linear

Table 5. Coefficients and statistical criteria of relations (16a), (16b), and (17) between pK_{a_1} and pK_{a_2} values of phosphonic and carboxylic acids $XPO(OH)_2$ and XCOOH*[52].

(17)	5	−1.196±0.0116	0.805±0.021	−0.363±0.036	0.320±0.052	−3.805±0.055	41	0.9976	0.159

*Regressions were calculated from statistically and electrostatically corrected pK_a values for the acids $XPO(OH)_2$ (see reviews[49,52]) and XCOOH (compilation[52]).

dependence of ΔpK_P on ΔpK_C, which moreover passes through the origin, indicates either absence of any specific interactions of the substituents with the POOH fragment (e.g. involving *d*-orbitals of the phosphorus atom) or complete proportionality of the contribution by such interactions to the resonance contribution (which is described by the "carbon" constants σ_{res}^{+}) and (or) to the inductive contribution.

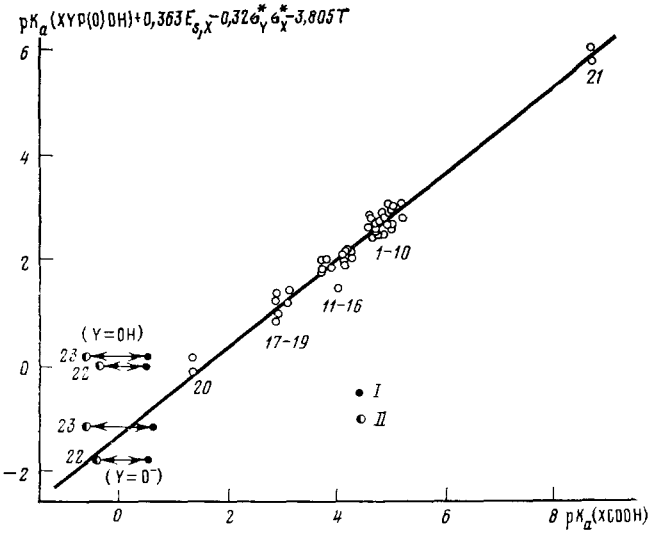

Figure 5. Graphical illustration of relation (17) [52] between the statistically and electrostatically corrected pK_{a_1} and pK_{a_2} values (Y = OH and O^-) of phosphonic acids XYPOOH and the pK_a values of carboxylic acids XCOOH, with X: 1) $n\text{-}C_3H_7$; 2) CH_3; 3) C_2H_5; 4) $iso\text{-}C_3H_7$; 5) $s\text{-}C_4H_9$; 6) $t\text{-}C_4H_9$; 7) $iso\text{-}C_4H_9$; 8) $n\text{-}C_4H_9$; 9) $t\text{-}C_5H_{11}$; 10) $(CH_3)_3.SiCH_2$; 11) $C_6H_5CH_2$; 12) $HOCH_2$; 13) C_6H_5; 14) HO; 15) $BrCH_2CH_2$; 16) H; 17) $ClCH_2$; 18) $BrCH_2$; 19) ICH_2; 20) Cl_2CH; 21) O^-; 22) F_3C; 23) Cl_3C; I) with $pK_a > 0$ for the acids CF_3COOH and CCl_3COOH; II) $pK_a < 0$ for these acids.

The steric effect exerted[47-54] by substituents X and Y on the strengths of XYPOOH acids cannot be regarded as an artefact, since the magnitude of the sensitivity coefficient δ is very stable: it depends neither on the size of the sample nor on the specific form of the equation. Exclusion of the steric contribution always impairs the accuracy of the description of experimental data, which is shown especially clearly by recent self-consistent values[76] for the pK_{a_2} of several phosphonic acids.

It is noteworthy that the steric contribution to the pK_a of XYPOOH acids may be considerable despite the small sensitivity coefficient δ to this type of interaction. The reason is the large absolute magnitudes of the constants E_s for bulky substituents[97]. The appearance of a steric contribution is obviously due not to steric hindrance by substituents to detachment of a proton but to their destabilisation of the anion by causing steric hindrance to formation of its solvation sheath. The view that substituents cause significant steric hindrance to solvation of carboxylate anions was expressed many years ago[98,75] and is supported by recent data[99,100].

Thus the results presented in this Review are evidence firstly of the adequacy of the list of types of intramolecular interaction used and of the satisfactory applicability of the mathematical models of the individual types of interaction using the "carbon" constants σ^*, E_s, and σ_{res}^{+} to represent the influence of substituents on the properties of four-coordinated quinquevalent phosphorus compounds, and secondly that the mathematical models of interactions (inductive, steric, resonance) and the corresponding substituent constants do indeed contain chemical and physical meaning axiomatically "incorporated" in them. Furthermore, the results of a recent series of studies[47-54] yet again confirm the objective character and a definite universality of the axiomatics of correlation analysis. Its limits of applicability in describing the influence of *P*-substituents on various properties of organophosphorus compounds are apparently determined by the general limits of applicability of the polylinearity principle[1,27] to these properties.

Analysis shows that the σ^{ph} constants widely used in organophosphorus chemistry are composite, comprising contributions by inductive, steric, and resonance effects of substituents#. The good description of diverse properties of organophosphorus compounds provided by these constants indicates that in many of their reaction series the relative contributions by individual interaction mechanisms to the overall effect of a *P*-substituent are about the same as in the dissociation of XYPOOH acids. Hence it is obvious that these constants are inapplicable only in reaction series in which the relative contributions differ markedly from those "incorporated" in these constants.

The σ^{ph} constants secure on important virtue—simplicity of the correlation equations—despite their complicated nature. In the Reviewers' opinion, therefore, they should be used as before to describe those reaction series to which they are readily applicable, provided comparison of organophosphorus reaction series with other series is not involved.

α-Alkoxy-compounds of Phosphorus and Some of Their Analogues

K.A.Petrov, V.A.Chauzov, and S.V.Agafonov

Data on the methods of synthesis of α-alkoxyalkyl derivatives of organophosphorus compounds are presented and their chemical properties and principal applications are examined.
The bibliography includes 305 references.

CONTENTS

I. Introduction 234
II. Methods of synthesis 234
III. Properties and applications 240

I. INTRODUCTION

The α-alkoxyalkyl derivatives belong to the large class of derivatives of organophosphorus compounds with functional group substituents, which have been vigorously investigated in recent years. Novel and convenient methods of synthesis have been proposed for these compounds and certain practical applications have been discovered. However, there are no reviews in the Soviet and foreign literature devoted to the chemistry of these compounds, which was the reason why the present review was undertaken.

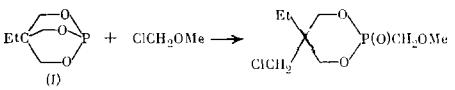
II. METHODS OF SYNTHESIS

α-Alkoxyalkyl derivatives of organophosphorus compounds are synthesised by several procedures which can be divided into two groups. The first group includes methods involving the α-alkoxyalkylation of tervalent phosphorus compounds, while the second comprises methods in which various groups in organophosphorus compounds are converted into α-alkoxy-groups.

1. α-Alkoxylation of Tervalent Phosphorus Compounds

(a) Alkylation of the Fully Esterified Tervalent Phosphorus Acids by α-Halogenoalkyl Ethers

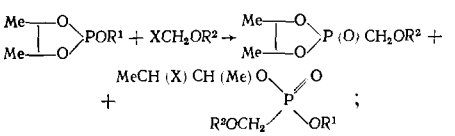
The esters of α-alkoxyalkylphosphonic[1-26] and alkyl(aryl)-phosphinic[24,27,28] acids, including compounds containing various functional groups in the hydrocarbon substituents, are obtained by this method:



$$R^1P(OR^3)_2 + XCH(R^3)OR^4 \xrightarrow[-R^3X]{\Delta} R^1(R^3O)P(O)CH(R^3)OR^4 ,$$

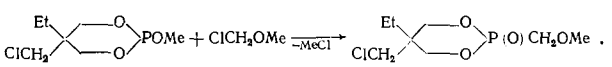
where R^1 is a C_1-C_4 alkoxy-group, including one containing a halogen, OCH_2CH_2OMe, OCH_2CH_2OEt, OC_6H_4Y, Me, Et, Ph, or ClC_6H_4, Y = Cl, NO_2, CN, or Me_2NSO_2, R^2 = a C_1-C_5 alkyl group, including one containing a halogen, R^3 = H, C_1-C_7 alkyl, Ph, CH_2Br, COMe, COOMe, COOEt, $CONH_2$, CONHEt, CON⟨⟩O, or $P(O)(OBu)_2$, R^4 = C_1-C_{18} alkyl, $(CH_2)_n$–Ph, $ZCH{=}CHCH_2$, or $ZCH{=}CHCH_2CH_2$ (n = 0, 1, or 2 and Z = H, Cl, Br, or C_1-C_5 alkyl), R^3R^4 = $-OCH_2CH_2-$, $(CH_2)_m$ (m = 3 or 4) $-O-C_6H_3Cl$, or $-CH_2CH_2-C_6H_4$, and X = Cl or Br.

4,5-Unsubstituted and monosubstituted 2-alkoxy(diethylamino)-1,3,2-dioxaphospholans[29-34] and the bicyclic phosphite (I) [35] react with ring opening:



$$R^1\text{-}C_2H_3O_2P^3 + XCH_2OR^3 \rightarrow XCH_2CH(R^1)O(R^2)P(O)CH_2OR^3$$

R^1 = H, Me; R^2 = NEt_2, OEt, OCH_2CH_2Y, Y = Cl, F, OEt;
R^3 = C_1-C_4 alkyl; X = Cl, Br, I



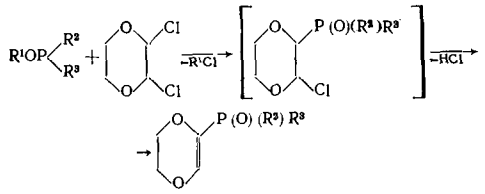
(I)

2-Alkoxy-4,5-dimethyl-1,3,2-dioxaphospholans interact with alkyl chloromethyl ethers to form a mixture of two substances[31]:

R^1 = Et, CH_2CH_2Cl; R^2 = C_1-C_4 alkyl; X = Cl, Br .

The reaction of 5-chloromethyl-5-ethyl-2-methoxy-1,3,2-dioxaphosphorinane with chloromethyl methyl ether proceeds with retention of the ring[34].

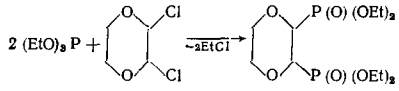
The methoxymethylation of tetraethyl methoxycarbonylmethylenediphosphonite is accompanied by the keto–enol migration of the ethoxy(methoxymethyl)phosphinyl group[36,37]:



$$[(EtO)_2P]_2CHCOOMe + 2MeOCH_2Cl \xrightarrow[-2EtCl]{} EtO(MeOCH_2)P(O)CH{=}C(OMe)OP(O)(OEt)CH_2Me .$$

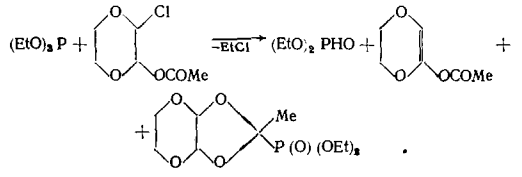
The alkylation of triethylphosphite with bishalogenodimethyl ethers yielded the corresponding diphosphonate[38]:

$$2(EtO)_3P + XCH_2OCH_2X \xrightarrow[-2EtCl]{} (EtO)_2P(O)CH_2OCH_2P(O)(OEt)_2 ;$$
X = Cl, Br .

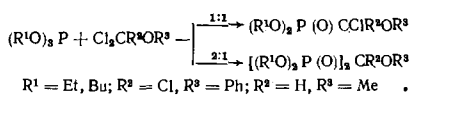


In the interaction of 2,3-dichloro-1,4-dioxan with 1 mole of trialkyl phosphite, phosphonite, or phosphinite the alkylation

product undergoes spontaneous dehydrochlorination[39,40]:

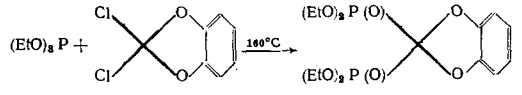


$R^1 = C_2—C_4$ alkyl; R^2, $R^3 = OR^1$, Et, Ph, ClC_6H_4 .



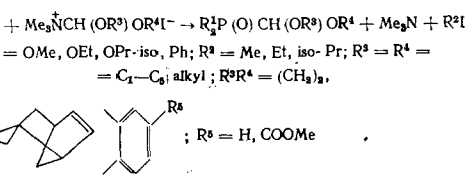
The reaction of 2,3-dichloro-1,4-dioxan with an excess of triethyl phosphite leads to 2,3-bis(diethoxyphosphinyl)-1,4-dioxan[5]:

The interaction of triethyl phosphite with 3-acetoxy-2-chloro-1,4-dioxan leads to a mixture of products[41]:



Mainly one or two chlorine atoms, depending on the reaction ratio, are substituted preferentially in trichloromethyl phenyl and dichloromethyl methyl ethers when these interact with trialkyl phosphites[9,26]:

$R^1 = Et, Bu$; $R^2 = Cl$, $R^3 = Ph$; $R^2 = H$, $R^3 = Me$.

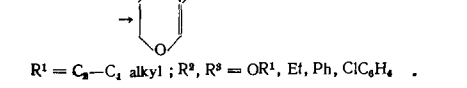


Bisphosphorylated benzodioxole has been obtained by the reaction of 2,2-di-chloro-benzo[*d*]dioxole with an excess of triethyl phosphite[5]:

When ethoxymethyltrimethylammonium chloride is used instead of α-chloroethers, the alkoxylation reaction proceeds only under severe conditions[42]:

Under analogous conditions, tervalent phosphorus acid esters are alkylated by the methoiodides of dimethylformamide acetals[43,44]:

$R^1 = OMe, OEt, OPr\text{-}iso, Ph$; $R^2 = Me, Et, iso\text{-}Pr$; $R^3 = R^4 =$ $= C_1—C_6$ alkyl; $R^3R^4 = (CH_2)_5$,

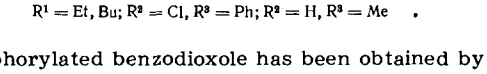


; $R^5 = H, COOMe$.

When alkyl phosphoroisocyanatidites are alkylated, the completion of the reaction requires prolonged refluxing of the mixture or the presence of a catalyst ($FeCl_3$):[45–47]

$n = 1, 2$; R^1, $R^2 = Me, Et$; $R^3 = H, Cl, CCl_3, MeOC(O), EtOC(O)$.

Alkylation of the ethyl ester of diphenylphosphinothious acid is complicated by oxidation-reduction processes and leads to a mixture of products[48]:



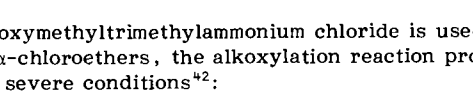
$R^1 = H, Me$; $R^2 = C_1—C_4$ alkyl.

(b) Alkylation of Ester-Chlorides of Tervalent Phosphorus Acids

By virtue of the ready heterolysis of the carbon–halogen bond, α-halogenoethers are some of the most reactive alkylating agents. However, in the reactions with highly nucleophilic derivatives of tervalent phosphorus considered above this feature of the chemical properties of α-halogenoethers is manifested only by some acceleration of the alkylation reaction or by its occurrence under milder conditions, compared with those required, for example, by alkyl halides.

The situation is different when the less nucleophilic ester-halides of tervalent phosphorus acids are used in the alkylation reactions; whereas the latter are only sluggishly alkylated by alkyl halides or not at all, they are capable of reacting effectively with α-halogenoalkyl ethers via the Arbuzov reaction. Thus dialkyl halogenophosphites[49–53] and 2-chloro-1,3,2-dioxaphospholans[31–33,54,55] interact to form the ester-halides of alkoxyalkylphosphonic acids:

$R^1 = Et, Bu, Am$; $R^2 = H, Cl, Me, COOMe$; $R^3 = H, Cl$; $R^4 = Et, Bu$; $X = Cl, F$



$R^1 = H, Me$; $R^2 = H, Cl$; $R^3 = C_1—C_4$ alkyl; $X = Cl, Br$

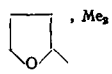
The less nucleophilic alkyl phosphorodichloridites (difluoridites) are alkylated by α-chloroethers only in the presence of electrophilic catalysts—$FeCl_3$, $AlCl_3$, BF_3, etc.:[7,56–64]

$R^1 = Me, Bu$; $R^2 = C_1—C_4$ alkyl, $PhCH_2$, CH_2Cl; $R^3 = H, CCl_3, CO_2Me$; $R^4 = H, Cl$; $X = Cl, F$.

All the halogen atoms in bis-α-chloroethyl and α,α-di-iodoethyl methyl ethers are substitutes when the latter interact with methyl phosphorodichloridite[56]:

Together with alkyl phosphorodichloridites, acetyl phosphorochloridites or acetyl phosphonochloridites, obtained as intermediates when a mixture of ethyl(phenyl)dichlorophosphine or ethyl phosphorodichloridite and an α-chloro-ether is acted upon by acetic anhydride, also react with α-chloroalkyl ethers[64,65]:

$R = Et, Ph, OEt$



The chlorides of tervalent phosphorus acids and some of their derivatives also react with acetals and the orthoesters of carboxylic acids to form α-alkoxyalkyl derivatives of phosphorus. As a result of the exchange of the alkoxy-group between the acid chloride and the acetal or orthoester, α-chloroalkyl ethers and neutral esters or ester-chlorides of

tervalent phosphorus acids are formed initially and their interaction ultimately yields α-alkoxyalkyl compounds of phosphorus.

Phosphorus trichloride[67,68], alkyl phosphorodichloridites[68–70], diaryl phosphorochloridites[71,72], dialkyl phosphorochloridites[70–78], phenyldichlorophosphine[78,79], ethyldichlorophosphine and diethylaminoethylchlorophosphine[80], diethyl- and diphenyl-chlorophosphines[69,71,75,76,78,79,81], and aryl(alkyl) chlorophenylphosphonites[79] have been made to undergo this reaction:

$$R^1(R^2)PCl + R^3R^4C(OR^5)OR^6 \xrightarrow{-R^5Cl} R^1(R^2)P(O)CR^3R^4OR^5$$

$R^1 = Cl$, Et, Ph, OAlk, OAr; $R^2 = R^1$, NEt_2; $R^3 = H$, Me, OEt;

$R^4 = H$, Me, Et, Pr, Ph, CH_2CH_2OAlk,  , Me_2  $(Me)CH_2$—,

 ; $R^3R^4 = (CH_2)_5$; $R^5 = $ Alk, cyclo-C_6H_{11}, $CH_2CH{=}CH_2$,

CH_2CH_2OBu, CH_2CH_2Cl, CH_2CO_2Alk; $R^6 = R^5$, CH_2COAlk.

A mixture of trialkyl phosphite and phosphorus trichloride in proportions of 2 : 1 can be used in these reactions instead of dialkyl phosphorochloridites[20,72,75,82]. The interaction of phosphorus trichloride with three moles of an orthoester or an acetal[20,69,72–74,82–85] and also the reaction of alkyl(aryl) phosphorodichloridites[69,74,82] and phenyldichlorophosphine[69,78,79] with two moles of an acetal or an orthoester lead to the same products:

$$PCl_3 + 3R^1O(R^2O)CR^3R^4 \xrightarrow[-R^2Cl]{ZnCl_2} (R^2O)_2P(O)CR^3R^4OR^1 + 2ClCR^3R^4OR^1$$

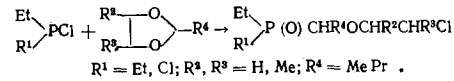
$R^1 =$ Alk, $CH_2CH{=}CH_2$, CH_2CH_2Cl; $R^2 = R^1$, CH_2COOMe; $R^3 = H$, Me, Et; $R^4 = H, OR^1$

$$ROPCl_2 + 2CHR^1(OR^2)OR^3 \xrightarrow{-R^2Cl} RO(R^3O)P(O)CHR^1OR^3 + ClCHR^1OR^3$$

$R =$ Et, Bu, Ph; $R^1 = H$(Me, OEt; $R^2 =$ Et, Bu; $R^3 = R^2$, CH_2COOMe

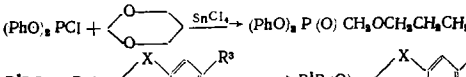
$$PhPCl_2 + 2R^1CH(OR^2)OR^3 \xrightarrow{-R^2Cl} Ph(R^3O)P(O)CHR^1OR^2 + ClCHR^1OR^2$$

$R^1 = H$, Me, OEt, $R^2 =$ Alk, $CH_2{-}CH{=}CH_2$; $R^3 = R^2$, CH_2COOMe.



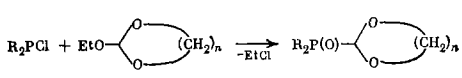
The reaction of phenyldichlorophosphine with methylal is accompanied by an oxidation-reduction process and leads to di(methoxymethyl)phenylphosphine oxide[79]:

$$2PhPCl_2 + 2(MeO)_2CH_2 \rightarrow PhP(O)(CH_2OMe)_2 + 2MeCl + PhPOCl_2.$$



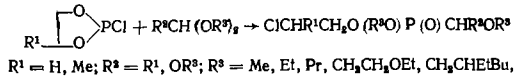
The interaction of dimethylformamide acetal with phosphorus trichloride leads to a mixture of products[86]:

$$PCl_3 + 3(MeO)_2CHNMe_2 \rightarrow [(MeO)_2P(O)]_2CHNMe_2 + (MeO)_3P + (MeO)_2P(O)CH(OMe)_2 + HCONMe_2 + Me_4\overset{+}{N}Cl^- + MeCl$$



In the reactions of cyclic acetals with tervalent phosphorus acid halides the ring is opened[72,87,88], while in the reactions of cyclic orthoesters the ring is retained[78,89,90]:

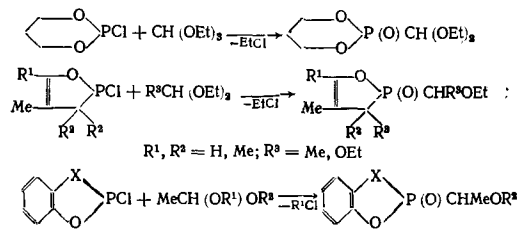
$R^1 =$ Et, Cl; R^2, $R^3 = H$, Me; $R^4 =$ Me Pr.



$R^1 =$ OEt, Ph; $R^2 =$ small alkyl; $R^3 = H$, OMe; X = O, S

R = OEt, Ph; $n = 2, 3$.

The reactions of acetals and orthoesters with alkylene phosphorochloridites proceed both with ring opening[34,72,77,82,91] and with retention of the ring in the latter compounds[72,77]:



$R^1 = H$, Me; $R^2 = R^1$, OR^3; $R^3 =$ Me, Et, Pr, CH_2CH_2OEt, $CH_2CHEtBu$, $(CH_2)_nCl$, $n = 2, 4$;

R^1, $R^2 =$ Me, $R^3 =$ Me, Et, Pr; R^1, $R^2 = H$, $R^3 = CH_2{-}CH{=}CH_2$.

Propylene phosphorochloridite[78], chloro-oxaphospholens[92], o-phenylene phosphorochloridite, and salicyl phosphorochloridite[70,93] interact with acetals and an orthoester with retention of the ring:

R^1, $R^2 = H$, Me; $R^3 =$ Me, OEt

$R^1 =$ Me, Et; $R^2 =$ Et, CH_2COEt; X = O, COO.

Acyl phosphites[73], including those obtained by the reaction[94]

$$(EtO)_2POC(O)Me + HC(OEt)_3 \rightarrow (EtO)_2P(O)CH(OEt)_2 + MeC(O)OEt$$

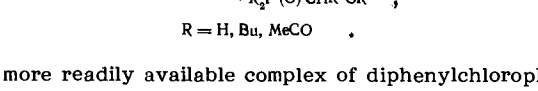
$$PCl_3 + (RO)_2CHMe + (MeCO)_2O \rightarrow RO(Cl)P(O)CHMeOR + 2MeCOCl$$

R = Bu, Pr, Et,

interact with orthoesters similarly to phosphorochloridites.

The interaction of aryldichlorophosphines[95,96], alkyldichlorophosphines[97,98], and dialkyl phosphorochloridites[96,99,100] with acetalacylals proceeds with formation of a mixture of acid chlorides, ester-chlorides, ester-anhydrides, and acid esters of α-alkoxyethylarylphosphinic or α-alkoxyethylphosphonic acids. The interaction of dialkyl phosphorochloridites with an acetal-orthoformate also leads to a mixture of products[101].

(c) Alkylation of Chlorophosphines and Phosphoramidochloridites with α-Halogenoalkyl Ethers



Under mild conditions, dialkyl(aryl)chlorophosphines are alkylated by α-halogenoalkyl esters[102–107]:

$$R^1_2PCl + R^2CHClOR^3 \rightarrow R^1_2(Cl)\overset{+}{P}CH(R^2)OR^3Cl^-;$$

(II)

$R^1 =$ Et, Ph, C_6H_4Me; $R^2 = H$, Me, CH_2Cl; $R^3 =$ small alkyl or halogenoalkyl.

When complex (II), which is stable at low temperatures, was treated with hydrogen sulphide, the corresponding phosphine sulphides were obtained[102–104], while treatment with water, aqueous alcohol, acetic acid, alcohol, or a pyridine–water mixture yielded phosphine oxides[102–106]:

R = H, Bu, MeCO.

The more readily available complex of diphenylchlorophosphine and aluminium chloride can be used in this reaction instead of free diphenylchlorophosphine[108,109].

Ethyl *N*,*N*-diethylphosphonamidochloridite reacts similarly with alkyl chloromethyl ethers in the cold, forming a complex whose decomposition with hydrogen sulphide or sulphur dioxide is accompanied by deamination[110–113]:

$$Et_2N(Et)PCl + ClCH_2OR \rightarrow Et_2N(Cl)\overset{+}{P}(Et)CH_2ORCl^- \rightarrow$$
$$\rightarrow \begin{cases} \xrightarrow{H_2S} Et(Cl)P(S)CH_2OR \\ \xrightarrow{SO_2} Et(Cl)P(O)CH_2OR \end{cases}$$
R = small alkyl.

Phosphorodiamidous chlorides are alkylated by alkyl halogenomethyl ethers also with formation of quasi-phosphonium salts, whose decomposition with hydrogen sulphide or alcohols in the presence of tertiary amines leads to the diamides of alkoxymethylphosphonothioic acids[114,115]; the decomposition of the phosphonium salts with alcohols in the absence of a hydrogen chloride acceptor leads to amidoesters, while decomposition with alcohols and hydrogen chloride results in the formation of the diesters of alkoxymethylphosphonic acids[113,115–117,119]:

$$(Et_2N)_2PCl + X\,CH_2OR \rightarrow (Et_2N)_2\overset{+}{P}(Cl)CH_2ORX^- \rightarrow$$
$$\rightarrow \begin{cases} \xrightarrow{Et_3N+H_2S} (Et_2N)_2P(S)CH_2OR \\ \xrightarrow{Et_3N+R^1OH} (Et_2N)_2P(O)CH_2OR \\ \xrightarrow{R^1OH} Et_2N(R^1O)P(O)CH_2OR \\ \xrightarrow{R^1OH+HCl} (R^1O)_2P(O)CH_2OR \end{cases}$$
R, R^1 = small alkyl; X = Cl, Br, I .

The complexes of aryldichlorophosphines and aluminium chloride readily interact with alkyl chloromethyl ethers; after the alcoholysis of the reaction products, the esters of alkoxymethylarylphosphinic acids were isolated[120]:

$$ArPCl_2 \cdot AlCl_3 + ROCH_2Cl \rightarrow [ROCH_2(Ar)\overset{+}{P}Cl_2][AlCl_4]^- \xrightarrow{R^1OH} \rightarrow ROCH_2(Ar)P(O)OR^1$$
Ar = Ph, $CH_3C_6H_4$; R, R^1 = small alkyl.

(d) Alkylation of Tervalent Phosphorus Acid Salts with α-halogenoalkyl Ethers

When sodium, potassium[1,9,16,21,38,40,121–124], or silver[125] dialkyl phosphites were heated at 100 °C with α-chloroalkyl ethers, the corresponding phosphonates and diphosphonates were obtained:

$$(R^1O)_2POM + XCH_2(OR^2)R^3 \rightarrow (R^1O)_2P(O)CHR^3OR^2 + MX \xrightarrow[-R^1X]{\Delta} \rightarrow MO(R^1O)P(O)CHR^3OR^2$$
$$2(R^1O)_2POM + XCH_2OCH_2X \rightarrow [(R^1O)_2P(O)CH_2]_2O + 2MX$$
R^1 = C_1–C_4 alkyl, CH_2CH_2OAlk, $CH_2CH{=}CH_2$, Ph; R^2 = C_1–C_4 alkyl, CH_2Ph; R^3 = H, P(O)$(OBu)_2$; R^2R^3 = $(CH_2)_4$, $-CHMe-CH_2CH_2CHCl-$;
X = Cl, Br, I; M = Na, K, Ag .

The reaction of sodium, potassium, and halogenomagnesium salts of phosphinous acids with alkyl chloromethyl ethers on refluxing in tetrahydrofuran results in the formation of the corresponding phosphine oxides[126–131]:

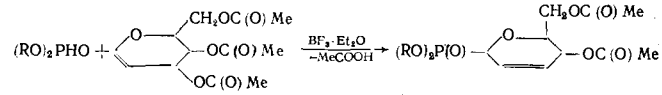
$$R^1_2POM + ClCH_2OR^2 \rightarrow R^1_2P(O)CH_2OR^2 + MCl$$
R^1 = Et, Bu, CH_2Ph; R^2 = C_1–C_{10} alkyl, $-CH_2-$  ,
CH_2CH_2OMe, $(CH_2CHR^3O)_nAlk$; R^3 = H, Me; n = 1, 3;
M = Na, K, MgBr .

The alkoxymethylation of lithium phenylphosphides[132] and the product of the metallation of tetramethylphosphorodiamidous chloride[133] with alkyl halogenomethyl ethers resulted in the formation of the corresponding phosphines and amides of phosphonic acids:

$$Ph_2PLi \rightarrow \begin{cases} \xrightarrow{ClCH_2OMe} Ph_2PCH_2OMe \\ \xrightarrow{ClCH_2OCH_2Cl} Ph_2PCH_2OCH_2PPh_2 \end{cases}$$
$$(Me_2N)_2PCl + Na \rightarrow (Me_2N)_2PNa \xrightarrow{BrCH_2OR[O]} (Me_2N)_2P(O)CH_2OR$$
R = C_1–C_4 alkyl.

(e) Other Methods for the α-Alkoxyalkylation of Tervalent Phosphorus Compounds

α-Alkoxyalkylphosphonates can be sometimes obtained by prolonged heating of trialkyl(aryl) phosphites with aldehydes[134–136]:



$$(R^1O)_3P + R^3CHO \rightarrow (R^1O)_2P(O)CHR^3OR^1$$
R^1 = Et, Ph; R^3 = H, C_1–C_3 alkyl, $CH_2CH{=}CH_2$, Ph; *p*-MeC_6H_4 .

A chloroform–sodium methoxide mixture alkylates neutral phosphites under mild conditions[137]:

$$R^1O(R^2O)POR^3 + CHCl_3 + MeONa \rightarrow R^1O(R^2O)(R^3O)P(OMe)CH(OMe)_2$$
R^1R^2 = $(CH_2)_2$, R^3 = Me; R^1 = R^2 = R^3 = Me .

Incompletely esterified tervalent phosphorus acids are α-alkoxyalkylated by acetals[138], vinyl ethers[139], keten acetals[140], and the orthoesters of carboxylic[141–144] and carbonic[118] acids:

$$(R^1O)_2PHO + (R^2O)_2CHC_6H_4R^3 \xrightarrow[-R^2OH]{180–210\,^\circ C} (R^1O)_2P(O)CH(OR^2)C_6H_4R^3$$
R^1 = Et, Bu; R^2 = Et; R^2_2 = CH_2CH_2; R^3 = H, OH, NO_2

R = Me, Et

$$(EtO)_2PHO + CH_2{=}C(OEt)_2 \rightarrow (EtO)_2P(O)CMe(OEt)_2$$
$$R^1R^2P(X)H + R^3C(OR^4)_3 \xrightarrow{-R^4OH} R^1R^2P(X)CR^3(OR^4)_2$$
R^1 = OAlk, Et, ClC_3H_1; R^2 = OMe, OEt, Et; R^3 = H, Me, OEt;
R^4 = Me, Et, Pr; X = O, S .

Phosphorylated formals are formed also by the interaction of phosphorous and hypophosphorous acids with an excess of orthoformate[145–149]:

$$H(X)P(O)OH + CH(OR)_3 \rightarrow H(X^1)P(O)OR \xrightarrow[-ROH]{CH(OR)_3} (RO)_2CH(X^1)P(O)OR$$
$X = X^1 = H$; X = OH, X^1 = OR; R = C_1–C_3 alkyl.

Treatment of dialkyl phosphites and diarylphosphine oxides with dimethylformamide methylal leads to phosphinylated aminoacetals[150]:

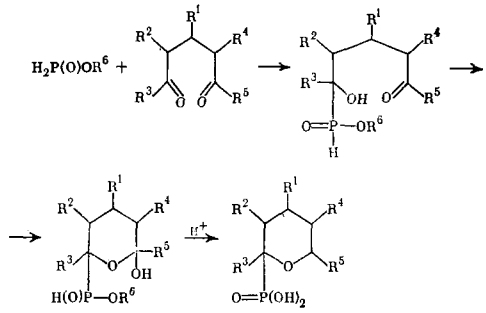
$$R_2PHO + Me_2NCH(OMe)_2 \rightarrow R_2P(O)CH(NMe_2)OMe + MeOH$$
R = EtO, iso-PrO, Ph.

Phosphonium[23,151,152] and cyclic bisphosphonium salts[132] have been obtained by the alkylation of phosphines with α-chloroalkyl ethers[132]:

$$Ph_3P + ClCHR^1OR^2 \rightarrow Ph_3\overset{+}{P}CHR^1OR^2Cl^-$$
$R^1 = H$; R^2 = Me, Bu; R^1R^2 = $(CH_2)_3$,

$$Ph_2P(CH_2)_nPPh_2 + ClCH_2OCH_2Cl \rightarrow Ph_2\overset{+}{P}\langle O(CH_2)_n\rangle\overset{+}{P}Ph_2 2Cl^-$$
n = 1, 2 .

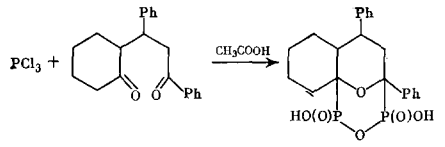
The alkylation of triphenylphosphine with 1,2-dibromoethyl ether is accompanied by dehydrobromination[153]:



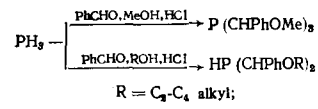
$$Ph_3P + BrCH_2CHBrOEt \xrightarrow{-HBr} Ph_3\overset{+}{P}C(OEt){=}CH_2Br^- .$$

The interaction of triphenylphosphonium tetrafluoroborate and α-cyclohexyloxytetrahydrofuran also leads to an

α-alkoxyalkylphosphonium salt[23]:



Tetrahydropyranylphosphonates are obtained on heating 1,5-diketones with hypophosphorous acid or alkyl hypophosphites[154–157]:

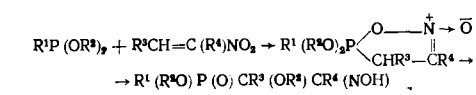


R^{1-5} = H, Ph; $R^2R^3 = (CH_2)_4$; R^6 = H, Et, Bu, CH_2Ph .

The anhydride of tetrahydropyranyldiphosphoric acid has been isolated together with other products in the reaction of 1,5-diketones with phosphorus trichloride in acetic acid[158]:

Phosphine[159] and diphenylphosphine[160] react with benzaldehyde and alcohols in the presence of hydrogen chloride to form α-alkoxybenzylphosphines:

R = C_2-C_4 alkyl;



$$Ph_2PH + PhCHO + MeOH \xrightarrow{HCl} Ph_2PCHPhOMe + H_2O \quad .$$

1,3-Oxaphosphorinanes, 1,3-oxaphospholans, and 1,3-oxaphosphepans have been obtained by the reaction of alkyl-ω-hydroxyalkylphosphines with aldehydes[161–166]:

R^1 = Ph, *t-Bu*, C_8H_{17}; R^2 = H, Me, Et, Ph; R^3 = Ph, *t-Bu*; n=2–4

The addition of trialkyl phosphites and dialkyl phosphonites to α,β-unsaturated nitro-compounds with subsequent isomerisation of the intermediate phosphoranes leads to the oximes of α-alkoxy-β-ketophosphonates and phosphinates[167,168]:

R^1 = OR^3, Ph, Me; R^2 = Me, Et; R^3 = Me, Ph, C_6H_4X; R^4 = H, Me .

2. Methods for the Conversion of Substituted Alkyl Groups in Organophosphorus Compounds into α-Alkoxyalkyl Groups

(a) Substitution Reactions of Chloro(sulphonyloxy)methyl Derivatives of Organophosphorus Compounds

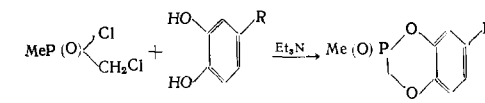
This method is of limited importance for the synthesis of compounds with a single α-alkoxyalkyl group at the phosphorus atom, because the methods of synthesis of such compounds described above are more effective. Thus the alkoxylation of arenesulphonyloxymethylphosphonates is accompanied by side reactions involving the transesterification and dealkylation of the ester groups at the phosphorus atom, which lowers the yield and hinders the isolation of the desired products[169]:

$$R^1SO_2OCH_2P(O)(OR^2)_2 + R^3ONa \rightarrow R^3OCH_2P(O)(OR^2)_2 + R^3OCH_2P(O)(ONa)OR^2 + R^3OCH_2P(O)(OR^3)OR^2$$

R^1 = Ph, Me; R^2 = iso-Pr, Bu; R^3 = Pr, Bu, C_6H_{13}, $CH_2CHBuEt$, $CH_2P(O)$ (O-Pr-iso)$_2$.

However, this method may be convenient for the synthesis of compounds with two and three α-alkoxyalkyl groups at the phosphorus atom because of the relatively ready availability of, for example, bis- and tris-chloromethyl(hydroxymethyl) derivatives of organophosphorus compounds. Thus bis-alkoxymethylphosphinates[127,170–173] and trisalkoxymethylphosphine oxides[173] have been obtained by this method:

$$(ClCH_2)_nP(O)R^1_{3-n} + nR^2ONa \rightarrow (R^2OCH_2)_nP(O)R^1_{3-n} + nNaCl$$



n = 1–3; R^1 = OMe, OEt, OPr, Me, CH_2Cl, Ph; R^2 = C_1–C_8, alkyl, CH_2CH_2OMe, CH_2CH_2OBu .

The interaction of bischloromethyl-[174] and α-hydroxyalkylchloromethyl-phosphinic acids[174,175] with an aqueous solution of sodium hydroxide leads to 1,3-oxaphosphetans:

X = Cl, R = H; X = OH, R = Me .

The reaction of catechol with the chloride of (chloromethyl)-methylphosphinic acid leads to benzo-1,4,2-dioxaphosphorinanes[176]:

R = H, Me .

The alkylation method has been used to obtain aryloxymethyl derivatives of organophosphorus compounds[171–173,177–181]:

$$(XCH_2)_nP(O)R^1_{3-n} + R^2_mC_6H_{5-m}ONa \xrightarrow{-NaX} (R^2_mC_6H_{5-m}OCH_2)_nP(O)R^1_{3-n}$$

R' = OH, OMe, OEt, OBu, Me; R^2 = Me, Cl, Br, NO_2, COOMe; n = 1 – 3; m = 0 – 3; X = Cl, $OSO_2C_6H_4R^3$; R^3 = Cl, H, Me, NO_2 .

However, in certain cases the reaction of an α-halogenoalkyl derivative of the organophosphorus compound with an alkoxide or phenoxide proceeds differently—with formation of products of nucleophilic[182–184] or pseudoallyl [in the case of phosphorus(III) compounds] rearrangements[185–189]:

R^1 = CH_2Ph, OEt, NEt_2; R^2 = CH_2Ph, PhNH, CH_2COOEt; R^3 = H, Me; R^4 = Me, Ph

$$(ClCH_2)_2P + RONa \xrightarrow{ROH} (ROCH_2)_2P(O)Me + R_2O + NaCl$$

R = C_1 – C_{10} alkyl.

The Darzens reaction constitutes a convenient method of synthesising α,β-epoxyalkyl derivatives of organophosphorus compounds[190–193]:

$$(ClCH_2)_nP(O)(OR^1)_{3-n} + R^2R^3CO \xrightarrow{R^4M} (R^2R^3C{-}CH)_nP(O)(OR^1)_{3-n}$$

R^1 = Me, Et; R^2 = H, Me; R^3 = Et, —CH<, iso-Pent, Ph, p-MeC_6H_4, p-C_6H_4OMe; R^2R^3 = $(CH_2)_6$, o,o'-$C_6H_4C_6H_4$; R^4 = EtO, t-BuO, H; M=Na, K; n = 1,2 .

The reaction of chloromethylphosphonate with dimethyl sulphide, followed by the conversion of the sulphonium salt into an ylid and its subsequent treatment with an aldehyde, is a variant of this reaction[194]:

$$ClCH_2P(O)R^1R^2 + Me_2S \rightarrow [Me_2\overset{+}{S}CH_2P(O)R^1R^2]\,Cl^- \xrightarrow{NaCH_2S(O)Me} \rightarrow [Me_2\overset{+}{S}\overset{-}{C}HP(O)R^1R^2] \xrightarrow{MeCHO} MeCH{-}CHP(O)R^1R^2 + Me_2S$$

R^1 = OEt, OPr, SEt; R^2 = R^1, N(Ph)Me .

(b) Alkylation of α-Hydroxyalkyl Derivatives of Organophosphorus Compounds

The preparative advantages of this method are due to the ready availability of α-hydroxyalkyl derivatives of organophosphorus compounds. Thus treatment of the sodium salts of such compounds[195–205] with alkyl halides yielded a series of alkoxymethyl derivatives of organophosphorus compounds:

$$R^1_nP(O)(CH_2ONa)_{3-n} \xrightarrow[-NaX]{R^3X} R^1_nP(O)(CH_2OR^3)_{3-n}$$

R^1 = alkyl, alkoxy; R^3 = alkyl, CH_2COOEt, $CH_2CH{-}CH_2$, $CH_2CH_2OCH{=}CH_2$, $CH_2SiR^3R^4_2$ (R^3 = Me, Et; R^4 = R^3, OEt); $CH_2C{\equiv}CH$, C(Me)(COOEt)$_2$, C(Me)$_2$C≡CH, C(Me)$_2$C≡C—CH=CH_2; X = Cl, Br; n = 0 – 2 .

Certain hydroxymethyl derivatives of organophosphorus compounds are alkylated directly in the presence of sodium alkoxide or a sodium hydroxide solution[206–210]:

$$(R^1O)_2P(O)CH_2OH + Me_2SO_4 + R^2ONa \rightarrow (R^1O)_2P(O)CH_2OMe + Na_2SO_4 + R^2OH$$

$$(HOCH_2)_nP(O)(OH)_{3-n} + R^1X + R^2ONa \xrightarrow{H^+} (R^1OCH_2)_nP(O)(OH)_{3-n} + NaX + R^2OH$$

R^1 = small alkyl . $CH_2CH{=}CH_2$; R^2 = R^1, H; X = Cl, Br; n = 2,3

The esters and nitriles of acrylic and methacrylic acids also behave as alkylating agents[211]:

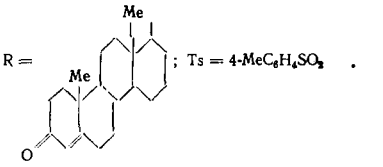
$$(R^1O)_2P(O)CHR^4OH + CH^2{=}CR^2R^3 \xrightarrow{R^1ONa} (R^1O)_2P(O)CHR^4OCH_2CHR^2R^3$$

R^1 = Me, Et, iso-Pr; R^3 = HMe; R^3=CN, COOMe; R^4 = H, Me, Et .

The α,β-epoxy-derivatives of organophosphorus compounds are obtained by treating the corresponding halogenohydrins with bases[212–216]:

$$XCHR^1CR^2(OH)P(O)R^3R^4 \xrightarrow{B} R^1CH{-}CR^2P(O)R^3R^4$$

R^1 = H, Me, Ph; R^2 = H; R^1R^2 = $(CH_2)_4$; R^3 = OH, ONH_4, C_1—C_4, alkoxy-group, Ph; R^4 = R^3, $OCHMeCO_2Alk$; B=NaOH, KOH, anion-exchange resin; X = Cl, Br



The initial halogenohydrins are usually obtained by the addition of dialkyl phosphites to α-halogenocarbonyl compounds; it is possible to combine the addition and cyclisation stages by adding dialkyl phosphite to the α-halogenocarbonyl compounds in the presence of sodium alkoxide[217–218] or sodium dialkyl phosphite[218–226]:

$$R^1R^3CXC(O)R^3 + (R^4O)_2PONa \rightarrow [R^1R^2CXC(ONa)R^3P(O)(OR^4)_2] \xrightarrow{-NaX} \rightarrow R^1R^3C{-}CR^2P(O)(OR^4)_2$$

R^1 = H, Me; R^2 = R^1, Ph; R^3 = Me, Et, t-Bu, Ph, C_6H_4OMe; R^2R^3 = $(CH_2)_4$; R^4 = Me, Et, Bu, CH_2Ph .

An α-tosyloxyketone has also been used in the latter reaction instead of α-halogenoketones[227]:

$$RC(O)CH_2OTs + (EtO)_2PONa \rightarrow (EtO)_2P(O)CH{-}CHR$$

R = ; Ts = 4-$MeC_6H_4SO_2$.

2-Dialkoxy-2-alkylphosphinyltetrahydrofurans have been obtained by a similar method[223,226]:

$$R^1C(O)CH_2CH_2CH_2Cl + (R^2O)_2PONa \rightarrow (R^2O)_2P(O)C(ONa)R^1CH_2CH_2CH_2Cl \rightarrow \xrightarrow{-NaCl} (R^2O)_2P(O)\text{-}(R^1)\text{-}O$$

R^1 = Me, Et; R^2 = Et, Bu .

When an attempt is made to epoxidise 2-chloro-1-hydroxyethane-1,1-diphosphonic acid with alkali[228,229], the following rearrangement takes place,

$$ClCH_2(HO)C(PO_3H_2)_2 \xrightarrow[2)H^+]{1)NaOH} H_2O_3PCH_2C(O)PO_3H_2 .$$

α,β-Epoxypropylphosphonates have been obtained by treating α-chloroethoxymethylphosphonates (obtained from hydroxymethylphosphonates, acetaldehyde, and hydrogen chloride), with a zinc–copper alloy or phenyl-lithium[230,231]:

$$(RO)_2P(O)CH_2OH + MeCHO \xrightarrow{HCl} (RO)_2P(O)CH_2OCHClMe \xrightarrow{PhLi} \rightarrow (RO)_2P(O)CH{-}CHMe$$

R = Me, Et

The hydroxymethyl groups of bishydroxymethylphosphinic acid are alkylated by epoxyethane[232]:

$$(HOCH_2)_2P(O)OH + CH_2{-}CH_2 \rightarrow (HOCH_2CH_2OCH_2)_2P(O)OCH_2CH_2OH .$$

(c) Other Methods

Epoxyphosphonates are obtained by the epoxidation of the double bond in the α,β-alkenyl derivatives of organophosphorus compounds by biochemical methods[233], peracids[234,235], metal peroxides[236], t-butyl peroxide[237], and hydrogen peroxide in an alkaline medium or in the presence of tungstic

acid salts[235,237–240]:

$$R^1CH{=}CR^2P(O)R^3_2 \xrightarrow{[O]} R^1CH{-}CR^2P(O)R^3_2$$

$R^1 = H$, Me, Ph, OR^4; $R^2 = H$, Me; $R_2 = OH$, ONa, ONH_4, OMe, OEt, OCH_2CH_2Cl, Ph, $C{\equiv}CPh$; $R^4 = Et$, Bu, iso-Bu; $R^1R^2 = (CH_2)_3$, $(CH_2)_4$

$$MeCH{=}CH(R^1O)P(O)OP(O)(OR^1)R^3 + H_2O_2 \xrightarrow{OH^-} MeCH{-}CH(R^1O)P(O)OP(O)(OR^1)R$$

$R^1 = Na$; $R^1_2 = Ca$; $R^3 = OMe$, OEt, OPr, $OCH_2CH_2R^3$, OCH_2COOMe, Me, Ph, CH_2Ph, CH_2COOMe; $R^3 = OMe$, CN, $\overset{+}{N}Me_3$, $CH_2\overset{+}{N}H_2CHMe_2$, $CH_2\overset{+}{N}Me$, CH(Me)OMe.

α-Methyl(phenyl)-β,β-diphenylepoxyethylphosphonates have been synthesised by the reaction of α-ketophosphonates with diphenyldiazomethane[241,242]:

$$(MeO)_2P(O)C(O)R + Ph_2CN_2 \rightarrow (MeO)_2P(O)CR{-}CPh_2$$

$R = Me$, Ph, C_6H_4X, $X = Me$, Cl, Br.

α-Phosphorylated ketals have been obtained by converting α-keto-derivatives of organophosphorus compounds into ketals with the aid of triethyl orthoformate[244]:

$$R^2O(R^1)P(O)C(O)Me + CH(OEt)_3 \xrightarrow{H_2SO_4} R^2O(R^1)P(O)C(OEt)_2Me$$

$R^1 = OBu$, Opent, Ph; $R^2 = Pr$, Bu, Pent.

III. PROPERTIES AND APPLICATIONS

1. Chemical Properties

(a) Substitution Reaction at the Phosphorus Atom

The dichlorides of alkoxymethylphosphonic acids are converted into the dichlorides of alkoxymethylphosphonothioic acids by reaction with phosphorus pentasulphide[58,60,245]. The chlorides of ethylalkoxymethylphosphinic acids and the dichlorides and ester-chlorides of alkoxymethylphosphonic and alkoxymethylphosphonothioic acids readily react with alcohols[7,16,50,58,60,64,110–112], alkoxides[60], and mercaptans[7,60], are converted into fluorides by treatment with arsenic trifluoride[52], are converted into amides by treatment with secondary amines[16,110,112], and are hydrolysed by water to acids[110,112], which are esterified by trialkyl phosphites on heating[146,147,176,208]. The ester-chlorides of alkoxymethylphosphonic acids are readily converted into anhydrides on heating; when the latter react with alcohols or phenols, the monoesters of alkoxymethylphosphonic acids are obtained[68,248]:

$$nR^1O(Cl)P(O)CH_2OR^1 \xrightarrow[-R^1Cl]{\Delta} -[-O-P(O)CH_2OR^1]_n \xrightarrow{nR^2OH} \rightarrow R^2O(HO)P(O)CH_2OR^1$$

$R^1 = C_1$—C_8 alkyl; $R^2 = R^1$, Ph, $C_6H_4NO_2$-*p*.

The diethyl ester of (2-acetoxyethoxy)methylphosphonic acid readily cyclises on heating[249]:

$$MeC(O)OCH_2CH_2OCH_2P(O)(OEt)_2 \xrightarrow{\Delta} \text{(cyclic)}P(O)OEt + MeCOOEt$$

Dibutylethoxymethylphosphine oxide has been obtained by the reaction of diethyl ethoxymethylphosphonate with butyllithium[250].

Like other alkyl esters of phosphonic acids, alkoxymethylphosphonates hydrolyse in an alkaline medium with formation of salts of the monoesters of alkoxymethylphosphonic acids[203], while on refluxing with hydrochloric acid they hydrolyse to alkoxymethylphosphonic acids[4,26,203].

Diethyl diethoxymethylphosphonate is converted, on treatment with hydrobromic acid, into diethoxymethylphosphonic acid, while its treatment with gaseous dry hydrogen chloride is accompanied by the partial dissociation of the C–P bond and leads to a mixture of diethyl phosphite and diethyl ethoxychloromethylphosphonate[90].

The reaction of α-alkoxyalkylphosphonates with an equimolar amount of phosphorus pentachloride yields the ester-chlorides of the corresponding acids in satisfactory yields[19,52].

When an excess of phosphorus pentachloride is used, the C–P bond is cleaved and a complex mixture of products is obtained instead of the expected acid dichloride[251,252]. Analogous processes occur on treatment of α-alkoxyalkylpyrophosphonates and α-alkoxyalkylphosphine oxides with phosphorus pentachloride[252].

When alkylalkoxymethyl derivatives of organophosphorus compounds are acted upon by alkalies under severe conditions, the alkoxymethyl groups are split off[174,189]:

$$(C_8H_{17}OCH_2)_2P(O)Me + KOH \rightarrow C_8H_{17}OCH_2(Me)P(O)OK + C_8H_{17}OMe$$

$$\text{(cyclic)}P(O)R + NaOH \rightarrow MeOCH_2(R)P(O)ONa$$

$R = OH$, Me.

The phenyl groups are split off preferentially in the interaction of quaternary α-alkoxyalkylphenylphosphonium salts with potassium or sodium hydroxide[23,79,152]:

$$Ph_2R^1\overset{+}{P}CHR^2OR^3X^- \xrightarrow{MOH} PhR^1P(O)CHR^2OR^3 + PhH + MX$$

$R^1 = Ph$, Me; $R^2 = H$; $R^3 = Me$; $R^2R^3 = (CH_2)_3$; $X = Cl$, I, BF_4; $M = Na$, K.

α-Alkoxyethyltriphenylphosphonium chloride and α-alkoxy-β-bromoethyltriphenylphosphonium bromide are cleaved by water in a different manner[253–255]:

$$Ph_3\overset{+}{P}CH(OR)MeCl^- \xrightarrow[-HCl]{H_2O} Ph_3P + [MeCH(OH)OR]$$

$$Ph_3\overset{+}{P}CH(OR)CH_2BrBr^- \xrightarrow[-2HBr]{H_2O} Ph_3PO + [ROCH{=}CH_2]$$

$R = Et$, Bu.

When the diethyl esters of α,β-epoxyalkylphosphonic acids are heated with alcoholic solutions of sodium dialkyl phosphites, the diethoxyphosphinyl group is split off and dialkyl esters of β-ketophosphonic acids are formed[256]:

$$(EtO)_2P(O)\text{(cyclic)}CHMe + (R^2O)_2PONa \rightarrow [(EtO)_2P(O)CR^1(ONa)CHMeP(O)(OR^2)_2] \rightarrow$$

$$\rightarrow (EtO)_2PONa + R^1C(O)CHMeP(O)(OR^2)_2$$

$R^1 = H$, Me; $R^2 = Et$, iso-Pr, Bu.

The reduction of alkoxymethyldiphenylphosphine oxides with lithium aluminium hydride or trichlorosilane yielded the corresponding phosphines, which were converted by alkylation into phosphonium salts[79,152]. A cyclic bisphosphonium salt has been synthesised by the alkylation of the bisdiphenylphosphinomethyl ether with ethylene bromide[132]:

$$Ph_2PCH_2OCH_2PPh_2 + BrCH_2CH_2Br \rightarrow Ph_2\overset{+}{P}\text{(cyclic)}\overset{+}{P}Ph_2 \cdot 2Br^-$$

On heating and treatment with acids, zinc chloride, or boron trifluoride etherate, α,β-epoxydiphosphonates[193,212,243,257–259] and 2-methoxy-2-diphenylphosphinyl-1-phenyl-1-propanol[260] are converted into β-keto-derivatives of organophosphorus compounds as a result of α → β migration:

$$(R^1O)_2P(O)\text{(cyclic)}CR^2{-}CR^3R^4 \rightarrow (R^1O)_2P(O)CR^3R^4C(O)R^2$$

$R^1 = Me$, Et; $R^2 = H$, Me, t-Bu, Ph, *p*-XC_6H_4; $X = OMe$, Me, Cl, Br; $R^3 = H$, Ph; $R^4 = H$, Me, Ph; $R^3R^4 = (CH_2)_n$, *o*, *o*′-$C_6H_4C_6H_4$; $n = 3, 5$

$$Ph_2P(O)\underset{\underset{CH(Ph)OH}{|}}{C}(Me)OMe \xrightarrow{CF_3COOH} Ph_2P(O)CH(Ph)C(O)Me$$

(b) Substitution Reaction at the α-Carbon Atom

Treatment of alkoxymethyltriphenylphosphonium chloride with alkyl(aryl)-lithium or alkoxides leads to an ylid, which reacts with aldehydes and ketones to form triphenylphosphine oxide and alkyl vinyl ethers[151,261,262]:

$$Ph_3\overset{+}{P}CH_2OR^1Cl^- \xrightarrow[-B\cdot HCl]{B} Ph_3P{=}CHOR^1 \xrightarrow{R^2R^3CO} R^2R^3C{=}CHOR^1 + Ph_3PO$$

R^1 = Me, Bu, Ph, *p*-MeC_6H_4; $R^2 = R^1$, H; $R^3 = R^1$; $R^2R^3 = (CH_2)_n$; $n = 4-7$.

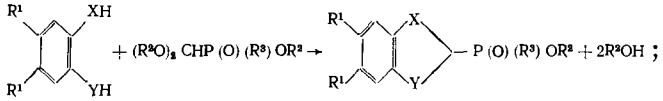
Alkoxyethylphosphonates are also suitable for the synthesis of the latter[14,16,17,25,26,263]:

$$(R^1O)_2P(O)CH(A)OR^2 \xrightarrow[-RH]{1)MR;2)R^3R^4CO} (R^1O)_2P(O)CA(OR^2)CR^3R^4OM \xrightarrow{\Delta} \rightarrow R^3R^4C{=}C(A)OR^2 + (R^1O)_2P(O)OM \ ;$$

R^1 = Me, Et, Bu; $R^2 = R^1$, Ph, CH_2CH_2OMe; A = P(O)$(OR^1)_2$, COOR^1, $CONH_2$, CONHPr, C(O)Me, CON⟨⟩O, Ph, H; $R^3 = R^1$, H, Ph; $R^4 = R^2$, H, ⟨⟩ , *p*-XC_6H_4; X = OMe, Me, Cl; $R^3R^4 = (CH_2)_n$; $n = 4, 5$, MR = Li, iso-Pr_2NLi, NaH, t-BuOK, n-BuONa.

When α-methoxyethyldiphenylphosphine oxide was allowed to react with lithium di-isopropylamide and then with benzaldehyde, 2-methoxy-2-diphenylphosphinyl-1-phenyl-1-propanol was isolated[260]:

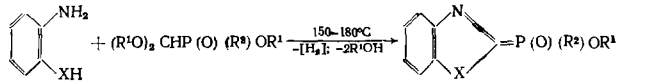
$$Ph_2P(O)CH(Me)OMe \xrightarrow[2)PhCHO;H_2O]{1)\ iso\text{-}Pr_2NLi} Ph_2P(O)C(Me)(OMe)CH(Ph)OH \ .$$



Metallation of alkoxymethylphosphonates followed by treatment with chlorotrimethylsilane, chloromethyl ethyl ether[250], sulphur, and methyl iodide[264] yielded α-substituted phosphonates:

$$(Me_2N)_2P(O)CH_2OEt \xrightarrow[-BuH]{BuLi} (Me_2N)_2P(O)CHLiOEt \xrightarrow[-LiCl]{RCl} (Me_2N)_2P(O)CHROEt \ ;$$

R = $SiMe_3$, CH_2OEt .



Chlorination of dialkyl methoxymethylphosphonates with sulphuryl chloride leads to α-chloromethyoxymethylphosphonates[9].

Reactions involving the substitution of α-alkoxy-groups are also known. Thus cyclic phosphorylated formals and aminomercaptals are obtained by the transacetalisation of phosphorylated dialkylformals with *o*-bisphenols[265] and *o*-aminothiophenol[266]:

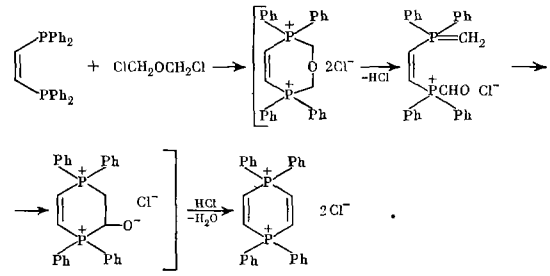
R^1 = H; $R^1_2 = (CH)_4$; R^2 = Et, Pr, Bu; R^3 = OEt, OBu, Ph, *p*-MeC_6H_4; X = Y = O; X = NH, Y = S .

When *o*-aminophenol and *o*-phenylenediamine are used in this reaction, phosphorylated derivatives of benzoxazole and benzimidazole are obtained as a result of the oxidation of the transacetalisation products during isolation[267–268]:

X = NH, O; R^1 = small alkyl; R^3 = Ph, *p*-MeC_6H_4, OR^1 .

α-Dialkylamino-α-methoxymethyl derivatives of organophosphorus compounds interact with thionyl chloride to form phosphorylated ammonium salts[150,269] and also with dialkyl phosphites and diphenylphosphine oxide to form dialkylaminomethanebisorganophosphorus compounds[150]:

$$(EtO)_2P(O)CH(NMe_2)OMe \xrightarrow[R_2PHO]{SOCl_2} \begin{cases} (EtO)_2P(O)CH{=}\overset{+}{N}Me_2Cl^- \\ (EtO)_2P(O)CH(NMe_2)P(O)R_2 \end{cases} ;$$



R = OEt, Ph.

α-Alkoxy-β-halogenoethylphosphonates are readily dehydrochlorinated by sodium hydroxide[3], while 2-dialkoxyphosphinyl-3-chloro-1,4-dioxans and α-alkoxy-β-chloroethylphosphine oxides eliminate hydrogen chloride even in the course of distillation[39,40,104,106].

α-Ethoxyvinyltriphenylphosphonium bromide readily combines with thiophenol via its double bond[153]:

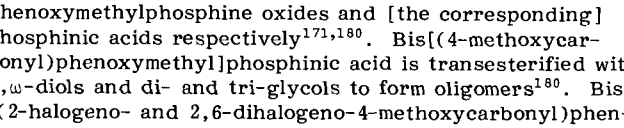
$$Ph_3\overset{+}{P}C(OEt){=}CH_2Br^- + PhSH \rightarrow Ph_3\overset{+}{P}CH(OEt)CH_2SPhBr^- \ .$$

The rearrangement occurring in the alkylation of *cis*-bisdiphenylphosphinoethylene with bischloromethyl ether has been described[270]:

2-Diphenylphosphinyl-2-methoxy-1-methyl-3-tosyloxypentane isomerises in an acetate solution as a result of the 2 → 3 migration of the methoxy-group[260]:

$$Ph_2P(O)C(OMe)(CHMe_2)CH(Me)OTs \xrightarrow{AcOH-AcONa} \rightarrow Ph_2P(O)CH(COMe)CHMe_2 + Ph_2P(O)CH(CHMe_2)C(OMe){=}CH_2 \ ;$$

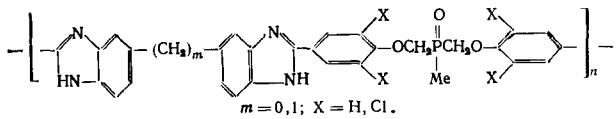
Ts = 4-$MeC_6H_4SO_2$.



(c) Other Reactions

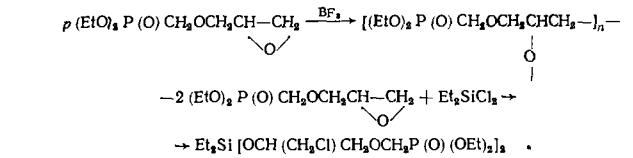
Propargyloxymethylphosphonates enter into the Mannich reaction[198]:

$$(R^1O)_2P(O)CHR^2OCH_2C{\equiv}CH + CH_2O + HNR^3_2 \xrightarrow{(AcO)_2Cu} \rightarrow (R^1O)_2P(O)CHR^2OCH_2C{\equiv}CCH_2NR^3_2 \ ;$$



R^1 = Et, Pr, Bu; R^2 = H, Me; R^3=Et; $R^3_2 = (CH_2)_5$.

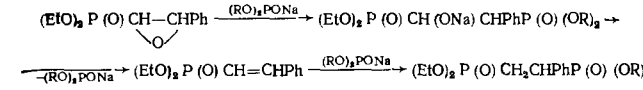
On treatment with formaldehyde, the disodium salt of phenoxymethylphosphonic acid is hydroxymethylated, while the free acid is converted into a polymer[272]:



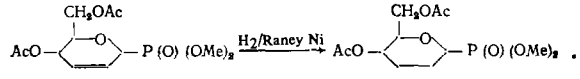
On treatment with sodium hydroxide in alcohol, bis[(4-methoxycarbonyl)phenoxymethyl]phosphine oxides and the corresponding phosphinic acids are converted into carboxyphenoxymethylphosphine oxides and [the corresponding] phosphinic acids respectively[171,180]. Bis[(4-methoxycarbonyl)phenoxymethyl]phosphinic acid is transesterified with 1,ω-diols and di- and tri-glycols to form oligomers[180]. Bis-[(2-halogeno- and 2,6-dihalogeno-4-methoxycarbonyl)phenoxymethyl]methylphosphine oxides and the carboxylic acids obtained from them by hydrolysis respectively undergo transesterification or esterification with ethylene glycol, diethylene glycol, and 1,2-propylene glycol to form thermostable self-extinguishing resins[273–275].

The condensation of bis[(4-methoxycarbonyl)phenoxymethyl]methylphosphine oxide or bis[(4-carboxy-2,6-dichloro)phenoxymethyl]methylphosphine oxide with 3,3'-diaminobenzidine tetrahydrochloride or 3,3',4,4'-tetra-aminodiphenylmethane yields resins with a high thermal stability[276]:

$m = 0,1$; X = H, Cl.



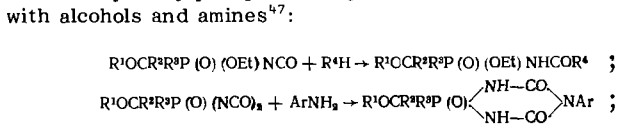
2,3-Epoxypropylenoxymethylphosphonate polymerises on treatment with boron trifluoride[196] and on heating interacts with dichlorodiethylsilane with opening of the oxiran ring[277]:



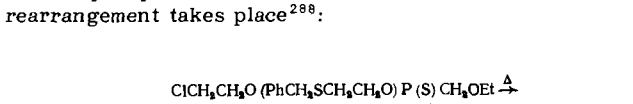
Treatment of epoxyphosphonates with an alcoholic solution of boron trifluoride etherate or sulphuric acid leads to β-alkoxy-α-hydroxyethylphosphonates[237].

The oxiran ring in α,β-epoxyphosphonates is opened to form α-hydroxyphosphonates with β-functional substituents on treatment with an aqueous solution of sulphuric acid, aniline, ammonia[278], water, amines, alcohols, mercaptans, potassium cyanide, and malonates[229,279–283].

Epoxyphosphonates interact with sodium dialkyl phosphite, forming bisphosphonates[284]:



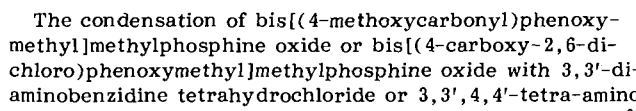
The multiple carbon–carbon bond in unsaturated glycosyl phosphonates is readily hydrogenated under the usual conditions[285]:



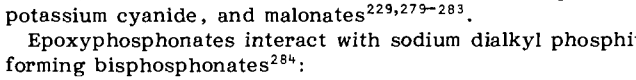
(−)-*cis*-α,β-Epoxypropylphosphonic acid has been isolated from the racemic mixture by resolving the latter with the aid of α-phenylethylamine[286,287].

The β-chloroethyl esters of alkoxymethylphosphonic acids are converted into the β-mercaptoethyl esters on treatment with sodium sulphide and subsequent acidification, while treatment with sodium mercaptide leads to β-alkylthioethyl esters[288]. Alkylation of the silver salt of *cis*-α,β-epoxypropylphosphonic acid with halogeno-derivatives yielded the corresponding esters[289].

α-Alkoxymethylphosphonoisocyanitidates readily combine with alcohols and amines[47]:



When phosphonothionates are heated, the thione–thiol rearrangement takes place[288]:



2. Applications of α-Alkoxyalkyl Derivatives of Organophosphorus Compounds

α-Alkoxyalkyl derivatives of organophosphorus compounds have been recommended in several fields. One of these involves their use as pesticides. Certain esters of alkoxymethylphosphono(di)thioic acids have been tested for this purpose. They were found to exhibit a high insectidal activity and a comparatively low toxicity for warm blooded animals[7,56,58,60,104]:

The second application is in medicine: certain compounds of this class, for example mixed alkyl and *p*-nitrophenyl esters of α-methoxyalkylphosphonic acids, have an antienzymatic activity and an insignificant toxicity for mammals and have been recommended for therapy[230]. The esters of bisallyloxymethylphosphinic acid are able to suppress the activity of the central nervous system[210] and are therefore of definite therapeutic interest.

Among α-epoxy-derivatives of organophosphorus compounds, an effective antibiotic has been discovered—1-*R*,2-*S*-1,2-epoxypropylphosphonic acid[191,287,292]; its derivatives, for example, its salts with aminoacids[241], and epoxypropylpyrophosphonic acids also have a high bactericidal activity [240,293]:

The third application involves the use of alkoxymethylphosphine oxides as extractants[294], for example, for uranium and thorium, particularly when the latter are to be extracted from sulphuric acid solutions[189,205]:

The most effective extractants are alkoxymethyldialkylphosphine oxides, whose extracting capacity approaches that of trialkylphosphine oxides[294]. In the above series trisalkoxymethylphosphine oxides are the least effective, but even their activity exceeds by three orders of magnitude that of tributyl phosphate[205].

The fourth practical application involves the use of the products of the polycondensation of bisaryloxymethylphosphinic acids with formaldehyde as ion-exchange resins[177,178,272], which proved to be selective in relation to certain polyvalent ions.

Carboxyalkoxymethylphosphonic acids, for example, $H_2O_3PCH_2OCH_2COOH$, have been recommended as complexones for the prevention of the deposition of salts[202,203].

The fifth application involves the use of di(tri)halogeno-alkoxy(phenoxy)methylphosphonates[6,8,181] and the products resulting from the addition of alcohols, mercaptans, amines, cyanides, sulphides, etc. to α-epoxyphosphonates[278–283] as fire-proofing additives to polymers and textiles.

The possibility of using α-alkoxyalkylphosphonates, α-alkoxyalkylphosphinates, and α-alkoxyalkylphosphine oxides as solvents which effectively solvate alkali metal cations[85,127,188,271,295,296], plasticisers[2,85,170], phytopharmaceutical preparations[8], monomers[177,272], etc. has been indicated. It has also been noted that higher alkoxymethylphosphinic acids have effective surface-active properties[4,297].

After the present review had been sent to the editors, several publications describing the synthesis and properties of α-alkoxyalkyl compounds of phosphorus appeared.

Phosphorus ylids have been obtained by the alkylation of the phosphorus atom in the *C*-phosphorylated malonic ester with alkyl chloromethyl ethers[298] and diethoxymethyl acetate[299].

The interaction of chlorodiphenylphosphine with a series of dimethyl acetals led to the synthesis of α-methoxyalkyldiphenylphosphine oxides[300]. Bis(α-diphenylphosphinyl)benzyl ether has been obtained, together with other products, by heating chlorodiphenylphosphine with benzaldehyde[301].

The alkylation of hypophosphorous acid by orthoformates in the presence of toluene-*p*-sulphonic acid, leading to a mixture of bisdialkoxymethylphosphinate and alkyl dialkoxymethylphosphonite, has been described[302].

The reactions of primary and secondary phosphines with alcohols and aromatic aldehydes in the presence of toluene-*p*-sulphonic acid have been investigated[303]. It has been shown that, depending on the type of substituents in the aromatic ring, either α-alkoxybenzylphosphines or benzylidenebisphosphines are obtained.

A study has been made of the thermal cleavage of 1-alkoxy-2-bromoethyl and α-alkoxyalkyl derivatives of triorganophosphonium salts, involving the formation of triorganophosphine oxide in the former case and triorganophosphine in the latter case[304].

When electrophiles (hydrogen bromide, tetrapropyldiborane) are added to (α-alkoxyvinyl)triphenylphosphonium salts, the directing influence of the alkoxy-group predominates over that of the positively charged phosphorus atom[305].

Organic Complexes of Univalent Gold

K.I.Grandberg

Studies on the synthesis and reactivities of gold(I) complexes σ-linked to alkyl, aryl, unsaturated, and carbonyl-containing ligands, π-complexes with olefins and acetylenes, anionic, ylid, and carbene complexes, and also gold complexes with a bridging carbon atom derived from an organic group are examined.
The bibliography includes 167 references.

VII. Organogold compounds with a bridging carbon atom 259

I. INTRODUCTION

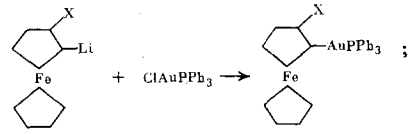
The chemistry of organic complexes of univalent gold has developed extremely vigorously in recent years. The first stable organometallic derivatives of univalent gold of the type RAuL, where L is a ligand containing phosphorus, arsenic, nitrogen, or sulphur, were obtained in 1959; in the first decade research developed mainly on the synthesis of such compounds by traditional methods—using organolithium, organosodium, or organomagnesium compounds. However, in the 1970's there was a qualitative change in the nature of the studies. New types of organic complexes of univalent gold were discovered: π-olefin, π-acetylene, carbene, anionic, and ylid complexes, as well as gold complexes with a bridging carbon atom. Fundamentally new methods of synthesis of organogold compounds were developed and hitherto unknown agents for the introduction of gold were discovered, which made it possible to obtain a wide range of alkyl and aryl complexes of gold(I) with different substituents, including functional groups, in the organic moiety. Furthermore, there has been a growth of interest in the study of the mechanisms of the reactions of organic derivatives of gold, which was aroused primarily by the more extensive utilisation of noble metals and their compounds as catalysts as well as their applications in medicine and radioelectronics.

Several reviews have now been published, most of these dealing with data on the organic complexes of both univalent and tervalent gold[1-5]. Puddephatt's monograph[6], containing extensive information about organic derivatives of gold in different valence states, was published in 1978. However, hitherto there has been no single review on organic complexes of univalent gold.

This review is devoted to the chemistry of such complexes. The data have been arranged systematically in terms of different types of organic complexes of gold(I).

II. σ-COMPLEXES OF THE TYPE RAuL

1. σ-Alkyl and σ-Aryl Complexes of Gold(I)



Historically the first and largest class of organic complexes of univalent gold comprises linear σ-alkyl and σ-aryl complexes of the type RAuL. Phosphines are usually employed as the stabilising ligand L;[7] very few examples of complexes with phosphites[8], arsines[9], and isonitriles[10] are known.

(a) Methods of Synthesis

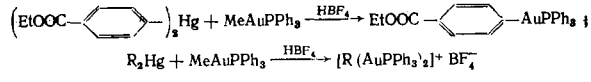
The first phosphine complexes of alkyl- and aryl-gold were obtained in 1959 from complex gold halides and organolithium and organomagnesium compounds. For a long time, this was the only procedure for synthesising compounds of this type[7, 11-13]:

$$PhCH_2MgCl + ClAuPPh_3 \rightarrow PhCH_2AuPPh_3 .$$

Lithium derivatives of aromatic π-complexes (ferrocene and cymantrene) give rise to high yields of organogold σ-complexes on treatment with triphenylphosphine complexes of gold halides[14-16]:

X = H, Cl, OMe, CH_2NMe_2 .

Organogold complexes with ligands such as diphenylferrocenyl- and triphenylferrocenyl-phosphines have been obtained via organolithium and organomagnesium compounds. The diphenylferrocenylphosphine complex of gold bromide reacts with organolithium and organomagnesium compounds like its triphenylphosphine analogue[17]:



$$BrAuPPh_2C_5H_4FeC_5H_5 \xrightarrow{MeMgI} MeAuPPh_2C_5H_4FeC_5H_5 ;$$
$$BrAuPPh_2C_5H_4FeC_5H_5 \xrightarrow{p\text{-}MeC_6H_4Li} p\text{-}MeC_6H_4AuPPh_2C_5H_4FeC_5H_5 .$$

The triphenylphosphine complex of gold bromide reacts with methylmagnesium iodide, but does not react with aryl- and alkenyl-lithium and organomagnesium compounds[17]:

$$BrAuP(C_5H_4FeC_5H_5)_3 + MeMgI \rightarrow MeAuP(C_5H_4FeC_5H_5)_3 .$$

A preparative method of synthesis of organogold complexes with a wide range of organic groups via organomercury derivatives was proposed in 1978.[18-21] When organomercury compounds R_2Hg are acted upon by a phosphine complex of

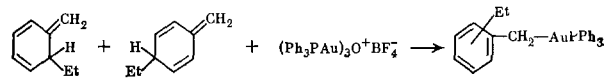
methylgold $MeAuPR'_3$ in the presence of HBF_4, either mononuclear or dinuclear organogold complexes are formed depending on the groups R and R' and the reaction conditions[21,22]:

$$R_2Hg + MeAuPPh_3 \xrightarrow{HBF_4} [R(AuPPh_3)_2]^+ BF_4^-$$

where R = ferrocenyl, β-naphthyl, α-thienyl, styryl, cymantrenyl, tolyl, or phenyl.

The dinuclear organogold complexes can be converted into mononuclear complexes readily by treatment with nucleophiles[21,22]:

$$[R(AuPPh_3)_2]^+ BF_4^- \xrightarrow{Cl^-} RAuPPh_3 + ClAuPPh_3 .$$

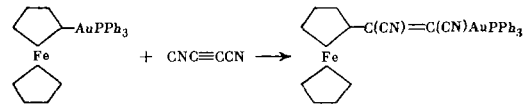


The synthesis of organomonogold complexes from the dinuclear complexes is of significant preparative importance, because a wide variety of dinuclear complexes are obtained in high yields from organomercury derivatives or by inserting gold into ferrocenes (see below).

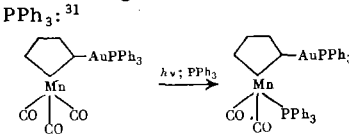
Perhalogenoaryl derivatives of gold(I) are formed when phosphine complexes of univalent gold salts react with organic derivatives of tervalent thallium[23,24]:

$$(C_6F_5)_2TlBr + MeCOOAuPPh_3 \rightarrow C_6F_5AuPPh_3 + (C_6F_5)TlBr(OCOMe) .$$

Apart from the methods of synthesis of σ-complexes of gold enumerated above, based on the use of various organometallic derivatives or on the gold insertion reaction, single examples of the preparation of complexes of alkyl- and aryl-gold by other methods have been described.



Isomeric trienes, generated from *o*- and *p*-ethyltoluenes, react with tris(triphenylphosphinegold)oxonium tetrafluoroborate via the aromatising metallation mechanism[25] with formation of a benzyl derivative of gold[26]:



When the triphenylphosphine complex of gold pentafluorobenzoate is heated, it is decarboxylated and pentafluorophenylgold is formed[27,28]:

$$C_6F_5COOAuPPh_3 \xrightarrow{120^\circ} C_6F_5AuPPh_3 + CO_2 .$$

Other organogold compounds have been obtained from the ferrocenyl, cymantrenyl, and methyl derivatives of gold[30-32]. Thus when ferrocenyl(triphenylphosphine)gold is treated with the dinitrile of acetylenedicarboxylic acid, the acid is inserted in the Au–C bond and an organogold derivative of ferrocenyldicyanoethylene is formed[30]:

When cymantrenylgold is treated with triphenylphosphine or is exposed to ultraviolet light, one of the CO groups is substituted by PPh_3:[31]

Fluorinated alkenes react with phosphine complexes of methylgold under ultraviolet irradiation with insertion of the fluoroalkyl group in the Au–C bond[28,29]:

$$CF_2{=}CF_2 + MeAuPPh_3 \xrightarrow{h\nu} MeCF_2{-}CF_2AuPPh_3 .$$

On treatment with CF_3I, the methyl group in the phosphine complex of methylgold is exchanged for the trifluoromethyl group[32]:

$$MeAuPPh_3 + CF_3I \rightarrow CF_3AuPPh_3 + MeI .$$

Diazomethane reacts with the triphenylphosphine complex of gold chloride with insertion of methylene in the gold–chlorine bond and the formation of the chloromethyl derivative of gold[33]:

$$ClAuPPh_3 + CH_2N_2 \rightarrow ClCH_2AuPPh_3 .$$

Aromatic isonitriles react with $ClAuPPh_3$ in alcohol in the presence of alkali to form organic σ-derivatives of gold[34-36]:

$$ClAuPPh_3 + ArNC + ROH \xrightarrow{KOH} Ph_3PAu{-}C(OR){=}NAr .$$

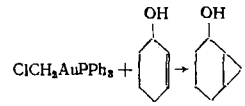
The same complexes have been obtained by the exchange reaction between gold chloride and organosilver compounds[37]:

$$Ph_3PAuCl + Ag{-}C(OEt){=}NC_6H_4CH_3 \rightarrow AgCl + Ph_3PAu{-}C(OEt){=}NC_6H_4CH_3 .$$

The phosphine complexes of arylgold have been isolated after adding phosphine to oligomeric aromatic complexes of the type $(XArAu)_n$.[38]

(b) Properties

The phosphine σ-complexes of organometallic derivatives of univalent gold are solids, which are readily soluble in benzene, chloroform, methylene chloride, and tetrahydrofuran. The complexes are monomeric in solutions, are diamagnetic, and have a linear structure[7,38,39]. The dipole moments of the alkyl and aryl derivatives of the phosphine complexes are lower than those of the corresponding halogeno-complexes: $MeAuPEt_3$ (5.5 D), $MeAuPPh_3$ (5.6 D), $C_6F_5AuPEt_3$ (6.2 D), and $ClAuPEt_3$ (8.4 D); this indicates a low polarity of the Au–C bond[6,7,40,41].



The majority of the phosphine complexes of the type RAuL readily decompose on heating in the solid state and particularly in solutions. The ferrocenylphosphine complexes have the highest thermal stability[17]. The triphenylphosphine complex of methylgold decomposes on heating to 100 °C with formation of ethane, metallic gold, and triphenylphosphine:

$$2MeAuPPh_3 \xrightarrow{100^\circ} C_2H_6 + 2Au + 2PPh_3 ,$$

while heating of ethylgold gives rise to n-butane. It has been shown that the rate of reaction is independent of the presence of oxygen and is retarded after the addition of triphenylphosphine. It has been suggested that the first stage involves the dissociation of the complex with formation of the free phosphine and methylgold, which reacts further with the initial complex[41,42]:

$$MeAuPPh_3 \rightleftarrows MeAu + PPh_3 ;$$
$$MeAu + MeAuPPh_3 \rightarrow C_2H_6 + 2Au + PPh_3 .$$

The triphenylcomplex of chloromethylgold readily decomposes on heating of its benzene solution[33]. If the decomposition is carried out in the presence of 3-cyclohexenol, then the intermediate carbenoid species adds to the double bond with formation of bicyclo[4,1,0]-2-heptanol:

Many organic complexes of gold are sensitive to light. The intermediate formation of methyl radicals has been detected in the photolysis of $MeAuPPh_3$ in deuterochloroform, giving rise

to a set of products: MeD, C_2H_6, $MeCDCl_2$, etc.:[43]

$$MeAuPPh_3 \xrightarrow{h\nu} [MeAuPPh_3]^S \rightarrow [MeAuPPh_3]^T \xrightarrow{CDCl_3} \rightarrow ClAuPPh_3 + Me^{\cdot} + {}^{\cdot}CDCl_2 .$$

The reactivity of organogold complexes is analogous to that of organomercury compounds, but the organogold derivatives are chemically more active and the range of their reactions is much wider. The reactions of complexes of alkyl- and arylgold with a wide variety of reagents, grouped in accordance with several types, are presented below.

A. Reactions with Dissociation of the Au–C Bond

Reactions with protic acids. Protic acids readily cleave the Au–C bond in alkyl and aryl complexes of gold. Thus methyl-,[7] phenyl-,[44] ferrocenyl-,[14] and cymantrenyl-gold[15] react with hydrogen halides, carboxylic acids, and hydrocyanic acid. It has been noted that the triethylphosphine complex of phenylgold is resistant to the action of an aqueous ethanol solution of hydrogen chloride[7]:

$$MeAuPPh_3 + HCl \rightarrow ClAuPPh_3 ,$$
$$PhAuPPh_3 + CH_3COOH \rightarrow CH_3COOAuPPh_3 ,$$
$$C_5H_5FeC_5H_4AuPPh_3 + HCN \rightarrow NCAuPPh_3 .$$

The reaction of aromatic complexes of gold with HBF_4 is specific, giving rise to dinuclear cationic complexes of gold (see below).

The reactions of phosphine complexes of methylgold with benzenethiol[45] and benzeneselenol[46] give rise to methane and gold mercaptide or selenide. The formation of the methyl radical has been detected in the reaction mixture by EPR:

$$MeAuPMe_3 + PhSH \rightarrow PhSAuPMe_3 + CH_4 ,$$
$$MeAuPMe_2Ph + PhSeH \rightarrow PhSeAuPMe_2Ph + CH_4 .$$

On reaction with trifluoromethylacetylene and phenylacetylene, which behave as protic acids, the corresponding gold acetylide is formed[28,29,47]:

$$MeAuPMe_2Ph + CF_3C{\equiv}CH \rightarrow CF_3C{\equiv}CAuPMe_2Ph + CH_4 .$$

Even weak protic acids, such as diphenylphosphine and diphenylarsine, cleave the Au–C bond with liberation of methane and the formation of insoluble gold-containing polymers[46].

Reactions with hydrogen halides and acid anhydrides. The reactions of ferrocenyl- and phenyl-gold with carboxylic acid anhydrides of halides entail the dissociation of the Au–C bond, but products of the electrophilic substitution of the gold atom are not formed[48].

Thus, when ferrocenylgold is treated with acetic anhydride or acetyl chloride, the products are ferrocene, biferrocenyl, a gold(I) salt, and acetaldehyde[48]. On treatment with powerful electrophiles, for example, acetylium and nitronium tetrafluoroborates, ferrocene and biferrocenyl are also obtained and a dinuclear cationic organogold complex is formed: $[R(AuPPh_3)_2]^+BF_4^-$ (see below[48]).

The reactions of phenylgold with carboxylic acid chlorides and nitronium tetrafluoroborate do not give rise to electrophilic substitution products—ketones and nitrobenzene[48]. The results can be readily explained from the standpoint of the mechanism involving one-electron transfer as the first elementary step in the above reactions.

The most convincing example of this is provided by the reaction of ferrocenyl-, phenyl-, or cymantrenyl-gold with ferrocenium tetrafluoroborate, which manifests strikingly the properties of a one-electron acceptor. In the first reaction stage the ferrocenium cation accepts an electron and is converted into ferrocene, while the organogold compound, having lost an electron, decomposes into a radical and triphenylphosphinegold tetrafluoroborate. This coordination-unsaturated compound reacts with a molecule of the initial organogold compound of triphenylphosphine when the latter is added to the reaction mixture[48]:

$$RAuPPh_3 + (C_5H_5)_2Fe^+BF_4^- \rightarrow (C_5H_5)_2Fe + [R^{\cdot}] + [Ph_3PAu^+BF_4^-]$$
$$\downarrow \qquad\qquad \downarrow PPh_3$$
$$R{-}H + R{-}R \quad (Ph_3P)_2Au^+BF_4^- .$$

Reactions with alkyl halides. The experimental data accumulated so far suggest that many reactions of organic complexes of gold(I) involve oxidative addition with subsequent reductive elimination of the resulting gold(III) complex and the formation of new univalent gold complexes†. Only the mechanism of the reactions of phosphine complexes of alkylgold with alkyl halides has been studied in detail[32,49–54].

The interaction of alkylgold complexes with alkyl halides proceeds via oxidative addition, which is characteristic not only of organic derivatives of univalent gold but also of complexes of other transition metals[55]. The final products of the reaction of methyl iodide with the triphenylphosphine complex of methylgold are ethane and the triphenylphosphine complex of gold iodide:

$$MeAuPPh_3 + MeI \rightarrow C_2H_6 + IAuPPh_3 .$$

It has been established experimentally that the reaction proceeds via the following mechanism:

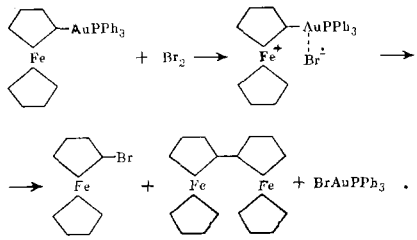
$$MeAuPPh_3 + MeI \rightarrow Me_2AuIPPh_3 ,$$
$$Me_2AuIPPh_3 + MeAuPPh_3 \rightarrow Me_3AuPPh_3 + IAuPPh_3 ,$$
$$Me_3AuPPh_3 \rightarrow C_2H_6 + MeAuPPh_3 .$$

The initial stage of the reaction involves the oxidative addition of methyl iodide to the univalent gold atom. The dimethylgold iodide formed then reacts rapidly with the complex of the initial methylgold, giving rise to a complex of trimethylgold, which undergoes reductive elimination under the reaction conditions with formation of ethane and a gold iodide complex[49–52].

The mechanism proposed has been confirmed by the reactions of other derivatives of alkylgold. Thus the final products of the reaction of triphenylphosphine complexes of ethylgold with methyl iodide are a gold iodide complex and butane[51]:

$$EtAuPPh_3 + MeI \rightarrow (Me)(Et)AuIPPh_3 \rightarrow (Me)(Et)_2AuPPh_3 + IAuPPh_3$$
$$\rightarrow MeAuPPh_3 + C_4H_{10} .$$

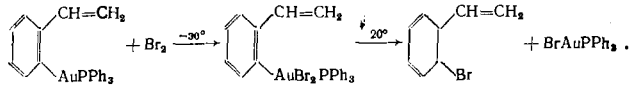
When trimethyl- and dimethylphenyl-phosphine complexes of methylgold are used, only the product of the oxidative addition of methyl iodide, namely Me_2AuIL, was isolated from the reaction mixture[53,54]. The complexes of methylgold also react with CF_3I; the nature of the final reaction products depends, as for methyl iodide, on the nature of the ligand[32]. In the case of the trimethylphosphine complex a tervalent gold compound was isolated, while transalkylation takes place in the reaction involving the triphenylphosphine complex. The reaction with the methyldiphenylphosphine ligand gives rise to a mixture of trifluoromethyl derivatives of univalent and tervalent gold[32]:



$$MeAuL + CF_3I \rightarrow \begin{cases} \xrightarrow{L=PPh_3} CF_3AuL + MeI \\ \xrightarrow{L=PMe_3} (CF_3)Me_2AuL + IAuL . \end{cases}$$

The triphenylarsine complex of pentachlorophenylgold reacts with MeI to form an oxidative addition product[9].

† The data on this question have been described in detail in Dyadchenko's review (see the next review in this issue).



Presumably other reactions, and in particular the reactions of gold(I) complexes with metal halides and salts, proceed analogously, since in some instances the intermediate oxidative addition products have been isolated.

Reactions with halogens. The reactions with bromine and chlorine have been studied in detail in relation to the organogold derivatives of the ferrocene, cymantrene, and benzene series[14,15,44,56,57]. Together with the halogenoderivatives of aromatic systems, compounds of the type RH or R–R are formed in this reaction. For the ferrocenyl compounds of gold, the ratio of bromoferrocene and biferrocenyl varies as a function of the rate and order of mixing of the reactants. When bromine is added rapidly to ferrocenylgold, *mainly bromoferrocene* is formed, while under the conditions of a slow addition there is an appreciable increase of the amount of biferrocenyl. The reaction of ferrocenylgold with bromine and chlorine proceeds specifically also in another respect; at low temperatures in organic solvents an unstable product of the addition of the halogen molecule to the organogold compound is formed initially[56,57]:

It may be that the intermediate complex of ferrocenylgold with a halogen molecule has the structure of a ferrocenium salt, in which the radical-anion is coordinated to the gold atom. This is confirmed indirectly by the finding that in the case of the less reactive organomercury derivatives of ferrocene, a complex of this type has been isolated and investigated[58].

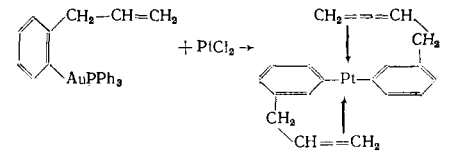
However, one cannot rule out the possibility that the substitution of the $AuPPh_3$ group by bromine or chlorine in the aromatic series involves the oxidative addition of the halogen to the gold atom with subsequent reductive disproportionation of the resulting tervalent gold compound. The possibility of reaction via this mechanism is confirmed by the finding that, in the reaction of *o*-vinylphenylgold with bromine at –30 °C, the product of the addition of the halogen to gold was isolated. At room temperature reductive elimination takes place with formation of gold bromine and *o*-bromostyrene[59]:

Perhalogenoaryl complexes of gold react either with cleavage of the Au–C bond or with its retention and the formation of aryl halide complexes of tervalent gold, depending on the nature of the halogen and the initial complex[9,10,60–64]. Thus the arsine complex of pentafluorophenylgold reacts with chlorine to form only the oxidative addition product; reaction with bromine involves partial cleavage of the Au–C bond in addition to the above reaction, while the reaction with iodine entails the complete cleavage of the Au–C bond[9];

$$C_6F_5AuAsPh_3 + I_2 \rightarrow C_6F_5I + IAuAsPh_3 .$$

The isonitrile complexes of perhalogenoarylgold[62] and the triphenylarsine complex of pentachlorophenylgold react with halogens to form only the oxidative addition products[9].

Reactions with metal salts and organometallic compounds. Organic complexes of gold react with metal salts usually with cleavage of the Au–C bond, but sometimes they proceed with retention of this bond and the formation of the products of the oxidative addition to the gold atom. The reaction of the phosphine complexes of alkyl- and aryl-gold with mercury salts has been studied in greatest detail. Under mild conditions, mercury(II) chloride reacts with methyl-, ethyl-,[65] phenyl-,[44] benzyl-, ferrocenyl-, and cymantrenyl-gold[2], giving rise to high yields of the products of the cleavage of the gold–carbon bond.



This reaction has served as a model for the investigation of the mechanism of electrophilic substitution at a saturated carbon atom. It has been shown[65] that, for the majority of alkyl complexes of gold, the reaction proceeds via an S_N2 mechanism. Mercury(II) reacts via an S_N1 mechanism in polar solvents with complexes of alkylgold having powerful electron-accepting substituents.

Before the publication of the study of Gregory and Ingold[65], data on the mechanism of substitution in organometallic compounds were obtained mainly in relation to organomercury compounds. However, later a mechanism of the "oxidative addition–reductive elimination" type was proposed as an alternative[49]:

$$RAuPR'_3 + HgX_2 \rightarrow R{-}\underset{\displaystyle X}{\overset{\displaystyle HgX}{\underset{|}{\overset{|}{Au}}}}PR'_3 \rightarrow XAuPR'_3 + RHgX .$$

It is known that adducts corresponding to an intermediate of this type have been obtained for phosphine complexes of iridium[61]. On the basis of the experimental data available at present, it is impossible to make a choice between these two mechanisms.

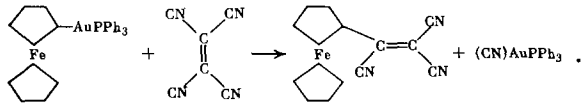
Both platinum halides[59] and platinum and palladium halide complexes[67] react with complexes of the type of RAuL in which a gold atom is substituted for platinum or palladium:

The complexes of methylgold react with tervalent gold halides and their complexes to form a univalent gold halide and an alkyl derivative of tervalent gold[50,52,54,67]. The reaction involves the transfer of the methyl group from the Au(I) atom to the Au(III) atom[52,68]:

$$2MeAuPMe_2Ph + Br_3AuPMe_2Ph \rightarrow 2BrAuPMe_2Ph + Me_2BrAuPMe_2Ph .$$

In the triphenylphosphine complexes of ethyl- and phenylgold, the Au–C bond is cleaved by $TiCl_3$,[60] while perhalogenoaryl derivatives of gold(I) react with thallium halides via the oxidative addition mechanism with formationof perhalogenoaryl derivatives of gold(III):[9,60,62–64,67]

$$C_6Cl_5AuAsPh_3 + TlCl_3 \rightarrow \textit{cis}\text{-}C_6Cl_5AuCl_2AsPh_3 + TlCl .$$



When chloromethylgold is treated with KI and NaCN, chlorine substitution products are not formed. The reaction of chloromethylgold with KI gives a high yield of triphenylphosphinegold iodide, while the reaction with NaCN gives rise to methyltriphenylphosphonium dicyanoaurate[33]. The formation of the latter salt is probably associated with the fact that, when chloromethylgold reacts with NaCN, the CN^- anions are coordinated to the gold atom with ejection of a chloride ion and the stabilisation of the intermediate species as a result of the abstraction of a proton from the solvent

with subsequent migration of the methyl cation, leading to the formation of a phosphonium salt:

$$ClCH_2AuPPh_3 \xrightarrow{2CN^-} \left[Ph_3PAu(CN)-CH_2-CN \right]^- \xrightarrow{H_2O} [Ph_3PCH_3]^+[Au(CN)_2]^- .$$

The triphenylphosphine complex of phenylgold exchanges the phenyl group for the perfluorophenyl group on treatment with $(C_6F_5)_2TlAr$.[24]

Other reactions. The reactions of phosphine complexes of ferrocenyl- and phenyl-gold with tetracyanoethylene (TCE) at room temperature proceed in different ways. In the reaction of ferrocenylgold one of the CN groups is substituted by the ferrocenyl residue, while in the reaction of phenylgold two $AuPPh_3$ groups add to the double bond of TCE:[2,29]

The phosphine complexes of methylgold react with hexafluoroacetone to form a product of addition of the carbonyl group, containing two $AuPPh_3$ groups[27,28]:

$$MeAuPPH_3 + (CF_3)_2C{=}O \rightarrow C_2H_6 + Ph_3PAu{-}O{-}C(CF_3)_2{-}AuPPh_3 .$$

The reaction with hexafluoroacetone hydrate gives rise to $(CF_3)_2C(OAuPPh_3)_2$.[28]

B. Reactions with Retention of the Au–C Bond

The reactions of RAuL with retention of the gold–carbon bond but with a change in the oxidation state of gold take place when the complexes interact with alkyl halides, halogens, and metal salts (see above). The reactions involving the substitution of the ligand L by another less strongly bound ligand without the dissociation of the Au–C bond have been described for complexes of the type RAuL. In the arylgold compounds the Ph_3P ligand has been replaced by the more electron-donating triferrocenylphosphine ligand[17]:

$$p\text{-}CH_3C_6H_4AuPPh_3 \xrightarrow{P(C_5H_4FeC_5H_5)_3} p\text{-}CH_3C_6H_4AuP(C_5H_4FeC_5H_5)_3 .$$

Alkylphosphines are readily displaced from the complex by triphenylphosphine[68]:

$$MeAuPMe_3 + PPh_3 \rightarrow MeAuPPh_3 + PMe_3 .$$

On the basis of such exchange reactions, the series based on the electron-donating properties of the ligands in the methylgold complexes has been established[68]:

$$PPh_3 > PEt_3 > PMe_3 \geqslant AsPh_3 .$$

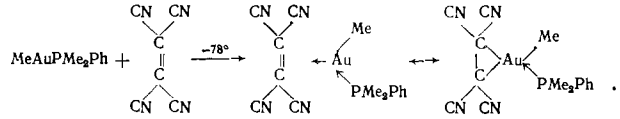
It has been shown that the exchange of ligands in methylgold complexes involves an associative mechanism[8,69,70]:

$$MeAuL \underset{-L'}{\overset{+L'}{\rightleftharpoons}} MeAu\begin{matrix} L' \\ L \end{matrix} \rightleftarrows MeAuL' .$$

The exchange of a monodentate ligand for a bidentate ligand has been achieved in methylgold complexes[68]:

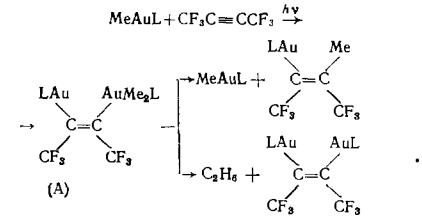
$$MeAuPMe_3 + Me_2P{-}CH_2{-}CH_2PMe_2 \xrightarrow[-PMe_3]{} \underset{AuMe}{MeP}{-}CH_2{-}CH_2{-}\underset{AuMe}{PMe_2} .$$

In the σ-linked complexes $Ph_3PAu{-}C(OR){=}NAr$ there is a nitrogen atom capable of complex formation. Complexes of this type readily give rise to picrates and also behave as unusual organometallic ligands in relation to another transition metal[71]:



$$Ph_3PAu{-}C(OMe){=}NC_6H_4Me + Rh_2(CO)_4Cl_2 \rightarrow Ph_3PAu{-}C(OMe){=}NC_6H_4Me$$
$$\downarrow$$
$$Cl{-}Rh(CO){-}CO$$
$$\downarrow$$
$$CO$$

C. Reactions Involving Insertion in the Au–C Bond



Methylgold complexes react with fluorinated alkenes under ultraviolet irradiation with insertion of the fluoroalkyl fragment in the Au–C bond[27–29]. It may be that the reaction proceeds via the intermediate formation of a π-complex with the olefin:

$$MeAuPPh_3 + CF_2{=}CF_2 \xrightarrow{h\nu} MeCF_2{-}CF_2AuPPh_3 .$$

The phosphine complexes of methylgold react with TCE at low temperatures to form a very unstable 1 : 1 complex[29,47]. The parameters of the infrared and ultraviolet spectra of this complex are inconsistent with the usual charge-transfer complexes of the product involving the insertion of the TCE fragment in the Au–C bond. On the basis of these spectroscopic data and by analogy with the isoelectronic phosphine complex of platinum[72], a metal-containing ring structure was attributed to the tetracyanoethylene complex of methylgold:

The reactions with alkynes sometimes lead only to the product of the insertion of the alkyne in the carbon–metal bond; in most instances a mixture of products is formed[28]. In the reaction of phosphine complexes of methylgold with hexafluorobut-2-yne under ultraviolet irradiation or on heating, a product (A), incorporating a *cis*-bridged C_4F_6 fragment and two gold atoms in different oxidation states, is formed initially[27,47,73,74]. ^1H NMR, Mössbauer spectroscopic, and X-ray spectroscopic data, confirming the proposed structure, are available for this product with L = PMe_3:[47,73,75]

In the presence of an excess of hexafluorobut-2-yne the intermediate (A) can decompose in a manner which depends on the nature of the ligand and the solvent: either with elimination of MeAuL and the formation of the product of the insertion of the $CF_3C{=}CCF_3$ group in the Au–C bond or with reductive elimination at the Au(III) centre and formation of ethane and $(AuL)CF_3C{=}CCF_3(AuL)$. In both cases the *cis*-derivatives of hexafluorobut-2-ene are formed.

In the reaction of but-2-yne with methylgold, only $Ph_3PAuMeC{=}CMeAuPPh_3$ was isolated in a low yield[28] while the reaction with $MeOOCC{\equiv}CCOOMe$ involves decomposition to metallic gold and the formation of two products, one of which results from the insertion of acetylene in the Au–C bond, while the other is *cis*-$LAuMe_2(MeOOC)C{=}C(COOMe)Me$.[29] Ferrocenylgold reacts with acetylenedicarboxylic acid to form the product of the insertion of the alkyne in the Au–C bond (see above).

Methylgold[29] and arylgold[59,76,77] react with SO_2 at low temperatures, SO_2 being inserted in the Au–C bond with formation of gold sulphinate complexes:

$$RAuPPh_3 + SO_2 \rightarrow R-\overset{\overset{O}{\|}}{\underset{\underset{O}{\|}}{S}}-AuPPh_3 ;$$

$$R = Me,\ o\text{-}CH_2{=}CHC_6H_4 .$$

It has been shown that, in contrast to copper and silver sulphinate complexes in which the metal atom is linked to the oxygen atom, the gold sulphinate complexes have the Au–S bond[29,59,76,77].

2. σ-Alkenyl Complexes of Gold(I)

The σ-alkenyl complexes have been obtained by the reaction of complex gold halides with organosodium[79] or organomagnesium[13,79,80] compounds:

$$C_5H_5Na + ClAuPPh_3 \rightarrow C_5H_5AuPPh_3 ;$$
$$CH_2{=}CHMgBr + ClAuPPh_3 \rightarrow CH_2{=}CHAuPPh_3 .$$

The synthesis via organomercury derivatives is more general[22,81]. Depending on the nature of the alkenyl group and the ligand, the reaction of organomercury compounds with the methylgold complex in the presence of HBF_4 gives rise to either mononuclear organogold complexes:

$$[PhCH{=}C(COOMe)]_2Hg \xrightarrow{MeAuPPh_3;HBF_4} PhCH{=}C(COOMe)AuPPh_3$$

or to the dinuclear complexes, which can be readily converted into the mononuclear complexes by treatment with various nucleophiles:

$$(PhCH{=}CH)_2Hg \xrightarrow{MeAuPPh_3;HBF_4} [PhCH{=}CH(AuPPh_3)_2]^+BF_4^- .$$

The σ-alkenyl complexes are also formed when methylgold interacts with acetylenic compounds via the insertion of the unsaturated group in the Au–C bond (see above).

The σ-alkenyl complexes of gold are solids stable in air, which are readily soluble in chloroform, methylene chloride, and benzene; they are associated in solution in benzene. The styryl derivatives of gold are coloured yellow.

The cyclopentadienyl derivatives of gold may be expected to have either the η^5-structure, similar to that of the triphenylphosphine complex of cyclopentadienylcopper[82], or the η^1-structure, established for the cyclopentadienyl derivatives of mercury. Careful analysis of infrared and ^1H NMR spectra of the triethyl- and triphenyl-phosphine complexes of cyclopentadienyl- and methylcyclopentadienyl-gold, obtained at different temperatures, showed that, like the cyclopentadienyl derivatives of mercury, these compounds constitute an example of stereochemically non-rigid organometallic compounds with η^1-coordination of the cyclopentadienyl ligand[78,84,85].

The reactivity of the alkenyl derivatives of gold has been studied mainly in relation to vinylgold. The gold–carbon bond is readily broken by hydrogen halides, halogens, dithiocyanogen, and mercury salts. The vinyl derivative of gold is resistant to the reaction of dilute acetic and hydrochloric acids:

$$\begin{array}{ccc} PhCOOAuPPh_3 & & ClAuPPh_3 \\ \uparrow PhCOOH & & \uparrow HCl \\ NCSAuPPh_3 \xleftarrow{(SCN)_2} & CH_2{=}CHAuPPh_3 & \xrightarrow{Hal_2} HalAuPPh_3 \\ \downarrow HgCl_2 & & \downarrow KMnO_4;\ Me_2CO \\ CH_2{=}CHHgCl + ClAuPPh_3 & & MeC(O)CH_2AuPPh_3 \end{array} ;$$

$$Hal = Cl,\ Br,\ I .$$

When an acetone solution of $KMnO_4$ was allowed to react with vinylgold, a stable product of the oxidation of the vinyl group was not isolated, gold-substituted acetone being obtained[86].

Reactions involving the cleavage of the gold–carbon bond have been used to confirm the configuration of the styryl derivatives of gold. Thus the interaction of *trans*-styrylgold with iodine in dimethylformamide (DMF) or with mercury(II) bromide yielded the *trans*-isomers of the corresponding styrene derivatives[80]:

$$trans\text{-}PhCH{=}CHAuPPh_3 \begin{cases} \xrightarrow[DMF]{I_2;CdI_2} trans\text{-}PhCH{=}CHI + IAuPPh_3 \\ \xrightarrow{HgBr_2} trans\text{-}PhCH{=}CHHgBr + BrAuPPh_3 . \end{cases}$$

trans-Styryl(triphenylphosphine)gold is unusually readily converted into the *cis*-isomer. Whereas for the mercury derivatives this transition requires a high temperature, ultraviolet irradiation, or treatment with peroxides, the transformation of *trans*-styrylgold into the *cis*-isomer takes place when its solutions are allowed to stand at room temperature or in chromatography on Al_2O_3.[80]

In order to determine the configuration of the phosphine complexes of 1-methoxycarbonyl-2-phenylvinylgold, they were protolysed[22] and *trans*-cinnamic acid and the corresponding gold chloride complexes were isolated in high yields.

3. σ-Alkynyl Complexes of Gold(I)

Gold acetylide C_2Au_2 was obtained as early as 1900; it is an explosive powder with a polymeric structure[87]. Other alkynyl complexes, for example, gold phenylacetylide, proved to be more stable. These complexes have been obtained by treating gold halides with alkali metal acetylides[88]. Gold phenylacetylide was isolated after gold ketenide had been treated with phenylacetylene[89].

A series of very stable gold phenylacetylide complexes with phosphines, arsines, amines, and isonitriles were obtained in 1962. They are formed readily from sodium phenylacetylide and gold halides in the presence of the corresponding ligand[40]:

$$PhC{\equiv}CH \xrightarrow{1)CH_3COONa;\ 2)AuBr} (PhC{\equiv}CAu)_n \xrightarrow{L} PhC{\equiv}CAuL .$$

Yet another method of synthesis of these compounds involves the reaction of an alkyne with methylgold complexes[28,29,47]:

$$MeAuL + RC{\equiv}CH \rightarrow RC{\equiv}CAuL + CH_4 ;$$
$$R = Ph,\ CF_3 .$$

Gold phenylacetylides, stabilised by n-donor ligands, are thermally stable solids, which are readily soluble in many organic solvents; they are usually monomeric in solution with exception of the amine complexes[6,40]. The amine complexes are associated via hydrogen bonds[90]. The activity of the σ-alkynyl complexes has not been studied. It is only known that gold phenylacetylide gives rise to diphenylbutadiyne in the presence of $CuCl_2$:[91]

$$2PhC{\equiv}CAu + CuCl_2 \rightarrow PhC{\equiv}C{-}C{\equiv}CPh + CuCl + 2AuCl .$$

4. Carbonyl-Containing Derivatives of Gold(I)

α-Gold-substituted ketones, gold-substituted acetaldehyde, β-dicarbonyl-gold containing complexes, and gold ketenide are now known. Gold-substituted carbonyl compounds of various types have become readily available after the discovery of a new gold-substituting agent—tris(triphenylphosphinegold)oxonium salts[92,93].

Gold-containing oxonium salts are obtained in high yields in the reaction of coordination-unsaturated cation Ph_3PAu^+ with water in an alkaline or acid medium. The Ph_3PAu^+ ion is generated in solution when triphenylphosphinegold chloride reacts with silver tetrafluoroborate[5].

The most convenient method of synthesis of tris(triphenylphosphinegold)oxonium salts is the reaction of triphenylphosphinegold halides with silver oxide and sodium tetrafluoroborate or potassium permanganate[93]:

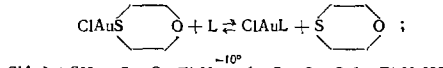
$$Ph_3PAuX + Ag_2O \xrightarrow{NaBF_4} (Ph_3PAu)_3O^+BF_4^- \quad (Ph_3PAu)_3O^+MnO_4^- \ (KMnO_4);$$
$$X = Cl, Br.$$

X-Ray diffraction study of tris(triphenylphosphinegold)-oxonium tetrafluoroborate showed that the $(Ph_3PAu)_3O$ fragment has a pyramidal structure: the oxygen atom is displaced from the plane formed by the three gold atoms. The Au–Au distances are 3.03 and 3.215 Å, which suggests Au–Au interaction in the oxonium cation[5].

Gold-containing oxonium salts are crystalline substances, which melt with decomposition and are decomposed by halide ions. Thus treatment of a solution of a tris(triphenylphosphinegold)oxonium salt in chloroform with an aqueous NaCl solution results in a quantitative yield of triphenylphosphinegold chloride and sodium hydroxide[93]:

$$(Ph_3PAu)_3O^+BF_4^- + 3NaCl + H_2O \rightarrow 3Ph_3PAuCl + NaBF_4 + 2NaOH.$$

Gold-containing oxonium salts proved to be excellent gold-substituting agents—this is the first example of the utilisation of metal-containing oxonium salts as metallating agents. Gold-containing oxonium permanganate reacts with acetone and other ketones containing the methyl group, forming ketones substituted with gold in the methyl group[94]:

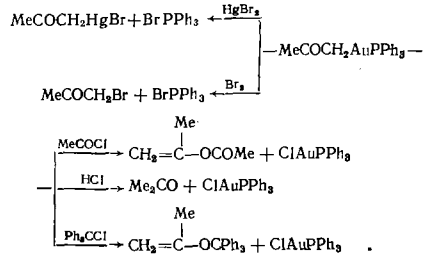


$$R{-}C(O){-}CH_3 + (Ph_3PAu)_3O^+MnO_4^- \rightarrow R{-}C(O){-}CH_2AuPPh_3;$$
$$R = Me, Et, Ph, C_5H_5FeC_5H_4.$$

Gold-substituted acetone and acetylacetone have also been obtained by the reaction of triphenylphosphinegold bromide, silver oxide, and the corresponding ketone[95]:

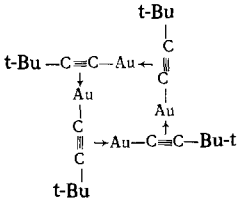
$$Ph_3PAuX + Ag_2O \xrightarrow[Me_2CO]{X=Br} MeC(O)CH_2AuPPh_3 \quad \xrightarrow[(MeCO)_2CH_2]{X=Cl} (MeCO)_2CHAuPPh_3.$$

The cation Ph_3PAu^+, the structural unit of many gold compounds, is a soft Lewis acid and does not usually form bonds with hard oxygen-containing anions. Thus the gold atom in gold acetylacetonate is linked to a carbon atom, while the atoms of the majority of transition metals, including copper and silver, are linked to an oxygen atom in diketonates[96]. The gold–carbon bond is also formed in gold-substituted ketones and in gold-substituted acetaldehydes[94,97]. α-Gold-substituted carbonyl compounds have also been obtained by the reaction of a gold-containing oxonium salt with enol ethers[5]. When vinyl ethers and esters are treated with oxonium tetrafluoroborate, gold-substituted acetaldehyde is formed[94,97].



Like copper and silver, gold forms the ketenide $Au_2C{=}C{=}O$ when a gold chloride complex is treated with keten at −10 °C in acetonitrile in the presence of 2,6-dimethylpyridine (L) and triethylamine[89]:

$$ClAuL + CH_2{=}C{=}O + Et_3N \xrightarrow{-10^\circ} Au_2C{=}C{=}O{\cdot}L + Et_3N{\cdot}HCl + L.$$



The complex gold ketenide readily loses the ligand at room temperature and gives rise to a polymeric gold ketenide, which is explosive in the solid state and is virtually insoluble in the majority of organic solvents. In the presence of aniline, gold ketinide reacts with phenylacetylene to form acetanilide and gold phenylacetylide.

The reactions of α-gold-substituted carbonyl compounds have been studied in greater detail in relation to gold-substituted acetone. Thus triethylenephosphinegold-substituted acetone reacts with electrophiles similarly to the reaction of α-mercurated carbonyl compounds, with cleavage of the metal–carbon bond and the formation of the corresponding *C*- and *O*-derivatives. The reactions involving the carbon atom proceed with acids, mercury(II) chloride, diazomethane, and bromine[5,33,98]. The reactions involving the O atom take place with carboxylic acid chlorides and chlorotriphenylmethane:

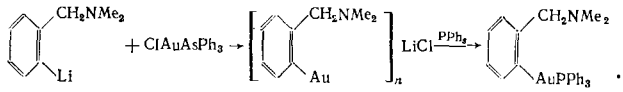
5. The Complexes $(RAu)_n$

There are few example of organic gold complexes of the type $(RAu)_n$ which exist without an outer stabilising ligand L. In such complexes the group σ-linked to the gold atom usually contains either a multiple bond or a heteroatom, which play the role of complex-forming agents in relation to another gold atom, giving rise to oligomerisation or polymerisation of the compound. Examples of such compounds are the σ-alkenyl and σ-alkynyl derivatives of gold. It has been suggested that gold t-butylacetylide exists in the form of a tetramer, for which the following structure has been proposed[1]:

The study of the infrared spectra of this and other alkynyl complexes of gold has shown that the π-coordination of the gold atom with a triple bond is extremely weak[40,88]. In oligomers this bond is readily ruptured even after the addition of a ligand having very weak electron-donating properties, for example Et_3As.[6]

An example of a compound in which intermolecular coordination involves the double bond is provided by cyclopentadienylgold, obtained when an olefin complex of gold chloride is treated with cyclopentadienylsodium or cyclopentadiene in the presence of triethylamine[78]:

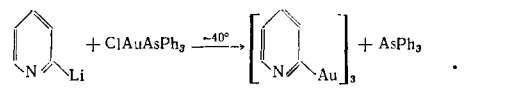
$$C_5H_5Na + ClAuL \rightarrow (C_5H_5Au)_n + L + NaCl.$$



Cyclopentadienylgold is a yellow powder stable only up to −30 °C and almost insoluble in organic solvents. It has a polymeric structure. On treatment with PPh_3, its triphenylphosphine complex is readily produced[78].

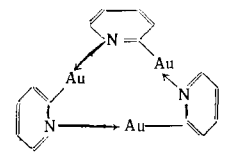
Another group of complexes of the type $(RAu)_n$ includes compounds in which the σ-linked ligand contains a nitrogen atom, which functions as a complex-forming agent.

The only phenyl derivatives of gold which exists without a stabilising outer ligand, is 2-dimethylaminomethylphenyl gold[38], obtained from the mixed Au–Li cluster of arylgold:

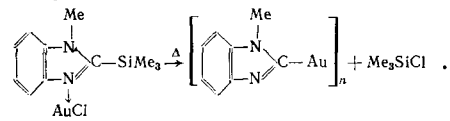


$$R_4Au_2Li_2 + Me_3SnBr \rightarrow RSnMe_3 + (RAu)_n + LiBr\ ;$$
$$R = 2\text{-}Me_2NCH_2C_6H_4\ .$$

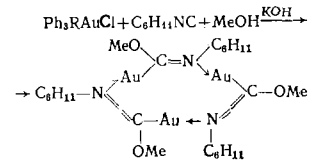
The same compound is also formed in the reaction of the lithio-derivative of dimethylaminomethylbenzene with the triphenylarsine complex of gold chloride. Triphenylarsine was isolated in a quantitative yield and a solid residue, consisting of an LiCl–RAu mixture, was obtained, but the pure derivative of arylgold could not be isolated from this mixture. The formation of the latter was confirmed by the isolation of its stable triphenylphosphine complex after the addition of PPh_3 to the reaction mixture[38]:



2-Dimethylaminomethylphenylgold is a colourless substance, thermally stable up to 117 °C, has a polymeric structure, and is almost insoluble in organic solvents. The group (containing a nitrogen atom) σ-linked to the gold atom plays the role of the stabilising ligand for the gold atom in another molecule.



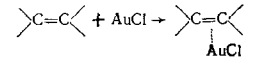
A coordination of the same type can be proposed for pyridylgold and other nitrogen-containing aromatic heterocycles. Derivatives of pyridyl- and quinolinyl-gold have been obtained via their lithio-derivatives and triphenylarsine complexes of gold chloride[99,100]:



These compounds are solid, sparingly soluble polymeric substances, stable in air at room temperature, which are sensitive to the action of light. The structure of a cyclic trimer with coordination of the nitrogen atoms to the gold atoms has been proposed for pyridylgold:

Yet another example of complexes of this type is provided by the gold-containing derivatives of 1-methylbenzimidazole[101]:

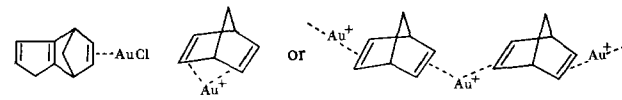
The reaction of aliphatic isonitriles with gold chloride complexes in the presence of alcohol and alkali results in the formation of alkoxy(alkylamino)methylgold complexes[34–36], which are trimeric in solution and, like pyridylgold, have a planar heteroatomic ring:



Similar cyclic trimers have been obtained from carbene complexes of gold[102] (see also Section V below).

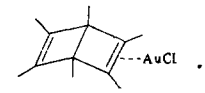
Cyclic trimers are stable solids, do not react with CO and PPh_3 under normal conditions[36], and react with bromine and iodine via the oxidative addition mechanism, forming cyclic trimeric complexes of tervalent gold[103].

III. π-OLEFIN AND π-ACETYLENE COMPLEXES OF GOLD



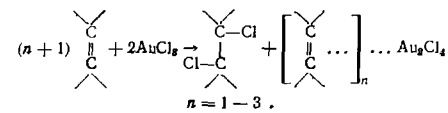
The first olefinic π-complexes of gold(I) were described by Hüttel and Dietyl[104] and Chalk[105]. Complexes of this type are intermediates in reactions involving an olefin and gold compounds as catalysts[106].

The π-complexes of gold(I) are formed at low temperatures as a result of the interaction of the olefin with gold chloride[107,108]:



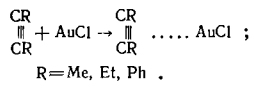
Both acyclic and cyclic olefins undergo the reaction[107–109]. The π-complexes of gold(I) are relatively unstable and readily split off the olefin ligand. Their stability increases with increase of the molecular weight of the olefin[107]. A stable complex has only been isolated for $C_{12}H_{24}$ and olefins with higher molecular weights[107]. Stable π-complexes of cyclic olefins have been isolated only for cycloheptane and compounds with larger rings[109]. The complexes with dienes and trienes are more stable than the corresponding complexes of mono-olefins[107,109,110].

The structure of the complexes cannot be regarded as reliably established, since there are no X-ray diffraction data and a conclusion has been reached about the structure of the complexes on the basis of infrared spectroscopic and ^1H NMR data. A structure in which gold is coordinated to one of the two double bonds has been proposed for the dicyclopentadienyl π-complex; in norbornadiene both double bonds participate in the formation of the π-complex[109]:

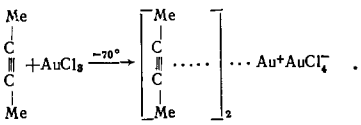


Cyclo-octatetraene reacts with AuCl at −45 °C to form an unstable complex of unknown structure, which is almost fully dissociated in ethereal solution[111].

Hexamethyl-substituted Dewar benzene reacts with AuCl to form a π-complex with coordination of the gold atom to only one of the double bonds of the diene[112]:



After the interaction of olefins with tervalent gold salts at low temperatures, complexes were isolated with an overall formula corresponding to the composition Au_2Cl_4.olefin.[105,108,111,113] However, the diamagnetism of these compounds as well as Mössbauer spectroscopic data show that one is dealing not with bivalent gold compounds but with a mixture of gold(I) and gold(III) derivatives formed on reduction of half of the initial gold(III) salt by the excess olefin[114]:



With cyclo-octatetraene (COT), a complex of the same type, having the composition $COT.Au_2Cl_4$, was obtained[111].

Hüttel and Forkl[115] were the first to isolate π-complexes of gold salts with alkynes. The interaction of substituted acetylenes with AuCl at low temperatures leads to the formation of relatively unstable complexes (with the exception of the toluene complex):

R=Me, Et, Ph .

Pyridine readily displaces the unsaturated ligand from these complexes, giving rise to AuCl.Py (Py = pyridine). If the same alkynes are acted upon by anhydrous $AuCl_3$ at temperatures between −30° and −70 °C, complexes having the composition $(alkyne)_2.Au_2Cl_4$ are formed. They are mixed complexes of univalent and tervalent gold, similar to those described previously for olefinic π-complexes[115,116]:

A π-complex of gold with a cyclic alkyne has been obtained recently. Cyclo-octyne reacts with AuBr to form a stable 2 : 1 π-complex: [117]

The fact that the complex has the cyclo-octyne and not the diene structure has been confirmed by its reaction with cyclone as well as infrared spectroscopic data. The diene synthesis reaction led to the isolation of the corresponding adduct[117].

IV. ANIONIC COMPLEXES OF GOLD

In the first studies on the synthesis of alkyl derivatives of gold using alkyl-lithium compounds, it was already postulated that anionic complexes of the type $(R_2Au)^-$ may be formed[40]. A detailed investigation of anionic gold complexes was begun with the studies of Tamaki and Kochi[118]. After the addition to an ethereal solution of MeAuL of an equivalent amount of methyl-lithium at a low temperature, the authors[118] were the first to detect by ^1H NMR the formation of an anionic complex of dimethylgold[118,119]:

$$MeAuL+MeLi\rightarrow[Me_2AuL]^-Li^+ .$$

Asymmetric anionic complexes with different alkyl radicals, for example, $[(Me_3C)MeAuL]^-Li^+$, are formed also under the same conditions[118].

The attempts to isolate dialkylaurates with phosphine ligands were unsuccessful. However, it was possible to isolate and characterise a pyridine complex of the lithium salt of dimethylgold, which is unstable in air[118]:

$$[Me_2AuL]^-Li^+ + Py \rightarrow [Me_2AuPy_2]^-Li^+ .$$

When the aprotic polyamine *N,N,N',N''*,*N''*-pentamethyldiethylenetriamine (PMDT) was used as the chelating agent for the lithium ion in the reaction of methylgold with methyl-lithium, a white solid, having the composition $Li(PMDT)AuMe_2$, was isolated. It is stable in the solid state in the light and at room temperature for several months, but rapidly decomposes in protic solvents and under the influence of atmospheric moisture[120]. Spectroscopic study of this hitherto unique stable representative of dialkylanionic complexes showed that it is made up of a linear dialkyl anion and a chelate cation[120]. It has so far been impossible to replace the lithium cation in the complex and also to use other complex-forming agents for lithium.

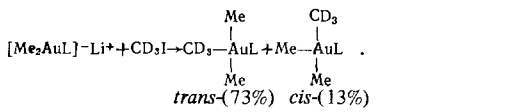
Perhalogenoaryl anionic complexes are entirely stable in air and in the light both in the solid state and in solution. Perchloro- and perfluoro-phenyl anionic complexes of two types are known: homoligand and heteroligand. They are readily formed at low temperatures in ether from the tetrahydrothiophen complex of gold chloride and perhalogenoaryl-lithium[121–123]. When equimolar amounts of the initial reactants are employed, heteroligand anionic complexes are formed:

while in the presence of an excess of perhalogenoaryl-lithium, homoligand anionic complexes are isolated:

Dialkylaurates react with various electrophiles under milder conditions than the corresponding neutral complexes[118,124,125]. Their protolysis and their reactions with bromine and alkyl halides have been described[118,124,125].

The protolysis of lithium ethylmethyl(triphenylphosphine)-aurate takes place readily at 0 °C on treatment of its ethereal solution with hydrogen chloride[124]. The reaction resulted in the isolation of methane, ethane, and the triphenylphosphine complexes of methyl- and ethyl-gold:

$$[MeEtAuPPh_3]^-Li^+ + HCl \rightarrow CH_4 + C_2H_6 + MeAuPPh_3 + EtAuPPh_3 + LiCl .$$



The reaction of dialkylaurates with bromine leads to a mixture of products in which the trialkylgold complex predominates[124]:

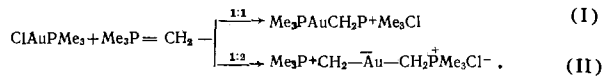
$$[Me_2AuPPh_3]^-Li^+ + Br_2 \rightarrow Me_2AuBrPPh_3 + LiBr \xrightarrow{[Me_2AuPPh_3]^-Li^+} \rightarrow Me_3AuPPh_3 + MeAuPPh_3 .$$

Under the influence of halogens and perfluoroaryl derivatives of tervalent thalium, perhalogenoaryl anionic complexes give rise to oxidative addition products[121–123]:

$$[(C_6Cl_5)_3Au]^- \xrightarrow{I_2} [(C_6Cl_5)_2AuI_2]^- .$$

The reaction of dialkylaurates with alkyl halides also proceeds via the oxidative addition mechanism[118,124,125]. The study of the stereochemistry of this reaction showed that mainly the *trans*-isomer is formed[118]:

trans-(73%) *cis*-(13%)



Perfluorophenylaurate reacts with bis(triphenylphosphine)-gold perchlorate, the ligand being substituted with formation of a neutral complex of perfluorophenylgold: [123]

$$[(C_6F_5)_2Au]^-Bu_4N^+ + (Ph_3P)_2Au^+ClO_4^- \rightarrow 2C_6F_5AuPPh_3 + Bu_4N^+ClO_4^- .$$

V. YLID COMPLEXES OF GOLD

The formation of extremely stable ylid complexes is characteristic of all Group IB metals[126,127]. The ylid complexes of gold, first obtained in 1973, have been investigated very vigorously in recent years. The interest in compounds of this kind is associated primarily with their unusually high thermal stability for organogold complexes. These complexes have also found applications in medicine in recent years[128].

Depending on the reactant ratio, the interaction of $ClAuPMe_3$ with $Me_3P{=}CH_2$ leads to the formation of various phosphonium salts[127–130]:

(I)

(II)

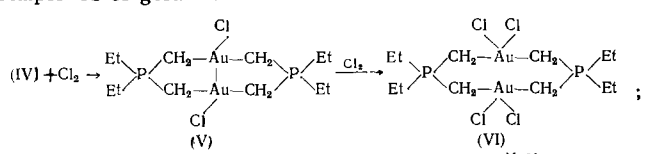
In the presence of a large excess of the ylid, an eight-membered heterocyclic compound (III) with two gold atoms is obtained[127–129,131]:

(III)

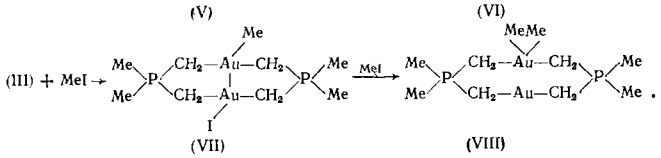
Compounds of types (I), (II), and (III) have been obtained for a series of alkylphosphines, for example for triethyl-, tributyl-, and dimethylcyclopropyl-phosphines[128,131,132] and also for triphenylphosphine ylids[130,133].

Phosphonium salts of types (I) and (II), in which the hydrogen atom of the methylene group has been substituted by the Me_3Si group, have been described[130]. As-analogues of cyclic ylid complexes have been obtained[131].

The complex



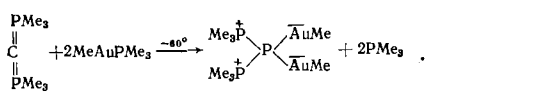
(IV)



has been studied by X-ray diffraction and its Mössbauer and ESCA spectra have been investigated[134]. In complex (IV) there are two parallel linear –C–Au–C– fragments whose gold atoms hardly interact.

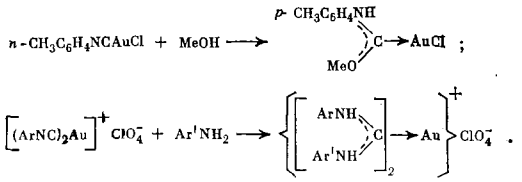
The ylid complexes of gold are solid substances stable in air and in the light. The thermal stability of these complexes, some of which actually sublime and distil *in vacuo* without decomposition, is unusually high[127,129,130,132].

The ylid complexes of type (III) readily undergo oxidative addition reactions under the influence of halogens and alkyl halides[129,135]. Thus, when complex (IV) was treated with chlorine, a dinuclear cyclic complex (V) was obtained, from which a gold(III) ylid complex (VI) was formed on further treatment with chlorine. Treatment of complex (III) with methyl iodide gives rise to complexes (VII) and (VIII). Complexes (V) and (VII), in which the gold atom is in the unusual oxidation state of +2 according to Mössbauer and ESCA spectroscopic data, are of special interest[134]. According to X-ray diffraction data, the Au–Au distance in complex (V) is 2.60 Å and is the smallest in all the known organic complexes of gold[135]:

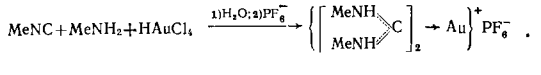


(V) (VI)

(VII) (VIII)

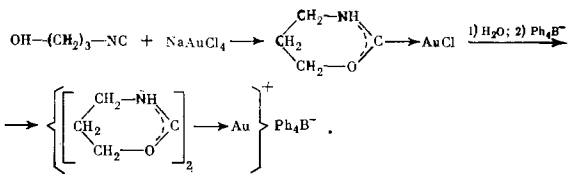


Hexamethylcarbodiphosphorane[136] reacts with two molecules of $MeAuPMe_3$ to form a complex in which the tetrahedral carbon atom is linked to two gold atoms[137]:

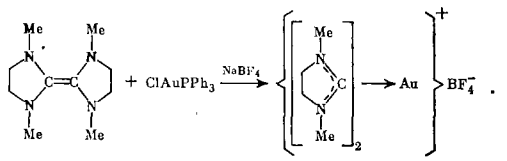


VI. CARBENE COMPLEXES OF GOLD

In 1971 two groups of investigators obtained almost simultaneously carbene complexes of gold[138,139].

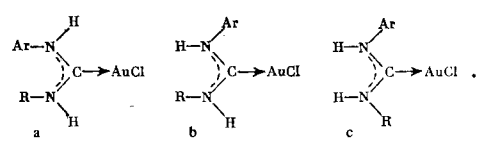


Two types of carbene complexes containing either one or two carbene ligands have been described for univalent gold. Both mono- and di-carbene complexes are formed readily from isonitrile complexes of gold in the presence of an amine or an alcohol[36,102,140–145]:

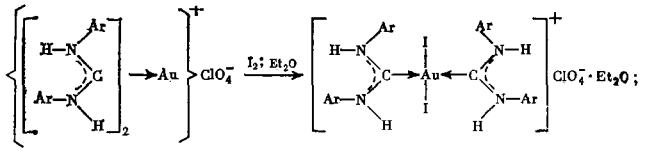


Instead of using isonitrile complexes, one can introduce into the reaction a univalent or tervalent gold salt and the isonitrile in the presence of an amine or alcohol[36,140,142]. In view of the highly nucleophilic properties of the amines, the reactions with the latter always proceed under milder conditions than with alcohols[145]:

Hydroxy-substituted isonitriles react with gold compounds to form a cyclic alkoxy(alkylamino)carbene complex[146]:

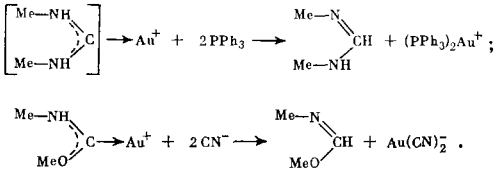


Olefins activated by electron-donating substituents are converted into carbene complexes on reaction with gold salts[147,148]:



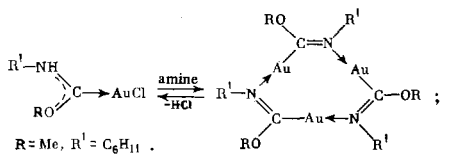
The carbene complexes of gold are white solids stable in air but sensitive to light. Some of them exhibit a luminescence of different colours and durations on irradiation with ultraviolet light[140]. This property has proved useful for the determination of the purity of the complexes. Carbene complexes with substituted tetrazoles are used in medicine as anti-inflammatory preparations[144].

Spectroscopic studies have shown that the rotation about the C–O and C–N bonds is limited, that the multiplicity of these bonds is greater than unity, and that the carbene ligand has a planar structure[142,143]. In conformity with this structure, the carbene complexes exist in the form of geometrical isomers. Among the three possible geometrical isomers a–c, isomer b predominates[142,143,145]:



a b c

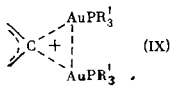
The reactivity of the carbene complexes has been little investigated. As for the majority of the organic complexes of gold, they readily undergo reactions involving oxidative addition of the halogen and ligand exchange reactions. The oxidative addition of iodine or bromine to the dicarbene complex of gold(I) leads to a dicarbene complex of gold-(III):[62,140,141,149]



Ar = *p*-$CH_3C_6H_4$.

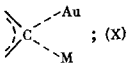
According to X-ray diffraction data, the tervalent gold complex is square planar with *trans*-carbene ligands[149,150]. The carbene ligand is substituted on treatment with other fairly powerful electron-donating ligands such as triphenylphosphine, cyanide, or isonitrile[140,142,145]:

It is noteworthy that the last reaction has served as a key to the explanation of the catalytic effect of added $HAuCl_4$ in reactions involving α-addition of amines to isonitriles, leading to substituted formamidines. The role of the gold salt reduces to the formation of the isonitrile complex of gold(I), which is converted into a carbene complex in which the carbene ligand is substituted by the isonitrile ligand, giving rise to a substituted formamidine and the initial isonitrile complex of gold(I).[140,142]



The deprotonation reaction, leading to the formation of organic σ-derivatives of gold, is specific to the carbene complexes. On treatment with bases, the deprotonation takes place with formation of cyclic trimers[36,102] (see above). This reaction is reversible and, on treatment with acid, carbene complexes are reformed from the trimer[36,102,151]:

R = Me, R' = C_6H_{11} .



VII. ORGANOGOLD COMPOUNDS WITH A BRIDGING CARBON ATOM

Like the majority of transition metals, gold forms organometallic compounds with a metal–metal bond. The dinuclear cationic complexes $[R(AuPR'_3)_2]^+X^-$, in which the organometallic fragment (IX) of the molecule is a three-membered gold-carbon ring with an Au–Au bond and a bridging carbon atom, have been fairly thoroughly investigated[5]:

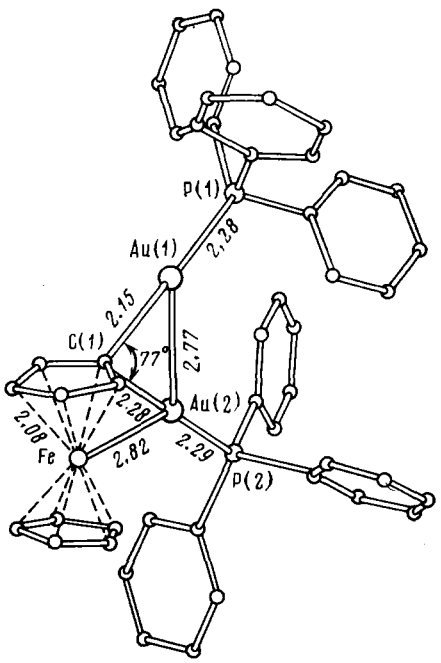
(IX)

Aryl compounds of gold in which the bridging carbon atom is linked to different metal atoms, one of which is gold and the other is zinc, copper, silver, or lithium [compounds (X)] are also known:

; (X)

M = Zn, Li, Cu, Ag .

Compounds of this type are usually dimeric and form metal–carbon macrorings—for example, triphenylgoldzinc.



1. Homonuclear Cationic Complexes $[R(AuPR'_3)_2]^+X^-$

Dinuclear cationic complexes of type (IX) have been obtained for phenyl, ferrocenyl, cymantrenyl, and alkenyl derivatives of gold and both their structures and chemical behaviour have been studied in detail[2,5,152,153].

(a) Structure

The structures of the dinuclear cationic complexes of gold have been determined by infrared, ultraviolet, Raman, and NMR spectroscopy and also by X-ray diffraction.

The most stable ferrocenyl complex has been studied by X-ray diffraction[154,155]. It was established that the Au–Au distance in this complex (2.77 Å) is shorter than the Au–Au distance in the metal (2.88 Å), while the Au(1)–C(1)–Au(2) angle is much smaller than the tetrahedral value, which indicates the existence of a bond between the two gold atoms (see Figure). The plane of the three-membered Au(1)C(1)Au(2) ring is almost perpendicular to the plane of the cyclopentadienyl ring and the C(1) carbon atom occupies a bridging position between the two gold atoms. The interaction of C(1) with the two gold atoms must be regarded as a two-electron three-centre bond. Cluster compounds of copper and silver with a bridging ferrocenyl group have been described recently[156,157].

The structure of bis(triphenylphosphinegold)ferrocenium tetrafluoroborate.

The study of the ultraviolet and infrared spectra of the tolyl complex[158], the study of the *p*-fluorophenyl complex by ^{19}F NMR,[159] and the Raman spectroscopic study of the styryl complex[81] have shown that the aryl and alkenyl cationic complexes have a structure of type (IX), in which the carbon atom of the organic group occupies a bridging position between two gold atoms.

(b) Methods of Synthesis

From organogold compounds. When organogold complexes were treated with HBF_4, dinuclear complexes of type (IX) were obtained in high yields[2,5]:

$$RAuPR_3' + HBF_4 \rightarrow [R(AuPR_3')_2]^+BF_4^- + RH \ .$$

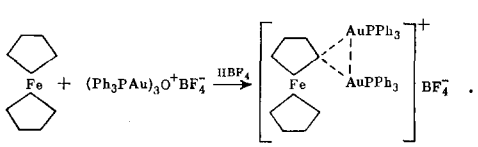
The cation R'_3PAu^+ can be conveniently generated from R'_3PAuCl on treatment with silver tetrafluoroborate.

From organomercury compounds. When organomercury derivatives R_2Hg are treated with phosphine complexes of methylgold in the presence of HBF_4, mercury is substituted by gold in a series of aryl, alkenyl, ferrocenyl, cymantrenyl, and heterocyclic organomercury compounds[21,22,160]. Depending on the group R in the initial organomercury derivative, various types of organogold complexes are formed. Thus treatment of diaryl- and distyryl-mercury derivatives with electron-accepting substituents in the group with phosphine complexes of methylgold and HBF_4 led to the isolation of only the organomonogold complexes[21]:

$$R_2Hg + MeAuPPh_3 \xrightarrow{HBF_4} RAuPPh_3 \ ;$$

R=X—C_6H_4, where X=*p*-, *m*-COOEt, *o*-I; PhCH=C(COOMe).

Cationic dinuclear complexes are formed from diferrocenylmercury derivatives having both electron-donating and electron-accepting substituents, from distyryl-, dicymantrenyl-, and dithienyl-mercury, and also from diaryl compounds of mercury having electron-donating substituents in the aromatic ring[21,22,160]:

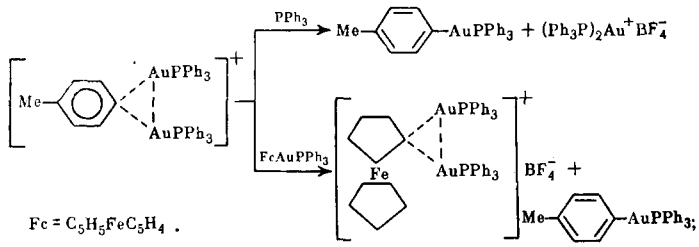


$$R_2Hg + MeAuPPh_3 \xrightarrow{HBF_4} [R(AuPPh_3)_2]^+BF_4^- \ ;$$

R=X—$C_5H_4FeC_5H_4$, where X=H; Cl; Br, OMe, COOMe; Y—C_6H_4, where Y=H, Me, NH_2.

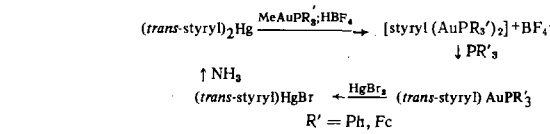
A characteristic feature of *p*-halogenoarylmercury derivatives is that, by altering the reaction conditions, it is possible to obtain from them both dinuclear gold complexes and organomonogold compounds[21].

It is noteworthy that organogold complexes having the same geometrical configuration as the initial organomercury compound have been obtained from the *trans*-isomers of alkenyl derivatives of mercury[22,81].



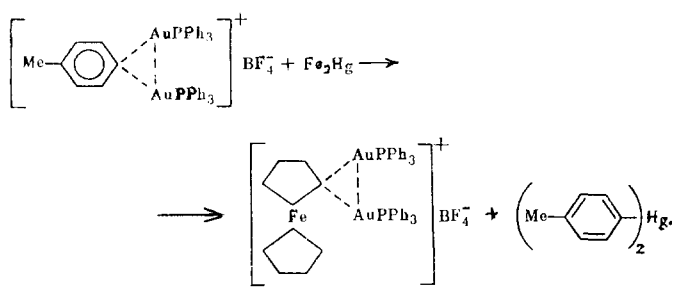
Substitution of gold in ferrocene and its derivatives. Ferrocene and its derivatives react with tris(triphenylphosphinegold)oxonium tetrafluoroborate at room temperature in the presence of HBF_4 to form dinuclear cationic complexes[161,162]:

The preferential formation of homoannular substituted compounds on substitution of gold in chloro-, bromo-, methoxy-, acetyl- and nitro-ferrocenes is apparently caused by the additional stabilisation of the cationic centre in the 1,2-isomer by the coordination of the gold atom to the substituent[162].



(c) Reactions

The study of the chemical behaviour of dinuclear organogold compounds has shown that reactions of two types are characteristic of these compounds—those involving only one or both $AuPR'_3$ groups. The first type involves the striking ability of the complexes $[R(AuPr'_3)_2]^+BF_4^-$ to enter into various reactions involving the transfer of the $R'_3PAu_3^+$ cation. The reaction proceeds readily under the influence of nucleophiles such as phosphines, amines, and halide ions. Another organogold compound can also fulfil the role of the nucleophile[2,5]:

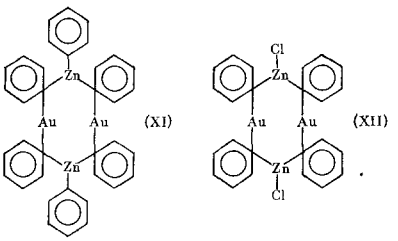


A feature of the reactions of alkenyl dinuclear complexes should be noted. Thus the dinuclear cationic complex obtained from the triphenylphosphine complex of *trans*-styrylgold generates, under the influence of triphenylphosphine or ferrocenylgold, an organomonogold compound having the same geometrical configuration as that of the initial *trans*-styrylgold[81].

A series of reactions, illustrated schematically below, have been carried out for *trans,trans*-distyrylmercury[81]:

An analogous sterochemical result has also been obtained for *trans,trans*-di(1-methoxycarbonyl-2-phenylvinyl)mercury[22].

The reactions of the cationic complexes with organometallic compounds belong to the second type. Thus the interaction of the cationic tolyl complex with diferrocenylmercury results in the formation of ditolylmercury and a dinuclear ferrocenylgold complex in high yields[2,19]:



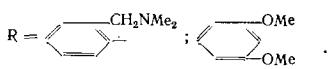
The mild reaction conditions and the high yields of products make it possible to use the dinuclear cationic complexes of gold for the synthesis of new organogold complexes with different organoelemental ligands, including gold-containing ligands.

2. Heterometallic complexes of arylgold

Heterometallic cluster complexes of arylgold of type (X) have been described by two groups of Dutch investigators.

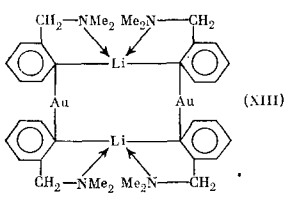
De Graaf and coworkers[163,164] obtained aryl complexes containing gold and zinc; Van Koten and coworkers[39,165-167] investigated arylgold complexes containing also lithium, silver, or copper atoms.

Triphenylgoldzinc was isolated after treating diphenylzinc with an ethereal solution of $AuCl_3$ or AuCl(CO).[163] The compound is dimeric in benzene; since it has a dipole moment close to zero, a dimeric structure (XI) was attributed to it. ^1H and ^{13}C NMR data also agree with the dimeric structure. If diphenylzinc and AuCl(CO) react in proportions of 1 : 1, a compound having the composition $Ph_2AuZnCl$ is formed, for which structure (XII) has been proposed. Here the phenyl groups at the zinc atom have been substituted by chlorine atoms:



Whereas triphenylgoldzinc is extremely sensitive to atmospheric moisture, its chlorine-containing analogue is much more stable.

Analogues of compounds (XI) and (XII) have been obtained for *p*-ditolylzinc, whereas for other arylzinc derivatives with electron-donating substituents, only complexes of type (XII) have been isolated[164]. Organozinc and organogold compounds are known to form the most stable complexes with nitrogen- and phosphorus-containing ligands respectively. Accordingly, the reaction of triphenylgoldzinc with bipyridyl and tetramethylethylenediamine gives rise to complexes via the zinc atom, while the interaction with triphenylphosphine and diphos leads to phosphine complexes of phenylgold[164]:



$$XI \xrightarrow{(C_5H_4N)_2} 2Ph_3AuZn\cdot(C_5H_4N)_2$$
$$XI \xrightarrow{PPh_3} 2Ph_2Zn + 2PhAuPPh_3 .$$

The triphenylphosphine complexes of arylgold or gold bromide react with aryl-lithium compounds to form mixed Au–Li clusters with bridging aryl groups[38]:

$$(RLi)_4 + BrAuPPh_3 \rightarrow R_4Au_2Li_2 ;$$

$R =$  ;

Bis[2-(dimethylaminomethyl)phenyl]goldlithium is a dimeric compound thermally stable up to 170 °C; structure (XIII) has been proposed for it[4,38]:

This mixed Au–Li cluster has served as the starting material for the synthesis of a stable phenyl derivative of univalent gold, existing without an external stabilising ligand—(2-dimethylaminomethyl)phenylgold[38] (see above). In addition, other cluster complexes of gold have been obtained from compound (XIII). Thus the reaction of compound (XIII) with copper(II) bromide led to the isolation in a high yield of a dimeric (in benzene) cluster containing gold and copper atoms[165,166]:

$$R_4Au_2Li_2 + 2CuBr \rightarrow R_4Au_2Cu_2 + 2LiBr .$$

The reaction of compound (XIII) with $(CF_3SO_3)Cu$ and $(CF_3SO_3)Ag$ yielded new hexanuclear clusters containing gold and copper and gold and silver respectively[167]:

$$R_4Au_2Li_2 + (CF_3SO_3)M \rightarrow R_4M_1Au_2(CF_3SO_3)_2 ;$$
$$M = Cu, Ag .$$

The Oxidation-reduction Reactions of Gold Complexes

V.P.Dyadchenko

The review deals with reactions involving oxidative addition to both organogold compounds and to gold complexes without Au-C bonds. Furthermore, the review includes reactions involving the reductive elimination of alkyl groups from tervalent gold complexes.
The bibliography includes 66 references.

CONTENTS

I. Introduction 265
II. Oxidative addition reactions 265
III. Reductive elimination from tervalent gold compounds 269

I. INTRODUCTION

The oxidation addition reactions constitute one of the types of reactions characteristic of organometallic σ-compounds of transition metals. The most familiar reagents capable of oxidative addition are halogens, alkyl halides, and alkyl disulphides. However, the range of these compounds is being continually expanded. Oxidative addition is nowadays regarded as one of the stages in the protolysis of certain organometallic compounds by hydrogen halides.

Despite the fact that the oxidative addition reactions are known for derivatives of many metals, their characteristics are by no means clear. The most convenient objects for the investigation of these reactions are compounds of gold and platinum group metals. This is due to the fairly high stability of the organometallic σ-derivatives of these elements and also the simplicity with which the stereochemistry of the process can be followed.

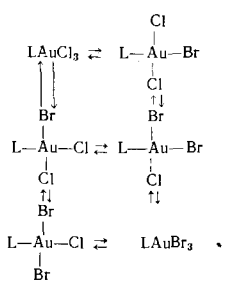
This review is devoted to reactions of organogold compounds of the oxidative addition type. The reductive elimination processes can be logically related to the former reactions and are also considered in the present review.

Apart from its general theoretical importance, the study of reactions involving oxidative addition to gold(I) complexes is also important from the preparative standpoint, because gold(I) compounds are much more readily available than gold(III) compounds.

II. OXIDATIVE ADDITION REACTIONS

1. Reactions Involving Oxidative Addition to Complex Salts LAuX

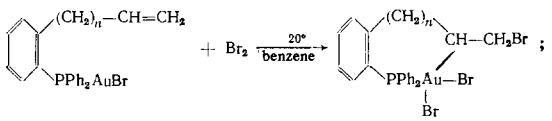
When phosphine[1-5] and arsine complexes[3] of univalent gold halides react in polychlorohydrocarbons with an excess of the halogen of the same type as in the halide, gold trihalide complexes are formed in high yields:



$$R_3PAuX + X_2 \rightarrow R_3PAuX_3 ;$$
$$X = Cl, Br, \text{or } I;\ R = Et,\ Ph,\ \text{cyclo-}C_6H_{11},\ \text{or } C_5H_5FeC_5H_4;$$
$$Ph_3AsAuCl + Cl_2 \rightarrow Ph_3AsAuCl_4 .$$

A mixture of ethanol and tetrahydrofuran can also be used as the solvent[3]. The infrared spectra of the complexes have been investigated[6].

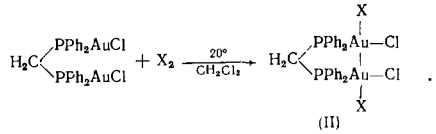
The same product is formed in the reactions of Et_3PAuBr with iodine and of Et_3PAuI with bromine in equimolar amounts. This result was initially explained by the high mobility of the halogens in $Et_3PAuBrI_2$ and Et_3PAuBr_2I and by the formation of the more stable of the above two compounds in both reactions[1]. However, later investigations by NMR showed[7,8] that the process involves the formation of a mixture of all possible complexes of the type $LAuX_aY_{3-a}$ with an approximately statistical distribution of the halogens X and Y. Thus, for the reaction



$$Et_3PAuBr + Cl_2 \xrightarrow[h\nu]{25^\circ} Et_3PAuBr_{3-a}Cl_a ;$$
$$a = 0,\ 1,\ 2,\ 3 .$$

the following equilibrium states have been discovered[8]:

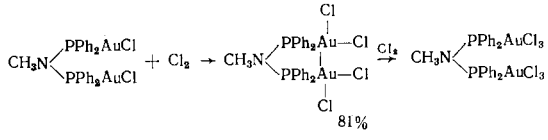
Deviations for the statistical distribution of the halogen atoms in this reaction have been observed only for complexes with a large amount of bromine—$LAuClBr_2$ and $LAuBr_3$.[8] The behaviour of the univalent gold in this reaction is analogous to that of the isoelectronic platinum(II) complexes Br_aCl_{4-a}. $.PtL_2$, for which a statistical distribution of halogen atoms has also been observed[9].



When the phosphine complexes of AuBr in which the ligand contains C=C double bonds are treated with bromine, organic derivatives of tervalent gold are formed as a result of the addition of gold to the double bond[10]:

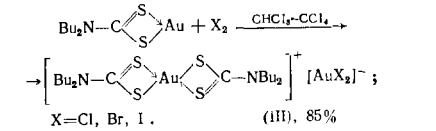
$n = 0$ or 1. (I)

The structure of the resulting yellow crystalline compounds (I) has been determined by X-ray diffraction[10]. In both compounds (I) the gold atom has the square planar environment characteristic of gold(III). The five-membered ring in compound (I) ($n = 0$) has the envelope conformation, while the six-membered ring in compound (I) ($n = 1$) has the twist-boat conformation. The Au–C bond in compounds (I) persists also in solutions (according to ^1H NMR data).[10]



The reaction with halogens of AuCl complexes containing bidentate phosphine ligands and in which two gold atoms are in close proximity in space can lead to the formation of gold compounds with a formal oxidation state +2. Thus the reaction of equimolar amounts of a halogen and the complex of AuCl with bis(diphenylphosphino)methane leads to the formation of compound (I):[11]

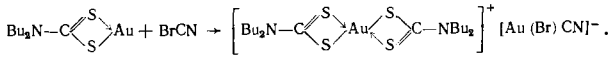
(II)



$Me_2C(PPh_2AuCl)_2$ reacts analogously with chlorine and bromine. The reaction involving $H_2C(PPh_2AuI)_2$ with iodine leads to an unstable complex $H_2C(PPh_2AuI)_2.I_2$, which readily loses iodine *in vacuo* or on recrystallisation. Infrared, ^{197}Au Mössbauer, and X-ray electron spectroscopic data have shown that the oxidation state of the gold in complexes (II) is intermediate between +1 and +3.[11]

When compound (II) is treated with an excess of a halogen, the tervalent gold complexes $H_2C(PPh_2AuClX_2)_2$ are formed. Analogous reactions have been performed for another bisphosphine complex[12]:

81%



The reactions of halogens with other gold salts have been much less thoroughly investigated. When gold butylthiocarbamate is treated with halogens, the products are either the tervalent gold compound $Bu_2NCS_2AuBr_2$ [13,14] or salt-like complexes containing both Au(I) and Au(III):[15]

X=Cl, Br, I. (III), 85%

The structure of the bromide (III) has been established by X-ray diffraction (the tervalent gold atom has a square planar environment)[15].

An analogous compound has been obtained on treatment with bromocyanogen[15]:

The reactions of arsine and phosphine complexes of gold salts with tervalent thallium compounds have been studied in greater detail. Thus, when triphenylphosphinegold chloride and $TlCl_3$ are refluxed in chloroform, a gold trichloride complex is formed in 95% yield[16]:

$$Ph_3PAuCl + TlCl_3 \rightarrow Ph_3PAuCl_3 + TlCl\ .$$

The reaction of LAuX with bis(pentafluorophenyl)thallium halides in benzene leads to bis(pentafluorophenyl)gold halides[17–20]:

$$LAuX + (C_6F_5)_2TlZ \rightarrow (C_6F_5)_2Au(X)L + TlZ\ ;$$
$$L=PPh_3,\ AsPh_3;\ X=Cl,\ Br,\ I;\ Z=Br,\ I\ ;$$
$$[-CH_2PPh_2AuCl]_2 + (C_6F_5)_2TlBr \rightarrow [-CH_2PPh_2Au(C_6F_5)_2Cl]_2\ .$$

It has been established for bis(pentafluorophenyl)gold chloride that the C_6F_5 groups are in the *cis*-positions relative to one another[17]. The isonitrile complex of AuCl reacts analogously[21]:

$$PhNCAuCl + (C_6F_5)_2TlBr \xrightarrow[benzene]{80°;1.5\ h} PhNCAu(C_6F_5)_2Cl + TlBr\ .$$

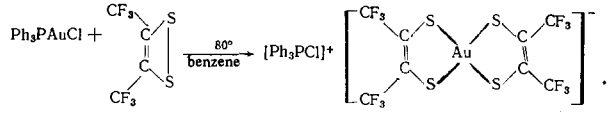
The reaction of t-BuNCAuCl yields a mixture of products which are difficult to separate[21].

Pentachlorophenylthallium(III) compounds can function as oxidants in relation to gold complexes, but in this case a complex of univalent gold is formed together with the gold(III) compound:

$$Ph_3PAuCl + (C_6Cl_5)_2TlCl \xrightarrow{-TlCl} (C_6Cl_5)_2Au(Cl)PPh_3 + C_6Cl_5AuPPh_3\ .$$

This result has been explained by the lower oxidising capacity of $(C_6Cl_5)_2TlCl$ compared with that of pentafluorophenyl derivatives of thallium[22].

When Ph_3PAuCl reacts with a fully substituted organic compound of thallium(III), oxidation is not observed at all and only a gold(I) compound is formed[23]:



$$Ph_3PAuCl + (C_6HCl_4)_3Tl \xrightarrow{CHCl_3} Ph_3PAuC_6HCl_4\ .$$

In contrast to complexes of univalent gold halides, the triphenylphosphine complexes of gold(I) nitrate, perchlorate, acetate, and thiocyanate react with perfluorophenylthallium compounds to form only univalent gold derivatives[19]:

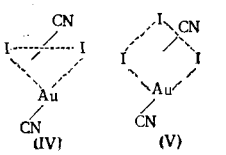
$$Ph_3PAuZ + (C_6H_5)_2TlX \rightarrow Ph_3PAuC_6F_5\ ;$$
$$Z=NO_3,\ ClO_4,\ CH_3COO,\ SCN,\ X=Br,\ I\ .$$

The causes of the difference between the reactivities of gold halides and those of other gold(I) salts are not discussed in the literature, but the differences agree satisfactorily with the greater ease of reductive elimination in the compounds $LAuR_2Z$ for $Z = NO_3$ or ClO_4 compared with Z = halogen (see below).

The reaction of triphenylphosphinegold chloride with the disulphide $(CF_3)_2C_2S_2$ has been described[24]. During the reaction, the phosphine ligand is displaced and an anionic complex of tervalent gold is formed, its structure having been established by X-ray diffraction[25]:

The gold atom in the anion of this complex has a square planar coordination and the S...S distances are 3.23 Å.

2. Reactions Involving Oxidative Addition to the Aurates $M^+[Au(X)Y]^-$



When a slight excess of halogens is allowed to act on potassium dicyanoaurate in H_2O-CH_3OH, tervalent gold aurates are formed[26–29]:

$$K[Au(CN)_2] + X_2 \rightarrow trans\text{-}K[Au(CN)_2X_2]\ ;$$
$$X=Cl,\ Br,\ I\ .$$

The infrared spectra of the compounds obtained have been studied in detail[27,28] and it has been shown that the reaction involves *trans*-addition.

It has been observed that the addition of iodine is greatly accelerated in the presence of the iodide ion[30]. This effect has been explained by the preferential *trans*-disposition of iodine atoms in the transition state of the reaction with I_3^-

compared with the addition of I_2 [cf. the transition states (IV) and (V)]:

(IV) (V)

Oxidative addition products have been obtained by treating with alkyl bromides or iodides the dialkylaurates(I), which are readily obtained when phosphine complexes of alkylgold-(I) are acted upon by alkyl-lithium compounds. In the resulting tervalent gold compounds two methyl groups are in the *trans*-positions relative to one another[31,32]. The yields of gold(III) complexes range from 30 to 70%:

$$Li^+[Me_2AuPPh_3]^- + RX \rightarrow R{-}AuMe(PPh_2) + LiX ;$$

R=Et, Bu, iso-Bu; X=Br, I ;

$$Li^+[R(Me)AuPPh_3]^- + MeI \rightarrow R{-}AuMe_2PPh_3 + LiI ;$$

R = iso-Pr, t-Bu, or noe-C_5H_{11};

$$Li^+[Me_2AuPPh_3]^- + CD_3I \xrightarrow{LiI} \underset{73\%}{CD_3{-}AuMe_2PPh_3} + \underset{13\%}{Me{-}AuMe_2PPh_3} .$$

If the phenyl group is present in the gold(III) compound obtained, then the compound has the *cis*-configuration[31,32]:

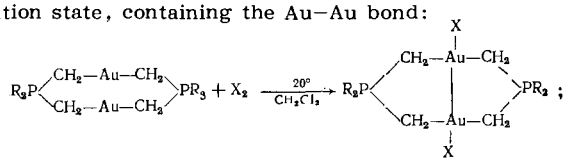
$$\left.\begin{array}{l} Li^+[Me_2AuPPh_3]^- + PhI \\ Li^+[Ph(Me)AuPPh_3]^- + MeI \end{array}\right\} \rightarrow Me{-}AuMePhPPh_3 + LiI .$$

When equimolar amounts of bromine and lithium dimethylaurate react, a mixture of methyl derivatives of univalent and tervalent gold is formed, probably as a result of the following reactions[32]:

$$Li^+[Me_2AuPPh_3]^- + Br_2 \rightarrow Me_2Au(Br)PPh_3 + LiBr ;$$

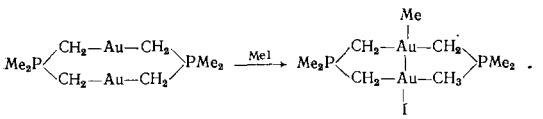
$$Li^+[Me_2AuPPh_3]^- + Me_2Au(Br)PPh_3 \rightarrow Me_3AuPPh_3 + MeAuPPh_3 + LiBr .$$

In contrast to dimethylaurate, the mixed complex (VI) is converted into gold(III) compounds in high yields on treatment with bromine or bis(pentafluorophenyl)thallium bromide[33]:



$$Bu_4N^+[C_6F_5AuBr]^- \xrightarrow{Br_2} \underset{65\%}{Bu_4N^+[C_6F_5AuBr_3]^-}$$

$$Bu_4N^+[C_6F_5AuBr]^- \xrightarrow{(C_6F_5)_2TlBr} \underset{90\%}{Bu_4N^+[(C_6F_5)_3AuBr]^-} .$$

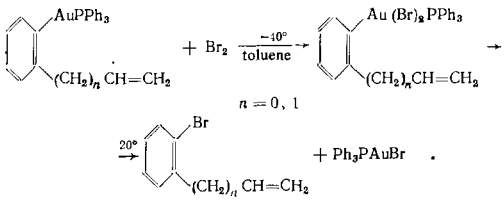


(VI)

Thus the oxidative addition of univalent gold to aurates constitutes a convenient and promising method of synthesising organic derivatives of tervalent gold.

Reactions involving the oxidative addition of halogens[34-36] and methyl iodide[36] have also been achieved for close analogues of dialkylaurates—the ylid complexes of gold. The spatial proximity of the gold atoms in these dinuclear complexes and their structural rigidity permit in this instance the formation of gold compounds (VII), with a formal +2 oxidation state, containing the Au–Au bond:

R = Me, or Et, X = Cl, Br, or I, (VII), 36—85%



When gold(II) complexes are acted upon by an excess of halogen or MeI, they are converted into tervalent gold compounds.

The presence of the transannular Au–Au bond in compound (VII) has been demonstrated by an X-ray diffraction study of compound (VII, X = Cl), in which the distance between the gold atoms is 2.597 Å.[34] In the initial ylid complex of univalent gold the Au...Au distance is 3.023 Å.[37]

3. Reactions Involving Oxidative Addition to the Polyhalogenoaryl Compounds $C_6X_nH_{5-n}AuL$

The Au–C bond in the aryl and the similar ferrocenyl organogold compounds $RAuPR'_3$ is readily ruptured by halogens with formation of $R'_3PAuHal$.[38-41] Unstable oxidative addition products have been detected only in the reaction of *o*-vinylphenyl- and *o*-allylphenyl-(triphenylphosphine)gold with bromine[42]:

$n = 0, 1$

However, the gold(III) complexes have been fairly poorly characterised.

On the other hand, the polyhalogenoaryl compounds of gold(I) are readily converted into gold(III) complexes on treatment with halogens, thallium trichloride, and methyl iodide.

The reaction with halogens[16,20,21,43-46] leads to the formation of the corresponding dihalides (VIII):

$$C_6X_5AuL + Hal_2 \xrightarrow[CCl_4 \text{ or } CH_2Cl_2]{0^\circ} C_6X_5Au(Hal)_2L ;$$

(VIII), 34—85%

X = F, Cl, or Br; Hal = Cl, Br, or I, L = PEt_3, or PPh_3, $AsPh_3$, PhNC, or RNH—C—R' .

The *trans*-configuration of the coordination environment of gold has been demonstrated for the dichloride (VIII).[21,44-46] The *trans*-dihalides (VIII) are readily converted into the *cis*-isomers on heating[16,45,46].

The formation of the products of the cleavage of the C–Au bond on treatment with halogens has been observed only for the perfluorophenyl compounds[16,43-45]. The proportions of the products of the oxidative addition and of the cleavage of the C–Au bond depend on the nature of both the halogen and of the stabilising ligand L. For $C_6F_5AuPPh_3$, the amount of the oxidative addition product increases in the sequence Cl < Br < I, while the opposite sequence holds for C_6F_5AuAs. Ph_3: I < Br < Cl.[45] However, the C–Au bond cannot be ruptured by halogens even in the perfluorophenyl derivative of gold when the ligand is phenylisonitrile[21].

Refluxing of C_6X_5AuL in chloroform in the presence of $TlCl_3$ also leads to $C_6X_5AuCl_2L$, but in this case the *cis*-isomer is formed:

$$C_6X_5AuL + TlCl_3 \xrightarrow{CHCl_3} \underset{60-90\%}{cis\text{-}C_6X_5Au(Cl)_2L} + TlCl ;$$

L = PEt_3, PPh_3, or $AsPh_3$; X = F 16, Cl 16, 44, 46, or Br 45.

The complexes of ethyl- and phenyl-gold do not give rise to gold(III) compounds under these conditions[16]:

$$RAuPPh_3 + TlCl_3 \rightarrow Ph_3PAuCl + TlCl\ ;\quad R = Et, \text{ or } Ph.$$

The reaction of pentachlorophenyl(triphenylarsine)gold with methyl iodide[44], leading to a mixture of isomeric gold(III) complexes, has been achieved:

$$C_6Cl_5AuAsPh_3 + MeI \rightarrow \underset{60\%}{C_6Cl_5\,(Me)\,Au\,(I)\,AsPh_3}\ .$$

$C_6F_5AuAsPh_3$ also reacts with methyl iodide, but the products of this reaction have not been determined[44].

Thus reactions involving oxidative addition to polyhalogenoaryl compounds of univalent gold constitute a convenient method of synthesising the corresponding gold(III) complexes.

4. Reactions Involving Oxidative Addition to the Alkyl Complexes RAuL

The reactions of methylgold complexes with MeI and CF_3I have been studied in fair detail. The first studies on this problem showed that the reaction of methyl(triphenylphosphine)gold with methyl iodide in benzene or in MeI at 20 to 25 °C leads to ethane and a gold iodide complex[47,48]:

$$MeAuPPh_3 + MeI \rightarrow C_2H_6 + Ph_3PAuI;$$
$$[-CH_2P\,(Ph)_2\,AuMe]_2 + MeI \rightarrow [-CH_2P\,(Ph)_2\,AuI]_2 + C_2H_6\ .$$

Methyl iodide reacts analogously with silicon-containing derivatives of univalent gold[47]:

$$Ph_3PAuCH_2SiMe_3 + MeI \rightarrow Ph_3PAuI + Me_3SiEt\ ;$$
$$Ph_3PAuOSiMe_3 + MeI \rightarrow Ph_3PAuI + MeOSiMe_3\ .$$

NMR study of the interaction of methyl iodide with phosphine complexes of methylgold[48,49] as well as kinetic data[50] have shown that the reaction is a multistage process, the first two stages [(1) and (2)] being rapid:

$$MeAuL + MeI \rightarrow Me_2Au\,(I)\,L\ ; \quad (1)$$
$$Me_2Au\,(I)\,L + MeAuL \rightleftarrows Me_3AuL + LAuI\ ;\quad L = PMe_3,\ PMe_2Ph,\ PMePh_2 \text{ or } PPh_3. \quad (2)$$

Reaction (2), which leads to a complex of trimethylgold, is analogous to the exchange of methyl groups between platinum and gold compounds[7]:

$$cis\text{-}Pt\,(Me)_2\,L_2 + LAuBr \rightleftarrows trans\text{-}PtBr\,(Me)\,L_2 + MeAuL\ .$$

The subsequent fate of the Me_3AuL formed in reaction (2) depends greatly on the nature of the ligand L. For L = PPh_3, reductive elimination of ethane and subsequent interaction of $MeAuPPh_3$ with methyl iodide take place:

$$Me_3AuL \rightarrow C_2H_6 + MeAuL\ . \quad (3)$$

The overall result is thus the formation of methane and of a gold iodide complex.

However, the triphenylphosphine complex of trimethylgold can be isolated with a high yield when the reaction is carried out at 0 °C:[48]

$$MeAuPPh_3 + MeI \xrightarrow[0°,\ 6\ days]{\text{in soln. in MeI}} \underset{87\%}{Me_3AuPPh_3} + Ph_3PAuI\ .$$

The complexes of trimethylgold with ligands such as PMe_3 and PMe_3Ph are more stable than Me_3AuPPh_3 and equilibrium (2) shifts towards the formation of the oxidative addition product via the reaction of MeAuL with an excess of methyl iodide [reaction (1)]. Thus a complex of dimethylgold iodide has been obtained in a high yield from the trimethylphosphine complex[49]:

$$MeAuPMe_3 + MeI \xrightarrow[20°,\ 3\ weeks]{\text{in soln in MeI}} cis\text{-}Me_2Au\,(I)\,PMe_3\ .$$

When L = $PMePh_2$, a mixture of products is formed as a result of reactions (1)–(3).[50]

The mechanism of the interaction of methyl iodide with methylgold complexes discussed above is consistent with the higher rate of formation of butane compared with the rates of formation of ethane and propane on interaction of MeI with an ethylgold complex[48]:

$$EtAuPPh_3 + MeI \rightarrow C_4H_{10} + C_3H_7 + C_2H_6 + Ph_3PAuI\ .$$

However, the cause of the decomposition of the trialkylgold complex [reaction (3)] is not clear, since it is known that the complex Me_3AuPPh_3 is fairly stable at 20–25 °C.[51] It may be that the elimination of ethane is in this instance catalysed by methyl iodide[48].

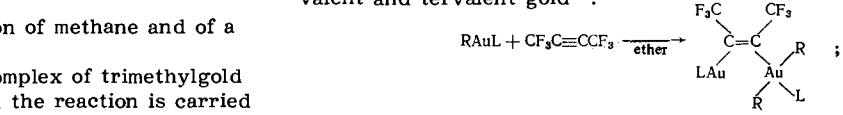
Trifluoroiodomethane reacts with MeAuL similarly to methyl iodide[49,52]. In this case, when L = PMe_3 or PMe_2Ph, the isomeric complexes (IX) are formed in high yields:

$$MeAuL + CF_3I \rightarrow Me_2Au\,(CF_3)\,L + LAuI\ ;\quad L = PMe_3,\ PMe_2Ph\ (IX). \quad (4)$$

Reaction (4) in methylene chloride leads to *trans*-(IX), while in CF_3I the product is *cis*-(IX). In other solvents (ether, acetone) a mixture of the *cis*- and *trans*-isomers is formed[49].

The triphenylphosphine complex reacts with trifluoroiodomethane differently[52]:

$$MeAuL + CF_3I \rightarrow CF_3AuL + MeI\ ;\quad L = PPh_3\ . \quad (5)$$



When L = $PMePh_2$ a mixture of products corresponding to reactions (4) and (5) is formed[52].

The inhibiting influence of a radical trapping agent (galvinoxyl) on reaction (4) has been observed and a radical mechanism of the formation of compound (IX) has been proposed on this basis[52]:

$$CF_3^{\cdot} + MeAuL \rightarrow [MeAu\,(CF_3)\,L]^{\cdot} \xrightarrow{CF_3I} Me\,(CF_3)\,Au\,(I)\,L + CF_3^{\cdot}\ ;$$
$$Me\,(CF_3)\,Au\,(I)\,L + MeAuL \rightarrow Me_2Au\,(CF_3)\,L + LAuI\ .$$

The poor reproducibility of the kinetic data has also been adduced as an argument in support of the radical reaction mechanism. However, the intermediate paramagnetic bivalent gold compound (X) was not detected and the authors[52] do not consider the radical mechanism to be the only one possible.

An unusual example of oxidative addition is provided by the reaction of hexafluorobut-2-yne with complexes of methyl- and ethyl-gold. This results in the formation of the dinuclear organogold compounds (XI), containing both univalent and tervalent gold[53]:

R = Me, or Et; L = PMe_3, PMe_2Ph, or $PMePh_2$. (XI), 40–77% .

The groups R in compounds (XI) are in the *trans*-positions relative to one another. In the case of $MeAuPMe_3$ the *cis*-isomer is formed in addition to the *trans*-isomer. On interaction with hexafluorobut-2-yne, the triphenylphosphine complex $MeAuPPh_3$ yields the dinuclear organogold compound $Ph_3PAuC(CF_3)=C(CF_3)AuPPh_3$, which does not contain tervalent gold[54,55]. There are data indicating a radical mechanism of the reaction of hexafluorobut-2-yne with alkoxygold complexes[53].

Thiophenol[56] and selenophenol[57] react with methylgold complexes without the formation of gold(III) compounds:

$$MeAuL + PhSH \rightarrow CH_4 + PhSAuL\ ;$$
$$L=PMe_3,\ PMePh_2 \text{ or } PPh_3;$$
$$MeAuPMe_2Ph + PhSeH \rightarrow PhSeAuPMe_2Ph\ .$$

The reactions have a radical mechanism. Compounds containing the P–H and As–H bonds react analogously and polymeric products are obtained[57]:

$$MeAuPMe_2Ph + Ph_2ZH \rightarrow (AuZPh_2)_x\ ;$$
$$Z = P, \text{or As.}$$

III. REDUCTIVE ELIMINATION FROM TERVALENT GOLD COMPOUNDS

One of the factors determining the result of the interaction of univalent gold compounds with reagents capable of oxidative addition is the thermal stability of the resulting gold(III) complex, which is directly related to the possibility of reductive elimination.

Hitherto reductive elimination had been studied virtually only for alkylgold(III) complexes. This process, which leads to the formation of a univalent gold compound, has been known for a fairly long time for organogold compounds without stabilising ligands[58]:

$$RAuX_2 \rightarrow RX + AuX\ ;$$
$$R_2AuX \rightarrow AuX + \text{hydrocarbons.}$$

The compounds *cis*-$[Me_2AuL_2]ClO_4$ are fully stable at 20 °C in the solid state, but decompose rapidly with formation of ethane at an elevated temperature, particularly in solution (under the conditions of the study of the ^1H NMR spectrum):[59]

$$\underset{\text{(XII)}}{\textit{cis}\text{-}[Me_2AuL_2]ClO_4} \xrightarrow{CHCl_3} C_2H_6 + [L_2Au]ClO_4;\quad L=PPh_3,\ AsPh_3,\ SbPh_3\ .$$

It is significant that methane is not formed under these conditions even in trace amounts.

A necessary condition for the ready occurrence of the reductive elimination reaction involving complexes (XII) was believed to be the presence of bulky ligands L. Thus *cis*-$[Me_2Au(PMePh_2)_2]ClO_4$ is stable under conditions where its triphenylphosphine analogue decomposes[59]. However, it was shown later that the oxidative addition reactions are facilitated while reductive elimination is hindered for alkylgold complexes and the isoelectronic platinum complexes with increase of the electron density at the metal atom[60,61].

The rate of elimination of two methyl groups in the complexes *cis*-$Me_2Au(X)L$ depends on the nature of X and increases in the sequence $Cl < CF_3COO < NO_3 < CF_3SO_3$.[62]

The reductive elimination in trialkylgold complexes has been studied in greatest detail. Thus, when the complex Me_3AuPPh_3 is heated to 120 °C in xylene, biphenyl, or in the absence of a solvent, ethane is eliminated[51]:

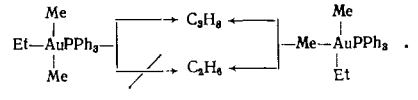
$$Me_3AuPPh_3 \xrightarrow[87\%]{120^\circ} C_2H_6 + MeAuPPh_3\ .$$

Further decomposition of the univalent gold complex takes place at a higher temperature.

In the presence of free triphenylphosphine, the rate of elimination of two alkyl groups from R_3AuPPh_3 diminishes. It is therefore believed[63] that the reductive elimination is preceded by the dissociation of the complex [reaction (6)]:

$$R_3AuPPh_3 \rightleftarrows R_3Au + PPh_3\ . \qquad (6)$$

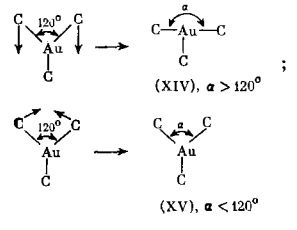
Further decomposition of trialkylgold can take place both intramolecularly and intermolecularly, which has been demonstrated in the study of the thermolysis of an equimolar mixture of Me_3AuPPh_3 and $(CD_3)_3AuPPh_3$ at 80 °C.[64] In non-coordinating solvents (decalin, chlorobenzene, and dibutyl ether) the ratio of the C_2H_6, CH_3CD_3, and C_2D_6 formed is nearly statistical, which indicates the occurrence of the intermolecular elimination process, probably via a dinuclear intermediate of type (XIII):



$$Me_3AuPPh_3 \rightleftarrows Me_3Au + PPh_3\ ;$$
$$Me_3Au + (CD_3)_n AuPPh_3 \rightleftarrows Me_3Au(CD_3)_n AuPPh_3\ ;$$
$$n = 1 \text{ or } 3; \qquad \text{(XIII)}$$
$$\text{(XIII)} \rightarrow MeAuPPh_3 + CD_3AuPPh_3 + C_2H_6 + C_2D_6 + CH_3CD_3\ .$$

In solvents such as dimethylformamide and dimethyl sulphoxide the cross-product CH_3CD_3 is formed only in trace amounts, which indicates intramolecular elimination. In this case the dissociation stage (6) is apparently followed by the coordination of the alkyl derivative of gold(III) to the solvent Sol:[64]

$$Me_3Au + Sol \rightleftarrows Me_3Au\cdot Sol\ ;$$
$$Me_3Au\cdot Sol \rightarrow MeAu\cdot Sol + C_2H_6, \text{ etc.}$$

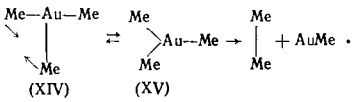


Intramolecular and intermolecular elimination pathways have also been observed in the thermolysis of $CD_3(Me)_2AuPPh_3$.[64] Apart from the nature of the solvent, the character of the process is strongly influenced also by the concentration of the gold(III) complex; with increase of concentration, the contribution of intermolecular elimination also increases.

Under the conditions of intramolecular elimination, the two alkyl groups in the *cis*-positions relative to one another are split off[63,64]. Thus the thermolysis of *trans*-$Et(Me_2)AuPPh_3$ leads mainly to the formation of propane, while the decomposition of the *cis*-isomer results in the formation of ethane and propane in comparable amounts:

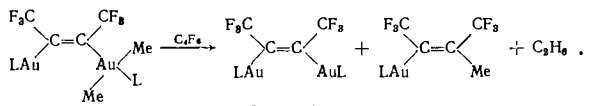
The relative ease of elimination depends on the nature of the alkyl group. Thus methyl groups are eliminated with greater difficulty than ethyl groups[48], which agrees with the greater strength of the bond between the metal and the primary carbon atom.

A quantum-chemical calculation on the transition state in the reaction involving reductive elimination from a trimethylgold complex has been performed[64]. In the trimethylgold formed on dissociation of Me_3AuPPh_3 the highest occupied $4e'$ orbital is doubly degenerate if Me_3Au has the C_{3h} symmetry (the C–Au–C angles are 120°). This orbital can be only half-occupied, which should lead to a distortion of the C–Au–C angles according to the Jahn–Teller theorem, removing the degeneracy thereby. T-shaped (XIV) or Y-shaped (XV) symmetry distortions are possible:



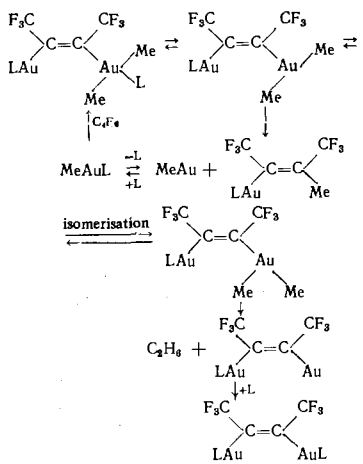
(XIV), $\alpha > 120^\circ$;

(XV), $\alpha < 120^\circ$.

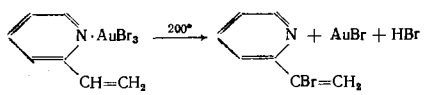


A molecular orbital calculation on the Me_3Au molecule has shown[64] that the T-shaped configuration (XIV) corresponds to the energy minimum. The vibrations of the two *cis*-Me groups towards one another lead to their spatial approach and a transition of the molecule to the Y-shaped configuration (XV), in which the coordination of the gold approaches

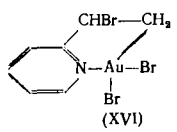
the linear form; under these conditions, elimination takes place:



(XIV) (XV)



The only example of the elimination of an alkenyl group from a gold(III) complex is provided by the decomposition of the dinuclear hexafluorobutenyl derivatives (XI) catalysed by hexafluorobut-2-yne:[53]



The mechanism proposed for this reaction is based on the hypothesis of the intramolecular *cis*-elimination:

A reductive elimination stage has been proposed for the thermolysis of the complex of $AuBr_3$ with 2-vinylpyridine[65]:

It has been suggested that gold adds initially to the C=C double bond with formation of the cyclic compound (XVI), from which AuBr and HBr are then split off:

(XVI)

---o0o---

The data presented in the review show that the ability of a complex RAuL or the corresponding tervalent gold derivative to undergo oxidative addition or reductive elimination reaction depends greatly both on the group R and on the ligand L. However, it is at present difficult to reach an unambiguous conclusion concerning the nature of this dependence and particularly to give preference to steric or electronic factors.

The data on the oxidative addition of halogens and alkyl iodides to anionic complexes of univalent gold and to polyhalogenoaryl derivatives showed that these reactions involve in most cases *trans*-addition. However, the above conclusion cannot be extended to all types of organogold compounds, since, even within the framework of anionic complexes, there are deviations from the general rule for this class of compounds: the phenyl derivatives give rise to the *cis*-isomers. It is not clear whether this entials a change in the stereochemistry of the transition state or whether all aspects are determined by the difference between the thermodynamics of the *cis*- and *trans*-isomers of the compounds formed.

The oxidation-reduction interconversions of organometallic derivatives of univalent and tervalent gold have been little studied and, what is most important, only in isolated instances. In particular, reactions of organogold compounds with alkyl and especially aryl halides have been hardly investigated (the reaction of complexes of methylgold with methyl iodide is an exception). Despite this, one can already speak of the synthetic value of oxidative addition as a method of synthesis of organic derivatives of tervalent gold which are difficult to obtain.

Interesting results may be expected from the study of oxidative addition to zerovalent gold complexes, the first representative of which has been obtained quite recently[66].

Polymeric Derivatives of Adamantane

A.P.Khardin and S.S.Radchenko

The literature data on the synthesis and properties of polymers with fragments of the polyhedral structures of adamantane and 1,1'-biadamantane are surveyed. The inter-relation between the structures of the polyhedral monomers and their reactivities is examined. A distinctive feature of the adamantane-containing polymers, together with their high thermal stability, is their resistance to hydrolysis and oxidation and to the action of light and solvents.
The bibliography includes 114 referenees.

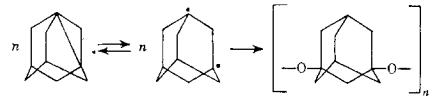
I. INTRODUCTION

Compounds with a polyhedral structure have attracted the attention of investigators from the standpoint of the possibility of obtaining polymers with valuable practical properties. An example of this is provided by the carbaborane-containing polymers the methods of synthesis of which are based on the functional transformations of carbaboranes—polyhedral systems with a boron–carbon skeleton[1].

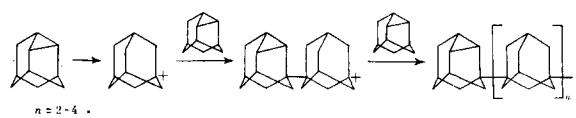
One of the "growth points"[2] in organic chemistry at the present stage consists of studies in the field of polyhedral hydrocarbons and in the first place adamantane, first detected in petroleum by Landa[3] in 1933. These studies developed further after Schleyer et al.[4] achieved the isomerisation of tetrahydrobicyclopentadiene to adamantane in the presence of aluminium halide. The ease of this rearrangement can be accounted for by the high thermodynamic stability of adamantane; treatment of all the known $C_{10}H_{16}$ isomers with Lewis acid inevitably leads to this tricyclic hydrocarbon[5]. The antiviral activity of 1-aminoadamantane hydrochloride was discovered in 1964.[6] Since then there has been a continuous growth of the number of studies on adamantane and related polyhedral hydrocarbons; they have been surveyed in a whole series of reviews[7-19]. Certain special fields concerning heteroadamantanes[20,25] and the pharmacological activity of adamantane derivatives[21,22] have been examined. The first monograph on adamantane has been published recently[22].

Fairly numerous studies, described mainly in patents, have been made on polymeric adamantane derivatives. However, if one disregards a brief review on adamantane polymers[23] quoting four original communications, the literature on this field has not been surveyed. At the beginning of 1977 a review was published[24] on the structure and stereochemistry of adamantanoid hydrocarbons in which certain problems of the stereochemistry of polyadamantanes—low-molecular-weight linear polymers—were examined together with those concerning higher adamantane homologues. Studies on silicon-containing polymeric derivatives of adamantane have been described in a review[25].



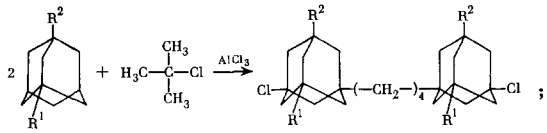
II. CARBOCHAIN POLYMERS OF ADAMANTANE

Polyadamantane was obtained for the first time[26] from 3,3'-dibromo-1,1'-biadamantane by the Wurtz reaction:



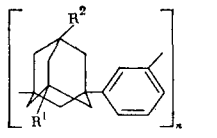
The polymer (melting point above 420 °C) was a white powder insoluble in the usual organic solvents and resistant to the action of concentrated hydrochloric acid and 5 *N* solution of alkali. According to X-ray diffraction data, the polyadamantane had a degree of crystallinity in excess of 80%.

Dehydroadamantanes may serve as another source of polyadamantane. 1,3-Dehydroadamantane is an extremely reactive compound; on heating to 130–160 °C, it is converted into a solid polymer without fusion[27]. In solutions in the presence of atmospheric oxygen 1,3-dehydroadamantane forms an adamantane polyperoxide with opening of the inner cyclopropyl ring even at room temperature[28]:



On heating, the polyperoxide decomposes explosively in the temperature range 146–180 °C.

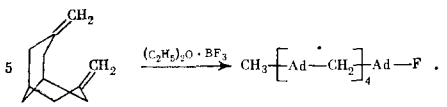
Polyadamantane is also formed on polymerisation of 2,4-dehydroadamantane under the influence of aluminium chloride[29]. The reaction proceeds via a stage involving the formation of the adamantyl cation and subsequent hydride transfer from 2,4-dehydroadamantane:



Interesting results have been obtained in the polycondensation of polybromoadamantanes under the influence of metallic sodium[30]. The product is a three-dimensional carbon polymer and consists of the carbon nuclei of adamantane. It consists of a white powder with a carbon content of ~ 99% and a density of 2 g cm^{-3}. It is insoluble in organic solvents.

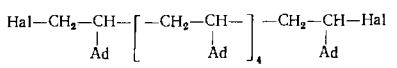
Oligomers consisting of two and three adamantane nuclei and short methylene chains between them have been obtained by the polycondensation of adamantane and its homologues with alkyl halides in the presence of $AlCl_3$ or $AlBr_3$.[31] An example is provided by the reaction between alkyladamantane and t-butyl chloride:

R^1 and R^2 = CH_3, or C_2H_5



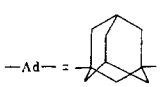
The process takes place at 20–30 °C in the course of 1 h. The number of nuclei in the chain can be increased by employing a large excess of the initial adamantane homologue. The copolymers of adamantane and benzene can serve as another example of mixed polyadamantanes[32]:

where R^1 and R^2 = alkyl and n = 9–10.

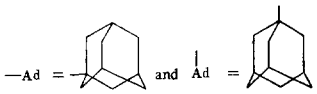


The reaction of alkyladamantane with di-t-alkylbenzenes takes place in the presence of Lewis acids at temperatures between 0° and +25 °C for equimolar reactant ratios. The resulting polymer with a molecular weight of 2300 is a solid, which melts at 250 °C and forms protective films and coatings with a high resistance to thermal oxidation[32].

Polyadamantane with methylene bridges in the chain is a product of the cationic polymerisation of 3,7-bismethylenebicyclo[3.3.1]nonane in an organic solvent (n = 4)[33]†:

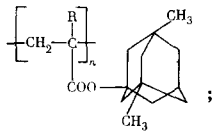


The polymer is insoluble in organic solvents and melts above 340 °C.



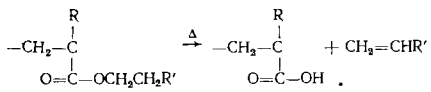
Certain polymers of vinyl derivatives of adamantane are known. Under the influence of $AlCl_3$ or $AlBr_3$ in methylene chloride, vinyladamantane gives rise to a solid product which is insoluble in organic solvents[34]. On the basis of the results of elemental analysis, a formula has been proposed for the oligomer#:

† Here and henceforth



Here and henceforth

The homopolymer of 1-allyladamantane and its copolymer with vinylcyclohexane have been obtained by polymerisation in the presence of a complex catalyst—(iso-BuO)$_3$Al–$TiCl_4$.[35] However, no information about the properties of these polymers is presented in the relevant communication.

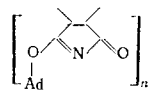


Adamantyl acrylates and methacrylates polymerise under the influence of free-radical and anionic catalysts[36,37] and also under ultraviolet irradiation[38].

The study of the kinetics of the radical polymerisation showed that both the methacrylates and the vinyl esters of adamantane derivatives are highly reactive[39], i.e. the adamantyl group does not inhibit polymerisation. The principal distinctive properties of such polymers are high glass points, considerable surface hardness, brittleness and low mechanical strength, and insignificant contraction on polymerisation. These properties are due to the presence in the macromolecules of the bulky adamantyl group, which increases the rigidity of the polymer chains:

R = H, or CH_3.

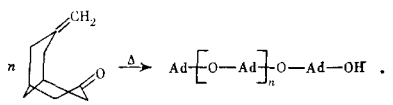
One of the causes of the thermal degradation of polyacrylates is the cleavage of the ester side-groups with formation of an olefin:



The reaction does not occur for poly(adamantyl acrylates) and this is a particular reason for their high thermal stability.

Solutions of poly(adamantyl acrylates) are very viscous, which led to their use as thickening agents for lubricating oils[38]. For example, a 1% solution of poly(dimethyladamantyl acrylate) with a molecular weight of 80000 has the same viscosity as a 2% solution of poly(methyl methacrylate) with a molecular weight of 117000.

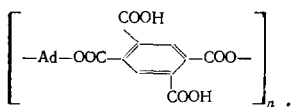
Acrylate and methacrylate esters of adamantanols copolymerise with methyl methacrylate, styrene, acrylonitrile, and vinyl chloride[37]. The properties of the copolymers depend on their composition, but in all cases copolymerisation with adamantyl acrylates leads to an increase of the glass points and of the hardness of the copolymers.



The influence of bulky substituents on the stereoregularity of the polymers of vinyl ethers and esters has been studied[42]. Investigation of the infrared spectra of the polymer films showed that the adamantyl group promotes a high syndiotacticity of the poly(vinyl carboxylate) and the isotacticity of the vinyl ether. The orienting effect of the adamantyl group is similar to that of the t-butyl group, which can be regarded as the open-chain analogue of the adamantyl group. Like adamantyl methacrylates, poly(adamantyl vinyl ethers) have high softening temperatures (210–225 °C). The homo- and co-polymerisation of the heterocyclic derivative 5-(1′-adamantyloxy)-2H, 2-pyrrolone with various vinyl monomers have been studied in detail[43]. Spectroscopic investigations have shown that the polymerisation takes place as a result of the partial dissociation of the C=C bond in the heterocycle:

The presence of the pyrrolone heterocycle in the polymer chain led the authors[43] to investigate the photochemical properties of the polymer films. It was found that, on ultraviolet irradiation, photochemical transformations, accompanied by the formation of cyclopropyl isocyanate groups, take place in the polymer. The copolymers of 5-(1′-adamantyloxy)-2*H*, 2-pyrrolone are characterised by an alternation of the comonomer units and the high values of the parameters $Q = 3.40$ and $e = 1.59$ indicate, according to the authors, electron-accepting properties of the substituent—the adamantyl group. The homo- and co-polymers of 5-(1′-adamantyloxy)-2*H*, 2-pyrrolone have high glass points (220–245 °C). On thermolysis of the homopolymer, the adamantyl group migrates to the nitrogen atom with formation of poly-*N*-(1-adamantyl)maleimide.

III. POLYETHERS, POLYESTERS, POLYSULPHONES, AND POLYCARBONATES OF ADAMANTANE



The polyether may have been the first polymeric heterochain derivative of adamantane obtained[44]. In their study of the possibility of synthesising the adamantane nucleus from bicyclic systems, Stetter et al.[44] observed that, when 3-methylenebicyclo[3.3.1]-7-nonanone is heated in an inert solvent in the presence of toluene-*p*-sulphonic acid, a polyether derived from adamantane is formed with a quantitative yield:

Polyethers have been synthesised by the reaction of the phenoxides derived from 1,3- and 2,2-bis(4′-hydroxyphenyl)-adamantanes with di(4-chlorophenyl) sulphone and 4,4′-difluorobenzophenone[45] and also by the reaction of 3,3′-dibromo-1,1′-biadamantane with diphenoxyethane[40,41].

Numerous studies, described mainly in patents[46–55], have been devoted to the synthesis of polyesters based on adamantanedicarboxylic acids or adamantane diols. The starting compounds for the synthesis of adamantane-containing polyesters are either the diesters of adamantanedicarboxylic acids (transesterification with glycols) or the highly reactive chlorides of the corresponding dicarboxylic acids. Calcium acetate–antimony dioxide[40] and sodium hydride–hexabutoxytitanate[41] systems as well as tetraisopropyl titanate and toluene-*p*-sulphonic acid[46–48] can be used as transesterification catalysts. The chloride of adamantane-1,3-dicarboxylic acid is highly reactive. The rate constant for its reaction with diethylene glycol, for example, in the temperature range 100–140 °C varies from 0.0044 to 0.0203 litre mol^{-1} s^{-1}.[56]

The majority of the polyesters have a low molecular weight owing to the steric influence of the adamantane nucleus. This is demonstrated by the esterification of adamantane-1,3-diols by tetracarboxylic acid dianhydrides[51]. If the reaction is carried out in dimethylformamide (DMF) at a low temperature (60 °C) and in the presence of toluene-*p*-sulphonic acid, then a linear non-cross-linked polyester with free carboxy-groups is obtained:

This can be explained by the fact that, in the esterification of the first carbonyl group in one of the anhydride moieties by adamantane-1,3-diol, the bulky adamantyl group causes steric hindrance of the reaction of the second adamantanediol molecule with the carbonyl group adjoining the esterified group. On the other hand, the second anhydride moiety is not sterically hindered and reacts with the diol. This type of polyester is soluble in 5% aqueous sodium bicarbonate solution and can be cross-linked by glycols, di-isocyanates, and other functional compounds and also on heating. Some of the properties of the linear polyesters are presented in Table 1.

Table 1. The properties of adamantane-containing polyesters.

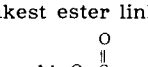
Unsaturated polyesters, which subsequently acquire a structure in the presence of peroxides, can be obtained by the reaction of adamantane-1,3-diol with maleic anhydride. Their composition and properties can be varied within wide limits by adding other dianhydrides, for example, phthalic dianhydride or comonomers—styrene and methyl methacrylate[48].

The polyesterification of the chloride of adamantane-1,3-carboxylic acid by bisphenols in high-boiling solvents[53] or under the conditions of acceptor-catalytic polycondensation in solution[54] leads to adamantane-containing polyesters with a fairly high molecular weight:

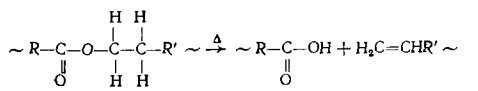
Mixed polyarylates have been synthesised by the high-temperature polycondensation of 2,2-bis(4′-hydroxyphenyl)-adamantane, cardo-bisphenols, and the chlorides of isophthalic and terephthalic acids[58,59]. The polyarylates have a crystalline structure and the degree of their crystallinity depends on the content of adamantane groups.

Mixed polyesters have also been obtained by the joint polyesterification of the phenyl esters of aromatic hydroxy-acids and adamantanecarboxylic acids[50]:



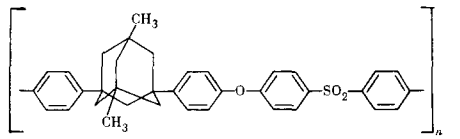
The reaction is carried out under fairly severe conditions (330 °C, 0.3 mmHg) in the presence of dibutyltin as the catalyst.

Thermostable adamantane-containing polyesters, produced by the bulk condensation of 1,3-bis(4′-methoxycarbonylphenyl)adamantane with ethylene glycol, have been described[52]:

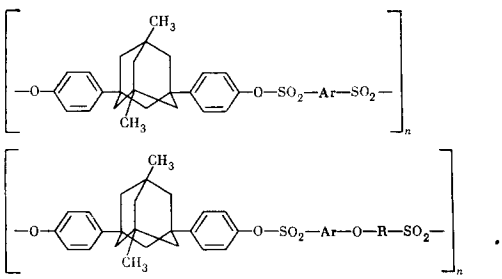


The reaction is carried out under conditions resembling those in the synthesis of poly(ethylene terephthalate). In the first stage at 160 °C and 0.3 mmHg a diglycol ether is obtained and is then gradually heated in the presence of antimony oxide to 245 °C at a pressure of 0.15 mmHg.

Adamantane-containing polyesters have fairly high glass points and softening temperatures (Table 1) and it has been noted in a number of studies[46,47,55] that they are highly resistant to thermal and oxidative degradation and exhibit an effective hydrolytic stability. This is particularly notable when adamantanediol is used. In this case the adamantane nucleus adjoins the weakest ester linkage



and prevents its being acted upon by hydrolysing agents[46]. In addition one of the ways of decomposing the polyesters involves the elimination of hydrogen from the β-position in the alcoholic residue with formation of two fragments of the macromolecule with terminal carboxy- and olefinic groups:



On the other hand, the formation of a double bond in the adamantane nucleus is impossible under these conditions, so that the decomposition of adamantanediol polyesters is difficult[55]. Both linear and cross-linked polyesters are highly resistant to the action of ultraviolet light and sunlight[48]. These properties make adamantane-containing polyesters useful as protective coatings and packing materials.

A whole series of polyesters based on 1,3-bis(4′-hydroxyphenyl)-5,7-dimethyladamantane have been described. The reaction of the latter with di(halogenophenyl) sulphones yielded polysulphones, for example[60]:

The reaction is carried out in an organic solvent in air at 160 °C. A necessary condition is preliminary synthesis of the disodium salt of a bisphenol by the reaction of the latter with an aqueous NaOH solution. Using bisarenesulphonic acid esters or chlorides instead of dihalogenosulphones, one can obtain the corresponding polysulphonates[61,62]:

Triethylamine is used as the HCl acceptor. The reaction takes place fairly rapidly (1—2 h) and yields a high-molecular-weight product with an intrinsic viscosity of 1.1—1.2 dl g^{-1}. In contrast to the usual polysulphonates, the adamantane-containing polysulphones and polysulphonates are rigid and strong but not brittle. They soften at 180 °C and exhibit a high resistance to oxidation.

Table 2. The properties of polycarbonates and copolycarbonates based on 1,3-bis(4′-hydroxyphenyl)adamantane and bisphenol A.[63,64]

Property	Bisphenol A	1,3-bis(4′-hydroxyphenyl)adamantane	Bisphenol A: 1,3-bis(4′-hydroxyphenyl) adamantane = 1 : 1

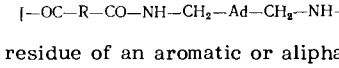
Bisphenols derived from adamantane have been used in the synthesis of polycarbonates and copolycarbonates. 1,3-Bis-(4′-hydroxyphenyl)adamantane is treated with phosgene in solution in methylene chloride in the presence of pyridine at 25—30 °C.[63] The copolycarbonate derived from 1,3-bis(4′-hydroxyphenyl)adamantane and 2,2-bis(4′-hydroxyphenyl)-propane (bisphenol A), taken in equimolar proportions, is obtained under analogous conditions[64]. Table 2 presents

certain properties of adamantane-containing co- and polycarbonates and compares them with a commercial polycarbonate—Lexan.

Bisphenols containing the adamantane nucleus in the form of a cardo-group have also been proposed for the synthesis of polycarbonates[65]. Depending on the method of preparation (low-temperature or interfacial polycondensation), these polycarbonates have crystalline or amorphous structures. The presence of adamantyl cardo-groups in the polycarbonates leads to an appreciable increase of their heat resistance and thermal stability. Depending on the structure of the bisphenol, the softening temperature is 240–310 °C and the temperature of the onset of decomposition is 300–350 °C.



IV. ADAMANTANE-CONTAINING POLYAMIDES

Polyamides are some of the first polymers for which the effectiveness of the introduction of adamantane nuclei into polymer chains has been demonstrated. Adamantane-containing polyamides, obtained in the melt, like nylon-6,6, from a salt of 1,3-diaminoadamantane and sebacic acid[66] or a salt of adamantanedicarboxylic acid and 1,4-bis(aminomethyl)-cyclohexane[67], have a low molecular weight.

The conditions for the synthesis of the polyamides from the chloride of adamantane-1,3-dicarboxylic acid by emulsion and interfacial polycondensation have been studied in detail[67–69].

In the first case a high-molecular-weight polyamide (η_{ln} = 1.45) can be obtained in a high yield by carrying out the process in the presence of a small excess of the acid chloride at 10–30 °C and for an overall concentration of the reactants of 0.33 M. The reaction is performed by pouring a solution of the acid chloride in tetrahydrofuran (THF) into an aqueous solution of the diamine. Sodium carbonate is used as the HCl acceptor. In the interfacial polycondensation a solution of the acid chloride in an aromatic or chlorinated hydrocarbon is added with stirring to an aqueous solution of the diamine. Pyridine, triethylamine, and NaOH can also serve as the HCl acceptors.

High-molecular-weight polyamides with $\eta_{ln} \leq 5.0$ and having the general formula[70]

where R is a residue of an aromatic or aliphatic dicarboxylic acid, have been obtained by the solid-phase polycondensation of a salt of a mixed diamine—1,3-bis(aminomethyl)adamantane—with a dicarboxylic acid. The properties of the polyamides obtained are presented in Table 3.

Among adamantane-containing polyamides, poly(*m*-phenyleneadamantylene-1,3-dicarboxamide)—the product of the condensation of *m*-phenylenediamine with the chloride of adamantane-1,3-dicarboxylic acid—is of greatest interest:

Films and fibres can be obtained from it by appropriate methods. The properties of a polyamide film of this kind are presented in Table 4.[49] The polyamide softens at 294 °C and loses not more than 0.86% of its weight on being kept in air for 2 h at 325 °C.

Table 4. Properties of a poly-*m*-phenyleneadamantane-1,3-dicarboxamide film[49].

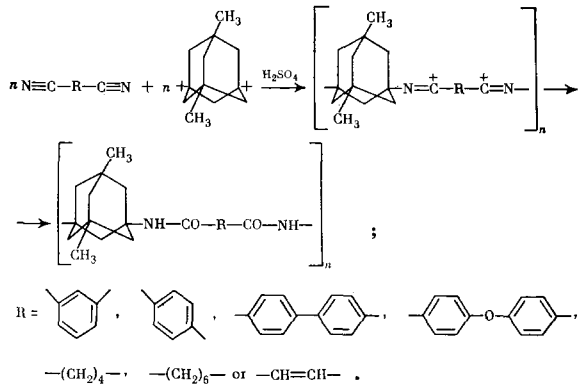
* Notation: σ_f = flexural strength (MPa); E_f = flexural modulus (MPa); σ_t = tensile strength (MPa); ε_e = elongation at break (%); H_R = Rockwell hardness.



A fibre can be obtained from a solution of this polyamide in DMF by the wet moulding method[71]. An interesting feature of poly(*m*-phenyleneadamantylene-1,3-dicarboxamide) is that both the polyamide itself and the fibre obtained from it are amorphous and, in contrast to many polymers, the fibre does not crystallise on being kept at temperatures in the range between the glass and yield points. A special technique was therefore developed for drawing the moulded fibre in contact with a hot plate which makes it possible to follow the morphological changes occurring in the fibre during such treatment over a narrow temperature range[72]. The fibre has been drawn at 325 °C with a drawing factor of 6:1 and at a drawing rate of 220000% min^{-1}. The properties of the drawn fibre are presented in Table 5.[73]

Table 5. The properties of fibre based on poly-*m*-phenyleneadamantylene-1,3-dicarboxamide.

Property	Fibre	
	moulded	drawn
[η] (conc. sulphuric acid)	1.5	—
Linear density (denier)	—	7.3
Strength, g $denier^{-1}$	0.62	4.0
Initial modulus, g $denier^{-1}$		51.4
ϵ_e, %	19.9	—
Elasticity, %	72.2	25.2

However, in this case too the crystallinity of the fibre is low. The fibre is crystallised when it is kept in DMF or dimethylacetamide vapour. The fibre which was extended beforehand crystallises under these conditions in the course of several seconds[74]. The polyamide fibre has a high thermal stability, retaining 50% of its initial strength on being kept at 250 °C for 100 h[71].

A method employing the ability of dihalogeno- or dihydroxyadamantanes to form carbonium ions in highly ionising medias such as concentrated sulphuric or polyphosphoric acid has also been proposed for the synthesis of adamantane-containing polyamides[75,76]. The second reagent is an aliphatic, aromatic, or alicyclic dinitrile. The concentration of sulphuric acid is of decisive importance in this reaction; if it is below 99%, then the rate of polymerisation is low and the oxidative decomposition of the reactants predominates. At an acid concentration above 118% the process becomes difficult to control and is accompanied by the decomposition of the polyamide formed. The mechanism of this reaction can be illustrated by the following scheme:

In sulphuric acid, the reaction is carried out in the temperature range between −10° and 20 °C and in polyphosphoric acid between 70° and 110 °C. Polyamides have been obtained by this method in almost quantitative yields with η_{ln} between 0.5 and 1.2 and glass points in excess of 300 °C.

V. ADAMANTANE-CONTAINING POLYURETHANES

Adamantane-containing polyurethanes can be obtained by the reaction of 1,3-adamantylene di-isocyanate[77] or 1,3-di-isocyanato-5,7-dimethyladamantane[78] with polyols, which are usually polyalkylene or polyoxyalkylene glycols, polyester glycols, castor oil, and sorbitol polyesters. The reactivity of adamantylene di-isocyanate is considerably lower than that of aromatic di-isocyanates (Table 6). In the synthesis of adamantane-containing oligoester-urethanes it is therefore necessary to employ catalysts—NEt_3 or dibutyltindilaurate[80].

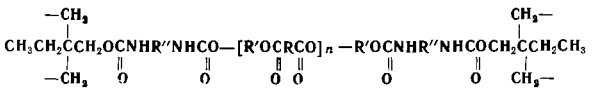


Table 6. The constants for the interaction* of di-isocyanates with poly(diethylene glycol adipate)[79].

Di-isocyanate	10^2k, litre mol^{-1} s^{-1}
2,4-Tolylene di-isocyanate	31.30
1,6-Hexamethylene di-isocyanate	5.26
1,3-Bis(isocyanatomethyl)adamantane	3.27
1,3-Adamantylene di-isocyanate	0.59

* k = reaction rate constant.

The hardening of liquid urethane rubbers with 1,1,1-tris-(hydroxymethyl)propane is fairly slow and the formation of a three-dimensional polyurethane network at 80 °C terminates after 10–12 h.[81] The properties of vulcanised polyurethanes are presented in Table 7. The increase in the chain lengths of oligomeric polyesterurethanes, based on tetramethylene glycol, when they interact with diamines[66] or with hydrazine hydrate[82] leads to the formation of light-resistant adamantane-containing polyurethane-ureas from which "Spandex" fibre is made. The films obtained from solutions of this polymer in DMF are transparent and have a low optical density and a high resistance to ultraviolet light (Table 8).

Table 7. The properties of adamantane-containing network polyurethanes* [81]

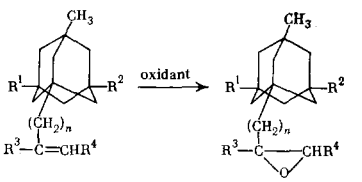
* Notation: Ar =  ; ε_0 = residual deformation at break; M_{av} = average molecular weight of the network polymer; $t_{o.d.}$ = temperature of onset of decomposition; for the significance of the remaining parameters, see the footnotes to Tables 1 and 4.

Table 8. Changes in the properties of linear polyurethanes on irradiation with ultraviolet light (in a AIPST-2-4-2 optical weather apparatus)[83]*.

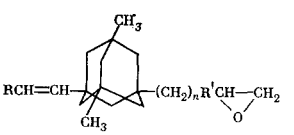
Di-isocyanate	Before irradiation			After irradiation		
	σ_t	ϵ_e	D	σ_t	ϵ_e	D
1,3-Adamantylene di-isocyanate	3.3	187	0.1	2.2	122	0.14
Diphenylmethylene di-isocyanate	3.7	123	0,41	2.3	50	1.16
1,3-Bis(isocyanatomethyl) adamantane	3.1	346	0.1	2.2	245	0 14

* Notation: D = optical density (relative units); for the significance of the remaining notation, see the footnote to Table 4.



The replacement of 1,3-adamantylene di-isocyanate by 1,3-bis(isocyanatomethyl)adamantane makes it possible to obtain light-resistant polyurethanes with a higher elasticity[84]. An increase of light resistance is observed also for cross-linked polyurethanes. Thus polyurethane films obtained from poly(diethylene glycol adipate), 1,3-adamantylene di-isocyanate, and 1,1,1-tris(hydroxymethyl)propane turn yellow to a much lesser extent and lose 33% of the initial strength on irradiation with ultraviolet light, compared with films based on 2,4-tolylene di-isocyanate (72% loss of strength).[85] The rate of gas evolution from adamantane-containing polyurethanes under these conditions is lower by a factor of two, while the rate of absorption of oxygen is lower by a factor of 1.5 than for polyurethanes based on 1,6-hexamethylene di-isocyanate and 2,4-tolylene di-isocyanate.

Another advantage of adamantane-containing polyurethanes is their increased hydrolytic stability. This effect is particularly notable when the adamantylene group is attached to an ester group, i.e. for polyurethanes obtained from adamantane-containing oligoester-glycols[85]. The films obtained from such a polyurethane do not change in the course of three months in 5% H_2SO_4 and NaOH solutions and swell only by 3%, while similar polyurethanes derived from aliphatic oligoester-glycols decompose after 20–25 days.



The products of the interaction of 1,3-adamantylene di-isocyanate with 1,3-diaminocyclohexane or 1,4-diaminobutane as well as butane-1,4-diol have been described[66]. In the first case the products are polyureas soluble in DMF and melting at 275 °C and in the second the product is a thermoplastic film-forming polyurethane.

VI. EPOXY-RESINS BASED ON ADAMANTANE DERIVATIVES

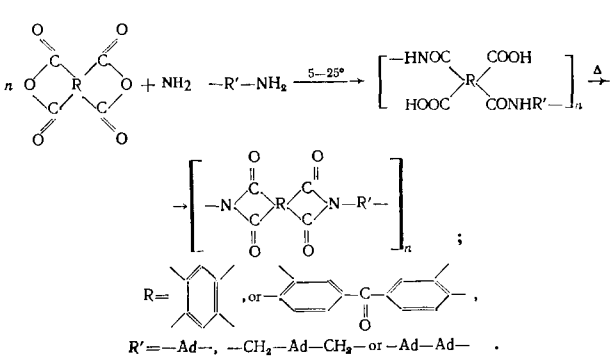
Adamantane-containing epoxides have been obtained by the oxidation of the corresponding alkenyladamantanes[86,87]:

The oxidants are organic and inorganic peroxides, hydroperoxides, and hydrogen peroxide. The oxidation is carried out in the liquid phase in the temperature range from 5° to 50 °C in the presence of $Mo(CO)_6$. Epoxyadamantanes are obtained in yields up to 86% and are purified by distillation. Vinyl- and allyl-epoxyadamantanes having the general formula

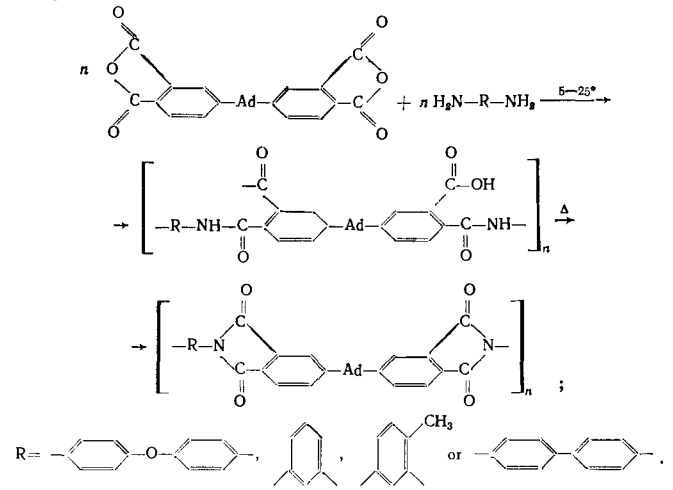
can be obtained in this way. Polymerisation of these compounds in the presence of tri-isobutylaluminium and aluminium trisacetylacetonate yielded polyepoxides which are viscous liquids or solids and are likely to be useful as additives to lubricating oils and as components of adhesives. Polyepoxides with vinyl or allyl groups can be vulcanised, giving rise to rubber-like materials[86].

The reaction of adamantane-1,3-diol with the anhydride of cyclohexenecarboxylic acid led to the formation of a diester, which was converted into the bis-3,4-epoxycyclohexanecarboxylic acid ester of adamantane-1,3-diol by epoxidation with peracetic acid[88]. The product has a melting point of 31–32 °C and contains 19.8% of epoxy-groups.

The bisphenol derived from 5,7 dimethyladamantane[89], which reacts with epichlorohydrin in the presence of NaOH at 85–100 °C, is used as the starting compound for the synthesis of epoxy-resins. After isolation and washing free of salts, by the usual methods, the epoxy-resin

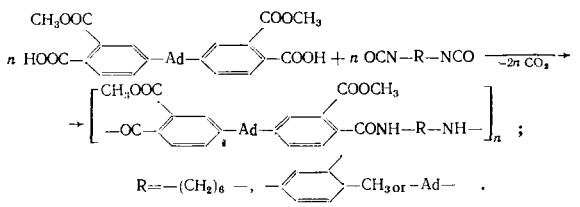


is a solid glass-like product of amber colour which melts at 47 °C.



The hardening of epoxy-resins based on the bisphenols derived from adamantane, 1,1'-biadamantane, and isopropylidene on heating has been investigated[90,91]. The degree of hardening was inferred from the disappearance of the 415 cm^{-1} absorption band (due to the epoxy-group) in the infrared spectra and from determinations of the hardness of the specimens. Complete hardening was achieved after 13 h at 165 °C for the diglycidyl ether of the isopropylidenebisphenol, after 20 h at 200 °C for the diglycidyl ether of the bisphenol from adamantane, and after 88 h at 250 °C from the diglycidyl ether of the bisphenol from 1,1'-biadamantane. The hardened epoxy-resins derived from adamantane and 1,1'-biadamantane are superior as regards heat resistance and thermal stability to the polyepoxide with the isopropylidene groups. The softening temperatures of these resins are 250° and 220 °C compared with 180 °C for the polyepoxide based on the isopropylidenebisphenol, while the temperature of the onset of weight loss is 390° against 340 °C. In addition, they decompose at 400 °C leaving a larger amount of carbon residue than the corresponding polyepoxides without adamantane rings.

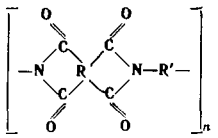
VII. CYCLOCHAIN POLYMERS OF ADAMANTANE



Among the cyclochain polymers with adamantane fragments in the main chain, polyimides have been most thoroughly investigated. They have been synthesised by a two-stage scheme. In the first stage a polyamidoacid is obtained by the reaction of diaminoadamantane with the dianhydride of an aromatic tetracarboxylic acid[92,93]:

The polyamidoacid is an intermediate in the reaction between an aromatic diamine and 1,3-bis(3',4'-dicarboxyphenyl)adamantane[94,95]:

In the second stage the polyamidoacid is subjected to cyclodehydration by heating it *in vacuo* at temperatures up to 300 °C. The reaction between the adamantane-containing dianhydride and the adamantane-containing diamine leads to low-molecular-weight polyamidoacids which are insoluble in organic solvents[92,96]. A similar result has been noted also in the synthesis of polyamidoesters by the reaction of the dimethyl ester of 1,3-bis(3',4'-dicarboxyphenyl)adamantane with di-isocyanate[97]:



The basicity of adamantane-containing diamines is fairly high (pK_{a1} = 16.22–17.75) and that of 1,3-bis(aminoethyl)adamantane is at the level of aliphatic amines[98]. The formation of low-molecular-weight polyamidoacids is more likely to be explained by the low solubility and the reduced reactivity of the adamantane-containing dianhydride[99].

High-molecular-weight soluble adamantane-containing polyamidoacids with an intrinsic viscosity up to 4.8 dl g^{-1} are obtained when the above reactions are carried out in an aprotic solvent—inorganic salt system[100]. For example, in the presence of LiCl the rate constants for the formation of adamantane-containing polyamidoacids increase by a factor of 5–5.5.[99]

A distinctive feature of adamantane-containing polyimides is their high resistance to hydrolysis and the action of organic solvents and certain chemicals. A film made of the polyimide based on 1,3-bis(3',4'-dicarboxyphenyl)adamantane and di(4-aminophenyl)ether loses not more than 14% of its initial strength after a five day exposure to a 10% solution of NaOH and does not dissolve in concentrated H_2SO_4; on the other hand, the polyimide film based on pyromellitic dianhydride decomposes under analogous conditions[95].

A similar effect is also achieved when 1,3-bis(aminoethyl)-adamantane is used[101]. The introduction of 20% of this diamine instead of di(4-aminophenyl)ether in the synthesis of a polyimide based on pyromellitic dianhydride increases by a factor greater than 2 the hydrolytic stability of the polyimide film.

Table 9. The properties of adamantane-containing polyimides.

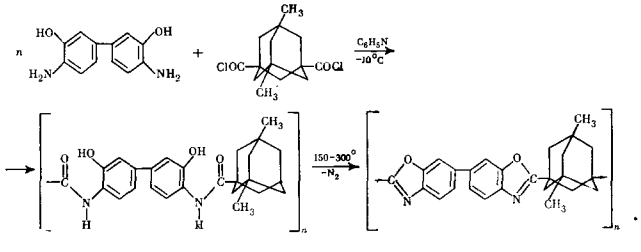
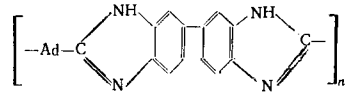
** For the designations and dimensions of the parameters, see the footnotes to Tables 1 and 4.

A whole series of soluble adamantane-containing polyimides with a high resistance to hydrolysis and an increased resistance to thermal oxidation have been obtained from cardo-diamines and cardo-dianhydrides[102-104]. They were synthesised in a single stage by heating the reactants in nitrobenzene to 210 °C. The polyimides soften on heating and can be worked by pressing or by casting from solution.

The polyimides obtained from the dianhydrides of aromatic tetracarboxylic acids and 1,3-bis(aminomethyl)-5,7-dimethyladamantane have an interesting property[105,106]:



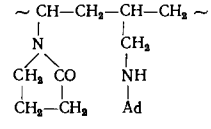
While their thermal stability is not inferior to that of aromatic polyimides, they are colourless—in contrast to the former polymers they do not have a characteristic yellow colour. Compared with similar polyimides based on 1,3-diaminoadamantane, they have a higher molecular weight. The properties of the polyimides synthesised are presented in Table 9.



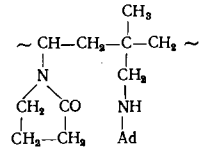
Heat-resistant polyester imides are obtained by the reaction of aromatic diamines with 1,3-adamantylenebistrimellitic dianhydride[107]. The polyimidoacid obtained in the first stage (viscosity 5.5 S) is converted into the imido-form at 300 °C for 16 h. The resulting polyester-imide film does not decompose on heating to 390 °C and has a glass point of 235 °C.

Adamantane-containing polybenzoxazoles obtained by low-temperature polycondensation from the chloride of 5,7-dimethyladamantane-1,3-dicarboxylic acid and 3,3′-dihydroxybenzidine have unusual properties[109]:

The prepolymer obtained in the first stage with η_{ln} = 1.13 gives rise to a colourless film soluble in water on pressing at specified temperatures. Thermal cyclisation of the film with a stepwise increase of temperature from 150° to 350 °C yielded a colourless polybenzoxazole soluble in water. The film has σ_t = 1.2 MPa and E_e = 210 MPa, losing ~ 10% of its weight on heating to 500 °C.



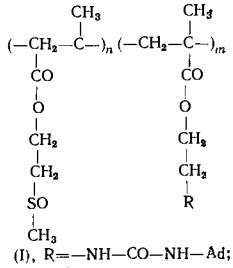
The synthesis of a polybenzimidazole from the diphenyl ester of adamantanedicarboxylic acid and 3,3′-diaminobenzidine has been described[110]:



The polymer has a low molecular weight (η_{ln} = 0.19) and is soluble in DMF and dimethyl sulphoxide (DMSO), but its thermal stability is lower than that of aromatic polybenzimidazoles: it begins to decompose in nitrogen at 540 °C.

VIII. BIOLOGICALLY ACTIVE ADAMANTANE-CONTAINING POLYMERS

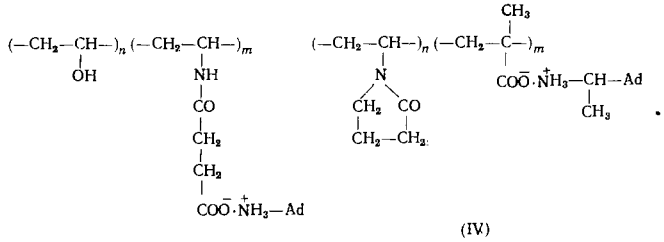
Progress in the chemistry of adamantane is to a large extent associated with the biological activity of some of its functional derivatives[6,21]. However, only a few studies have been made on the polymeric adamantane derivatives used in medicine. The copolymers of *N*-vinylpyrrolidinone and *N*-allylaminoadamantane[111]



as well as the reduced products of the interaction of 1-aminoadamantane and the copolymer of *N*-vinylpyrrolidinone and crotonaldehyde[111], i.e.

have been proposed as potential antiviral agents. Water-soluble 2-(methylsulphinyl)ethyl methacrylate–2-*N*-(1′-adamantyl)ureidoethyl methacrylate (I) and the quarternary

ammonium salts of *N*-(1-adamantyl)chloroacetamide–2-dimethylaminoethyl methacrylate (II) copolymers have been described in another study[112]:



(I), R=—NH—CO—NH—Ad;

(II), R=—$\overset{+}{N}(CH_3)_2$—CH_2CONH—Ad .

It was found that only copolymer (II), containing ammonium groups, exhibits an antiviral activity.

Polymeric complexes of the salt type, obtained by treating with 1-aminoadamantane (III) and 1-(2′-aminoethyl)adamantane (IV) the copolymers of poly(vinyl alcohol) and *N*-vinylpyrrolidinone with *N*-vinylamidosuccinic and crotonic acids, have been studied in greater detail[113,114]:

(IV)

The study of the polymeric products showed that they are less toxic than the hydrochlorides of amino-derivatives of adamantane and that their prophylactic effect lasts five times longer. Two medicinal preparations with prolonged antiviral activity have been developed on their basis.

---o0o---

Analysis of published data permits the definite conclusion that the introduction of the polyhedral adamantane molecule into polymers significantly improves some of their properties. The vast majority of adamantane-containing polymers are heat-resistant and soften at high temperatures. An important feature of these polymers is their high resistance to oxidation and hydrolysis and to the action of light and solvents. The properties of adamantane-containing polymers are superior to those of familiar industrial polymers and can find applications in various branches of technology.

Monometal Hydrido-complexes of Transition Metals

G.L.Soloveichik and B.M.Bulychev

Published information on the chemistry of these complexes stabilised by cyclopentadienyl and other ligands is systematised, and modes of formation of a metal-hydrogen bond in their synthesis are discussed. Consideration is given to the influence on this bond of the structure of various types of transition-metal hydrides containing one, two, or three cyclopentadienyl groups in the coordination sphere. The possibility of stabilising the bond with σ-donor ligands is discussed. The chemical properties of these compounds and the possibility of their use as catalysts are examined. A list of 160 references is included.

I. INTRODUCTION

Intensive research has been undertaken during recent years on the preparation and properties of molecular hydrides of transition metals. The unfailing interest taken in them is associated with the development of modern views on the nature of the chemical bond and the stereochemistry of complexes containing a hydrido-ligand, as well as the theory and practice of homogeneous and heterogeneous catalysis of the reactions of unsaturated compounds. One of the most interesting and least studied aspects is catalysis on systems of the Ziegler–Natta type. Hydrido-complexes containing a transition metal together with a non-transition metal can be taken as models of the active centres in these systems. In most cases such complexes can be regarded as derivatives of individual transition-metal hydrides.

The most effective electron-donor ligands stabilising a metal–hydrogen bond are π-accepting (carbonyl, nitrosyl, phosphines, phosphites, arsines, etc.) and π-donor groups (η-cyclopentadienyl, related groups, and to a less extent arsines). π-Accepting ligands form coordinatively saturated mononuclear compounds (phosphorus- or arsenic-containing hydrides) or cluster compounds (carbonyl hydrides), which with rare exceptions do not yield complexes with compounds of non-transition metals, Lewis acids. These hydrides have been studied in some detail, and surveyed in reviews[1–5].

Most of the dimetal hydrido-complexes reported contain cyclopentadienyl ligands. Dicyclopentadienyl hydrides of transition metals have been covered in previous reviews[1,6,7]. During the past five to six years, however, results of fundamental importance have been obtained on the structure of known compounds of this type and on the synthesis of new ones, especially dinuclear complexes containing ($\eta:\sigma=C_5H_4$) groups or a fulvalene ligand (η-C_5H_4–η-C_5H_4). In this connection definite interest attaches also to the less stable monocyclopentadienyl hydrides of type $C_5H_5ML_3H_n$ and $C_5H_5ML_2H_n$, which are isoelectronic with the dicyclopentadienyl hydrides $(C_5H_5)_2M'H_n$, as well as the recently prepared transition-metal hydrides stabilised with σ-donor ligands (groups containing nitrogen or oxygen).

Hydrides have been described containing one, two, or three cyclopentadienyl groups attached to a transition-metal atom. The most stable and most thoroughly studied are dicyclopentadienyl hydrides, which can be subdivided into two main groups—the true dicyclopentadienyl hydrides of general formula $(\eta\text{-}C_5H_5)_2MH_n$ ($n = 1–3$) and the so called bismetallocene hydrides—in the latter of which the metal–hydrogen bond is formed by rearrangement, accompanied by dimerisation, in an unstable metallocene $(C_5H_5)_2M$ with migration of hydrogen from a cyclopentadienyl group to the metal atom. Dimerisation is effected either through a bridging fulvalene ligand η-C_5H_4–η-C_5H_4 (structures of the "stable titanocene" type[8]) or by two $\eta:\sigma=C_5H_4$ groups (structures of niobocene type[9]).

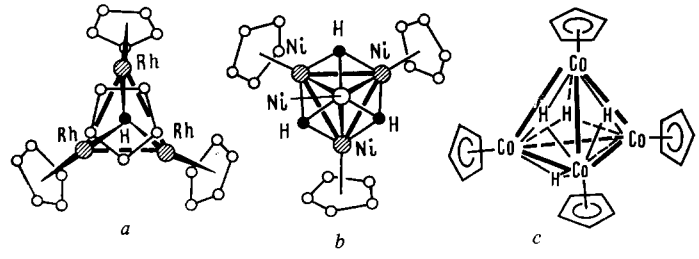

Figure 1. Structure of monocyclopentadienyl hydrides: *a*) $(C_5H_5)_4Rh_3H$;[10] *b*) $(C_5H_5)_4Co_4H_4$;[11] *c*) $(C_5H_5)_4Ni_4H_3$.[12]

The unstable monocyclopentadienyl hydrides of transition metals are stabilised either by the addition of two-electron and in some cases one-electron ligands or by the formation of clusters, among which $(C_5H_5)_4Rh_3H$,[10] $(C_5H_5)_4Co_4H_4$,[11] and $(C_5H_5)_4Ni_4H_3$[12] are known. In all these compounds the hydrogen atoms are attached to three transition-metal atoms, and are located above the plane of the triangle formed by the latter (Fig.1). Stabilisation by means of electron-donor ligands results in the formation of complexes of type $C_5H_5M(ArH)H_n$, $C_5H_5ML_3H_n$, $C_5H_5ML_2H_n$, and $C_5H_5MLXH_n$, where $n = 1–3$, L is a two-electron ligand, and X a one-electron ligand. These compounds are isoelectronic with dicyclopentadienyl hydrides $(C_5H_5)_2MH_n$ of the metals on the right or on the left in the Periodic Table.

Descriptions have appeared not only of neutral cyclopentadienyl hydrides but also of anionic (of metals in Groups IV and V) and cationic (in Groups VI–VIII) complexes.

II. METHODS OF PREPARATION OF CYCLOPENTADIENYL HYDRIDES OF TRANSITION METALS

Methods of obtaining cyclopentadienyl hydrides are in general the same as those for other transition-metal hydrides stabilised with π-accepting ligands. Possible sources of hydrido-hydrogen are molecular hydrogen, cyclopentadienyl groups, hydrides and alkyl compounds of non-transition metals and boron, compounds containing mobile hydrogen atoms, in particular Brønsted acids, and also apparently solvent molecules in certain cases. Our survey of general methods for synthesising cyclopentadienyl hydrides of transition metals will be based on the classification suggested in Ref.7†.

1. Reactions with Molecular Hydrogen

(1a) Oxidative addition

Hydrogen adds reversibly to permethyltitanocene to give the corresponding titanium(IV) dihydride[13]:

$$(C_5Me_5)_2Ti + H_2 \rightleftarrows (C_5Me_5)_2TiH_2 . \qquad (1)$$

Chromocene reacts with carbon monoxide and hydrogen under high pressures to yield[14] $C_5H_5CrH(CO)_3$. Formation of an anionic complex $Na^+(C_5H_5)_2TiH_2^-$ in the system comprising dicyclopentadienyltitanium dichloride with sodium naphthalide in an atmosphere of hydrogen also probably involves oxidative addition of hydrogen to unstable dicyclopentadienyltitanium followed by reduction[15].

We may note also the displacement of π-bonded ligands by hydrogen, reported for dinitrogen complexes of zirconium (II)[16] and molybdenum(0)[17]:

$$[(C_5Me_5)_2Zr(N_2)]_2N_2 + H_2 \xrightarrow[25°C]{\text{toluene}} (C_5Me_5)_2ZrH_2 + N_2 .$$

(1b) Hydrogenolysis of Metal–Carbon σ-bond

In some cases a metal–alkyl bond is very readily split by hydrogen with formation of metal–hydrogen bond. Thus dicyclopentadienyldimethyltitanium reacts with hydrogen even under low pressures, but the reaction becomes explosive when the pressure is raised above 250 mmHg[18] [Cp = C_5H_5]:

$$2Cp_2TiMe_2 + 3H_2 \xrightarrow[pH_2 \leqslant 250\ mmHg]{\text{solid phase}} (Cp_2TiH)_2 + 4CH_4 .$$

A similar reaction has been reported for bispentamethylcyclopentadienyldimethyl compounds of uranium and thorium[19]:

$$2(C_5Me_5)_2MMe_2 + 4H_2 \xrightarrow[25°C]{\text{toluene}} [(C_5Me_5)_2MH_2]_2 + 4CH_4 .$$

(1c) Hydrogenolysis of Metal–Metal Bond

Fission of a metal–metal bond by hydrogen has been reported only for cyclopentadienyl carbonyls of Group VI metals. Tricarbonylcyclopentadienylchromium hydride is formed[20] by the action of hydrogen on bis(tricarbonylcyclopentadienylchromium) at 150 atm and 70 °C. The corresponding reaction with the molybdenum compound takes place under still more severe conditions[14].

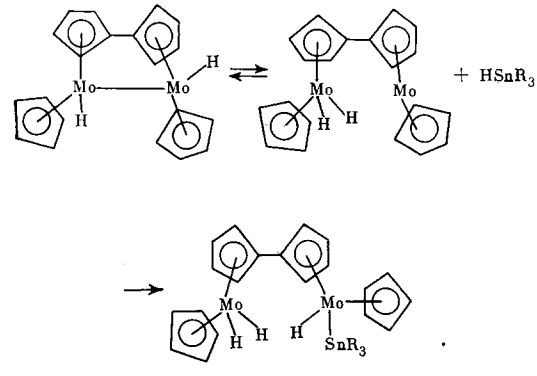
2. Oxidative Addition of H–Z Compounds

Compounds containing a sufficiently mobile hydrogen atom can add to low-valency transition-metal complexes to form M–H and M–Z bonds. The H–Z compounds may be hydrocarbons or hydrides of elements of the germanium subgroup.

(2a) Oxidative Addition of Hydrocarbons

Reduction of dicyclopentadienylzirconium dichloride with metallic sodium in the presence of naphthalene in oxolan forms a naphthyl hydrido-complex

$$(C_5H_5)_2Zr\mu(H)\mu(2\eta^1 : 2\eta^2\text{-}C_{10}H_7)Zr(C_5H_5)_2$$



apparently by addition of naphthalene to the metastable dicyclopentadienylzirconium[21].

Cyclopentadienyl hydrides of transition metals have been obtained also by the oxidative addition of cyclopentadiene. Thus photoreaction of the latter with $C_5H_5Nb(P(C_6H_5)_3)_2(CO)_2$ gives the dihydride $C_5H_5Nb(P(C_6H_5)_3)_2(CO)H_2$, which is isoelectronic with $(C_5H_5)_2MoH_2$.[22] An analogous reaction has been reported for $Ni(P(C_6H_{11})_3)_2$[23] and $M(CO)_3(NCCH_3)_3$, where M = Cr, Mo, W.[24–26] The respective reaction products are $C_5H_5NiP(C_6H_{11})_3H$ and $C_5R_5M(CO)_3H$ (R = H, CH_3).

The action of atomic molybdenum and tungsten on excess of cyclopentadiene forms the dicyclopentadienyl dihydrides, with yields of 40–50% from the latter metal. Subliming the products of the reaction of atomic tungsten with a mixture of cyclopentadiene and an arene gives the complexes $C_5H_5W(ArH)H$.[27]

(2b) Oxidative Addition of Hydrides of the Germanium Subgroup

The photochemical action of trichlorosilane on cyclopentadienyl carbonyls of manganese, iron, and cobalt and also on arene carbonyls of chromium is accompanied by the evolution of carbon monoxide and the formation of cyclopentadienyl hydrides containing a metal–silicon bond[28]. The action of trialkylstannanes on $(C_5H_5MoH)_2(C_5H_4\text{–}C_5H_4)$ yields $C_5H_5MoH_2\text{-}\mu\text{-}(C_5H_4)C_5H_5Mo(H)SnR_3$, probably by oxidative addition to molybdenum(II)[29]:

† The numbering in the columns denoting "preparation" in Tables 1, 5, and 7 corresponds to the subheadings in this Section.

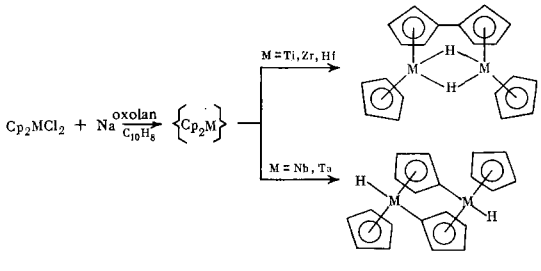
3. Protonation of Cyclopentadienyl Compounds of Transition Metals

Cyclopentadienyl hydrides of Groups VI–VIII transition metals possess lone pairs of electrons, and react with Brønsted acids to form metal–hydrogen bonds (oxidative addition of protons). The acids usually employed are tetrafluoroboric, hexafluorophosphoric, concentrated sulphuric, and anhydrous hydrohalic. Protonation of neutral complexes yields cationic hydrides. Dicyclopentadienyl hydrides $(C_5H_5)_2MH_n$ (M = Mo, W, Re, Tc) and also ferrocene give stable ionic complexes $(C_5H_5)_2MH_{n+1}^+X^-$. The carbonyl complexes $C_5H_5W(CO)_2H$[30] and $C_5H_5Ir(CO)_2P(C_6H_5)_3$[31] undergo analogous reactions, forming unstable hydrido-cations. Protonation accompanied by ligand substitution has been reported[32]:

$$CpRh(C_2H_4)_2 + BF_3\cdot H_2O + PPh_3 \xrightarrow{CH_3OH} [CpRh(PPh_3)_2H]^+[BF_4]^- .$$

Protonation of dinuclear cyclopentadienyl carbonyls of transition metals yields dinuclear hydrido-complexes $[C_5H_5M(CO)_3]_2H^+X^-$ (M = Mo, W) and $[C_5H_5M(CO)_2]_2H^+X^-$ (M = Fe, Ru).[30] A complex $[(C_5H_5)_2WH]_2H^+ClO_4^-$ has been obtained by the cathodic reduction of dicyclopentadienyltungsten dihydride in acetonitrile[33]. All these complexes apparently[33] contain a linear M–H–M bridge.

Anionic cyclopentadienyl carbonyls of molybdenum and tungsten also undergo protonation, forming neutral hydrides. Deuteroacetic acid yields the corresponding deuterides[14–34]:



$$CpM(CO)_3^-Na^+ + CH_3COOD \rightarrow CpM(CO)_3D + CH_3COONa$$
$$M=Mo, W .$$

4. Reduction of Cyclopentadienyl Compounds of Transition Metals

Mild reduction of dicyclopentadienyl hydrides $(C_5H_5)_2MH_n$ (n = 2,3) in some cases yields the compounds $(C_5H_5)_2MH_{n-1}$. Further reduction results in unstable metallocenes $(C_5H_5)_2M$, which undergo rapid rearrangement with incorporation of metal at a carbon–hydrogen bond of a cyclopentadienyl group to give dimeric bismetallocene hydrides.

(4a) Reduction by Alkali Metals

Reduction of dicyclopentadienyl dichlorides $(C_5H_5)_2MCl_2$ by alkali metals (sodium and to a less extent potassium) in the form of amalgams or naphthalene complexes is the principal method of preparation of bismetallocene hydrides of titanium[35–37], zirconium and hafnium[38,39], and niobium and tantalum[9,40]:

This reaction can be accomplished with catalytic quantities of naphthalene[39]. At −80 °C it leads to formation of the complex $C_5H_5Ti\mu$-(σ : η-C_5H_4)$Ti(C_5H_5)_2.C_4H_8O$,[41] treatment of which with toluene gives the non-solvated complex. A titanium–hydrogen bond may[41] be present. Intermediate formation of monomeric $(C_5H_5)_2M$ has been demonstrated by electron spin resonance in the case of niobocene[40]. Treatment of niobocene $C_5H_5Nb(H)(\mu = C_5H_4)_2Nb(H)(C_5H_5)_2$ with sodium naphthalide gives the anionic complex $Na_2[C_5H_5Nb(H)\mu$-$C_5H_4]_2$.[42] An analogous reaction has been reported for the titanium compounds $(C_5H_5)_2TiR_2$.[43]

(4b) Photochemical and Thermal Decomposition of Dicyclopentadienyl Hydrides and Alkyls of Transition Metals

Photolysis and thermal decomposition of $(C_5H_5)_2MR_2$ (M = Ti, Zr) and $(C_5H_5)_2MH_2$ (M = Mo, W) lead to the formation of bismetallocene hydrides. The course of the reaction and the composition of the final products are significantly influenced by the nature of the solvent.

Thermolysis of $(C_5H_5)_2MR_2$ (M = Ti, Zr, V) is usually accompanied by migration of hydrogen atoms of the cyclopentadiene ring to transition-metal atoms and elimination of an RH group[44–47]. A mixture of products is formed, containing π,σ-bound C_5H_4 groups and perhaps metal–hydrogen bonds[45]. Partial retention of the dicyclopentadienyl structure has been noted only with vanadium[47]. In contrast to thermolysis, the photolysis of $(C_5H_5)_2Ti(C_6H_5)_2$ has a radical mechanism[48]. In solvating solvents dicyclopentadienyltitanium hydride is formed, but in inert solvents the metastable dicyclopentadienyltitanium, which in an atmosphere of carbon monoxide is converted into the carbonyl $(C_5H_5)_2Ti(CO)_2$.[48]

Exposure (λ = 366 nm) of an iso-octane solution of $(C_5H_5)_2MoH_2$ gives a polymeric product $[(C_5H_5)_2Mo]_x$ of undetermined structure[49]. Replacement of iso-octane by ethanol[50] or toluene[51] as solvent yields a dinuclear compound

$$C_5H_5Mo\mu\text{-}[\sigma : \eta\text{-}C_5H_4)_2MoC_5H_5$$

perhaps by stabilisation of the intermediate monomeric compound $(C_5H_5)_2Mo$ by the solvent. Photolysis of $(C_5H_5)_2WH_2$ in diethyl ether gives $(C_5H_5WH)_2\mu = (\sigma : \eta = C_5H_4)_2$, but in tetramethylsilane *cis*- and *trans*-$(C_5H_5WH)\mu$-(σ : η-$C_5H_4)_2$. .$(C_5H_5WCH_2Si(CH_3)_3)$ are formed[50,51]. Furthermore, the thermal decomposition of $(C_5H_5)_2W(CH_3)H$ in cyclohexane yields the isomers $(C_5H_5WH)\mu$-(σ : η-$C_5H_4)_2(C_5H_5WCH_3)$.[51]

(4c) Cathodic and Other Reductions

Tervalent tungsten hydride $(C_5H_5)_2WH$ has been obtained as a complex with phenanthraquinone by electrolysis of $(C_5H_5)_2WH_2$ at a controlled potential. The cations $[(C_5H_5)_2W(R)H]^+$ and $[((C_5H_5)_2WH)_2H]^+$ have been obtained similarly[33].

Niobium(IV) and tantalum(IV) hydrides identified by electron spin resonance, have been obtained[52] by treating the $(C_5H_5)_2MH_3$ with di-t-butyl peroxide:

$$Cp_2NbH_3 + BuO^\cdot \xrightarrow[-80^\circ C]{h\nu} Cp_2NbH_2 + BuOH .$$

(4d) Reactions of Compounds of Transition Metals in Lower States of Oxidation

Double decomposition between cyclopentadienylsodium and low-valency transition-metal compounds can be used to obtain bismetallocene hydrides with intermediate formation of the dicyclopentadienyl compounds. Thus reactions involving titanium(II) chloride and dimeric molybdenum(II) acetate

yield fulvalene complexes containing methyl–hydrogen bridges (in the case of titanium)[53] and terminal bonds (molybdenum)[54].

5. Use of Alkyl and Hydride Compounds of Non-transition Metals and of Boron

Alkyl and hydride derivatives of Groups I–III metals (usually lithium, magnesium, or aluminium) and also hydroborates are the most frequent reactants for obtaining cyclopentadienyl hydrides of transition metals. The most convenient are hydro-aluminates and -borates, mostly solutions of lithium tetrahydroaluminate in ether or oxolan or of sodium tetrahydroborate in alcohol. The recent availability of new reagents such as $NaBH(C_2H_5)_3$, $LiAlH(OC_4H_9\text{-}t)_3$, and $NaAlH_2(OCH_2CH_2OCH_3)_2$ has extended significantly the range of solvents employed (in particular to aromatic hydrocarbons) and the overall possibilities of the method. The starting materials usually employed are transition-metal complexes containing bonds between metal and halogen or pseudohalogen, which is exchanged for an ElH_4^- group or a hydride anion. In all cases the reaction involves intermediate formation of more or less stable dimetal complexes containing M–C–El or M–H–El bridges. A metal–hydrogen bond is formed by three principal mechanisms—elimination of an alkene from a metal–carbon σ-bond, homolytic elimination of a hydro-borate or -aluminate group ElH_4^-, and hydrolysis of M–H–El bridges or direct M–El bonds.

(5a) Elimination of Alkene from Alkyl–Metal Complexes

In the reaction between dicyclopentadienyltitanium di- or mono-chloride and organo-lithium or -magnesium compounds electron spin resonance has revealed the presence in solution of anionic complexes $(C_5H_5)_2TiH_2^-M^+$ (M = Li, Na, MgX)[55–57]. The hydrogen originates in alkyl groups[57].

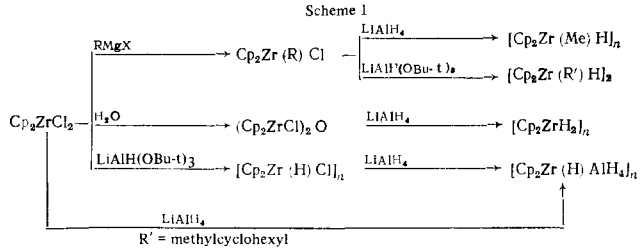
Successive treatment of $C_5H_5Co(P(CH_3)_2C_6H_5)I_2$ with isopropylmagnesium bromide and hexafluorophosphoric acid in oxolan gives the cationic complex $[C_5H_5Co(P(CH_3)_2C_6H_5)H]^+.[PF_6]^-$.[58] The tetraphenylcyclobutadiene complex $C_5H_5Mo(CO)(C_4(C_6H_5)_4)H$ is obtained similarly[59]. An unusual photochemical reaction of tungsten hexachloride with cyclohexa-1,3-diene, cyclopentadienylmagnesium bromide, and isopropylmagnesium bromide in ether yields the complex $C_5H_5W(\eta\text{-}C_6H_6)H$.[60]

(5b) Splitting of Tetrahydro-borate and -aluminate Groups

The action of hydroborates and especially of alkali-metal hydroaluminates on complexes of transition metals in higher states of oxidation usually involves reduction of the transition metal (except zirconium). Thus the reaction of triscyclopentadienyluranium monochloride with lithium triethylhydro-borate or tetrahydroaluminate yields solvated triscyclopentadienyluranium, presumably via an unstable intermediate $(C_5H_5)_3UH.L$.[61]

The complicated reaction of higher chlorides of niobium, tantalum, molybdenum, tungsten, rhenium, and technetium with the tetrahydroborate and the cyclopentadienyl of sodium in oxolan provides a general method for obtaining dicyclopentadienyl hydrides of those metals[62–65]. Although it requires precise observance of the procedure, it does not always give high yields. Application to the preparation of dicyclopentadienylniobium trihydride requires a high pressure of hydrogen (800 atm) over the reaction mixture[63], but that of dicyclopentadienyl-molybdenum or -tungsten dihydride needs low temperatures of −(100–120) °C. Sodium tetrahydroborate has been used to obtain dicarbonylcyclopentadienyl-iron and -ruthenium monohydrides[66,34] from corresponding halides.

In some cases the transition-metal cyclopentadienyl tetrahydroborates formed undergo homolytic fission only under the influence of stronger Lewis bases:



$$Cp_2M\left(\begin{smallmatrix} H & & H \\ & B & \\ H & & H \end{smallmatrix}\right)_n + n\,L \rightarrow Cp_2MH_n + n\,BH_3\cdot L\ .$$

Thus dicyclopentadienylzirconium bistetrahydroborate forms the corresponding hydrido-monotetrahydroborate in the presence of an equimolecular quantity of trimethylamine, and the dihydride $[(C_5H_5)_2ZrH_2]_x$ with double that quantity[67]. Dicyclopentadienyltitanium tetrahydroborate does not undergo this reaction[67], although the tetrahydroborate group is decomposed by triethylamine in the presence of carbon monoxide, when dicarbonyldicyclopentadienyltitanium is obtained[68]. Use of excess of phosphine (phosphite) for this purpose yields phosphorus-containing hydrides: thus for the monocyclopentadienylchromium complex[69]

$$CpCrCl_2\cdot C_4H_8O \xrightarrow[\text{oxolan}]{NaBH_4} CpCr(BH_4)_2 \xrightarrow{P(OMe)_3} CpCr[P(OMe)_3]_3H\ .$$

Several dicyclopentadienyl hydrides of zirconium(IV) have been obtained by the action of lithium tetrahydroaluminate or tri-t-butoxyhydroaluminate on chlorine-containing complexes[70,71] (Scheme 1).

Scheme 1

The complexes $C_5H_5M(NO_2)H$ (M = Mo, W) have been obtained by treating the corresponding chlorides with sodium bismethoxyethoxydihydroaluminate in toluene[72]. An analogous method has been used to prepare $C_5H_5Mo(C_6H_6)H$[73] and $C_5H_5Mo(diphos)H_3$.[74] In several cases the resulting transition-metal (titanium, niobium, etc.) hydroaluminates are not decomposed by the solvent with formation of a metal–hydrogen bond and a solvated aluminium hydride: thus the TiH_2Al link is not broken even by triethylamine[75]. Conducting the reaction between dicyclopentadienyltitanium dichloride and lithium tetrahydroaluminate in non-solvating solvents (alkenes) gives fulvalene hydrides $(\eta\text{-}C_5H_4\text{–}\eta\text{-}C_5H_4)(C_5H_5Ti.(X)(Y)TiC_5H_5)$, where X, Y = H, Cl.[76]

A heterogeneous exchange reaction with sodium hydride has also been described. Thus triscyclopentadienyl- and also bisindenyl-cerium(IV) hydrides have been obtained from the chlorides heated in oxolan at 100 °C for 5–6 h.[77]

(5c) Hydrolysis of Compounds Containing Metal–Hydrogen–Element and Metal–Element Bonds

Reaction between $(C_5H_5)_2NbCl_2$ and $NaAlH_2X_2$ (X = H, C_2H_5, $CH_3OCH_2CH_2O$) gives an equimolecular mixture of $(C_5H_5)_2NbH_3$ and $(C_5H_5)_2NbH_2AlX_2$.[78] When X = H, only $(C_5H_5)_2NbH_2AlH_2$ is formed in the course of time, but conducting the reaction in the presence of carbon monoxide, a

trialkylphosphine, or ethylene gives the $(C_5H_5)_2Nb(H)L$ in at most 50% yield (trialkylphosphines do not react with $(C_5H_5)_2NbH_2AlH_2$). This reaction is assumed to involve disproportionation of the niobium(IV) dihydride[78]:

$$Cp_2NbCl_2 + NaAlH_4X_2 \xrightarrow[-NaCl,\ -AlHX_2]{\text{oxolan}} Cp_2NbH_2 \begin{cases} \longrightarrow Cp_2NbH_3 \\ \longrightarrow Cp_2NbH \xrightarrow{AlHX_2} Cp_2NbH_2AlX_2 \end{cases}$$

Hydrolysis of the reaction mixture and also of the individual $(C_5H_5)_2NbH_2AlH_2$ gives high yields of $(C_5H_5)_2NbH_3$. Hydrolysis takes place unsymmetrically: reaction with deuterium oxide yields $(C_5H_5)_2NbH_2D$ isomers and deuteroxy-groups attached to the aluminium atom[78].

Mild hydrolysis of the complex $[C_5H_5Ti\mu\text{-}(H)\mu\text{-}(H_2Al.(C_2H_5)_2)TiC_5H_5](C_{10}H_8)$ gives a 70% yield of stable titanocene[79]. The cation $(C_{10}H_8)(C_5H_5Mo(H)(OH)MoC_5H_5)^+$ has been obtained by treating "bismetallocene hydrides" of molybdenum with aqueous hexafluorophosphoric acid[51,80]. Transition-metal cyclopentadienyl hydrides are formed not only by hydrolytic fission of bridging hydrogen bonds but also by the fission of bonds between the transition metal and a non-transition metal, when hydroxo-groups combine with the more electropositive atom. Thus hydrolysis of the molybdenum complexes $[(C_5H_5)_2Mo(H)Li]_4$ $(C_5H_5)_2Mo(H)MgBr.2C_4H_8O$, and others containing molybdenum–magnesium and molybdenum–aluminium bonds gives high yields of $(C_5H_5)_2MoH_2$.[81–83] A similar reaction has been reported for $(C_5H_5)_2Ta(H)_2Li$.[84]

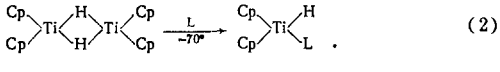
III. TRANSITION-METAL HYDRIDES STABILISED WITH CYCLOPENTADIENYL σ-DONOR AND LIGANDS



1. Dicyclopentadienyl Hydrides of Transition Metals

Quantum-chemical calculations indicate that the metal atom associated with the inclined rings in $(C_5H_5)_2ML_n$ molecules ($n = 1-3$)[85-88] has three hybrid orbitals, used in forming bonds with ligands and lying in the plane of symmetry yz. According to modern views[87,88] these orbitals have the form depicted in Fig.2. The highest is the $2a_1$ orbital. In the case of a single σ-bonding ligand such as hydrido, with orbitals $1a_1$ (and b_2) filled with electrons, a symmetrical structure is observed with the ligand located on the z axis. In the case of unfilled orbitals overlapping with lower orbitals is energetically more favourable, and the ligand is located between y and z axes[88]. When two ligands are present, the $2a_1$ and b_2 orbitals give two equivalent molecular orbitals, which is closely similar to Alkock's model[86]. With $n = 3$ the ligands form an AB_2 system, which is consistent with the earlier model of Ballhausen and Dahl[85]. Most of the compounds studied conform to the eighteen-electron rule[88].

The complexes $(C_5H_5)_2MH_n$ ($n = 1-3$) are typical covalent compounds. Their physicochemical properties are listed in Table 1.

Group IV

Dicyclopentadienyltitanium(III) hydride exists in two modifications: the grey–green form is polymeric[89], and the violet form apparently dimeric[18]. Association of the electron-deficient $(C_5H_5)_2TiH$ molecules is facilitated by energetic factors[88], and is apparently effected by hydrogen bridges. Absorption bands due to terminal titanium–hydrogen bonds are absent from the infrared spectra, but bands at 1450 and 1140 cm^{-1} are assigned to unsymmetrical stretching vibrations of Ti–H–Ti bridges in dimer and polymer respectively[18]. The action of electron donors (oxolan, triphenylphosphine) stronger than hydride hydrogen results in homolytic fission of hydrogen bridges and formation of unstable monomeric hydrides $(C_5H_5)_2Ti(H)L$:[18]

(2)

The presence of a vacant orbital is the obvious reason why dicyclopentadienylzirconium(IV) hydride $(C_5H_5)_2ZrH_2$ and the related compounds $(C_5H_5)_2Zr(H)X$ (X = Cl, CH_3, AlH_4) are formed as polymers. They are almost non-volatile and insoluble in organic solvents[67,70], except in the cases of the sterically hindered $(C_5H_5)_2Zr(H)R$ (R = methylcyclohexyl)[71] and $(C_5H_4C(CH_3)_3)_2ZrH_2$ (dimer in benzene).[91] The vibrational bands due to the metal–hydrogen bond in the compounds correspond to bridging hydrogen atoms (Table 1): they are located at 1390 cm^{-1} for X = Cl, and at 1500 and 1310 cm^{-1} for X = CH_3.[70] The compound $(C_5H_5)_2Zr(H)BH_4$ is a monomer containing terminal zirconium–hydrogen bonds[67].

Absorption bands ν(Zi–H) are absent[21] from the infrared spectrum of the dinuclear naphthyl hydrido-complex

$$(C_5H_5)_2\overline{Zr\mu\text{-}(H)\mu\text{-}(2\text{-}\eta^1:1\text{-}2\eta^2\text{-}C_{10}H_7)Zr}(C_5H_5)_2 .$$

X-Ray determination of the structure (Fig.3*a*) could not locate the hydrogen atom[21], but its presence follows from stereochemical considerations, nuclear magnetic resonance data (Table 1), and chemical properties (reactions with iodomethane and hydrogen chloride)[21,97].

The unusual complex $((C_5H_5)_2TiN)_2H_3$ is obtained by treating $(C_5H_5)_2Ti\mu(\sigma:\eta\text{-}C_5H_4)TiC_5H_5$ with ammonia, when one mole of hydrogen is evolved, or with a primary or secondary amine[90,98]. X-Ray structural analysis indicates[90] that a molecule of the complex contains the usual wedge-shaped $(C_5H_5)_2Ti$ sandwiches and a planar metal ring TiN_2Ti (the hydrogen atoms could not be located). A band at 1585 cm^{-1}, which is displaced when nitrogen-14 is replaced by nitrogen-15 and hydrogen by deuterium in the original ammonia, is apparently due to vibration of a Ti–H–N bond. The chemical properties of the complex undoubtedly indicate the hydride character of all the hydrogen atoms not present in cyclopentadienyl groups[99]. This, together with the presence of only one unpaired electron per molecule, suggested[90] that the hydrido-atoms were present at the positions indicated in Fig.3*b*.

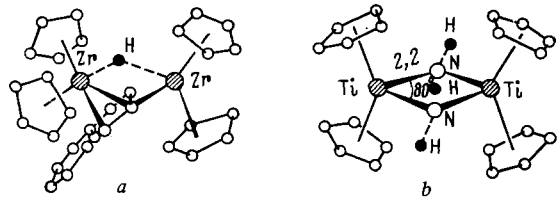


Figure 3. Molecular structure of: *a*) $(C_5H_5)_2\overline{Zr(H)(C_{10}H_7)Zr}.(C_5H_5)_2$;[21] *b*) $((C_5H_5)_2TiN)_2H_3$.[90]

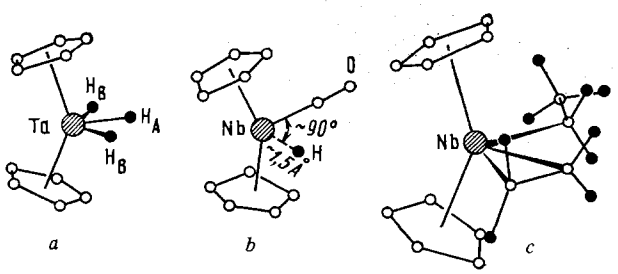
Besides neutral dicyclopentadienyltitanium(III) hydrides electron spin resonance has detected the formation of anionic complexes $(C_5H_5)_2TiH_2^-M^+$ (M = Li, Na)[55-57,100] and $(C_5H_5)_2.TiHCl^-M^+$.[15] The Ti–H–M bond in them is largely covalent in character, the degree of covalency increasing in the sequence Na < Li < MgX < $AlCl_2$ < AlH_2.[100]

The parameters of the e.s.r. spectra of dicyclopentadienyltitanium(III) hydrides are listed in Table 2. The e.s.r. method is extremely useful also for investigating paramagnetic dicyclopentadienyl hydrides of other transition metals, in particular of niobium(IV) and tungsten(III) (below), which exist only in solution.

The dicyclopentadienyl trihydrides of niobium and tantalum are quite similar in properties, differing only in reactivity: the former is far more active than the latter, which is consistent with the fairly severe conditions for its preparation[63]. All three valency orbitals of the $(C_5H_5)_2M$ group in these compounds are involved in forming metal–hydrogen bonds. As a consequence, the complexes are monomeric, and are not protonated in strong acids[92].



Because of the abnormally intense absorption bands ν(Ta–H) of terminal bonds it was assumed[92] that the tantalum–hydrogen bond in the trihydride is largely ionic in character. The nuclear magnetic resonance spectrum of the trihydrides in the high-field region consists of a triplet (A) and a doublet (B_2) (Table 1) with the intensity ratio 1 : 2, which corresponds to the AB_2 system of protons[92]. The spectroscopic data have recently been confirmed by structural investigations[102] (Fig.4*a*, Table 3).

Both hydrides develop a strong tendency to eliminate a hydrogen molecule[107], which is consistent with a mass-spectrometric study of the tantalum complex (the main peak corresponds to the ion $C_{10}H_{11}Ta^+$).[108]

Scheme 2

M=Nb, Ta; X=H, Et, OCH_2CH_2OMe; L= CO, PR_3, C_2H_4

Heating the niobium trihydride in the absence of a ligand leads to formation of niobocene[63]. This reaction, like the others in Scheme 2, involves intermediate formation of unstable $(C_5H_5)_2NbH$.[63,78] This explains also the hydrogen–deuterium exchange of hexadeuterobenzene with molecular hydrogen in the presence of the trihydride[63,107].

Heating the trihydrides with a trialkylphosphine, carbon monoxide, or an alkene gives complexes $(C_5H_5)_2M(H)L$, in which the lone pair of electrons occupies one of the valency orbitals (obviously $1a_1$) of the $(C_5H_5)_2M$ group[63,109]. In the niobium and tantalum complexes $(C_5H_5)_2MHL$ with L = PR_3, CO (π-accepting ligands) the chemical shift of the hydrido-protons is observed upfield relative to the initial hydrides (similarly for $(C_5(CH_3)_5)_2Z(L)H_2$), but ν(M–H) is displaced to longer wavelengths. With a π-donor ligand (ethylene) the opposite shifts are observed (Table 4).

Table 3. Structural data on dicyclopentadienyl hydrides of transition metals.

$(Cp_2WH)_2H$+ClO_4–	—	—	145.6	—	—	1.8	—	—	[33]
$[(C_5Me_5)_2ThH_2]_2$	—	—	—	2.29	2.29	2.03	—	58	[106]

X-Ray structural analysis has shown[103] that in the $(C_5H_5)_2Nb(H)CO$ molecule the carbonyl group and presumably the hydrogen atom lie in the *yz* plane (Fig. 4b). According to n.m.r. data the structure of the $(C_5H_5)_2Nb(H)C_2H_4$ complex is closely similar to that of the ethyl complex $(C_5H_5)_2$.$Nb(C_2H_4)C_2H_5$, in which the ethylenic carbon atoms and the α-carbon atom of the ethyl group also lie in the *yz* plane[104] (Fig. 4c).

Because of the presence of a lone pair of electrons the compounds $(C_5H_5)_2M(H)L$ are Lewis bases. Thus treatment of $(C_5H_5)_2Nb(H)CO$ with hydrogen chloride at −30 °C is

stated[110] to give an unstable cationic complex $(C_5H_5)_2Nb(CO).H_2^+Cl^-$, which decomposes with the evolution of hydrogen. Donor–acceptor complexes containing metal–metal bonds have been reported to be formed by $(C_5H_5)_2Nb(H)CO$ with iron tetracarbonyl[111] and zinc tetrahydroborate[112].

Paramagnetic dicyclopentadienyl dihydrides of niobium and tantalum, isoelectronic with $[(C_5H_5)_2TiH_2]^-$, have been reported[52] (Table 2).

Groups VI–VIII

According to the scheme of molecular orbitals of $(C_5H_5)_2ML_n$ in Fig. 2 the hydrides $(C_5H_5)_2MH_2$ (M = Mo, W) should possess a lone pair of electrons. In fact research shows[93–95,105,113] that these monomeric hydrides contain two equivalent terminal hydrogen atoms (Fig. 5*a*). The small HMoH angle (Table 3) is consistent with Alcock's model[86] (lone pair ~ 80% localised on *y* axis[105]). However, the structure of the protonated tungsten complex $[(C_5H_5)_2WH_3]^+Cl^-$ is closely similar to that of the niobium trihydride[102]: i.e. the central hydrogen atom is apparently situated on the *z* axis (hydrogen atoms not located).

The presence of the lone pair in the dihydrides determines their chemical behaviour. They are readily protonated by strong acids to cations $(C_5H_5)_2MH_3^+$ isoelectronic with the tantalum trihydride[62], and form donor–acceptor complexes with transition-metal carbonyls[114] and other Lewis acids (BX_3, AlX_3).[93,94,115,116] The spectroscopic characteristics of the M–H bond remain unchanged.

For tungsten a paramagnetic hydride $(C_5H_5)_2WH$ (Table 2) and a cationic hydrido-complex $((C_5H_5)_2WH)_2H^+ClO_4^-$ have also been described[33]. In the spectra of the cation ν(W–H) differs by 180 cm^{-1} and τ_{WH} by 3.9 ppm (all hydrogen atoms equivalent) from the values for the initial dihydride. X-Ray data indicate that the cation contains a linear W–H–W bridge (Table 3) (positions of hydrogen atoms estimated by analogy with the structure of the molybdenum dihydride) and terminal tungsten–hydrogen bonds[33] (Fig. 5*b*).

The rhenium and technetium monohydrides $(C_5H_5)_2MH$ contain two lone pairs, apparently occupying equivalent orbitals. However, only one orbital is protonated, which is attributed to weakening of the basic strength by acquisition of a positive charge. The ionic adduct $(C_5H_5)_2ReH_2^+Cl^-$ is completely stable, and sublimes in a vacuum at 140 °C without decomposition[64]. The two hydrogen atoms in the cation are equivalent, so that its structure is analogous to that of the isoelectronic molybdenum dihydride[105]. Adducts of the rhenium monohydride with BX_3 and with $Al(CH_3)_3$ have been described[93,115].

With Group VIII metals all valency orbitals in $(C_5H_5)_2M$ are occupied by lone electron pairs, and only formation of ions isoelectronic with the rhenium monohydride can be expected. Indeed ferrocene in strongly acid media gives a high-field ^1H n.m.r. signal corresponding to the $(C_5H_5)_2FeH^+$ ion[117], and a stable complex $(C_5H_5)_2FeH^+AlCl_4^-$ has been isolated[96].

Complete replacement by methyl groups of the hydrogen atoms in the cyclopentadienyl rings leads to significant stabilisation of the higher valency states. As an example, the titanium(IV) hydride $(C_5(CH_3)_5)_2TiH_2$ is stable at room temperature[13]; cryoscopic measurements indicate that this compound, like the zirconium derivative[16], is monomeric in benzene.

The low titanium–hydrogen and zirconium–hydrogen frequencies of terminal bonds (Table 1) indicate the instability of the latter. Indeed, equilibrium (1) is readily displaced to the left when the reaction mixture is heated above room temperature. The energy of a titanium–hydrogen bond in bispentamethylcyclopentadienyltitanium dihydride has been estimated[13] as 242.4 kJ mole^{-1}, which is comparable with those of the corresponding molybdenum–hydrogen and tungsten–hydrogen bonds (respectively 258.7 and 286.8 kJ mole^{-1}) obtained by combustion[118], or 251.4 and 305.2 kJ mole^{-1} from calorimetric measurements on the reactions of the dicyclopentadienyl dihydrides with tetrachloromethane in solution)[119].

The vacant orbital of the zirconium atom is involved in forming unstable complexes $(C_5(CH_3)_5)_2ZrH_2.L$, where L = CO, PF_3 (Table 4).[16]

Freezing-point measurements indicate that the thorium and uranium dihydrides are dimeric, which is related to the great size of the central atom[19]. The molecular structure containing terminal and bridging hydrogen atoms (thorium–hydrogen frequencies respectively 1410, 1360 and 1215, 1115 cm^{-1})[19] has been confirmed by X-ray examination[106] for $[(C_5(CH_3)_5)_2ThH_2]_2$ (Fig. 5*c* and Table 3). It is noteworthy that an *f*-element (thorium) departs from the classical geometry of $(C_5H_5)_2ML_3$: three hydrogen atoms do not lie in the single *yz* plane[106].

2. "Bismetallocene Hydrides" of Transition Metals

(a) Complexes Containing a Fulvalene Ligand

Bismetallocene hydrides containing a fulvalene (η-C_5H_4–η-C_5H_4) bridging ligand are now known for titanium, zirconium, hafnium, and molybdenum (Table 5).

Table 5. Physicochemical properties of bismetallocene hydrides of transition metals.

Although no direct determination of the structure of "stable titanocene" has yet been made, infrared[37] and ^{13}C n.m.r.[8] spectroscopic data suggest the presence of bridging hydrogen atoms and a fulvalene ligand $(C_5H_5TiH)_2(C_{10}H_8)$ (Fig. 6*a*,*b*). It is consistent with X-ray data for the titanocene derivatives $(C_{10}H_8)(C_5H_5TiCl)_2$[120] and $(C_{10}H_8)(C_5H_5.TiOH)_2.C_4H_8O$[121] (Fig. 6*a*,*b*) and $(C_{10}H_8)(C_5H_5Ti(H)(H_2Al.(C_2H_5)_2)TiC_5H_5)$[79] obtained by the action of hydrogen chloride, water, and triethylaluminium respectively on $(C_{10}H_8).(C_5H_5TiH)_2$.

"Titanocene" and its derivatives $(C_{10}H_8)(C_5H_5TiX)_2$ are diamagnetic[36,120,121]. Coupling of the spins probably takes place through the fulvalene ligand, not through the bridging atoms[120]. A direct titanium–titanium bond, whose existence had been assumed[35], is obviously not formed, since for X = Cl, OH the Ti–Ti distance exceeds significantly the sum of the covalent radii (Table 6). Decreasing this distance would lead to excessive steric hindrance: in particular, with Ti–Ti = 2.7 Å the dihedral angle α (Fig. 6*a*) would be ~ 29°. Because of the presence of a single vacant orbital the complexes $(C_5H_5TiX)_2(C_{10}H_8)$ are Lewis acids, and give 1 : 1 complexes with oxolan[53,121].

"Zirconocene" and "hafnocene" are isomorphous with $(C_{10}H_8)(C_5H_5TiH)_2$, and possess similar chemical properties and physicochemical characteristics, which indicates similarity of structure between all three compounds[36,39].

Reactions involved in the synthesis and interconversion of molybdenum hydrides containing bridging ligands η-C_5H_4–η-C_5H_4 and σ : η-C_5H_4 are shown in Scheme 3 [29,51,54,80]. Neutral fulvalene hydrides of molybdenum contain terminal molybdenum–hydrogen bonds, whereas the cationic complexes are supposed to contain Mo–H–Mo bridges, with τ_{MoH} displaced upfield (Table 5). The metal–metal bond in molybdenum(III) hydrides is readily broken to give molybdenum(IV) dihydrides. Steric hindrance in the latter is apparently eliminated by the arrangement of two metal atoms on different sides of the plane of the fulvalene ligand[54].

(b) Complexes Containing Bridging (σ : η-C_5H_4) Groups

The paramagnetic complex $(C_5H_5)_2Ti\mu$-(σ : η-C_5H_4)TiC_5H_5 gives with oxolan an equimolecular adduct[41] (Fig. 7*a*), which may contain a bridging hydrogen atom according to X-ray examination, although infrared bands corresponding to the bridging bonds have not been detected. Indirect evidence of the presence of a hydrido-atom may be provided by the high catalytic activity of this compound in the hydrogenation and isomerisation of alkenes[124]. Under hydrogen pressures of 1–10 atm it absorbs one mole of the gas to form an unstable

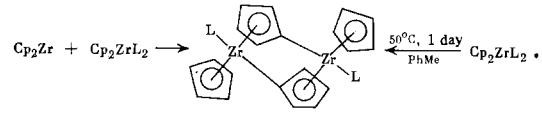
grey–green deposit, which loses hydrogen when the pressure is released. The infrared spectrum of the deposit contains a broad band at 1140 cm^{-1}, corresponding to vibration of a bridging titanium–hydrogen bond[124].



Niobocene (and obviously the isomorphous tantalocene) contain both the usual η^5-C_5H_5 groups and $\sigma:\eta$-C_5H_4 groups linking the niobium atoms in the dimer (Fig. 7*b*).[9] The length and spectrochemical characteristics of the niobium–hydrogen bond (Tables 5 and 6) are closely similar to the corresponding parameters of known transition-metal hydrides. Niobium–niobium bonds are apparently absent[9], as also in the fulvalene complex $(C_{10}H_8)(C_5H_5)_2Nb_2Cl$ (Fig. 6*c* and Table 6).[122] The corresponding hydrido-derivative has not been obtained.

Reduction of niobocene and its analogue containing Si–O–Si bridges between the rings gives the anionic complex $Na_2[C_5H_5Nb(H)(C_5H_4)]_2$.[42] On passing from the neutral compound to the dianion isoelectronic with tungstocene[123] the ν(Nb–H) frequency increases (Table 5) and the Nb–Nb distance (Fig. 7*c*, Table 6) increases, while the dihedral angle of the Nb–$C_{C_5H_4}$ bond diminishes[42].

An interesting reaction of $((C_5H_5)_2Mo(H)Li)_4$ with nitrous oxide gives a mixture of isomers $(C_5H_5MoH)_2(C_5H_4)_2$ (Table 5), which when heated or acidified form hydrido-complexes with a fulvalene ligand (Scheme 3).[80] In contrast to molybdenum, with which the fulvalene hydrides are the more stable[51], only the complexes containing bridging $(\sigma:\eta\text{-}C_5H_4)$ groups are known with tungsten (Tables 5 and 6 and Fig. 7*d*,*e*).

The above compounds are characterised by terminal metal–hydrogen bonds and exist as separable *cis*- and *trans*-isomers. The M, H, $C_{C_5H_4}$, and M′ atoms lie in the same plane[9], which is consistent with theoretical results on the nature of the bond in wedge-shaped sandwiches[85–88].

Besides hydrido-complexes bismetallocenes have been described containing μ-$(\sigma:\eta\text{-}C_5H_4)$ groups and no metal–hydrogen bond. A dark red diamagnetic complex isoelectronic with niobocene has been obtained[125]:

Hence it was assumed[125] that stable zirconocene, in contrast to titanocene, may contain $(\sigma:\eta\text{-}C_5H_4)$ groups. Formation of the corresponding molybdenum compound $C_5H_5Mo(C_5H_4)_2.MoC_5H_5$[51] is shown in Scheme 3.

3. Monocyclopentadienyl Hydrides of Transition Metals

Monocyclopentadienyl hydrides of transition metals are known, stabilised with arenes, carbon monoxide, nitric oxide, phosphines, phosphites, SiX_3, and SnX_3 (Table 7), isoelectronic with the dicyclopentadienyl hydrides $(C_5H_5)_2NbH$, $(C_5H_5)_2NbH_3$, $(C_5H_5)_2MoH_2$, $(C_5H_5)_2WH$, and $(C_5H_5)_2ReH$, and also the cation $(C_5H_5)_2FeH^+$ (Section III, 1).

Monocyclopentadienyl complexes of transition metals with ligands giving a total of four (three) electrons are formally analogous to dicyclopentadienyl hydrides of transition metals situated one (two) places to the left in the Periodic Table, but the monocyclopentadienyl hydrides possess an additional lone pair of electrons. Supplying five electrons ($C_5H_5ML_2XH_n$ complexes) changes neither the state of oxidation nor the electronic configuration of the transition metal

in comparison with $(C_5H_5)_2MH_n$. The coordination of one six-electron ligand (arene) or three two-electron π-accepting ligands yields hydrides isoelectronic with dicyclopentadienyl hydrides of immediate neighbours on the right in the Periodic Table.

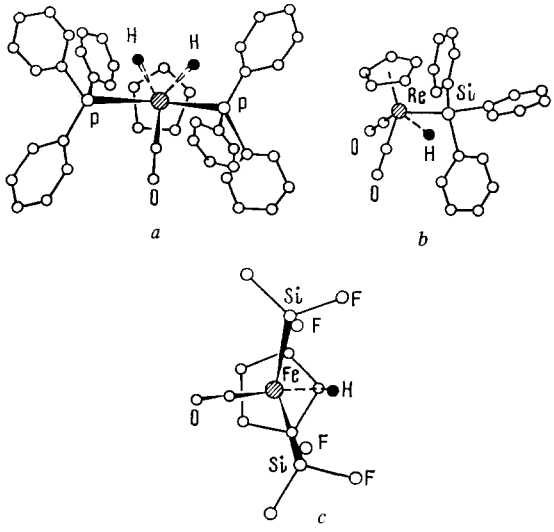


Figure 8. Molecular structure of: *a*) $C_5H_5Nb(CO)(P(C_6H_5)_3).H_2$;[22] *b*) $C_5H_5Re(CO)_2(SiCl_2C_6H_5)H$;[134] *c*) $C_5H_5Fe(CO)(Si.(CH_3)F_2)H$.[136]

It had previously been assumed that the ligand group $(CO)_3$, like an arene, should lead to the formation not only of electronic but also of structural analogues of $(C_5H_5)_2MH_n$[6,60,131]. However, X-ray examination of a series of complexes $C_5H_5M(CO)_2(SiX_3)H$ (M = Mn, Re)[133,134] and $C_5H_5Fe(CO).(SiX_3)_2H$[135,136] showed them to have a piano-stool configuration (Fig.8), in good agreement with n.m.r. results. The hydrogen atoms could not be located, and their positions were estimated from an analysis of non-bonded contacts. The length and spectroscopic characteristics of the metal–hydrogen bond (Table 7) are those usual for transition-metal hydrides.

In the case of $C_5H_5M(CO)_2(PR_3)H$ complexes *cis*- and *trans*-isomers have been obtained that differ markedly in spin–spin coupling constant (J_{P-H} ratio ~3, Table 7). Compounds containing two or more hydrogen atoms exhibit a rapid exchange of hydride protons on the n.m.r. time-scale: i.e. they are stereochemically fluximal.[17,74,126,132]

The chemical properties of monocyclopentadienyl hydrido-complexes of transition metals have been little studied, although their reactions with water, acids, halogens, and halogenated hydrocarbons are similar to those of the dicyclopentadienyl analogues. Thus $C_5H_5W(NO)_2H$ is hydrolysed by water with the evolution of hydrogen[72], whereas $C_5H_5W.(CO)_3H$ and electronic analogues of ferrocene are protonated in strong acids (Table 7).

Protonation of dinuclear complexes containing a metal–metal bond, of the types $(C_5H_5M(CO)_3)_2$ (M = Mo, W) and $(C_5H_5M(CO)_2)_2$ (M = Fe, Ru), form cationic complexes analogous to the dicyclopentadienyl complex $((C_5H_5)_2WH)_2H^+ClO_4^-$[33] and apparently containing M–H–M bridges[30]. Values of τ_{MH} in the cations $(C_5H_5M(CO)_3)_2H^+$ and $(C_5H_5M(CO)_2)_2H^+$ (some of the complexes were isolated as the fluorophosphates) are respectively 30.99, 34.8, 36.3, and 28.58 ppm for M = Mo, W, Fe, and Ru.[30]

It is interesting that protonation of the cation $(C_6H_6)M.(PR_3)_3H^+$, isoelectronic with $(C_5H_5)_2FeH^+$, gives the only known dinuclear cation $(C_6H_6)Mo(PR_3)_3H_2^{2+}$ (usually only one pair of electrons is protonated), which is attributed to the possibility of effective delocalisation of the positive charge[132].

4. Triscyclopentadienyl Hydrido-complexes of Transition Metals

Such hydrides are almost unknown. The brown complex $(C_5H_5)_3CeH$ has been reported[77], having an absorption line $\nu(Ce-H) = 2040\ cm^{-1}$. An attempt to isolate the corresponding uranium complex was unsuccessful[61]. The complex of the corresponding zirconium hydride with triethylaluminium has been isolated[137] from the $(C_5H_5)_4Zr-Al(C_2H_5)_3$ catalytic system; the link is formed by a single hydrogen bridge Zr–H–Al.

5. Transition-metal Hydrides stabilised with σ-Donor Ligands

Transition-metal hydrides stabilised with one-electron σ-donor ligands came to be studied comparatively recently. Hydrides of titanium, uranium, and thorium are known in addition to the relatively well studied zinc hydrides (configuration d^{10}) stabilised with nitrogen-containing ligands.

Reduction of diphenoxytitanium dichloride with alkali metals or sodium tetrahydroborate yields a series of hydro-complexes[138]:

$$(PhO)_2TiCl_2 \xrightarrow[oxolan]{NaBH_4} \{Ti(OPh)_2Cl(C_4H_8O)_2\}_2H$$
$$(PhO)_2TiCl_2 \xrightarrow[PhMe]{K} \{Ti(OPh)_2\}_3H$$
$$(PhO)_2TiCl_2 \xrightarrow[oxolan]{Na/tig.\ N_2} \{Ti(OPh)_2\}_3(N_2)H\ .$$

Titanium–hydrogen absorption bands have not been detected in them, but their hydride character is confirmed by the formation of chloroform on treatment with tetrachloromethane. The titanium atoms are assumed to be linked by bridging hydrogen atoms and phenoxy-groups[138].

Stable complexes $[((CH_3)_3Si)_2N]_3MH$ (M = U, Th) have been obtained[139] by boiling the corresponding chlorides with $NaN(Si(CH_3)_3)_2$ in oxolan. The hydride hydrogen originates from the solvent, as is confirmed by experiments with octadeutero-oxolan. These hydrides can be obtained also by treating the chloride with t-butyl-lithium or lithium triethylhydroborate in pentane. The metal–hydrogen bond in them has a fairly low stretching frequency, 1430 and 1480 cm^{-1} for the uranium and thorium complexes respectively[139], close to that for the corresponding terminal bond in $[(C_5(CH_3)_5)_2.ThH]_2$ (Table 1).

IV. CHEMICAL PROPERTIES OF TRANSITION-METAL CYCLOPENTADIENYL HYDRIDES

Since in the work covered above attention has been paid mainly to preparing and establishing the structure of the hydrido-complexes, their chemical properties have remained almost uninvestigated. Reactions demonstrating the presence of a metal–hydrogen bond have been mainly studied.

1. Thermal Stability and Reaction with Oxygen

Almost all cyclopentadienyl hydrides of transition metals decompose when heated, with the evolution of hydrogen and often without melting. Published data on decomposition points are given in Tables 1 and 7. The dicyclopentadienyl complexes are more stable than hydrides containing a single cyclopentadienyl group. In a series of compounds of the same type the stability increases regularly with the atomic number of the metal. As a consequence, it has proved impossible to obtain molybdenum analogues of certain tungsten complexes[30,72]. Hardly any detailed study has been made of the thermolysis of cyclopentadienyl hydrides of transition metals. Quantitative evolution of hydrido-hydrogen has been reliably determined in only a few cases (for $(C_5(CH_3)_5)MH_2$ (M = Ti, Zr, U)[13,16,19], $C_5H_5M(CO)_3H$ (M = Cr, Mo, W), and $C_5H_5Fe(CO)_2H$[3,4]). In most cases the decomposition of dicyclopentadienyl hydrides apparently involves the cyclopentadienyl ligand, yielding bridging C_5H_4 or $C_{10}H_8$ groups.

Hardly any study has been made of the action of oxygen on cyclopentadienyl hydrides of transition metals, although many publications emphasise the great sensitivity of these compounds (especially of Groups IV and V) to oxidation.

2. Reactions of Hydrido-complexes with Water and Acids

The reactivity of cyclopentadienyl hydrides of transition metals towards water and aqueous acids, involving the evolution of hydrogen, diminishes regularly on passing from left to right along the Periodic Table: whereas compounds of Group IV transition metals are hydrolysed vigorously by water, those of Group V are moderately hydrolysed, and hydrides of Groups VI–VIII metals are not in general hydrolysed. This is due to diminution in the hydride character of the metal–hydrogen bond (or negative charge on the hydrogen atom). The reactivity of the dicyclopentadienyl hydrides towards the reduction of ketones varies similarly[140]. It is interesting that the complex $C_5H_5W(NO)_2H$, isoelectronic with $(C_5H_5)_2NbH$, is hydrolysed with the evolution of hydrogen, in contrast to $(C_5H_5)_2WH_2$.[72]

The composition of the hydrolysis products was not usually studied, but formation of a hydroxyl derivative of stable titanocene by the action of a stoichiometric quantity of water has been reported[121]. Reaction with hydrogen halides (aqueous or anhydrous) generally results in replacement of a hydrido-ligand by halogen[37,76,124]. Treatment of the dicyclopentadienyl hydrides of tervalent titanium, tantalum, and zirconium with hydrogen chloride leads to oxidation of the metal with evolution of hydrogen and formation of the dichlorides $(C_5H_5)_2MCl_2$.[16,21,109]. This reaction provides a method for identifying a metal–hydrogen bond (see also subsection 3) when n.m.r. investigation is impossible, while infrared metal–hydrogen absorption bands are overlapped by other bands or even are not observed. Evolution of hydrogen deuteride on reaction with deuterium oxide or chloride is regarded as a reliable criterion[7]. Thus this method has shown the presence of a titanium–hydrogen bond in the complex $((C_5H_5)_2.TiN)_2H_3$[90,99] and in the product of the action of diphenylzinc on $(C_5H_5)_2Ti(C_6H_5)_3$.[141] The latter is assumed to contain a fulvalene ligand and two η-C_5H_4 groups linked through the zinc atom[141].

In some cases acid hydrolysis apparently involves intermediate formation of a dihydrido-complex. Thus the cations $C_5H_5M(CO)_3H_2^+$ (M = Mo, W) are formed when the monohydrido-complexes are treated with hexafluorophosphoric acid. The complex tungsten cation evolves hydrogen rapidly, and its molybdenum analogue almost instantaneously[30].

It is assumed also that $(C_5H_5)_2NbH_2(CO)^+$ is formed by the action of hydrogen chloride on the monohydrido-complex[110]:

$$Cp_2NbCl_2 \xrightarrow[2)\ NEt_3,\ CO]{1)\ NaBH_4} Cp_2Nb(H)CO \xrightarrow[-30^\circ]{HCl} \rightarrow Cp_2NbH_2(CO)^+Cl^- \xrightarrow[-H_2]{\Delta} Cp_2Nb(Cl)CO\ .$$

It is noteworthy that its action on niobocene, in contrast to titanocene[37], gives the usual $(\eta$-$C_5H_5)_2NbCl_2$.[42] A similar course is shown by other reactions of oxidative addition involving niobocene[40] and also $(C_5H_5)_2Ti(\sigma:\eta$-$C_5H_4)TiC_5H_5$.[124] These reactions may be expected to apply generally to all hydrides containing μ-$(\sigma:\eta$-$C_5H_4)$ groups, but not to complexes having a fulvalene ligand.

The action of acids on cyclopentadienyl hydrides of Groups VI–VIII transition metals gives protonated complexes, which are discussed in the appropriate subsections.

3. Reactions of Hydrido-complexes with Halogens and Halogenated Hydrocarbons

The action of halogens on the cyclopentadienyl hydrides leads to replacement of a hydrido-ligand by halogen[72], often accompanied by oxidation of the transition metal. For example, "niobocene" gives with bromine dicyclopentadienylniobium dibromide[42], and iodine acts on $(C_5H_5MoH_2)_2(C_5H_4$–$C_5H_4)$ to give the molybdenum(IV) complex $(C_5H_5MoI_2)_2(C_5H_4$–$C_5H_4)$.[29]

The formation of chloroform when a complex is treated with tetrachloromethane also provides a reliable criterion of the presence of a metal–hydrogen bond[7]. The titanium–hydrogen bond in phenoxytitanium hydrides has been demonstrated in this way[138]. In the course of the reaction hydrogen is replaced by halogen with formation of corresponding complexes. Methods of preparation of cyclopentadienyl halides have been described for the complexes $[((CH_3)_3Si)_2N]_3MH$ (M = Th, U)[139] and $C_5H_5Mo(CO)_3H$[142] with tetrachloromethane, and for $(C_5H_5)_2MH_2$ (M = Mo, W)[143] and $C_5H_5Mo(diphos).H_3$[74] with bromoform. The reactivity of $CHal_nH_{4-n}$ diminishes as n decreases, but it has been reported[7] that dichloromethane acts on $(C_5H_5)_2MH_3$ (M = Nb, Ta). Iodomethane is an extremely effective agent, in some cases enabling the content of hydrido-hydrogen to be determined quantitatively (from the evolution of methane) on reaction with $((C_5H_5)_2TiN)_2H_3$,[90] $(C_5H_5)_2Zr(H)(C_{10}H_7)Zr(C_5H_5)_2$,[21] $C_5H_5MoH(\sigma:\eta$-$C_5H_4)_2Mo(H).(C_5H_5)_2$, and $(C_5H_5)_2MoH_2$,[143] and also the corresponding iodo-derivatives to be obtained[51,143].

4. Complex Formation with Lewis Acids

Lewis acids (BX_3, AlX_3, MgX_2, $M(CO)_n$, etc.) form with the cyclopentadienyl hydrides two types of complexes—either of donor–acceptor type containing a metal–metal bond involving the lone pair of a Group VI or VII transition-metal hydride or with a hydrogen bridge—which are the subject of a detailed survey[144]. Here we note merely that the formation of equimolecular adducts having an M–M′ bond hardly changes the spectrochemical characteristics of the metal–hydrogen bond. However, the involvement of hydrogen atoms in forming bridging bonds leads to considerable shifts, in the frequency of this bond (up to 100–350 cm^{-1}) to longer wavelengths, and in τ_{MH} (up to 3–6 ppm) upfield[144].

5. Metallation of Hydrido-complexes at Metal–Hydrogen Bonds

Metallation of the metal–hydrogen bond in cyclopentadienyl hydrides has been effected by the action of butyl-lithium. The reaction with the dicyclopentadienyl dihydrides of molybdenum and tungsten gives cyclic tetramers $[(C_5H_5)_2M(H)Li]_4$ containing M–Li–M bonds.[81] Treatment of the molybdenum hydride with Grignard reagents and aluminium alkyls also results in fission of a molybdenum–hydrogen bond and formation of complexes containing bonds between molybdenum and respectively magnesium[82] and aluminium[83]. Analogous metallation by n-butyl-lithium has been described for $(C_5H_5MoH)_2(C_5H_4{-}C_5H_4)$[29] and $(C_5H_5)_2TaH_3$.[84] Apparently the metal–hydrogen bonds in the thorium and uranium complexes $[((CH_3)_3Si)_2N]_3MH$ also undergo metallation during preparation of the deuterated complexes[139]:

$$[(Me_3Si)_2N]_3ThH_2 \xrightarrow[2)\ CF_3COOD]{1)\ n\text{-}LiBu} [(Me_3Si)_2N]_3ThD\ .$$

All metallation products are strong nucleophiles, extremely sensitive to oxygen and readily hydrolysed with regeneration of the metal–hydrogen bond.

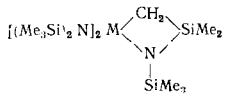
6. Reactions of Hydrido-complexes with Donor Molecules

Reaction with donor molecules may or may not involve a metal–hydrogen bond.

The presence of vacant orbitals on a transition-metal atom usually results in the formation of solvates. Stable titanocene gives an adduct with oxolan[35–37], and niobocene adducts with acetonitrile and aromatic hydrocarbons[40]. Monomeric $(C_5(CH_3)_5)_2ZrH_2$ gives unstable equimolecular complexes with carbon monoxide and phosphorus trifluoride[16]. The orbitals of Groups VI–VIII metals are filled with d-electrons, and the hydrido-complexes acquire basic properties. However, the reaction of carbon monoxide with $(C_5H_5MoH)_2(C_5H_4{-}C_5H_4)$ (Scheme 3) probably involves addition of the donor molecule to the isomer $C_5H_5MoH_2(C_5H_4{-}C_5H_4)C_5H_5Mo$ at the molybdenum(II) atom[54].

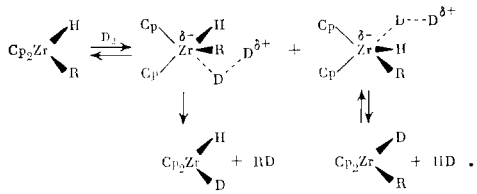
Ligand substitution not involving a metal–hydrogen bond

$$CpML_3H + L' \rightarrow CpML_2L'H + L$$



has been reported for L = CO, L′ = PR_3, $P(OR)_3$, and M = Mo, W[128] and for L = $P(OCH_3)_3$, L′ = CO, and M = Cr.[69]

A TiH_2Ti bridge undergoes homolytic fission by donor molecules (oxolan, PR_3)[15,19] (Eqn.2).



Hydrido-ligands are displaced from $(C_5H_5)_2Ti(\sigma:\eta\text{-}C_5H_4)$.$TiC_5H_5.H_2$[124] and (ArH)Mo$(P(C_6H_5)_3)_2H_2$[17] by nitrogen to form dinitrogen complexes. Carbon monoxide "displaces" a hydrogen atom from a cyclopentadienyl group in $(C_5H_5)_2ReH$ to give the cyclopentadiene complex $C_5H_5Re(CO)(C_5H_6)$.[145] Such ligands as carbon monoxide, trialkylphosphines, and alkenes displace two hydrogen atoms from $(C_5H_5)_2MH_3$ (M = Nb, Ta) (Scheme 2)[63,109]. Reaction between $((C_5H_5)_2TiN)_2H_3$ and carbon monoxide is accompanied by partial evolution of hydrogen and formation of a complex, from which $(C_5H_5)_2Ti.(CO)_2$ can be obtained by pyrolysis[99].

7. Isotope Exchange

Solid $((C_5H_5)_2TiH)_2$ exchanges protons of its cyclopentadienyl rings for deuterium in an atmosphere of the latter. Subsequent treatment with hydrogen chloride yields $(C_5D_5)_2.TiCl_2$.[57] The reaction apparently involves a hydride-transfer stage. An analogous reaction has been described for $[((CH_3)_3Si)_2N]_3MH$ (M = U, Th).[146] Formation of the completely deuterated product $[((CD_3)_3Si)_2N]_3MD$ is assumed to involve an intermediate four-membered metallobutane ring derivative

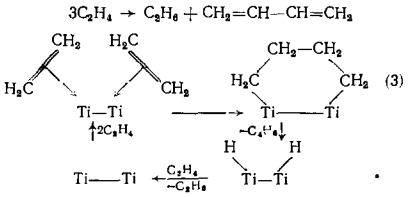
isolated on pyrolysis of the hydride[146]. Deuterium exchange in $(C_5H_5)_2Zr(H)R$ apparently proceeds via an intermediate five-coordinated complex[71]:

On contact of $C_5H_5Cr[P(OCH_3)_3]_3H$ with deuterium more than 50% of the hydrogen atoms are exchanged, presumably via a hydrogen-detachment stage and oxidative addition of deuterium[69].

Catalytic isotope exchange has been reported[63,107] between benzene and deuterium or between hexadeuterobenzene and hydrogen in the presence of $(C_5H_5)_2TaH_3$ (Scheme 2). Isotope exchange with $(C_5H_5)_2ReH$ and $(C_5H_5)_2MH_2$ (M = Mo, W) in the presence of deuterium oxide is accelerated by acids (owing to formation of protonated complexes)[34,62,64].

8. Reactions of Hydrido-complexes with Unsaturated Molecules

Alkyl complexes are formed by the action of alkenes on cyclopentadienyl hydrides of transition metals. Titanocene absorbs an equimolecular quantity of an alkene[147,148], with disappearance of the band at 1230 cm^{-1}.[148] Zirconium(IV) hydrides such as $(C_5H_5)_2ZrH_2$ and $(C_5H_5)_2Zr(H)Cl$ respectively give the complexes $(C_5H_5)_2ZrR_2$ and $(C_5H_5)_2Zr(R)Cl$[91,149]. Addition of ethylene to $(C_5H_5)_2Nb(H)(C_2H_4$[63] and of tetrafluoroethylene to $C_5H_5M(CO)_3H$ (M = Mo, W)[150] and $C_5H_5Fe(CO)_2H$[151] yields the corresponding ethyl complexes.



Conjugated dienes form the corresponding π-allyl complexes, as e.g. with $((C_5H_5)_2TiH)_2$[18] and $C_5H_5Mo(diphos)H_3$.[74] However, the complexes $C_5H_5M(CO)_3H$ (M = Cr, Mo, W) hydrogenate dienes selectively, and are converted into $(C_5H_5M(CO)_3)_2$.[152,153] Reaction between $(C_5H_5)_2WH_2$ and isoprene results in hydrogenation of the latter and formation of the complex $(C_5H_5)_2W(H)C_6H_5$, obviously by oxidative addition of benzene to dicyclopentadienyltungsten[154].

Dicyclopentadienylmolybdenum dihydride adds readily[155] at C:C and N:N bonds to give respectively $(C_5H_5)_2Mo(H).(CR{:}CHR)$ and $C_5H_5Mo(H)(RN.NHR)$.

9. Catalytic Activity of Hydrido-complexes

Catalytic activity is exhibited by cyclopentadienyl hydrides only of transition metals in Groups IV and V, mainly titanium and zirconium. It was reported[156] that titanocene was an effective catalyst for the hydrogenation of alkenes, but recent work has shown[15] that its activity is less by factors of 10^3–10^4 than that of systems comprising $(C_5H_5)_2TiCl_2$ with a metal alkyl. Alkenes are dimerised by titanocene in the presence of a methylhydropolysiloxane[157]. Titanocene and

$(C_5H_5)_2Ti(\sigma:\eta\text{-}C_5H_4)TiC_5H_5$ catalyse also the conversion of ethylene into butadiene, which probably involves double β-elimination:

Other hydrogenation catalysts are $(C_5H_5)_2Ti(\sigma:\eta\text{-}C_5H_4)\cdot TiC_5H_5$,[124] $((C_5H_5)_2TiN)_2H_3$,[99] and the zirconium compounds $(C_5H_5)_2ZrH_2$[91,149] and $(C_5H_5)_2Zr(H)(C_{10}H_7)Zr(C_5H_5)_2$,[21] which readily add alkenes at metal–hydrogen bonds (subsection 8).

The intermediate species $(C_5H_5)_2TiH$ (or $(C_5H_5)_2Ti(H)Cl$) is assumed to be the true catalyst, in systems based on $(C_5H_5)_2TiCl_2$ together with AlR_3, LiR, MgRX, $LiAlH_4$, or $HAl(N(C_3H_7)_2)_2$ (in non-solvating solvents), for hydrogenation[15], intramolecular cyclisation of cyclododecatriene[157], hydrometallation of alkenes[158], etc. This hypothesis is consistent with the catalytic activity of $(C_5H_5)_2TiCH_3$ after treatment with hydrogen[159]. In the case of systems containing aluminium hydrides, however, the catalytic activity of $(C_5H_5)_2TiH$ is doubtful, owing to the formation of very stable dimetal complexes having bridging hydrogen bonds[144].

Catalytic hydrogenation of ethylene on the complex $(C_5H_5)_2\cdot Nb(H)(C_2H_4)$ has been reported[63]. Blocking of the terminal hydrogen atom (by complex formation with triethylaluminium) inhibits the catalyst[160].

Use of Chemical Lasers to Determine the Rate Constants of Reactions Between Atoms and Molecules and the Rate Constants of the Relaxation of Vibrationally Excited Molecules

G.V.Pukhal'skaya and S.Ya.Pshezhetskii

The application of chemical lasers to the determination of the rate constants of reactions and of the relaxation of vibrational excitation is discussed. The following procedures are reviewed: the measurement of the time lag of the generation with respect to the leading edge of the pulse used to initiate the reaction, the measurement of the generation decay time, the use of competing reactions to measure the rate constants of "non-laser" reactions, and also methods of measuring the relative rate constants for the population of different levels in the reaction product (the "equal amplification temperature" method, the "zero amplification temperature" method, and the "grating selection" method). 71 references.

I. INTRODUCTION

Several methods of measuring the rate constants of reactions of atoms and radicals with molecules in the gas phase are available: spectroscopy, mass spectrometry, ESR, etc. However, the rate constants determined by different methods often show serious discrepancies, which complicate the selection of values for use in kinetic investigations. The differences in the rate constants of fast reactions of atoms and radicals with molecules are especially large. Furthermore, the range of application of these methods is often limited. Therefore the development of new experimental methods of measuring the rate constants of reactions of atoms and radicals with molecules is of great interest. A new method of measuring the rate constants of the relaxation of excited molecules would also be of great use.

The development of chemical lasers created the possibility of using the generation of radiation to measure the rate constants of the "pumping" reactions taking place in the lasers. These include, in particular, reactions such as

$$A + BC \rightarrow AB^{\dagger} + C$$

where A is an atom, BC is a molecule, and $AB^{\dagger}$ is a molecule formed in a vibrationally excited state. If the "pumping" reaction is a chain reaction the generation is determined by

several rate constants. For example,

$$Cl + H_2 \xrightarrow{k_1} HCl + H$$
$$H + Cl_2 \xrightarrow{k_2} HCl^{\dagger} + Cl .$$

The presence of several rate constants makes their determination more difficult. Furthermore, relaxation of the vibrationally excited molecules takes place in parallel with the other reactions, and this further complicates the determination of the kinetic constants k_1 and k_2. Nevertheless, as has been demonstrated experimentally, these difficulties can be overcome, and under certain conditions the kinetic constants of the reactions between atoms and molecules are relatively easily found from measurements of the oscillation parameters, with a precision at least equal to that of the more traditional methods.

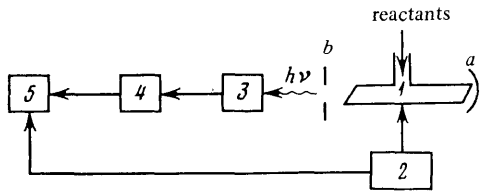

Figure 1. Block diagram of a chemical laser: *1*) laser tube, *2*) initiation system, *3*) monochromator, *4*) i.r. detector, *5*) oscillator.

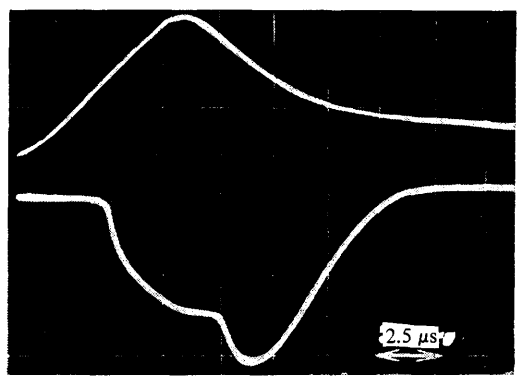

Figure 2. Oscillograms of the initiation pulse (upper trace) and the generation pulse (lower trace).

The basic principles of the determination of the kinetic and relaxation constants by using chemical lasers can be briefly illustrated as follows. The radiation from a chemical laser arises from a chemical reaction which produces excited molecules with a population inversion in different vibrationally excited states. A block diagram of the chemical laser is shown in Fig.1. The chemical reaction takes place in a cell containing the gas mixture within an optical resonator consisting of the mirrors *a* and *b* (the latter being half-silvered). The reaction in the chemical laser is initiated by atoms formed by the dissociation of molecules under the influence of a light pulse or a pulsed electrical discharge.

The length of the initiating pulse depends on the parameters of the initiating equipment used. The beginning of the initiation pulse is separated from the onset of laser generation by a time interval imposed by the need to reach the threshold concentration of the inverted population of excited molecules, which depends on the radiation losses in the resonator. The length of this time lag can be measured from oscillographic displays of the generation and initiation pulses, as shown in Fig.2.

II. DETERMINATION OF THE CONSTANTS BY MEASURING THE OSCILLATION DELAY TIME

1. Principle of the Method

By measuring the oscillation delay time t_1 and equating the concentration of population-inverted molecules at time t_1 to the threshold value needed to satisfy the self-excitation condition we can obtain an equation for the required rate constant. Allowance must be made for the radiation losses in the resonator. The experimental conditions (initiation, pressure of reactants, amount of inert diluent) are chosen so as to make the consumption of reactants and the temperature rise of the working mixture during the time lag period negligibly small.

The possibility of measuring rate constants by the oscillation delay time method was first demonstrated by Basov and coworkers[1]. Chester and Hess[2] measured the dependence of the oscillation delay time (with respect to the leading edge of the initiating light pulse) on the rate constant of the "pumping" reaction, on the intensity of the initiating light flux, on the radiation losses in the resonator, on the composition and pressure of the gas mixture, and on the relaxation processes. They considered a chemical laser operating by the reaction RF + H_2 + B (where B is an inert gas). The atomic fluorine formed by the photolysis of RF takes part in the "pumping" reaction

$$F + H_2 \xrightarrow{k_{H_2}} HF^{\dagger} + H \qquad (1)$$

giving population-inverted $HF^{\dagger}$ molecules.

The basic kinetic equations are

$$d[RF]/dt = -s(t)[RF] \qquad (2)$$
$$d[F]/dt = qs(t)[RF] - k_{H_2}[F][H_2] \qquad (3)$$
$$d[H_2]/dt = -k_{H_2}[F][H_2] \qquad (4)$$
$$d[HF]/dt = -d[H_2]/dt \qquad (5)$$

where $s(t) = \Phi \int \sigma(\lambda) I(\lambda, t) d\lambda$, Φ is the yield of the photodissociation RF, $\sigma(\lambda)$ is the molecular absorption coefficient of RF, $I(\lambda, t)$ is the local intensity of the light flux at the wavelength λ, and q is the number of F atoms formed by the dissociation of the RF molecule.

It was shown[2] that the temperature rise due to light absorption and to reaction (1) in time t_1 is negligible, and can be made even smaller by adding an inert gas to the reaction mixture. The frequency of the initiating light is chosen to lie outside the absorption bands of hydrogen and of the diluent gas. It was also shown[2] that the reactions of H, H_2, and HF with R and RF during time t_1 can be ignored, and so can also the recombination of atoms in the volume and at the walls. The process can be treated as quasi-isothermal.

In order to simplify the solution of the system of equations (2)–(5) the experimental conditions must be chosen so that the functions I and s can be expressed as

follows:

$$I(\lambda, t) = I_0(\lambda)\, t^m$$
$$s(t) = \Phi \int \sigma(\lambda)\, I_0(\lambda)\, d\lambda t^m = s_0 t^m,\ m > 0.$$

The initial conditions are $[F]_0 = [HF]_0 = 0$.

The system (2)–(5) can be transformed into

$$d[H_2]/dt = -k_{H_2}\left\{[H_2]_t - [H_2]_0 + q[RF]_0\left(1 - \exp\left(\frac{-s_0 t^{m+1}}{m+1}\right)\right)\right\}[H_2]_t\ , \qquad (6)$$

By solving Eqn.(6) we can find $[HF]_t$:

$$[HF]_t = [H_2]_0 - [H_2]_t\ .$$

Let $\Delta n(t)$ be the difference in concentration between the $HF^\dagger$ molecules in the vibrationally excited levels $(v+1)$, $(J-1)$ and v, J, corresponding to the emission of a laser line with maximum amplification:

$$\Delta n(t) = [HF_{v+1,\,J-1}]_t - [HF_{v,J}]_t\ .$$

We then have $d[\Delta n(t)]/dt = f_{H_2} d[HF]/dt - k'[M]_t \Delta n(t)$, where f_{H_2} is the difference between the probabilities of formation [by reaction (1)] of HF molecules in the upper $(v+1)$ and in the lower (v) level, and k' is the rate constant for the relaxation on M molecules.

Eqn.(6) can be integrated numerically, but alternatively the solution can simply be expanded in powers of t, retaining only the first-order terms. Since the time interval is small, deactivation occurs mainly by collisions with the initial H_2, RF, and diluent molecules, and we can assume that $[M]_t = [M]_0$. Therefore

$$\Delta n(t) \simeq \frac{f_{H_2} q k_{H_2} [RF]_0 [H_2]_0 s_0 t^{m+2}}{(m+1)(m+2)} \times \left\{1 - \frac{k_{H_2}[H_2]_0 t}{m+3} - \frac{k'[M]_0 t}{m+3} + \ldots\right\}\ , \qquad (7)$$

Oscillation begins after time t_1 (measured from the beginning of the initiating pulse), when $\Delta n(t)$ reaches the critical (threshold) value Δn_{thr}, depending on the radiation losses in the resonator:

$$\Delta n(t_1) = \Delta n_{thr}\ , \qquad (8)$$

Retaining only the lower-order term, i.e. ignoring the relaxation of the excited $HF^\dagger$ molecules, we obtain from (7) and (8) the following expression for the generation time lag, which includes the required constant k_{H_2}:

$$t_1 = \left\{\frac{(m+1)(m+2)\Delta n_{thr}}{f_{H_2} q k_{H_2} [RF]_0 [H_2]_0 s_0}\right\}^{1/(m+2)}. \qquad (9)$$

If $m = 1$ we have

$$t_1 \sim (g_0/\alpha\alpha' s_0)^{1/3} p_{tot}^{-2/3}$$

where p_{tot} is the total pressure of the mixture, α and α' are the mole fractions of H_2 and RF, and g_0 is the threshold amplification of the laser i.e. the amplification at the onset of oscillation.

The threshold amplification is related to the radiation losses in the resonator by the expression

$$(1-l)\exp(2g_0 L) = 1\ , \qquad (10)$$

where l is the loss of radiation in the resonator for a single passage of the beam, determined by the precision of the optical assembly, the reflectivity of the mirrors, the transparency of the windows in the laser tube, etc. L is the length of the optical path in the active medium.

Thus the rate constant of the "pumping" reaction can be determined, in principle, by measuring the oscillation delay time.

2. Rate Constants of the Reactions of Atoms and Radicals with Molecules

a) Reaction of F *atoms with* CH_4, HCl, *and* HBr. By using an $HF^\dagger$ laser the rate constants of the reactions of F atoms with other hydrogen-containing RH molecules can be determined from formula (9) if these reactions are used in "pumping" the laser. The equation for the "pumping" reaction (including the wanted k_{RH} constant) is

$$F + RH \xrightarrow{k_{RH}} HF^\dagger + R\ , \qquad (11)$$

Since formula (9) was obtained by ignoring the relaxation of the vibrationally excited $HF^\dagger$ molecules we must test whether the experimental conditions were correctly chosen, i.e. whether the condition $t_1 \propto p_{tot}^{-2/3}$ is obeyed when the intensity of the light flux is a linear function of time. If this expression applies we can find the ratio of the generation time lags in mixtures of H_2 + RF + B and RH + RF + B for equal partial pressure of RF and of the hydrogen donors. If $m = 1$ we have from Eqn.(9)

$$k_{RH} f_{RH}/k_{H_2} f_{H_2} = (t_1^{H_2}/t_1^{RH})^3$$

since the experimental conditions are specially chosen to make Δn_{thr}, q, $[RF]_0$, and s_0 the same in the two experiments, and $[H_2]_0 = [RH]_0$; f_{RH} is a quantity analogous to f_{H_2} and corresponds to reaction (11).

By using this method we have determined[3,4] the ratios $k_{CH_4}/k_{H_2} = 2 \pm 0.2$, $k_{HCl}/k_{H_2} = 0.25$, and $k_{HBr}/k_{H_2} = 1.3 \pm 0.2$. In the calculation we adopted the values $f_{CH_4} = 0.44$, $f_{H_2} = 0.37$, and $f_{HCl} = 0.33$ (obtained by averaging published data), and $f_{HBr} = 0.12$ (given by Jonathan and coworkers[5]).

b) The H + ClF *reaction.* The measurement of the oscillation delay time has been used to determine the rate constants of "pumping" reactions involving other atoms. Thus, the rate constant of the reaction H + ClF → $HCl^\dagger$ + F has been determined[6]. The experiment involved measuring the oscillation delay time on $HF^\dagger$ and $HCl^\dagger$ molecules in a chemical laser working on a mixture of ClF + H_2. The formation of F and Cl atoms took place by photodissociation of ClF.

The main sub-threshold processes are

$$ClF + h\nu \rightarrow Cl + F$$
$$F + H_2 \xrightarrow{k_{H_2}} HF^\dagger + H \qquad (1)$$
$$H + ClF \xrightarrow{k_{ClF}^{(1)}} HCl^\dagger + F \qquad (12)$$
$$H + ClF \xrightarrow{k_{ClF}^{(2)}} HF^\dagger + Cl\ , \qquad (13)$$

The Cl + H_2 reaction is much slower than the F + H_2, and it can be ignored in a sub-threshold process. Theoretical calculations[7,8] suggest that $k_{ClF}^{(1)} < k_{H_2}$, $k_{ClF}^{(2)} < k_{H_2}$, and $k_{ClF}^{(1)} > k_{ClF}^{(2)}$: this suggestion was confirmed by kinetic measurements[9], which gave $k_{ClF}^{(1)}/k_{ClF}^{(2)} = 6.1$, and by i.r. chemiluminescence measurements[10], which gave $k_{ClF}^{(1)}/k_{ClF}^{(2)} = 6.7 \pm 0.8$. Therefore in the pre-threshold period we can legitimately ignore the formation of $HF^\dagger$ by reaction (13) in comparison to reaction (1), and assume that the consumption

of hydrogen atoms is negligible before the onset of generation on $HCl^{\dagger}$.

By solving the equation for the change in concentration of atomic fluorine with a linearly time-dependent light flux, and by integrating the equation for the change in concentration of HF, we can arrive at the threshold concentration of population-inverted excited $HF^{\dagger}$ molecules:

$$\Delta n_{\text{thr}}^{\text{HF}^{\dagger}} = f_{\text{H}_2} \int_0^{t_{l_1}} k_{\text{H}_2} [\text{H}_2]_0 [\text{F}]_t \, dt \qquad (14)$$

where t_{l_1} is the generation time lag for the P_2 (3) transition of the HF molecules, which occurs first.

By the same procedure we can determine the threshold concentration of population-inverted excited $HCl^{\dagger}$ molecules:

$$\Delta n_{\text{thr}}^{\text{HCl}^{\dagger}} = f_{\text{ClF}} \int_0^{t_{l_2}} k_{\text{ClF}}^{(1)} [\text{ClF}]_0 [\text{H}]_t \, dt \qquad (15)$$

where f_{ClF} is a coefficient analogous to f_{H_2} corresponding to reaction (12), and t_{l_2} is the oscillation delay time for the P_2 (5) transition of the HCl molecules. Furthermore

$$\Delta n_{\text{thr}}^{\text{HF}} / \Delta n_{\text{thr}}^{\text{HCl}} = \sigma_{v,J\to v',J'}^{\text{HCl}} / \sigma_{v',J\to v',J'}^{\text{HF}}$$

where $\sigma_{\nu,\ J \to \nu',\ J'}$ is the cross-section of the initiating radiation for the given vibrational–rotational transition of the HF and HCl molecules,

$$\sigma_{v,J\to v',J'} \simeq A_{v,J\to v',J'} M^{1/2} / \nu^3$$

where $A_{\nu,\ J \to \nu',\ J'}$ is the Einstein coefficient for the transition, ν is the transition frequency, and M is the molecular weight.

From the ratio of Eqns.(14) and (15) we can obtain an expression for $k_{\text{ClF}}^{(1)}$. We calculated this constant by using Einstein coefficients taken from Refs.11 and 12, and an assumed k_{H_2} value of 2.5×10^{-11} cm^3 s^{-1}. The values $f_{\text{H}_2} = 0.36$ and $f_{\text{HCl}} = 0.31$, which describe the differences in occupancy probability of the $\nu = 2$ and $\nu = 1$ levels for HF and HCl molecules, were obtained by averaging published values for HF [13–15] and for HCl [16,17] (for the reaction $H + Cl_2 \to HCl^{\dagger} + Cl$). In this way the value $k_{\text{ClF}}^{(1)} = (3.7 \pm 0.4) \times 10^{-12}$ cm^3 s^{-1} at 300 K was obtained for the first time. The i.r. chemiluminescence method[18] had yielded only the ratio of this constant to the rate constant of the reaction $H + Cl_2 \to HCl^{\dagger} + Cl$, equal to 1.99.

c) The $OD^{\dagger} + O_3$ *reaction.* Measurements of the oscillation delay time on $CO_2^{\dagger}$ molecules in a chemical laser working on an $O_3 + D_2 + CO_2$ mixture have been used[19] to determine the rate constant of the reaction between the OD radical and O_3. The main reactions in this mixture are

$$\begin{aligned}
&O_3 + h\nu \xrightarrow{k_0(t)} O(^1D) + O_2\\
&O(^1D) + D_2 \xrightarrow{k_1} OD^{\dagger}(v) + D\\
&D + O_3 \xrightarrow{k_2} OD^{\dagger}(v) + O_2\\
&OD^{\dagger}(v) + CO_2 \xrightarrow{k_3^v} OD^{\dagger}(v-1) + CO_2^{\dagger}\\
&O(^1D) + M \xrightarrow{k_4} O(^3P) + M\\
&OD^{\dagger}(v) + O_3 \xrightarrow{k_5} \begin{cases} \to DO_2 + O_2\\ \to OD + O + O_2\\ \to D + 2O_2 \end{cases}\\
&O(^1D) + O_3 \xrightarrow{k_6} O_2 + O_2\\
&OD^{\dagger}(v) + D_2 \xrightarrow{k_7^v} OD^{\dagger}(v-1) + D_2
\end{aligned}$$

where $CO_2^{\dagger}$ is a CO_2 molecule in the (00°1) state, k_3^{ν} and k_7^{ν} are the rate constants for the reactions in the OD radical in the level ν, and $k_0(t)$ is the rate constant for the formation of $O(^1D)$ atoms from ozone under the influence of light.

3. Rate Constants of the Relaxation of Vibrational Excitation

The determination of the rate constants for the relaxation of vibrational excitation is very important in chemical kinetics, because vibrational excitation plays a key role in overcoming the activation barriers of reactions. The measurement of relaxation rate constants is especially important in the theory of chemical lasers because the intensity and duration of the generation are largely determined by relaxation processes.

The relaxation rate constants of vibrationally excited molecules can be measured, at present, by monitoring the intensity of laser-excited fluorescence at room temperature or by heating the gas mixture in a shock tube, or by the i.r. chemiluminescence method. As we shall show, the laser method (by measuring the generation time lag) can be used to determine the rate of relaxation and of transfer of vibrational excitation under appropriately chosen conditions (composition of the laser mixture, and other factors which determine the relaxation processes).

a) The $OD^{\dagger} + CO_2$, $OD^{\dagger} + D_2$ *processes.* Measurements of the oscillation delay time have shown[19] that at 300 K the rate constant of the deactivation of OD radicals ($\nu = 1$) by collisions with D_2 molecules is $k_7^1 = (3.1 \pm 0.7) \times 10^{-14}$ cm^3 s^{-1}, and the rate constant of the transfer of vibrational energy from the OD radical ($\nu = 1$) to CO_2 is $k_3^1 = (1.9 \pm 0.7) \times 10^{-12}$ cm^3 s^{-1}. The latter value is significantly higher than the value $k_3^1 = (0.5 \pm 0.25) \times 10^{-12}$ cm^3 s^{-1} obtained[20] by a similar method but without allowance for the radiation loss in the resonator. Thus failure to correct for losses in the resonator can yield low values of the rate constant.

b) The $DF^{\dagger} + CO_2$ *reaction.* The measurement of the oscillation delay time has been used[1] to determine the rate constant of the transfer of vibrational energy from the $DF^{\dagger}$ molecule to the CO_2 molecule. The time lag of the generation was measured for the (00°1 → 10°0) transition of the CO_2 molecule in a chemical laser working with an $F_2 + D_2 + CO_2$ mixture. The most important elementary processes in such a mixture are

$$\begin{aligned}
&F_2 + h\nu \xrightarrow{k_0(t)} 2F\\
&F + D_2 \xrightarrow{k_1} DF(v) + D\\
&D + F_2 \xrightarrow{k_2} DF(v) + F\\
&DF(v) + CO_2 \xrightarrow{k_3} DF(v-1) + CO_2(00°1)\\
&CO_2(00°1) + M \xrightarrow{k_4} CO_2(00°0) + M \qquad (16)\\
&DF(v) + M \xrightarrow{k_5} DF + M \qquad (17)
\end{aligned}$$

where M is any molecule in the mixture.

In the initial stages of a chemical reaction, lasting ~10^{-5} s after initiation, the processes (16) and (17) can be ignored, because the vibrationally excited states of the DF and CO_2 molecules have fairly long lifetimes. If we also ignore the time (~10^{-6} s) for the establishment of a quasi-stationary concentration of D atoms according to the equation $k_1[F][D_2] = k_2[D][F_2]$ we may characterise the formation of vibrationally excited DF and CO_2 molecules by the expressions

$$(d/dt)[DF(v)] = W(t) - k_3[DF(v)][CO_2] \qquad (18)$$

$$(\mathrm{d}/\mathrm{d}t)[\mathrm{CO_2}(00^\circ 1)] = k_3[\mathrm{DF}(v)][\mathrm{CO_2}] \cdot \quad (19)$$

The reaction rate $W(t)$ in Eqn.(18) is given by

$$W(t) = 2k_1[\mathrm{F_2}][\mathrm{D_2}]\{1 + k_1[\mathrm{D_2}]/k_2[\mathrm{F_2}]\}^{-1}\int_0^t k_0(t')\,dt' \cdot \quad (20)$$

Integration of (18) and (19) gives

$$[\mathrm{CO_2}[00^\circ 1)]_t = k_1[\mathrm{CO_2}]\int_0^t \{\exp(-k_3[\mathrm{CO_2}]t')\int_0^{t'}\exp(k_3 \times \times[\mathrm{CO_2}]t'')W(t'')\,\mathrm{d}t''\}\,\mathrm{d}t' \cdot \quad (21)$$

Laser action begins at time t_1 after the front of the light pulse. During this time the occupancy of the upper lasing level of the CO_2 molecule reaches the threshold value. If this threshold value and the reaction rate $W(t)$ are known, the rate constant for the transfer of vibrational energy (k_3) can be determined by Eqn.(21).

It is assumed that the shape of the initiating pulse can be described by the expression

$$k_0(t) = \gamma_1 t\exp(-\gamma_2 t) \quad (22)$$

where the coefficients γ_1 and γ_2 define the amplitude and the duration of the pulse. From Eqns.(20)–(22) we obtain, after integration,

$$[\mathrm{CO_2}(00^\circ 1)](t_l) = W'f(\alpha, \gamma_2, t_l)$$

where $\alpha = k_3[\mathrm{CO_2}]$, and W' is calculated by the expression

$$W' = 2k_1[\mathrm{F_2}][\mathrm{D_2}]\{1 + k_1[\mathrm{D_2}]/k_2[\mathrm{F_2}]\}^{-1}\gamma_1/\gamma_2^2 .$$

The quantity W' is the reaction rate after the end of the initiation pulse, i.e. at $t \to \infty$: it can be obtained from the expression $P = \hbar\omega_L VW'$, where P is the generated power, $\hbar\omega_L$ is the energy of the laser photon, and V is the volume of the laser tube.

Ignoring the radiation loss in the resonator we can write

$$W'f(\alpha, \gamma_2, t_l) = [\mathrm{CO_2}]\exp(-\hbar\omega(10^\circ 0)/kT).$$

Inserting into this expression experimental values of t_1, W', γ_2, and $[CO_2]$, and solving it for α, we obtain the rate constant for the transfer of vibrational energy from DF to CO_2: $(1.5 \pm 0.5) \times 10^{-12}$ cm^3 s^{-1} at 300 K. This is lower than the value obtained by other methods. For example, measurements of this constant from the laser-induced fluorescence of the DF molecules[21] and from their chemiluminescence[22] gave 6.4 ± 10^{-12} and 5×10^{-12} cm^3 s^{-1} at 350 and 300 K respectively.

The rate constant for the transfer of vibrational excitation from DF to CO_2 has been determined[23] with allowance for the loss of radiation in the optical resonator. The expression for the threshold population density of the upper lasing level of CO_2 includes a term which corrects for these losses. Allowance was made also for the time to establish quasi-stationary concentrations of F and D atoms (through the formation of fluorine atoms in the working mixture under the influence of light from the pulsed lamp). The shape of the pulse of radiation emitted by the lamp was described by the expression $k_0(t) = \gamma_1 t^3\exp(-\gamma_2 t)$, which gives a more exact time dependence of the radiation intensity than the expression $k_0(t) = \gamma_1 t\exp(-\gamma_2 t)$. The rate of the chemical reaction at the end of the light pulse was determined by comparing the characteristics of the laser working under different conditions rather than by measuring the power of the laser emission. With these improvements the rate constant for the transfer of energy from the first vibrational level of the DF molecule to the CO_2 molecule was found to be $(8.2 \pm 0.5) \times 10^{-12}$ cm^3 s^{-1}, i.e. close to the values obtained by other methods.

c) Relaxation of $HF^\dagger$ on chlorine fluorides. The oscillation delay time method has been used to measure the rate constants of the relaxation of vibrationally excited $HF^\dagger$ molecules in order to determine the role of this relaxation on the reactions of other species used in the chemical lasers. From the laser generation in $ClF_n + H_2(CH_4)$ mixtures the rate constants of the relaxation of $HF^\dagger$ molecules on various chlorine fluorides have been determined[24]. The main pre-threshold processes in these lasers are

$$ClF_n + h\nu \xrightarrow{s(t)} ClF_{n-1} + F$$

$$F + RH \xrightarrow{k_{RH}} HF(v) + R$$

$$HF(v) + RH \xrightarrow{k_{rel}^{RH}} HF + RH$$

$$HF(v) + ClF_n \xrightarrow{k_{rel}^{ClF_n}} HF + ClF_n$$

where k_{rel}^{RH} and $k_{rel}^{ClF_n}$ are the rate constants for the relaxation of HF(v) molecules on RH and ClF_n molecules respectively. The relaxation of HF(v) on HF can be ignored under these conditions, since the concentration of HF has been shown[2] to be three orders of magnitude lower than the concentration of reactants during the period preceding the achievement of the oscillation threshold.

The spectral composition of the radiation shows that $v = 2$ for the $ClF_5 + H_2(CH_4)$ and $ClF + H_2(CH_4)$ systems, i.e. that the first transition is $P_2(3)$. For the $ClF_3 + H_2(CH_4)$ system, $v = 1$, and the first transition is $P_1(6)$. Hence in the latter system the following relaxation is fast:

$$HF(v=2) + ClF_3 \rightarrow HF(v=1) + ClF_3, \quad (23)$$

The kinetic equations for the concentration of atomic fluorine and for the density Δn of population-inverted $HF^\dagger$ molecules take the form

$$\mathrm{d}[F]/\mathrm{d}t = s(t)[ClF_n]_0 - k_{RH}[F][RH]_0 \quad (24)$$

$$\mathrm{d}(\Delta n)/\mathrm{d}t = f_{RH}k_{RH}[F][RH]_0 - k\Delta n \quad (25)$$

where $s(t) = s_0 t\exp(-t/t_{max})$, t_{max} is the time at which $s(t)$ reaches a maximum, and

$$k = k_{rel}^{RH}[RH]_0 + k_{rel}^{ClF_n}[ClF_n]_0.$$

In order to determine the relaxation rate constants we must choose conditions such that the pressure of chlorine fluoride is higher than that of RH, since the constants k_{RH} and k_{rel}^{RH} are quite large [according to Hancock and Green[25], $k_{rel}^{H_2} = 0.7 \times 10^{-12}$ cm^3 s^{-1} for HF ($v = 1$)]. Solving the system of equations (24), (25) for the conditions

$$(k_{RH} + k_{rel}^{RH})[RH]_0 \ll k_{rel}^{ClF_n}[ClF_n]_0;\ 1/t_{max} \ll k_{rel}^{ClF_n}[ClF_n]_0$$

gives

$$\Delta n(t) = s_0\frac{f_{RH}k_{RH}}{2k^3}[(kt)^2 - 2kt + 2 - 2e^{-kt}], \quad (26)$$

The generation time lags with respect to the leading edge of the initiating pulse were measured for exit mirrors made of Ge and CaF_2 (t_1' and t_1'' respectively). Since $g_0 \propto \Delta n$, by using the experimental time lags t_1' and t_1'' for two different mirrors but identical compositions of the reactant mixture we can obtain from Eqn.(10)

$$g_0''/g_0' = \Delta n(t_1'')/\Delta n(t_1') = \lg(1 - l'')/\lg(1 - l') = C \quad (27)$$

where l' and l'' characterise the radiative losses in the resonator with Ge and CaF_2 exit mirrors respectively. By combining (26) and (27) we obtain an equation for k. The constant C can be calculated[2] from the condition $C = (t_1''/t_1')^3 \cong$

3 for low pressures. To study the relaxation on ClF_3 molecules the system of equations (24), (25) must be supplemented by an equation describing the population of the first level as a result of the relaxation of the second level during process (23).

Table 1. Relaxation rate constants (10^{12} k_{rel}, cm^3 s^{-1}) of the vibrational excitation at 300 K, obtained by measurements of the time lag (I) and of the luminescence decay (II).

Process	I	II
$OD(v=1)+CO_2 \rightarrow OD(v=0)+CO_2$	1.9±0.7 [19]	—
$OD(v=1)+D_2 \rightarrow OD(v=0)+D_2$	0.031±0.007 [19]	—
$DF(v=1)+CO_2 \rightarrow DF(v=0)+CO_2$	8.2±0.5 [23]	6.4* [21]; 5 [22]
$HF(v=2)+ClF_5 \rightarrow HF(v=1)+ClF_5$	5.1±1.7 [24]	—
$HF(v=1)+ClF_5 \rightarrow HF(v=0)+ClF_5$		
$HF(v=2)+ClF \rightarrow HF(v=1)+ClF$	0.16±0.03 [24]	0.02** [26]
$HF(v=1)+ClF \rightarrow HF(v=0)+ClF$		
$HF(v=1)+ClF_3 \rightarrow HF(v=0)+ClF_3$	5.6±1.7 [24]	3.4 [27]

*At 350 K.
**For the second process.

Numerical values of the relaxation rate constants are given in Table 1. The k_{rel} values are combined constants for the relaxation of the second and first level for ClF_5 and ClF, and of the first level for ClF_3. These values agree in order of magnitude with the relaxation rate constants calculated from luminescence quenching data[26,27].

d) The $HCl^+ + HCl$ *relaxation.* Gorshkov and coworkers[28] measured the rate constant of the exchange reaction

$$HCl(v=m)+HCl(v=n) \rightarrow HCl(v=m-1)+HCl(v=n+1)$$

by comparing calculated and measured time dependences of the amplification in an HCl chemical laser. The apparatus consisted of two chemical lasers initiated by flash photolysis and working on an $H_2 + Cl_2$ mixture, mounted on a common optical axis, and operated in the oscillator regime and as an amplifier respectively. The reaction in the oscillator (with formation of a laser pulse) was started at a known time after the beginning of photolysis in the amplifier. The amplification of the oscillator output was determined in a series of experiments with increasing time intervals between the pulses in the amplifier and the oscillator. A computer programme based on the accepted model of the ($H_2 + Cl_2$) laser was used to calculate the time dependence of the population inversion and of the amplification for a single vibrational–rotational transition of the HCl molecule. A comparison of the experimental results with those of the computer model gave the probable range of values for the rate constant of the relaxation of HCl^+ by ν–ν exchange.

III. DETERMINATION OF THE KINETIC CONSTANTS BY MEASURING THE OSCILLATION DECAY TIME

The measurement of the rate constant of the "pumping" reaction from the shape of the laser pulse depends on the fact that the relaxation of the lasing molecules, as well as several other processes, can be ignored under certain experimental conditions (low pressure, short and weak initiation reaction). In this case the decay of the laser signal is exponential, with an exponent depending only on time, on the rate constant of the "pumping" reaction, and on the initial concentration of the molecules taking part in that reaction.

1. Principle of the Method

The first reported measurement[29] of the rate constant of a "pumping" reaction from the shape of the laser pulse was aimed at determining the rate constants of the reactions of atomic fluorine with hydrogen, methane, and hydrogen chloride molecules. A more detailed description of the method appears in Ref.30, where an $NF_3 + H_2(D_2)$ laser is used to determine the rate constants of the reactions of atomic fluorine with hydrogen and deuterium molecules. The main processes in the working mixture of such a laser are:

$$NF_3 \xrightarrow{k_1} F + NF_2 \text{ (initiation)}$$

$$F + H_2 \xrightarrow{k^n_{H_2}} HF(v=n) + H \quad (1)$$

$$HF(v=n) + HF(v=m) \underset{}{\overset{k_2}{\rightleftarrows}} HF(v=n-1) + HF(v=m+1) \quad (28)$$

$$HF(v=n) + H_2(v=m) \underset{}{\overset{k_3}{\rightleftarrows}} HF(v=n-1) + H_2(v=m+1) \quad (29)$$

$$H_2(v=n) + H_2(v=m) \underset{}{\overset{k_4}{\rightleftarrows}} H_2(v=n-1) + H_2(v=m+1) \quad (30)$$

$$HF(v=n) + M \xrightarrow{k_5} HF(v=n-1) + M \quad (31)$$

$$H_2(v=n) + M \xrightarrow{k_6} H_2(v=n-1) + M \quad (32)$$

$$HF(v=n) \xrightarrow{k_7} HF(v=n-1) + h\nu_{n,n-1} \quad (33)$$

$$HF(v=n) + h\nu_{n,n-1} \rightleftarrows HF(v=n-1) + 2h\nu_{n,n-1} \text{ (stimulated emission)}.$$

In this scheme (1) is the "pumping" reaction, (28), (29), and (30) describe vibrational–vibrational energy exchange (for seven HF levels and three H_2 levels), (31) and (32) are vibrational–translational energy exchange processes, and (33) is the spontaneous emission from HF^+.

Difficulties in this method arise from the influence of a large number of elementary processes on the rate of excitation of the vibrational levels of the HF molecules, which determines the power of the oscillation. If the rates of these processes are comparable, it is not easy to extract information on any particular elementary act from the time dependence of the laser power. Therefore the constants can be determined by the "oscillation decay" method only if the parameters of the system are chosen so that the elementary act of interest plays a predominant role among all the other possible elementary acts.

Numerical calculations[30] for the $NF_3 + H_2$ system have shown that such a regime can be realised at low pressures of the $NF_3 + H_2$ mixture ($\leq$10 mmHg) and by using a weak initiation of the reaction ($[F]_0 \leq 10^{14}$ cm^{-3}). The calculations took account of reactions (1) and (28)–(33). They led to the conclusion that under certain conditions the main contribution to the excitation of the vibrational levels of HF comes from the reaction $F + H_2 \rightarrow HF(\nu = n) + H$. The contributions from other processes are at least two orders of magnitude lower (Fig.3).

By examining the material balance equations for the density of photons in the resonator and for the occupancy of the vibrational levels of HF we can show that in the quasi-stationary approximation the power of the laser radiation (in the absence of relaxation processes) is proportional to the rate of "pumping" by the reaction $F + H_2 \rightarrow HF^+ + H$. The balance equations which allow for the chemical pumping and

for the stimulated emission are

$$dn_v/dt = \alpha_v W(t) - B_{v,v-1}\Delta_{v,v-1}\rho_{v,v-1} + B_{v+1,v}\Delta_{v+1,v}\rho_{v+1,v}$$

$$d\rho_{v,v-1}/dt = B_{v,v-1}\Delta_{v,v-1}\rho_{v,v-1} - \rho_{v,v-1}/\tau_p$$

where n_ν is the population density of the vibrational level ν, $\rho_{\nu,\nu-1}$ is the density of photons in the resonator, α_ν is the probability of forming a molecule in the level ν by an elementary reaction act, $B_{\nu,\nu-1}$ is the Einstein coefficient for the stimulated emission by the transition $\nu \to \nu - 1$, τ_p is the lifetime of a photon in the resonator, $\Delta_{\nu,\nu-1}$ is the difference in population density between the levels ν and $\nu - 1$, and $W(t)$ is the reaction rate, i.e.

$$W(t) = k_{H_2}[F][H_2], \qquad (34)$$

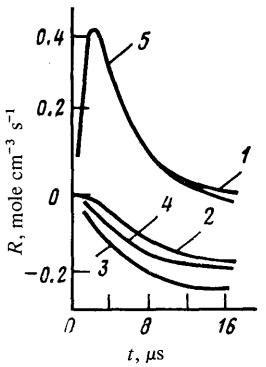

Figure 3. Rate of excitation R_i of the HF vibrational levels in the i-th process as a function of time t: *1*) $10^5 R_1$, *2*) $10^8 R_{28}$, *3*) $10^7 R_{29}$, *4*) $10^8 R_{31}$, *5*) 10^5 d[HF($\nu = 2$)]/dt.

The suggestion that laser action takes place in one vibrational–rotational transition of each band ($\nu \to \nu - 1$) does not materially affect these conclusions[30].

The power density of the radiation emerging from the resonator is

$$P = \sum_v \frac{\rho_{v,v-1}}{\tau_p}\hbar\omega_{v,v-1}.$$

For the scheme involving four equidistant levels in the quasi-stationary approximation ($d\rho_{\nu,\nu-1}/dt = d\Delta_{\nu,\nu-1}/dt = 0$) we can write

$$P = \frac{1}{2}\hbar\omega_L W(t)(3\alpha_3 + \alpha_2 - \alpha_1 - 3\alpha_0) \qquad (35)$$

where $\hbar\omega_L$ is the energy of the laser photon.

Since the concentration of fluorine atoms $[F]_0$ created by the initiating pulse is small in comparison with the initial concentration of hydrogen molecules $[H_2]_0$ we can put $[H_2]_t = [H_2]_0$. Then,

$$[F]_t = [F]_0 \exp(-k_{H_2}[H_2]_0 t), \qquad (36)$$

In the derivation of Eqn.(36) the initiating pulse was assumed to be shorter than the characteristic time of the chemical reaction. This assumption is valid under the chosen experimental conditions. From (34) and (36) we arrive at

$$\ln P(t) \sim k_{H_2}[H_2]_0 t.$$

Thus, having determined τ (the time constant of the decay of the laser pulse), and knowing $[H_2]_0$, we can calculate the rate constant:

$$k_{H_2} = 1/\tau[H_2]_0.$$

The heating of the gas by elastic collisions of electrons and heavy particles can be shown to be negligible[31]. The heating effect of the chemical reaction on the gas mixture is estimated to be less than 1 K. Heating through the relaxation of the vibrational energy of the molecules excited by the discharge becomes appreciable (at low pressures) during the later stages of the process, when the chemical reaction has gone to completion. We can therefore assume that the reaction takes place isothermally at the wall temperature of the reaction vessel.

The k_{H_2} and k_{D_2} constants have been measured[30] at 195 and 295 K. The k_{H_2} value for 295 K was close to the recommended[32] value $k_{H_2} = 2.5 \times 10^{-11}$ cm^3 s^{-1}. On the other hand the value $k_{H_2} = 6.3 \times 10^{-11}$ cm^3 s^{-1}, given in Ref.29 for room temperature, is too high, possibly because some of the fluorine atoms taking part in the reaction F + H_2 had an excess of energy, acquired during the photo-initiation. Under the chosen experimental conditions[29] the thermalisation time of the "hot" fluorine atoms could have been comparable to the time of the chemical reaction.

The decay of laser action for reactions initiated by an electric discharge has been used to determine the rate constants of reactions between fluorine atoms and a series of organic and of inorganic molecules[33]. However, the experimental conditions were not optimised for the measurement of rate constants, and the results may be in error by a factor of 1.5–3.

2. Comparison of the Rate Constants of the Reactions of Fluorine Atoms Determined by Different Methods

Rate constants determined from measurements of the delay of time agree satisfactorily with those calculated from the decay of laser oscillation[3]. Measurements of the oscillation decay time in conjunction with initiation by an electric discharge have been used to determine the rate constants of the reactions of fluorine atoms with hydrogen, methane, and hydrogen chloride molecules. By measuring the generation time lag (with photo-initiation) the ratios k_{CH_4}/k_{H_2} and k_{HCl}/k_{H_2} have been determined. The results are summarised in Table 2, from which we note that in spite of the different methods of initiation the agreement between the various results is generally good.

For comparison Table 2 also gives the rate constants obtained by other methods. For the k_{H_2}, k_{CH_4}, and k_{HCl} constants, which have been measured in many laboratories, we have adopted the values recommended in recent review articles[32,34]. It is evident from Table 2 that the rate constants determined by laser methods are fully consistent with those obtained by other methods.

Thus, in spite of the many assumptions necessarily made in the laser methods of determining kinetic constants (neglect of the relaxation of the population-inverted molecules, constancy of reactant concentrations, and failure to allow for the slower reactions), the reaction rate constants measured by these methods are as precise as those measured by other methods.

IV. THE COMPETING REACTION METHOD OF MEASURING THE RATE CONSTANTS OF REACTIONS IN CHEMICAL LASERS

The main weakness of the above laser methods of determining the kinetic constants of reactions between atoms and molecules is their severely limited range of application (to "pumping" reactions only). The scope of the method was broadened very substantially by our development[43] of a variant based on the standard kinetic method of using competing reactions. A substance whose molecules can interact with the atoms involved in the "pumping" reaction is introduced into the active medium of the laser. As a result, the atoms are contributing to two reactions in parallel within the chemical laser: 1) the "pumping" reaction, leading to laser action, and 2) the competing reaction, which suppresses the rate of the "pumping" reaction by lowering the concentration of the participating atoms. This leads to an increase in the oscillation delay time, and to a decrease in the decay time constant of the laser action. By measuring these characteristic times in the presence and in the absence of the competing reaction we can determine its rate constant.

Table 2. Comparison of the rate constants for F + X reactions determined by different methods at 300 K.

X	$10^{11}k_X$, cm^3 s^{-1}	k_X/k_{H_2}	Method
H_2	2.5	—	I [32]
H_2	2.4±0.1	—	II [30]
H_2	2.2±0.4	—	II [3]
D_2	2.12±0.10	0.86	II [30]
D_2	—	0.56	III [15]
D_2	—	0.62	IV [35]
D_2	—	0.61	V [36]
D_2	—	0.52	VI [37]
D_2	2.14	0.59	VII [38]

Br_2	31±9	—	VI [41]

Notes. The k_X values for X = O_2 + O_2 and X = O_2 + N_2, determined by measuring the time lag[4] and by ESR respectively[42], are (1.0 ± 0.3) × 10^{-32} and (1.4 ± 0.4) × 10^{-32} cm^6 s^{-1}. Methods: I) recommended value, II) measurement of decay time, III) chemical laser, IV) competing reactions, V) calculated, VI) mass spectrometric, VII) ESR, VIII) measurement of delay time, IX) i.r. chemiluminescence.

*Value of k_{HBr}/k_{CH_4}.

**Assuming k_{CH_4}/k_{H_2} = 2 (after Ref.3).

The application of the competing reaction method in chemical lasers has substantially increased the range of reactions whose rate constants can be measured by laser methods. By using competing reactions we can measure the rate constants of a large number of reactions which do not give rise to laser emission. The combined method has been applied in a number of reactions between fluorine atoms and various molecules.

1. Application of the Method in Measurements of the Oscillation Delay Time

The competing reaction method was first used in conjunction with measurements of the delay time to determine the rate constant of the F + Cl_2 reaction[3], by measuring the generation time lag in H_2 + RF + He and H_2 + RF + Cl_2 + He mixtures.

The main processes in the H_2 + RF + Cl_2 + He mixture are

$$RF + h\nu \rightarrow R + F$$

$$F + H_2 \xrightarrow{k_{H_2}} HF^\dagger + H \qquad (1)$$

$$F + Cl_2 \xrightarrow{k_{Cl_2}} ClF + Cl\,. \qquad (37)$$

The Cl + H_2 reaction can be ignored, because its rate is much lower than the rates of reactions (1) and (37).

By solving the equation for the time dependence of the concentration of atomic fluorine (assuming a linear time dependence of the initiating light flux and constant reactant concentrations) we can find the threshold concentration of population-inverted excited $HF^\dagger$ molecules:

$$\Delta n_{thr} = f_{H_2} \int_0^{t_3} k_{H_2}[H_2]_0[F]_t\,dt\,.$$

The delay times of laser action by the $P_2(3)$ transition of the $HF^\dagger$ molecule were measured in H_2 + RF + Cl_2 + He and H_2 + RF + He mixtures (t_{l_1} and t_{l_2} respectively). Under these conditions $\Delta n_{thr\,1} = \Delta n_{thr\,2}$. Hence we can obtain a transcendental equation for determining k_{Cl_2}.

The same method was used[4] to determine the rate constants of the reactions

$$F + Br_2 \xrightarrow{k_{Br_2}} FBr + Br$$

$$F + O_2 + O_2 \xrightarrow{k_{O_2}} FO_2 + O_2\,,$$

2. Application of the Method in Measurements of the Oscillation Decay Time

a) Principle of the method. The oscillation decay time is measured for the $HF^\dagger$ molecules of a chemical laser operating on a mixture of RF + H_2 + X + He, where X is a molecule for which we wish to determine the time constant of the reaction with atomic fluorine (k_X).[43] In this laser reaction (1) is the "pumping" reaction. In the presence of the X molecules, which react with fluorine atoms, reaction (1) competes with the following reaction:

$$F + X \xrightarrow{k_X} \text{products}\,. \qquad (38)$$

Reaction (38) lowers the rate of reaction (1) and shortens the time constant of the decay of the laser action. Since at low pressures and for short and weak initiating pulses the oscillation strength is proportional[30] to the rate of reaction (1), and therefore to the concentration of atomic fluorine, the decay of the signal in this case is described by an exponential function with the exponent

$$-(k_{H_2}[H_2]_0 + k_X[X]_0)t$$

where $[H_2]_0$ and $[X]_0$ are the initial concentrations of hydrogen molecules and of the additive respectively. By

measuring the time constant of the decay of the laser signal (τ), and knowing $[H_2]_0$ and $[X]_0$, we can calculate k_X:

$$k_X = 1/\tau[X]_0 - k_{H_2}[H_2]_0/[X]_0.$$

The rate constant of the reference reaction (k_{H_2}) is accurately known. If necessary, other chemical laser "pumping" reactions can be used as the reference reaction.

This method was first used[3] to determine the rate constant of the reaction $F + Cl_2 \xrightarrow{k_{Cl_2}} FCl + Cl$, in conjunction with the following "pumping" reactions:

$$F + CH_4 \rightarrow CH_3 + HF^\dagger$$
$$F + HCl \rightarrow HF^\dagger + Cl.$$

The constant $k_{Cl_2} = (6.2 \pm 3.1) \times 10^{-11}$ cm^3 s^{-1} at 300 K was obtained.

b) Use of the method to measure the rate constants of the reactions of fluorine atoms with organic molecules containing multiple bonds. The determination of these constants is complicated by the simultaneous presence of two reactions: the removal of an F atom with formation of HF and the addition of an F atom at the multiple bond. The addition reaction does not lead to the formation of $HF^\dagger$ molecules with a population inversion. The removal reaction may cause inversion [for example, $F + C_2H_4$, $F + C_3H_6$, $F + iso\text{-}C_4H_8$, $F + (CH_3)_2CO$], or it may produce HF molecules without population inversion (for example, in the $F + C_6H_6$ and $F + CH_3CN$ reactions).

Table 3. Rate constants of F + M reactions (where M is a molecule containing multiple bonds) at 300 K.

**At 283 K.

***The following methods were used to determine the total interaction constant k_{tot}: I) measurement of the oscillation decay time in conjunction with a competing reaction, II) measurement of the oscillation decay time, III) radio-gas chromatography.

However, even if laser action takes place with the HF molecules, it can be so weak as to make the rate constant of the reaction impossible to measure otherwise than by the competing reaction method. This situation exists, for example, in the reactions $F + C_2H_4$ and $F + (CH_3)_2CO$, and therefore the rate constants of these reactions were determined by the present method by arranging for these reactions to compete with the pumping reaction $F + H_2$. The same method was used to determine the rate constants of the reactions $F + C_6H_6$ and $F + CH_3CN$, since in these systems oscillation does not take place on HF. The rate constants of the reactions $F + C_3H_6$ and $F + iso\text{-}C_4H_8$ were measured in the usual way by using the formula $k_{RH} = 1/\tau[RH]_0$, where $RH = C_3H_6$ or $iso\text{-}C_4H_8$, since in these systems adequate laser action on the HF molecules was obtained[45]. The measured rate constants are listed in Table 3.

The main disadvantage of applying this method of measuring rate constants to molecules with multiple bonds is that the relative contributions of the addition and removal reactions cannot be distinguished, since the measurement gives the sum of the rate constants of these reactions. However, by using existing data on the ratios of these constants[46,47] and on the rate constants of the removal reactions calculated from i.r. chemiluminescence measurements[39] we can arrive at the separate rate constants of the removal reaction (k_{rem}) and of the addition reaction (k_{add}) for these molecules (Table 3). It is clear from Table 3 that the agreement between constants determined by the laser method[45], the luminescence method[39], and the radio-gas chromatography method[48–50] is satisfactory.

Of course, if the method is applied to molecules in which the addition reaction cannot take place these complications disappear, and the constants can be determined directly. The method is suitable also for other classes of molecules. The laser method in the competing reaction variant can be applied to any atom able to undergo a reaction in which excited molecules showing a population inversion are formed.

V. METHODS OF MEASURING THE RELATIVE RATE CONSTANTS FOR THE POPULATION OF DIFFERENT LEVELS IN THE REACTION PRODUCT

Measurements of the occupancy of different vibrational levels in the molecules of reaction products can be relevant in various applications of chemical kinetics. The use of chemical lasers can offer quantitative information on the population N_v of the vibrational levels of reaction products and on the relative rate constants k_v for the formation of the product in different vibrational states.

1. The "Equal Amplification Temperature" Method

The "equal amplification temperature" method allows the ratio of the rate constants k_v/k_{v-1} for the $v \rightarrow v-1$ transition, which has the maximum amplification, to be measured directly. The method was first proposed[51] for the $F + H_2$ and $F + CH_4$ reactions. By careful temperature control in chemical lasers operating with $UF_6 + H_2(D_2)$ and $UF_6 + CH_4(CD_4)$ mixtures, and using photo-initiation, conditions giving two vibrational–rotational transitions simultaneously and with the same amplification were obtained. The ratio N_v/N_{v-1} of the occupancies of the states taking part in the first transition at the generation threshold was determined. This ratio can be identified with the ratio k_v/k_{v-1} if vibrational deactivation can be ignored. Addition of a known amount of inert diluent is sufficient to bring about a rapid rotational equilibrium[52]. Under these conditions the rotational temperature of the system is close to the initial temperature of the laser mixture, which is determined by the external application of heat to the laser tube. The self-heating of the mixture as a result of the laser reaction is negligible.

The time lag between the beginning of the $P_2(4)$ and of the $P_2(3)$ transition of the HF molecule in the $UF_6 + H_2$ system was found to decrease as the temperature of the laser tube was increased, the intensity of the $P_2(3)$ transition

decreasing while that of the $P_2(4)$ transition increased. The temperature corresponding to equal time lags (and amplifications) for the $P_2(3)$ and $P_2(4)$ transitions was found. This temperature was termed the "equal amplification temperature" for the $P_2(3)$ and $P_2(4)$ transitions.

According to Patel[53], the relative amplification $\alpha_v(J)$ of the transition ($v \to v-1$, $J-1 \to J$) is

$$\alpha_v(J) = \text{const}\ \frac{JN_{v-1}}{kT_n^{1/2}T_{\text{rot}}}\left[\frac{N_v}{N_{v-1}}B_v \exp\left(\frac{-B_vJ(J-1)}{kT_{\text{rot}}}\right) - B_{v-1}\exp\left(\frac{-B_{v-1}J(J+1)}{kT_{\text{rot}}}\right)\right] \quad (39)$$

where k is Boltzmann's constant, B_v is the rotational constant of the vibrational level v, T_n is the translational temperature, and T_{rot} is the rotational temperature (with $T_n = T_{\text{rot}}$ in the present case). When the two transitions $P_v(J)$ and $P_v(J+1)$ have equal amplifications, i.e. $\alpha_v(J) = \alpha_v(J+1)$, the ratio N_v/N_{v-1} can be obtained from the previous equation:

$$\frac{N_v}{N_{v-1}} = \frac{B_{v-1}}{B_v} \times \times \frac{J\exp[-B_{v-1}J(J+1)/(kT_{\text{rot}})] - (J+1)\exp[-B_{v-1}(J+1)(J+2)/(kT_{\text{rot}})]}{J\exp[-B_vJ(J-1)/(kT_{\text{rot}})] - (J+1)\exp[-B_vJ(J+1)/(kT_{\text{rot}})]} \quad (40)$$

where T_{rot} is the equal amplification temperature. As was stated above, $N_v/N_{v-1} = k_v/k_{v-1}$.

The method has been used to obtain the ratios k_2/k_1 for the reaction F + H_2,[51] k_3/k_2 for the reaction F + D_2,[51] k_3/k_2 for the reaction F + CCl_3D,[54] and k_4/k_3 for the reaction F + HI.[55]

Berry and Pimentel[56] have modified Eqn.(40) in order to allow for vibrational–rotational interaction, which had been previously ignored. They also examined the effect of pressure on the shape (width) of the line and on the amplification, and they extrapolated their experimental results to low pressures. At the equal amplification temperature they measured the following ratios of the rate constants for the population of the levels in the HCl molecules produced by the light-induced removal of HCl from dichloroethylene: k_3/k_2 for the 1,1 isomer and k_2/k_1 for the *cis*- and *trans*-1,2 isomers.

The "equal amplification temperature" method gives only the k_v/k_{v-1} ratio: for the other ratios it can only give upper limits, since when the oscillation threshold is reached these transitions are affected by the previous laser emission. The method has been improved[57] by using a "tandem" chemical laser with two laser tubes in the same resonator simultaneously initiated by flash photolysis. In this case the ratio of the rate constants could be measured even for transitions which do not give maximum amplification. For the photodehydrochlorination of dichloro-ethylene the k_3/k_2 and k_2/k_1 ratios of the HCl molecules were obtained for the 1,1 isomer and for the *cis*-1,2 isomer.

Molina and Pimentel[58] have described another improvement of the "equal amplification temperature" method, involving the inclusion of a diffraction grating in the optical resonator. This allows previous selection of the vibrational–rotational transitions, and hence it allows the measurement of different k_v/k_{v-1} ratios (not only those corresponding to transitions with maximum amplification). The method was used to measure the k_1/k_0 ratio for the light-induced removal of HCl from 1,1-dichloro-ethylene. The agreement with the results obtained by other methods for the ratio of the rate constants was satisfactory[58].

The drawback of using a diffraction grating in the "equal amplification temperature" method is that only the ratios of constants for transitions with relatively high amplification can be measured, since the radiation losses in the resonator are rather high. This disadvantage can be overcome by combining the tandem laser configuration and the diffraction grating, as in the "zero amplification temperature" method[58].

2. The "Zero Amplification Temperature" Method

The method[58] relies on the fact that the relative amplification of the lines in the P and R branches has different dependences on J and T. If $N_v/N_{v-1} < 1$, a single transition in the P branch will have a positive amplification over a range of temperature, but on raising the temperature the amplification will change sign. On the other hand, if $N_v/N_{v-1} > 1$, the transition in the R branch will have positive amplification at certain temperatures but the amplification will become negative as the temperature is lowered. At almost any ratio of the level occupancies (not too close to unity) there will be transitions in the P and R branches with zero amplification at accessible temperatures. The temperature at which the amplification of the transition changes from positive to negative has been termed the "zero amplification temperature".

The apparatus includes two laser tubes within a single resonator (tandem scheme). The resonator consists of a mirror and a diffraction grating in the Littrow configuration, which allows operation of the laser only on one (chosen) transition. The "leading" reaction in one tube should have enough amplification to emit radiation from this transition without assistance from the "subsidiary" reaction in the second tube, for which we wish to measure the ratio of the rate constants. If the "subsidiary" reaction gives positive amplification for the transition being studied, the time lag will be shorter than in the absence of the "subsidiary" reaction. Conversely, if the "subsidiary" reaction gives negative amplification the time lag increases. By varying the temperature of the "subsidiary" reaction we can determine the "zero amplification temperature" of this reaction. The occupancy ratio can then be found from the "zero amplification" equation, obtained by equating to zero the amplification expression [Eqn.(39)]:

$$\frac{N_v}{N_{v-1}} = \frac{B_{v-1}}{B_v}\exp\left\{\frac{hc}{kT_{za}}[B_vJ(J\mp1) - B_{v-1}J(J\pm1)]\right\}$$

where the upper sign refers to the transition $P_v \to v-1$. $[(J-1) \to J]$ and the lower sign refers to the transition $R_v \to v-1[J \to (J-1)]$; T_{za} is the zero amplification temperature.

The "zero amplification temperature" method usefully complements the "equal amplification temperature" method. Each has a number of advantages, depending on the properties of the reaction of interest. The "zero amplification temperature" method needs a suitable "leading" reaction, offering stable generation of the required transitions with an amplification sufficient to overcome the relatively large losses in the resonator. If such a reaction can be found, the results are more readily interpretable than those of the "equal amplification temperature" method. In particular, there is no need to correct for vibrational–rotational interaction or for the pressure dependence of the line shape.

3. Determination of the Temperature Dependence of the Ratio of Constants

Though the chemiluminescence and molecular beam methods give qualitative information on the effect of temperature on the reactions of interest, a quantitative interpretation is very difficult. Chemical lasers offer a far more satisfactory

method of studying the temperature dependence of the distribution of the reaction product over the vibrational states. In the laser experiments the temperature is the primary experimental variable, and the conditions are chosen so as to ensure precisely defined rotational and translational temperatures.

Both the "equal amplification temperature" and the "zero amplification temperature" method can be used to obtain temperature dependences. The former can be used because the transitions with maximum amplification vary with temperature. For example[59], in the F + D_2 removal reaction the "equal amplification temperature" for the $P_3(4)-P_3(5)$ transitions ($v = 3 \rightarrow 2$ band) of the product DF is 301 K, for the $P_3(5)-P_3(6)$ transitions it is 567 K, and for the $P_3(3)-P_3(4)$ transitions it lies below 153 K. This gives the temperature dependence of the k_3/k_2 ratio.

The "zero amplification temperature" method can be used to obtain temperature dependence because transitions with different J values have different "zero amplification temperatures". Transitions for which the "zero amplification temperature" is accessible must be chosen. The method has been used[59] to determine the temperature dependence of the ratios of constants k_v/k_{v-1} for the F + H_2 removal reaction. For the $v = 3 \rightarrow 2$ band the measurements were carried out on transitions of the P branch, since in this case $k_3/k_2 < 1$. The "leading" reaction was F + HBr → HF^+ + Br. For the $v = 2 \rightarrow 1$ band the measurements were made on the R branch because in this case $k_2/k_1 > 1$. This time the "leading" reaction was F + CH_4 → HF^+ + CH_3. By using a combination of the "equal amplification temperature" and the "zero amplification temperature" method the temperature dependence of the ratios of constants k_3/k_2 and k_2/k_1 was obtained[59]. The combined method has also been used[60] to study the effect of rotation on the distribution of vibrational energy in the F + H_2 reaction at different temperatures by using hydrogen enriched with the *para*-modification.

The temperature dependence of the ratio of constants has been obtained[61] also for another class of reactions: insertion–removal between NH and fluoromethanes. Though the flash photolysis of HN_3 in the presence of fluorinated methanes and argon does not yield laser generation, it was possible to measure the k_v/k_{v-1} ratios as a function of temperature for CF_4, CF_3H, and CF_2H_2 by using the "zero amplification temperature" method in a tandem scheme.

4. The "Diffraction Grating Selection" Method

This method relies on a frequency-selective resonator consisting of a mirror and a diffraction grating in the Littrow configuration. As mentioned above this resonator allows the laser to be operated on a single, chosen, vibrational–rotational transition. Measurements of the relative time lags of the various transitions can be used to characterise the vibrational population inversion in terms of the optical amplification coefficients[15]. According to Patel[62],

$$\alpha_{v,J\rightarrow v',J'} = (\text{const})\, \nu \Delta\nu_D^{-1} |R_{v,J\rightarrow v',J'}|^2 \left(\frac{N_{v,J}}{g_J} - \frac{N_{v',J'}}{g_{J'}}\right) H^P_{v,J\rightarrow v',J'} \quad (41)$$

where ν is the frequency of the transition and $\Delta\nu_D$ is its Doppler width. Furthermore,

$$|R_{v,J\rightarrow v',J'}|^2 = |M_{v\rightarrow v'}|^2 S_{J'} F_{v,J\rightarrow v',J'}$$

where $M_{v \rightarrow v'}$ is a matrix element of the transition, $S_{J'} \equiv J'$ for transitions of the P branch and $S_{J'} \equiv J' + 1$ for transitions of the R branch, $F_{v,\ J\rightarrow v',\ J'}$ is the vibrational–rotational interaction factor, and $H^P_{v,\ J\rightarrow v',\ J'}$ is a correction factor for the line width, depending on the pressure, which includes the Doppler and the collision broadening. For a rotationally thermalised sample we have

$$N_{v,J} = N_v g_J \exp[-\Delta E^v_{\text{rot}}(J)/kT]/Q^v_{\text{rot}}$$

where $\Delta E^v_{\text{rot}}(J)$ is the rotational energy of the state (v, J), and Q^v_{rot} is the rotational distribution function.

The amplification coefficients were calculated from published data on the transition frequencies, rotational energies, vibrational matrix elements, vibrational–rotational interaction factors, and collision line widths. For the amplification to be positive, the population inversion ($N_{v,\ J}/g_J - N_{v',\ J'}/g_{J'}$) in Eqn.(41) must be positive. This requirement leads to the following conditions: for a transition in the R branch

$$\frac{N_v}{N_{v-1}} \geqslant \frac{Q^v_{\text{rot}}}{Q^{v-1}_{\text{rot}}} \exp\left(\frac{\Delta E^v_{\text{rot}}(J+1) - \Delta E^{v-1}_{\text{rot}}(J)}{kT}\right)$$

and for a transition in the P branch

$$\frac{N_v}{N_{v-1}} \geqslant \frac{Q^v_{\text{rot}}}{Q^{v-1}_{\text{rot}}} \exp\left(\frac{\Delta E^v_{\text{rot}}(J-1) - \Delta E^{v-1}_{\text{rot}}(J)}{kT}\right),$$

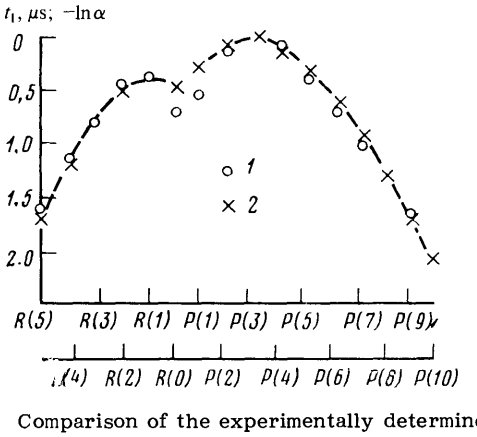

Figure 4. Comparison of the experimentally determined delay time t_1 (*1*) and the calculated values ln α (*2*) for $v = 2 \rightarrow 1$ transitions in HF. The amplification coefficients were calculated by Eqn.(41) for $N_2/N_1 = 3.35$ (without allowing for the factor $H^P_{v,\ J\rightarrow v',\ J'}$). The −ln α values for the $P_2(3)$ and $P_2(8)$ transitions were fitted to the measured delay times by using the expression $\alpha = \exp(-at_1)$. Introducing the pressure correction into Eqn.(41) improves the agreement for $N_2/N_1 = 3.45$ and the correspondence between the $R_2(0)$ and $P_2(1)$ transitions, which have anomalously high collision line widths.

Thus we can obtain the lower limits for $N_v/N_{v-1} = k_v/k_{v-1}$ by suitably choosing the experimental conditions (no relaxation effects, rotational equilibrium, constant temperature during the laser action). Furthermore these quantities can be determined by comparing experimentally measured time lags with calculations by the empirical equation $\alpha = \exp(-at_1)$, where a is an empirical constant.

The agreement between experimental and calculated values of t_1 is optimised by varying N_v/N_{v-1} in Eqn.(41). The procedure is illustrated in Fig.4 for the transitions of the

$v = 2 \rightarrow 1$ band of the HF molecule formed in the reaction $F + H_2$. In this way the k_v/k_{v-1} ratios have been determined for the reactions $F + H_2$, $F + D_2$, F + HD, and F + DH.[15] The results are given in Table 4. For comparison the Table also gives some values of k_v/k_{v-1} obtained by i.r. chemiluminescence and corrected (for the first time) for (v, v) and (v, R, T) energy transfer. The v–v exchange for HF → HF and HF → H_2 and the v–R, T exchange with HF, H_2, F, Ar, CF_3I, and N_2H_4 have been calculated[63]. It was shown that for the $F + H_2$ reaction the initial N_2/N_1 ratios (equal to k_2/k_1) should be greater than those measured at time t_1. The ratio N_3/N_2 is almost insensitive to the energy exchange processes, whereas N_1/N_0 is extremely sensitive and very difficult to determine.

Table 4. k_v/k_{v-1} ratio for the HF (DF) molecules formed by removal reactions at 300 K.

**Measured by i.r. chemiluminescence: all other values obtained by a chemical laser method.

***Estimated from the intensity of the laser bands in the free oscillation regime.

The "diffraction grating selection" method can be used to study some isotope effects[15]. Obviously,

$$\alpha_{v,J\rightarrow v'jJ'} = N_{\text{tot}}\,\alpha'_{v,J\rightarrow v',J'}$$

where N_{tot} is the total number of HF molecules and α′ is the amplification coefficient per molecule.

If the reactant concentrations in the F + H_2 and F + HD systems are chosen so as to give identical amplification coefficients for the same transitions (as shown by the equality of the time lags) we can write

$$k_{F+H_2}[H_2]_0\,\alpha'_{F+H_2} = k^{HF}_{F+HD}[HD]_0\,\alpha'_{F+HD}$$

for equal concentrations of atomic fluorine in the two experiments and $[F] \ll [H_2]_0$, $[HD]_0$; k^{HF}_{F+DF} is the rate constant of the reaction $F + HD \rightarrow HF^{\dagger} + D$. These experiments gave $k^{HF}_{F+HD}/k_{F+H_2} = 0.38 \pm 0.03$ at 300 K, and $k^{DF}_{F+HD}/k_{F+D_2} = 0.50 \pm 0.03$, where k^{DF}_{F+DH} is the rate constant of the reaction $F + DH \rightarrow DF^{\dagger} + H$.

By combining these results with the kinetic isotope effect $k_{F+H_2}/k_{F+D_2} = 1.79 \pm 0.10$ at 300 K (obtained by measuring the full emission intensity in the free generation regime) we can calculate the intramolecular kinetic isotope effect $k^{HF}_{F+HD}/k^{DF}_{F+HD} = 1.4 \pm 0.1$ at 300 K.

The "grating selection" method has been used to study the distribution of vibrational energy in the HCl molecules formed by flash photolysis of different chloro-ethylenes[65]. Since vibrational relaxation was negligible under the conditions of those experiments we can write $N_v/N_{v-1} = k_v/k_{v-1}$. The results are shown in Table 5. For comparison the k_v/k_{v-1} values obtained by the "equal amplification temperature method" in several forms are also shown in the Table.

Table 5. k_v/k_{v-1} ratios for HCl molecules formed by photoremoval from M molecules at 300 K.

Notes. Methods: I) diffraction grating selection[65], II) equal amplification temperature[56], III) and IV) equal amplification temperature with a tandem arrangement[57] or a diffraction grating[58].

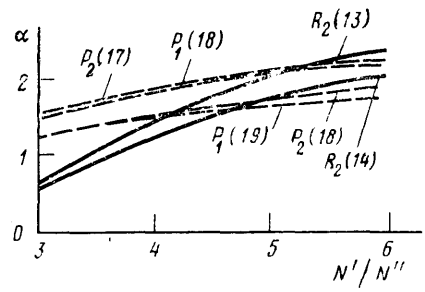

Figure 5. Relative amplification coefficients α as a function of the population inversion N'/N'' for some rotational transitions of the $A \rightarrow X$ (0, 0) band of the CN radical, calculated by assuming rotational and spin-orbit equilibrium of the CN* radical ($A^2\Pi_i$ at 300 K).

The frequency-selective resonator has been used also[66] to determine the ratio of the populations of the upper and the lower level of a laser working on an electronic transition of the CN radical formed by flash photolysis of methyl isocyanide. The relative optical amplification coefficients for the laser transitions in this case were calculated from the expression

$$\alpha = \text{const}\cdot S_{J'}\left(\frac{N'}{N''}\,\frac{\exp(-E'_{\text{rot}}/kT)}{Q'_{\text{rot}}} - \frac{\exp(-E''_{\text{rot}}/kT)}{Q''_{\text{rot}}}\right)\left(\frac{N'}{N''}+1\right)^{-1} \quad (42)$$

where $S_{J'}$ is the intensity of the rotational line, and the primes ′ and ″ refer respectively to the upper ($A^2\Pi_i$, $v' = 0$)

and the lower ($X^2\Sigma^+$, $v''=0$) laser level. The relative amplification coefficients are shown in Fig.5 as a function of the population inversion for several transitions of the $A \rightarrow X$ (0, 0) band of the CN radical. The intersections of these lines give the lower limits of the ratio N'/N''. For example, the transition R_2 (13) begins to emit before the transition P_1 (18), and therefore it has a greater amplification. This gives $N'/N'' > 5.1$. By comparing the curves for different transitions we see that $N'/N'' \cong k'/k'' > 5.3$, where k' and k'' are the rate constants of the processes which populate the upper and the lower level respectively. Similar calculations of the population ratio of the upper and the lower level can be made without a selective resonator for a laser working in the free generation regime, but in this case Eqn.(42) is applied only to the transition with maximum amplification. In this way the ratios $N'/N'' \cong k'/k''$ have been obtained for the populations of the upper ($A^2\Pi_{3/2}$, $v'=0$) and the lower ($X^2\Sigma^+$, $v''=0$) level of the CN radical formed by flash photolysis of CH_3NC, CF_3CN, HCN, C_2F_5CN, $(CN)_2$, and BrCN.[67]

The method has been used also to determine the population ratio of the upper and the lower level in HF and HCl molecules formed by insertion–removal reactions between $O(^1D)$ and fluorinated and chlorinated methanes[68–70]. The results are shown in Table 6.

Table 6. Estimates of the population ratios $N_v/N_{v-1} = k_v/k_{v-1}$ from the maximum amplification transitions for $O(^1D)$ + M addition–removal reactions.

M	Emitting molecule	v	k_v/k_{v-1}
CHF_3	HF	2	0.8 [68]
CH_3F	HF	1	0.35 [68]
$CHCl_3$	HCl	1	0.50 [69]
CH_3Cl	HCl	1	0.61 [69]
$CHCl_2F$	HF	2	0.8 [70]
$CHCl_2F$	HCl	1	0.5 [70]
$CHClF_2$	HF	2	0.8 [70]

The "grating selection" method was applied[71] in the determination of the relative population of levels in the HF molecule formed by the insertion–removal reaction $O(^3P)$ + fluoro-ethanes. The result was $N_1/N_0 \cong k_1/k_0 = 0.52 \pm 0.02$ for C_2H_3F and $N_1/N_0 \cong k_1/k_0 = 0.61 \pm 0.04$ for *cis* and *trans*-1,2-$C_2H_2F_2$ and C_2HF_3.

Thus the laser generation produced by chemical reactions in a resonator can yield important information on the rate of elementary processes in the reaction medium. Laser methods can be used to measure the rate constants of the reactions of atoms and radicals with molecules, the rates of transfer and relaxation of vibrational excitation, and the rate constants for the formation of the reaction product in different energy states. The use of competing reactions widens the scope of the laser methods and allows the rate constants of processes which are not true "laser" reactions to be determined. Thus the method has adequate generality. In spite of the many assumptions made in the oscillation delay time and oscillation decay methods, rate constants can be determined to a precision comparable to that of other methods. However, no other method is comparable to the laser methods for determining the state of vibrationally excited products.

Electronic Spectroscopy of Charge-transfer Complexes as a Method for the Investigation of Intramolecular Interactions in Organic and Organoelemental Compounds

P.G.Sennikov and A.N.Egorochkin

The application of electronic absorption and emission spectroscopy of intermolecular donor-acceptor complexes (charge-transfer complexes) in the study of intramolecular effects of substituents in organic and organoelemental compounds is considered.

The bibliography includes 176 references.

I. INTRODUCTION

When donor (D) and acceptor (A) molecules interact with partial transfer of electron density, a donor–acceptor complex [a charge-transfer complex (CTC)] is formed:

$$D+A \rightarrow [D^{\delta+}A^{\delta-}]. \quad (1)$$

The theory of the CTC and their role in physical and chemical processes have already been considered[1-10], but virtually no systematic account has been given of data concerning the application of the electronic spectra of intermolecular CTC to the study of intramolecular interactions in donor and acceptor molecules, particularly in the case of organoelemental donors.

According to Eqn.(1), the appearance of fractional charges in D and A is accompanied by a redistribution of electron density in the molecules. However, for the ground state (GS) of weak π,π and π,σ complexes (which will be the subject of subsequent discussion) such redistribution is slight as a consequence of the small charge transfer from the donor to the acceptor[1,3]. In the ground states of the remaining complexes the contribution of the valence (donor–acceptor) interactions is not decisive in the overall balance of the intermolecular forces (see, for example, Foster[6]). When the complex undergoes a transition to an excited state, the electronic configurations of the species comprising the complex are altered even in the case of weak D–A bonds and the degree of charge transfer from D to A increases sharply. On the basis of the Mulliken theory[3], one can therefore speak of a new energetic state of the components of the complex—the charge-transfer state (CTS). In particular, the parameters of the electronic spectra of weak CTC contain information about this state. It is shown below that the intramolecular interactions in the ground and charge-transfer states as a rule do not differ in principle but many fine effects in the CTS are manifested more distinctly. Therefore the excited state of the CTC constitutes a convenient model for the investigation of a wide variety of problems associated with the distribution of electron density in the CTC components.

The main studies of recent years, devoted to the intramolecular interactions in the molecules of π-donors (derivatives of benzene, naphthalene, certain heterocyclic compounds, etc.) using the electronic spectroscopy of weak CTC, are analysed in this review. Particular attention is devoted to organoelemental π-donors.

II. ELECTRONIC ABSORPTION SPECTRA OF CHARGE-TRANSFER COMPLEXES

1. Principles of the Application of the Spectroscopy of Charge-Transfer Complexes in the Study of Intramolecular Interactions

The charge-transfer frequency ν_{CT} (the parameter which is most readily determined experimentally and is proportional to the energy of the transition with charge transfer) and the intensity of the charge-transfer band in the electronic absorption spectra of the CTC can be used to investigate the nature of the distribution of electron density in the donor molecules[3]. Fig.1 presents the energy diagram for a weak CTC, from which it follows directly that the energy of the electron transition with charge transfer is defined by the equality

$$h\nu_{CT} = W_E - W_N = W_E - \Delta H = I_D - E_A + E_C + R_E - W_N \quad (2)$$

where W_E and W_N are the energies of the excited and ground states of the CTC respectively, $W_N = \Delta H$ is the enthalpy of formation of the CTC (for weak complexes, $|\Delta H| < 10$ kcal mol^{-1}), I_D the "adiabatic" ionisation potential of the donor molecule, equal to the energy of the electronic transition from the lowest vibrational level of the ground state of the neutral molecule to the lowest vibrational level of the ion D^+, E_A the "adiabatic" electron affinity of the acceptor A, E_C the Coulombic energy whose evolution stabilises the complex in the excited state, and R_E the energy of the destabilisation of the excited complex due to the contribution of the structure D...A, the interaction in which is of the van der Waals type. The contribution of this structure to the ground state of the CTC is decisive[3], the system being stabilised by the "charge transfer energy" R_N.

The quantitative relation between the energy of the charge-transfer transition $h\nu_{CT}$, the ionisation potential of the donor I_D, and the electron affinity of the acceptor E_A is[1]

$$h\nu_{CT} = I_D - (E_A - E_C + W_0) + (\beta_0^2 + \beta_1^2)/[I_D - (E_A - E_C + W_0)], \quad (3)$$

where W_0 is the sum of the terms characterising the van der Waals interaction in the ground state, $\beta_0 = H_{01} - W_0 S$ and $\beta_1 = H_{01} - W_1 S$ are matrix elements with $H_{01} = \int \psi_0 H \psi_1 d\tau$ and $S = \int \psi_0 \psi_1 d\tau$, ψ_0 and ψ_1 being the wave functions of the structures D...O and D^+A^- respectively.

A parabolic relation between $h\nu_{CT}$ and I_D has been obtained for weak complexes of the π,π and π,σ types involving a series of isotypical donors and a constant acceptor[1]:

$$h\nu_{CT}=I_D-C_1+C_2/(I_D-C_1) \quad , \qquad (4)$$

where C_1 and C_2 are constants whose significance is clear from a comparison of Eqns.(3) and (4). For donors with ionisation potentials in the range $7 < I_D < 9$ eV, Eqn.(3) can be satisfactorily approximated by the linear relation[11]

$$h\nu_{CT}=aI_D+b \quad , \qquad (5)$$

where a and b are constants. For CTC between π-donors and iodine, $a = 0.87$ and $b = 0.36$.[1]

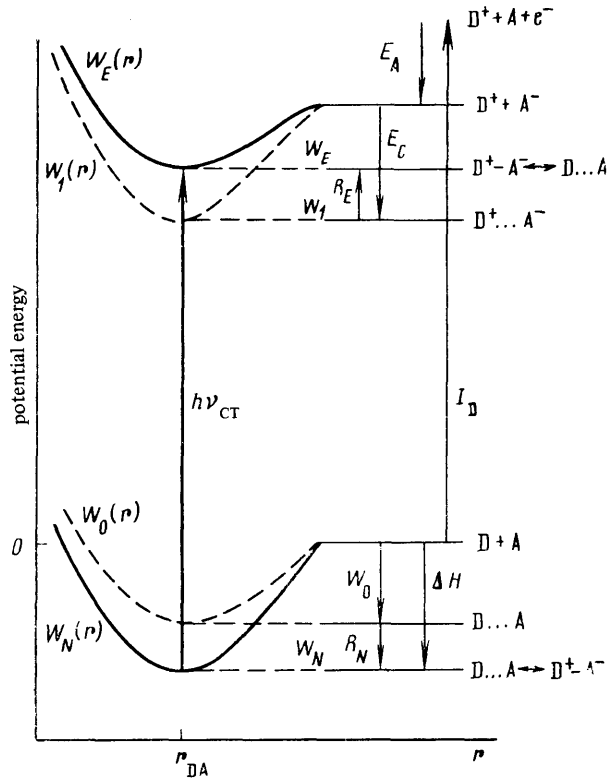

Figure 1. Energy diagram for a weak charge-transfer complex.

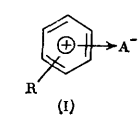
Eqn.(5) defines the dependence of the frequency ν_{CD} on the influence of the substituents and the donor, since I_D reflects the change in the donor–acceptor properties of the donor molecule on substitution. This follows, for example, from the Koopmans theorem[12], according to which the ionisation potential of the ith energy level of the molecule is approximately equal to the energy of the corresponding molecular orbital (MO) with the sign reversed.

On the other hand, the Hammett σ constants are traditionally used in physical organic chemistry for the estimation of the effects of substituents. The criterion of the applicability of a particular parameter (including the spectroscopic parameter) to the determination of the dependence of the reactivity of the structure is provided by a linear relation between the parameter and the σ constants[13,14]. It is also necessary that the correlated parameter should have the significance of the Gibbs free energy for the given process. The literature data (see, for examples, Ref.15–17), show the applicability of the Hammett relations to weak donor–acceptor interactions, i.e. the following linear relation holds for the ground states of π,π- and π,σ-complexes (as well as n,σ-complexes [5]):

$$\ln\frac{K_x}{K_0}=\rho_{CT}\sigma \quad , \qquad (6)$$

where K_x and K_0 are the equilibrium constants for the complex formation processes involving substituted (K_x) and (K_0) donors, ρ_{CT} is the reaction constant [corresponding to Eqn.(1)], which depends only on the type of process and characterises the sensitivity of the reaction centre to the influence of substituents, and σ is the constant of the substituent determined by its nature and position in the molecule.



As for the usual chemical processes[13,14], the applicability of Eqn.(6) to the formation of CTC has been studied in detail for benzene derivatives. For three acceptors differing significantly as regards their electron affinities (the affinities[19] E_A are given in brackets), the values of ρ_{CT} (cal mol^{-1}) are as follows[18]: -0.41 for 1,3-dinitrobenzene (0.9), -0.59 for p-chloranil (2.0), and -0.98 for tetracyanoethylene (2,3). The low values of ρ_{CT} indicate a low degree of charge transfer in the ground states of weak CTC and a low sensitivity of the ground states of benzene derivatives (D) to the electronic influence of the substituents in processes of type (1). On transition of the CTC to an excited state, the degree of charge transfer increases sharply (for the excited state of the hexamethylbenzene–tetracyanoethylene complex, it is approximately 0.8 compared with 0.05–0.1 for the ground state[1]).

The values of ρ^*_{CT} (cal mol^{-1}) in the CTS of benzene derivatives (complexes with tetracyanoethylene) are between -10 (Kuznetsov et al.[20]) and -19 (Hanstein et al.[21]). This indicates, firstly, a high sensitivity of the charge-transfer state of the π-donors to the electronic effects of the substituents and, secondly, shows that the use of the excited states of the CTC as a model for the investigation of the mechanisms of certain electrophilic addition reactions is promising because the above values of ρ^*_{CT} are close to the values of ρ for many of the reactions characterised by an ionic transition state. It follows from the principle of the linear free energy relations[13] that[18,21]

$$(h\nu_{CT,x}-h\nu_{CT,0})/(2,3RT)=\rho^*_{CT}\sigma \quad , \qquad (7)$$

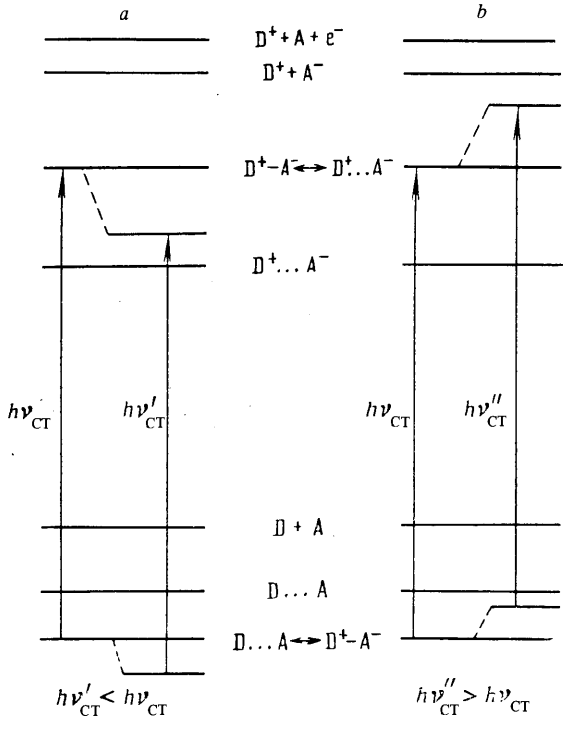
where $h\nu_{CT,x}$ and $h\nu_{CT,0}$ (cal) are the energies of the charge-transfer transitions of substituted and unsubstituted donor molecules respectively, R the gas constant, T(K) the absolute temperature, and ρ^*_{CT} (cal mol^{-1}) the reaction constant referring to the formation of an excited CTC. The energy of the charge-transfer transition and the σ constants of the substituents are in this case determined in a liquid solution, i.e. with allowance for the solvation effect.

The structure of the excited state of the CTC involving benzene derivatives is usually represented schematically as follows:

(I)

It is therefore possible to postulate that Eqn.(7) should hold best when the scale of the Brown–Okamoto electrophilic σ^+ constants[22], taking into account the positive charge on the reaction centre (the benzene ring is such a centre in relation to the π-acceptor), is used.

Eqns.(5) and (7) serve as a basis for the quantitative study of the influence of substituents on the reactivity of π-donors in a charge-transfer state. The appearance of a positive charge on the donor centre in the CTS does not significantly diminish the aromatic character of the π-donors. On the other hand, for ethylene derivatives (see below), where the positive charge is localised at the C = C bond, the multiplicity of the latter diminishes sharply in the CTC.[23]



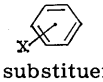


Figure 2. The influence of the electron-donating (*a*) and electron-accepting (*b*) substituents X on the positions of the energy levels in the ground and excited states of CTC for benzene derivatives of the type

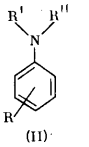
a) *+I* or *+M* effect of the substituent; *b*) *–I* or *–M* effect of the substituent.

The influence of substituents on ν_{CT} (in the case of CTC derived from benzene) is illustrated clearly by the energy scheme for the CTC presented in Fig.2. The introduction of an electron-donating substituent increases the electron density in the ring via the inductive (*–I*) on conjugation (*–M*) mechanisms, which stabilises the ground and charge-transfer states of the complex. However, in view of the greater sensitivity of the CTS to electronic effects, already discussed above, the energy of this state diminishes to a greater extent after the introduction of a substituent of this kind. This results in a decrease of the energy of the charge-transfer transition ($h\nu'_{CT}$) of the donor molecule and in a bathochromic shift of the CT band in the electronic spectrum. The introduction of an electron-accepting substituent (with an *–I* or a *–M* effect) has the opposite effect, destabilising the complex and increasing the energies of the ground and charge-transfer states, the latter to a greater extent. This entails an increase of the energy of the charge-transfer transition ($h\nu_{CT}$), which is manifested by hypsochromic shifts of the CT band. The nature of the influence of the electronic nature of the substituent on the energy of the charge-transfer transition follows also from the molecular-orbital study of the formation of the CTC.[24]



2. Benzene Derivatives

Charge-transfer complexes derived from benzene serve as model compounds for the investigation of many aspects of complex formation[25]. Comparison of the results of the study of the CTC by electronic spectroscopy with data obtained by independent methods makes it possible to obtain information about the mechanisms of the intramolecular interactions in various electronic states.

Such comparative analysis for a series of benzene derivatives has been carried out, for example, by Kuznetsov et al.[26]. The electron density at the donor centre in the CTS has been estimated in terms of the frequency ν_{CT} in the spectra of the complexes with tetracyanoethylene (TCE) and that in the ground state was estimated in terms of $\Delta\nu$, which is the frequency shift of the stretching vibration of the O–H bond of phenol in the infrared spectrum on formation of the O–H...π hydrogen bond between phenol and benzene derivatives. The $\Delta\nu$ and ν_{CT} for a series of compounds are linked by an empirical linear relation

$$\Delta\nu = -0{,}0074\ \nu_{CT} + 237 \qquad (8)$$

which shows that the effects of the substituents in the ground and charge-transfer states do not differ fundamentally. However, the experimental points for compounds with substituents having a lone electron pair (LEP)† [of the type of OCH_3, SCH_3, $N(CH_3)_2$, etc.] or substituents tending to become polarised in the CTS (I, $CH=CH_2$, etc.) deviate from Eqn.(8) towards lower values of ν_{CT}; the deviations δ (kcal mol^{-1}) = $\nu_{CT}^{exp} - \nu_{CT}^{calc}$ are between 10 and 20 kcal mol^{-1}. This is caused by the appearance of the electromeric *+E* effect in the CTS (increase of the n,σ, σ,π, and π,π conjugation as a consequence of the electron density deficit in the benzene ring) and by the significant contribution of the LEP of the heteroatom to the highest occupied molecular orbital (HOMO) in the corresponding compounds. We shall consider in greater detail the intramolecular interactions in the CTS of compounds of the type indicated.

(II)

$R' = R'' = H, CH_3$

†Here and henceforth in this review the $\Delta\nu$ and ν_{CT} are quoted in cm^{-1}.

The frequencies ν_{CT} in the spectra of the CTC of the aromatic amines (II) with TCE are linearly related to the basicity expressed by the pK:[27]

$$pK = -0.449 \cdot 10^{-3}\ \nu_{CT} + 11.05 \quad . \qquad (9)$$

o-Halogenoanilines do not obey this relation. Despite the π,π-character of the complexes of anilines with TCE, in the presence of halogens in the *ortho*-position there is a possibility of a direct overlap of the *p*-orbitals of the halogen atoms and the π-orbitals of the TCE molecule.

Tetracyanoethylene can react with aromatic amines[27] and it is therefore preferable to use weaker π-acceptors, for example, 1,3,5-trinitrobenzene (TNB).[28] The substituents examined by Kravtsov and Faingor[28] included a series of organomercury derivatives, so that information about the donor–acceptor properties of the Hg–X fragment was obtained from the ν_{CT} data. The following relation holds for the CTC of organic derivatives of dimethylaniline and TNB:

$$\nu_{CT} = 2130\sigma_p^+ + 20490;\ \dot{\rho}_{CT} = -4.49^{\dagger} \quad . \qquad (10)$$

It was used to calculate the σ_p^* constants of the substituents[28]. When organomercury substituents are introduced into the ring, the CT band undergoes a hypsochromic shift, which indicates the electron-accepting properties of such substituents. For α-substituted *N*,*N*′-dimethyl-*p*-toluidines, there is a linear relation between ν_{CT} and the inductive σ_I constants of the substituents in the methyl group:

$$\nu_{CT} = 3120\sigma_I + 19550;\ \dot{\rho}_{CT} = -6.58\ (r = 0.971) \quad . \qquad (11)$$

This indicates a predominantly inductive interaction of the substituent with the aromatic ring. An analogous correlation has been obtained for organomercury substituents of the type of HgX with different X:

$$\nu_{CT} = 2880\sigma_I + 19960;\ \dot{\rho}_{CT} = -6.07\ (r = 0.991) \quad . \qquad (12)$$

It follows from Eqns.(11) and (12) that the transmission properties of the mercury atom are weaker than those of the methylene unit.

The spectra of the CTC formed by compounds of the type $C_6H_5ECH_3$ (E = O, S, Se, or Te) (III) have been investigated in fair detail. The electron-donating properties of compounds (III) increase on passing from E = O to E = Te,[29] apparently mainly as a result of the increasing *n*-character of the highest occupied molecular orbital. Indeed the ionisation potentials of the *n* electrons of sulphur, selenium, and tellurium are smaller than the first ionisation potential of benzene and the orbital of the heteroatom therefore makes the main contribution to the HOMO of thio- and seleno-anisoles. The nature of the HOMO of the anisole molecule is determined by the symmetrical π_S-orbital of the ring, because the ionisation potential of the *n* electrons of the oxygen atom is greater than the first ionisation potential of benzene. Nevertheless all compounds of type (III) are donors of the π-type.

The electron-donating properties of the compounds XC_6H_4-ECH_3 (IV) become weaker as the position of X varies in the series *para*- > *ortho*- > *meta*-.[29] Owing to steric interactions, in *ortho*-substituted compounds (IV) there is a possibility of a breakdown of the coplanarity of X and the remainder of the molecule, which leads to an alteration of the electron-donating capacity of the compound as a whole[29,30]. As was to be expected, the electrophilic σ^+ constants proved to be preferable to the usual Hammett σ constants for the description of the correlation with ν_{CT} in the spectra of the CTC formed by compounds (IV).[31,32] The sensitivity of the HOMO to substitution in the ring of compound (IV) diminishes in the series of substituents O > S > Se as a consequence of the increasing localisation of the HOMO at the heteroatom and the appreciable conformational inhomogeneity (see also Vtyurina and Chmutova[34]).

The substituents have a complex influence on the ν_{CT} in the spectra of CTC formed by compounds of the type C_6H_5ER (V).[33] For E = O, the frequencies ν_{CT} vary in the following sequence of R: $CH_3 > C_2H_5 >$ iso-$C_3H_7 \ll$ t-C_4H_9. The sequence R = $CH_3 \cong C_2H_5 <$ iso-$C_3H_7 \ll$ t-C_4H_9 holds for sulphides and selenides. The conformation of the molecules of compounds (V) depends on the nature of E. Planar conformers are obtained for E = O, in which R influences the conjugated system mainly inductively and a non-planar configuration and the steric inhibition caused by this is possible only for R = t-C_4H_9. For E = S or Se, the steric effects of the substituents R are stronger and there is monotonic decrease of the energy of the HOMO with increasing bulk of R.

Variation of the bulk of the group R alters the ratio of the intensities of the long-wavelength and short-wavelength bands in the electron absorption spectra of CTC of compounds (V),[34] as in other benzene derivatives[36,37]. Bulky substituents (of the type of t-C_4H_9) decrease the intensity of the long-wavelength band both as a result of the decrease of the electron-donating capacity of the substituents as a consequence of the decrease of n,π conjugation and as a result of the increase of the contribution of the "transverse" orientation of the complex for steric reasons[35].

In contrast to the isologous anisoles, the intramolecular interactions in the CTS of phenol derivatives have been less thoroughly studied. The following linear correlations between ν_{CT} and σ^+ constants have been established for phenol derivatives:

(a) Monosubstituted phenols[38]:

$$\nu_{CT} = 5000\sigma_p^+ + 20500;\ \rho_{CT}^+ = -10.0\ (r = 0.998)\ ; \qquad (13)$$

(b) *para*-Substituted 2,6-di-t-butylphenols[39]:

$$\nu_{CT} = 2830\sigma_p^+ + 17400;\ \dot{\rho}_{CT}^+ = -5.9\ (r = 0.992) \quad . \qquad (14)$$

A linear relation between ν_{CT} and $\Delta\nu$ (a property of the ground state) holds for monosubstituted phenols[38]. In contrast to benzene derivatives (see above), $\Delta\nu$ represents in this instance the shift of the stretching vibration frequency of the O–H bond in the infrared spectra of phenols on formation of an intermolecular hydrogen bond by the latter with tetrahydrofuran (a characteristic of the acidity of phenols). The points corresponding to compounds containing the O or S heteroatom deviate from the relation

$$\Delta\nu = 0.0194\ \nu_{CT} - 90\ (r = 0.970) \qquad (15)$$

towards lower values of ν_{CT}. The cause of the deviation is the same as for the benzene derivatives examined above—enhancement of the degree of n,π conjugation of the electron-donating substituents on passing from the ground state (+*M* effect) to the CTS (+*E* effect) and the increase of the *n*-character of the HOMO. The presence of even one bulky substituent in the *ortho*-position relative to the OH group alters the nature of the intramolecular interactions in phenol derivatives[40].

The quality of the $\nu_{CT} = f(\sigma^+)$ correlations improve somewhat when σ^+ and σ^- constants are used simultaneously: for more than 30 trisubstituted phenols with two *ortho*-substituents, the following relation holds according to the

---

#Here and henceforth ρ_{CT}^* (cal mol^{-1}) is the slope of the plot of $\nu_{CT} = f(\sigma)$ [see Eqn.(7)].

data of Sennikov et al.[39]:

$$\nu_{CT} = 3840\Sigma(\sigma^+ + \sigma_0) + 18900 \quad . \qquad (16)$$

The considerable role of steric effects in the CTS is also indicated by the absence of a simple relation of type (15) for *ortho*-substituted phenols[40]. The significant decrease of the absolute value of the constant ρ^*_{CT} for shielded phenols [cf. Eqns.(13) and (14)] implies a decrease of the sensitivity of the HOMO of 2,6-di-t-butylphenols to structural changes in the molecule in the CTS, caused evidently mainly by the steric effects of the two t-butyl groups. The absence of fundamental changes in the influence of the *para*-substituent on transition of the molecules of 2,6-di-t-butyl phenols from the ground states to the CTS is indicated by the linear relation between ν_{CT} and the integral intensity $A^{1/2}$ of the ν(O–H) band in the infrared spectra of phenols[39]:

$$A^{1/2}\ (\text{mol}^{-1/2}\ \text{litre}^{1/2}\ \text{cm}^{-1}) = 0.69 \cdot 10^{-4}\nu_{CT} + 0.056\ (r = 0.980). \qquad (17)$$

A property of phenol derivatives which is of practical importance, namely their antioxidant capacity, characterised quantitatively by the rate constant k for the chain termination reaction in the radical oxidations of hydrocarbons [reaction (18)] or some other quantities[43], is linearly related to the energy of the HOMO of phenols[41,42]:

$$R'OO^{\cdot} + ROH \xrightarrow{k} R'OOH + RO^{\cdot} \quad . \qquad (18)$$

This enabled Lloyd[44] and Razuvaev et al.[45] to compare the ν_{CT} in the spectra of the CTC between phenols and TCE with data for the antioxidant activity. There is a parallel variation of ν_{CT} and the residual strain in the polymers, characterising the degree of their degradation[44]. A quantitative relation has also been established[45] between the logarithms of the rate constant of reaction (18) (R′ = styrene) and ν_{CT} in the spectra of the CTC formed by *meta*- and *para*-substituted unshielded phenols and *para*-substituted 2,6-di-t-butylphenols:

$$\ln k \cdot 10^{-3} = -7.67 \cdot 10^{-4}\ \nu_{CT} + 16.70\ (r = 0.999)\ ; \qquad (19)$$

$$\ln k \cdot 10^{-3} = -10.13 \cdot 10^{-4}\ \nu_{CT} + 18.80\ (r = 0.996)\ . \qquad (20)$$

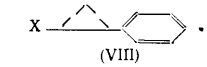
These results make it possible to regard ν_{CT} as a characteristic of the inhibiting capacity of phenolic antioxidants.

The study of the intermolecular interactions in the CTS of the ether XC_6H_4-OR (R is a constant fragment capable of conjugation with the heteroatom), can yield information about the involvement of the heteroatom (oxygen) in the transmission of conjugation effects. The nature of the conjugation effects in molecules of *para*-substituted phenyl vinyl and isobutenyl phenyl ethers XC_6H_4-O-CH = $C(CH_3)_2$ (VI) has been considered by quantum-mechanical methods, by the spectroscopy of the CTC with TCE, and by kinetic procedures[46,47]. A linear relation between the energy of the HOMO and the σ_p^+ constants of the constituents in the benzene ring follows from the calculations of the electronic structure in the ground state of phenyl vinyl ethers[47]:

$$E_{HOMO} = 0.58\sigma_p^+ + 10.92. \qquad (21)$$

This molecular orbital is localised mainly on the oxygen atom and on the alkene carbon atoms. There is a linear correlation between $h\nu_{CT}$ and the σ_p^+ constants for compounds (VI)¶:

$$h\nu_{CT} = 0.56\sigma_p^+ + 2.39;\ \rho^{\cdot}_{CT} = -9.4\ (r = 0.990)\ . \qquad (22)$$

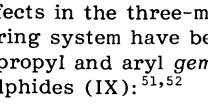


According to Donnay et al.[46], the similar slopes of relations (21) and (22) confirm the presence of a common conjugational system in molecules of isobutenyl phenyl ether (VI) [we may note that the correlation expressed by Eqn.(22) apparently refers to the CTS and not to the ground state of the molecule of compound (VI) as suggested by Donnay et al.[46]]. Quantum-mechanical calculations on analogous molecules[29] also indicate the presence of a single conjugated aromatic ring–heteroatom–double bond system in which the nature of the HOMO is determined by the interaction of the heteroatom not only with the ring but also with the α,β-double bond (in contrast to, for example, allyl derivatives where the influence of the double bond in the β,γ-position relative to the heteroatom is of subsidiary importance). However, the contribution of the heteroatom to the HOMO (i.e. its involvement in the transmission of conjugation effects) becomes significant only for C = S or Se. As already mentioned, for ethers the contribution of symmetrical π_S-orbitals of the ring predominates. This was confirmed by the impairment of the correlation between ν_{CT} and the σ^+ constants on passing from ethers to selenides. The role of the conformational effect increases in the same sequence[31]. The high accuracy of correlation (22) therefore indicates that the coordination of the TCE molecule to the benzene ring predominates.

The intramolecular interactions in the CTS of aryl benzyl ethers $C_6H_5CH_2OC_6H_4X$ (VII) have been investigated[48]. In this case the correlation between $h\nu_{CT}$ and σ^+ is

$$h\nu_{CT} = 0.45\sigma_p^a + 2.40;\ \rho^+_{CT} = -7.66\ (r = 0.970)\ . \qquad (23)$$

Unfortunately we are unaware of studies devoted to complexes of derivatives of diphenyl ether with TCE. Comparison of such data with the above results[48] would enable one to elucidate the role of the methylene unit in the transmission of electronic effects in the CTS.



Brown and Treylor[49] examined the intramolecular interactions in the CTS of 2-substituted phenylcyclopropanes (VIII):

(VIII)

It follows from the electronic spectroscopic data for the CTC of these compounds with TCE that the cyclopropyl group is a much more powerful electron donor than, for example, the ethyl group. The authors[49] attribute this to the σ,π conjugation of the cyclopropane and benzene fragments. However, the substituents X in the 2-position in the three-membered ring (for example, the methoxy-group) hardly influence the donor–acceptor properties of the molecule of compound (VIII) in the CTS. From this, one can conclude that the ability of the cyclopropyl group to transmit the π-electronic effect in the CTS is negligible, which is confirmed by the results of Mancini et al.[50]

The conjugation effects in the three-membered ring–heteroatom–benzene ring system have been considered in relation to aryl cyclopropyl and aryl *gem*-dichlorocyclopropyl ethers and sulphides (IX):[51,52]

(IX)

$R^I = R^{II} = H, Cl;\ E = O, S$.

The ν_{CT} data for the complexes of compound (IX) with TCE (classified as of the π,π-type) indicate the electron-accepting properties of the cyclopropane fragment of the molecule of

¶Here and henceforth the values of $h\nu_{CT}$ are expressed in eV.

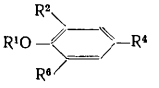
compound (IX) in the CTS, which is determined by both the inductive ($-I$) and conjugation effects.

The intramolecular interactions in phenyl derivatives of group (VIa) elements of different complexity have been investigated in a series of studies[53-56,59] (data for the ν_{CT} and the equilibrium constants K_C for complexes with π- and σ-acceptors were used). It was shown that the electron-donating properties of the diaryl ethers, sulphides, and selenides as well as the stability of their complexes with iodine (CTC of the n,σ-type) become enhanced in the sequence O (K_C = 0.39 litre mol^{-1}; ν_{CT} = 29000 cm^{-1}) < S (3.90; 28600) < Se (27.8; 28200).[54] The increased stability of the selenium complexes compared with the sulphur-containing analogues is due to the high basicity and large size of the selenium atom[53,54]. The equilibrium constants for the CTC of substituted diphenyl sulphides increase with decrease of ν_{CT}, i.e. as the electron-donating properties of the sulphides become more pronounced[54]. The quantity ρ_{CT} for the correlation between $\lg K_C$ and σ for diphenyl sulphides (−0.54) is somewhat smaller than the corresponding values for thiophenols (−1.11).[53] This is associated with the smaller change in electron density at the sulphur atom under the influence of substituents as a consequence of the conjugation intramolecular transmission of the electronic effects between the two phenyl groups via the bridging sulphur atom. Another cause of the decreased sensitivity of diphenyl sulphides to structural changes is apparently associated with the steric hindrance by the phenyl groups of the approach of the σ-acceptor to the reaction centre (the sulphur atom).

The ability of the selenium bridge to transmit the electronic effects between two aromatic systems is much smaller than that of the sulphur-containing bridge, which can be seen from the high value $\rho = -2.1$ for diphenyl selenides, indicating a high sensitivity of the electron density at the selenium atom to external perturbations. The introduction of a methylene fragment between the heteroatom and the benzene ring (the CTC of aryl benzyl sulphides with iodine[54,57]) disturbs the transmission of electronic effects described above. The study of the spectra of the CTC of diphenyl sulphides with TCE showed[55,56] that *para*-substituted sulphides exhibit the most marked electron-donating properties as a consequence of the direct polar conjugation of the LEP of the heteroatom with *para*-substituents (Cl, OCH_3, etc.) via the π-electron system, mentioned above for thio- and seleno-anisoles. The anomalously weak electron-donating properties of bis(*o*-dimethylphenyl) sulphide (compared with those of alkyl sulphides) have been considered[55] as a result of the breakdown of the conjugation of the LEP of the sulphur atom with the two benzene rings. The marked conformational changes in such compounds have been confirmed by data obtained by independent methods[58]. The correlation between $\lg K_C$ and the σ constants of TCE is characterised by $\rho = -0.74$, which is close to $\rho = -0.64$ obtained for the CTC of the same sulphides with iodine[54]. This result suggests that the HOMO in these and other complexes are isotypical.

It is known[1] that the K_C for the complexes of typical π-donors with TCE are higher than for CTC with I_2. As the n-donor character is enhanced, the K_C of the complexes with iodine increase and for the pure n-donors they are much higher than the K_C for the complexes with TCE. The K_C for the complexes of diphenyl sulphides[55] with iodine are somewhat higher than those for the complexes with TCE, which indicates a mixed n,π-character of the HOMO of diphenyl sulphides.

This problem has been considered in more detail in relation to aryl diphenylmethyl sulphides $X^1C_6H_4(X^2C_6H_4)CHSC_6H_4Y$ (X).[56,59] The two phenyl fragments and the thiophenyl system are in this instance potential donor centres. Analysis of the ν_{CT} and the K_C for the complexes of compounds (X) with TCE and iodine shows that electrophilic attack by the iodine atom is directed preferentially to the sulphur atom (HOMO of the n,π-type) and not to the diphenylmethyl system. The effect of the substituent X is determined by the inductive mechanism and the sensitivity of the complex formation reaction with I_2 to the influence of the substituent is low because of the long distance between the substituent and the sulphur atom. The fragment Y acts on the sulphur atom via both inductive and resonance mechanisms and the resulting effect is approximately four times greater. The interaction of compounds (X) with a π-acceptor (TCE) is of an appreciably more complex type: TCE interacts with both the phenylthio-system and with the diphenylmethyl group.



The intramolecular interactions in large series of disulphides and diselenides of the type $X-C_6H_4-E-E-C_6H_4-X$ (XI, E = S or Se) have been investigated[60]. Whereas the CTC of aromatic disulphides with I_2 have not been detected spectrophotometrically[53], the complexes of diaryl diselenides absorb in the range 270–390 nm. The linear relation between ν_{CT} and σ^+ is characterised by the quantity ρ^*_{CT} = −2.0. According to the authors[60], in the case of compounds (XI) a single molecular orbital, incorporating not only the central fragment $-C_6H_4-Se-Se-C_6H_4-$ of the test molecules but also the substituents X, is involved in the formation of complexes. As in the monosulphides and monoselenides, in aromatic disulphides and diselenides the intramolecular interactions are strongly manifested between substituents in the *para*-positions in the benzene rings. The sharp difference between the electron-donating properties of diaryl disulphides and diaryl diselenides in relation to iodine can be explained by the fact that the LEP of the sulphur atoms in the $(XC_6H_4)_2S_2$ molecules are incorporated to a greater extent in the π-system of the conjugated multiple bonds compared with the $(XC_6H_4)_2Se_2$ molecules. Comparison of the reaction constants for the CTC of compounds (XI) with TCE (ρ^*_{CT} = −2.89 for the sulphides and −2.04 for the selenides) indicates a somewhat greater sensitivity of the sulphur-containing compounds to the electronic effects of substituents (an analogous relation has been observed also for thio- and seleno-anisoles). The sensitivity of the disulphides greatly increases (ρ^*_{CT} = −7.32) when one of the phenyl groups in compounds (XI) is replaced by a methyl group.

We shall now consider the intramolecular interactions in the CTC of aryl derivatives of Groups IVB elements. In view of the lower electronegativity of the silicon atom (1.9) compared with that of carbon (2.6) [61] and the high inductive constant of the trimethylsilyl group [$\sigma^* = -0.9$ compared with $\sigma^* = -0.3$ for $C(CH_3)_3$],[63] an enhancement of the electron-donating properties of organosilicon derivatives compared with their carbon analogues may be expected. However, the results of spectrophotometric studies on the CTC of the compounds C_6H_5-X (XII) indicate the opposite situation[62]. This finding can be accounted for by the manifestation of the effect of the $d_\pi-p_\pi$ interaction due to the partial transfer of the π-electron density from the benzene ring to the vacant 3*d* orbitals of silicon, which acts in opposition to the $+I$ effects of the silyl groups.

Different aspects of this effect have already been considered[64]. The group $CH_2Si(CH_3)_3$ has more marked electron-donating properties than the trimethylsilyl group. Thus the following series based on the variation of the electron-donating properties of compounds (XII) as a function of X has been established: $CH_2Si(CH)_3 > CH_3 >$

$Si(CH_3)_3$; it is valid also for compounds containing several substituents in the ring[62].

Different aspects of the effects of the d_π–p_π interaction and σ,π conjugation in the charge transfer state have been considered[65–67].

(XIII)

Analysis of the values of ν_{CT} in the sterically hindered organosilicon phenols and ethers (XIII) shows[68] that the replacement of the $(CH_3)_3C$ group by $Si(CH_3)_3$ leads to an increase of ν_{CT} and hence to an enhancement of the electron-accepting properties of the phenols (in relation to the larger series of organosilicon and organogermanium phenols, this problem has been considered by Sennikov et al.[39]). An analogous relation has been observed also for the organosilicon ethers [$R^1 = Si(CH_3)_3$]; comparison of the values of ν_{CT} for the latter with the ν_{CT} for phenols shows that the trimethylsilyl group of the $Ar–O–Si(CH_3)_3$ fragment is a stronger electron acceptor than $C(CH_3)_3$ or the hydrogen atom.

Consequently the effect of the d_π–p_π interaction does not remain unchanged and depends significantly on the nature of the substituent X in the $(CH_3)_3Si$-X fragment. This observation has been confirmed by the study of the CTC of *para*-substituted organosilicon ethers p-XC_6H_4–O–Y (XIV) (compared with anisoles).[69,70] Whereas compounds (XIV) with $Y = Si(CH_3)_3$ exhibit weaker electron-donating properties compared with anisoles, with $Y = CH_2Si(C_2H_5)_3$ there is a considerable enhancement of the π-donor properties. The separation of the oxygen and silicon atoms by the $-CH_2-$ group disturbs the d_π–p_π interaction of the LEP of the oxygen atom with the 3*d* orbitals of silicon[71], which is manifested by a lower sensitivity of the HOMO of the molecule of compound (XIV) with $Y = CH_2Si(C_2H_5)_3$ to the electronic effects of substituents compared with compounds (XIV) in which $Y = Si(CH_3)_3$.

Analysis of the donor–acceptor properties of organosilicon ethers with the groups O–Si≤, O–Si–Si≤, and O–CH_2–Si≤[71] leads to the conclusion that the *n*-orbital of the oxygen atom interacts with the π_s-orbital of the benzene ring. The influence of the organic substituent R in C_6H_5OR on the nature of the HOMO is weak and is transmitted mainly via the inductive mechanism. It is believed essential[71] to take into account the interaction of the LEP of the oxygen atom with the σ orbitals of the neighbouring C–Si or Si–Si bonds in the ethers with $R = Si(CH_3)_3$, $CH_2Si(CH_3)_3$, or $Si_2(CH_3)_5$ (taking into account photoelectron spectroscopic data).

The electronic absorption spectra of the CTC of more than 70 organosilicon and organogermanium derivatives of benzene with TCE have been considered in a number of studies[65–67], where the electronic effects of the organoelemental substituents in the ground and charge-transfer states were also compared. The donor–acceptor properties of the compounds in the ground states were characterised in terms of the quantity $\Delta\nu$ (see above). The points corresponding to compounds with substituents whose degree of conjugation with the ring does not change significantly on transition from the ground to the charge transfer state fit on the plot of Eqn.(8) described above. Such substituents include also fragments with the M–Ar bond (M = Si or Ge), which indicates the constancy of the manifestation of the d_π–p_π interaction in the ground and charge transfer states. The points corresponding to the benzyl derivatives of silicon and germanium deviate from correlation (8) towards lower values of ν_{CT} (analogously to the derivatives of benzene with substituents containing a heteroatom with LEP). The anomalously pronounced electron-donating properties of benzyl derivatives can be explained by the effect of the σ,π conjugation of the C–M bond with the benzene ring in the CTS.[65] For the benzyl derivatives of silicon and germanium, the σ,π conjugation occurs even in the ground state but, on passing to the CTS, it becomes much more marked[67]. The effect of the σ,π conjugation is impaired after the introduction of a second methylene group into the molecule (compounds of the type $C_6H_5CH_2CH_2MR_3$).[72] The degree of σ,π conjugation diminishes following the enhancement of the electron-accepting properties of the substituents at the atom M.[73]

Specific electronic effects obtain for organosilicon derivatives of benzene with an Si–Si bond. Recently the interaction of the Si–Si σ-bond with unsaturated fragments has been studied by various physical methods, including spectrophotometry of the CTC.[62,74–78] Analysis of the CT band in the electronic spectra of complexes of benzene derivatives containing the SiR_2SiR_3 and CH_2SiR_3 groups has shown[62] that the ν_{CT} of the long-wavelength bands corresponding to these compounds are 20200 and 20400 cm^{-1} respectively. Thus the disilanyl substituent exhibits the same σ-donor properties as the trimethylsilylmethyl substituent, the properties being more marked than the electron-accepting properties of the same fragment due to the d_π–p_π interaction. Subsequent studies[74–78] confirmed the occurrence of σ(Si–Si)–π conjugation in phenylpolysilanes. The electron-accepting properties of fragments containing the polysilicon chain are apparently determined by the silicon atom which is closest to the benzene ring[78].

The determination of the coordination centre of the π-acceptor (TCE) in the study of the intramolecular interactions in the π-complexes of metals (data for the CTC of cyclopentadienyl derivatives of iron, cobalt, and nickel[4,79]) has been the subject of controversy; the problem was whether this centre is the cyclopentadienyl ring or the metal atom[80,81]. The authors of two reviews[4,79] believe that the compounds most probably form complexes of the π,π-type. This question has been investigated for arenechromium, arenemolybdenum, and arenetungsten tricarbonyls of the type $XC_6H_5M(CO)_3$ (XV, M = Cr, Mo, or W).[82–86] It has been concluded[83,84] that there are two coordination centres in arenemetal tricarbonyls—the benzene ring in complexes with TNB and the metal atom in complexes with TCE. However in other studies[85,86] data for the CTC spectra have been interpreted from the standpoint of the coordination of both π-acceptors solely to the aromatic ring.

The following relations have been obtained for the complex-formation reactions of arenechromium tricarbonyls with TNB (a weak π-acceptor) and TCE (a strong π-acceptor):[86]

$$\text{TNB}: \nu_{CT} = 1060\Sigma\sigma^+ + 20700;\ \rho^*_{CT} = -2.23\ (r = 0.870)\ ; \quad (24)$$

$$\text{TCE}: \nu_{CT} = -1550\,\Sigma\sigma^+ + 13300;\ \rho^*_{CT} = +3.27\ (r = 0.950). \quad (25)$$

The inversion of the sign of the reaction constant ρ^*_{CT} on passing from complexes with TNB to those with TCE indicates a change in the mechanism of the transmission of electronic effects. This change is associated with the ability of the $Cr(CO)_3$ group to manifest electron-accepting properties in the presence of a fairly small positive charge on the ring (complexes with TNB, $\rho^*_{CT} < 0$) and electron-donating properties when there is an appreciable deficit of electron density at the donor centre (complexes with TCE, $\rho^*_{CT} > 0$). For CTC with *p*-chloranil, *p*-bromanil. and trinitrophenol, which have intermediate E_A values, the correlation between ν_{CT} and σ^* constants is impaired, which indicates a smooth

variation of the mechanism of the transmission of the electronic effects in the system $Cr(CO)_3$ group–benzene ring–π-acceptor. The following series based on the enhancement of the electron-accepting properties of arenemetal tricarbonyls has been obtained from spectrophotometric data for the CTC of compounds (XV) with TCE:[86] Cr < Mo << W.

Relations of the type $\nu_{CT} = f(\sigma)$ make it possible to apply the spectrophotometry of the CTC to the evaluation of the σ constants of the substituents. It was shown in the introduction to this review that the greatest efficiency of this method is to be expected in the calculation of the σ^+ constants. On the other hand, the possibility of using this method also for the determination of σ constants using the equation

$$\nu_{CT} = 10\,000\,\Sigma\sigma + 23\,900 \quad . \qquad (26)$$

has likewise been demonstrated[87,88].

Eqn.(26) holds only for benzene derivatives without substituents whose electronic influence increases sharply on transition from the ground to the charge-transfer state. Otherwise one must employ either the equation[21]

$$\nu_{CT} = 9200\sigma_p^+ + 26200 \quad , \qquad (27)$$

or, according to Kuznetsov et al.[65], the equation

$$\nu_{CT} = 5260\sigma_p^+ + 24800 \quad . \qquad (28)$$

The significant difference between the slopes of relations (27) and (28) can be explained by the different methods used to derive them. Eqn.(27) has been derived for several benzene derivatives containing substituents with known σ^+ constants in the range 0 to −1.4, while Eqn.(28) has been obtained by combining two equations[87,88]:

$$I_D\ (eV) = 0.80\sigma_p^+ + 9.67 \quad ; \qquad (29)$$

$$\nu_{CT} = 7500\ I_D - 41\,000, \quad . \qquad (30)$$

Eqn.(29) is valid only for mono- and di-substituted benzenes. When the equation for a large series of polysubstituted benzenes[89] is used instead of Eqn.(29), the numerical values of the parameters in Eqn.(28) approach those in Eqn.(27). Despite these deficiencies, Eqns.(27) and (28) are used to calculate the σ_p^+ constants for different substituents, including organoelemental substituents[21,65,90].

An attempt has been made to calculate the inductive σ_I constants of substituents of the type CH_2CR_3 from spectrophotometric data for CTC.[91]

3. Naphthalene Derivatives

There are a number of reviews on the CTC of naphthalene derivatives[1,2,4], but the available data on the intramolecular interactions in the CTC of these compounds are fragmentary. In contrast to the benzene derivatives[92,93], the electronic absorption spectra of the CTC of substituted naphthalenes exhibit three bands (which is consistent with the molecular orbital theory[62]), the third shortest-wavelength band having a very low intensity. The influence of the substituents on the first and second CTC bands is analogous to that of benzene but the sensitivity to this influence of the charge-transfer transitions corresponding to these bands depends on the type of substitution (see, for example, Evans et al.[94]). The introduction of both the $C(CH_3)_3$ and $Si(CH_3)_3$ groups increases the energy of the HOMO of naphthalenes (compared with the unsubstituted derivatives) as a consequence of the inductive +*I* effect (the bathochromic shift of both bands in the spectrum corresponds to this)[94]. However, despite the large +*I* effect of the trimethylsilyl group for organosilicon derivatives, a large bathochromic shift of the CT bands is not observed owing to the effect of d_π–p_π interaction in silylnaphthalenes.

Analysis of the ν_{CT} data also shows that, for 1-, 1,4-, and 1,5-substituted derivatives, the first (long-wavelength) band is more sensitive to the electronic influence, whereas for 2-, 2,6-, and 2,7-derivatives the second (short-wavelength band) is more sensitive. The effect of the d_π–p_π interaction in naphthalene derivatives has also been studied by Kuznetsov et al.[95]; it was found that 1-substituted derivatives have more pronounced electron-donating properties than 2-substituted derivatives, which agrees with the data of Evans et al.[94] The NH_2, OCH_3, and OH groups are significantly stronger electron donors in relation to the hydrogen atom than the $Si(CH_3)_3$ group, which again indicates the d_π–p_π interaction between the 3*d* orbitals of the silicon atom and the naphthalene ring.

The study of the intramolecular interactions in the CTC of 1-substituted naphthylpolysilanes[78] established the following series based on the enhancement of the electron-donating properties of the substituents: H < $Si(CH_3)_3$ < CH_3 < $Si_2(CH_3)_5$ < n-$Si_3(CH_3)_7$ < iso-$Si_3(CH_3)_7$ < $Si(CH_3)_3CH_2$. In contrast to benzene polysilicon compounds, the ionisation potential of the naphthalene system (8.12 eV) is lower than that of the σ-system of the substituents, including polysilanes: 8.69 eV for $Si_2(CH_3)_6$ and 8.19 eV for $Si(CH_3)_3$.[78] Therefore, when the molecular σ- and π-orbitals in naphthylpolysilanes overlap, the HOMO is mainly of the π-character. The data for the CTC spectra of 1- and 2-substituted naphthylpolysilanes have been discussed[96] from the standpoint of the σ,π conjugation of the Si–Si bond with the π-system of the naphthalene ring, but the authors unjustifiably neglected the d_π–p_π interaction.

4. Derivatives of Ethylene and Cyclopropane and Saturated Compounds

The study of the spectra of the CTC of alkyl vinyl ethers CH_2 = CH–OR (XVI) with TCE established[97] that the electron-donating properties of compounds (XVI) in the CTC increase in the following sequence of R: CH_3 < C_2H_5 < iso-C_3H_7 < t-C_4H_9, which agrees with the reactivity data[97]. We may note that a somewhat different relation has been observed for compounds (V), which are formal analogues of compounds (XVI). The view[97] that in alkyl vinyl ethers (in contrast to the aromatic analogues) the effects of the conjugation of the alkoxy-group with the double bond play a secondary role must be regarded as insufficiently well founded from the standpoint of the results of the study of Lopatin et al.[98].

Comparison of the frequencies ν_{CT} in the spectra of the CTC of the alkenyl derivatives of silicon of the type CH_2 = CH–$(CH_2)_n$–SiR_3 (XVII) (*n* = 1, 2) and the related carbon compounds with TCE on the basis of the results of Kuznetsov et al.[99] does not rule out the possibility of an interaction of the d_π–p_π type between the Si–C and C = C bonds for *n* = 1 in the CTS. In reality the usual σ,π conjugation is evidently an interaction of this type. A comparative study of the intramolecular effects in the alkenyl derivatives of carbon, silicon, germanium, and tin in the ground and charge-transfer states has been carried out[98]. The electronic influence of the substituents in the ground state was characterised, as for benzenes[26], by the frequency shift Δν of the stretching vibration of the O–H bond in the infrared spectrum of phenol (an electron acceptor) when it forms hydrogen bonds with the π-systems of ethylene derivatives. The electronic effects in the CTS are characterised by the value of ν_{CT} in the spectra of the CTC with iodine.

The data of Lopatin et al.[98] indicated an important role of the effects of the d_π–p_π interaction and σ,π conjugation in the ground and charge-transfer states. The electronic effects in the ground and charge-transfer states of a number of compounds are linearly related:

$$\Delta\nu = -0.00806\ \nu_{CT} + 342\ (r = 0.980). \qquad (31)$$

In contrast to the benzyl derivatives of silicon and germanium, the experimental points for the alkyl derivatives are consistent with Eqn.(31), which indicates the absence of a sharp increase of the effect of the σ,π conjugation in the allyl derivatives of the elements of the silicon subgroup on transition from the ground to the charge-transfer state. A number of features, which have not been noted for benzene derivatives, have been observed for ethylene derivatives[26], which is associated[98] with the lower multiplicity of the carbon–carbon bond compared with the π-system of the benzene ring in the CTS. The substituent $(CH_3)_3SiSi.(CH_3)_2$ participates in two opposite effects of conjugation with the multiple bond: the d_π–p_π effect (electron accepting) and the σ,π effect (electron donating)[98]. According to some data[77,78], the influence of the second effect predominates.

Cyclopropane and its organic and organosilicon derivatives also form CTC with iodine[1,99]. As the electron-accepting properties of the substituent at the silicon atom linked to the cyclopropane ring are enhanced, a hypsochromic shift of the CT band is observed. The introduction of the methyl group into the cyclopropane fragment is accompanied by a decrease of ν_{CT} and in the presence of electron-accepting fluorine atoms in the three-membered ring ν_{CT} increases. Consequently, despite the specific electronic structure of cyclopropane and its derivatives[100], the nature of the influence of the substituents in the cyclopropane fragment (not containing the benzene ring—this case was examined above) on the position of the band in the spectra of the CTC of these compounds is the same as for the typical π-donors (benzene, naphthalene and ethylene derivatives).

Similar relations have been established also for the interaction of π- and σ-acceptors with saturated compounds of Group IVB metals: permethylpolysilanes[74–78], polygermanes[101], hexamethyldistannanes[101–103], and tetra-alkyl derivatives of germanium, tin, and lead[101,104,105]. Saturated tetra-alkyl monosilanes do not form complexes with TCE apparently as a consequence of the fairly high ionisation potential of the Si–C bond. However, it has been shown[106] that the marked distortion of the valence angles of the atoms involved in the formation of small rings with participation of silicon atoms leads to an appreciable decrease of the ionisation potentials of the corresponding monosilanes (the ionisation potential of 1,1-dimethyl-1-silacyclobutane is 9.4 eV compared with 10.5 eV for tetramethylsilanes[107]).

The silacyclobutanes  –SiRR′ formed give rise to CTC with TCE and there is a linear relation between ν_{CT} and the sum of the inductive constants of the substituents R and R′ at the silicon atom

$$h\nu_{CT} = 2.38\ \Sigma\sigma_{IR,R'} + 3.56\ . \qquad (32)$$

Information about the d_π–p_π interactions has been obtained in the study of complexes of saturated silicon-containing sulphides R–S–R′ (XVIII) with TCE.[108] The attachment of silicon to the sulphur atom lowers the energy of the orbital occupied by the LEP of sulphur, which is manifested by hypsochromic shifts of the CT band and indicates the operation of the effect of the d_π–p_π interaction. This interaction breaks down when the silicon and sulphur atoms are separated by the $-CH_2$-fragment.

Electronic absorption spectroscopy of CTC has also been used to study the electronic structure of the silatranes

$RSi(OCH_2CH_2)_3N$ (XIX).[109–112]

5. Heterocyclic Compounds

In contrast to benzene derivatives, the electronic effects in the CTS of heteroaromatic compounds with an excess of π-electrons[113] have been less thoroughly investigated (see the review on the CTC of pyrrole derivatives[114]). A comparative study of the CTC of five-membered heterocycles with various π-acceptors[115,116] established that the π-donor capacity falls in the sequence pyrrole > furan ≥ thiophen and all the heterocycles are stronger electron donors than benzene. On the other hand, the stability of the CTC of benzene with TCE (the K_C constant) is higher, probably as a consequence of more favourable conditions for the mutual overlap of the orbitals.

Analysis of the values of ν_{CT} and K_C for thiophen, selenophen, and tellurophen[117,118] as well as photoelectron spectroscopic data (ionisation potentials) indicate unambiguously the π-character of the HOMO of thiophens. The π,σ-character of the CTC of thiophens with iodine is demonstrated by the different nature of the variation of the K_C for methyl-substituted thiophens and pyrroles. The K_C for the latter decrease in the sequence of substituents $3\text{-}CH_3 > 2\text{-}CH_3 > H > 2,6\text{-di-}CH_3$, which agrees with the increase of the steric hindrance around the reaction centre (the nitrogen atom). On the other hand, the K_C for the series of thiophens increase in the same sequence, which corresponds to the predominance of the electronic effects over steric effects. This is also indicated by the appreciably different equilibrium constants for the complex-formation reactions of thiophen ($K_C = 0.61$ mol^{-1}), pyridine ($K_C = 160$ mol^{-1}), and tetrahydrofuran ($K_C = 315$ mol^{-1}) with I_2.

It has been established that[118] the following relation holds for the CTC of thiophens and benzenes with TCE:

$$\lg K_C^t = 0.9 \lg K_C^b + 0.2\ . \qquad (33)$$

The slope, which is close to unity, indicates the similarity of the HOMO of the two classes of the compounds. A linear relation has also been established between $\lg K_C^t$ and the Hammett σ constants[118] ($\rho_{CT} = 1.6$). In the CTC with TCE, iodine, and chloranil the HOMO is of the mixed n,π-type.[11] On passing to 5,5-dimethyl-2,2-bithienyl the CTC are stabilised by the $+I$ effect of the methyl group. It follows from the K_C for bithienyl and methylthiophen that the conjugation of the two thiophen rings in 2,2-bithienyl increases the basicity of the donor to a greater extent than the $+I$ effect of two methyl groups.

It has been remarked that[120] examination of the intramolecular interactions of thiophen derivatives in CTC is important for the understanding of the mechanism of the adsorption of these compounds on silochrome in experiments on gas-adsorption chromatography. Furan and thiophen derivatives in CTC exhibit approximately the same electron-donating properties[115,116,118]. The fact that 2-phenylfuran is a stronger electron donor than furan confirms, according to Eittah and Hamed[121], the formation of CTC of the π,π-type. The low frequencies ν_{CT} indicate significant conjugation effects in 2-phenylfuran, which confirms indirectly the planar structure of this molecule. The conjugation effects

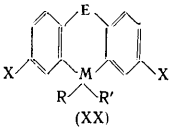
are enhanced on passing to 2,5-diphenylfuran, whose molecule is evidently also planar. The conclusion that phenylfurans have a quasi-rigid structure, reached on the basis of electronic spectrosopic data for CTC,[121] has been confirmed by quantum-mechanical calculations.

The intramolecular interactions in the CTC of organic and organoelemental derivatives of thiophen and furan have been investigated systematically[122–124]. The replacement of the methyl group in methylthiophen by the $Si(CH_3)_3$ group leads to an appreciable weakening of the electron-donating properties of the compound. Thus the effect of the d_π–p_π interaction, opposed to the *+I* effect of the silyl groups, is characteristic of derivatives of thiophen as well as the derivatives of benzene, naphthalene, and ethylene discussed above. The electronic effects of the substituent in the CTS of thiophen derivatives have been compared with the electronic effects in the ground state (investigated by measuring the chemical shift τ using NMR data).[123] For a series of compounds, the values of τ and ν_{CT} are linearly related:

$$\tau\,(\text{p.p.m.}) = 6.30 - 0.00015\,\nu_{CT} \quad . \qquad (34)$$

The linear relation shows that the electronic effects of the substituents do not change fundamentally on passing from the ground to the charge-transfer state. The points corresponding to compounds with thienyl substituents deviate from relation (34) towards lower values of ν_{CT}, indicating an increase of the effect of the n,π conjugation of the substituents with the ring in the CTS (the *+E* effect).

The observed relations are similar to those discussed above for benzene derivatives[26]. At the same time, in contrast to benzene derivatives, an increase of the degree of the d_π–p_π interaction between the 3*d* orbitals of the silicon atoms and the π electrons of the thiophen ring has been observed in the CTS of substituted thiophen. This effect is manifested only in the presence of two electron-accepting substituents in the thiophen ring. The values of ν_{CT} in the spectra of the CTC of organoelemental derivatives of thiophen and furan with TCE [122–124] indicate a diminution of the electron-accepting properties of the elements of the silicon subgroup in the sequence Si > Ge > Sn, which is analogous to that for derivatives of benzene and determined by the effect of the d_π–p_π interaction, which weakens on passing from silicon to tin.

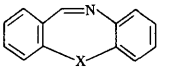


An analogy with benzene derivatives is also observed as regards the sharp enhancement of the electron-donating properties in the CTS of derivatives with substituents of the type $CH_2Si(CH_3)_3$, which is a consequence of the σ,π conjugation. The frequencies ν_{CT} of thiophen and furan derivatives are linearly related[124]:

$$\nu_{CT}^{t} = 0.46\nu_{CT}^{f} + 11000 \quad . \qquad (35)$$

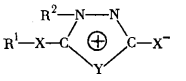
The relation describes compounds with both organic and organoelemental substituents. Despite the lower ionisation potential of thiophen compared with furan[125], thiophen derivatives with electron-donating substituents [CH_3–, $C(CH_3)_3$–] have greater and not smaller frequencies ν_{CT} compared with their furan analogues. The reason for the inversion of the ν_{CT} in thiophen and furan derivatives is the greater sensitivity of the HOMO of furan derivatives to the influence of ring substituents[124]. According to some data[125,126], the sensitivity of the HOMO of aromatic compounds to the influence of substituents varies in the sequence furan > pyrrole > thiophen > benzene.

Derivatives of tetrathiafulvalene and tetrathiatetracene as well as certain other sulphur-containing heterocycles have attracted attention recently in connection with the discovery of conducting properties in their crystalline CTC and radical-ion salts[127,131]. These investigations established in particular[128] that the radical-ion salts derived from compounds in which there is a maximum charge transfer from the donor to the acceptor (tetracyanoquinodimethane) in liquid solution have high conductivities. Consequently the properties of molecular complexes in the liquid solution predetermine the conducting properties of the compounds formed from the given series of components in the solid phase.



The spectra of the CTC of heterocyclic anthracene-like compounds of type (XX) have been investigated in a series of studies[132–134]:

(XX)



E = N – C_2H_5, O, S;
M = Si, Ge, Sn;
R, R' = CH_3, C_6H_5, H .

The joint analysis of ν_{CT} data[133,134], the ionisation potentials[135], and the results of X-ray diffraction analysis[136,137] of these compounds has shown that the enhancement of the electron-donating properties takes place in parallel with the increase of the dihedral angle between the rings. The latter corresponds to an approach of the molecular skeleton to the planar structure and to an increase in the degree of conjugation in the sequences O < S < N and Sn < Ge < Si. As already mentioned, similar relations hold for phenylfurans[121]:

(XXI)

X = CH_2, O, S, NCH_3, C=O

(XXII)

X = O, S, $NCOR^1$, $NCSR^2$,
Y = O, S, NR^2, NH_2 .

The linear correlation between ν_{CT} and the ionisation potentials (electronic spectroscopic data for the CTC with CTE and photoelectronic spectroscopic data[138])

$$\nu_{CT} = (1.20 \pm 0.06)\ I_D - (6.3 \pm 0.5) \qquad (36)$$

has been established for derivatives of 11*H*-dibenzo[*b*,*f*]-azepine (XXI). The charge-transfer complexes of certain mesoionic compounds of type (XXII) have been investigated[139,140]. Analysis of the ν_{CT} data made it possible to assign the CTC of compound (XXII) with TCE to the π,π-type and to estimate the relative electron-donating capacities of the exocyclic groups in mesoionic heterocycles in the CTS.

III. PROSPECTS FOR THE APPLICATION OF THE ELECTRONIC EMISSION SPECTROSCOPY OF CHARGE-TRANSFER COMPLEXES

The application of the electronic absorption spectroscopy of the CTC to the study of intramolecular interactions is effective only on formation of comparatively stable complexes giving rise to a sufficiently intense CT band in the electron spectrum. The high sensitivity of the electronic emission spectroscopy makes it important for the study also of weak CTC. The following main applications are promising in this connection.

1. The study of the electronic emission spectra of the CTC formed in the ground state (a version which is the direct opposite of electronic absorption spectroscopy). The information thus obtained is important for the understanding of the nature of the donor–acceptor bonds[141–144]. For example, it has been shown[141,142] that the position of the CTC

emission band in the spectra of a series of benzene derivatives is determined directly by the ionisation potentials of the donors (for the same acceptor). However, overall, the electronic emission spectra of the CTC have not been as thoroughly investigated and described systematically as the electronic absorption spectra and this method has not therefore found extensive applications in physical organic chemistry.

2. Many more studies have been made (see, for example, the relevant reviews[145-147]) on the electronic emission spectra of the CTC formed only in an excited state (exciplexes) via the mechanism

$$^1D^* + A \rightleftharpoons (D^+A^-)^* \rightarrow D + A + h\nu_{CT}^{em} . \qquad (37)$$

Numerous experimental data, starting with the work of Leonhardt and Weller[148], established a linear relation between the energy of the fluorescence maximum of the exciplex $h\nu_{exc}^{fl}$, the ionisation potential of the donor I_D, and the electron affinity of the acceptor E_A similar to Eqn.(5).

Apart from these two methods, the following two indirect procedures for the investigation of weak CTC, in which the quenching of the luminescence of one of the components of the complex due to the complex formation in the excited or ground state is considered, are also important.

3. The study of the influence of the formation of non-luminescent CTC in an excited state from luminescent components. This dynamic quenching process (of the second kind[157]) corresponds to the following scheme:

$$D^* + {}^1Q \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} (DQ)^* \begin{cases} \xrightarrow{k_c} {}^1D + {}^1Q & (38) \\ \xrightarrow{k_{ict}} {}^3D^* + {}^1Q & (39) \end{cases}$$

(where Q is the molecule of the quenching agent) and its kinetics are described by the familiar Stern–Volmer equation[145]:

$$\varphi_0/\varphi = 1 + k_q\tau_0[Q] = 1 + K_q[Q] , \qquad (40)$$

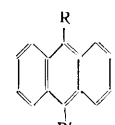
where ϕ_0 and ϕ are the luminescence quantum yield in the absence and presence of the quenching agent respectively, τ_0 is the lifetime of the excited state in the absence of the quenching agent (seconds), [Q] the molar concentration of the quenching agent, k_q the observed rate constant for the quenching of the luminescence (litre mol^{-1} s^{-1}), $K_q = k_q\tau_0$ the Stern–Volmer quenching constant (litre mol^{-1}), k_c the true rate constant for quenching in the complex (litre mol^{-1} s^{-1}), and k_{ict} the rate constant for the possible intersystem crossing (litre mol^{-1} s^{-1}).

For the majority of systems in solvents of low viscosity, k_q is of the order of magnitude of 10^9–10^{10} litre mol^{-1} s^{-1}, which is close to a diffusion-controlled constant $k_{dif} = 8RT/300\eta$, where R is the gas constant (J mol^{-1} K^{-1}), T the temperature (K), and η the viscosity (P). It can be shown[145] that the following relation can be derived for Scheme (38) or (39):

$$k_q = k_c k_1/(k_c + k_{-1}) . \qquad (41)$$

For strong quenching agents, $k_c \gg k_{-1}$ and we obtain

$$k_q \cong k_1 \cong k_{diff} , \qquad (42)$$



i.e. the quenching efficiency is determined exclusively by the diffusion of the species forming the intermediate complex. For a weak quenching agent ($k_c \ll k_{-1}$),

$$k_q = k_c k_1/k_{-1} = K_c k_c , \qquad (43)$$

where K_c is the equilibrium constant of the complex formation process. In this case K_q is independent of the viscosity of the solution and should be determined by the donor–acceptor properties of the fluorophor and the quenching agent.

There have been a number of studies which have confirmed this hypothesis. Thus the quenching of the fluorescence of naphthalene derivatives by carbon tetrachloride and dimethylaniline has been investigated[149]. In the first case the quenching rate constant k_q diminishes from 1.3×10^{10} litre mol^{-1} s^{-1} for 1-methoxynaphthalene to 1.3×10^7 litre mol^{-1} s^{-1} for 1-cyanonaphthalene; on the other hand, in the second case the quenching rate constant increases from 5.7×10^7 to 2.8×10^9 litre mol^{-1} s^{-1}. This indicates different donor–acceptor natures of the naphthalene derivatives: they behave as electron acceptors in the complexes with CCl_4 and as electron donors in the complexes with $NH(CH_3)_2$. Such reversal of the donor–acceptor nature of the quenching mechanism has been observed in the benzonitriles–anisoles[150] and benzophenones–substituted benzenes[151] systems.

The problem has been studied in detail in relation to the quenching of 9- or 9,10-substituted anthracenes (An) by various substances[152-155]:

(XXIII)

For the quenching of An having the general formula (XXIII) by triphenylphosphine (Pp), linear correlations have been established between the logarithm of k_q and the σ constants of the substituents, the values of ρ for compounds with electron-accepting and electron-donating substituents being 0.55 and 3.34 respectively. The positive sign of ρ shows that the quenching takes place in the complex $\overset{+}{An}Pp$ and that the quenching process is more sensitive to structural changes in the molecules for all electron-donating substituents. Analogous data have also been obtained using *N*,*N*-dimethylaniline as the acceptor. On quenching of anthracenes (XXIII) by tris(pentafluorophenyl)phosphine (PPp),[155] the opposite relation is observed: the Hammett correlations $\lg k_q \propto \sigma$ have negative reaction constants: $\rho = -1.15$ for compounds with electron-accepting substituents and $\rho = -0.78$ for compounds with electron-donating substituents. Consequently the quenching takes place via the complex $\overset{+}{An}PPp^-$. Whereas in the quenching of the naphthalene derivatives by acetyl chloride in a liquid solution the quenching efficiency (the Stern–Volmer constant) increases with decrease of the ionisation potentials of the naphthalene derivatives[158], in the quenching of polycyclichydrocarbons by tetracyanoethylene in a liquid solution the process is controlled by diffusion[159]. The quenching of the fluorescence of the acridinium ion (acceptor) by alkyl and aryl bromides and iodides (donors) probably[160] proceeds via the formation of an exciplex [see Scheme (39)], i.e. constitutes an intersystem crossing. In the case of quenching agents with ionisation potentials I_D less than 8.7 eV the process is controlled by diffusion, in accordance with Scheme (42). For $I_D > 8.7$ eV, the quenching proceeds via a charge-transfer complex, in conformity with Scheme (43). The dependence of the free energy of formation of the exciplexes on the donor–acceptor properties of the components has been examined[161,162].

4. The study of the influence of the formation of non-luminescent complexes in the ground state on the luminescence of the components:

$$^1D + {}^1Q \overset{K_c}{\rightleftarrows} {}^1(DQ) . \qquad (44)$$

For many problems in physical organic chemistry (particularly for the study of intramolecular interactions), this case (quenching of the first kind[157]) is of special interest. The literature data on this problem are extremely limited and refer mainly to liquid solutions.

According to Parker[163], quenching of the first kind is described by the Stern–Volmer equation, but the quenching constant K_Q represents the equilibrium constant of the complex formation process (44). The experimental quenching constants in this case as a rule exceed the equilibrium constants determined from the absorption spectra[164–170]. Positive deviations from the linear Stern–Volmer equation are then observed and the experimental curve is described satisfactorily by the equation[164,168–170]

$$\varphi_0/\varphi = (1+K_q[Q])(1+K_Q[Q]) \quad , \qquad (45)$$

where K_q is the constant of the dynamic quenching process (of the second kind) and K_Q is the constant of quenching of the first kind, i.e., according to Parker, the equilibrium constant for the complex formation process.

The validity of Eqn.(45) implies that two quenching mechanisms—of the first and second kinds—operate simultaneously in liquid solutions. It has been shown[170] in relation to the quenching of chlorophyll and its derivatives by aromatic nitro-compounds that the contribution of the quenching of the first kind increases as the donor–acceptor bonds are strengthened. The complex picture of the luminescence quenching process involving CTC described above hinders the application of this method to the study of weak complexes in the ground state and intramolecular interactions. However, this possibility appears when the luminescence is quenched as a consequence of the formation of complexes in the ground state in a low-temperature matrix, where the diffusion of molecules is eliminated and only the mechanism of the quenching of the first kind operates. This case has been examined in a study[171] where a linear relation between the logarithm of the Stern–Volmer quenching constant and the charge-transfer frequencies in the absorption spectra of the CTC has been found for the quenching of naphthalene derivatives by TCE at 77 K:

$$\ln K_Q \cdot 10^{-4} = -7.40\ \nu_{CT} + 14 \quad . \qquad (46)$$

In addition, a linear correlation has also been established between K_Q and K_C [the equilibrium constant of the complex formation reaction between naphthalene derivatives and TCE at 298 K (the Benesi–Hildebrand method)]:[172]

$$K_Q \cdot 10^{-4} = (2.16 \pm 0.22)\ K_c + (0.49 \pm 0.33) \quad , \qquad (47)$$

the fact that $K_Q \neq 0$ is obtained for $K_C = 0$ (the absence of complex formation in the ground state) being possibly associated with the presence of contact complexes in solution.

The method for the investigation of complex formation described above, which can be referred to as static quenching of luminescence of the first kind, can be used when (a) the linear Stern–Volmer relation holds in the working range of the concentrations of the quenching agent and (b) there is a linear relation between the logarithms of the quenching constant (or in a special case between the constants themselves) and the donor–acceptor characteristics of the substances—fluorophors or quenching agents (ionisation potentials, electron affinities, σ constants, charge-transfer frequencies, etc.). Subject to tests of the validity of the given conditions, the method has been used to investigate complex formation on the ground states of indigo–π-acceptors[173] and organometallic compounds–oxygen (or t-butyl peroxide) systems[174–176]. In the latter case valuable information was obtained about the intramolecular interactions in organomercury compounds.

* * *

Thus electronic absorption and emission spectroscopies are informative methods for the investigation of intramolecular interactions in the molecules of the species involved in charge-transfer complexes and of the characteristics of complex formation in general. The information thus obtained is important not only for the study of the mutual influence of atoms in organic and particularly organoelemental compounds (the facts concerning this field have been vigorously accumulated and treated systematically) but also for the establishment of empirical relations between the structures and reactivities of compounds and for the modelling of primary reactions in complex chemical transformations. In the latter instance, particularly for the recording of weak complexes of organoelemental compounds, emission spectroscopy in low-temperature matrices is extremely promising.

Polyhedral Organic Molecules and Ions—Structural Analogues of Organometallic Clusters

V.I.Minkin and R.M.Minyaev

The results of experimental and theoretical studies are considered and the principles of the stabilisation of non-classical and highly strained polyhedral structures of organic molecules and ions are formulated. The electron count rules regulating the stability of definite polyhedral forms are analysed. The analogy between the electronic structures of organic and organometallic clusters is demonstrated.
The bibliography includes 189 references.

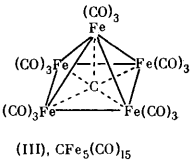
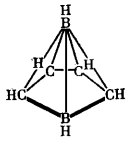
I. ORGANOMETALLIC AND HYDROCARBON CLUSTERS

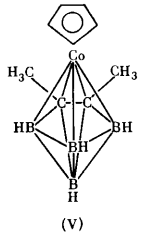
Hydrocarbon chains and rings incorporating heteroatoms (oxygen, nitrogen, sulphur, etc.) as individual units make up the skeletons of organic molecules. The usual method of joining together several rings in a molecule is annelation, i.e. fusion in one plane via a common edge, while the formation of three-dimensional structures in which planar rings would correspond to individual faces of polyhedra is not characteristic of organic compounds.



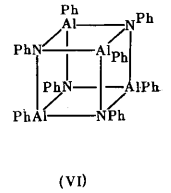
In contrast to organic chemistry, inorganic, coordination, and organometallic chemistry abound in examples of polyhedral structures: boranes, carbaboranes, transition metal carbonyl clusters, etc. Compounds (I)–(VI), chosen for illustration, comprise some of the smallest polyhedra: the tetrahedron, the tetragonal and pentagonal pyramids, the pentagonal bipyramid, and the cube.



(I), $Jr_4(CO)_{12}$



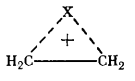
(II), $C_2B_3H_5^{2-}$



(III), $CFe_5(CO)_{15}$

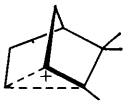
(IV), $C_4B_2H_6$

(V)



(VI)

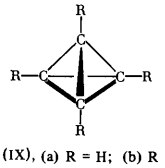
The causes of the above difference consist in the characteristics of the electronic structures of organic and organometallic compounds. In a hydrocarbon chain or ring of an organic molecule each individual bond can be described as a two-centre two-electron bond and the number of bonding electron pairs is equal to the number of bonds, in complete agreement with the requirements of the classical theory of valence. On the other hand, in the above structures of carbaboranes and clusters the total number of valence electrons is insufficient for the formation of "normal" two-centre two-electron bonds between all the atomic centres in close proximity, which determines their classification as electron-deficient or excess-orbital compounds. However, the geometrical configurations of these compounds ensure the maximum filling of all the bonding many-centre orbitals by electrons[1–5], enabling at the same time each atom to retain around itself the number of electrons corresponding to the inert gas electronic configuration[6].



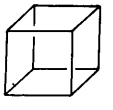
Thus, in essence, the three-dimensional structure of the molecular skeleton in electron-deficient compounds, the deviations from the standard valence angles [the bonds between carbon atoms in compounds (II)–(V)], and the unusually high coordination numbers [ranging from 5 for the carbon atom in the carbido-carbonyl cluster (III) and in the series of closo-carbaboranes[5,7] to 8 for the carbon atoms in the carbido-carbonyl clusters of cobalt and osmium[8]] are due to the necessity to observe the principal requirement of the stability of the molecular structure—the maximum utilisation of all the valence electrons for bonding. The latter becomes possible for a geometrical structure of the molecule which ensures the most effective interaction between the orbitals and its constituent fragments. The conditions for the maximum overlap of such orbitals are in general different from the requirements of the standard geometry and the usual valence limitations. The classical theory of structure and classical stereochemistry therefore lose their predictive power and the ability to describe such structures.

This fairly rare situation is encountered in organic chemistry mainly in two fields: the chemistry of non-classical ions[9] and strained structures[10]. Non-classical ions are usually understood as organic cations (electron-deficient species) containing one or more σ-bridges[9,11,12], as in the cation (VII)

or in the norbornyl cation (VIII).



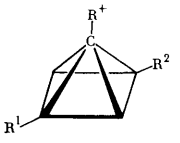
(VII), X = H, Hal, or CH_3



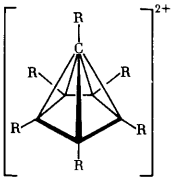
(VIII)

The enforced departure from the classical description of the cations of this type places them among the most controversial structures in organic chemistry. Thus, according to Dewar's count[13], more than 500 studies were devoted to the theoretical and experimental investigation of the norbornyl cation (VIII) as early as 1977.

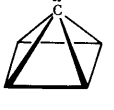
In contrast to the non-classical ions, in the strained molecules, starting from cyclopropane, the standard rules of valence hold, but the valence angles are highly distorted. The compensation of the angular and bond strain necessary to ensure stability is achieved by concentrating the electron cloud within the molecular skeleton and not along the lines of individual skeletal bonds[14]. Examples of compounds of this type with regular polyhedral structures (platonic bodies) are provided by tetrahedrane (IX)[15] and cubane (X)[16].



(IX), (a) R = H; (b) R = t-C_4H_9



(X)



Compounds (IX) and (X) are organic analogues of clusters (I) and (VI) respectively and, like the pyramidal non-classical cations of types (XI) and (XII) obtained recently[18-20], have the same polyhedral structure as the isoelectronic *nido*-carbaboranes (II) and (IV). A pyramidal structure has been predicted by calculations[17] also for the metastable isomer of the neutral hydrocarbon C_5H_4 (XIII), whose electron deficiency is caused by the removal of the electron pair of the apical carbon from involvement in the formation of skeletal bonds.

(XI), (a) R = R^1 = R^2 = H;
(b) R = R^1 = CH_3; R^2 = H (Ref.18)
(c) R = R^1 = R^2 = CH_3 (Ref.19)

(XII), (a) R = H;
(b) R = CH_3 (Ref.20).

(XIII)

Evidently the structural similarity of the two series of compounds (I)–(IV) and (VI), on the one hand, and (IX)–(XIII) on the other, examined above, is not fortuitous and is determined by analogies between their electronic structures. Nevertheless the synthesis of compounds (IXb), (X), (XIb), and (XIIb) was treated by organic chemists as a sensation. Increasing amounts of experimental and calculated data are being accumulated nowadays on the unusual polyhedral structures of organic molecules and ions and it is becoming increasingly clear that there are common factors governing the structures of these and structurally analogous organometallic and inorganic compounds.

There is reason to believe that, from the standpoint of the nature of the chemical bond, the field of polyhedral compounds in organic chemistry is closest to organometallic and inorganic chemistry. The aims of the present review are as follows: (a) to elucidate the causes of this analogy, (b) to examine the experimental and theoretical data on polyhedral organic structures which have already accumulated, and (c) to examine the descriptive and predictive possibilities of a general qualitative approach to the study of the causes of the stabilisation of the non-classical polyhedral organic molecules and ions based on the so-called reconstruction or fragment analysis.

II. RECONSTRUCTION ANALYSIS OF THE MOLECULAR ORBITALS OF COMPLEX MOLECULES

The principal idea of reconstruction analysis is to reproduce the molecular orbitals (MO) of the entire molecule A–B–C–D–... from data for the energies and forms of the molecular orbitals of its individual fragments. This physically clear idea, which combines the simplicity and logic of classical structural representations with the quantum-mechanical description of many-centre interactions, has been used in a whole series of theoretical investigations, starting with Dewar's work[21], but has been developed most logically by Hoffmann[22,23]. His two brief reviews contain an extremely valuable bibliography on this topic.

In essence, the above problem is one of perturbation theory. Its solution at different levels of approximation has been analysed in detail[24-28]. We shall consider here briefly the most important relations for the simplest case of the interaction of two molecular fragments in terms of the one-electron approximation where the overall result of the interaction of the fragments is determined by the sum of the orbital interactions.

1. The Interaction of Fragment Orbitals

When two non-degenerate orbitals ϕ_a and ϕ_b having the energies ε_a and ε_b and belonging to fragments A and B respectively interact, two new orbitals of the overall system A–B are formed (ϕ'_a and ϕ'_b, Fig.1). The lower orbital ϕ'_a is then stabilised by the amount

$$\Delta\varepsilon_a = \frac{(H_{ab} - \varepsilon_a S_{ab})^2}{\varepsilon_a - \varepsilon_b} \quad , \qquad (1)$$

while the upper orbital ϕ'_b is destabilised by the amount

$$\Delta\varepsilon_b = \frac{(H_{ab} - \varepsilon_b S_{ab})^2}{\varepsilon_b - \varepsilon_a} \quad , \qquad (2)$$

where H_{ab} is the matrix element of the interaction operator $\langle\phi_a|H'|\phi_b\rangle$ and $S_{ab} = \langle\phi_a|\phi_b\rangle$ is the overlap integral of the orbitals ϕ_a and ϕ_b.

Like the orbital energies of the occupied and lowest unoccupied molecular orbitals, the quantity H_{ab} is negative. Since $\varepsilon_a < \varepsilon_b$ (Fig.1a), it is seen from Eqns.(1) and (2) that, in terms of absolute magnitudes, $\Delta\varepsilon_a < \Delta\varepsilon_b$. Consequently if the two orbitals of the fragments ϕ_a and ϕ_b are occupied by pairs of electrons which are transferred to the MO of the A–B system, then the overall effect of such interaction is destabilisation. The effect of the four-electron destabilisation is none other than the well known exchange repulsion of occupied electron shells. The possibility of describing this effect by Eqns.(1) and (2) depends on being able to take into account the overlap integral S_{ab} between the interacting orbitals.

A simple relation is usually postulated between H_{ab} and S_{ab}[26-28]:

$$H_{ab} = kS_{ab} \quad , \qquad (3)$$

where k varies within wide limits as a function of the method of calculation: from −8.55 eV (the Hückel molecular orbital method[26]) to −39.7 eV (the SCF MO methods[28]), etc.

Taking into account Eqn.(3), it is easy to determine which factors influence the orbital interactions. The main factor is the overlap integral between the orbitals, which is determined by the symmetry of the orbitals and their mutual orientation. The second factor is the proximity of the energy levels of the fragment orbitals. The strongest interaction corresponds to degenerate ($\varepsilon_a = \varepsilon_b = \varepsilon$) orbitals ϕ_a and ϕ_b (Fig.1*b*). In this case the stabilisation energy of the lower orbital ϕ'_a and the destabilisation energy of the upper orbital ϕ'_b of the A–B system are calculated in terms of the first-order perturbation theory with the aid of the relations

$$\Delta\varepsilon_a = \frac{H_{ab} - \varepsilon S_{ab}}{1 + S_{ab}} \quad ; \qquad (4)$$

$$\Delta\varepsilon_b = \frac{-H_{ab} + \varepsilon S_{ab}}{1 - S_{ab}} \quad . \qquad (5)$$

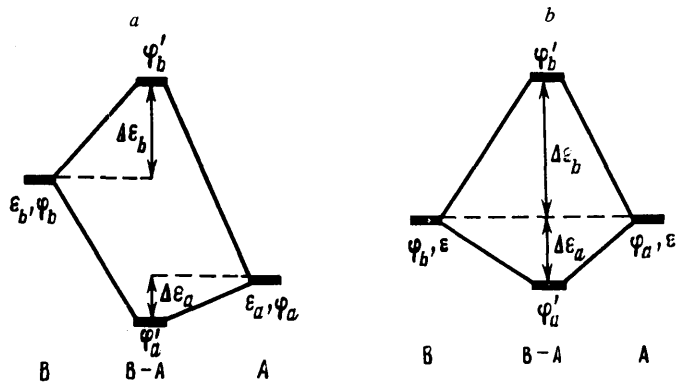


Figure 1. The formation of the MO of the A–B system (ϕ'_a, ϕ'_b) from the orbitals of the fragments A and B (ϕ_a and ϕ_b): *a*) interaction of non-degenerate orbitals; *b*) interaction of degenerate orbitals.

The orbitals of the A–B system (ϕ'_a and ϕ'_b) can be represented as a linear combination of the orbitals of the fragments A and B:

$$\varphi_a' = \varphi_a + \lambda\varphi_b \quad , \qquad (6)$$

$$\varphi_b' = \varphi_b + \mu\varphi_a \quad , \qquad (7)$$

and in absolute magnitude the coefficients λ and μ are less than unity, i.e. the orbital ϕ'_a involves a greater contribution of ϕ_a and the orbital ϕ'_b involves a greater contribution of ϕ_b. The interactions of the orbitals are additive in pairs, so that the above scheme can be readily extended to the interaction of a large number of orbitals belonging to additional fragments.

2. Fragmentation of the System. Group and Bond Orbitals

An important problem is how to isolate most effectively the fragments the interaction of the orbitals of which is most important for the determination of the stability (or instability) of the system as a whole. In the language of the LCAO-MO method, the problem is reformulated into one involving the determination of the delocalised MO of a complex system in the form of a linear combination of localised MO of its fragments, i.e. in the form of Eqns.(6) and (7).

Analysis of the wave functions and the electron distributions for a wide range of organic and inorganic compounds[29–31] has shown that, for both saturated and unsaturated and conjugated compounds, the delocalised MO can be constructed from a small number of localised group orbitals, which can be transferred from one system to another (transferable orbitals). For hydrocarbon systems, such groups are CH, CH_2, and CH_3; in the molecules with heteroatoms these are their isoelectronic fragments. Even in molecules with many-centre bonds—boranes and their derivatives[32], transition metal clusters[2,5], and π-complexes[22]—it is possible to isolate the group orbitals of several main fragments—the "building blocks" of the delocalised MO of a wide variety of compounds.

Fig.2 presents the group orbitals of the hydrocarbon fragments CH_n constructed in the form of linear combinations of the atomic orbitals of carbon (2*s*, $2p_x$, $2p_y$, $2p_z$) and hydrogen (1*s*). All the orbitals can be divided into two groups. The first includes the σ-orbitals (σ_{CH}, σ_{CH_2}, σ_{CH_3}), whose form ensures the accumulation of electron density in the region of C–H bonds. On formation of the molecule from the CH groups, these orbitals interact weakly with one another, since the overlap between them is insignificant [see Eqns.(1), (2), (4), and (5)]. Such orbitals are regarded as bonding[29]. In contrast to the group σ-orbitals, a considerable proportion of the electron density in the orbitals of the π- and *n*-types is distributed outside the range of the bonds within the groups. The interaction of such group orbitals determines the formation of new bonds and the stabilisation or destabilisation of the structure made up of several groups. The conditions for the maximum overlap of the group π- and *n*-orbitals, which depend on the relative positions of the groups, dictate the resultant geometry of the system.

We shall illustrate these postulates by analysing the MO of molecules of the type A_2H_4 formed from the group orbitals of the AH_2 fragments (Fig.3). Only group orbitals with suitable symmetry properties are combined. The nature of the stabilisation of the planar structure of C_2H_4 is related to the interaction of boundary group orbitals (*n* and *p*), leading to the formation of bonding σ_{CC} and π_{CC} orbitals of ethylene. By virtue of the considerable overlap, the interaction of the *n*- and *p*-orbitals leads to a greater splitting of their levels, the stabilisation of the bonding combination of *n*-orbitals, and the formation of bonding $\pi(1b_{1u})$-MO (lying below the atomic *p*-level).

The C_2H_4 molecule is an example of a fully occupied system of bonding MO, which is the reason for its stability in the D_{2h} configuration. For the hydrazine molecule N_2H_4, having two electrons more than the ethylene molecule, the additional electrons in the D_{2h} structure should occupy the antibonding $\pi^*(1b_{2g})$-MO. Because of this, the stable conformation of the molecule does not consist of the planar D_{2h}-form but is represented by a skewed structure (the angle of rotation about the N–N bond is ~ 90°), pyramidalised at the nitrogen atoms, in which the energetically unfavourable π*-MO is not formed[34,36].

Analysis of the scheme of orbital interactions leads to a series of general and important postulates[28,29,34,37,38], which will be used in the subsequent discussion.

(1) The main type of orbital interactions of fragments, which determines the stability of the system, is the interaction of boundary and immediately adjoining orbitals of the *n*- and π-types. The interaction of the σ-orbitals lying below is of the repulsion type but, by virtue of the small overlap of such orbitals belonging to different fragments, the repulsion effect is comparatively weak.

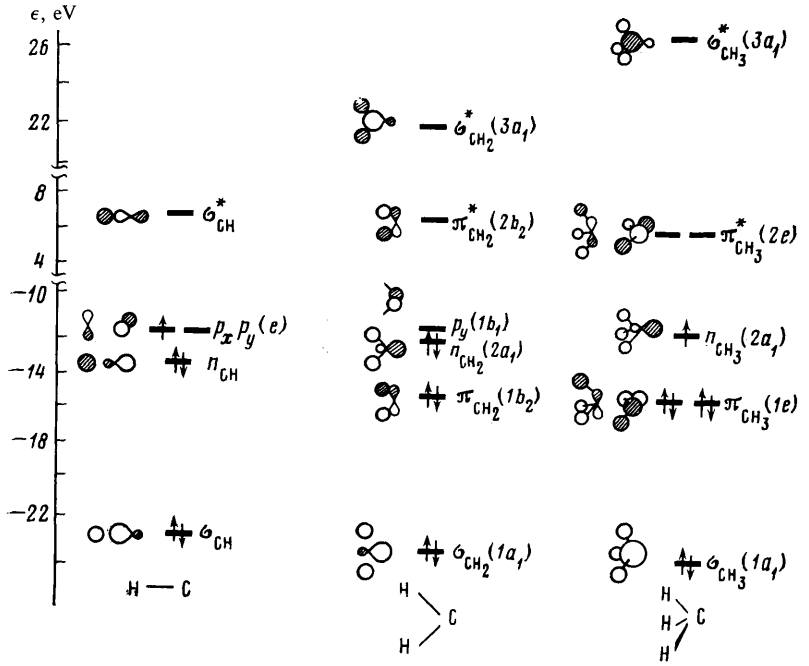

Figure 2. Group orbitals of the hydrocarbon fragments CH, CH_2, and CH_3.[29,33,34] The orbital energies have been calculated by the extended Hückel method[35].

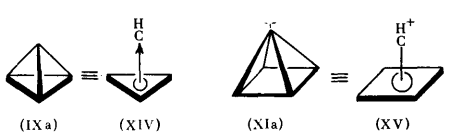


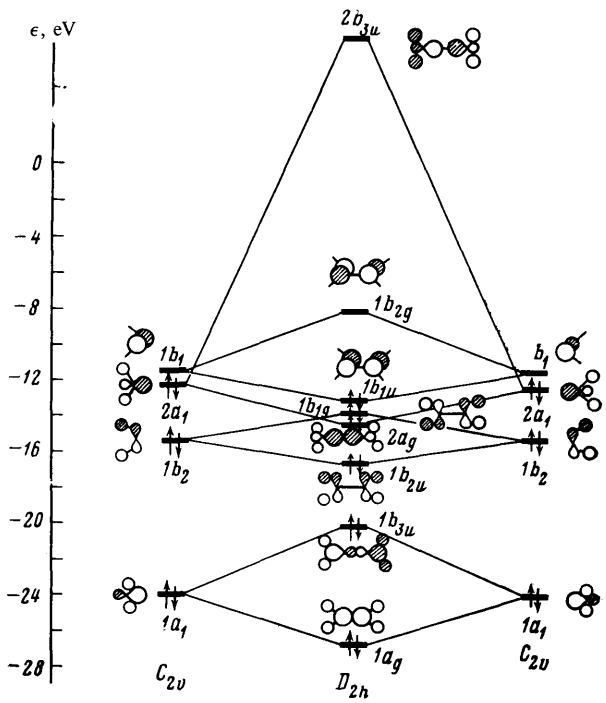
(2) Systems where the number of electrons does not exceed twice the number of bonding orbitals correspond to stable structures. This postulate constitutes the basis of all the electron count rules describing the stability of typical structures.

(3) Within the framework of the MO methods neglecting direct allowance for electron repulsions, there are no special limitations imposed on the method of fragmentation of the complex molecule or ion. However, for a qualitatively clear analysis, it is better to isolate fragments reflecting to the maximum extent the symmetry of the system and having valence orbitals of the *n*- and π-types.

3. Fragmentation of the Polyhedra

The last postulate is particularly important when the method of reconstruction analysis is applied to the determination of the MO of polyhedral structures. The structural units of the polyhedron are the vertices, edges, and faces; in a molecular system atoms or σ-linked groups, π-bonds, and conjugated cyclic fragments correspond to them. In relation to hydrocarbons, on which attention is concentrated in the present review, the vertices are C, CH, CH_2, CH_3, the edges are HC≡CH, while the faces are the $(CH)_n$ rings, where $n \geq 3$.

Pyramidal forms can be made up of these structural units by adding vertices to the basal plane, for example, via scheme (XIV) for tetrahedrane and (XV) for the cation $(CH)_5^+$.



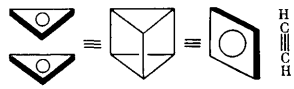


Figure 3. The formation of the MO of a molecule of the type A_2H_4 from the group MO of the AH_2 fragments. The filling with electrons for C_2H_4 and CH_2 is illustrated (calculation by the extended Hückel method).

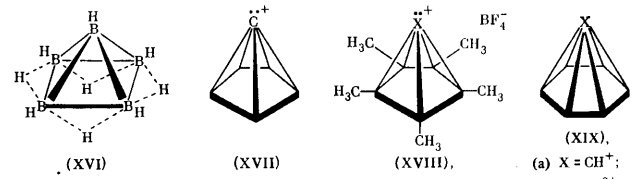
More complex polyhedral molecules can be fragmented in several ways, using the above structural elements. Thus the prismane molecule can be made up either by the parallel superposition of two cyclopropenyl rings or by adding the acetylene edge to the cyclobutadiene ring.

This fragmentation scheme originated from the topological classification of the interactions of chains into *peri-*, *spiro-*, *longi-*, and *lati*-cyclic types developed by Goldstein and Hoffmann[39]. Indeed, although rings are absent from this scheme, they are obtained by the pericyclic combination of two or several conjugated chains (ribbons).



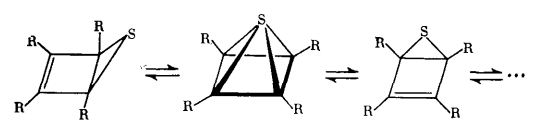
Thus, apart from the orbitals of the CH_n groups (Fig.2), the orbitals of the π-bonds (Fig.3) and those of conjugated rings $(CH)_n$ are required for the construction of the MO of polyhedral hydrocarbon structures on the basis of reconstruction analysis. The conjugated rings can be readily obtained by combining n group orbitals of CH, the full analogy between the schemes for the formation of delocalised σ- and π-MO being retained[29,30]. The different versions of the combination of the above fragments (as well as the isoelectronic heteroatomic groups) into polyhedral structures will be examined below in succession and the electronic requirements for their stability will be analysed. The results of the theoretical analysis will be compared with the results of experimental investigations.

III. PYRAMIDAL STRUCTURES

1. Pyramidal Hydrocarbons and Their Heteroanalogues

The simplest pyramidal structure is that of the tetrahedrane molecule (IXa). The problem of the synthesis of tetrahedrane was formulated more than half a century ago and stimulated a vigorous investigation of methods for the synthesis and reactions of its possible precursors[10,40]. Nevertheless the tetra-t-butyltetrahedrane (IXb) obtained recently still remains the only fairly completely characterised compound with a carbon skeleton of type (IX).[15,41] The strain energy E_{str} of the tetrahedrane molecule is 148.8 kcal mol^{-1} according to latest estimates[42], i.e. ~ 25 kcal mol^{-1} for each C–C bond, which is the upper known limit for strained organic compounds. The reason for the high value of E_{str} is evidently high angular strain.

The next member of the series of pyramidal hydrocarbons $(CH)_n$, namely the cation $(CH)_5^+$ (XIa)≡(XV) is not only a strained but also a non-classical structure with a pentacoordinate carbon atom at the vertex. The possibility of the existence of such a cation was first postulated by Williams[43], who emphasised the fact that it is isoelectronic with the pyramidal pentaborane B_5H_9 (XVI). Analysis and calculations by the extended Hückel method by Stohrer and Hoffmann[44] explained the nature of the stabilisation of this non-classical structure and almost simultaneously Masamune et al.[18] reported the experimental discovery of the dimethyl derivative (XIb), which is stable in acid media. Reactions leading to derivatives of the first pyramidal cation (XI) have been studied in detail (see the reviews[45,46] and a communication[19]) and the stability of the C_{4v} structure of the cation has been confirmed by a whole series of semiempirical[44,45,47–50] and non-empirical[51,52] calculations.



(XVI) (XVII) (XVIII), (a) X = Ge; (b) X = Sn (XIX), (a) X = CH^+; (b) X = Sn^{2+}; (c) X = Pb^{2+}.

In 1973 Hogeveen and Kwant[20,53] reported a new pyramidal C_{5v} hydrocarbon—the hexamethyl derivative of the dication $(CH)_6^{2+}$ (XIIb). An analogous pyramidal C_{5v} structure has been predicted by MINDO/3 calculations also for the metastable isomer of the cationic phenylcarbene (XVII)[54] and quite recently Jutzi et al.[55] synthesised the extremely stable germanium and tin analogues of the cationic carbene (XVIII) and demonstrated their C_{5v} structure by direct X-ray diffraction study. However, it was found that the pyramidal C_{6v} structure (XIXa), discussed as long as 20 years ago as one of the possible structures of the norbornadienyl cation[56], does not correspond to a minimum on the potential energy surface (PES) for the cation $(CH)_7^+$,[57] while the tin dication (XIXb)[58] and the lead dication (XIXc)[59] have the C_{6v} symmetry in the crystal.

The pyramidal C_{4v} structure of the hydrocarbon C_5H_4 (XIII) (pyramidane) has been shown by MINDO/3[17,60] and non-empirical[61] calculations to correspond to a fairly deep local minimum on the PES. Despite the fact that the tetracoordinate carbon atom at the apex has an extremely strained pyramidal bond configuration[62,63] (approximately sp^6 [sic.cf.Ref.62 (Ed. of Translation)] hybridisation), the strain energy per C–C bond corresponds to only 19 kcal mol^{-1}, which makes it possible to regard the synthesis of compound (XIII) as a realistic task.

The hypothesis of the formation of a pyramidal structure of type (XX) has also been put forward to account for the mechanism of the isomerisation of 2-phenylthiophen to 3-phenylthiophen[64] and of the peripheral migration of the sulphur atom in Dewar thiophen (XXI, R = CF_3)[65]:

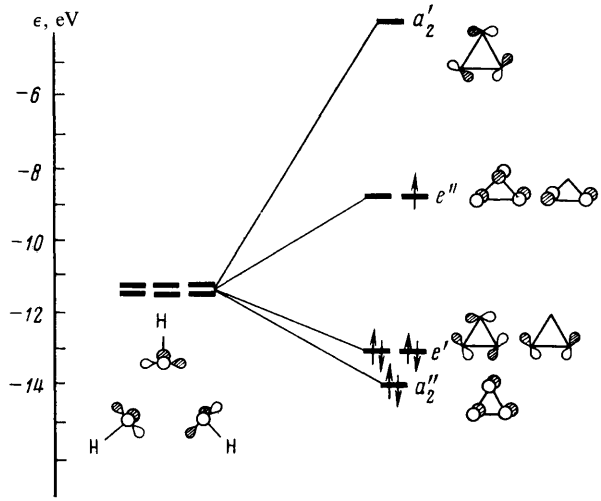
(XXIa) (XX) (XXIb)

However calculations have shown[66] that the structure (XX, R = H) corresponds to a maximum and not a minimum on the PES for the model reaction.

The data presented make it necessary to seek an answer to the question why the existence of organic pyramidal structures (IX), (XI), (XII), (XVIII), and (XIX, b and c) is possible, while others, which should formally be formed in accordance with the same principle, cannot be realised.

2. The Eight Electron Rule

The causes of the stability of some and of the instability of other C_{nv} pyramidal structures become clear in the reconstruction analysis of the MO. Compounds with a pyramidal structure can be regarded as organic π-complexes of type (XXII) formed by the [n]annulene conjugated fragment and the apical X atom or X–R group.



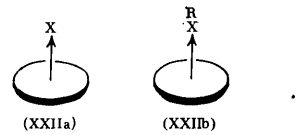


Figure 4. The formation of the MO of [3]annulene from the orbitals of three CH groups. The three p_z-orbitals of CH constitute a Hückel system and form the π-MO (a_2'', e''). The three p_y-orbitals constitute the Möbius system and form the σ-MO of the system of levels which is the inverse of that of π-MO.[67] For the complete $(CH)_3$ system, an admixture of the MO formed by the bonding CH orbitals to the molecular orbitals e' and a_2' is observed. The energies of the levels have been obtained by a calculation using the extended Hückel method.

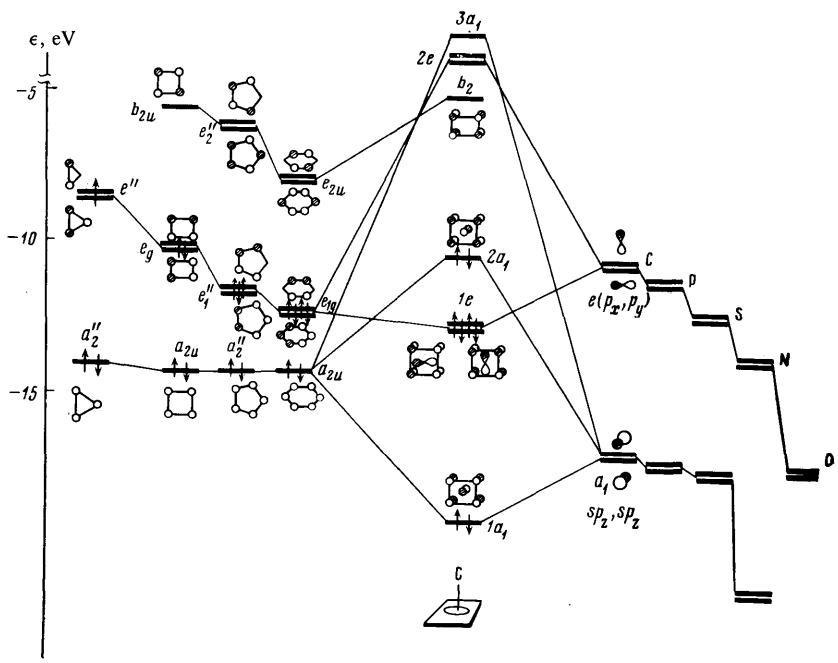
The MO for such structures are usually constructed from the atomic or group [in the case of compound (XXIIb)] orbitals of the apical centre and the orbitals of the basal ring. The latter can be formed from the orbitals of the CH group (Fig.2) and only the MO produced by combining p-AO are capable of significant interaction with the orbitals of the apical centre, i.e. have energies close to the latter and there is adequate overlap.

Fig.4 illustrates the formation of the MO of [3]annulene from the p-AO of three CH groups. Analogous systems of π-MO and Walsh σ-MO are characteristic of any [n]annulene ring. The MO obtained by mixing the bonding σ_{CH} orbitals lie outside the valence band and their electron density is concentrated in the band of the C–H bonds[29].

Calculations have shown that, as the X, XH, or XR vertex approaches the basal ring, the overlap integrals of the valence orbitals of the above groups with the π-MO of the [n]annulene ring are greater by a factor of 3–5 than the integrals for the overlap with the Walsh σ-MO. Since the energy of the interaction of orbitals is proportional, according to Eqns.(1) and (2), to the square of the overlap integral S_{ab}^2, it follows that in a qualitative study it is sufficient to take into account only the interaction between π-MO of the basal ring.



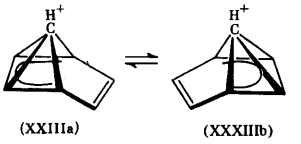


Figure 5. The reconstruction analysis of the MO of C_{nv} pyramidal systems formed by the [n]annulene ring and the apical atomic centre. The molecule of pyramidane has been chosen as an example. The MO energies have been calculated by the extended Hückel method; the energies of the hybrid orbitals were taken from Hinze and Jaffé.[68] For the C_{4v} and C_{5v} structures with an apical atom more electronegative than phosphorus and for all C_{3v} structures, an inversion of the $1e$ and $2a_1$ levels is observed.

We shall consider initially pyramidal structures of type (XXIIa) to which compounds (XIII), (XVII), (XVIII), and (XX) belong. The valence orbitals of the apical atom can be conveniently regarded as a pair of hybrid sp_z-orbitals and a pair of p_x- and p_y-orbitals. Fig.5 presents a generalised[17, 54,55,66,69] correlation diagram for the C_{nv} pyramidal system (XXIIa). The interaction of the lowest π-orbital of annulene with a pair of hybrid orbitals of the apical atom, having identical symmetry properties, leads to the formation of the bonding ($1a_1$), non-bonding ($2a_1$), and antibonding ($3a_1$) MO. Since the initial fragment orbitals are completely filled with electrons, the resulting effect of this orbital interaction is destabilisation. The fragments are bound together as a consequence of the mixing of the lowest e-MO of the ring with the p-AO of the apical atom and the formation of the bonding $1e$-level of the C_{nv} pyramidal system.

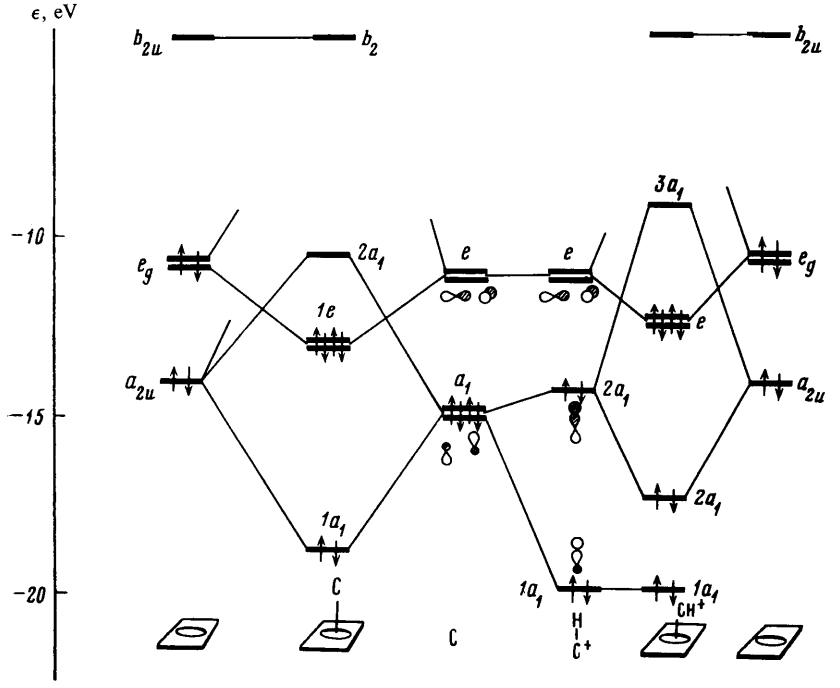
Thus the orbital interactions of the fragments of any C_{nv} pyramidal structure described above give rise to three bonding and one non-bonding MO, which can accommodate eight electrons. If the number of π-electrons of the basal ring and of the valence electrons of the apical centre (it has been suggested[70] that these electrons be referred to as "inner") exceeds eight, the antibonding MO is filled, which destabilises the structure. Indeed the hypothetical structures of pyramidane (XIII), the cationic carbene (XVII), as well as compounds (XVIII) and (XIX, b and c) meet the above requirement, whereas the C_{4v} structure (XX) and the C_{6v} structure (XIXa) each contain 10 inner electrons and do not actually occur. In order to become adapted to the requirement of an eight-electron shell, such structures are distorted to give less symmetrical forms: (XXIa) for thiophen and (XXIII) for the norbornadienyl cation, for which the fluctuating conformation with a single "disconnected" π-bond is stable[71,72].

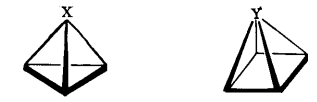
(XXIIIa) (XXXIIIb)

The correlation diagrams for pyramidal structures of type (XXIIb)[44,46,70] are analogous to that presented in Fig.5, which is due to the similarity of the fragment orbitals. Fig.6 illustrates the relation between the structure of the MO of the (XXIIa) and (XXIIb) systems. The significant difference is that the non-bonding $2a_1$ level in structures (XXIIa) is transformed into the low-lying $1a_1$ level of the X–R bond, which stabilises the structure. Like structure (XXIIa), structures (XXIIb) contain four bonding MO, which can be filled by not more than eight electrons, including the π-electrons of the basal ring, the valence electrons of the atom X, and one additional electron from the group R involved in the formation of the electron pair of the X–R σ-bond.

In combination with the analogous conclusion for compounds (XXIIa), the above conclusion can be regarded as the formulation of the eight electron ($8e$) rule for the stability of C_{nv} pyramidal structures. The $8e$ rule can be understood as the tendency of the apical atom of the non-transition element to build up its electron shell to that of the corresponding inert gas. In this sense, it is analogous to the familiar 18 electron rule for transition elements.

Taking into account the $8e$ rule, it is possible to postulate the capacity for the existence of pyramidal organic molecules and ions of types (XXIV) and (XXV).





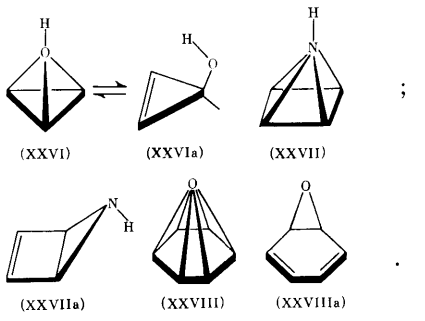


Figure 6. Relation between the correlation diagrams for the MO of the pyramidal structures (XXIIa) and (XXIIb). Pyramidane and the $(CH)_5^+$ cation have been chosen as examples.

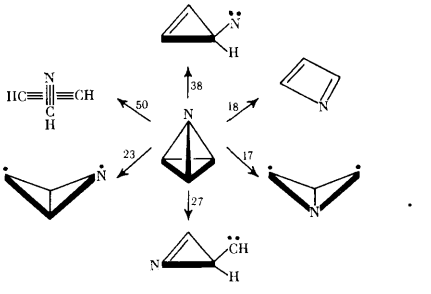
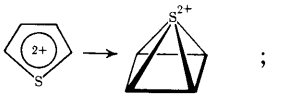


(XXIV), X = C⁻, CH, N, P, O⁺, or S⁺ (XXV), Y = C, CH⁺, Si, SiH⁺, N⁺, P⁺, O²⁺, or S²⁺ .

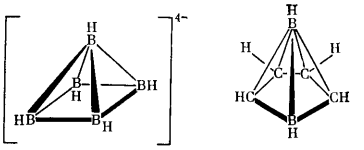
Calculations[69,73] by the MINDO/3 method with complete optimisation of all the geometrical parameters have indeed shown that all the structures quoted above for the C_{3v} and C_{4v} symmetry correspond to local minima on the PES. On the other hand, the non-classical structures (XXVI)–(XXVIII), which do not satisfy the 8*e* rule, correspond to maxima on the PES and relax to the stable forms (XXVIa)–(XXVIIIa):



(XXVI) (XXVIa) (XXVII) ; (XXVIIa) (XXVIII) (XXVIIIa) .

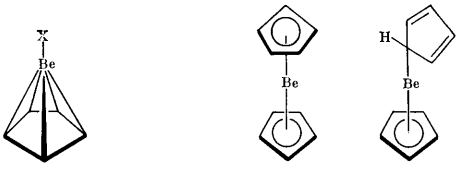
The validity of the 8*e* rule implies merely that the structure corresponds to a minimum on the PES for a molecule or ion. In order that such a structure should have a sufficiently long lifetime, it is necessary that it should have adequate kinetic stability in relation to different possible isomerisation and ring decomposition reactions. Detailed non-empirical[74] and MINDO/3[75] calculations on such transformations have been made for the tetrahedrane molecule, which is kinetically stable despite its strain. The pyramidane molecule has analogous properties[76]. The above schematic formulation[69] of the ring decomposition and isomerisation reactions involving another hitherto unknown pyramidal structure, namely that of azatetrahedrane (XXIV, X = N), where the numerals above the arrows indicate the activation barriers (kcal mol^{-1}) calculated by the MINDO/3 method, also indicates the kinetic stability of this compound even in relation to more stable isomers {azacyclobutadiene, 3-azabicyclobutane[1.1.0]diyl} and the decomposition products:

On the basis of the rule formulated above, it is possible to predict transformations which should lead to non-classical pyramidal structures. Non-empirical and MINDO/3 calculations[77] suggest that the thiophen dication (XXIX) is unstable and relaxes without an activation barrier to the pyramidal dication (XXV, Y = S^{2+}):



(XXIX) (XXV), Y = S^{2+} .

3. Pyramidal Structures in a Series of Boranes and Organometallic Compounds of Non-transition Metals



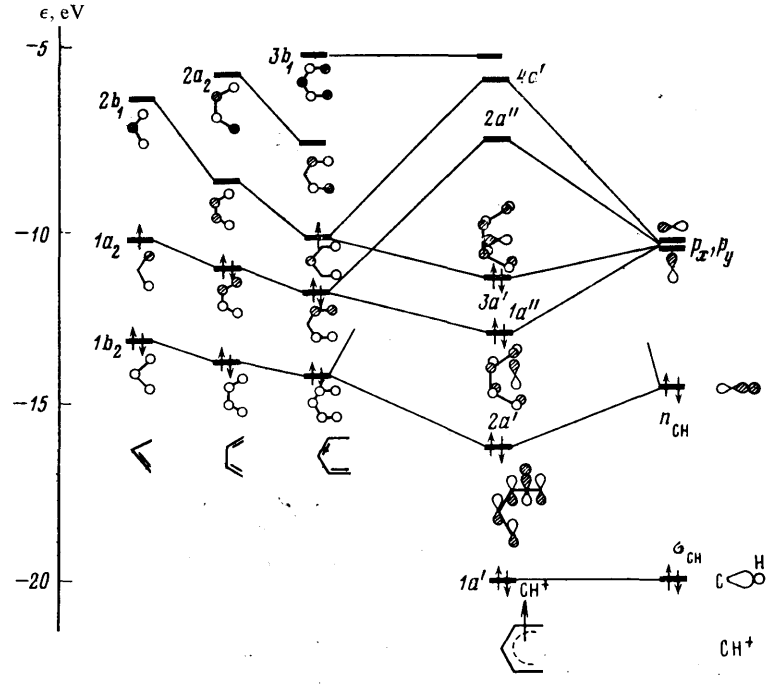
In contrast to organic compounds, the pyramidal (*nido*) structures are not an exception but the rule in the series of boranes and carbaboranes[1,4,7,78]. Electron count rules, taking into account the so-called skeletal electrons of all the groups[2–5], which are discussed above (see Section VI) have also been developed for these compounds. The 8*e* rule constitutes an equivalent formulation.

On the basis of the fragmentation scheme examined above, Lipscomb[1] predicted that the $B_nH_n^{4-}$ anions should have the pyramidal *nido*-structure, for example, compound (XXX, $n = 5$). Indeed the sum of the π-electrons of the basal ring (0) and the electrons of the apical group (8) is 8. The pyramidal structure (II) is expected[4] for the dianion $C_2B_3H_5^{2-}$ (2 + 6 inner electrons), isoelectronic with compound (XXX). For the stable *nido*-carbaborane $C_4B_2H_6$ (XXXI), this structure has been established experimentally[7,79] (4 + 4 inner electrons). In general any carbaboranes $C_4B_{n-4}H_n$ and the dianions $C_2B_{n-2}H_n$ should have the $C_{(n-1)v}$ pyramidal *nido*-structure:

(XXX) (XXXI) .

Numerous pyramidal C_{5v} structures have been found for derivatives of cyclopentadienylberyllium hydride (XXXII). Data on the structures of and theoretical calculations for these compounds have been described[70,80]. The beryllocene molecule (XXIII), whose structure has been investigated by all possible experimental methods, including electron diffraction and low-temperature X-ray diffraction measurements[31,81–83], is of special interest in this series. The sandwich structure (XXXIIIa) and the half-sandwich structure (XXXIIIb) are believed to be most probable. The latter belongs to type (XXIIb) and corresponds to the 8*e* rule, to which Jemmis et al.[80] relate the results of their calculations (STO-3G basis set), indicating that structure (XXXIIIb) is preferable. Recent more complete calculations[82] using an extended basis set led to an analogous conclusion. It is of interest that the structure of the MO of the valence band obtained in this calculation is exactly consistent with the qualitative scheme in Fig. 6.

(XXXII), (a) X = H, (b) X = CH_3, (c) X = BH_4, (d) X = Cl, (e) X = Br (XXXIIIa) (XXXIIIb) .



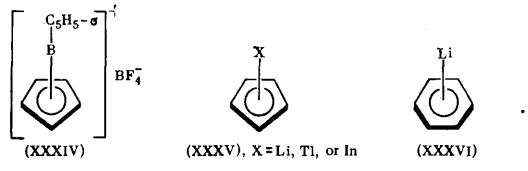


Figure 7. Reconstruction analysis of the MO of the non-classical cations formed by a polyene chain and a CH^+ vertex. The cation (XXXVIII) has been taken as an example. The MO energies have been calculated by the extended Hückel method.

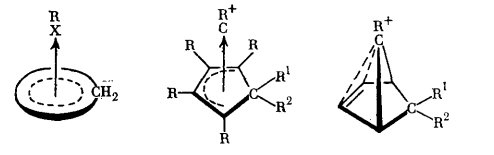
A pyramidal structure has been established by X-ray diffraction for the cation (XXXIV), which is isoelectronic with beryllocene[84]. Cyclopentadienylthallium[85] and cyclopentadienylindium[86] have analogous structures in the gas phase (8 inner electrons). According to calculations[87,88], cyclopentadienyl-lithium also has the C_{5v} structure (XXXV). The number of inner electrons in this compound is 6, which leads to additional stabilisation, since the non-bonding $2a_1$ MO (Fig.5) remains unoccupied. Presumably, in conformity with the 8*e* rule, the stable form of cycloheptatrienyl-lithium has the pyramidal C_{7v} structure (XXXVI):



(XXXIV) (XXXV), X = Li, Tl, or In (XXXVI)

4. Homoconjugated Rings in the Basal Plane

Cyclic groups produced by the insertion of methylene and isoelectronic groups in one or several bonds of the [*n*]annulene ring also have a system of π-orbitals suitable for effective binding to the apical group. Such substitution diminishes but does not abolish the endocyclic orbital interactions and, according to a theorem[39], the symmetry of the π-orbitals in such a ring does not change compared with the initial conjugated ring. Consequently the type of interaction of these orbitals with those of the apical fragment does not change and the 8*e* rule can be extended to pyramidal structures, in the basal plane of which there is a polyene group, isolated π-bonds, and individual π-centres, the relative disposition of which is close to that of a closed ring.

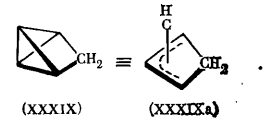


Fig.7 illustrates the formation of four bonding MO in structures of type (XXXVII) in relation to the homo-$(CH)_5^+$ cation (XXXVIII):

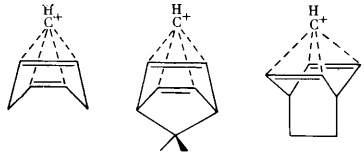
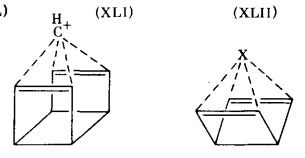
(XXXVII) (XXXVIII) (XXXVIIIa)

In contrast to the C_{nv} pyramidal systems (XXIIb), the structures (XXXVII) have only a plane of symmetry and the apical centre is not equidistant from all the π-centres coordinated to it. The latter follows from ^{13}C NMR data for a series of hexamethylbicyclo[2.1.1]hexenyl cations (XXXVIII, R = CH_3)[45,46] and has been confirmed by MINDO/3 calculations[19].

The structure of the molecule of homotetrahedrane (XXXIX), which has been recently synthesised[40], can also be represented by analogy with scheme (XXXVII) as one involving the stabilising interaction of the 3π-electron allyl fragment with a 5-electron group CH [structure (XXXIXa)]:



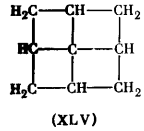
(XXXIX) (XXXIXa)



The form of the MO of the polyene chain (Fig.7) explained satisfactorily the asymmetrical orientation of the apical group X. Thus the displacement of this group towards the centre of the allyl fragment in compound (XXXIXa) and conversely towards the terminal atoms of the butadiene fragment in

compound (XXXVIII) is determined by the conditions for the maximum overlap of the interacting orbitals of the polyene and apical centre.

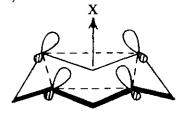
The bishomo-$(CH)_5$ cation (XL)[45,89] and a series of derivatives of the cations (XLI)[90–92] and (XLII)[93] have been synthesised from suitable precursors and have been studied in detail. Calculations on compounds (XL)[45] by the MINDO/2 method and on compounds (XLI)[50] and (XLIII)[94] by the MINDO/3 method demonstrated their high kinetic stability in relation to various rearrangements. It has been shown by the same computational procedure that structures (XL)–(XLIII), containing at their vertices other four-electron groups instead of CH^+, as well as structure (XLIV) correspond to the minima on their PES.[95]



(XL) (XLI) (XLII)

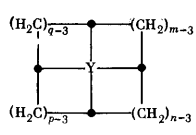
(XLIII) (XLIV), X = CH^+, C, or N^+

The polyhomopyramidal structures are unusual. Compound (XLV), which has been called[96] fenestrane (from the latin fenestra = window), containing the tetrahomocyclobutadiene ring on the periphery, has attracted special attention in connection with the possibility of a sterically constrained planar configuration, or a configuration flattened to the maximum extent, of its central tetracoordinate carbon atom[10,97,98]. MINDO/3 calculations[99] have shown that two conformations of fenestrane, with flattened tetrahedral (XLVa) and pyramidal (XLVb) configurations of the central carbon, are possible. The basis set of orbitals in the pyramidal conformation (XLVc) is topologically equivalent to that of pyramidane.

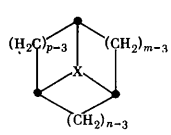


(XLV)

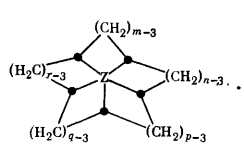
(XLVa), ΔH_f = 108.5 kcal mol^{-1}; S_4



(XLVb), ΔH_f = 137.8 kcal mol^{-1}; C_{4v}



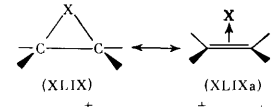
(XLVc)



According to Greenberg and Liebman[10,100], compounds (XLV) can be regarded as members of the general series of [*m.n.p.q*] fenestranes (XLVI), i.e. [4.4.4.4]fenestranes. It has been suggested[99] that the definition of fenestranes be extended to *n*-gonal "windows" in such a way that compounds of types (XLVII) and (XLVIII) can be defined as [*m.n.p*]fenestranes and [*m.n.p.q.r*]fenestranes:

(XLVI, Y = CH^+, C, N^+, or S^{2+})

(XLVII, X = CH, or N)

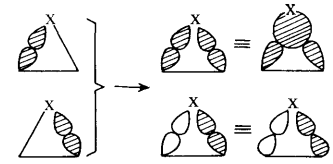


(XLVIII, Z = B, BeH, or CH^{2+})

The validity of the 8*e* rule for the (XLVI)–(XLVIII) system has been confirmed by direct MINDO/3 calculations with optimisation of the geometry[99,101]. It is noteworthy that the series of fenestranes defined in the above manner includes as the initial members tetrahedrane as [3.3.3]fenestrane, pyramidane as [3.3.3.3]fenestrane, and the dication (XII) as [3.3.3.3.3]fenestrane, which were discussed above.

5. Three-membered Rings–Apex above the π-Bond

When the size of the polyene chain in compound (XXXVII) or of the basal ring in compound (XXII) is reduced to the limiting extent, it is possible to arrive at a two-dimensional version of the interaction of the apex and the π-bond, i.e. the three-membered ring (XLIX). In view of the large deviations from the normal valence angles, structures of this type are highly strained and the usual ideas concerning the nature of the bonding reflect inadequately the characteristics of their electronic structure:



(XLIX) (XLIXa)

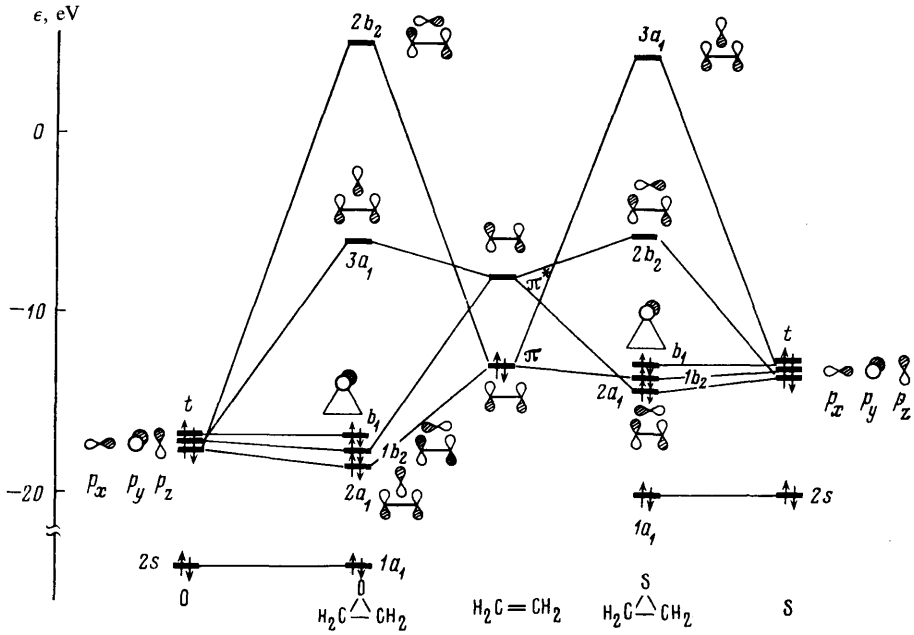
X = CH_2, CH_3^+, BH_3, NH, NH_2^+, O, OH^+, S, SH^+, F^+, Cl, or Ag^+.

In this connection Walsh[102] stated as early as 1947 that the structures of cyclopropane (X = CH_2), oxiran (X = O), and other compounds of type (XLIX) correspond to the π-complexes (XLIXa). The MO of these compounds were first described by Dewar[103], who recently examined in detail the genesis and evolution of the ideas in this field[104].

The correlation diagrams in Fig. 8 illustrate the mechanism of the binding of the fragments of the molecules of compounds (XLIX) in relation to oxiran and thi-iran (X = O or S). The stabilisation is due to the effect of the $\pi \rightarrow p_z$ and $p_x \rightarrow \pi^*$ interactions, referred to respectively as direct and reverse donation. The ratio of the contributions of these interactions depends on the relative positions of the levels of these orbitals, i.e. on the electronegativity of the atom X. When the electronegativity of X is high, as in the case where X = O, the difference between the energies of the *p*- and π*-orbitals is large and the orbital interaction is weak [see Eqns. (1) and (2)]. In Fig. 8 this is reflected by the slight changes in the form of the fragment orbitals in the oxiran MO $1b_2$ and $2b_2$, in conformity with Eqns. (6) and (7). In three-membered rings of this type the reverse donation effect is small and these structures qualify, in terms of the adopted terminology, as π-complexes. In the case of thi-iran the lower electronegativity of the sulphur atom is responsible for the comparable magnitudes of the direct and reverse donation effects. It has been suggested that such compounds be regarded as[104] normal three-membered rings.

Such subdivision is naturally extremely arbitrary, which is clear from a simple argument[105]. Symmetrised combinations (Lb) of the orbitals of two X–C σ-bonds of structure (XLIX) (normal three-membered ring) constitute none other than two bonding MO $2a_1$ and $1b_2$ (Lc), corresponding to the forward and reverse donation in the π-complex model (Fig. 8):

(La) (Lb) (Lc)



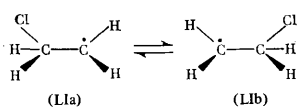


Figure 8. Correlation diagram for the MO of compounds (XLIX, X = O or S). In view of the high electronegativity of oxygen the $p \rightarrow \pi^*$ back-donation in epoxyethane is insignificant.

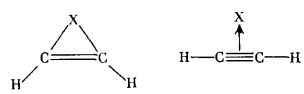
The significance of the above subdivision consists in the fact that it emphasises the ratio of the contributions of the forward and reverse donation, i.e. the stabilisations of the MO $2a_1$ and $1b_2$, and makes it possible to relate this ratio to the geometrical features and the reactivities of compounds (XLIX). The following series of groups X, in which the π-complex character of compounds (XLIX) diminishes, has been proposed[104]:

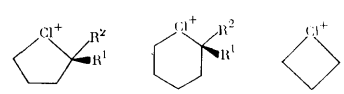
$$H^+ > SiH_3^+ > P^+ > CH_3^+ > Cl^+ > OH^+ \sim SH^+ \sim$$
$$\sim O \sim NH_2^+ \sim NH \sim PH_2^+ \sim S > CH_2 \sim PH > SiH_2 .$$



It follows from the correlation diagram in Fig.8 that the 8*e* rule should hold for the "pyramidal" structures (XLIX). Consequently, local minima on the PES should correspond to structures satisfying this rule. Indeed the stable cyclic cations (XLIX) with X = RS^+,[106,107] Cl^+,[108,109] and RO^+[110] have been discovered experimentally. A whole series of studies have been made[104,111–115] on calculations of their electronic and steric structures. The cation (XLIX, X = F^+), in which the $p \rightarrow \pi^*$ interaction is very weak, has aroused particular controversy. Nevertheless non-empirical calculations[111] and MINDO calculations with a detailed specification of the location of the stationary points on the PES[114] demonstrated the presence of a minimum for the cyclic form, located 10.3 kcal mol^{-1} (STO-3G) or 18.7 kcal mol^{-1} (MINDO) above the minimum for the 2-fluoroethyl cation $FCH_2CH_2^+$.

The introduction of additional electrons into the highly antibonding MO $2b_2$ (Fig.8) destabilises sharply the cyclic structure. Thus the radical (LI) is incapable of existing in the cyclic form (XLIX, X = Cl)[116] and the corresponding anion totally decomposes into ethylene and the chloride ion[117]:

(LIa) (LIb)



On the basis of the orbital interactions of the fragments of compound (XLIXa), it is possible to understand also the secondary characteristics of the structure: the rehybridisation of the basal atoms and the displacement of the O–H, B–H, and N–H bonds from the plane of the ring. The σ-orbitals of the above bond are then included in the interaction with the non-bonding MO b_1 of the ring (Fig.8). This orbital forms an overall closed π-system with the π_4-MO of the acetylenic fragment in the three-membered rings (LII):

(LII) (LIIa)

For X = O or S, this system is antiaromatic, which constitutes a powerful destabilising factor. Nevertheless, the extremely unstable compounds oxirene (X = O)[118,119] and thi-irene (X = S)[120] have been discovered experimentally.

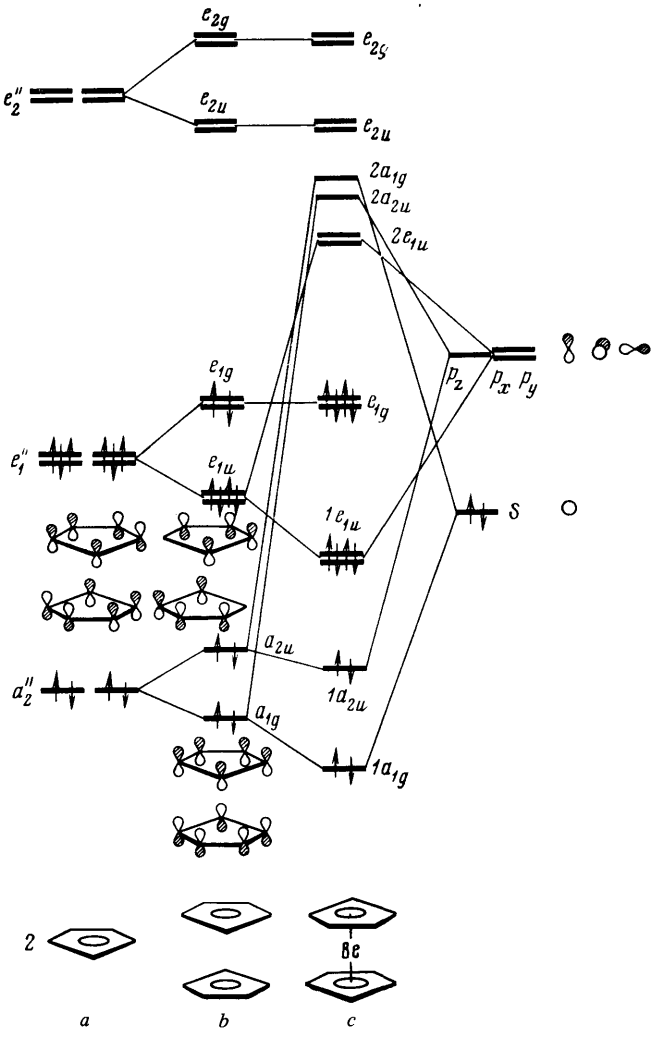
The separation of the π-centres of the basal bond, i.e. transition to groups of the type $H_2C-(CH_2)_n-CH_2$, does not alter the form of the boundary orbitals. Olah[121,122] demonstrated the existence in solution of the stable cyclic halogenonium ions (LIII, *a* and *b*):

(LIIIa) (LIIIb) (LIIIc)

Theoretical and experimental study of the ion (LIIIa) demonstrated the high stability of the cyclic form relative to the classical open-chain isomer[123]. An analogous result has been obtained in calculations[124] for chloronium ions (LIII, *b* and *c*).

IV. SANDWICH STRUCTURES

Compounds of the sandwich type (LIV), the first representative of which was ferrocene (LV, M = Fe), discovered in 1951, constitute the most important type of organometallic compounds of transition elements[125]. However, analogous compounds of the non-transition elements in Periods II and III are unknown.



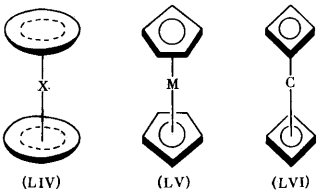


Figure 9. Correlation diagram for the MO of the beryllocene molecule in the sandwich form (D_{5d} symmetry) according to Jemmis et al.[80]: *a*) MO of two non-interacting cyclopentadienyl fragments; *b*) the splitting of the MO of the cyclopentadienyl rings which have approached one another to the equilibrium distance; *c*) MO of the structure (XXXIIa). Only the bonding combinations of the orbitals of the two cyclopentadienyl rings which have approached one another are shown.

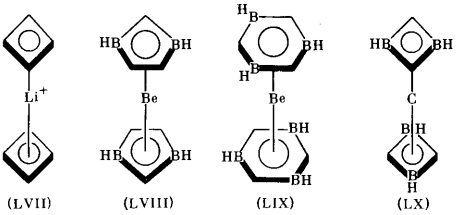
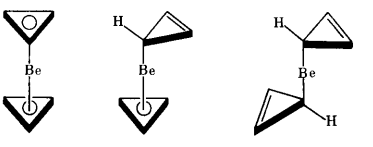


As already mentioned, the sandwich structure (XXXIIa) ≡ (LV) has not been confirmed for beryllocene (M = Be) in the light of the latest investigations:



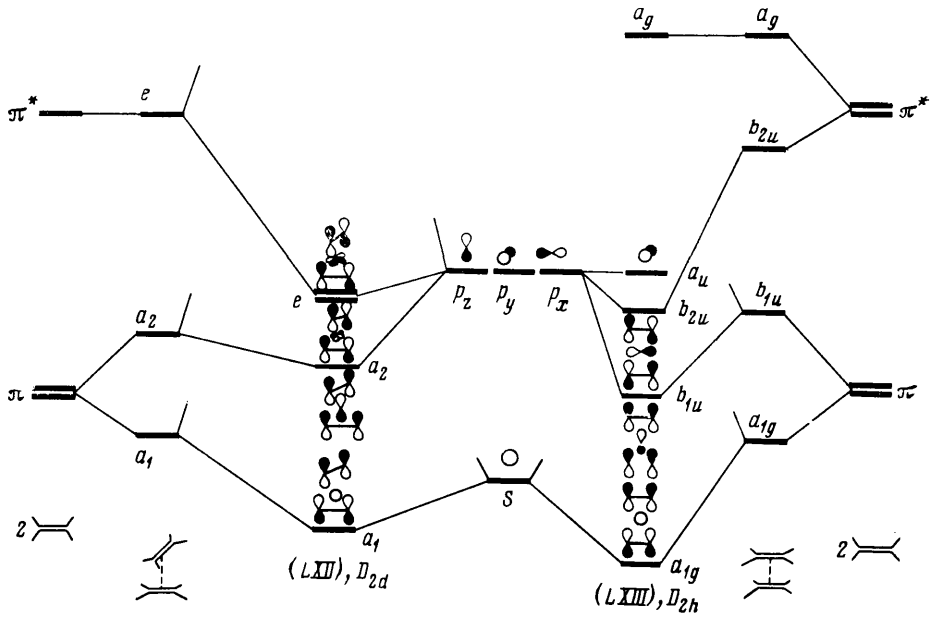
(LIV) (LV) (LVI)

The causes of this are the rigid electronic limitations for structures (LIV): the sandwich structures of compounds of non-transition elements must contain in the π-orbitals of the cyclic fragments and in the valence orbitals of the central atom not more than eight electrons[70]. This conclusion can be clarified by the reconstruction analysis of the MO of the sandwich compound (LV) (Fig.9).

Only four bonding MO orbitals can be formed by the fragment orbitals of compound (LIV) in both D_{nd} and D_{nn} geometry. Since there are 12 "inner" electrons in the biscyclopentadienylberyllium sandwich, this structure is unstable. For another 12-electron structure, namely that of the hypothetical hydrocarbon bis(η^4-cyclobutadienyl)carbon (LVI), the strain energy calculated by the MINDO/3 method is 31 kcal mol^{-1} for each C–C bond[126], which is much higher than the values for tetrahedrane and pyramidane. On the other hand, structures (LVII)–(LIX)[70] and (LX)[126], which satisfy the requirement of the 8*e* rule for sandwich structures, can be stable. Thus the calculated heat of formation of compound (LX) is −7 kcal mol^{-1} against 476 kcal mol^{-1} for compound (LVI).

When the approaches to sandwich structures (LIV) are considered, one must bear in mind that, even when the requirements of the 8*e* rule are met, an alternative to the pyramidal form exists for the majority of them, as in the case of biscyclopropylideneberyllium (LXI). Calculations[70] have shown that structure (LXIb) is preferable to structure (LXIa), but the bis(η'-cyclopropylidene) form (LXIc) is energetically most favourable. The cause of this tendency is determined by the fact that, although the *e*″-MO of [3]annulenes are in fact stabilised by the interactions with the central atom in the π-complex, nevertheless a strong antibonding character is retained within the ring (Fig.5), which is eliminated in structure (LXIc). The important role of this factor in the analysis of the stability of sandwich structures in relation to various fragmentations was pointed out for the first time by Lopatko et al.[127]

(LXIa) (LXIb) (LXIc)



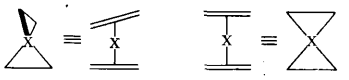


Figure 10. Correlation diagram for the MO of the orthogonal and planar spirorings (LXII) and (LXIII). The bonding MO are shown.

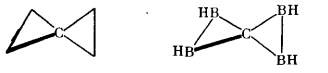
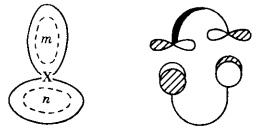


The spirocyclic compounds (LXII) can be regarded as a special case of sandwich structures. The structural alternatives—D_{nd} or D_{nh} symmetry[125,128]—usual for sandwich compounds (LIV) reduce in the given instance to a choice between orthogonal and coplanar dispositions of the multiple bonds of the fragments:

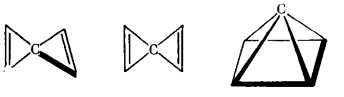
(LXII) (LXIIa) (LXIIIa) (LXIII)



It is clear from the correlation diagram in Fig.10 that the orthogonal structure (LXII) is preferable, since the p_y-orbital of the central atom in compound (LXIII) remains isolated. The structure of the MO in compound (LXII) is analogous to that of compound (LIV) (Figs.9 and 10). The bonding MO of structure (LXII) accommodate 8 electrons, i.e. spirans with a four-electron central atom (C, N^+) are stable, whereas the stabilisation of the planar structure (LXIII) requires a two-electron centre (Be, B^+).

Another version of the stabilisation of a planar spiran involves the replacement of the carbon atoms and the nodes of the ethylene fragments by boron atoms. This approach to the problem of the stabilisation of a planar tetracoordinate carbon atom was put forward by Hoffmann[129] and developed by Schleyer, Pople, and coworkers[98,130]. As an example, we present the differences between the energies of the planar and orthogonal conformations of spiropentane (LXIV) and tetraboraspiropentane (LXV) obtained in non-empirical calculations (STO-3G and 4-31G basis sets):

(LXIV), ΔE = 167 kcal mol^{-1} (LXV), ΔE = 6 kcal mol^{-1}



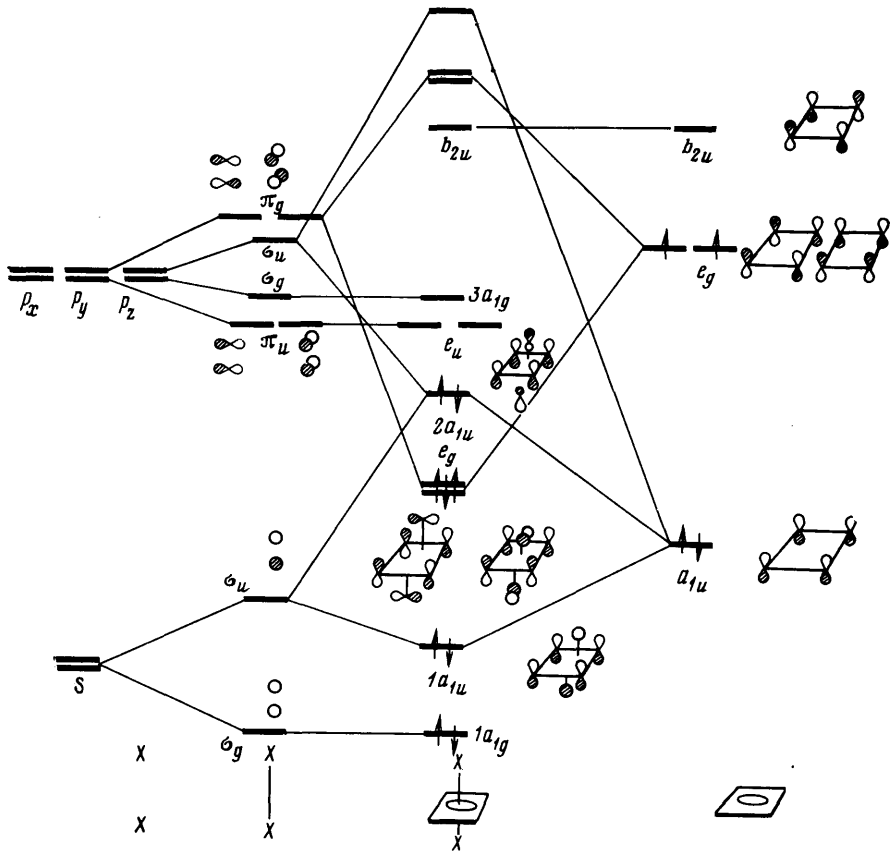
The spirans (LXII) can be formally regarded as the first members of the series of spirarenes (LXVI) with even m and n[131,132]. The main type of orbital interaction in such systems involves the overlap of antisymmetric orbitals (LXVII).

(LXVI) (LXVII)

The stabilisation of $[m,n]$spirarenes with odd m and n is achieved if the following electron count rule is obeyed: m and n must be equal to $4q + 3$, where $q = 0,1,2,...$[39,132]. The theory of spiro-conjugation and the experimental consequences of this effect have been examined in reviews[132,133].

Orbital interactions of type (LXVII) occur in addition to $p-\pi$ interactions in spirans of type (LXII) where the double bonds have been replaced by triple bonds. The spiropentadiene (LXVIII), for which the isomerisation PES has been investigated by the MINDO/3 and extended Hückel methods, constitutes an interesting case[17]. It has been found that the planar D_{2h} form (LXVIIIa) corresponds to the transition state (57 kcal mol^{-1}) in topomerisation via a diagonal twist mechanism; PES contains a second minimum, whose depth is smaller than that of the minimum corresponding to structure (LXVIII) by only 14 kcal mol^{-1} and which corresponds to the structure of pyramidane (LXVIIIb) = (XIII).

(LXVIII) (LXVIIIa) (LXVIIIb) ≡ (XIII)



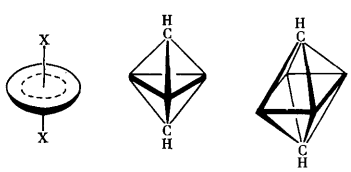


Figure 11. Correlation diagram for the MO of bipyramidal D_{nh} structures (LXIX)[69]. The D_{4h} structure has been adopted as an example.

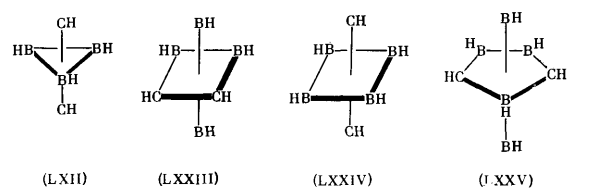
V. BIPYRAMIDAL STRUCTURES



The addition of yet another vertex to the pyramid entails the formation of bipyramidal structures (LXIX) (inverted sandwiches).

(LXIX) (LXX) (LXXI)

In their study of the cation $(CH)_5^+$, Stohrer and Hoffmann[44] already discussed the trigonally bipyramidal D_{3h} form (LXX) and found it to be less favourable than the pyramidal C_{4v} structure (XIa). MINDO/3 calculations[46] showed that the energy difference reached is 100 kcal mol^{-1} and, what is most important, structure (LXX) does not have the properties of a local minimum in the PES of $(CH)_5^+$. The D_{3h} form of the anion $(CH)_5^-$ does not have these properties either[134]. Formally the D_{4h} structure (LXXI) of $(CH)_6$, isomeric with benzene, contains six pentacoordinate carbon atoms. Non-empirical calculations[135,136] indicate an extreme instability.

The unusual valence states of the carbon atoms in compounds (LXX) and (LXXI) are not, however, the main reason for their instability, since the replacement of some of their CH vertices by BH gives rise to stable bipyramidal *closo*-carbaboranes $C_2B_{n-2}H_n$,[2,4,7] for example:

(LXII) (LXXIII) (LXXIV) (LXXV)

We shall consider the electronic requirements which must be met by the stable bipyramidal structure. Fig.11 shows that only those combinations of the orbitals of apical centres can interact with the π-MO of the central ring which are antisymmetric in relation to its plane. The lowest π-MO a_{1u} produces on interaction with $\sigma_u(s)$- and $\sigma_u(p_z)$-orbitals the bonding ($1a_{1u}$), non-bonding ($2a_{1u}$), and antibonding molecular orbitals of the pyramidal structure, of which the first two are stabilised. Two π_g-orbitals of the apical centres give rise to a further two stabilised MO on interaction with the e_g-MO of the ring. Instead of the $\sigma_g(s)$-combination, it is possible to isolate five stabilised MO, which ensure bonding between the central ring and the pair of apical centres. They can be populated by not more than 10 electrons (counting the π-electrons in the ring and the valence electrons of both apices), which constitutes the 10*e* rule for the stability of bipyramidal structures (LXIX)[69].

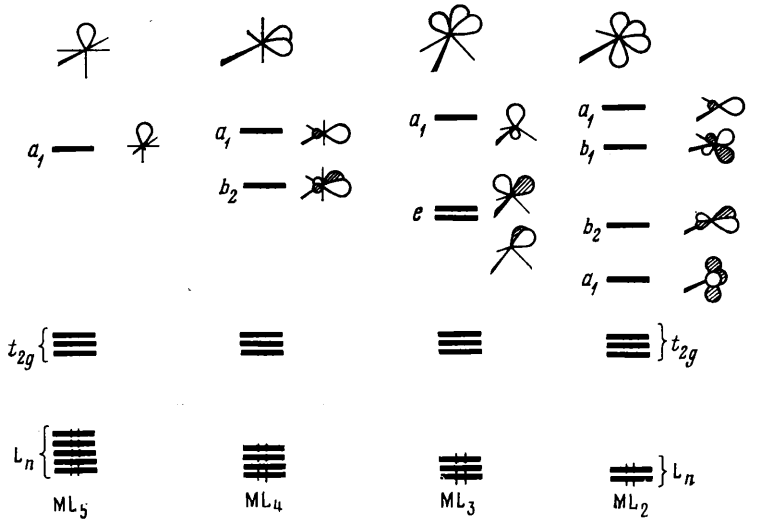


Figure 12. The group orbitals of the ML_n fragments in which M is an atom of a transition element and L are two-electron ligands (CO, Cl, PX_3, etc.). The analytical functions of the MO have been published[144,145]. The a_1 and b_2 levels for ML_n and a_1 and e for ML_3 are inverted relative to the corresponding levels of the CH_2 and CH groups (Fig.2) owing to the contributions of the d-orbitals to the group MO of ML_n and the changes in the nodal properties of their orbitals[67]. The assignment of the energy levels of the ML_n groups to the π-MO of polyenes and annulenes has been published[145].

It is clear from this rule that the probability of observing bipyramidal organic molecules or ions is small. Each CH^+ group contributes its 4 electrons. Consequently the central ring must add not more than two π-electrons, i.e. the system must have a high positive charge: +3 for (LXX) and +4 for (LXXI). Such a high electron deficit is impossible simply for electrostatic reasons[137].

On the other hand all the carbaboranes (LXXII)–(LXXV) as well as the bipyramidal (*closo*)dianions of the boranes $B_nH_n^{2-}$ (n = 5–7)[1,138] satisfy the 10*e* rule. The bipyramidal D_{4h} structure has been predicted by calculations[139] for the Li_6 cluster.

VI. THE PRINCIPLE OF THE ISOLOBAL ANALOGY AND THE ELECTRON COUNT RULES FOR POLYHEDRAL ORGANOMETALLIC COMPOUNDS AND CLUSTERS OF TRANSITION METALS

Despite the fact that the atoms of transition elements use not only the valence s- and p-orbitals in the formation of bonds but also the close d-orbitals, the development of ideas concerning the nature of the chemical bond in organometallic compounds and clusters of transition metals has led recently to the discovery of profound analogies between the electronic structures of these compounds and the structurally isotypical compounds of non-transition elements.

1. Isolobal Analogy

An important step towards the discovery of the above analogy was the introduction of the concept of electronically equivalent groups, i.e. groups whose central atoms lack the same number of electrons for the complete filling of the valence electron shell[140,141]. In this sense the Cl atom and the radicals CH_3 and $Mn(CO)_5$, which give rise to the stable dimers Cl_2, C_2H_6, and $Mn_2(CO)_{10}$, are electronically equivalent.

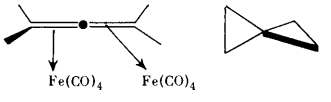
A more exact correspondence between the valence possibilities of groups formed by non-transition and transition elements has been established by the definition by Hoffmann and coworkers[22,142–144] of isolobal (from the English word lobe) groups, i.e. groups for which the number, symmetry properties, forms, and energies of the boundary orbitals are approximately the same. By generating the groups ML_n (n = 2–5) from the ML_6 octahedron as a result of the successive abstraction of two-electron ligands L, Hoffmann and coworkers obtained the MO of the above groups (Fig.12).

The transition metal atom participates in the formation of bonds via nine orbitals: five md-orbitals, one $(m + 1)s$-orbital, and three $(m + 1)p$-orbitals. The three d-orbitals of the axially symmetrical fragment ML_n do not mix with the ligand orbitals and give rise to a low-lying weakly split level, which corresponds closely to the t_{2g} level in octahedral complexes. The interaction of n orbitals of n two-electron ligands with the remaining orbitals of the central atom gives rise to n bonding and n antibonding (not shown in Fig.12) MO of the group ML_n, localised at the M–L bonds. Thus $6-n$ orbitals of the group ML_n remain in the valence band and are filled with $x-2(6-n)$ electrons, where x is the number of valence electrons of the metal.

The group ML_n utilises the above $6-n$ valence orbitals for bonding to other ligands or similar groups. Although these group orbitals involve considerable contributions from the d-orbitals in the metal atoms[22,142–145], their form and symmetry properties are analogous to those of the orbitals of the CH, CH_2, and CH_3 groups examined above (Fig.2). We shall compare the CH and $Co(CO)_3$ groups; the similarity between their boundary a_1- and e-orbitals is readily seen, the cobalt atom in $Co(CO)_3$, like the carbon atom in CH, having three electrons (x = 9 for Co) to fill them. Such

electrons, consumed in the formation of bonds between groups when the latter are combined into skeletal and polyhedral structures, are referred to as skeletal electrons[2-5]. Atomic groups typical for organic structures are compared in the Table with the isolobal and electronically equivalent groups of transition metals.

Isolobal electronically equivalent groups*.

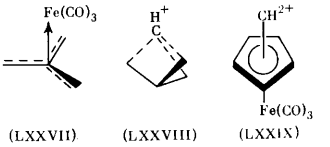


Group	v	$N_{s.e.}$	Group ML_n
CH, N, O+	5	3	$Co(CO)_3$, Ni-(Cp-η^5), $Ir(CO)_3$
CH+, C, BH	4	2	$Fe(CO)_3$, $Os(CO)_3$, Co-(Cp-η^5)
CH^{2+}, C+, BeH	3	1	$Mn(CO)_3$, Fe-(Cp-η^5)
CH^{3+}	2	0	$Cr(CO)_3$, $Fe(CO)_2$, Cr-(C_6H_6-η^6)
CH_2	6	4	$Fe(CO)_4$
CH_3	7	5	$Mn(CO)_5$

* Here ν is the number of valence electrons and $N_{s.e.}$ is the number of skeletal electrons.

Chain, cyclic, skeletal, and cluster structures, obtained by combining isolobal groups, also possess analogous systems of valence orbitals and their structural possibilities are therefore similar. Thus the orbitals of the cyclic clusters $Fe_3(CO)_{12}$ and $Fe_3(CO)_9$ are analogous to the MO of cyclopropane and cyclopropenyl[146] (Fig. 4), while the orbitals of the tetrahedral cluster (I) and their filling with valence electrons are analogous to those of tetrahedrane. Using the idea of the isolobal nature of the η^5-cyclopentadienyl and CH^+ groups, it is easy to show by calculation that the bipyramidal structure (V) meets the requirements of the 10*e* rule [two π-electrons from the five-membered ring and four electrons from each of the BH and Co-(Cp-η^5) groups].

We shall quote some further examples of pyramidal and bipyramidal organometallic structures together with the corresponding non-classical hydrocarbon structures made up of isolobal fragments. Detailed data concerning the structures of the above and other similar organometallic structures are contained in reviews[2-5,125,128,147-149].



The importance of the concept of isolobal properties is that it constitutes a direct bridge linking the structural ideas of organic chemistry with the involved structural images of the chemistry of transition elements. It makes it possible to discover the analogy between the electronic structures of outwardly completely different classes of organic and organometallic compounds—for example it can be seen that the π-complex (LXXVI) is an organometallic spiropentane:

(LXXVI) (LXIV)
