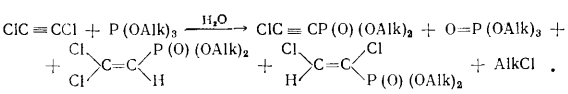
Remarks. The table does not include compounds listed in the review of Ionin et al.[8] and a number of compounds quoted without an indication of the constants. A patent has been taken out[49] for a method of synthesis of the previously unknown[8] tetraethyl acetylenediphosphonate.



1. The Mechanism of the Rearrangement

Since the interaction of halogenoacetylenes with trialkyl phosphites is analogous to the usual rearrangement with participation of halogenoalkanes as regards the character of the rearrangement and the structure of the products, in this instance too one can put forward the usual mechanism of the rearrangement with the intermediate formation of a quasi-phosphonium compound[3]. Subsequent kinetic studies[15] confirmed the two-stage character of the rearrangement. The reaction is of second order (of first order with respect to each reactant). $\Delta H^{\neq} = 17-18$ kcal mol^{-1}, $-\Delta S^{\neq} = 26-29$ e.u. and the Hammett reaction constant $\rho \cong 2$ have been obtained for a series of chloro- and bromo-ethynylarenes p-$XC_6H_4C{\equiv}CY$ (X, Y = Cl, Cl; Cl, Br; H, Br; Me, Cl; Me, Br; MeO, Cl). The high negative activation entropy indicates the formation of a pair of ions in the rate-determining stage, which corresponds to a quasi-phosphonium mechanism of the rearrangement; the high value of ρ is an indication of the proximity of the reaction centre to the aryl group, which may correspond to attack by the nucleophile on the carbon atom nearest to the halogen (direction *a* in the scheme presented below). However, studies using a proton donor as a trap for the intermediate carbanions made it possible to specify the first stage in greater detail and to discover two possible directions of attack by the nucleophile—on the C(1) carbon atom and on the halogen atom X.[12,15,16]

Direction *b* has been confirmed by the formation of free acetylene (reduction, reaction *c*). Since the kinetic characteristics of the processes occurring when the reaction is carried out in the presence of alcohol change only slightly, the addition of a proton donor does not alter the mechanism radically. The occurrence of the reaction via pathway *e* has been confirmed experimentally in the interaction of tri-isopropyl phosphite with 1-bromoethynylcyclohexanol[16]:

and the study of the interaction of dichloroacetylene with trialkyl phosphites, which in the presence of moisture takes place partly with formation of dihalogenovinylphosphonate[12,17]:

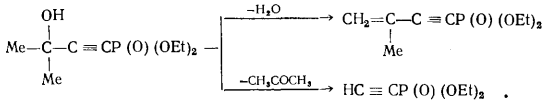
Thus the rearrangement proceeds via two competing pathways—with attack by the nucleophile on the C(1) atom and on the halogen atom.

The reactions of halogenoacetylenes with tertiary phosphines take place analogously but stop at the stage of the quaternary phosphonium salt[18—21].

2. Other Methods of Synthesis of Acetylenic Compounds With a Phosphorus-Containing Group At the Triple Bond

In order to assess the significance of the Arbuzov rearrangement as a method of synthesis of phosphonoacetylenic compounds, we shall consider other methods of synthesis of these substances[22,23]. The traditional method of synthesis of hetero-substituted acetylenes, namely the reaction involving metal acetylides, has been used mainly for the synthesis of compounds with a tricoordinate phosphorus atom and also for the preparation of unsubstituted ethynylphosphonate, which is difficult to obtain[8]. In the synthesis of higher derivatives, this method is relatively unsuitable owing to the difficulty of isolating the products.

The addition of phosphorus pentachloride to acetylenic hydrocarbons with subsequent dehydrochlorination is convenient for the synthesis of ethynylphosphonates but is restricted to a narrow range of compounds[24—26]:



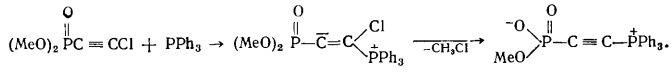
This method is inapplicable to higher alkylacetylenes, since it leads to phosphonates with multiple bonds remote from the phosphorus atom.

Phosphorus-containing propadiene derivatives readily undergo prototropic isomerisation with migration of the double bond to the phosphorus-containing group[27,28]. This property can be used for the synthesis of 1-propynylphosphonates and the analogous phosphine oxides in a single stage via the acetylene–allene–acetylene isomerisation of propargyl phosphites or propargyl phosphinites[29]:

$$(AlkO)_2POCH_2C\equiv CH \rightarrow CH_2=C=CHP(O)(OAlk)_2 \rightarrow MeC\equiv CP(O)(OAlk)_2 .$$

The reaction involving higher acetylenic phosphonates stops at the allene stage and prototropic isomerisation under the influence of bases leads to a mixture of compounds in which isomers with a triple bond remote from the phosphorus atom predominate[28].

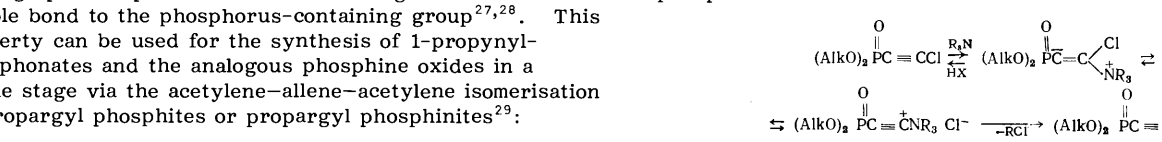
The formation of certain acetylenic phosphonates by the reaction of halogenoacetylenes with sodium dialkyl phosphites was mentioned above. The phosphonoacetylenic alcohols obtained by this method were converted into other derivatives—halides, enynylphosphonates, and unsubstituted ethynylphosphonate[6]:



The formation of acetylenic phosphines by the reaction of phosphides with halogenoacetylenes is known[30]. The synthesis of a series of compounds with a phosphorus(III) atom at the triple bond has been reported: primary and tertiary phosphines, phosphinite esters, and *N,N*-dialkylphosphinamidates[31–33].

A number of acetylenic phosphonates have been obtained as a result of subsequent reactions of halogenoethynylphosphonates formed when dihalogenoacetylenes and trialkyl phosphites react. These reactions will be considered in the next section.

III. REACTIONS OF HALOGENOETHYNYLPHOSPHONATES



1. Reactions with Retention of the Triple Bond

Chloro- and bromo-ethynylphosphonates, obtained by the reaction of dihalogenoacetylenes with tertiary phosphites, contain a halogen atom at the triple bond activated by the electron-accepting dialkyl phosphonate group. These compounds are capable of nucleophilic substitution of the halogen with retention of the triple bond, which makes it possible to synthesise a wide variety of ethynylphosphonic acid derivatives hitherto inaccessible. The possibility of involving these compounds in the Arbuzov rearrangement with formation of ethylidynediphosphonates was mentioned above. The interaction of chloroethynylphosphonate with triphenylphosphine leads to the formation of a quaternary phosphonium salt, but the resulting chloride anion attacks another electrophilic centre (the phosphonate group), which leads to the formation of a dipolar ion[19]:

Chloroethynylphosphonates react vigorously with tertiary aliphatic amines forming ynammonium salts. In the case of triethylamine such a salt is unstable and decomposes with formation of an ynamine on slight heating[34].

The ynammonium salt obtained from trimethylamine is more stable and the formation of the ynamine requires heating to 150–160 °C. On treatment with proton donors, the salt decomposes with liberation of the initial chloroethynylphosphonate[17,35]:

Ynamines are formed readily also on interaction of chloroethynylphosphonates with secondary amines, but in this case a second mole of the amine combines with the hydrogen chloride evolved[35].

The reaction with a sterically hindered primary amine (t-butylamine) proceeds analogously, but the proton migrates in the product with formation of a keten imine structure[36]:

The reaction with ammonia involves the prototropic shift of two hydrogen atoms and the triple bond migrates to the nitrogen atom with formation of phosphonoacetonitrile[5].

Stronger nucleophiles (alkoxide anions) attack the chloroethynylphosphonate at the phosphono-group, which leads to the rupture of the P–C bond and the formation of phosphates. However, on treatment with the phenoxide anion, it is possible to achieve the substitution of the halogen with formation of phenoxyethynylphosphonates[17]:

$$(AlkO)_2P(O)C\equiv CCl \xrightarrow{PhO^-} (AlkO)_2P(O)C\equiv COPh + Cl^- .$$

Treatment of chloroethynylphosphonate with an equivalent amount of sodium ethanethiolate leads to the substitution of the halogen by the ethylthio-group[17]:

$$(AlkO)_2P(O)C\equiv CCl + EtS^- \rightarrow (AlkO)_2P(O)C\equiv CSEt + Cl^- .$$

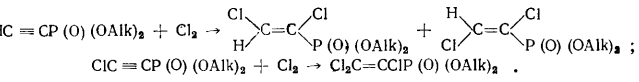
Neither reaction goes to completion and in the presence of an excess of the nucleophile they are accompanied by the addition of the latter with formation of ethylenic compounds and phosphonoacetic acid derivatives.

Chloroethynylphosphonate is reactive toward organomagnesium compounds, which makes it possible to obtain alkylethynylphosphonates[5]:

$$(AlkO)_2P(O)C\equiv CCl + EtMgBr \rightarrow (AlkO)_2P(O)C\equiv CEt .$$

The constants of the new compounds with a phosphorus-containing group at the triple bond are listed in Table 2.

2. Reactions Involving the Triple Bond



Ethynylphosphonates contain the highly reactive triple bond, which permits their use in the synthesis of a wide variety of organophosphorus compounds.

Catalytic hydrogenation of ethynylphosphonates at a palladium catalyst is stereospecific and *cis*-1-alkenylphosphonates are formed following the addition of one mole of hydrogen[25,37]:

cis-Ethylenediphosphonate[*cis*-$(EtO)_2P(O)CH=CHP(O).(OEt)_2$] has been obtained by hydrogenating acetylenediphosphonate.

Chlorination of ethynylphosphonate leads to the formation of a mixture of *cis*- and *trans*-addition products. The third (geminal) dichlorovinylphosphonate is formed in the Arbuzov rearrangement of dichloroacetylene and trialkyl phosphites in the presence of moisture (see Section II). Chlorination of chloroethynylphosphonate leads to the formation of a trichloroethylene derivative[12]:

Bromination results in a mixture of isomeric 1,2-dibromo-2-chlorovinylphosphonates[17].

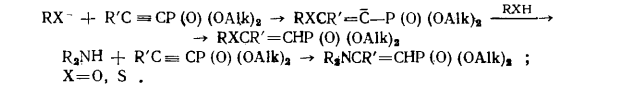


Table 2. Ethynylphosphonates obtained by different methods (other than the Arbuzov rearrangement)*.

Compound	Yield, %	B.p., °C (*p*, mmHg))	n_D^{20}	d_4^{20}
By the interaction of halogenoacetylenes with sodium dialkyl phosphites (Ref.7)

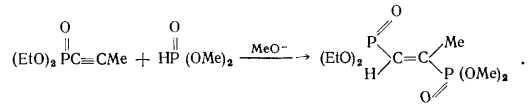
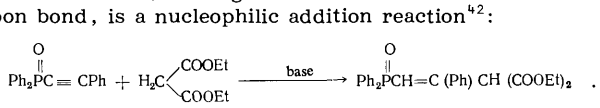
Et$_2$NC≡CP(O)(OEt)$_2$	44	145—147 (1)	1.4680	1.0538
Et$_2$NC≡CP(O)(OPr)$_2$	79	168 (1)	1.4689	1.0245

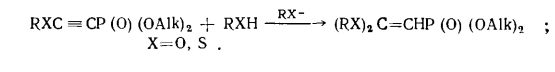


Note. The table does not include compounds quoted without an indication of their physicochemical constants.

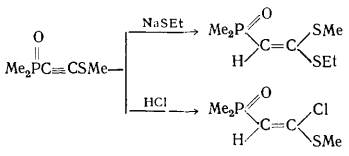
The addition of hydrogen halides to phosphine oxide with a triple bond takes place with difficulty, which can be explained by the protonation of the phosphoryl oxygen. On the other hand, hydrochlorination of chloroethynylphosphonate takes place fairly readily and leads to the formation of a geminal dichloride[12,17].



Ethynylphosphonates show a particular tendency to undergo nucleophilic addition reactions involving the triple bond. Alkoxide and thiolate anions as well as secondary amines attack the triple bond at the C(2) atom with formation of the corresponding 2-hetero-substituted vinylphosphonates[38-40]:

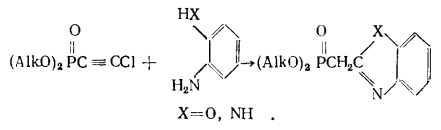


Dimethyl phosphite adds to the 1-propynylphosphonic ester with formation of the *E*-isomer of 1,2-propylenediphosphonate[41]:

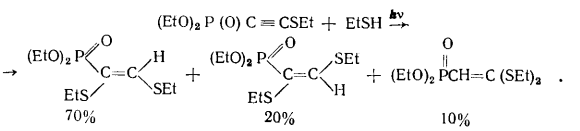


The condensation of diphenyl(phenylethynyl) phosphine with malonic ester, leading to the formation of a new carbon–carbon bond, is a nucleophilic addition reaction[42]:

Alkoxy- and alkylthio-ethynylphosphonates combine with a nucleophile at the C(2) atom with formation of 2,2-dihetero-substituted vinylphosphonates[17]:

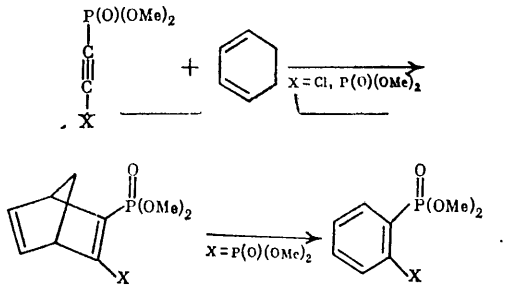


It has been shown[43] that the addition of a mercaptan and hydrogen chloride to dimethyl(methylthioethynyl)phosphine oxide proceeds in the same manner:

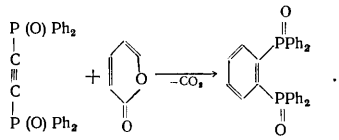


Hydration of hetero-substituted ethynylphosphonates results in the formation of phosphonoacetic acid derivatives.

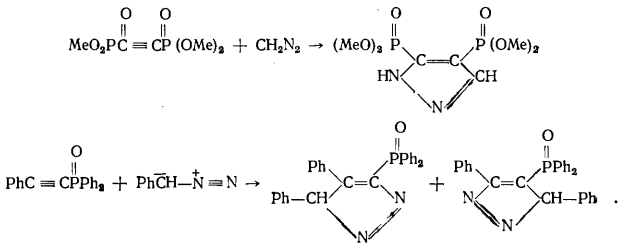
Treatment of halogenoethynylphosphonates with an excess of a nucleophile results in the substitution of the halogen and the addition of the nucleophile to the triple bond. Bifunctional nucleophiles lead to the formation of heterocyclic compounds[44,45]:



The interaction of ethylthioethynylphosphonate with ethanethiol in the absence of a basic catalyst and under the influence of ultraviolet light leads to the formation of a mixture of isomeric compounds in which 1,2-di(ethylthio)-vinylphosphonates predominate, which indicates a free-radical reaction mechanism[12]:



Ethynylphosphonates are reactive in diene synthesis and 1,3-dipolar cycloaddition reactions. Dimethyl chloroethynylphosphonate and tetramethyl acetylenediphosphonate interact with cyclohexa-1,3-diene to form norbornadiene



derivatives; in the second case the reaction can be completed by the formation of *o*-bis(dimethylphosphono)-benzene[11]:

The reaction of bis(diphenylphosphinyl)acetylene dioxide with dihydropyran-2-one leads to an analogous result[14]:

Diazoalkanes add to ethylidyne diphosphonate and diphenyl(phenylethynyl)phosphine oxide[14,16]. The second reaction proceeds non-regiospecifically:

Pudovik, Khusainova, and co-workers investigated a series of reactions involving 1,3-dipolar addition to ethynylphosphonates, established the regiospecificity of the reaction and the dipolar activity of the triple bond as a function of the substituents at the phosphorus atom, and analysed the reaction mechanism within the framework of the molecular orbital perturbation theory. These and other studies of dipolar addition to ethynylphosphonates have been described in a review[47].

Thus ethynylphosphonates undergo all typical reactions characteristic of compounds with an activated triple bond.

IV. THE ELECTRONIC STRUCTURE AND PHYSICAL CHARACTERISTICS OF ETHYNYLPHOSPHONATES

Quantum-chemical calculations in terms of the CNDO/2 approximation indicate the following distribution of effective charges in model ethynylphosphonates[17]:

XR	1	2	3	4	5
H	0.469	−0.256	−0.141	0.010	0.060
Cl	0.450	−0.221	−0.135	0.088	−0.047
SCH_3	0.439	−0.224	−0.127	0.020	−0.018

In the infrared spectra of ethynylphosphonates, the $\nu(C\equiv C) = 2175-2180\ cm^{-1}$ stretching vibration band corresponds to the triple bond and there is an absorption band due to the P=O group at 1240–1270 cm^{-1}. The ^{31}P NMR spectra of ethynylphosphonates show that the phosphorus atom attached to the triple bond resonates in the region of a strong field (from −8 to 10 p.p.m. in alkyl-, chloro-, bromo-, and alkylthio-ethynylphosphonates), undergoing slight downfield displacement in the presence of electron-donating substituents at the triple bond (−3.5 to −3.7 p.p.m. in alkoxyethynylphosphonates and −2.8 to −2.2 p.p.m. in dialkylaminoethynylphosphonates). In ethylnylphosphine oxides the resonance of the ^{31}P nuclei is observed in the range +7 to +9 p.p.m. (relative to 85% H_3PO_4).

The chemical shifts of the acetylenic carbon atoms in the ^{31}C NMR spectra of ethynylphosphonates vary with the substituents at the phosphorus and C(2) carbon atoms. These signals can be readily identified because of the significant difference between the $J_{^{13}C}$ and $J_{^{31}P}$ constants. 2-Hetero-substituted ethynylphosphonates are characterised by the following ^{13}C NMR parameters[12,17]:

Compound	$\delta_{C(1)}$	$\delta_{C(2)}$	$J_{C(1)-P}$	J (—P)
$(CH_3O)_2P(O)C{\equiv}CBr$	54.04	75.88	302.4	56.6
$(EtO)_2P(O)C{\equiv}CCl$	57.49	74.56	300.3	56.7
$(MeO)_2P(O)C{\equiv}CCl$	66.71	62.15	296.7	52.0
$(EtO)_2P(O)C{\equiv}CSEt$	82.40	90.00	284.0	71.3
$(PrO)_2P(O)C{\equiv}CNMe_2$	48.01	63.89	320.2	39.1

Ethynylphosphonates are characterised by considerable electrical dipole moments. Analysis based on an additive scheme indicates the polarisation of the system, which induces the appearance of an additional contribution of 0.7–1.0 D directed towards the phosphorus-containing group[48,50].

Halogenoacetylenes with a halogen atom at the triple bond and particularly those containing unsaturated or aromatic groups or a heteroatom as the second substituent in the ethynyl group undergo the Arbuzov rearrangement with formation of ethynylphosphonates. This reaction constitutes the most general method of synthesis of a wide variety of hitherto inaccessible highly unsaturated phosphorus compounds. The rearrangement involving dihalogeneoacetylenes, which leads, depending on the conditions, to the formation of acetylenediphosphonates or halogenoethynylphosphonates, is of special interest. The latter phosphonates are capable of participating in halogen substitution reactions with retention of the triple bond.

The reactions of ethynylphosphonates with participation of the triple bond make it possible to synthesise a wide variety of unsaturated and saturated functional derivatives of organophosphorus compounds.

Molecular Rearrangements Accompanied by the Migration of Phosphoryl Groups between Two nucleophilic Centres

A.N.Pudovik and M.G.Zimin

The review surveys instances of the reversible and irreversible migration of phosphoryl groups $\left(\geq P{=}O,\ \geq P{=}S,\ \geq P{=}N{-}\right)$ between two heteroatoms (N, O, S, and Se); this type of rearrangement is characterised by retention of the coordination number of the phosphorus atom. The rearrangements of phosphorylated aminoalcohols, mercaptoalcohols, oximes, and the products of the addition of partially esterified acids of tetracoordinate phosphorus to cyano-compounds, carbodiimides, and keten imines, proceeding via a stage involving the formation of unstable phosphoranes are considered. Much attention is devoted to tautomeric processes in which the phosphoryl, thiophosphoryl, and iminophosphoryl groups are the migrating moieties.
The bibliography includes 109 references.

I. INTRODUCTION

There has been a considerable development in recent years of the study of rearrangements accompanied by the migration of phosphoryl and other groups with a tetracoordinate phosphorus atom, whose driving force is the deficiency of electron density at the phosphorus atom. In an isomerisation process, the deficiency of electron density at the phosphorus atom in the final or intermediate product diminishes.

The study of rearrangements of this type makes it possible to discover the causes and factors promoting the stabilisation or rupture of bonds in the P–S–C, P–N–C, P–O–C, etc. groups present in derivatives of tetracoordinate phosphorus acids and throws light on the characteristics of the mechanism of nucleophilic substitution at the tetrahedral phosphorus atom. The phosphorylation and phosphoryl group transfer reactions are responsible for many vitally important biochemical processes.

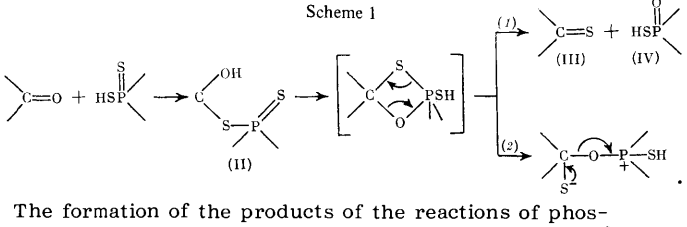
The aim of the present review was to examine and (wherever possible) to treat systematically studies devoted to rearrangements involving the migration of phosphoryl groups between two nucleophilic centres in which the coordination number of the phosphorus atom remains ultimately unaltered. Attention is devoted also to the preparative aspect, since the migration of phosphoryl groups is observed in the synthesis of many organophosphorus compounds and also in the preparation of biologically active phosphoric acid derivatives.

In view of the wide variety and novelty of the rearrangements considered, their mechanisms have been inadequately investigated and the schemes put forward are tentative and open to discussion. The most characteristic migrations of phosphoryl and thiophosphoryl groups are of the 1,3- and 1,4-types, which can occur via both intramolecular and intermolecular mechanisms depending on the nature of the nucleophilic centre and the migrating moiety. Sometimes the 1,3-migration is accompanied by the elimination of the phosphorus-containing group.

The 1,2-migrations of phosphoryl groups between two heteroatoms occur in tetracoordinate phosphorus derivatives (I) with P–P bonds and are always accompanied by a decrease of the coordination number of one of the phosphorus atoms; such reactions have been largely surveyed in earlier publications[1,2]:

$$RR^1P(X)-PRR^1(Y) \rightleftarrows RR^1P(Y)-X-PRR^1(Y)\ ;$$

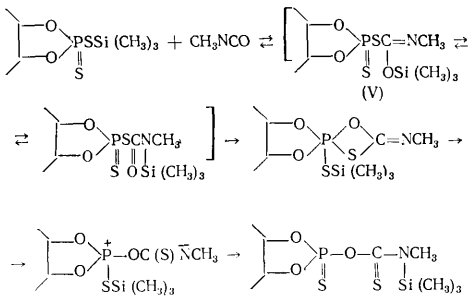
(I)



X, Y=O, S; R, R¹=Alk, AlkO, Ar, ArO, Alk_2N .

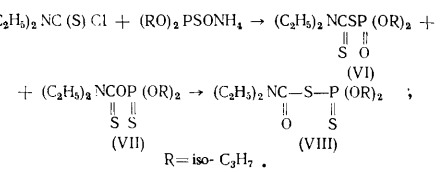
The isomerisation of symmetrical pyrophosphorothioates to asymmetric compounds[3] and of *S*-phosphorylthiocyanates to *N*-phosphorylisothiocyanates [4] has also been described in detail in the literature and is not therefore discussed here.

II. THE 1,3-S → O MIGRATIONS



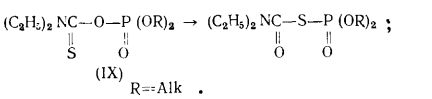
There are few examples of such migrations. The transformation of unstable *gem*-monothioketals (1-hydroxylalkyl phosphorodithioates) (II) into thiocarbonyl compounds (III) and tetracoordinate phosphorus thioacids can be regarded formally as the 1,3-O → S migration of the thiophosphoryl groups[5] (Scheme 1). A one-stage mechanism (pathway *1*) and not a two-stage mechanism (pathway *2*) is then postulated with formation of a transition state analogous to that in the Wittig reaction[6]:

Scheme 1



The formation of the products of the reactions of phosphorodithioic acid with aromatic aldehydes and ketones[6], carbostyril[7], carboxylic acid esters and amides[8,9], isocyanates[10,11], and triphenylphosphine oxide[11] and of *O,O*-dialkyl S-trimethylsilyl phosphorodithioates with benzaldehyde and acetophenone[12] has been described in terms of this or an analogous scheme. There are no data confirming the mechanism of these reactions which are referred to as the "*O,S*-exchange reactions".

A rearrangement of compounds (V) in which the 1,3-S → O shift is not accompanied by the elimination of the phosphorus-containing fragment, and it is therefore possible to assume that it proceeds via a number of stages, has been reported recently[13]:

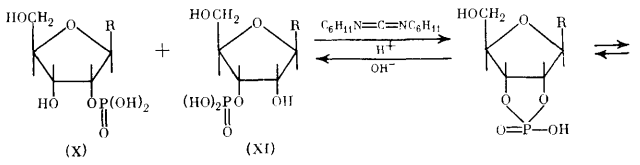


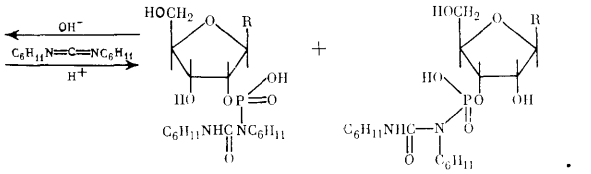
A thiophosphoryl group with acyclic substituents migrates in this situation to the nitrogen and not the oxygen atom[13].

When *N*,*N*-diethylthiocarbamoyl chloride reacts with ammonium di-isopropyl phosphorothioate in acetone, a mixture of *N*-acylation and *O*-acylation products [compounds (VI) and (VII)] is formed in proportions of 4 : 1; the *O*-acylation products (VII) predominate in dimethylformamide (in proportions of 3 : 1):[14]

On heating and vacuum distillation, the mixed anhydride (VII) rearranges to the carbamate (VIII).[14]

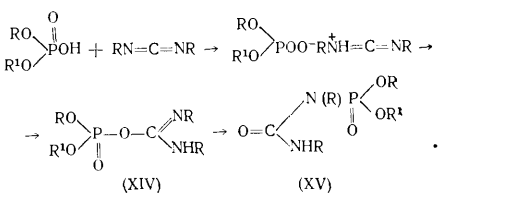
An analogous rearrangement of compounds (IX) with migration of the phosphoryl group takes place much more readily than in the synthetic process:





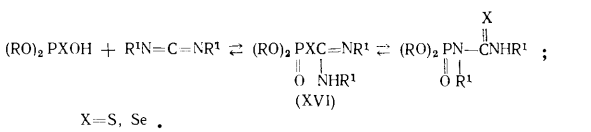
It has been shown that these rearrangements are irreversible both at room temperature and on heating.

III. REARRANGEMENTS OF IMIDOYL DERIVATIVES OF PHOSPHORIC AND PHOSPHOROTHIOIC ACIDS



The first reports of the 1,3-O → N migration of phosphoryl groups in imidoyl phosphates were associated with the development of the carbodiimide phosphorylation method, which has found extensive applications in the synthesis of biologically important phosphate esters[15,16]. *N*-Phosphorylated ureas (XII) and (XIII) were identified among the products of the reaction of phosphoric acid monoesters (X) and (XI) with dicyclohexylcarbodiimide (Scheme 2):[17]

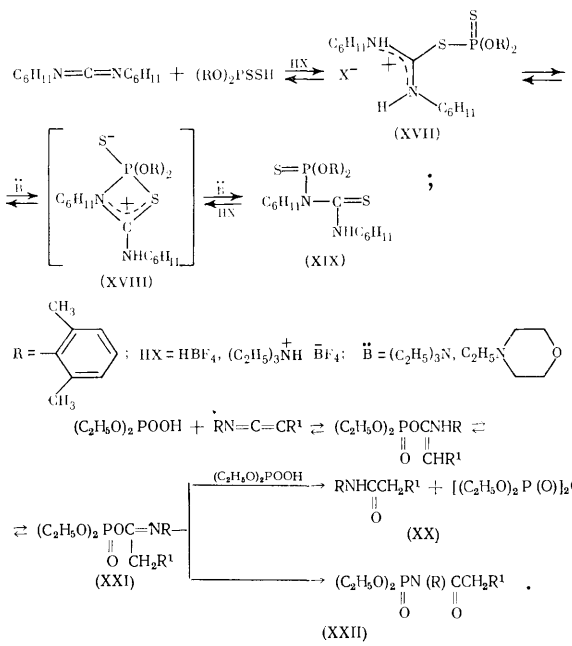
Scheme 2



Subsequently the formation of *N*-phosphorylated ureas in the carbodiimide phosphorylation method was frequently confirmed[18–22]. In all cases the initial formation of the intermediates (XIV), which rearrange to the ureas (XV), was postulated. The "imidoyls" (XIV) have been recently isolated[23]:

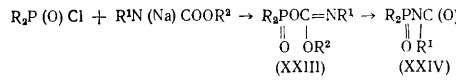
The rearrangements of analogous S- or Se-phosphorylated isothio- or isoselenoureas have been reported in a study of the reactions of dialkyl phosphorothioates, phosphoroselenoates, and phosphorodithioates with carbodiimides[24]. Dialkyl phosphorothioates and phosphoroselenoates add to the C=NH group via the sulphur or selenium atom respectively:

The addition products (XVI) can be detected by ^{31}P NMR.[25] Their rearrangement is reversible[24]; under the usual conditions, the equilibrium is almost wholly displaced to the right. In the reactions of dicyclohexylcarbodiimide with sterically hindered dialkyl phosphorodithioates the intermediate has been isolated in the form of a salt (XVII) with HBF_4,[23] while in the reactions with the corresponding dialkyl phosphates this cannot be done. According to X-ray diffraction data, the distance between the nitrogen and phosphorus atoms in the molecule of compound (XVII) is 3.49 Å. For the oxygen analogue with the same bond angle, the distance between the nitrogen and phosphorus atoms has been estimated as 2.34 Å, which is equal to the sum of the van der Waals radii of the nitrogen and phosphorus atoms; according to the authors[23], this is the cause of the faster rearrangement of *O*-phosphorylisoureas.



The rearrangement of *S*-thiophosphorylisothioureas (XVII) and the reverse rearrangement are controlled by the acidity of the medium[26]. Bases and acids promote the S → N and N → S migrations respectively. The rearrangement of compounds (XVII) and (XIX) proceeds via the intermediate (XVIII); the transformation (XIX) → (XVII) proceeds via the protonation of the nitrogen in the P–N bond (Scheme 3). The acid-catalysed transformations of compounds (XVII) and (XIX) into the initial compounds show that the reaction system is in overall equilibrium.

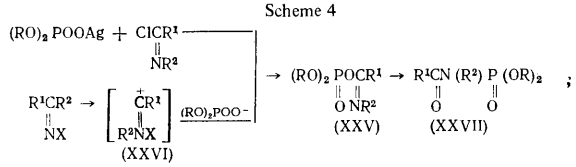
A kinetic study of the rearrangement of compounds containing the C–S–P fragment to *N*-phosphorylthioureas showed[26] that the reaction is of first order and takes place without the formation of other kinetically significant intermediates.



The study of the stereochemistry of the transformation of S(Se)-phosphorylisothio(seleno)ureas into *N*-phosphorylthio-(seleno)ureas [27] demonstrated the complete retention of the configuration at the phosphorus atom. The data obtained support an intramolecular isomerisation mechanism.

The products of the reactions of diethylphosphoric acid with keten imines[28] are, together with tetraethyl pyrophosphate and the amide (XX), the *N*-phosphorylated amides (XXII), formed as a result of the rearrangement of the *O*-phosphorylated derivatives (XXI).

Scheme 3

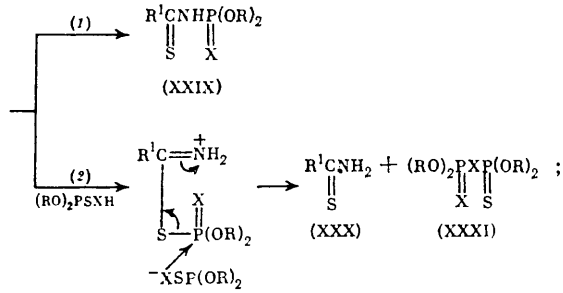


The kinetically controlled products of the phosphorylation of the sodium derivatives of alkyl carbamates are the imidoyl phosphates (XXIII), which were detected in the reaction mixture by infrared spectroscopy[29]:

Compounds (XXIII) readily isomerise to the *N*-phosphorylated carbamates (XXIV).

The high phosphorylating capacity of imidoyl phosphates stimulated investigators to develop convenient methods for their synthesis. The imidoyl phosphates (XXV) have been synthesised (in accordance with Scheme 4) by the reaction of iminochlorides with the silver salts of dialkylphosphoric acids and by a method involving the Beckmann rearrangement[30]. They have not been isolated in a pure form.

Scheme 4

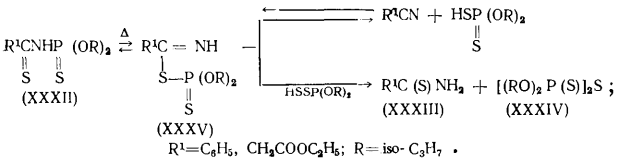


Their formation has been demonstrated by hydrolytic and aminolytic reactions. It has been noted that, when the substituent R^2 in compounds (XXV) is a methyl group, then isomerisation to compounds (XXVII) takes place readily, whereas in the case where R^2 is a secondary alkyl or phenyl group, there is no appreciable migration of the dibenzylphosphoryl group[31]. According to the data of Zieman et al.[32], the products of the reactions of the alkali metal or ammonium salts of dialkylphosphoric acids with iminochlorides are *N*-phosphorylated amides. The high stability of the imidoyl phosphates (XXV), formed as a result of the thermal Beckmann rearrangement from *O*-phosphorylated derivatives of acetophenone oxime is, therefore, incomprehensible[30].

The O → N migration of the phosphoryl groups in imidoyl phosphates is due to the considerable energy gain on formation of the amide structure, the energy of formation difference $E_{amide} - E_{imidoyl}$ being capable of reaching 20 to 25 kcal mol^{-1} and for this reason the rearrangements are usually irreversible. However, the transformation of *N*-phosphorylamides into *O*-phosphorylisoamides has been observed in the gas phase by mass spectrometry[33]. The analogous 1,3-S → N migrations of phosphoryl groups are reversible. The isomerisation of *N*-phosphorylthioamides has been observed mass-spectrometrically[34]. Such reversibility can also be illustrated in relation to the rearrangement of the products of the addition of partially esterified tetracoordinate thio-acids to cyano-compounds.

The reactions of tetracoordinate phosphorus thioacids with cyano-compounds have attracted the attention of investigators as a method of synthesis of thioamides[35]. In recent years they have been investigated from the standpoint of the rearrangements of imidoyl phosphorothioates. The products of the interaction of tetracoordinate phosphorus dialkylthio- and dialkyldithio-acids with nitriles[36-39], iminoesters[40,41], thiocyanates[42,43], phenyl cyanate[44], and cyanamides[45] isomerise. It has been shown in relation to a large number of examples that, in the first stage of these reactions, the phosphorus thio- and dithio-acids add to the cyano-group with formation of the imidoyl derivatives (XXVIII) (Scheme 5). Phosphoromonothioic acids attack the cyano-group via the sulphur atom[38,44]. However, these compounds are extremely unstable and isomerise even during the reaction to the corresponding *N*-phosphorylated thioamides, thio- and dithio-carbamates, and thioureas (XXIX) (pathway *1*). Compound (XXVIII) can be detected in certain cases by ^{31}P NMR.[37]

Scheme 5

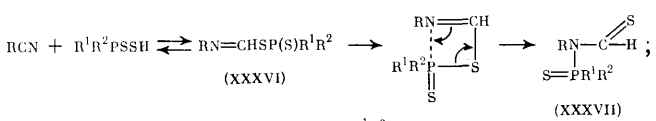


R^1=Alk, Ar, Alk_2N, AlkS, ArS, ArO, CCl_3, $CHCl_2$, $CH_2COOC_2H_5$; R=Alk .

The imidoyl phosphorothioates (XXVIII) also exhibit an exceptionally high phosphorylating capacity and are cleaved at the P–S bond already in the course of the reaction under the influence of the initial thio-acid (pathway *2*), which leads

to the formation of thioamides, thio- and dithio-carbamates, thioureas (XXX), and pyrophosphates (XXXI).

All these reactions are complex and a large number of a wide variety of products are formed. However, under certain conditions, the isomerised products can be isolated in high yields[36,43,46]:



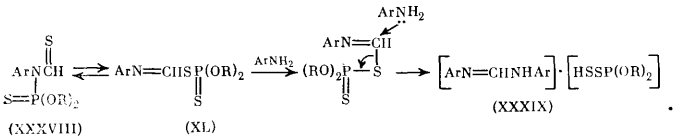
(XXXII) (XXXV) (XXXIII) (XXXIV)

$R^1=C_6H_5$, $CH_2COOC_2H_5$; R = iso-C_3H_7 .

On heating, there is a possibility also of the reverse N → S migration of the thiophosphoryl groups. Thus, when *N*-phosphorylated thiobenzamide or ethoxycarbonylthioacetamide (XXXII), obtained from phosphorous dithioacids and nitriles, were heated, the thioamides of the corresponding carboxylic acids (XXXIII) and pyrophosphorotrithioate were isolated[36]. Compounds (XXXII) are then converted into the imidoyl phosphates (XXXV) with a P–S–C linkage, which are in equilibrium with the initial dithioacids and nitriles, which is confirmed by the isolation of nitriles from the reaction mixture. The dithioacid formed as a result of the dissociation of compound (XXXV) cleaves the P–S bond in the imidoyl phosphorodithioate, as described above. This pathway is characteristic of all the reactions of tetracoordinate phosphorus thio- and dithioacids with cyano-compounds.

The products (XXXVI) of the α-addition of phosphorus dithioacids to 2,6-dimethyl- or 2,6-diethyl-phenylisonitrile (XXXVI) [47] isomerise to *N*-thiophosphorylthioformamides (XXXVII). The main products of the reactions of cyclohexyl-, phenyl-, 4-tolyl-, or 2,5-xylyl-isonitriles with phosphorus dithioacids (Scheme 6) are the formimidoyl phosphorodithioates (XXXVI).[48] In some cases they were isolated in a pure form.

Scheme 6

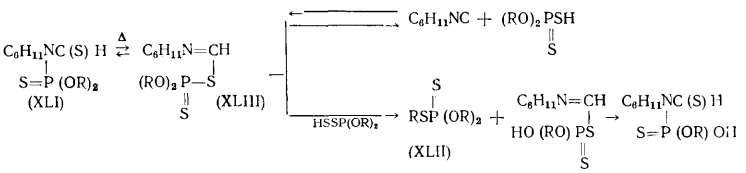


(XXXVI) (XXXVII)

R = C_6H_{11}, C_6H_5, 4-$CH_3C_6H_4$, 2,5-$(CH_3)_2C_6H_3$; R^1R^2 = AlkO .

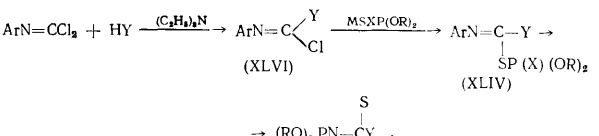
Even at room temperature, compounds (XXXVI) gradually isomerise to the thioformamides (XXXVII). It has been found[47] that the rearrangement is a first-order reaction. On replacement of the ethoxy-substituents at the phosphorus atom by methoxy-substituents, the rate of rearrangement increases. The reaction is sharply retarded on passing from phosphorodithioates to phosphonodithioates; derivatives of diphenylphosphinodithioic acid are altogether incapable of the rearrangement[47,48]. The tendency towards isomerisation increases with increase of the nucleophilicity of the nitrogen[48,49]. These data suggested[49] that the rearrangement proceeds via an intramolecular four-centre mechanism involving nucleophilic substitution at the tetrahedral phosphorus atom. However, the intramolecular character of this rearrangement cannot be regarded as rigorously demonstrated.

It is believed[47] that this isomerisation is irreversible. According to other investigations[48,49], heating of *N*-dialkylthiophosphorylthioformamides (XXXVIII) with aromatic amines leads to the formation of the phosphorodithioate salts of *N,N'*-diarylformamidines (XXXIX) (Scheme 7) with considerable yields (70–80%).



Scheme 7

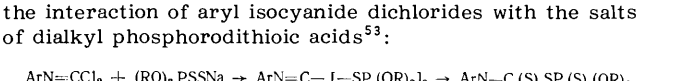
(XXXVIII) (XL) (XXXIX)



The formation of compound (XXXIX) can be explained only by postulating the reverse 1,3-N → S migration of the thiophosphoryl group, resulting in the formation of imidoyl phosphorodithioates (XL), which give rise to the salts (XXXIX) as a result of the attack by the amine on the imino-carbon atom. The direct interaction of compounds (XXXVIII) with amines results in the formation of other products[48,49].

O,O,S-Trialkyl phosphorodithioates (XLII) and cyclohexylisonitrile are obtained in high yields of pyrolysis *in vacuo* of *N*-dialkyl-*N*-cyclohexylthiophosphorylthioformamides (XLI), obtained by the reaction of phosphorus dithioacids with cyclohexylisonitrile[48]:

(XLI) (XLIII) (XLII)

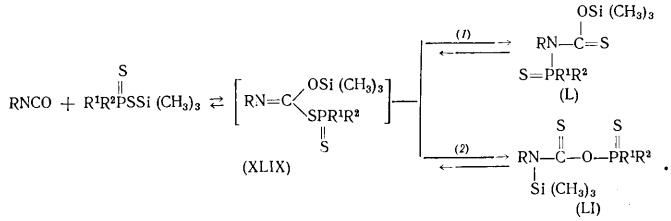


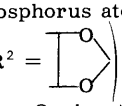
Evidently compounds (XLI) isomerise on heating to compounds (XLIII), which are in equilibrium with the initial isonitrile and the dithioacid. The dithioacid dealkylates[50] the ester group at the phosphorus atom, which results in the formation of the phosphorodithioates (XLII). According to Malz et al.[51], the stepwise substitution of the chlorine atoms in aryl isocyanide dichlorides initially by an alkoxy-, alkylthio-, or amino-group and then by the phosphorothioate or phosphorodithioate group results in the formation of stable compounds with the imidoyl structure of the type of (XLIV). It was later established[52] that in all cases the final products of these reactions are the products of the rearrangement of the imidoyl phosphates (XLIV), namely *N*-thiophosphorylated thio- and dithio-carbamates or the thioureas (XLV). It is noteworthy that, when salts of dialkylphosphoromonothioic acids are introduced into the reaction with the iminochlorides (XLVI), derivatives with the P=O group are formed:

(XLVI) (XLIV) (XLV)

X=O, S; M=H, Na, K, NH_4; R=C_3H_7, iso-C_3H_7; Y=OCH_3, iso-SC_3H_7, $N(C_2H_5)_2$.

The structure of *S,S*-bis(dialkylthiophosphoryl) isodithiocarbamates (XLVII) has been attributed to the products of the interaction of aryl isocyanide dichlorides with the salts of dialkyl phosphorodithioic acids[53]:



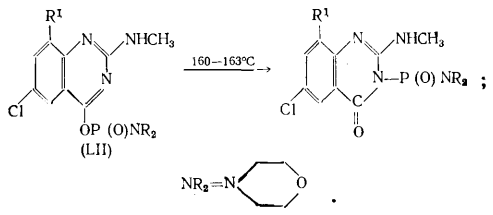


(XLVII) (XLVIII)

However, detailed studies have shown[54] that in this case compounds (XLVII) rearrange to *N*,*S*-bis(dialkylthiophosphoryl) dithiocarbamates (XLVIII). It is noteworthy that the isomerisation of compounds (XLIV) and (XLVII) takes place irreversibly even at 160 °C.

An interesting situation arises when two groups capable of migration are present in imidoyl phosphorothioates. When silyl phosphorodithioates react with isocyanates[13] (Scheme 8), the imidoyl phosphorodithioates (XLIX) are formed in the first stage. In the case of the acylic dialkoxy-derivatives ($R^1 = R^2 = OAlk$), the 1,3-S → N migration with formation of compound (L) is observed. The introduction of the phenyl or trichloroacyl substituent at the nitrogen atom hinders the S → N migration of the thiophosphoryl group, apparently owing to the reduction of the nucleophilicity of the nitrogen atom:

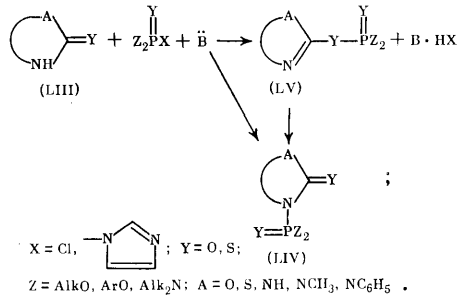
Scheme 8



If the phosphorus atom is incorporated in a five-membered ring ($R^1R^2 =$ ), then compounds (XLIX) rearrange via the 1,3-S → O migration of the thiophosphoryl group to the *N*-silyl derivative (LI).

There are several reports in the literature of the 1,3-S → N or O → N migrations of the phosphoryl and thiophosphoryl groups in the series of heterocyclic compounds. The phosphorylation of the ambident anions of heterocyclic amides[55] by phosphorochloridates takes place both at the oxygen atom and at the nitrogen atom. *O*-Phosphorylation is the kinetically controlled reaction stage.

The stability of compounds of type (LII) (Scheme 9) compared with the acyclic imidoyl phosphates (XXV) and (XXI) is due to the presence of a conjugated system of multiple bonds:

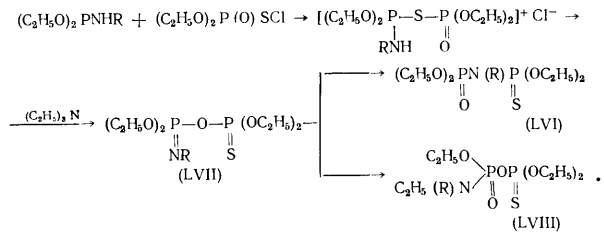


Scheme 9

The thermodynamically more favourable *N*-phosphorylated products are formed via the rearrangement of the *O*-derivatives, which has been demonstrated for compound (LII).

The phosphorylation of a series of heterocycles (LIII) containing urea, carbamate, thiourea, and dithiocarbamate fragments has been investigated (Scheme 10):[56]

Scheme 10



It was found that the phosphorylation is controlled by structural factors both in the substrate and in the reagent. In most cases *N*-phosphorylation products (LIV) are formed as a result of the isomerisation of the *O*- or *S*-phosphorylated intermediates (LV). In one instance the *S*-phosphorylation product (LV, A = Y = S, Z = OC_6H_5), which can be regarded as a model of "O-phosphobiotin", was isolated. However, this product does not rearrange. In the case of the oxygen analogues, evidence has been obtained for the existence of kinetically controlled *O*-phosphoryl derivatives on the basis of their ability to function as phorphoryl group transferring agents. The greater stability of the *S*-phosphorylation products compared with that of their oxygen analogues can be explained by the reduced electrophilicity of the phosphorus atom and the greater length of the P–S–C linkage compared with the P–O–C linkage, which hinders the intramolecular migration in the rigid cyclic molecule. Compounds with an open-chain structure, for example, phosphorylated isothioureas, readily isomerise[26,27] (see above).

Thus, in the 1,3-migration of phosphoryl and thiophosphoryl groups, there is a favourable situation in the N=C–O triad for an intramolecular reaction mechanism, while the question of the character of the migration in the N=C–S triad remains controversial; apparently these migrations proceed both intramolecularly and intermolecularly, depending on the structure, the experimental conditions, and the presence of catalysts.

Rearrangements accompanied by the 1,3-O → N migration of phosphoryl groups have been observed also in the iminophosphorus triad. After the reaction of phosphoramidites with phosphorylsulphene chloride[57,58], the phosphoramidite (LVI), formed via Scheme 11 as a result of the rearrangement of the phosphorimidate (LVII), was detected among the reaction products:

Scheme 11

Depending on the nature of the substituent at the nitrogen atom, compounds of type (LVII) are stabilised in two ways[58,59]. If R is an alkyl or phenyl group, the phosphorus-containing

substituent migrates with formation of compound (LVI). If R is an electron-accepting group, then the nucleophilicity of the nitrogen atom is reduced, which entails the migration of the ethyl substituent of the ethoxy-group with formation of compound (LVIII).

It has been found recently[60] that S → N migration takes place in the mixed anhydrides of phosphinimidic and phosphorodithioic acids (LIX):

$$(RO)_2P(S)-S-P(C_6H_5)_2 \rightarrow C_6H_5N(S)-P(OR)_2 ;$$
$$NC_6H_5 \qquad\qquad S=P(C_6H_5)_2$$
(LIX)

R=Alk .

The rearrangement proceeds irreversibly at room temperature.

IV. PHOSPHORYLOTROPIC TAUTOMERISM

The tautomeric processes in which the phosphoryl, iminophosphoryl, or thiophosphoryl groups are the migrating moieties (phosphorylotropism) were first observed for imidoyl derivatives of phosphorothioic acid[61].

A convenient method for the synthesis of compounds used in the study of phosphorylotropism may be provided by the reactions of isothiocyanates with sodium dialkyl phosphites involving the phosphonate–phosphorothioate rearrangement[49] of thiocarbamoylphosphonic acid derivatives in which the P–C bond is influenced by the neighbouring electron-accepting group. The characteristic features of this rearrangement have been investigated recently. It was found that the isomerisation of thiocarbamoylphosphonates requires the presence of electron-accepting substituents at the nitrogen atom[62] and the use of an equimolar or a nearly equimolar amount of a strong base in order to convert the thiocarbamoyl phosphonate into the ionised form active in the rearrangement.

The reactions of sodium di-isopropyl phosphite with methyl and allyl isothiocyanates in boiling benzene for 10–12 h lead to unisomerised products with a P–C bond[62]; the interaction of dialkyl phosphites and their analogues with isothiocyanates in the presence of catalytic amounts of bases under mild conditions has the same result[63–65].

The interaction of the sodium or potassium salts of dialkyl phosphites with phenyl isothiocyanate at 80–145 °C is accompanied by the phosphonate–phosphorothioate rearrangement of the phenylthiocarbamoylphosphonates (LX) to dialkyl *S*-phenyliminomethyl phosphorothioates and phosphorodithioates (LXI).[66] The products (LXI) are also formed on heating the pure phenylthiocarbamoylphosphonates (LX) in an equimolar amount of sodium dialkyl phosphite[66]:

$$C_6H_5NCS + HP(X)R_2 \rightarrow \underset{(LX)}{C_6H_5NHC(S)P(X)R_2} \xrightarrow{NaXPR_2}$$
$$\rightarrow \underset{(LXI)}{C_6H_5N{=}CH{-}S{-}P(X)R_2} \rightleftarrows C_6H_5NCH{=}S \quad ;$$
$$X{=}PR_2$$
(LXII)

X=O, S .

Compounds (LXI) are capable of phosphorylotropic tautomerism[62]. At room temperature the equilibrium is 90–95% displaced towards the thioformamide (LXII). However, like the compounds described by Zinin and co-workers[48,67], compounds (LXI) undergo further reactions on heating. The interaction of sodium di-isopropyl phosphite with phenyl isothiocyanate (Scheme 12), followed by treatment of the reaction mixture with methyl iodide, yielded a tautomeric mixture, from which compound (LXIII) and (LXIV) can be isolated[62]:

Scheme 12

$$C_6H_5NCS + (RO)_2PO^- \longrightarrow \underset{(LXV)}{C_6H_5N{-}C(S^-){-}P(OR)_2(O)} \longrightarrow$$

$$\xrightarrow{CH_3I} \underset{(LXIII)}{C_6H_5N{=}C(CH_3)SP(O)(OR)_2} \rightleftharpoons \underset{(LXIV)}{C_6H_5N(CH_3)C(S){-}P(O)(OR)_2} ;$$

R = iso-C_3H_7

It has been suggested[66,68] that the rearrangement of thiocarbamoylphosphonates proceeds via a three-centre $S_N2(P)$-mechanism. In the anion (LXV) there are two nucleophilic centres capable of attacking the electrophilic phosphorus atom. The nucleophilic reactivity of sulphur is apparently greater than that of nitrogen. This has also been demonstrated in relation to the reaction of *O,O*-di-isopropylthiophosphoryl isothiocyanate with sodium diethyl phosphite (Scheme 13):

Scheme 13

$$(RO)_2P(S)NCS + (C_2H_5O)_2PO^- \longrightarrow \underset{}{(RO)_2N{-}C(S^-){-}P(OC_2H_5)_2(O)} \longrightarrow$$

$$\xrightarrow{CH_3I,\ \Delta} \underset{(LXVI)}{(RO)_2PN{=}C(CH_3)SP(OC_2H_5)_2} ;$$

R = iso-C_3H_7 .

The 1,2-C → S migration product (LXVI) is then formed; compounds whose formation mechanism involves the 1,2-C → N migration of the diethylphosphoryl group were not detected. Separate experiments demonstrated that the presence of electron-accepting substituents at the imino-nitrogen atom in compounds of type (LXVI) prevents phosphorylotropic transformations. On the other hand, such transformations are characteristic of *N*-aryl-substituted compounds (LXVII), which can be obtained by the reaction of iminochlorides with salts of tetracoordinate phosphorus monothio- and dithioacids[61]:

$$RC(Cl){=}NC_6H_4Y + NaXSPR^1R^2 \rightarrow \underset{}{RC(SP(X)R^1R^2){=}NC_6H_4Y} \rightleftarrows \underset{(LXVIII)}{RC(S)N(C_6H_4Y){-}P(X)R^1R^2} ;$$
(LXVII)

X=O, S; Y=H, *p*-Br, *p*-CH_3, *p*-CH_3O, *p*-NO_2;
R=C_6H_5; R^1=R^2=AlkO .

The salts of tetracoordinate phosphorus monothio-acids always react via the sulphur atom of the thiophosphoryl group.

The occurrence of the phosphorylotropism of compounds of type (LXIII) and (LXVII) has been demonstrated by a combined infrared, ^1H NMR, and ^{31}P NMR spectroscopic study. Two signals in the ranges 58–64 and 78–85 p.p.m. (for the phosphorodithioate derivatives) or −3–−5 and 15–18 p.p.m. (for the phosphoromonothioate derivatives), referring to the thioamide (LXVIII) and imidothiolic (LXVII) forms respectively, are observed in the ^{31}P spectra at room temperature. On heating, the intensity of the indicator signal of the imidothiolic form (LXVII) increases, while that of the thioamide form (LXVIII) falls. When the initial temperature is restored, the system returns to the original state.

In certain cases the tautomers can be isolated in a pure form under the usual conditions. Thus the thioamide isomer is usually crystallised from solutions in pentane.

With increase of temperature, an increase of the content of the thermodynamically less favourable imidothiolic form (a) is observed in all cases (Table 1). Table 1 shows that the conversion of the isomer (A) into the isomer (B) is exothermic. The quantity ΔH does not change in the temperature range 19–120 °C.

*Here and henceforth a represents the content of the isomer (A).

The free energies ΔG do not exceed 2 kcal mol^{-1},[54] which falls within the range of tautomeric processes on the thermodynamic scale[69]. The quantities ΔH and $T\Delta S$ are comparable, from which it follows that the state of equilibrium is influenced not only by the difference between the heats of formation but also by the difference between the entropies. At room temperature the enthalpy factor predominates somewhat over the entropy factor, but, with increase of temperature, the entropy factor begins to play a major role and becomes dominant for imidoyl phosphorodithioates at 100 °C.

The observed relation reflects the influence of two opposed thermodynamic factors. As a consequence of the large barrier to the "amide rotation",[70] the transition to the thioamide entails the loss of degrees of freedom by the molecule and an increase of the absolute value of the entropy, which destabilises the thioamide. On the other hand, the large energy gain on formation of the P–N and C=S bonds stabilises the thioamide form.

Compounds with the P=O group are influenced by temperature to a lesser extent than their thio-analogues (Table 1). The enthalpy factor for these compounds predominates somewhat even at 100 °C; comparison of the ΔG shows that the replacement of the P=S group by P=O leads to an increase of the difference between the thermodynamic stabilities of the tautomers.

The composition of the tautomeric mixtures depends on the state of aggregation. In the crystalline state the imidothiolic isomer (A) is not usually detected by infrared spectroscopy. In the liquid phase at the same temperature the content of the isomer (A) is considerable.

The composition of the tautomeric mixture in solutions differs strongly from its composition in the liquid or crystalline state. Since the two forms belong to different classes of organic compounds, the influence of the nature of the solvent is significant. Transition to solutions affects the thermodynamic characteristics of the phosphorylotropic tautomerism in different ways and can entail a shift of equilibrium in the opposite direction. The equilibrium position in both the condensed phase and in solutions is influenced by the enthalpy and entropy factors.

The results of the study of the dependence of K_{TS} on the nature of the solvent (Table 2) were treated by the method described in Palm's book[71]. The regression equation is

$$\lg K_{TS} = 0.196 + (0.915 \pm 0.114)Y + (0.657 \pm 0.207)P + (0.124 \pm 0.017)\cdot 10^{-2} B \quad (r = 0.986),$$

where P is the polarisability, Y the polarity, and B the nucleophilicity of the solvent. The contribution of the electrophilicity of the solvent is insignificant. Thus the position of the tautomeric equilibrium is greatly influenced not only by electrostatic interactions but also by specific interactions.

The barrier to the *E*, *Z*-topomerisation of the imidoyl form is evidently low (~10 kcal mol^{-1}) and the individual tautomers are not detected by ^{1}H NMR in the temperature range 30 to 100 °C. The barriers to the "amide" rotation about the P–N bond in N-di-isopropylphosphorylthioacetanilide and *N*-di-isopropylphosphorylthiopropionanilide are 14.8 and 14.6 kcal mol^{-1} respectively[70]. The phosphorylotropism in the thioamide triad is the slowest dynamic process (ΔG = 20–21 kcal mol^{-1}) (Table 3).

It has been noted that the rate of equilibration for *N*-thiophosphorylthioamides depends on the concentration of the solution, which indicates the intermolecular character of the tautomerism. This is confirmed by the identity of the ^{1}H NMR spectra of compounds (LXIX) and (LXX) and the artificial mixture of the tautomers (LXIX)–(LXXII) prepared taking into account the intermolecular exchange:

EPR and ^{31}P NMR studies using the method of chemically induced nuclear polarisation have made it possible to exclude the radical mechanism of phosphorylotropism. It has been suggested[54] that the phosphoryl exchange involving the imidoyl derivatives of tetracoordinate phosphorus proceeds via the cyclic dimeric form (LXXXII) and constitutes a kind of transacylation reaction involving the transfer of the reaction centre (Scheme 14):

Scheme 14

(LXXXII)

The dependence of the tendency towards tautomerism on structural factors is consistent with the proposed mechanism. The introduction at the carbon atom of the C=N double bond in imidoyl phosphorothioates and imidoyl phosphorodithioates of substituents which promote the delocalisation of the positive charge on the carbon atom of the intermediate (LXXXII) facilitates the tautomeric transformations. This is manifested by the fact that the replacement of the phenyl group by the methyl group or by a hydrogen atom leads to the absence of tautomerism. In this case imidoyl phosphorodithioates (LXVII) readily isomerise at room temperature to the corresponding thioamides (LXVIII),[48,54] but the reverse transformation is observed only on heating. When the phenyl group is replaced by the t-butyl group, the imidoyl isomer is the only one present and is incapable of rearrangement.

The environment of the phosphorus atom influences radically the position of the tautomeric equilibrium (Table 4). With increase of the length of the alkoxy-group, the equilibrium is displaced somewhat towards the imidoyl isomer, while on replacement of the P=S by the P=O group, there is a sharp shift in the direction of the thioamide isomer. The replacement of one alkoxy-group at the phosphorus atom by an alkyl or phenyl substituent in compounds with both P=O and P=S groups results in the attainment of equilibrium only at 180–200 °C. It has been demonstrated by differential thermal analysis that the process proceeds via a single stage, which is not inconsistent with the proposed mechanism. When both alkoxy-groups are replaced by phenyl groups, the rearrangement of imidoyl phosphinodithioates does not take place either at room or elevated temperatures. The products of the postulated isomerisation (*N*-phosphinothioylthioamides), obtained by other methods[72], are incapable of the reverse rearrangement with the 1,3-N → S migration of the diphenylphosphinothioyl group. An increase of the barrier to the interconversion in this instance is evidently associated with the decrease of the electrophilicity of the phosphorus atom and steric hindrance. In particular, the ligand exchange in the intermediate (LXXXII) is hindered by the weaker apicophilic properties of the alkyl and phenyl groups compared with the alkoxy-groups[74].

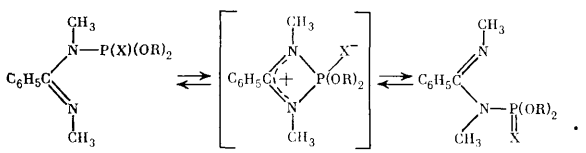
The introduction of electron-accepting substituents into the benzene ring at the nitrogen atom shifts the equilibrium towards the imidoyl isomer (Table 5). Electron-donating substituents displace the equilibrium in the opposite direction. When the aryl group is replaced by a methyl group or a hydrogen atom, the thioamide isomer is the only one present. For compound (LXXXIII), equilibrium, strongly displaced in the direction of the thioamide isomer, is

observed at elevated temperatures[75]. Thus substituents capable of delocalising the positive charge on the nitrogen atom of the intermediate (LXXXII) promote the tautomeric transformations.

It has been shown for compounds (LXXXIII) [75] that, when the capacities for the 1,3-migration of hydrogen and the phosphoryl group are identical, phosphorylotropic and not thione–thiol tautomerism obtains:

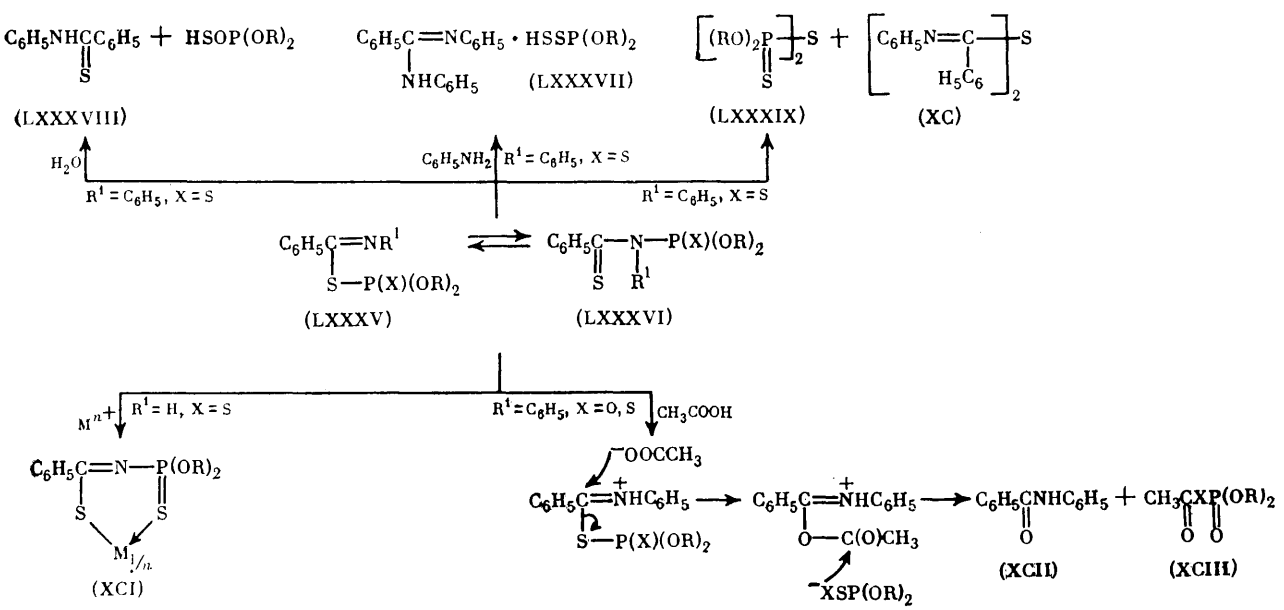
X=H, CH_3, CH_3O; R=C_3H_7, iso-C_3H_7 .



The study of the chemical behaviour of tautomeric *N*-phosphorylthioamides revealed their phosphorylating capacity and a high tendency to undergo reactions of the type of transacylation. When a mixture of the tautomers (LXXXV) and (LXXXVI) in benzene, where the contents of the imidoyl and amide forms are approximately the same, was treated with aromatic amines, the phosphorodithioate salts of arylamidines (LXXXVII) were isolated (Scheme 15). The tautomers (LXXXV) and (LXXXVI) hydrolyse to the thioamides (LXXXVIII), disproportionate with formation of the pyrophosphate (LXXXIX) and the sulphide (XC), and react with heavy metal ions to form complexes with the isoamide structure (XCI).[75,76] The products of the reaction of the tautomers (LXXXV) and (LXXXVI) with carboxylic acids are the amides (XCII) and the acyl phosphorothioates and phosphorodithioates (XCIII) (thioacetic acid reacts analogously).

The formation of the benzamides (XCII) and the phosphorothionates (XCIII) shows that the reactions with acids proceed via a mechanism involving transacylation as the first stage; this can be demonstrated by ^{31}P NMR and by isolating the product of the addition of di-isopropylphosphorodithioic acid to acrylonitrile when the reaction with acetic acid is carried out in the presence of the latter. These results suggest that the dissociative mechanism of the tautomeric transformation is unlikely. If the P=S bond were dissociated, one would expect the formation of thiobenzanilide and dialkyl phosphite, which, however, have not been isolated or detected by physicochemical methods.

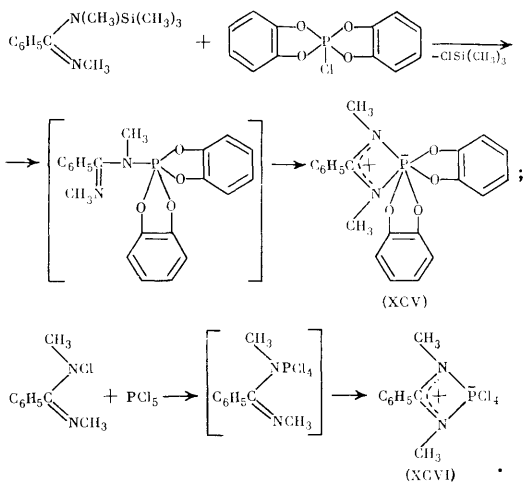
Thus not only the thioamide but also the imidoyl form possesses dual reactivity involving both electrophilic centres—the phosphorus atom and the carbon atom of the C=N bond.



After the discovery of phosphorylotropism in the thioamide triad, the stereochemical behaviour of the phosphorylated *N*,*N'*-dimethylbenzamidines was explained by the occurrence of tautomeric transformations (Scheme 16):[77]

Scheme 16

(XCIV)

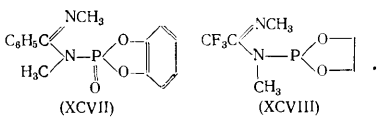


Scheme 15

M = Ag (I), Hg (II), Co (II), Ni (II)

The presence of the degenerate amidine triad, which makes it possible to enter automatically the region of tautomeric processes on the thermodynamic scale, and the existence of methods developed for the investigation of such tautomerism[69] made it possible to obtain important information about the mechanism of the phosphoryl exchange. The phosphoryl migrations in the amidine triad usually occur via an intramolecular mechanism, tentatively via a stage involving the formation of the cyclic intermediate (XCIV) with a trigonal-bipyramidal configuration of the phosphorus atom[73]. Treatment of amidine derivatives with spiro-chlorobis(phenylenedioxy)phosphorane or PCl_5 leads to the formation of the phosphorane derivatives (XCV) and (XCVI) via Scheme 17.[78]

Scheme 17

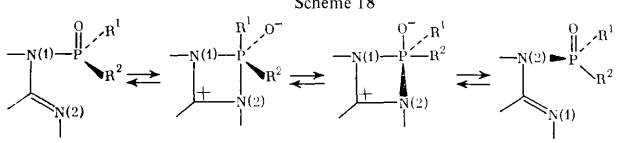


(XCV)

(XCVI)

Although this entails the formation of hexacoordinate and not pentacoordinate derivatives of phosphorus, presumably this type of mutual approach of reaction centres, necessary for intramolecular migrations, can be achieved also in phosphorane intermediates. However, the phosphorane intermediates cannot be detected by physicochemical methods.

It has been concluded[79] that there is no intermolecular exchange of phosphorus-containing groups when compounds (XCVII) and (XCVIII) are heated together. The intermolecular tautomeric process N ⇌ N′ with migration of phosphorus(III) was observed for the latter compound:

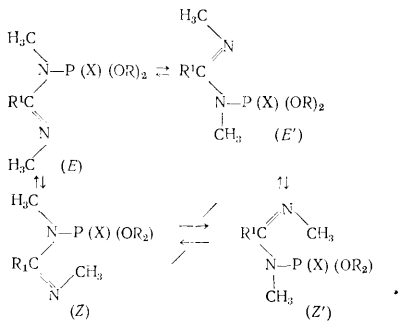


(XCVII) (XCVIII)

The intramolecular mechanism of the phosphoryl migration in amidines has been confirmed by the retention of the spin–spin coupling constants $J(PH)$ and $J(PC)$, whereas in the case of intermolecular migrations these constants would have been averaged out to zero[77].

The geometry of the amidine triad ensures the possibility of only the axial-equatorial disposition of the attacking and leaving nitrogen atoms in the phosphorane intermediate, so that, in conformity with the principle of microscopic reversibility, the latter should undergo ligand exchange via Scheme 18.[69]

Scheme 18

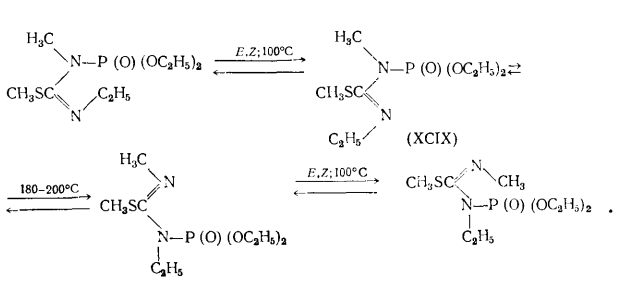


The negative activation entropies (Table 3) indirectly confirm the intramolecular multistage mechanism of the tautomeric transformation, requiring a considerable reorganisation of the molecule. A stereochemical study showed that the tautomeric transformations take place without inversion of the configuration of the phosphorus atom[79]. If the attack on, and elimination of, the nitrogen atom occurred synchronously, for example via an S_N2 mechanism, bypassing the permutation isomerisation stage, this would entail inversion of the configuration of the phosphorus atom. The considerable decrease of the free energy of activation for the tautomeric process (Table 3), involving the incorporation of the phosphorus atom in a dioxa- or benzodioxa-phospholan ring, stabilising the phosphorane intermediate, is consistent with the proposed mechanism[80].

Apart from phosphorylotropism, $E \rightleftharpoons Z$ topomerisation is observed for phosphorylated amidines. The activation energies for these processes can be similar [for example, for compounds (LXXIII), (LXXIV), and (LXXVII); Table 3].

Theoretical calculation of the ^1H NMR spectra for the four-position exchange of topomers ($Z \rightleftharpoons E \rightleftharpoons E' \rightleftharpoons Z'$; Scheme 19) and comparison of the theoretical and experimental spectra made it possible to exclude the possibility of phosphoryl migrations for the Z,Z-isomers:[79]

Scheme 19

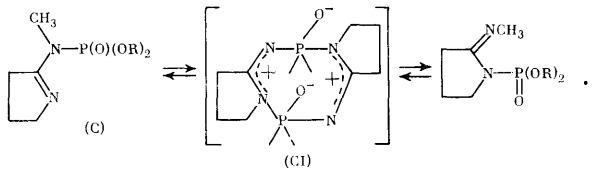


From the standpoint of the intramolecular mechanism, this can be explained by the unfavourable orientation of the unshared electron pair of the imino-nitrogen for a nucleophilic attack on the phosphorus atom.

The free energy of phosphoryl migrations (Table 3) is reduced somewhat when the $CHCl_2$ group at the carbon atom is replaced by a phenyl substituent, which promotes the delocalisation of the positive charge of the intermediate (XCIV). The introduction of electron-accepting substituents at the phosphorus atom greatly reduces the free energy of activation for the tautomeric transformation, which is caused by the increased electrophilicity of the phosphorus.

On passing from phosphorylated amidines to the corresponding derivatives of *S*-methylisothiourea (XCIX), the phosphoryl exchange is observed at a higher temperature (Scheme 20); $\Delta G^{\neq}$ increases to ~26 kcal mol^{-1}:[81]

Scheme 20



When even one alkyl group at the nitrogen atoms in *S*-alkyl-*N*-phosphorylisothioureas is replaced by hydrogen, the capacity for phosphorylotropism disappears[82]. Prototropic tautomerism occurs in this instance:

$$R^1R^2P(X)NHC(SR^3)=NH \rightleftarrows R^1R^2P(X)N=C(SR^3)NH_2 ,$$

X = O, S; R^1, R^2 = Alk, AlkO; R^3 = Alk, Ar .

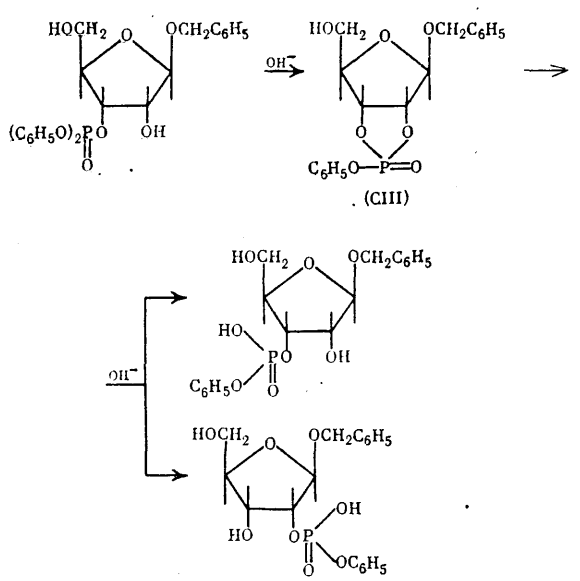
The incorporation of one of the nitrogen atoms of the amidine triad in the ring alters the mechanism of the phosphoryl migration[83] (Scheme 21):

Scheme 21

The rate of migration and the half-life of *N*-phosphorylated 2-methylaminopyrrolines (C) depend on the concentration of the solution and the nature of the solvent. On passing to polar solvents, the process is accelerated, which indicates the intermolecular character of the tautomerism; it has been suggested that its mechanism involves the formation of the polar dimeric form (CI) as the intermediate state. The thermodynamic quantities of activation $\Delta G^{\neq} = 28$ kcal mol^{-1} and $\Delta H^{\neq} \cong 21$ kcal mol^{-1} for this type of tautomerism exceed somewhat the values for intramolecular migrations (cf. Table 3), but the activation entropy is the same (−22 e.u.). It is of interest to note that the ratio of the isomers in deuterochloroform and nitrobenzene is approximately the same[83].

The influence of the nature of the heteroatoms between which the phosphoryl or thiophosphoryl groups migrate can be traced in relation to the rearrangements and tautomeric transformations of phosphorylated thioamides and amidines. The 1,3-O → N and N ⇌ N′ shifts take place most readily. They are less susceptible to acid–base catalysis and an intramolecular mechanism involving a four-membered phosphorane intermediate is preferred for such processes with the exception of those cases where this is prevented by the orientation of the unshared electron pair of the imino-nitrogen. With increase of the difference between the electronegativities and apicophilicities of the atoms, the rearrangement cannot always be fitted within the framework of the intramolecular mechanism. The 1,3-S ⇌ N and 1,3-Se ⇌ N shifts can be catalysed by acids and bases. Furthermore, the S(Se)–C bonds are unusually labile in the thio(seleno)-phosphorylated isothioamides, isothioureas, and isothiocarbamates, which is manifested by the ease of the dissociation of the P–S(Se)–C fragment with elimination of the thio- or seleno-phosphoryl group.

V. 1,4-MIGRATIONS AND LONGER-DISTANCE MIGRATIONS



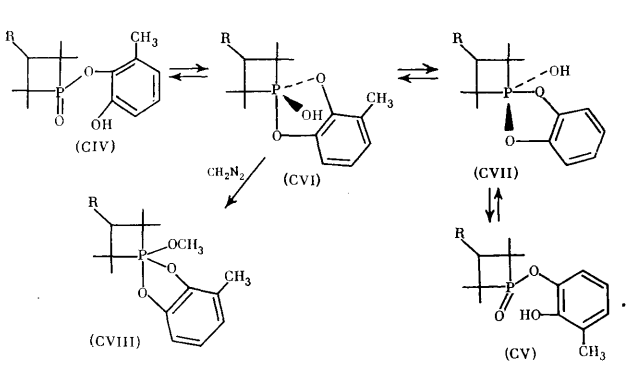
The 1,4-O ⇌ O′ shift of the phosphoryl group was first observed on refluxing an aqueous solution of 2-glycerophosphate (CII) in the presence of H_2SO_4.[84] This rearrangement is reversible[85]:

$$(HO)_2P(O)OCH(CH_2OH)CH_2OH \overset{H^+}{\rightleftarrows} (HO)_2P(O)OCH_2CH(OH)CH_2OH$$

(CII); 10% 90%

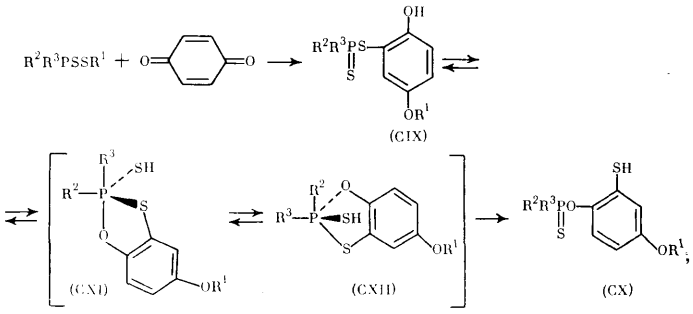
According to Khorana[15], the 1,4-O ⇌ O′ transfer of the phosphoryl group proceeds via the cyclic phosphate (CIII), as happens in the mild alkaline hydrolysis of sugar phosphates[86]. Under the influence of hydroxide ions, the phosphate ring can be cleaved on both sides (Scheme 22):

Scheme 22



An analogous scheme has been proposed also for the reactions of sugar phosphates with carbodiimides[15,19]. In this case the 1,4-O → O′ shift is also accompanied by the 1,3-O → N shift of the phosphoryl group.

It has been shown recently[87] that the reversible isomerisation of *o*-hydroxyphenyl phosphinates (CIV) to compounds (CV) proceeds via intermediates (CVI) and (CVII) of the hydroxyphosphorane type via Scheme 23.

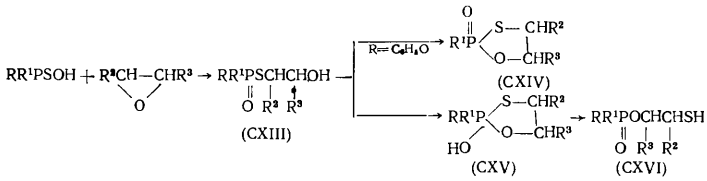


On treatment with diazomethane, the product of the methylation of the hydroxyphosphorane (CVIII) was isolated. The free energy of activation for the transition (CIV) ⇌ (CV) is 17.5 kcal mol^{-1}. When the phosphetan ring in compound (CIV), stabilising the spiro-phosphorane structure[88], is replaced by phenyl groups, the activation energy increases to 24.2 kcal mol^{-1}. The transition from phosphinates to their thio-analogues leads to an increase of the activation energy for the process by 4–5 kcal mol^{-1}. These results suggest that the isomerisation proceeds via a mechanism involving intramolecular nucleophilic substitution at the tetrahedral phosphorus atom:

Scheme 23

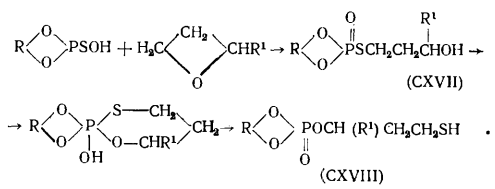
The isomerisation of *S*-(2-hydroxyphenyl) esters of phosphorus thioacids probably proceeds analogously via a stage involving the formation of mercaptophosphoranes. Products of type (CIX), formed in the reaction of dialkylphosphorodithioic acids and their silyl esters with *p*-benzoquinone, naphthoquinone, and *N*-benzenesulphonyl-*p*-benzoquinone, isomerise to phosphorothioates of type (CX).[89] This rearrangement proceeds only in one direction—towards the formation of the more acidic thiol (CX) (Scheme 24):

Scheme 24



$R^2R^3 = Alk_2, (AlkO)_2, —OC(CH_3)_2C(CH_3)_2O—, —OCH_2C(CH_3)_2CH_2O—$; $R^1 = H, Si(CH_3)_3$.

Diphenylphosphinodithioates rearrange only in the presence of an equimolar amount of triethylamine. The study of the kinetics of the isomerisation of *S*-2,5-dihydroxyphenyl esters of phosphorus dithioacids demonstrated the unimolecular nature of the process[90]. The replacement of the alkoxy-groups at the phosphorus atom in compounds (CIX) by alkyl groups reduces the rate of isomerisation, probably as a consequence of the decrease of the effective positive charge on the phosphorus atom, which hinders the attack on the *ortho*-hydroxy-group. In intermediates with the trigonal-bipyramidal structure (CXI) and (CXII), the alkyl substituents are forced to occupy apical positions. The interactions with three equatorial substituents reduce the apicophilicity of the groups having high steric requirements[91] and hence increases the energy of the intermediates. An appreciable acceleration of the isomerisation is observed for esters of cyclic ω-hydroxy- or ω-mercaptophosphates compared with their acyclic analogues, which may be associated with the cyclic spiro-hydroxyphosphoranes being favoured by energy factors to a greater extent[88]. The influence of the polarity and acidity of the solvents on the rate of rearrangements is very small, which indicates an insignificant charge separation in the transition state of the rate-determining stage.

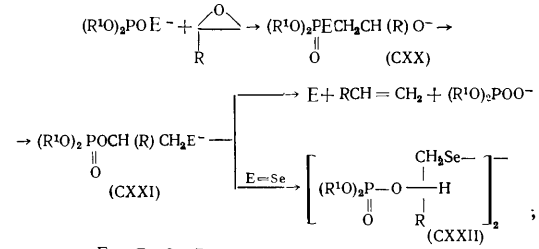


The replacement of a hydrogen atom in compound (CIX) by a trimethylsilyl group greatly stabilises the phosphorodithioate structure. In this case the S → O migration of the thiophosphoryl group can occur only in the presence of a basic catalyst or an excess of a sulphonating agent and the process becomes reversible. Its reversibility can be accounted for by the destabilisation of the phosphorodithioate structure due to the lower energy of the Si—S bond compared with the Si—O bond.

An analogous rearrangement of 2-hydroxyalkyl phosphorothioates was proposed as early as 1968 [92] and the isomerisation products were identified subsequently[93]:

The stability of *S*-(2-hydroxyalkyl) phosphorothioates (CXIII) is determined by the nature of the substituents at the phosphorus atom. Acyclic compounds are fairly stable at room temperature. The rate of their isomerisation increases[94] with decrease of the length of the alkoxy-groups $R = R^1$ in the sequence iso-C_3H_7 < C_2H_5 < CH_3. When the butoxy-group at the phosphorus atom is replaced by the t-butoxy-group, the capacity for rearrangement disappears[95]. In the presence of phenoxy-groups, isomerisation does not occur either, but there is an intramolecular substitution of the phenoxy-group with formation of compound (CXIV).[96] For a mixed environment of the phosphorus atom, the rate of isomerisation increases in the sequence[94] $R^2 = R^3 = H < R^2 = H, R^3 = CH_3 < R^2 = R^3 = CH_3$. A lower mobility of the thiophosphoryl group compared with the phosphoryl group has been observed[97,98]. 2-Hydroxyalkyl phosphorodithioates do not show a tendency towards isomerisation and the latter can be achieved only under more severe conditions[98]. The incorporation of the phosphorus atom in a five-membered ring accelerates the isomerisation to such an extent that 2-hydroxyalkyl phosphorothioates of the 1,3,2-dioxaphosphorinane series[99] can be detected only by ^{31}P NMR. The characteristics of the rearrangement discovered agree with the mechanism involving intermediate formation of the hydroxyphosphoranes (CXV), which are converted into the phosphates (CXVI). The influence of the dioxyalkylene ring at the phosphorus atom on the rate of isomerisation can be explained by the lower energy of hydroxyphosphoranes of type (CXV), containing two five-membered rings, compared with the intermediates containing one five- or six-membered ring. In certain cases the phosphorane intermediates have been detected by ^{31}P NMR.[99]

Conversely, the fact that the *S*-(3-hydroxyalkyl) phosphorothioates and phosphorodithioates, obtained by the addition of acyclic dialkylphosphorothioic and dialkyl phosphorodithioic acids to oxetans, do not isomerise can apparently be explained by the reduced stability of hydroxyphosphoranes with acyclic substituents at the phosphorus atom[100,101]. On the other hand, the products of the addition of five-membered cyclic phosphoromonothioic acids (CXVII) are readily converted into 3-mercaptoalkyl phosphates (CXVIII):[101]

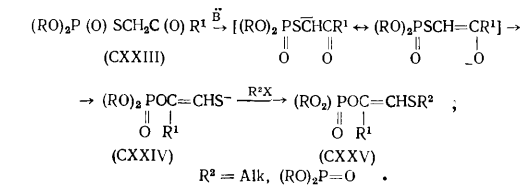


Derivatives of six- and seven-membered cyclic esters of phosphorus acids of type (CXVII) rearrange at 160–180 °C.[102]

The capacity of phosphoryl groups for 1,4-E → O (E = S, Se, or Te) migration is used to deoxygenate epoxides. The products of the interaction of salts of *O*,*O*-dialkylphosphoroselenoic[103] and *O*,*O*-dialkylphosphorotelluroic acids with olefin oxides are the olefins (CXIX), selenium (or tellurium),

and phosphates[104]. Their formation (Scheme 25) involves the rearrangement of the phosphoroselenoates or phosphorotelluroates (CXX):

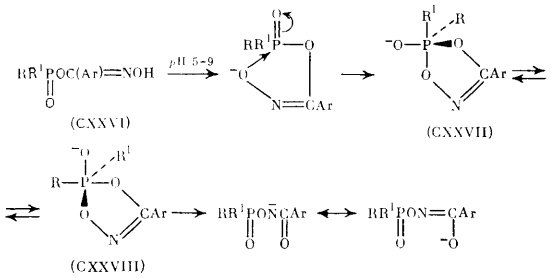
Scheme 25



E = Te, Se; R = alkyl or monosaccharide residue.

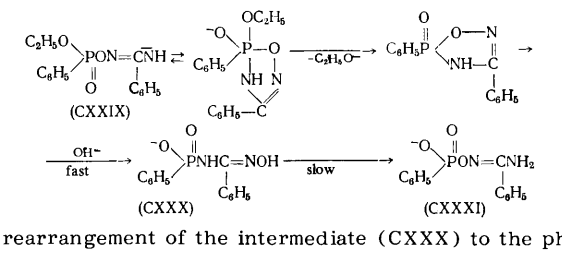
In the case of salts of phosphonoselenoic acid, the rearrangement products (CXXI) are capable of undergoing also an oxidation-reduction reaction, in which they are converted into the diselenides (CXXII).

When *S*-(2-Oxoalkyl) phosphorothioates (CXXIII) are acted upon by bases, they rearrange to the enol phosphates (CXXIV), which have been isolated in the form of the derivatives (CXXV) [105] (Scheme 26).



Scheme 26

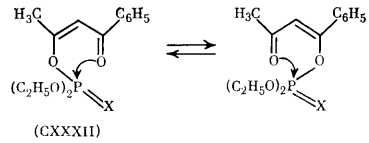
R^2 = Alk, $(RO)_2P{=}O$.



The mechanism of this rearrangement is probably analogous to that of the isomerisation of phosphorylated hydroxamic acids (CXXVI),[106] which proceeds in accordance with Scheme 27 via the intermediates (CXXVII) and (CXXVIII).

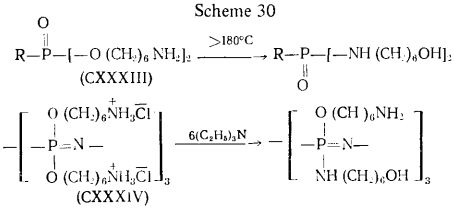
Scheme 27

The 1,4-O ⇌ N shift of the phosphono-group occurs in the alkaline hydrolysis of the imidoximes (CXXIX) [107] (Scheme 28):



Scheme 28

The rearrangement of the intermediate (CXXX) to the phosphate (CXXXI) is kinetically a first-order reaction.



It has been suggested[108] that the reversible rearrangement of the *Z*-topomers of the enol phosphates (CXXXII) derived from 1,3-diketones proceeds via a mechanism involving intramolecular nucleophilic substitution at the tetrahedral phosphorus atom (Scheme 29):

Scheme 29

In contrast to the corresponding acyl derivatives[69], phosphoryl exchange (Scheme 29) is observed only above 150 °C. This is explained by the more stringent steric requirements which must be met by the trigonal-bipyramidal transition state, in which both oxygen atoms must be located in the axial positions. The formation of phosphorane intermediates containing larger than six-membered rings is apparently not a characteristic process.

Scheme 30

Thus the isomerisation of the phosphorylated aminoalcohols (CXXXIII) and (CXXXIV) [109] must be regarded as an intermolecular process.

* * *

The data presented in this review makes it possible to combine the wide variety of rearrangements involving the migration of electron-deficient phosphoryl groups on the basis of the mechanism involving nucleophilic substitution at a tetrahedral phosphorus atom, so that the characteristic features of the phosphoryl migrations can be described in most cases from the standpoint of the "hydroxyphosphorane concept", which constitutes the foundation of the modern interpretation of this mechanism.

The discovery and investigation of phosphorylotropic tautomerism, which will make it possible to examine the fine details of many biochemical processes in which the nature of the elementary reaction step is analogous, has been a great success. The study of the characteristic features and limits of the occurrence of phosphoryl migrations opens new pathways to the synthesis of various new organophosphorus compounds. The development of simple methods of synthesis of imidoyl derivatives of tetracoordinate phosphorus thio-acids and the study of their properties constitute a new field in thiophosphorylation methods.

Organophosphorus Stabilisers of Polymers: Efficiency and the Mechanisms of Action

P.A.Kirpichnikov, N.A.Mukmeneva, and D.G.Pobedimskii

The review is devoted to studies constituting the scientific basis of the search for and selection of highly effective organophosphorus stabilisers of polymeric materials. The physical chemistry of the potential organophosphorus stabilisers and the stabilisers used in practice are examined from this standpoint. The mechanisms of the inhibiting effect of organic phosphites in various compositions are discussed and the relative contributions of the mechanisms considered to the overall inhibiting activity are estimated. The dependence of the reactivity of phosphites on their structure is examined and the quantitative characteristics of the main reactions of phosphites are discussed. The results obtained make it possible to predict the effectiveness of phosphites with different structures as inhibitors of the chain autoxidation and degradation reactions of polymers. The bibliography includes 100 references.

CONTENTS

I. Introduction 1051
II. Stabilisation of polymers at the degradative process initiation stage 1052
III. Stabilisation of polymers at the oxidation chains propagation and degenerate branching stages 1054
IV. The improvement of the effectiveness of organophosphorus stabilisers (synergism) 1058

I. INTRODUCTION

The effective protection of polymeric materials against ageing is an important scientific-technological problem. Numerous studies devoted to the urgent problem of the elucidation of the scientific basis of the ageing and stabilisation of polymers have been published in recent years. They were initiated by the work of Academician N.M.Emanuel'[1,2], who formulated the principles of the ageing and stabilisation of polymers.

Among the wide variety of organic compounds used as stabilisers, organic phosphites (OP) occupy a special place. They are used as stabilisers of polyolefins, raw and cured rubbers, heterochain polymers, and poly(vinyl chloride), and also as inhibitors of the polymerisation of diene hydrocarbons[3]. Numerous investigations in this field have been carried out in Kazan[4-7]. It has been estabilished that the most powerful stabilising antioxidant activity is shown by the aromatic and aromatic alkyl-substituted esters of phosphorous acid which do not colour polymeric materials during their processing and use, exhibit a considerable synergistic effect in mixtures with phenols, are readily blended, are involatile, and their susceptibility to oxidation by molecular oxygen is low.

Qualitative model estimates involving the interaction of phosphites with 1,1-diphenylethyl hydroperoxide[8] and the stable diphenylpicrylhydrazyl radical[9] made it possible to classify phosphites as inhibitors with a combined type of activity: they decompose hydroperoxides, supressing degenerate branching, and can terminate chains by reaction with peroxy-radicals; on the other hand, they are capable of enhancing the activity of catalytic admixtures of variable-valence metals and of blocking weak (as regards degradation) sites in the polymer chain. We shall note the most important phenomenological consequences of such polyfunctionality of organic phosphites.

Firstly, the reactions of organic phosphites with hydroperoxides lead to the intensification (synergism) of the action of typical inhibitors (phenols) in their mixtures with phosphites in the autoxidation of polymers, i.e. under conditions where the main source of radicals is the accumulating hydroperoxides.

Secondly, organic phosphites induce the destruction of peroxy-radicals, which leads to the appearance of induction periods in polymer oxidation processes. As will be shown below, the inhibiting effect of phosphites is associated with the kinetics of their radical-chain oxidation. This is indicated by the broad distribution of the stoichiometric inhibition coefficients for the oxidation reactions carried out in different phases (liquid and solid).

Table 1. Changes in the content of the inner $\diagdown C{=}C \diagup$ bonds $\bar{\gamma}$ in PVC macromolecules on heat treatment in the presence of organic phosphites (353–373 K).[17]

Composition	[OP], mol/mol PVC	τ, h	T, K	$[\eta]_0$, dl g^{-1}	$[\eta]$, dl g^{-1}	$10^4 \cdot \bar{\gamma}$, mol/mol PVC
PVC($\bar{M}_w^0$ = 127 500)	—	—	—	1.23	1.19	1.0
PVC + (I)	0.02	2	100	1.23	1.23	0
PVC + (I)	0.02	8	100	1.23	1.22	0
PVC + (II)	0.02	5	80	1.23	1.23	0
PVC ($\bar{M}_w^0$ = 99 000)	—	—	—	1.02	0.92	1.4
PVC + (I)	0.01	11	80	1.02	1.02	0

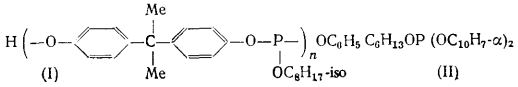
Notation: τ is the heat treatment time, $\bar{M}_w^0$ the viscosity-average molecular weight of the initial PVC, and $[\eta]_0$ and $[\eta]$ are the intrinsic viscosities of the PVC solutions before and after ozonisation respectively.

Thirdly, since reactions of organic phosphites with both peroxy-radicals and with hydroperoxides develop simultaneously in the polymer during its oxidation, the observed inhibiting effects under the conditions of the degenerate-branched chain oxidation can be accounted for by the combination of these two mechanisms or their competition.

Finally, the effects of the non-chain inhibition and colour-stabilisation of polymers of phosphites are closely related with the supression of the initiation and development of degradative processes.

The wide variety of the possible mechanisms of the stabilising effect of organic phosphites complicate the theoretical analysis of the process involving the stabilisation of polymers by phosphites. A series of studies have been carried out recently in which the principal properties of organophosphorus compounds as stabilisers of polymeric materials have been established and the principal mechanisms of their inhibiting and colour-stabilising action have been formulated and proved.

The aim of the present review is to analyse the present state of the experimental and theoretical studies (during the period 1973–1983) of the stabilisation of polymers by organophosphorus compounds. The review deals with the principal results of these studies and also with new systems whereby it is possible to represent more fully the kinetic model of the stabilising action of organophosphorus stabilisers.



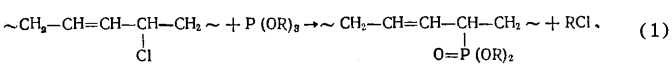
II. STABILISATION OF POLYMERS AT THE DEGRADATIVE PROCESS INITIATION STAGE

1. Poly(vinyl chloride)

The ability of organic phosphites to interact with "weak" sites in macromolecules[10], at which the decomposition of the polymer is initiated in the first place, was observed and demonstrated for the first time in relation to poly(vinyl chloride). As a consequence of the reaction of organic phosphites with the "weak" sections, the degradative processes are inhibited at the initiation stage, which increases the thermal stability of the polymer and leads to the preservation of its initial colour during ageing.

Until recently, in considering the mechanism of the stabilising action of organic phosphites, the complex poly(vinyl chloride) (PVC) dehydrochlorination process was regarded as a single-stage reaction[11–16]. The available literature data therefore make it possible to estimate only the overall effect of phosphites as regards PVC. Minsker et al.[17] published the results of a more detailed study of the influence of phosphite esters on the rate of dehydrochlorination of PVC.[18] The overall result is determined by the superposition of statistical dehydrochlorination processes at a rate w_c, leading to the random formation of isolated double bonds at any site within the macromolecules, and the HCl elimination process leading to the formation of a system of conjugated double bonds at a rate w_n.

It has been established[17] that the action of the phosphites



(I) (II)

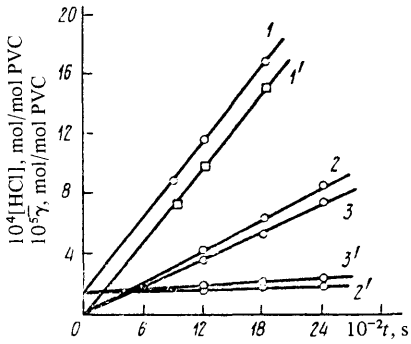
is manifested by an appreciable decrease (by more than an order of magnitude) of the rate of statistical dehydrochlorination w_c (Fig.1) (with retention or even some increase of the rate of formation of polyene sequences).

This suggests new pathways in the mechanism of the stabilisation of PVC biphosphites: organic phosphites interact with isolated unsaturated bonds >C=C< in the PVC macromolecules. As a consequence, the product of this reaction is not ozonised with subsequent oxidative cleavage; the molecular weight of PVC (a quantitative measure of the statistical dehydrochlorination of the polymer[19]) does not change.

Apart from the data presented in Fig.1, the quantitative "closure" of the inner >C=C< bonds in the polymer chains on heat treatment of PVC in the presence of phosphites constitutes an argument in support of this reaction (Table 1). Among the mechanisms of the stabilising action of organic phosphites in relation to PVC proposed previously, the possibility of the interaction with isolated >C=C< bonds was not taken into account.

The effects associated with the increase of the stability of PVC were usually attributed to the interaction of phosphites with a chlorine atom in the β-position relative to the >C=C< bond in the chloroallyl group[14,20]:

(1)



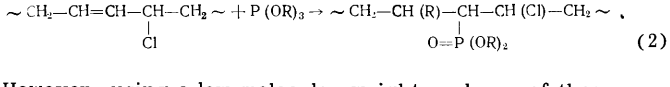


Figure 1. The overall (lines *1*–*3*) and statistical (lines *1′*–*3′*) dehydrochlorination of PVC in the prsence of 0.02 of a mole of phosphites per mole of PVC (448 K, $p = 10^{-2}$ mmHg, $M_w^0 = 127500$, 0.02 of an equivalent of $(C_{17}H_{35}COO)_2Ba$ per equivalent of PVC: 1) and 1′) without phosphite; 2) and 2′) in the presence of compound (I); 3) and 3′) in the presence of compound (II).[17]

The presence and formation of chloroallyl groups in the macrochains was believed to be the main cause of the activation of the HCl elimination process[21–24]. Taking into account the experimentally observed addition of organic phosphites to anomalous groups involving the saturation of the >C=C< bonds, an alternative mechanism was proposed[8]:

(2)

However, using a low-molecular-weight analogue of these groups (4-chloropent-2-ene), it has been shown in relation to model reactions that phosphites (353 K, 100 h; 443 K, 30 h) do not react with the β-chloroallyl groups (neither via the >C=C< bond nor via the C–Cl bond[25]). On the other hand, PVC treated with organic phosphites (with subsequent elimination of the latter) is characterised by a low initial rate of the HCl elimination reaction, the relation being analogous[17] to that described by curves *2* and *3* in Fig.1.

Thus reactions (1) and (2) cannot be adopted as the basis of the mechanism of the stabilising action of organic phosphites in relation to PVC, because this does not reflect the true nature of the phenomenon. This conclusion is particularly valid since it has been shown[18,26,27] that the β-chloroallyl groups are not responsible for the high rate of dehydrochlorination of PVC and that the low stability of

the polymer is caused by the presence in the macromolecules of the carbonylallyl groups ~C(=O)–CH=CH–CH(Cl)~, formed on oxidation of the chloroallyl groups[27]. The interaction of organic phosphites with the carbonylallyl groups in PVC, which leads to a decrease of their content† in the polymer macromolecules (Fig. 2) [28] and hence to a considerable decrease of the initial rate of dehydrochlorination of PVC (Fig. 3), proceeds also at room temperature[28]. Since the organic phosphite is introduced in a large excess relative to the carbonylallyl groups (this corresponds to the real PVC stabilisation conditions), the reaction proceeds in a pseudounimolecular regime and its rate is determined solely by $\bar{\gamma}_0$ (the kinetic plots for the consumption of the carbonylallyl groups can be made linear in terms of semi-logarithmic coordinates). The effective rate constants k for the interaction of organic phosphite with the carbonylallyl in PVC have been calculated for tri-isobutyl phosphite ($k = 0.11 \times 10^{-3}$ s^{-1} at 298 K) together with the parameters of the Arrhenius equation: $E_a = 71.4$ kJ mol^{-1} and $\lg A = 10 \pm 1$.

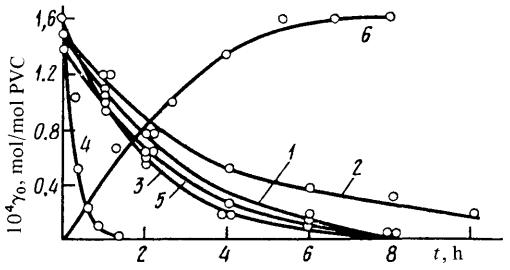

Figure 2. Dependence of the content of ketochlorallyl groups $\bar{\gamma}$ on the time of contact of PVC specimens with $(iso\text{-}C_8H_{17}O)_3P$ at different temperatures (lines *1*–*5*) and on the degradation time (448 K, 10^{-2} Pa) of modified PVC (line *6*); initial content ($10^4\bar{\gamma}_0$, mol/mol PVC): 1) and 6) 1.52; 2)–4) 1.62; 5) 1.42; temperature (K): 2) 289; 3)–5) 298; 4) 313.[28]

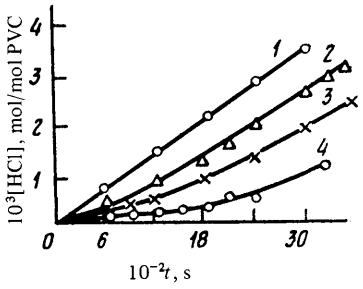

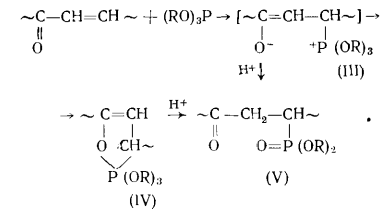

Figure 3. The elimination of HCl from PVC ($\bar{\gamma}_0 = 1.52 \times 10^{-4}$ mol/mol PVC) not containing $(iso\text{-}C_3H_7O)_3P$ (line *1*) and PVC subjected to a preliminary treatment with phosphite at 298 K; treatment time (h): 2) 1; 3) 2; 4) 6.[28]

†The quantitative content of the carbonylallyl groups $\bar{\gamma}$ is calculated from the viscosity-average molecular weight after the alkaline hydrolysis of the $(RO)_3P$-modified polymer[19].

It has been established that the interaction of phosphites with PVC proceeds via the ketovinyl fragment of the carbonylallyl group[29]:

(3)

This is demonstrated by the results obtained in the study of the competitive reactions of the phosphite (tributyl phosphite) with a mixture of methyl vinyl ketone (a model of the ketovinyl fragment) and 4-chloropent-2-ene, which models the β-chloroallyl group (353 K, equimolar reactant ratio). The phosphite reacts selectively with methyl vinyl ketone, while 4-chloropent-2-ene is isolated from the reaction mixture in an unchanged form apart from a certain amount of its dehydrochlorination products—piperylene and HCl.

The final reaction product—butyl 3-oxobutylphosphonate (V), identified by infrared spectroscopy ($\nu_{P=O} = 1250$ cm^{-1}, $\nu_{C=O} = 1730$ cm^{-1}), NMR($\delta_{^{31}P} = +31$ p.p.m.), and elemental analysis, is formed in the presence of a proton donor (HCl in the given reaction) as a consequence either of the protonation of the dipolar ion (III) or the conversion of the intermediate oxophospholen (IV) ($\delta_{^{31}P} = -31$ p.p.m.) into compound (V).[30] Under the real PVC stabilisation conditions, the proton donors can also be either HCl, always present in the polymer during its heat treatment even at relatively low temperatures, or other acid admixtures, H_2O, and phosphite hydrolysis products (alcohols, phenols, etc.).

At the same time during the degradation of the stabilised PVC the rate of evolution of HCl increases[28] to the value characteristic of the initial polymer. The content of the carbonylallyl groups increases in the same way (Fig. 2, curve *6*), which indicates the thermal decomposition of the saturated ketophosphonate groups under the PVC degradation conditions. Treatment of the curve for the accumulation of the carbonylallyl groups during the thermal degradation of the modified PVC in terms of the first-order reaction equation yields $k_{decomp} = (0.93 \pm 0.06) \times 10^{-3}$ s^{-1} at 448 K. At the polymer degradation temperature the ratio $k/k_{decomp} > 10^3$ ($k = 1.8$ s^{-1} at 448 K, calculated from E_a). Thus the high stabilising effectiveness of organic phosphites in relation to the thermal decomposition of PVC is caused, apart from other factors, by the high ratio of the rate constant for the formation of saturated ketophosphonate groups on interaction of organic phosphites with the carbonylallyl groups in PVC and the rate constant for the decomposition of the ketophosphonate groups under the conditions of the thermal degradation of the polymer.

It is significant that the correlation between the activity of phosphites in reactions with α,β-unsaturated ketones and their stabilising effect in PVC made it possible to demonstrate independently that the relatively high overall rate of dehydrochlorination of PVC is in fact determined mainly by the content of the ketochloroallyl structures in the polymer macromolecules.

Thus a new selective phosphorylation reaction, involving the ketovinyl groups of the "anomalous" ketochloroallyl fragments, was discovered for PVC at the degradative process initiation stage. The consumption of the inner double bonds in the carbonylallyl groups, as a result of such interaction of organic phosphite with PVC, results in the breakdown of conjugation in these groups and leads to a sharp decrease of the rate of dehydrochlorination of PVC.

This reaction is in fact the main cause of the inhibition of the formation of polyene sequences inducing the decomposition and colouring of the polymer.

Turning now to the reactions of phosphites with PVC considered in the literature, one should note that, in the inhibition of the decomposition of PVC, the reactions with HCl [31,32] hardly occur under the conditions of the real stabilisation of PVC in the presence of thermostabilisers; the reactions with polyenes $(\sim CH{=}CH\sim)_n$ can develop only under specific conditions[33]; as shown above, the reactions with the β-chloroallyl fragments also fail to make an appreciable contribution to the stabilisation of PVC. All these reactions can be interpreted as concomitant, playing a secondary role in the inhibition of the degradation and colouring of PVC.

2. Polyolefins

The active centres of the degradation process in polyolefins are double bonds, branches in the polymer chains with mobile hydrogen atoms, and carbonyl-containing groups[34].

In the study of polyethylene polymers containing various functional groups, it was found that phosphites are inert[35,36] in relation to hydroxy-groups and double bonds. However, phosphites effectively bind carbonyl groups, reducing their concentration in the initial polymer by a factor of 2–3. Analogous results were obtained in polyethylene (PE) and hexadecane subjected to preliminary oxidation. The introduction of phosphite esters lowers appreciably the intensity of the absorption band of the $>C{=}O$ group in the region of 1720 cm^{-1} in the infrared spectra of the polymer specimens.

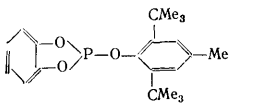
The reactivity of phosphite esters in relation to carbonyl groups increases on passing from the full to the acid esters and on replacement of aromatic substituents in the phosphite molecules by aliphatic substituents. Thus, under identical conditions, the concentration of the $>C{=}O$ groups is reduced to the extent of 45, 28, 20.5, and 18% by di-iso-octylphosphorous acid, 2,2'-methylenenbis(6-t-butyl-4-methylphenyl)phosphorous acid, tri-iso-octyl phosphite, and di-iso-octyl phosphite respectively. The observed decrease of the concentration of the $>C{=}O$ groups present in polyethylene, observed after the introduction of phosphites, must be attributed to the chemical interaction of the latter with the carbonyl groups, resulting in the formation of hydroxyphosphonate structures[37].

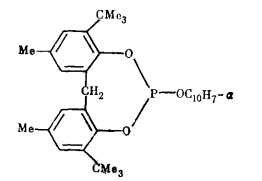
Thus a general trend in the stabilisation of the colour of polymers by phosphites, namely the deactivation of the reactive centres of macromolecules ("weak" bonds) initiating degradative processes, has been discovered in relation to polymers with fundamentally different decomposition mechanisms (PVC and polyolefins). Reactions of these types involve the chemical modification of macromolecules by polymer-analogue reactions, leading to an increase of the intrinsic stability of the polymer.

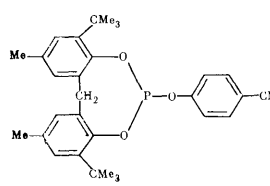
It is logical to assume that the observed reactions of phosphites with active anomalous fragments in macromolecules can occur also in the inhibition of the degradation of other polymers containing "weak" bonds of a similar type.

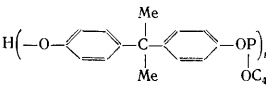
III. STABILISATION OF POLYMERS AT THE OXIDATION CHAIN PROPAGATION AND DEGENERATE BRANCHING STAGES

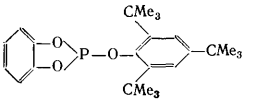
A problem concerning the stabilisation of polymers, which is important from the standpoint of practical applications, is that of the inhibition of the propagation and degenerate branching of chains in thermo-oxidative degradative processes, responsible for the natural ageing of carbochain polymers.











1. Inhibition of Chain Oxidation Processes

The liquid-phase oxidation of phosphorous acid esters by hydroperoxides and peroxy-radicals constitutes a good model for the understanding of their inhibiting effect in the oxidation of polyolefins[38].

(a) *Kinetics and mechanism of the reactions with hydroperoxides.* Quantitative tests of phosphites as hydroperoxide decomposing agents have been carried out by kinetic polarographic and radical trapping methods[39–42].

The kinetics and mechanism of the interaction of phosphorous acid esters depends significantly on their structure. The consumption of hydroperoxides in reactions with the full esters of phosphorous acids obeys first order kinetics with respect to each component. The rate constants for the reactions of phosphites do not vary over a wide range of reaction rates (10^2–10^3) and their stoichiometry is simple (1:1); certain typical values of k are listed in Table 2.

Table 2. The rate constants k, the activation energies E, and the pre-exponential factors A for the reactions of phosphites with cumenyl hydroperoxide (293 K).[38]

No.	Structure of phosphite	10^3k, litre mol^{-1} s^{-1}	E, kJ mol^{-1}	A, litre mol^{-1} s^{-1}
1	$(C_4H_9O)_3P$	83.3	24.7	$3.2\cdot10^3$
2	$(C_8H_{13}O)_3P$	77.9	25.5	$3.8\cdot10^3$

*Data obtained by Humpris and Scott[43].

**E and A obtained[44] for t-butyl hydroperoxide.

The reactions of hydroperoxides with the acid esters of phosphorous acids having the general formula

$$(RO)_2P(=O)H,$$

which are in tautomeric equilibrium with another reactive form, namely $(RO)_2POH$, have been investigated[45]. The rate constants have been calculated from the kinetic equation for termolecular reactions having kinetic orders $n = 2$ and 1 with respect to the hydroperoxide and the acid respectively[46]. The acids can be arranged in the following sequence in terms of the stoichiometric coefficients ν for the consumption of cumenyl hydroperoxide (CHP):

The Arrhenius relation governing the rate constant (20–100 °C) has been derived for *o*-phenylenephosphorous acid (PPA), which decomposes CHP catalytically:

$$k\ (\text{litre}^2\text{mol}^{-2}\,\text{s}^{-1}) = 2.5\cdot 10^{11}\exp(-15.6/RT).$$

Comparison with the ionisation constants determined by potentiometric titration[47] permits the conclusion that the acids having high pK values (>8) do not react; CHP is decomposed only by the strongest acids of the above series (pK < 8). This indicates qualitatively the involvement of the tautomeric forms of the test acids containing phosphorus (III) in the decomposition reaction of CHP as reactive species catalysing its decomposition. The same conclusion has been confirmed by the ^{31}P NMR spectra for PPA ($\delta_{^{31}P}$ = +129, +126 p.p.m.). The presence of two lines at the centre is apparently due to the presence of two conformers with a tervalent phosphorus atom.

Phosphorodithioic acids, having pronounced acid properties, show a high reactivity in reactions with CHP.[48] The study of the consumption of CHP in reactions with phosphorodithioic acids has shown that the latter participate in the reaction with anomalously high stoichiometric coefficients (in the range 7000–25000), which indicates the catalytic character of the decomposition of the CHP. As in the case of dialkyl(aryl) phosphites[47–49], this has been confirmed by the study of the consumption of CHP in the course of its stepwise addition to the reaction system. The rate of decomposition of CHP then remains the same as before, i.e. phosphorodithioic acid is the catalyst. This is also indicated by the absence of an induction period from the kinetic CHP decomposition curve.

The acid-catalysed decomposition of CHP apparently takes place via the mechanism of proton catalysis and is described by a second-order equation with respect to CHP and a first-order equation with respect to the acid[48].

From the standpoint of the effectiveness of the stabilising action of phosphites and acids, the determination of the contributions of the radical and non-radical pathways in the reactions with hydroperoxides is important. The yield of the radicals in the hydroperoxide + phosphite system has been estimated from the consumption of the stable nitroxy-radicals as "counters" of active radicals[40]; it proved to be from 0.02% for aliphatic phosphites to 5% for aromatic phosphites. For phosphorodithioic acids, the contribution of the radical pathway, estimated from the consumption of ionol, increases significantly (to 40%) as a function of structure.

The study of the chemically induced ^{31}P nuclear polarisation (^{31}P CINP) [50,52] in the reactions of phosphites with hydroperoxides has demonstrated unambiguously that the reactions proceed via two parallel (competitive) pathways—non-radical and radical, and that the radical mechanism, which leads to nuclear polarisation, plays a secondary role. Such competition is apparently due to the fact that, for the formation of the primary radical pair $[R'\dot{O}\ HO\dot{P}(OR)_3]$, the reaction of the phosphite with the hydroperoxide should be as a whole either strongly exothermic or it should proceed with a high activation energy, as shown in Fig. 4. The presence of the competitive non-radical pathway therefore enables the reaction to proceed to the formation of molecular products, bypassing the high-energy (endothermic) state of the radical pair[38].

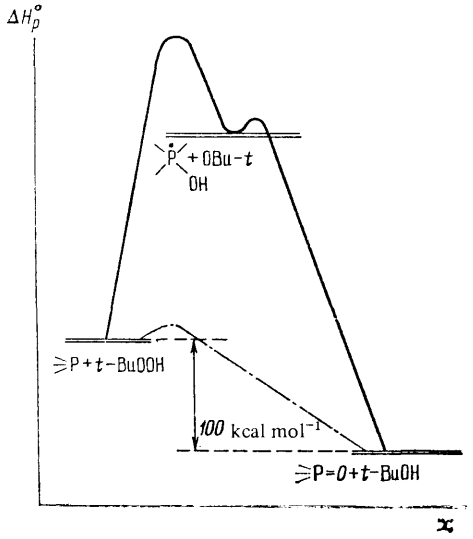

Figure 4. Schematic thermochemical diagram of the possible pathways in the reactions of phosphites with hydroperoxides[38].

The NMR spectra of the products of the reactions of phosphorus dithioacids with hydroperoxides also reflect the effects of nuclear polarisation during periods comparable to the reaction times[53].

Thus, one may conclude that reactions with hydroperoxides via several parallel mechanisms are characteristic of a wide range of esters of phosphorus acids.

(b) *Kinetics and mechanism of the initiated oxidation of organic phosphites.* The reactions of the radicals RO$^{\cdot}$ and $RO_2^{\cdot}$ with phosphites are classical objects of studies in the homolytic chemistry of phosphorus[54,55]; the results available in this field have been subjected to a critical analysis in a review[56]. Trialkyl phosphites are vigorously oxidised by alkylperoxy-radicals $RO_2^{\cdot}$ at 403 K; the oxidation has a chain mechanism and continues until the phosphite is completely exhausted. We shall adopt the conventional term "spontaneous oxidation" of phosphites.

The study of the kinetics of the comparatively weak ^{31}P CINP, observed in the oxidation of trialkyl phosphites under the conditions of an unbranched reaction (azobisisobutyronitrile, O_2, 338 K), demonstrated for the first time[57,58] that this reaction involves phosphorus-containing radicals and their radical pairs. Chemically induced nuclear polarisation occurs only in triethyl phosphite molecules formed in the kinetic chain cross-termination steps:

$$\left[\rangle\dot{P}{-}OR\,\dot{O}_2\,(RO)\,P{\langle}\right] \rightarrow \rangle P^{*}{=}O \quad .$$

Since the same product is formed in the chain propagation steps

$$RO_2^{\cdot} + \rangle P \rightarrow \rangle\dot{P}{-}O_2R \rightarrow \rangle P{=}O + \dot{O}R \;;$$

$$RO^{\cdot} + \rangle P \rightarrow \rangle\dot{P}{-}OR \rightarrow \rangle P{=}O + \dot{R} \xrightarrow{O_2} RO_2^{\cdot} \text{ etc.},$$

the molecules of phosphate with polarised nuclei are actually greatly "diluted" by the molecules of phosphate arising in the chain propagation reactions. Kinetic proof of this mechanism of the CINP has been presented[59] and the causes of the low polarisation coefficient (chain reaction with long chains) have been stated.

In order to discover the principal trends in the "spontaneous oxidation" of phosphites, the rates w_p of their chain oxidation have been analysed as a function of the rate of initiation w_i and the concentration of phosphites. The chain length ν is appreciably reduced (from ~10^4 units for trialkyl phosphites to 5–130 units for aromatic phosphites, particularly when shielded phenoxy-fragments are introduced into the phosphite molecule). Furthermore, on passing from aliphatic to aromatic phosphites, the $w_p \cong w_i^{1/2}$, relation observed for the former, changes to a relation of the type $w_p \cong w_i$, i.e. there is a change in the mechanism of the oxidation chain termination: the bimolecular chain termination is replaced by linear termination by secondary phenoxy-radicals. The latter can be formed via substitution reactions from kinetically unstable phosphoranyl radicals:

$$(ArO)_3\dot{P}OR \rightarrow (ArO)_2POR + ArO\dot{} \xrightarrow{RO_2^{\cdot}} \text{chain termination.}$$

This is precisely why the chemically induced ^{31}P nuclear polarisation is not observed in the chain oxidation of aromatic phosphites.

The appearance of phenoxy-radicals in the initiated phosphite oxidation reaction generates an additional chain transfer mechanism [taking into account the main $RO_2^{\cdot}(RO^{\cdot})$ + phosphite chain transfer pathway]; thus the addition of unsubstituted phenol stimulates the overall phosphite oxidation reaction.

(c) *Kinetics of the inhibition of oxidation processes by organic phosphites.* We shall examine the kinetic parameters, obtained recently characterising the effect of organic phosphites on the initiated oxidation of polyolefins in the solid phase and in the melt[57,60–63], as well as model oxidation reactions of low-molecular-weight substrates.

Fig. 5 presents the kinetic curve for the absorption of oxygen, typical for the phosphite-inhibited oxidation of both model hydrocarbons (styrene, tetralin, benzaldehyde, and low-molecular-weight polyethylene) and solid polyolefins (low-pressure polyethylenes, isotactic polypropylene). The inhibition parameters (determined from the O_2 absorption kinetics) in various substrate + oxygen + initiator + organic phosphite systems are presented in Table 3. The full organic phosphite esters terminate kinetic styrene and tetralin oxidation chains faster by more than an order of magnitude than a typical inhibitor (ionol). The rate constants for the reactions of the polymeric radicals $RO_2^{\cdot}$ with phosphites are comparable to (in solid polypropylene) or even smaller than (in fused polyethylene) the constants k_7 for the known amine and phenolic antioxidants as well as nickel and zinc carbamates. After the introduction of shielded phenoxy-groups into the phosphite molecule, the chain termination rate constant (k_7 or k_7/k_2) almost always increases; however, at the same time there is an increase in the stoichiometric inhibition coefficient f.

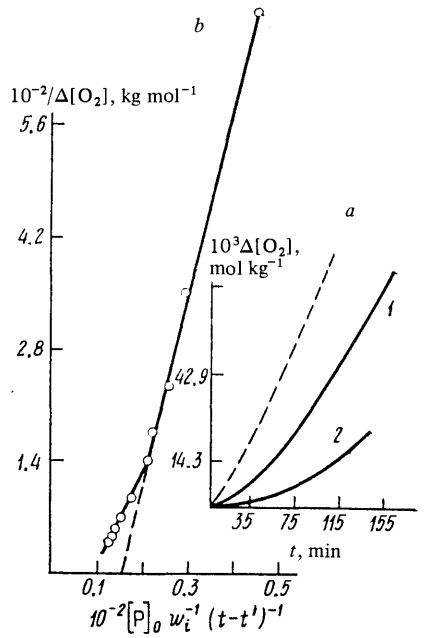

Figure 5. *a*) Kinetics of the initiated oxidation of polypropylene ($w_i = 3.8 \times 10^{-7}$ mol kg^{-1} s^{-1}, 358 K, p_{O_2} = 650 mmHg) in the presence of 1×10^{-2} [of a mole?] (line *1*) and 3×10^{-2} [of a mole?] (line *2*) of triphenyl phosphite (the dashed line represents the kinetics in its absence); *b*) linear kinetic plot in terms of the variables of the equation quoted by Denisov[64].

Table 3. Kinetic characteristics of the reactions of peroxy-radicals with organic phosphites[42].

**The parameters were evaluated by the computer modelling of the kinetics of the absorption of O_2.

***α = degree of crystallinity.

Direct quantitative estimates of the effectiveness of phosphites have convincingly demonstrated the validity of the early idea[4-7] that aromatic phosphites with shielded (or electron-donating) substituents should be more effective polyolefin stabilisers.

The interaction of aliphatic phosphites with peroxy-radicals proceeds with formation of alkyl radicals, which are actively involved in the oxidation chain propagation (i.e. powerful chain terminating agents—secondary radicals, for example aryloxy-radicals—are not formed). This is why the polymer is oxidised at a high rate even when the constant k_7 for trialkyl phosphite (for example, tri-iso-octyl phosphite) is greater than the constant k_2 for the chain transfer to the substrate[42].

In order to identify the reaction products of aromatic phosphites in the oxidation of a polyolefin, for example, polyethylene, the experiments were interrupted[61] at the end of the inhibited oxidation period (when the oxidation passed to the regime with the usual initiated reaction), while the low-molecular-weight products were extracted by carbon tetrachloride. Absorption frequencies characteristic of the C–O–P linkage and the aromatic ring were detected in the infrared spectra of the oxidised polymer; the inhibitor conversion products extracted from polyethylene contain the P=O and C–O–P fragments. This result can be explained qualitatively within the framework of the mechanism proposed:

$$R'OOR' \xrightarrow{w_i} R'O^{\cdot} \xrightarrow{RH} R^{\cdot},$$

$$R^{\cdot} + O_2 \rightarrow RO_2^{\cdot} \xrightarrow[k_2]{RH} R^{\cdot},$$

$$R^{\cdot} + RO_2^{\cdot} \rightarrow \text{products},$$

$$RO_2^{\cdot} + \text{—}P^{III}\text{—} \xrightarrow{k_7} \text{—}P^{V}(=O)\text{—} + RO^{\cdot}; \quad (4)$$

$$RO^{\cdot} + \text{—}P^{III}\text{—} \rightarrow \left[RO\text{—}\dot{P}\text{—}\right] \rightarrow RO\text{—}P^{III}\text{—} + ArO^{\cdot}, \quad (5)$$

$$ArO^{\cdot} + RO_2^{\cdot}\ (ArO^{\cdot}) \rightarrow \text{products}.$$

The mechanism postulates that the phosphite is oxidised by the $RO_2^{\cdot}$ radical to the phosphate [reaction (4)]; in addition, a reaction takes place in which a phosphite molecule is "inserted" in a seocndary alkoxy-macroradical $RO^{\cdot}$ with elimination of a phenoxy-radical (aryloxy-radical) [reaction (5)]. In conformity with the evidence presented by Denisov[64], the mechanism also includes the oxidation chain termination via the reaction between the alkyl macroradical ($\dot{P}$) and the peroxymacroradical ($PO_2^{\cdot}$).

The marked weakening of the inhibiting activity of tri-(6-t-butyl-4-methylphenyl) phosphite (VI) in fused polyethylene (Table 3) is apparently associated with the fact that diffusion- and structure-dependent hindrance, caused by the specific features of the solid phase, diminishes and the contribution of new chains, arising via the reaction of secondary phenoxy-radicals (from the phosphite) not only with the inhibitor but also with the polymer macromolecules, increases. In the liquid phase the coefficient f decreases still more markedly; in this case the chain "spontaneous oxidation" reaction of the phosphite plays an active role, creating powerful additional channels for the consumption of the inhibitor. In fact, in the inhibition of the oxidation of both styrene and tetralin, the coefficient f increases from $(1-1.5) \times 10^{-2}$ for $(PhO)_3P$ to $(5-6) \times 10^{-2}$ for the "shielded" phosphite (VI), i.e. in proportion to the reciprocal of the "spontaneous oxidation" chain length for these phosphites (the corresponding values of ν are 0.6×10^2 and 0.2×10^2 respectively) in *o*-dichlorobenzene[59]. Computer calculation of the rate of consumption w_p of the inhibitor (VI) in styrene showed[63,65] that it exceeds by an order of magnitude the "specified" rate of initiation w_i. Thus the phosphite is consumed via a chain mechanism with a chain length $\nu = 0.1 \times 10^2$. (The value obtained is close to the value of ν determined independently in experiments on the initiated oxidation of the same phosphite.)

If the effectiveness of the inhibition of oxidation by phosphites is determined by comparatively large rate constants k_T for their reactions with peroxy-radicals, then the duration of the stabilising action of the phosphites depends on the intensity of their competitive (coupled) chain "spontaneous oxidation", which determines the stoichiometric coefficient f of the inhibition. The set of such closely related processes is a specific feature of the inhibiting activity of organophosphorus oxidation inhibitors. Knowing these characteristics of the behaviour of organic phosphites, it is possible to predict the most effective regimes for the stabilisation of polyolefins (under storage and operating conditions) when the "spontaneous oxidation" of phosphite is suppressed and the duration of their stabilising action increases significantly.

Thus, in the oxidation reactions of both low-molecular-weight hydrocarbons and polyolefins, the most effective inhibition mechanism involves the interactionof the phosphites with peroxy-radicals.

The results presented above show that, in the presence of aromatic phosphites, the oxidation of polyolefins (in the solid phase and in the melt) and model hydrocarbons is a chain reaction with linear chain termination by phosphite molecules, i.e. typical mechanisms of the action of oxidation inhibitors operate.

2. Molecular Reactions of Organic Phosphites with the Products of the Thermal and Thermo-oxidative Degradation of Polymers

Under the conditions of an advanced polymer oxidation process, the non-chain inhibition reactions—via the interaction of phosphites with active functional groups and molecular decomposition products (peroxides, carbonyl-containing groups, isolated and conjugated double bonds, etc.)—also acquire a considerable importance.

The development of reactions of organic phosphites with the C=O groups formed in the thermo-oxidative degradation of polymers has been established for polyolefins[66,67], polychloroprene[68], etc.

Thus, under the conditions of the autoxidation of polyethylene in the presence of phosphite esters, a considerable retardation of the formation of carbonyl groups is observed compared with the polyethylene specimen not containing the organophosphorus additive[36]. It is noteworthy[66,67] that the polymer is then phosphorylated: the infrared spectra of the polyethylene reprecipitated after oxidation contains the absorption frequencies of the phosphoryl groups corresponding to the products of the reactions of phosphites with carbonyl compounds. The effectiveness in the reactions with carbonyl groups increases with increase of the concentration of the organophosphorus compound. When polyethylene contains ≥5 wt.% of the organophosphorus additive, the spectrum altogether fails to show the absorption lines of C=O groups in the course of 900 h.[66]

The ability of organophosphorus compounds to interact with C=O groups is correlated with the improvement of the operating characteristics of the polymer.

Experimental evidence for deactivation, under the influence of phosphites, of the reaction centres formed at the stage of extensive degradation of poly(vinyl chloride) and responsible for its colour is provided by the decrease of the rate

of dehydrochlorination and the weakening of the colour of the partly dehydrochlorinated PVC.[33] At the beginning of its heat treatment in the presence of phosphites, the latter reacts vigorously with the reaction centres present in the polymer; subsequent heat treatment leads to a monotonic increase of the amount of phosphorus in the degraded PVC as a consequence of the interaction of the phosphite with the active groups in the polymer as they are formed.

The observed phosphorylation of PVC must be attributed primarily to the interaction of the phosphites with the oxygen-containing fragments [reaction (3)]. When polyconjugated structures (chromophoric groups) arise in the macromolecules, organic phosphites weaken the colour of the polymer by breaking the conjugation chain ("symptomatic" stabilisation).

When the binding of the HCl evolved in the degradation of PVC and the formation of complexes of HCl with the double bonds intensifying the colour of the polymer are not effective, phosphites are capable of binding the HCl, which also leads to a weakening of the dehydrochlorination process and the stabilisation of the colour of the polymer[33]. The efficiency of the stabilising action of phosphites, due to their combination with HCl, depends on the degree of their dealkylation under the influence of HCl and the composition of their dealkylation products; the complete dealkylation, characteristic of $(RO_3)P$, leads to the formation of acid products of the type of $ROP(OH)_2$ and H_3PO_3, which accelerate the dehydrochlorination of PVC; aromatic phosphites $(ArO)_3P$ do not react with HCl. Mixed phosphites of the type of $ROP(OAr)_2$ are the most effective stabilisers of PVC; their interaction with HCl results in the formation of only $(ArO)_2P(=O)H$, which are inert on further exposure to HCl.[33]

It is significant that, under the conditions of the inhibition of advanced degradative processes, phosphites are capable of functioning as a "depot" of stabilisers[2], forming under the influence of dealkylating agents (the polymer decomposition products, particularly H_2O, HCl, RCOOH, etc.) the corresponding diaryl(alkyl) phosphites. The latter are active *in statu nascendi*, i.e. their main bulk exists in a bound state and the active form of the stabiliser is evolved from the latter gradually. This is particularly likely since dialkyl(aryl)phosphorous acids are extremely reactive in relation to free radicals[69,70], conjugated polyene systems[71], carbonyl compounds[72,73], etc.

Overall, the general trends in the structural selectivity of phosphites in reactions with the active centres for the decomposition and colouring of polymers have been discovered[74]; in relation to electrophiles (hydroperoxides, carbonyl-containing compounds, activated unsaturated structures, H_2O, HCl, etc.), the reactivity of phosphites decreases in the sequence

$$(RO)_3P > (RO)_2POAr > ROP(OAr)_2 > P(OAr)_3 .$$

Phosphites containing electronegative substituents R in the ester group are effective in reactions with polyene systems $(\sim CH{=}CH\sim)_n$ with $n \geq 4$, which are powerful nucleophiles.

Thus the study of the mechanism of the stabilisation of polymers by phosphites at advanced stages of the degradation makes it possible to predict effective procedures for the secondary stabilisation of polymeric products, i.e. the suppression of the processes which alter significantly the operating properties of the polymer. This means that phosphites are not merely the usual auxiliary additives; they acquire an independent and sometimes a decisive importance.

IV. THE IMPROVEMENT OF THE EFFECTIVENESS OF ORGANOPHOSPHORUS STABILISERS (SYNERGISM)

A distinctive property of organophosphorus stabilisers is their ability to exhibit synergistic effects in a mixture with other additives[3]. The synergism can be achieved either as a result of the enhancement of the functions of organophosphorus stabilisers as inhibitors of free-radical oxidation or by increasing their contribution to the non-chain inhibition processes. We shall consider certain examples of such synergism.

1. Kinetics and Mechanism of the Synergism in the Action of (M + P) Pairs in the Inhibition of an Initiated Oxidation Reaction

The phenomenon of a sharp intensification of the effectiveness of aromatic phosphites as inhibitors of the initiated oxidation of low-molecular-weight hydrocarbons (styrene, tetralin) and polyolefins under the influence of quadrivalent titanium compounds[75] and transition metal acetylacetonates $Macac_n$, where M = Co^{2+}, VO^{2+}, Cr^{3+}, Ni^{2+}, etc., has been observed[76]. The most important general properties of this phenomenon have been established.

In the presence of metal acetylacetonates the dependence of the induction period on the phosphite concentration has a "critical" character (Fig.6). This agrees well with the hypothesis[1] of the formation of a new, more effective inhibitor—a complex of the metal ion with the phosphite, which reacts vigorously with the peroxy-radical.

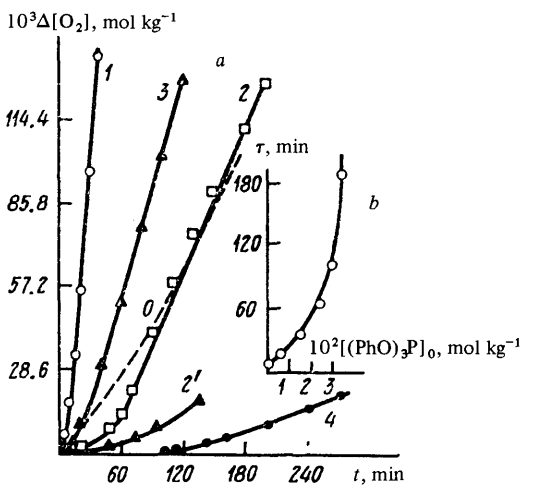

Figure 6. *a*) Kinetic curve for the absorption of oxygen by solid polypropylene (358 K, p_{O_2} = 650 mmHg, $w_i = 3.8 \times 10^{-7}$ mol kg^{-1} s^{-1}) in the presence of 3×10^{-3} mol kg^{-1} (line *1*) or 6×10^{-4} mol kg^{-1} (line *3*) of $Coacac_2$, of a mixture of 3×10^{-3} mol kg^{-1} of $Coacac_2$ + 3×10^{-2} mol kg^{-1} of $(PhO)_3P$ (line *2*), of a mixture of 6×10^{-4} mol kg^{-1} of $Coacac_2$ + 3×10^{-2} mol kg^{-1} of $(PhO)_3P$ (line *4*), and of 3×10^{-2} mol kg^{-1} of $(PhO)_3P$ (line *2'*); 0) curve for initiated oxidation in the absence of the metal complex and phosphite; *b*) dependence of the observed induction period τ on the initial $(PhO)_3P$ concentration in the oxidation of polypropylene in the presence of an initiator and 6×10^{-4} mol kg^{-1} of $Coacac_2$.[76]

Using the "critical" concentration of the phosphite, the rate constant k'_7 for the inhibition of the oxidation of styrene by the coordinated phosphite was obtained and was found to be much greater than not only the constant k_7 for the free phosphite but also the constant k_7 for the metal acetylacetonate and for the familiar reference inhibitor (ionol). The "activation" of the phosphite as an inhibitor when it is coordinated to the metal ion is satisfactorily confirmed by the computer calculation of the kinetics of the oxidation of styrene and its inhibition by the metal ion–phosphite composition[65,77].

The chain oxidation reaction passes from the region of the rapid distinctly catalytic process (in the presence of metal ions) to the region of a slow process with linear chain termination by the molecules of the coordinated phosphite. The study of the kinetics of this process made it possible to determine the quantitative parameters of the observed synergism[76]. Analysis of these parameters shows that the catalytic oxidation of polypropylene by metal ions is suppressed most effectively by the phosphite for the ratio $[M]/[P] \leq 6 \times 10^{-2}$, i.e. when the metal concentration in the polymer does not exceed 0.02 wt.% and the phosphite concentration is close to values usually employed (0.5–1.0 wt.%). The manifestation of "critical" concentrations is in fact characteristic of this range of [M]/[P] ratios.

The series of the relative "synergistic" activities of metal ions in compositions with phosphites in styrene, tetralin, and solid polypropylene have been established on the basis of the analysis of the quantitative parameters of the oxidation inhibition process[38]; overall they have the same direction in terms of the "strength" of the synergism, which implies that the nature of the observed synergism is the same in all cases regardless of the type of substrate oxidised. It has been discovered that the "strongest" compositions are those (based on $Niacac_2$) in which the organometallic component exhibits only a weak catalytic activity; this tendency can be used as a rule in selecting other compositions.

The general characteristics of the behaviour of the kinetically labile metal–phosphite complexes established in oxidation systems with participation of peroxy-radicals make it possible to predict the activity of a new class of oxidation inhibitors—individual stable metal complexes containing molecules of organic phosphites as the main ligands. A remarkable feature of these complexes, for example, the copper(I) complexes is, according to the literature[78–83], a significant increase of the stoichiometric inhibition coefficient, which implies that the reactions involving the additional consumption of the phosphite bound in the complex by a chain process are virtually suppressed. The study of the initiated oxidation of styrene and solid isotactic polypropylene has shown[78] that the copper(I) phosphite complexes (CuP) are more effective than the free non-coordinated phosphite; the quantitative characteristics of the inhibiting action of these complexes have been calculated and it has been shown that the termination of the kinetic oxidation chains by the inhibitor molecules involves the oxidation of the coordinated phosphite without change in the degree of oxidation of the central metal ion.

It is noteworthy that the reactions of the metal complex inhibitor or the products of its reaction with the polymeric hydroperoxide are important for polypropylene undergoing oxidation in the presence of an initiator. It has been found[78] that these reactions have a radical mechanism and proceed at high rates. They are in fact responsible for the "inhibitor $\rightleftharpoons$ catalyst" transition in the kinetic behaviour of the copper(I) phosphite complex observed in the course of the oxidation. In other words, when CuP is used favourable possibilities are created for controlling the regime of the polymer stabilisation under natural conditions, when there is no initiator (controlled stabilisation under uncontrolled conditions). An increase of the duration of the stabilising action of the CuP complexes can be achieved primarily by suppressing the hydroperoxide initiation channel. Below we shall consider a number of experimental facts confirming this idea.

2. The Synergism of Mixtures of Phosphite Complexes with Aromatic Amines

The aromatic amines *p*-toluidine, *o*-toluidine, and diphenylamine have been investigated[81] as "deactivators" of the ROOH groups, but the expected effect was observed only for *p*-toluidine (T) (we may note that *p*-toluidine inhibits weakly the oxidation of polypropylene).

Fig.7 presents as an example typical time variations of the absorption of O_2 in the system comprising polypropylene undergoing oxidation to which T + $Cu[(PhO)_3P]Cl$ or CuP mixtures have been added, the molar concentration ratios of the latter amounting to 0.5–2.0. The character of these relations indicates the occurrence of synergism and at the same time the actual suppression of the secondary processes involving the initiation of the oxidation of polypropylene. The synergistic effect depends in a definite manner on the inhibitor/deactivator ratio and on the concentration of the metal complex additive.

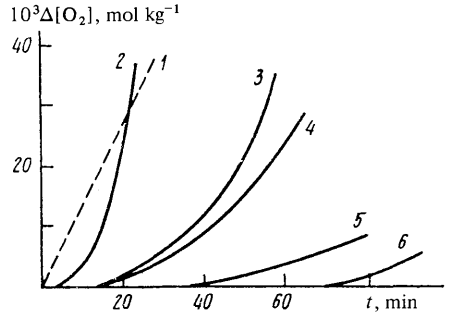

Figure 7. Kinetic curves for the absorption of oxygen by polypropylene undergoing oxidation (358 K, $w_i = 2.5 \times 10^{-6}$ mol kg^{-1} s^{-1}, $p_{O_2} = 650$ mmHg) in the absence of an inhibitor (line *1*) and in the presence of inhibitors: 2) [CuP] = 5×10^{-3} mol kg^{-1} and [T] = 2.5×10^{-3} mol kg^{-1}; 3) [CuP] = 5×10^{-3} mol kg^{-1} and [T] = 1×10^{-2} mol kg^{-1}; 5) [CuP] = 1×10^{-2} mol kg^{-1} and [T] = 1×10^{-2} mol kg^{-1}; 6) [CuP] = 1×10^{-2} mol kg^{-1} and [T] = 5×10^{-3} kg^{-1}.[78]

Thus, when [CuP] = 1×10^{-2} mol kg^{-1} and for the ratio [CuP]/[T] ≥ 1, there is a sharp increase of the induction period τ (see curves *5* and *6* in Fig.14); when [CuP] = 5×10^{-3} mol kg^{-1} for the ratio [CuP]/[T] = 0.5–2.0, the synergism is either much weaker (curves *3* and *4* in Fig.14) or is not observed at all (curve *2* in Fig.14). If the concentration of the amine exceeds that of the phosphite complex, the induction period, defined here as the time during

which $\Delta[O_2]$ reaches 5×10^{-3} mol kg^{-1}, at a constant overall mixture concentration [CuP] + [T] = 1.5×10^{-2} mol kg^{-1} diminishes as a consequence of the probable displacement of the phosphite as a ligand from the coordination sphere of the copper ion by the amine. This means that, in the presence of synergistic amine additives, the phosphite complex retains its key function—it terminates the kinetic chains in the oxidation of polypropylene.

The maximum value of f for the conditions [CuP] = 1×10^{-2} mol kg^{-1} and [CuP]/[T] = 2 amounts to 0.7, which exceeds by a factor greater than two the corresponding value of f obtained for CuP without an amine additive.

An inhibition mechanism has been proposed, in which the amine occupies a free site in the coordination sphere of the ion after the phosphite has been "converted" in the kinetic oxidation chain termination steps into phosphate incapable of coordination; the secondary complexes formed actively decompose the polymeric hydroperoxide to products which do not participate in the polymer oxidation chain propagation reactions. The mechanism has been confirmed kinetically and by analysing the reaction products[77].

3. The Functions of Organophosphorus Compounds in Polymer Systems Containing Phenolic Antioxidants

The effective stabilisation of polymers under the conditions of the development and branching of degradative processes is observed when phosphites are used also in combination with other additives, in the first place[84-86] polymer oxidation inhibitors (phenolic antioxidants). By binding the $RO_2^{\cdot}$ radicals, the latter suppress the spontaneous oxidation reactions of phosphites and thereby enhance the functions of phosphites as inhibitors of non-chain oxidation processes and colour stabilisers.

Not only phosphites[85,86] but also diarylphosphorous and diarylphosphorodithious acids[53] exhibit a high effectiveness with mixtures of phenolic antioxidants. The stabilising effect of the organophosphorus compounds then obtains primarily as a result of the decomposition by the latter of the hydroperoxides ROOH as well as other reactive molecular polymer decomposition products which have accumulated in the polymer undergoing oxidation. The synergistic effect (determined from the colour stability index) in the presence of binary mixtures of phosphites and phenolic antioxidants is characterised by a prolonged retention of the initial colour by such polymer systems and is due to the ability of the phosphites to decompose the chromophores formed as a result of the reactions of phenols and the associated admixtures, in particular of coordination-unsaturated metal ions[86-89].

It has been shown that a characteristic feature of the phosphites[90-92] and phenolic antioxidants[93-96] is the formation of coloured complexes with vanadium, titanium, etc. chlorides (modelling the components of the catalytic polymerisation systems), which are the cause of the appearance of colour in high-density polyethylene immediately after the introduction of phosphite and phenolic stabilisers (inert medium).

In the presence of phosphites, the colour stabilisation effect under the conditions of atmospheric ageing is due to the high rate of the subsequent inner-sphere hydrolysis of the phosphite coordinated to the metal (K_{hydr} = 10 s^{-1}), which leads to the formation of colourless products.

The effectiveness of the colour stabilisation is determined mainly by the competition between the phosphites and phenolic antioxidants in the formation of complexes with variable valence metals[91]. Thus chemical equilibrium is established in the ternary phosphite–bisphenol–metal chloride system (subject to the condition of similar stability constants of the phenolic and phosphite metal complexes) at comparable concentrations of the phosphite and bisphenol; the equilibrium shifts towards the formation of the phosphite complex in the presence of an excess of the phosphite:

$$VOCl_3 + L' \rightleftarrows VOCl_3 \cdot L' \rightleftarrows VOCl_3 \cdot L'' + L'$$

where L′ is the bisphenol and L″ the phosphite. A similar complex is formed after the introduction of an excess of the phosphite (2-ethylhexyl phosphite) into a hydrocarbon solution of the phenol [2,2′-methylenebis(6-t-butyl-4-methyl phenol)] complex of $VOCl_3$; the infrared spectra of the reaction mixture show an intense band in the region of the absorption of the hydroxy-group.

Analogous features of the behaviour of phosphites are observed also in a polymer system. Thus the effectiveness of the colour-stabilising action of phosphites in relation to high-density polyethylene depends on the stability of the phenolic metal complexes; when the stability constant of the complex of 2,2′-methylenebis(6-t-butyl-4-methylphenol) and $VOCl_3$ is $K_{st} = 8.7 \times 10^4$ litre mol^{-1}, an excess of the phosphite relative to the phenol concentration is necessary (by a factor of 3–7); for the higher stability constant $K_{st} = 3.5 \times 10^6$ litre mol^{-1} of the complex of 2,2-thiobis-(4-methyl-2-methylbenzylphenol) and $VOCl_3$, the required phosphite concentration increases by a factor of 5–10.

The greatest effectiveness in neutralising the action of coordination-unsaturated metals is to be expected for the sterically unhindered esters of the type of $(ArO)_3P$, $(ArO)_2$.POR, and $(RO)_3P$, etc. in conformity with the formation constants of their complexes with polyvalent metal ions.

A practical rule has been formulated on the basis of the results obtained: for the effective stabilisation of the colour of polymers containing coordination-unsaturated metal ions by vinary organic phosphite—phenolic antioxidant mixtures, it is desirable to introduce the components consecutively: the phosphite is introduced intitially and then the phenolic additive[97].

On the other hand, the chromophoric products of the oxidation of phenolic antioxidants, mainly quinonoid compounds, play a significant role in the appearance of a colour in the stabilisation polymers by phenols[91]. In this case the introduction of organic phosphites also leads to the elimination of colour from the polymer, which is associated with the conversion of the coloured quinonoid compounds into colourless benzene structures.

The reactivity of phosphites in relation to quinones decreases on passing from aliphatic phosphites of the type $(RO)_3P$ (E_a = 22–29 kJ mol^{-1}) to mixed alkyl aryl phosphites $(RO)_2POAr$ and $ROP(OAr)_2$ (E_a = 34–42 kJ mol^{-1}) and further to aromatic phosphites $(ArO)_3P$ (particularly those with an alkyl substituent in the ring)[98].

It is noteworthy that organic phosphites which hardly interact with quinones in model liquid-phase reactions are incapable of weakening appreciably the intensity of the colour of polyolefins even when present in a fourfold excess relative to the concentration of the product of the oxidation of the phenolic antioxidant in the polymer.

Thus new reactions of phosphites, involved in the stabilisation of the colour of complex polymer systems, have been discovered; they involve the chemical binding of the admixtures and the reaction products of the additives introduced. The observed features make it possible to recommend phosphites as synergistic additives for the enhancement of a specific functional activity in devising effective compositions, containing phenolic antioxidants, which do not become coloured.

4. The Stabilising Effects of Phosphite–Phosphite Systems

On the basis of the classification of phosphites in terms of their functional activity under the conditions of the development and branching of degradative processes in polymers, new types of synergistic mixtures have been proposed which make it possible to achieve the effective stabilisation of polymers[99,100]. These mixtures contain phosphites with different types of activity: an inhibitor of radical processes (a sterically hindered aromatic phosphite) and an acceptor of molecular polymer reaction products (aliphatic and mixed alkyl aryl phosphites).

In particular, mixtures of polyphosphite (I), 2,6-di-t-butyl-4-methylphenyl *o*-phenylene phosphite (VII) and 2,2-methylenebis(6-t-butyl-4-methylphenyl) naphthyl phosphite (VIII) with trinaphthyl phosphite proved effective for polyolefins. The mechanism of the stabilising action under these conditions can be explained by the fact that one of the phosphites, for example compound (I), (VII), or (VIII), for which the oxidation chain termination pathway is dominant, accepts the $RO_2^{\cdot}$ radicals, while the other, for example, trinaphthyl phosphite prevents degenerate branching by decomposing hydroperoxides.

This has been demonstrated kinetically by the displacement of the critical concentrations of the corresponding phosphites (free-radical inhibitors) towards lower values in the presence of trinaphthyl phosphite under the conditions of the inhibited oxidation of low-density polyethylene (473 K, 250 mmHg).

The finding that the replacement of trinaphthyl phosphite by dilauryl thiodipropionate (a typical hydroperoxide decomposing agent) and correspondingly of the polyphosphite (I) by 2,2'-methylenebis(6-t-butyl-4-methylphenol) (a typical inhibitor) leads to analogous results conserve as confirmation of the above mechanism. It is of interest that, when a number of phosphite inhibitors are used in compositions with powerful phenolic inhibitors, a synergistic effect is also observed[100]. This shows that, together with the termination of kinetic oxidation chains, such phosphites can also suppress degenerate branching. A particular tendency in their stabilising behaviour is determined by the competitive strength of the compound with synergistic activity.

Thus the elucidation of the complete phenomenological picture of the mechanism of the action of organophosphorus stabilisers, i.e. of the fundamental decisive pathways leading to the stabilisation of polymers by phosphites and systems based on them, permits a well-founded prediction of the structures of phosphites and their compositions most effective as inhibitors of chain initiation and propagation in the ageing process and as colour stabilisers for polymers and of the pathways leading to the enhancement of the key functions of phosphites as stabilisers.

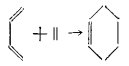
The Reactivity of Addends in the Diene Synthesis Reaction

A.I.Konovalov



The principal electronic factors determining the reactivity of addends in the diene synthesis reaction are considered. The applicability of the model taking into account both the donor-acceptor properties of the reactants and their relative stabilities with respect to the reaction described by delocalisation energies or reaction enthalpies is demonstrated. The unusual influence of the donor-acceptor interactions between the addends on their selectivity in the Diels-Alder reaction is also demonstrated and the qualitative differences between the effects of the pair interactions of the antisymmetric and symmetrical frontier orbitals are noted.
The bibliography includes 103 references.

I. INTRODUCTION

The diene synthesis reaction (the diene condensation or the Diels–Alder reaction) occupies one of the most important places in modern organic chemistry, constituting a simple and easy method for the synthesis of a wide variety of carbocyclic and heterocyclic systems containing a six-membered fragment:

The range of transformations embraced by the Diels–Alder condensation involves compounds of various types, starting with the simplest olefins and extending up to complex steroid systems[1].

The Diels–Alder reaction is of considerable theoretical interest. The study of its mechanism has been a long process, reflecting the evolution of theoretical views and experimental approaches in organic chemistry. The advances in the understanding of the mechanism of this reaction have been frequently described in reviews devoted to its various aspects[2].

The knowledge of the factors which determine the reactivity of the addends involved in the cycloaddition has played an important role. The study of the Diels–Alder reaction on the basis of non-empirical[3] and semi-empirical[4] quantum-chemical calculations of the potential surfaces of the reactions does not lead at present to unambiguous results[5] and does not permit broad generalisations based on the extensive experimental data obtained in the study of the reactivities of addends of various types. At the same time the approaches employing model ideas, based on the theory of frontier molecular orbitals[6] and on the concept of localisation[7] and permitting the employment of the experimental characteristics of the reactants and reactions for analysis, have already led to the understanding of many features, sometimes unexpected, which control the interaction of the components of the diene condensation. The present review is devoted to the consideration of the results obtained in this field.

II. THE FRONTIER-ORBITAL APPROACH TO THE PROBLEM OF THE REACTIVITY OF ADDENDS

The Diels–Alder reaction, accompanied by a significant loss of degrees of freedom, is characterised by an appreciable decrease of the entropy of the system. As a rule the entropy of reaction is between −30 and −40 e.u.,[8] which implies that the real processes can be only exothermic. Indeed, even for $\Delta H_0 = 0$ (a thermally neutral process), let alone processes with $\Delta H_0 > 0$, the equilibrium constants cannot exceed 10^{-6} for the entropies indicated[9], which corresponds to a virtually complete shift of the equilibrium towards the starting materials. In conformity with Hammond's postulate[10], the transition state in such real diene condensations should be relatively "early" and should be characterised by a low degree of formation of new bonds. Furthermore, diene synthesis is a reaction of components with relatively similar energies of the interacting orbitals. The set of factors indicated not only permits the classification of this reaction as "frontier-orbital-controlled"[11] but also makes it possible to understand why the theory of frontier molecular orbitals can be applied to the reactivity of the addends in its simplest form, developed by a number of investigators[12,13].

According to the approach investigated, a measure of the relative reactivity of a diene–dienophile system is the stabilisation energy of the transition state (ΔE_{st}) determined by the interaction of the highest occupied and the lowest unoccupied molecular orbitals (HOMO and LUMO) of the reacting species:

$$\Delta E_{st} = \Delta E^{\text{LUMO dienophile}}_{\text{HOMO diene}} + \Delta E^{\text{LUMO diene}}_{\text{HOMO dienophile}}, \quad (1)$$

$$\Delta E_{st} \cong K[1/(\epsilon_{\text{HOMO diene}} - \epsilon_{\text{LUMO dienophile}}) + 1/(\epsilon_{\text{HOMO dienophile}} - \epsilon_{\text{LUMO diene}})]. \quad (2)$$

According to Eqn.(2),[13] the quantity ΔE_{st} and hence the relative reactivity of the addends ($\lg k \propto \Delta E_{st}$) depend on the difference between the energies ε of the interacting orbitals. The smaller this difference, the higher the reactivity.

Depending on the different relative dispositions of the interacting orbitals of the diene and dienophile, determined by the structure of the addends, there is a possibility of various types of diene synthesis reactions[14] (Fig. 1). The case where the stabilisation energy is determined mainly by the interaction between the HOMO of the diene and the LUMO of the dienophile (the term $\Delta E^{\text{LUMO dienophile}}_{\text{HOMO diene}}$) because $(\varepsilon_{\text{HOMO diene}} - \varepsilon_{\text{LUMO dienophile}}) < (\varepsilon_{\text{HOMO dienophile}} - \varepsilon_{\text{LUMO diene}})$ corresponds to the "diene (donor) - dienophile (acceptor)" reaction type. An increase of the reactivity of the system following the introduction of electron-donating substituents into the diene and of electron-accepting substituents into the dienophile is characteristic of reactions of this type in conformity with the influence which these substituents exert on the change of the energies of the orbitals.

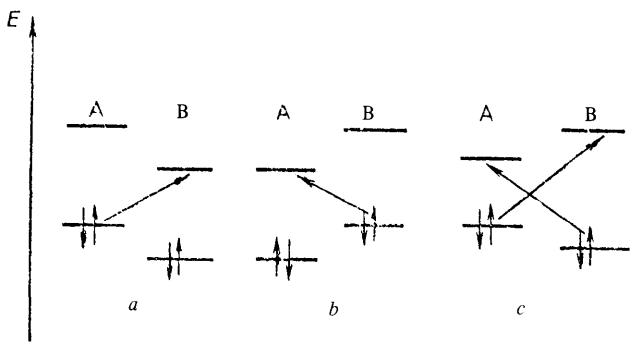

Figure 1. Schematic representation of the relative positions of the frontier orbitals of the addends in the diene synthesis reaction in condensations of the "diene (donor)–dienophile (acceptor)" type (*a*), the "diene (acceptor)–dienophile (donor)" type (*b*), and the "neutral" type (*c*); A = diene; B = dienophile.

Reactions of the "diene (acceptor)–dienophile (donor)" type are characterised by a different relative disposition of the orbitals in the diene and dienophile. In this case the interaction between the HOMO of the dienophile and the LUMO of the diene is decisive because $(\varepsilon_{\text{HOMO diene}} - \varepsilon_{\text{LUMO dienophile}}) > (\varepsilon_{\text{HOMO dienophile}} - \varepsilon_{\text{LUMO diene}})$. Reaction systems of this type are distinguished by an increase of reactivity following the introduction of electron-accepting substituents into the diene and of electron-donating substituents into the dienophile.

Reactions of these two types were known previously. Thus a theoretical interpretation based on the allowance for the intermolecular donor–acceptor interactions has been achieved for these reactions. However, analysis of the probable situations had led to the conclusion[14] that there is a possibility of the existence of yet another, unknown at the time, type of reaction, called the "neutral" type, where the energies of the pair interactions are comparable: $(\varepsilon_{\text{HOMO diene}} - \varepsilon_{\text{LUMO dienophile}}) \cong (\varepsilon_{\text{HOMO dienophile}} - \varepsilon_{\text{LUMO diene}})$, whence $\Delta E^{\text{LUMO dienophile}}_{\text{HOMO diene}} \cong \Delta E^{\text{LUMO diene}}_{\text{HOMO dienophile}}$. An increase of the reactivity of the diene–dienophile system should be expected for reactions of this type after the introduction of both electron-donating and electron-accepting substituents into either addend. Subsequent investigations demonstrated the actual existence of reactions of this type (see Section V).

III. REACTIONS OF THE "DIENE (DONOR)–DIENOPHILE (ACCEPTOR)" TYPE

The majority of reactions investigated at the present time belong to this type and one of the first conclusions concerning the electronic nature of the interacting components of diene condensations was that the diene must be an electron donor and the dienophile an electron acceptor[15]. The change in the reactivity of the system as the electronic character of the reactants is altered is consistent with the model considered above.

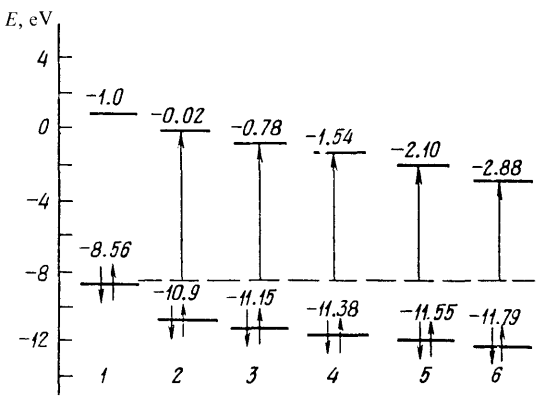

Figure 2. The relative positions of the frontier orbitals of cyclopentadiene (1) and cyanoethylenes: 2) acrylonitrile; 3) maleodinitrile and fumarodinitrile; 4) 1,1-dicyanoethylene; 5) tricyanoethylene; 6) tetracyanoethylene.

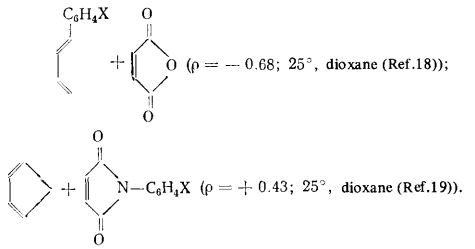

Table 1. The reactivities (k_2, litre mol^{-1} s^{-1}) of cyanoethylenes in the Diels–Alder reactions with cyclopentadiene, 9,10-dimethylanthracene (in dioxane at 20 °C),[13] and 1,3-diphenylisobenzofuran (in dichloroethane at 30 °C).[16]

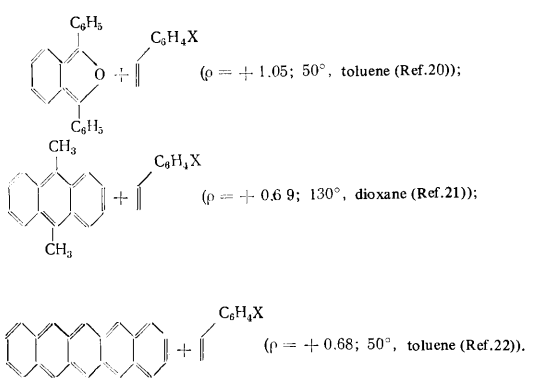
Dienophile	Cyclopentadiene	9,10-Dimethylanthracene	1,3-Diphenylisobenzofuran
Tetracyanoethylene	480	$1.3\cdot10^{4}$	10^{8}
Tricyanoethylene	4.83	5.88	10^{4}
1,1-Dicyanoethylene	$4.55\cdot10^{-1}$	$1.27\cdot10^{-1}$	$1\cdot10^{3}$
Maleodinitrile	$9.1\cdot10^{-4}$	$1.31\cdot10^{-4}$	1.3
Fumarodinitrile	$8.1\cdot10^{-4}$	$1.39\cdot10^{-4}$	$3.1\cdot10^{-1}$
Acrylonitrile	$1.04\cdot10^{-5}$	$8.9\cdot10^{-7}$	$3.0\cdot10^{-3}$

An example may be provided by the reactions of cyanoethylenes with electron-donating dienes. Table 1 illustrates the influence of the number of CN groups in the dienophile on the reactivity of the system. Fig. 2 illustrates the ratio of the energies of the frontier orbitals of cyclopentadiene and cyanoethylenes[17]. Evidently $(\varepsilon_{\text{HOMO diene}} - \varepsilon_{\text{LUMO dienophile}}) < (\varepsilon_{\text{HOMO dienophile}} - \varepsilon_{\text{LUMO diene}})$. As the cyano-groups



accumulate, the energy gap between the HOMO of cyclopentadiene and the LUMO of cyanoethylene diminishes and the reactivity increases. Thus the reactivity of the dienophile increases with increase of its electron-accepting character (its electron affinity).

The energies of the orbitals change analogously, but on a smaller scale, under the influence of substituents in the aromatic ring of the diene or the dienophile. In this case reactions of the "diene (donor)–dienophile (acceptor)" type should be characterised by reaction constants $\rho > 0$ when the substituents in the dienophile are varied and $\rho < 0$ when the substituents in the diene are varied. This type of phenomenon does indeed occur, for example, in the reactions of arylbutadienes with maleic anhydride and of cyclopentadiene with *N*-arylmaleimides:

In conformity with this, the sign of the reaction constants indicates a specific type of reaction and its low absolute value points to a synchronous reaction mechanism. Correlation data are now available for more than 10 reaction series of the "diene (donor) - dienophile (acceptor)" type and some of them have been listed[2].

It is of interest to examine reactions with participation of styrenes as dienophiles. These compounds provide a kind of test for the type of reaction, determined by the electronic character of the diene. Data concerning reactions involving certain electron-donating dienes are presented below:

In the last case an estimate of the frontier orbital energies shows (Fig.3*a* presents data concerning pentacene and unsubstituted styrene) that the system should be close to the "neutral type" if not actually of this type (the study was performed in order to detect "neutral" reactions). Nevertheless, a reaction of the "diene (donor)–dienophile (acceptor)" is observed. The possible causes of this phenomenon will be discussed below.

It is noteworthy that the influence of the substituents in the diene is described by the electrophilic constants σ^+; the influence of substituents in the dienophiles containing, apart from these substituents, other groups capable of direct polar conjugation with the +C reaction centre, is described by the Hammett constants σ, while the influence of substituents in styrenes is described by the nucleophilic constants σ^-.

Not all the reaction series obey rigorously the correlations (Table 2) but here too a tendency towards an increase of the reactivity of the system was observed as the electron-donating properties of the diene and the electron-accepting properties of the dienophile are enhanced.

Table 2. The reactivities (k_2, litre mol^{-1} s^{-1}) of acenes in the diene synthesis reactions with *N*-(X-phenyl)maleimides in toluene at 60 °C,[23,24] the ionisation potentials (I_D) of the acenes, and the electron affinities (E_A) of the dienophiles[23,24].

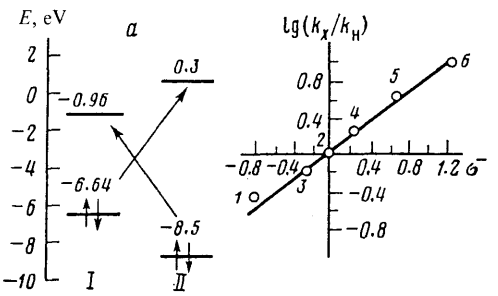
The reactivities (k_2, litre mol^{-1} s^{-1}) of substituted butadienes in the Diels–Alder reactions with maleic anhydride (dioxane, 30 °C), tetracyanoethylene (dioxane, 20 °C), and 4-phenyl-1,2,4-triazoline-3,5-dione (benzene, 25 °C) [26,27] and the ionisation potentials (I_D) of the dienes.

Diene	I_D, eV	PTAD	MA	ТЦЭ
2,3-Dimethylbuta-1,3-diene	8.76	183	$3.36\cdot10^{-4}$	$2.43\cdot10^{-1}$
trans-1-Phenylbuta-1,3-diene	8.16	63	$1.12\cdot10^{-4}$	$6.68\cdot10^{-2}$
2-Methylbuta-1,3-diene	9.04	46	$1.54\cdot10^{-4}$	$1.13\cdot10^{-2}$
Buta-1,3-diene	9.07	6.9	$6.83\cdot10^{-5}$	$5.19\cdot10^{-3}$
trans,trans-1,4-Diphenylbutadiene	7.54	5.1	$2.96\cdot10^{-6}$	$8.4\cdot10^{-3}$



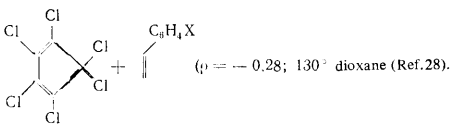


Figure 3. *a*) The relative positions of the frontier orbitals of pentacene (I) and styrene (II); *b*) dependence of the relative reactivities of styrenes [$\lg(k_X/k_H)$] in the diene synthesis reaction with pentacene on the nucleophilic constants of the substituents (toluene, 60 °C). Substituents X in styrenes: 1) *p*-$(CH_3)_2N$; 2) H; 3) *p*-CH_3O; 4) *p*-Br; 5) *m*-NO_2; 6) *p*-NO_2; $\rho = 0.685$; $r = 0.992$.

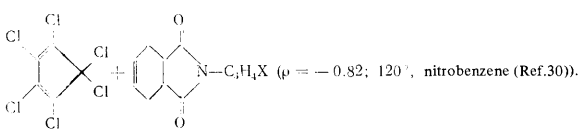
Finally, one should point out the existence of reaction series in which the variation of the reactivity of the system for a series of related compounds is inconsistent with the variation of the electronic character of the reactant, although there is no doubt about the assignment to a particular type

of reaction [in the given instance to the "diene (donor)–dienophile (acceptor)" type]. Table 3 presents data referring to the reactions of a series of butadienes with tetracyanoethylene (TCE), maleic anhydride (MA), and 4-phenyl-1,2,4-triazoline-3,5-dione (PTAD). Evidently phenylated butadienes have a reduced reactivity compared with that expected on the basis of their electron-donating properties. The reactivity series of substituted butadienes are found to be different in reactions with different dienophiles. The possible causes of this phenomenon will be examined below (in Section VII).

IV. REACTIONS OF THE "DIENE (ACCEPTOR)–DIENOPHILE (DONOR)" TYPE



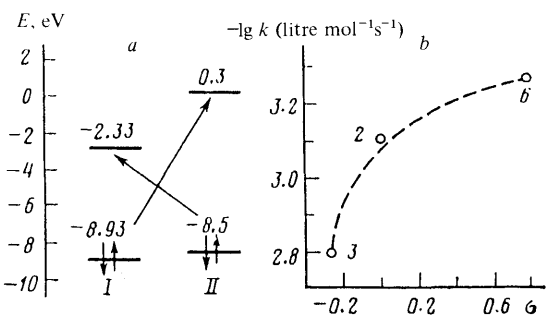
The existence of reactions of this type was first demonstrated as a result of a kinetic study of the reactions of hexachlorocyclopentadiene with styrenes:

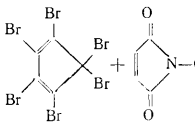
($\rho = -0.28$; 130° dioxane (Ref.28).

A conclusion concerning the type of reaction was reached on the basis of the sign of the reaction constant. Examination of the ratio of the energies of the frontier orbitals (Fig.4) confirms that this conclusion is well founded. The stabilisation of the transition state in the given system is due to the preferential interaction of the HOMO of the dienophile with the LUMO of the diene.

Hexachlorocyclopentadiene reacts as an electron-accepting diene also with dienophiles such as the *N*-arylimides of *cis*-4-cyclohexene-1,2-dicarboxylic acid and *N*-arylimides of *endo*- and *exo*-bicyclo[2.2.1]heptene-2,3-dicarboxylic acid[29,30], for example:

($\rho = -0.82$; 120°, nitrobenzene (Ref.30)).





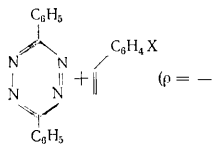


Figure 4. *a*) The relative positions of the frontier orbitals of hexachlorocyclopentadiene (I) and styrene (II); *b*) dependence of the reactivities of styrenes ($\lg k$) in the diene synthesis reaction with hexachlorocyclopentadiene on the Hammett σ constants (dioxane, 130 °C). The numbers of the styrenes correspond to the numbers of the compounds in Fig.3*b*.

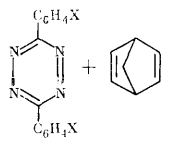
It is of interest that the reactions of hexabromocyclopentadiene are of the "diene (acceptor)–dienophile (donor)" type even with electron-accepting dienophiles such as *N*-arylmaleimides:



($\rho = -0.28$; 80°, benzene (Ref.31)).

Substituted tetrazines also behave as electron-accepting dienes. The influence of substituents in both the diene and the dienophile has been traced in relation to these compounds:

($\rho = -0.59$; 120°, nitrobenzene (Ref.2));

($\rho = +1.25$; 30°, dioxane (Ref.2)).

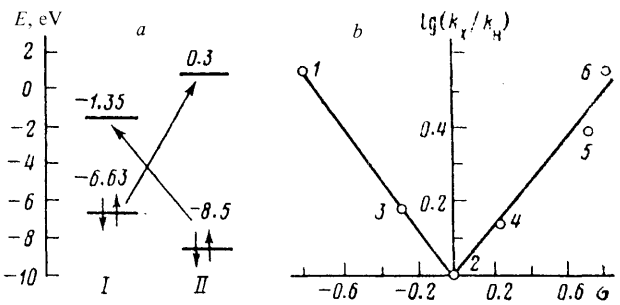


Figure 5. *a*) The relative positions of the frontier orbitals of 6,13-dichloropentacene (I) and styrene (II); *b*) dependence of the relative reactivities of styrenes in the diene synthesis reaction with 6,13-dichloropentacene on the Hammett σ constants (toluene, 50 °C). The numbers of the styrenes correspond to the numbers of the compounds in Fig.3*b*.

V. REACTIONS OF THE "NEUTRAL" TYPE

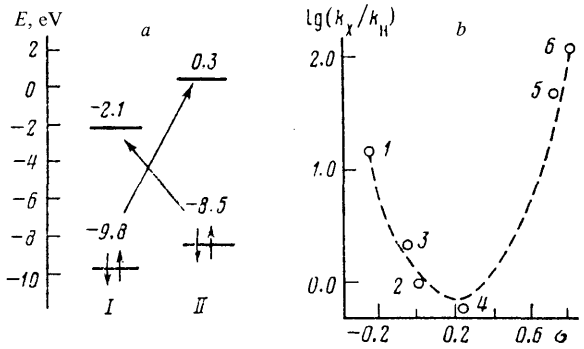
The experimental evidence for the occurrence of reactions of the "neutral" type was first obtained in the study of the interaction of cyclones (phencyclone, tetracyclone, and acecyclone) with styrenes and arylacetylenes[32–35]. According to Sustmann[14], when the arrangement of the frontier orbitals in the addends is nearly symmetrical (the neutrality condition), both electron-donating and electron-accepting substituents increase ΔE_{st} and hence should increase the reactivity of the system; thus the dependence of $\lg k$ on the σ constants of the substituents should be U-shaped. However, for a symmetrical disposition of the frontier orbitals, the differences between the energies of the HOMO and LUMO of the addends may be large and the reactivity of the system is therefore small. For this reason, the closeness of the orbitals in one of the addends must be adopted as the condition for

the occurrence of such reactions (the condition for reactivity). It is more likely that the levels are close to one another in dienes, which are usually more conjugated. Cyclones, which are intensely coloured, satisfy this condition. The "neutral" character of the reactions of cyclones with styrenes has been confirmed in recent studies[36].

The dienes which react with styrenes via a "neutral" mechanism proved to be also 6,13-dichloropentacene, 5,11-dichlorotetracene, and tetrachloro- and tetrabromo-*o*-quinones[25,37,38].

From data for the orbital characteristics of the reactants, it was initially postulated that, among polynuclear hydrocarbons, the diene capable of undergoing "neutral" reactions with styrenes may be pentacene. However, it was found that in this instance a reaction of the "diene (donor)–dienophile (acceptor)" type takes place (see Section III). After the introduction of chlorine atoms in the *meso*-positions (6,13-positions), i.e. after imparting electron-accepting properties to the diene, the "neutral" type of reaction can be observed (Fig.5).

Fig.6*a* presents estimates of the energies of the tetrachloro-*o*-quinone–styrene orbital system, which show that in this case the diene should be an electron acceptor relative to the dienophile; therefore, in formulating these experiments, reactions of the "diene (acceptor)–dienophile (donor)" type were expected. However, it was found that in this case reactions of the "neutral" type actually occur with inversion at the halogen as the substituent in the styrene molecule (Fig.6*b*).



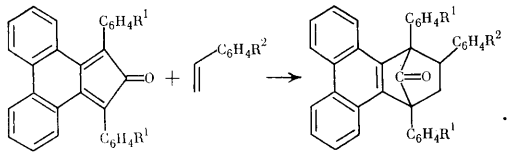


Figure 6. *a*) The relative positions of the frontier orbitals of tetrachloro-*o*-benzoquinone (I) and styrene (II); *b*) dependence of the relative reactivities of styrenes [lg (k_X/k_H)] in the diene synthesis reaction with tetrachloro-*o*-benzoquinone on the Hammett σ constants (dichloroethane, 30 °C). Substituents X in styrenes: 1) *p*-CH_3O; 2) H; 3) *m*-CH_3; 4) *p*-Cl; 5) *m*-NO_2; 6) *p*-NO_2.

A characteristic feature of all the reactions of the "neutral" type investigated is that the diene in these substances is to some extent an electron acceptor relative to the dienophile.

There exist data clearly demonstrating the possibility of transitions between the various types of reactions. Such transitions can be observed within narrow cross reaction series and more effectively when there is a sharp change in the electronic character of the reactants. An example of a transition of the first kind is provided by the change in the reactivity of substituted phencyclones in the Diels–Alder reactions with styrenes[39] (Table 4):

The variation of the reactivity of styrenes in reactions with various cyclones (Table 4) corresponds in all cases to the "neutral" type of reaction, but, on passing from the phencyclone containing the electron-accepting *p*-NO_2 substituents to the phencyclone with electron-donating *p*-CH_3O substituents, the reactivity of styrenes with electron-donating substituents diminishes and that of styrenes with electron-accepting substituents increases with inversion in the region of *p*-bromostyrene.

Table 4. The reactivities (10^3 k_2, litre mol^{-1} s^{-1}) of substituted phencyclones in the Diels–Alder reactions with styrenes (toluene, 40 °C).[39]

R^2	R^1					ρ
	p-NO_2	*p*-Cl	H	*p*-CH_3	*p*-CH_3O	
p-NO_2	6.12	11.7	18.2	22.0	23.2	−0.575
m-NO_2	4.52	7.00	7.90	11.2	9.30	−0.342
p-Br	8.15	8.70	7.50	9.45	7.40	0.008

p-$(CH_3)_2N$	710	112	74.8	45.5	54.8	1.124

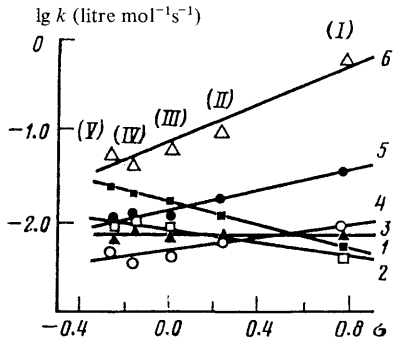

Figure 7. Dependence of the reactivities of the substituted phencyclones (I)–(V) in the diene synthesis reaction with styrenes (lines *1*–*6*) on the Hammett σ constants (toluene, 40 °C). Substituents R^1 in phencyclones: I) *p*-NO_2; II) *p*-Cl; III) H; IV) *p*-CH_3; V) *p*-CH_3O. Substituents R^2 in styrenes: 1) *p*-NO_2; 2) *m*-NI_2; 3) *p*-Br; 4) H; 5) *p*-CH_3O; 6) *p*-$(CH_3)_2N$.

The reactivity of cyclones varies somewhat differently in reactions with different styrenes (Table 4 and Fig.7). The reactions of cyclones with *p*-nitrostyrene are of the "diene (donor)–dienophile (acceptor)" type and the type of reactions remains unchanged but the reactivity and selectivity of the

reactants diminish. The reactions with *p*-bromostyrene are almost insensitive to the influence of the substituents in cyclones[13,14]. The reactions with unsubstituted styrene, *p*-methoxystyrene, and *p*-dimethylaminostyrene are of the "diene (acceptor)–dienophile (donor)" type. In the series of styrenes considered there is an increase of not only the reactivity but also of the selectivity of the reactants. As it were, "macroneutrality" is obtained, i.e. a transition from reactions of one type to another in a number of reaction series, in contrast to the "microneutrality" observed within the limits of a single reaction series.

A transition from reactions of one type to another has also been demonstrated for wider variations of dienes and dienophiles. The change in the type of reaction after the introduction of halogen atoms into the pentacene molecule has already been demonstrated (see Sections III and V); other examples also exist. Thus the reactions of indanocyclones, which have more pronounced electron-accepting properties than phencyclones, tetracyclones, and acecyclones, with styrenes are of the "diene (acceptor)–dienophile (donor)" type[40]; on the other hand, the reactions of cyclones with *N*-arylmaleimides and maleic anhydride–dienophiles with more pronounced electron-accepting properties than styrenes—are of the "diene (donor)–dienophile (acceptor)" type[41,42]. Reactions of an analogous type are observed in systems comprising phencylone and vinyl and isopropenyl dienophiles with electron-accepting substituents[43]. Hexabromocyclopentadiene (Section IV) and tetrabromo-5,5-dimethoxycyclopentadiene react with *N*-arylmaleimides in different ways. In the latter case the reaction of the "diene (donor)–dienophile (acceptor)" type is observed[31].

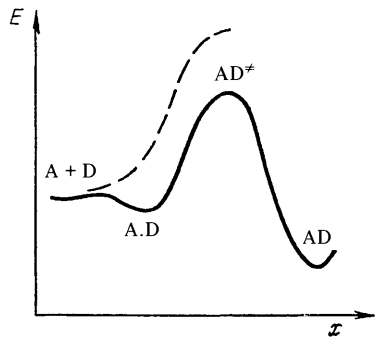

Figure 8. Schematic representation of the energy profile of the diene synthesis reaction proceeding via a charge-transfer complex stage; x = reaction coordinate.

Thus the above discussion demonstrates the applicability of the model based on the frontier-orbital aproach and indicates a significant influence of intermolecular orbital donor–acceptor interactions on the reactivity of diene–dienophile systems.

It is noteworthy that the donor–acceptor interactions between the addends involved in the diene synthesis have already attracted the attention of investigators for a long time. One of the signs of such interactions is the formation of complexes between the diene and the dienophile[44–49], which should be classified as charge-transfer complexes of the π,π-type according to the existing views[50].

The existing data for the relation between the donor–acceptor properties of the addends and the stability of the complexes which they form and the reactivity[51–53], data for the influence of solvents on the diene synthesis and complex formation[54–57], and the characteristic features of the kinetics of certain reactions with a negative temperature coefficient[58] permitted the conclusion that the charge-transfer complexes (CTC) formed between the addends arise in the course of the diene synthesis and are thus prereaction complexes[59]. Donor–acceptor interactions lead to the stabilisation of the system and to a decrease of the potential energy over the entire initial reaction pathway, including the prereaction stage (Fig.8). In this sense the CTC between the addends are prereaction complexes not only as regards their position in the chain of transformations but also as regards their physical nature, while the donor–acceptor interactions are one of the factors determining the reactivity of the system[60]. The formation of the CTC and their characteristics can serve as an indication of the manifestation and intensity of donor–acceptor interactions. According to Markov[61], the elucidation of the role of the CTC is an experimental prerequisite of the application of theoretical approaches based on the consideration of intermolecular orbital donor–acceptor interactions.

One should note that the following scheme is usually postulated for the energy profile of the reaction involving the formation of CTC during diene synthesis:

$$A + D \overset{K}{\rightleftarrows} A.D \overset{k_1}{\rightarrow} AD,$$

where A and D are the free addends (the acceptor and the donor), A.D is the complex, and AD is the adduct. This scheme presupposes that the adduct is formed only from the CTC and that the rate of reaction is proportional to its concentration [A.D]:

$$w = k_1[A \cdot D] = Kk_1[A] \cdot [D]. \qquad (3)$$

According to this scheme and Eqn.(3), on passing from systems forming complexes to those where complexes are not produced, the possibility of the reaction is eliminated ($k_{exp} = Kk_1 \to 0$, since $K \to 0$); however, this conflicts with what is observed in reality.

It is more correct to suppose[59] that in the case of systems with CTC the adduct is formed both from the complex A.D and directly from the free addend A and D. The reaction complex, following the same energy profile of the reaction, then proceeds via the CTC state but without a kinetically independent species being detected.

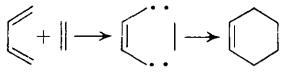
Overall we have a scheme according to which the addends in the initial state are divided, in accordance with the equilibrium constant, into bound (A.D.) and free (A and D). The adduct is formed from both[15,16]:

$$\begin{array}{ccccc} A + D & \overset{K}{\rightleftarrows} & A.D & \overset{k_1}{\rightarrow} & AD \\ \uparrow & & & & \uparrow \\ \multicolumn{5}{c}{\underline{\qquad\qquad k_2 \qquad\qquad}} \end{array}$$

The rate of the process is then described by the expression

$$w = k_1[A.D] + k_2[A][D] = (Kk_1 + k_2)[A][D]$$

and the quantity



$$k_{exp} = (Kk_1 + k_2) \to k_2 \text{ when } K \to 0$$

corresponds to the transition to systems without CTC mentioned above.

VI. DELOCALISATION ENERGIES. THERMOCHEMISTRY OF THE REACTIONS

The formation of the cycloadduct entails changes in the initial π-electron systems of the diene and dienophile, which correspond to the localisation of two π electrons in the 1,4-positions in the diene and two π electrons in the 1,2-positions

in the dienophile. The corresponding changes in the π-electron energy can be regarded as the 1,4-delocalisation (for the diene) and 1,2-delocalisation (for the dienophile) energies[7]:

Delocalisation is an endothermic process and the differences between the delocalisation energies of dienes and dienophiles characterises the difference between the stabilities of the reactants due to the delocalisation of the electrons. The concept of delocalisation was introduced by Brown[62] ("para-localisation" for polynuclear hydrocarbons as dienes) as the index of the reactivity of these compounds in diene synthesis on the grounds that compounds with a lower delocalisation energy should form more stable (as regards retrodecomposition) adducts, so that these compounds should be more reactive in conformity with the Bell–Evans–Polanyi principle.

The relation between the enthalpy of reaction (stability of the adducts) and the delocalisation energy is illustrated in Fig. 9,[60] according to which the enthalpy of reaction is determined mainly by the delocalisation energies ($L_{1,4}$ and $L_{1,2}$) and also by the energies of formation of new bonds and the energy of rehybridisation in the delocalised states ($E_\sigma + E_S$). If it is assumed that, in a reaction series with the same diene (or dienophile), the 1,4-delocalisation (or 1,2-delocalisation) energy, the energy of formation of new bonds, and the rehybridisation energy are constant, then the differences between the enthalpies of reaction should be determined by the differences between the 1,2-delocalisation (or 1,4-delocalisation) energies. The enthalpy of reaction in a given reaction series can then serve as a measure of the delocalisation energy.

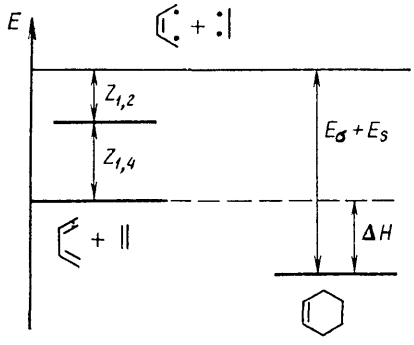


Figure 9. Schematic representation of the relation between the enthalpies of the diene synthesis reaction ΔH and delocalisation energies (for explanation, see text).

Until recently there were almost no literature data for the enthalpies of reaction. They were known for certain reversible reactions because they were determined from the temperature variation of the equilibrium constant[8]. As microcalorimetric methods have developed, the situation has changed, but reliable determinations of such quantities are so far restricted to rapid processes with a very reactive addend as at least one of the components; in particular, tetracyanoethylene and 1,3-diphenylisobenzofuran are used as the dienophile and the diene respectively (Tables 5 and 6).

Table 5. The enthalpies of the reactions[10,64] of various dienes with tetracyanoethylene at 25 °C, the increments in the enthalpies of reaction for the dienes (Δh_{IBF}),[63,64] and the ionisation potentials of the dienes.

Analysis of the existing data[63] shows that the enthalpies of the reactions of substituted anthracenes are satisfactorily correlated with the 1,4-delocalisation energies calculated for these reactions (Fig. 10). An analogous correlation has been observed also in a series of dienophiles, as shown in relation to cyanoethylene[16], the difference between the enthalpies of the reactions of tetracyanoethylene and acrylonitrile (4.5 kcal mol^{-1}) corresponding to the difference between the calculated delocalisation energies (4.4 kcal mol^{-1} [63]). The difference between the enthalpies of the reactions of anthracene and tetracene, amounting to 4.65 kcal mol^{-1}, also agrees with the calculated value of 5.5 kcal mol^{-1}.[7] In addition, correlations have been observed between the enthalpies of reactions involving the same compounds in different reaction series. Fig. 11 illustrates the relation between the enthalpies of the reactions of a series of dienes with tetracyanoethylene and 4-phenyl-1,2,4-triazoline-3,5-dione. The slope of the straight line in Fig. 11 is 1.0. These data show that the difference between the enthalpies of the reactions of dienes depends insignificantly if at all on the nature of the dienophile, i.e. are determined mainly by the properties of the diene. On the

other hand, the enthalpies of the reactions of a single dienophile can also differ from those for another dienophile, regardless of the nature of the diene, the difference being fairly constant. Fig.12 confirms this conclusion for other pairs of reactions. Furthermore, such differences are maintained in reactions of different kinds: for (4 + 2)- and (3 + 2)-cycloaddition or (4 + 2)- and (2 + 2)-cycloaddition[67,68].

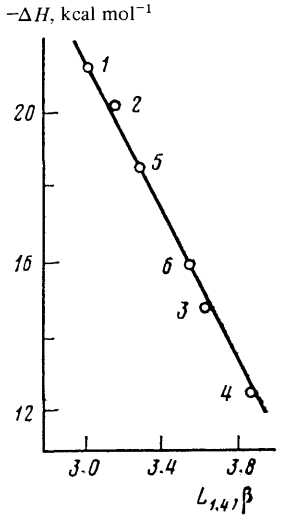

Figure 10. Dependence of the 1,4-localisation energies of substituted anthracene on the enthalpies of the reaction of these dienes with tetracyanoethylene: 1) 9,10-dimethylanthracene; 2) 9-methylanthracene; 3) 9-methoxyanthracene; 4) 9,10-dimethoxyanthracene; 5) anthracene; 6) 9-chloroanthracene; $r = 0.995$.

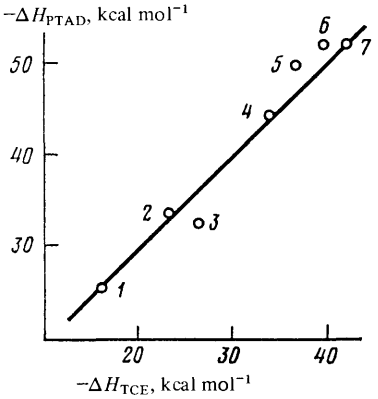

Figure 11. Relation between the enthalpies of the diene synthesis reactions of 4-phenyl-1,2,4-triazoline-3,5-dione (ΔH_{PTAD}) and tetracyanoethylene (ΔH_{TCE}) with various dienes: 1) 1,3-diphenylisobenzofuran; 2) *trans,trans*-1,4-diphenylbuta-2-diene; 3) cyclopentadiene; 4) *trans*-1-phenylbutadiene; 5) butadiene; 6) 2-methylbutadiene; 7) 2,3-dimethylbutadiene.

The results obtained (for a detailed analysis and a broad generalisation, the studies in this field should undoubtedly be continued) already justify the assumption that the differences between the enthalpies of the reactions reflect primarily the difference between the delocalisation energies of the addends, although they also represent an accumulation of other effects, including, for example, the energy of the *s-trans–s-cis* transition in the case of butadienes, etc. This conclusion is important for the understanding of the nature of the phenomenon, bearing in mind the subsequent application of these quantities (Section VII). The "transferability of the differences" makes it possible to estimate the enthalpies of the reactions which cannot be obtained or which have not so far been obtained by direct experimental determinations.

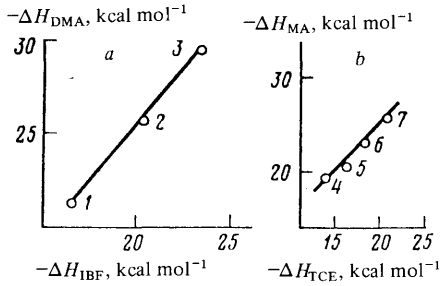

Figure 12. Relations between the enthalpies of the diene synthesis reactions of 9,10-dimethylanthracene (DMA) and 1,3-diphenylisobenzofuran (IBF) with various dienophiles (*a*) and of maleic anhydride (MA) and tetracyanoethylene (TCE) with various dienes (*b*): 1) tetracyanoethylene; 2) maleic anhydride; 3) *N*-phenylmaleimide; 4) 9-methoxyanthracene; 5) 1,3-diphenylisobenzofuran; 6) anthracene; 7) 9,10-dimethylanthracene.

*N-Phenylmaleimide.

For this purpose, at the present stage of the investigation, having adopted the reaction of tetracyanoethylene with 1,3-diphenylisobenzofuran as the standard, we have listed in Tables 5 and 6 the increments in the enthalpies of the reactions of dienes (Δh_{IBF}) and dienophiles (Δh_{TCE}) which represent the differences between the enthalpies of the reaction of the given diene with tetracyanoethylene or of the given dienophile with 1,3-diphenylisobenzofuran and the enthalpy of the standard reaction [between 1,3-diphenylisobenzofuran (IBF) and tetracyanoethylene (TCE)]. These quantities characterise respectively the relative stabilities of the adducts in the series of dienes and dienophiles considered here. The calculated enthalpy of the reaction of a

given diene (A) and a given dienophile (B) is then equal to the sum of their increments and the enthalpy of the reaction between the tetracyanoethylene and isobenzofuran (−16.5 kcal mol^{-1}):

$$\Delta H^{A+B}\ (\text{kcal mol}^{-1}) = \Delta h^{A}_{IBF} + \Delta h^{B}_{TCE} - 16.5.$$

Comparison of the quantities calculated in this way and the experimental values (Table 7) is illustrated in Fig. 13.

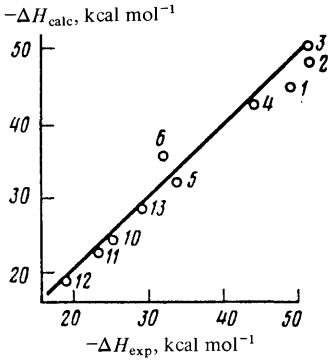

Figure 13. Relation between the experimental (ΔH_{exp}) and calculated (ΔH_{calc}) enthalpies of the diene synthesis reactions; the numbers against the circles correspond to the data in Table 7.

Certain enthalpies of the reactions of dienes, in particular hexachloro- and hexabromo-cyclopentadienes, with tetracyanoethylene have also been estimated from the data obtained. The calculated values are −9.9 and −6.8 kcal mol^{-1} respectively and show that the equilibrium in these reactions should be fully displaced towards the starting materials, i.e. reaction is virtually impossible. This explains the failure of the attempts to obtain the adducts of tetracyanoethylene with the above dienes[69]: it is not the low reactivity of the system but the position of the equilibrium which is responsible for the above phenomenon and, instead of being improved, the situation is actually aggravated by carrying out the reaction at high temperatures. It is indeed known, for example, that the reactions of tetracyanoethylene with 9-chloro-, 9-methoxy-, and 9,10-dimethoxy-anthracenes are reversible[70,71]. In the last instance the equilibrium is almost completely displaced towards the starting materials†. This justifies the assumption that the reactions with $\Delta H \geqslant -15$ kcal mol^{-1} should be reversible while the reactions with $\Delta H \geqslant -12$ kcal mol^{-1} cannot be achieved under the usual conditions.

It is also noteworthy that, according to Tables 6 and 7, in a series of dienophiles belonging to the same reaction series (cyanoethylenes, arylmaleimides, and vinyl and isopropenyl compounds), less stable adducts correspond to more reactive dienophiles in reactions of the "diene (donor)–dienophile (acceptor)" type, in conformity with the hypothesis put forward previously on the basis of model quantum-chemical calculations[60]. This is why the attempts to employ tetracyanoethylene as the competing "displacing" reagent in certain reversible reactions have been unsuccessful[70]. The choice based on the principle of the "reactivity" of the reagent led to an unstable adduct.

† The enthalpy of reaction was determined from data for the retrodecomposition of the adduct by a special method[63].

VII. THE REACTIVITY OF DIENE–DIENOPHILE SYSTEMS

After the qualitative establishment of the fact that the addends in the diene synthesis are of different electronic character, attempts were made to observe correlations between the reactivity of the dienes and dienophiles, on the one hand, and their donor–acceptor characteristics (ionisation potentials and electron affinities), on the other, in order to elucidate the role of the donor–acceptor interactions between the addends reflected in the formation of CTC. It has been shown[16,51,52,60] that such correlations are observed but only within the limits of narrow reaction series. Naturally, the influence of the constant reactant is not then taken into account.

Nevertheless, the model of the interaction of frontier molecular orbitals described in Section II provides a basis for the consideration of the reactivities of diene–dienophile systems with simultaneous allowance for both the electron-donating properties of one addend and the electron-accepting properties of the other. Thus, according to Section II, $\Delta E_{st} \propto$

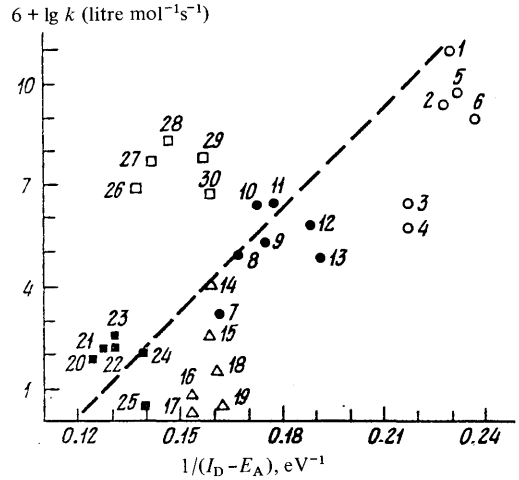

Figure 14. Dependence of the lg k on $1/(I_D - E_A)$ for different diene–dienophile systems. Reactions of tetracyanoethylene with anthracenes: 1) 9,10-dimethylanthracene; 2) 9-methylanthracene; 3) anthracene; 4) 9-chloroanthracene; 5) 9-methoxyanthracene; 6) 9,10-dimethoxyanthracene (dichloroethane, 25 °C [63]). Reactions of tetracyanoethylene with butadienes: 7) buta-1,3-diene; 8) 2-methylbuta-1,3-diene; 9) *trans*-1-methylbuta-1,3-diene; 10) 2,3-dimethylbuta-1,3-diene; 11) 2-methoxybuta-1,3-diene; 12) *trans*-1-phenylbuta-1,3-diene; 13) *trans,trans*-1,4-diphenylbuta-1,3-diene (methylene chloride, 20 °C [74]). Reactions of maleic anhydride with anthracenes: 14) 9,10-dimethylanthracene; 15) 9-methylanthracene; 16) anthracene; 17) 9-chloroanthracene; 18) 9-methoxyanthracene; 19) 9,10-dimethoxyanthracene (dioxane, 30 °C [73]). Reactions of maleic anhydride with butadienes: 20) buta-1,3-diene; 21) 2-methylbuta-1,3-diene; 22) *trans*-1-methylbuta-1,3-diene; 23) 2,3-dimethylbuta-1,3-diene; 24) *trans*-1-phenylbuta-1,3-diene; 25) *trans,trans*-1,3-diphenylbuta-1,3-diene (dioxane, 30 °C [74]). Reactions of 4-phenyl-1,2,4-triazoline-3,5-dione with butadienes; 26) buta-1,3-diene; 27) 2-methylbuta-1,3-diene; 28) 2,3-dimethylbuta-1,3-diene; 29) *trans*-1-phenylbuta-1,3-diene; 30) *trans,trans*-1,4-diphenylbuta-1,3-diene (benzene 25 °C [27]).

$1/(\varepsilon_{\text{HOMO diene}} - \varepsilon_{\text{LUMO dienophile}})$ for reactions of the "diene (donor)–dienophile (acceptor)" type and, since $\lg k \propto \Delta E_{st}$, it follows that $\lg k \propto 1/(\varepsilon_{\text{HOMO diene}} - \varepsilon_{\text{LUMO dienophile}})$; or, using experimental quantities, namely the ionisation potential I of the electron-donating diene and the electron affinity E_A of the electron-accepting dienophile, $\lg k \propto 1/(I_D - E_A)$.[12,17,72] Comparison of the reactivities of certain diene–dienophile systems with the reciprocals of the differences between the ionisation potentials of the dienes and the electron affinities of the dienophiles shows that in this instance the correlations are limited to individual reaction series[17,72,73] or are not observed at all[74].

The set of data referring to different diene–dienophile systems which can be considered from the above standpoint and discussed further is presented in Figs. 14 and 15#. Evidently, although a definite tendency towards an increase of the reactivity of diene–dienophile systems with decrease of the difference between the ionisation potential of the diene and the electron affinity of the dienophile is on the whole observed, there is no satisfactory correspondence between the quantities compared for the entire set of reactions under consideration. Detailed analysis demonstrates the existence of certain trends which can be explained if it is assumed that the reactivities of the addends are determined by the set of factors stabilising (donor–acceptor interactions) and destabilising (delocalisation) the transition state[60]. As already mentioned, the initial diene and dienophile systems undergo changes during the reaction corresponding to the delocalisation of the electrons in the 1,4-positions in the diene and the 1,2-positions in the dienophile and these changes are manifested in the energy of the transition state. In this connection one may note that, according to *ab initio* calculations for the reaction of butadiene with ethylene, its transition state is characterised by a considerable rearrangement of the initial systems and at the same time a low degree of formation of new bonds[3]. "From the standpoint of delocalisation", the reactivity of addends should be smaller the greater the delocalisation energy, i.e. the greater the energy expenditure required on the decomposition of the initial π-electron systems of the diene and dienophile on formation of the transition state and hence the adduct. Examination of the transition state stabilisation effects based on allowance for the donor–acceptor properties of the initial compounds ignores these differences between the addends. They can be taken into account by considering the enthalpies of the reactions of the diene–dienophile pairs which can serve as a measure of the delocalisation energies of the addends (Section VI).

The data in Figs. 14 and 15 are presented on the same scale and are comparable. The rate constants for reactions of different series refer to several different temperatures (20°, 25°, and 30 °C), because the activation parameters for the recalculation of the constants in conformity with the Arrhenius or Eyring equation were not available in all cases. There are also differences between the solvents. The calculation performed taking into account the activation parameters for similar reactions and with a known (low) sensitivity of the reaction rate constants to the nature of the solvent have shown that the above differences can lead to differences of the order of 0.3–0.5 in $\lg k$ for different reaction series. This does not exceed the limits of the errors within which the given problem is considered (among all the quantities used for the given study, the electron affinity is determined least accurately). The ionisation potentials and the electron affinities employed are listed in Tables 5 and 6 and were taken from the literature[16,17,25,27,64,65,73,74].

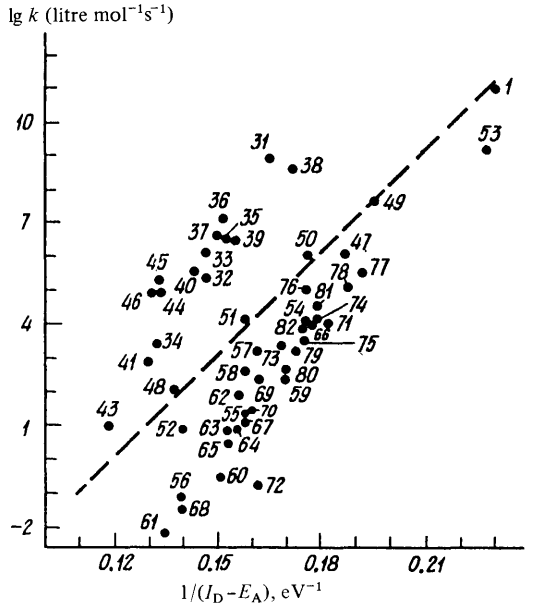

Figure 15. Dependence of $\lg k$ on $1/(I_D - E_A)$ for different diene–dienophile systems. Reactions of 1,3-diphenylisobenzofuran with dienophiles: 31) 1,1-dicyanoethylene; 32) fumarodinitrile; 33) maleodinitrile; 34) acrylonitrile; 35) maleic anhydride; 36) *N*-(*p*-nitrophenyl)maleimide; 37) *N*-phenylmaleimide (dioxane, 30 °C [16]). Reactions of cyclopentadiene with dienophiles: 38) tetracyanoethylene; 39) tricyanoethylene; 40) 1,1-dicyanoethylene; 41) fumarodinitrile; 42) maleodinitrile; 43) acrylonitrile (dioxane, 30 °C [75]); 44) maleic anhydride (dioxane, 30 °C [76]); 45) *N*-(*p*-nitrophenyl)maleimide; 46) *N*-phenylmaleimide (dioxane, 30 °C [19]). Reactions of cyclohexadiene with dienophiles; 47) tetracyanoethylene (methylene chloride, 20 °C); 48) maleic anhydride (dioxane, 30 °C [74]). Reactions of 9,10-dimethylanthracene with dienophiles: 1) tetracyanoethylene; 49) tricyanoethylene; 50) 1,1-dicyanoethylene; 51) fumarodinitrile and maleodinitrile; 52) acrylonitrile (dioxane, 20 °C [75]). Reactions of 9-methylanthracene with dienophiles: 53) tricyanoethylene; 54) 1,1-dicyanoethylene; 55) fumarodinitrile and maleodinitrile; 56) acrylonitrile (dichloroethane, 25 °C [77]); 57) *N*-(*p*-nitrophenyl)maleimide; 58) *N*-phenylmaleimide (dioxane, 25 °C [9]). Reactions of anthracene with dienophiles: 59) 1,1-dicyanoethylene; 60) fumarodinitrile and maleodinitrile; 61) acrylonitrile (dichloroethane, 25 °C [77]); 62) *N*-(*p*-nitrophenyl)maleimide; 63) *N*-phenylmaleimide (dioxane, 25 °C [9]). Reactions of 9-chloroanthracene with dienophiles: 64) *N*-(*p*-nitrophenyl)-maleimide; 65) *N*-phenylmaleimide (dioxane, 25 °C [9]). Reactions of 9-methoxyanthracene with dienophiles: 66) 1,1-dicyanoethylene; 67) 1,2-dicyanoethylene; 68) acrylonitrile (dichloroethane, 25 °C [9]); 69) *N*-(*p*-nitrophenyl)maleimide; 70) *N*-phenylmaleimide (dioxane, 25 °C [9]). Reactions of 9,10-dimethoxyanthracene with dienophiles: 71) 1,1-dicyanoethylene; 72) 1,2-dicyanoethylene (dichloroethane, 25 °C [77]). Reactions of tetracene with dienophiles: 73) maleic anhydride; 74) *N*-(*p*-nitrophenyl)maleimide; 75) *N*-phenylmaleimide. Reactions of pentacene with dienophiles: 76) maleic anhydride; 77) *N*-(*p*-nitrophenyl)maleimide; 78) *N*-phenylmaleimide. Reactions of 5,11-dichlorotetracene with dienophiles: 79) *N*-(*p*-nitrophenyl)maleimide; 80) *N*-phenylmaleimide. Reactions of 6,13-dichloropentacene with dienophiles: 81) *N*-(*p*-nitrophenyl)maleimide; 82) *N*-phenylmaleimide (toluene, 25 °C [25]).

We may draw attention to several phenomena which may be noted in the analysis of the data in Fig.14. The reactivity of butadienes in reactions with all three dienophiles investigated (tetracyanoethylene, maleic anhydride, and 4-phenyl-1,2,4-triazoline-3,5-dione) varies in such a way that the phenylated butadienes are less reactive than might have been expected on the basis of their electron-donating properties and the reactions with these butadienes are less exothermic (Table 5), which indicates higher delocalisation energies (Δh_{IBF} for 2,3-dimethylbuta-1,3-diene, *trans*-1-phenylbuta-1,3-diene, and *trans,trans*-1,4-diphenylbuta-1,3-diene are respectively −25.5, −17.5, and −6.7 kcal mol^{-1}). On the other hand, the differences between the reactivities of the three dienophiles examined are such that they correspond not only to the differences between their electron-accepting properties but also to the differences between the enthalpies of reaction (the Δh_{TCE} are 0, −3.9, and −8.5 kcal mol^{-1} respectively).

It is also striking that the reactivities of anthracenes in reactions with tetracyanoethylene and maleic anhydride (Fig.14) or arylmaleimides (Fig.15) differ very greatly, although the differences between their electron-donating properties are small. Furthermore, 9-methoxy- and 9,10-dimethoxy-anthracenes have particularly low reactivities. Overall, all anthracenes are less reactive than butadienes to a greater extent than might have been expected on the basis of their electron-donating properties. These phenomena are also understandable if account is taken of the observed differences between the enthalpies of the reactions (between the delocalisation energies) of these dienes.

Presumably the sensitivity to changes in the donor–acceptor interactions of the reactants is revealed most correctly in reaction series where the cyanoethylenes are varied. These compounds have very different electron-accepting properties, while the difference between their delocalisation energies is small (Table 6). The correlation straight line in Fig.15 corresponds to the 9,10-dimethylanthracene–cyanoethylenes reaction series. For comparison, it has been transferred to Fig.14 in the form of a dashed line.

Taking into account all the foregoing considerations, an attempt was made to examine the dependence of the reactivity of the same set of diene–dienophile systems on the set of donor–acceptor properties of the addends and their capacity for delocalisation in accordance with the equation

$$\lg k \propto /(I_D - E_A) - p\,\Delta H. \qquad (4)$$

Here both the parameter $1/(I_D - E_A)$ and ΔH reflect simultaneously the properties of both the diene and the dienophile.

According to Eqn.(4), the reactivity of the diene–dienophile system is greater the smaller the difference between the energies of the interacting orbitals ($I_D - E_A$) and the more exothermic the reaction (the higher the absolute value of ΔH).

Fig.16 illustrates the correlation between $\lg k$ and $1/(I_D - E_A) - 0.02\Delta H$§. The results obtained show that there is a large group of reactions (65 points refer to this group in Fig.16) which obey fairly satisfactorily the overall dependence of the reactivity of the diene–dienophile system on the parameters considered and for which the range of variation of the reaction rate constants amounts to 14 orders of magnitude. It includes the reactions of different dienophiles with butadienes and polynuclear compounds as the dienes.

§ In order to employ the experimental quantities directly in the given treatment, the calculation was performed for I_D and E_A expressed in eV and for ΔH expressed in kcal mol^{-1}. The adjustment of the measurements to the same system of units would require a simple alteration of the coefficients.

Compared with this group, an enhanced reactivity (for the same type of variation of the reactivity within the series) is shown in reactions involving cyclopentadiene and 1,3-diphenylisobenzofuran as dienes. This phenomenon can be explained if one takes into account the fact that the C(1)–C(4) distances in the dienes are different and that this influences their reactivity[78,79]; however, these distances are not apparently adequately reflected either in the electron-donating properties of the dienes or in the enthalpies of reaction.

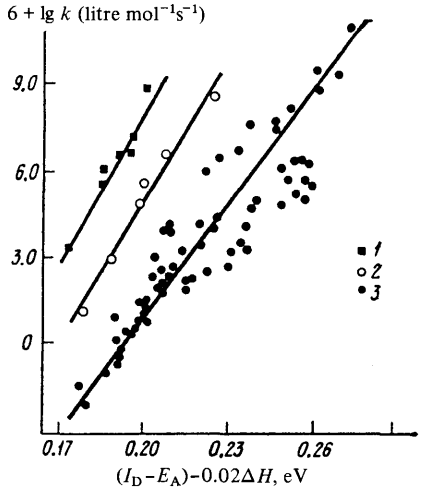

Figure 16. Dependence of the reactivity of addends in the diene synthesis reaction on the reciprocal of the difference between the ionisation potential of the diene and the electron affinity of the dienophile and on the enthalpies of reaction. Dienes employed: 1) cyclopentadiene; 2) 1,3-diphenylisobenzofuran; 3) butadienes and polynuclear compounds.

The view has been expressed that the role of the effects of the donor–acceptor interaction and delocalisation can change as a function of the position of the transition state on the reaction coordinate[80,81,73]:

$$\lg k \propto \alpha[1/(I_D - E_A)] + (1-\alpha)\Delta H,$$

where α varies from 1 to 0 along the reaction coordinate on passing from the starting materials to the products. Accordingly, the data for the reactions presented in Fig.16 were treated in terms of the equation

$$\lg k = 1/(I_D - E_A) - q(I_D - E_A)\cdot\Delta H,$$

according to which the sensitivity to the localisation effects depends on the intensity of the donor–acceptor interaction. The greater this intensity, the smaller the multiplier equal to the difference $I_D - E_A$. In this case the agreement between the calculated and experimental quantities is impaired. At present it would be premature to reach definite conclusions on the basis of these results. It is more correct to regard them as preliminary and to assume that they require further refinement. However, the main conclusion is not subject to any doubt, since both the energies of the donor–acceptor interaction and the delocalisation energies influence the reactivity of the diene–dienophile systems, constituting the principal electronic factors determining the reactivity of the addends.

Depending on the relative donor–acceptor interaction and delocalisation energies, there is a possibility of different combinations of the reactions[59,82], which are illustrated schematically in Fig.17 by energy profiles which refer to the two processes compared and differ only in the dienes or dienophiles; they can model the reaction series. The decrease of the energy in the prereaction state on the profiles corresponds to the donor–acceptor interactions and the relative positions of the final states correspond to the differences between the delocalisation energies of the addends. The combinations of the reactions can be divided into several types.

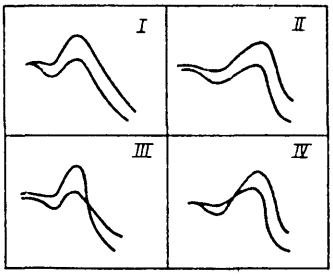

Figure 17. Energy profiles of reactions with different ratios of the donor–acceptor interaction and delocalisation energies (see text).

I. The donor–acceptor interaction and delocalisation energies vary in parallel from the standpoint of the influence on the rate of reaction; the relative reactivity of the addends is controlled by the donor–acceptor interactions. In this case the energy profiles of the reactions do not intersect and the stability of the adducts corresponds to the reactivity of the addends.

II. The donor–acceptor interaction and delocalisation energies vary in parallel, but the relative reactivity of the addends is controlled by delocalisation effects. In this case the energy profiles of the reaction also do not intersect and the stability of the adducts corresponds to the reactivity of the addends.

III. There is an antiparallel variation of the donor–acceptor interaction and delocalisation energies and the relative reactivity of the addends is controlled by the donor–acceptor interactions. In this case the energy profiles of the reactions intersect in the region of energies beyond the activation barrier; the stability of the adducts is inconsistent with the reactivity of the addends.

IV. There is an antiparallel variation of the donor–acceptor interaction and delocalisation energies and the relative reactivity is controlled by delocalisation effects; the energy profiles of the reactions intersect in the range of energies before the activation barrier; the stability of the adducts corresponds to the reactivity of the addends.

Without classifying the entire set of reactions in terms of the types indicated, it is possible to consider certain examples.

Reactions with strongly electron-donating dienes and electron-accepting dienophiles, in particular, the reactions of *meso*-substituted anthracenes with tetracyanoethylene in which the relative reactivity of anthracene corresponds to their electron-donating properties[63] and the "more reactive the reagent the greater its selectivity" rule holds[77] (see Section VIII) can be assigned to type I.

Reactions of type II are difficult to identify definitely. The study of the relation between reactivity and selectivity suggests that this type holds in reactions of arylmaleimides with anthracenes[9].

A striking example of reactions of type III is provided by the interaction of cyanoethylenes with any of the electron-donating dienes (cyclopentadiene, anthracenes, and isobenzofuran). The antiparallel variation of the electron-accepting properties and localisation energies of cyanoethylenes has been demonstrated by both quantum-chemical calculations[60,66] and by experimental data (Table 6). The reactivity of cyanoethylenes corresponds to their electron-accepting properties and increases from acrylonitrile to tetracyanoethylene, while the localisation energies (enthalpies of reaction) vary in the opposite sequence, which is consistent with the variation of the stabilities of the adducts demonstrated in relation to the reactions with 9,10-dimethoxyanthracene[69]. The reactions of butadiene or 1,4-diphenylbutadiene with tetracyanoethylene belong to type III. In this pair of reactions, 1,4-diphenylbutadiene, the more electron-donating diene, is more reactive (Table 3).

The replacement of tetracyanoethylene by maleic anhydride in reactions with the same dienes (butadiene and 1,4-diphenylbutadiene) leads to reactions of type IV. Butadiene, which is less electron-donating but has a smaller localisation energy, is more reactive. When the dienophile is altered, the donor–acceptor interaction energy changes (decreases) and the factor controlling the relative reactivity of the reactant (diene) is changed. Another example of the combination of type IV reactions may be provided by the reactions of butadienes with 4-phenyl-1,2,4-triazoline-3,5-dione compared with the reactions of the same butadienes with tetracyanoethylene. Tetracyanoethylene is more electron-accepting, but it is less reactive for "localisation" reasons. Incidentally, it is of interest also to compare the reactivities of the above dienes (butadiene and 1,4-diphenylbutadiene) in the reactions with 4-phenyl-1,2,4-triazoline-3,5-dione. In this case the reactivities of these dienes are comparable, in conformity with the "intermediate" electron-accepting properties of the dienophile.

Thus the donor–acceptor properties and localisation energies quoted as the two principal electronic factors in the study of the reactivities of addends explain many phenomena which previously appeared obscure.

VIII. THE SELECTIVITY OF ADDENDS IN THE DIENE SYNTHESIS REACTION

The selectivity S in reactivities is understood as the difference between the reactivities ($\lg k$) in the interaction of the given reactant with two others having different reactivities. On the basis of a study by the present author and his co-workers[77], we shall examine the pairs of reactions of two electron donors D_1 and D_2 with two electron acceptors A_1 and A_2. Then

$$S_{D_1} = \lg k_{D_1}^{A_1} - \lg k_{D_1}^{A_2};\ S_{D_2} = \lg k_{D_2}^{A_1} - \lg k_{D_2}^{A_2}$$

and the relative selectivity of the electron donors is described by the expression

$$S_{D_2}^{D_1} = S_{D_1}/S_{D_2} = (\lg k_{D_1}^{A_1} - \lg k_{D_1}^{A_2})/(\lg k_{D_2}^{A_1} - \lg k_{D_2}^{A_2}).$$

Similarly, for electron acceptors we have

$$S_{A_2}^{A_1} = S_{A_1}/S_{A_2} = (\lg k_{D_1}^{A_1} - \lg k_{D_2}^{A_1})/(\lg k_{D_1}^{A_2} - \lg k_{D_2}^{A_2}).$$

We shall assume that the electron-donating properties of D_1 are more prounced than those of D_2 and the electron-accepting properties of A_1 are more pronounced than those of A_2, which implies that $\varepsilon_{D_1}^{HOMO} > \varepsilon_{D_2}^{HOMO}$ (or $I_{D_1} < I_{D_2}$) and $\varepsilon_{A_2}^{LUMO} < \varepsilon_{A_2}^{LUMO}$ (or $E_{A_1} > E_{A_2}$). We shall consider the differences between the reactivities which are due to the differences between the energies of the donor–acceptor interactions [in conformity with the relation $\lg k_D^A \propto 1/(I_D - E_A)$]. Then

$$S_{D_2}^{D_1} = \frac{(I_{D_2} - E_{A_1})(I_{D_2} - E_{A_2})}{(I_{D_1} - E_{A_1})(I_{D_1} - E_{A_2})} ;$$

$$S_{A_2}^{A_1} = \frac{(I_{D_1} - E_{A_2})(I_{D_2} - E_{A_2})}{(I_{D_1} - E_{A_1})(I_{D_2} - E_{A_1})} .$$

For the conditions adopted above, we have the following relations:

$$(I_{D_2} - E_{A_1}) > (I_{D_1} - E_{A_1}); \quad (I_{D_2} - E_{A_2}) > (I_{D_1} - E_{A_2});$$
$$(I_{D_1} - E_{A_2}) > (I_{D_1} - E_{A_1}); \quad (I_{D_2} - E_{A_2}) > (I_{D_2} - E_{A_1}) .$$

Hence

$$S_{D_2}^{D_1} > 1, \quad S_{A_2}^{A_1} > 1 ,$$

i.e. the donor with more marked electron-donating properties and hence the acceptor with more pronounced electron-accepting properties should be more selective. In those cases where the relative reactivity of the addends is controlled by their donor–acceptor properties, this implies that the more reactive reactant should be more selective. This type of relation between reactivity and selectivity has been demonstrated for a whole series of examples of reactions of both the "diene (donor)–dienophile (acceptor)" type[20,24,77] and the "diene (acceptor)–dienophile (donor)" type[40]. Fig.18 presents data referring to the reactions of *N*-arylmaleimides with acenes.

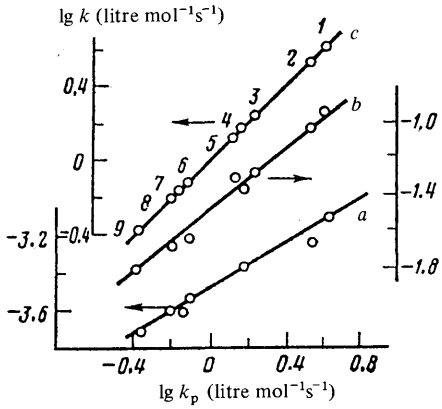

Figure 18. Dependence of the reactivities of *N*-(XC_6H_4)-substituted maleimides [X: 1) *m*-NO_2; 2) *p*-NO_2; 3) *p*-CH_3OCO; 5) *m*-Cl; 6) H; 7) *p*-CH_3; 8) *p*-CH_3O; 9) *p*-$(CH_3)_2N$] in reactions with anthracene (*a*), tetracene (*b*), and pentacene (*c*) on their reactivities in the reactions with pentacene ($\lg k_p$) (toluene, 60 °C).

The rule which states that "the more reactive the reactant the greater its selectivity" holds also in reactions of the "neutral"type in those cases where one of the donor–acceptor interactions between the addends exerts a preferential influence[34,39].

In those reactions where the relative reactivity is controlled by the delocalisation energies of the addends, the relation between reactivity and selectivity may be different, but in this instance too the selectivity of the reactants depends on their donor–acceptor properties. In this connection it is of interest to compare the variation of the reactivities and selectivities of three dienophiles: maleic anhydride, tetracyanoethylene, and 4-phenyl-1,2,4-triazoline-3,5-dione in reactions with buta-1,3-diene, 2-methylbuta-1,3-diene, and 2,3-dimethylbuta-1,3-diene (Fig.19, see also the data in Table 3). Tetracyanoethylene is more reactive and more selective than maleic anhydride. The relative reactivities of these dienophiles are controlled by the effects of the donor–acceptor interactions (tetracyanoethylene is significantly more electron-accepting than maleic anhydride but has a higher delocalisation energy). 4-Phenyl-1,2,4-triazoline-3,5-dione is more reactive than tetracyanoethylene (the relative reactivity is controlled in this instance by the delocalisation energies), but, in conformity with its electron-accepting properties, it occupies an intermediate position as regards selectivity between tetracyanoethylene and maleic anhydride. Another clear example is provided by the reactivities of cyanoethylenes in their interaction with substituted phencyclones (Section IX).

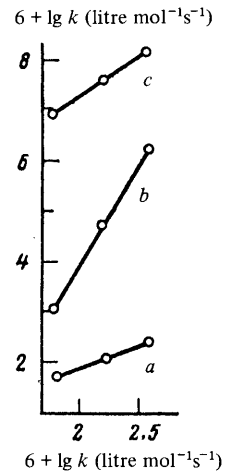

Figure 19. Dependence of the reactivities of maleic anhydride (*a*), tetracyanoethylene (*b*), and 4-phenyl-1,2,4-triazoline-3,5-dione (*c*) in the diene synthesis reactions with a series of dienes [1) butadienes; 2) isoprene; 3) 2,3-dimethylbutadiene] on the reactivities of these dienes in reactions with maleic anhydride ($\lg k_{MA}$).

IX. CYANOETHYLENES IN THE DIENE SYNTHESIS REACTION. QUALITATIVE DIFFERENCES BETWEEN THE EFFECTS OF THE INTERACTION OF ANTISYMMETRIC AND SYMMETRICAL FRONTIER ORBITALS

As mentioned above (Sections III and VII), the reactivities of cyanoethylenes in reactions with typical electron-donating dienes vary in accordance with their electron-accepting properties (electron affinities). It has been found that this

behaviour of cyanoethylenes is not always observed. Interesting data have been obtained in the study of their reactions with substituted phencyclones[83,84]:

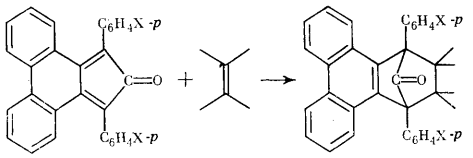

Fig. 20, which presents the corresponding correlation plots, shows that the variation of the reactivities of substituted phencyclones in reactions with each cyanoethylene is described satisfactorily by the Hammett σ constants (r varies from 0.993 to 0.999) with $\rho < 0$. In conformity with the conclusions reached in Section VIII, the absolute value of ρ (the selectivity) is then greater the more pronounced the electron-accepting properties of the cyanoethylene (Fig. 21), which indicates that the reaction is of the "diene (donor)–dienophile (acceptor)" type.

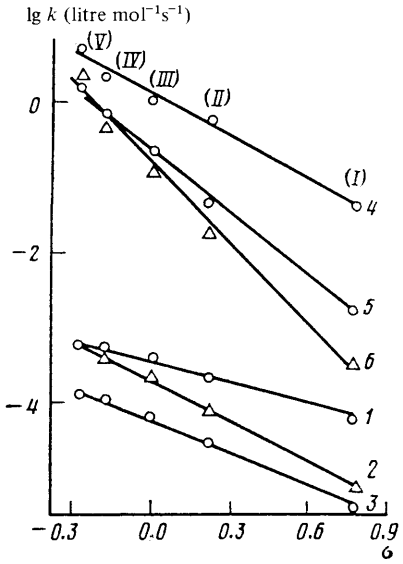

Figure 20. Dependence of lg k for the substituted phencyclones (I)–(V) in the reactions with cyanoethylenes (lines *1*–*6*) on the Hammett σ constants (chlorobenzene, 30 °C). Substituents X in phencyclones: I) p-NO_2; II) p-Cl; III) H; IV) p-CH_3; V) p-CH_3O. Cyanoethylenes: 1) acrylonitrile; 2) maleodinitrile; 3) fumarodinitrile; 4) 1,1-dicyanoethylene; 5) tricyanoethylene; 6) tetracyanoethylene.

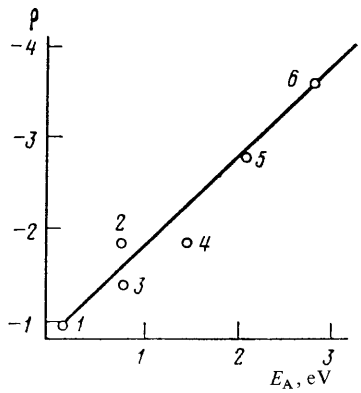
On the other hand, the relative reactivities of cyanoethylenes in the reactions with each phencyclone vary in an unusual manner. The reactivities do not correspond explicitly to one particular reaction type and depend on the electron-accepting character of the substituent in the cyclone. The possible causes capable of giving rise to this phenomenon have been analysed[83,84]. The behaviour of cyanoethylenes becomes understandable if it is assumed that their reactivites are determined not only by the electron-accepting properties but also by the delocalisation energies.

Table 8 presents equations describing the variation of the reactivities of cyanoethylenes taking into account their electron affinities and localisation energies in reactions with each phencyclone investigated. It is striking that, on passing from the phencyclone containing the electron-donating CH_3O substituent to one with the electron-accepting NO_2 substituent, the sensitivity of the diene to the localisation effects of the dienophiles increases. Taking into account the fact that the phencyclone containing the carbonyl group exhibits electron-accepting properties, the general conclusion that an enhancement of the electron-accepting properties of the dienes entails an increase of their sensitivity to the effects of the localisation of the dienophiles becomes apparent.



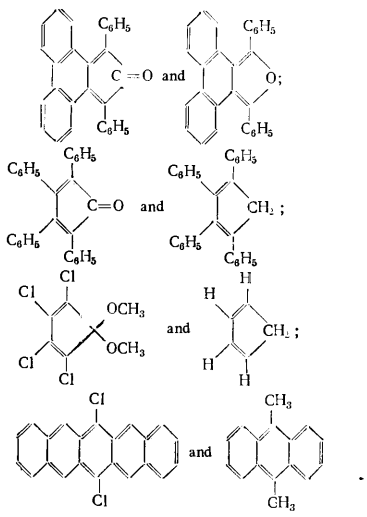


Figure 21. Dependence of the reaction constants for the reactions of substituted phencyclones with cyanoethylenes on the electron affinity of the dienophiles (chlorobenzene, 30 °C). The numbering of the dienophiles is the same as in Fig. 20.

The validity of this conclusion is demonstrated by the results of the study of the reactivities of cyanoethylenes with respect to the following pairs of dienes, having similar structures but differing in their electronic properties[83–88]:

The variation of the reactivities of cyanoethylenes in reactions with electron-donating dienes is determined by the electron-accepting properties of the dienophiles. In the reactions with electron-accepting dienes account must be taken of their localisation properties. A similar behaviour has been observed also in the reactions of substituted phencyclones with arylmaleimides and maleic anhydride[89].

Table 8. Correlation between the reactivities of cyanoethylenes as dienophiles in reactions with substituted phencyclones (k, litre mol^{-1} s^{-1}), and the electron affinities (E_A, β) and localisation energies (L, β) of the dienophiles (β is the resonance integral).

Substituent X in phencyclone	Equation	r
p-CH_3O	$\lg k = 30.16\,E_A - 6.64\,L + 33.39$	0.992
p-CH_3	$\lg k = 28.31\,E_A - 6.51\,L + 32.30$	0.986
H	$\lg k = 27.91\,E_A - 6.70\,L + 32.45$	0.986
p-Cl	$\lg k = 28.30\,E_A - 7.08\,L + 33.93$	0.986
p-NO_2	$\lg k = 27.03\,E_A - 7.54\,L + 33.78$	0.984

For further study, it is important to note that, according to the data in Section V, in reactions of the "neutral type" the dienes are as a rule electron-accepting in relation to the dienophiles (cyclones, dichloroacenes, and halogeno-*o*-quinones in reactions with styrenes). This makes it necessary to suppose that the interactions of the HOMO of the diene with the LUMO of the dienophile and of the HOMO of the dienophile with the LUMO of the diene are non-equivalent. The interaction of the HOMO of the diene with the LUMO of the dienophile is seen to be preferred.

On the basis of a theoretical analysis, it has been suggested[90,91] that there are fundamental differences between the interactions of the HOMO of the diene and the LUMO of the dienophile (antisymmetric orbitals), on the one hand, and of the HOMO of the dienophile and the LUMO of the diene (symmetrical orbitals), on the other. In the former case the electron density is concentrated between the reaction centres, ensuring conditions for the formation of the chemical bond. A change in the coordinates of the atomic nuclei promotes the reaction (Fig. 22). In the latter case, as a consequence of the resolution of the cross-overlapping, the electron density is concentrated in the central part of the intermolecular space and the changes in the coordinates of the atomic nuclei are not favourable for the reaction. Therefore, even in those cases where the interaction of the symmetrical orbitals predominates, the authors[90,91] believe that the interaction of the antisymmetric orbitals is responsible for the occurrence of the reaction (i.e. for the formation of new bonds). The interaction of symmetrical orbitals promotes the stabilisation of the prereaction charge-transfer complex (and to some extent of the transition state), but requires the localisation of the electrons on the reaction centres for the reaction to occur.

This approach explains also the characteristic features of reactions of the "neutral type" and of the more pronounced dependence of the reactivity of the addends on the delocalisation effects when the electron-accepting character of the diene becomes more marked, as well as the observed antiparallel variation of the stabilities of the charge-transfer complexes between the addends and their reactivities in reactions of the "diene (acceptor)–dienophile (donor)" type[92], in contrast to the parallel variation of these properties in reactions of the "diene (donor)–dienophile (acceptor)" type (Section V).

It is noteworthy that, when the interaction of the symmetrical orbitals predominates in the Diels–Alder reaction, the mechanism of the latter can change. Whereas the interaction of the antisymmetric orbitals promotes a synchronous reaction, the dominant interaction of symmetrical orbitals can lead to a two-stage reaction with formation of an intermediate. The available data, indicating the infringement of the "*cis*-principle" in reactions involving electron-accepting dienes such as hexahclorocyclopentadiene[93], acridizinium ions[94,95], and phenyldiazenium salts[96] provide an example of such behaviour. Despite the symmetry of the reactants, instances of the breakdown of the "*cis*-principle" have not so far been observed in reactions of the "diene (donor)–dienophile (acceptor)" type[1,97].

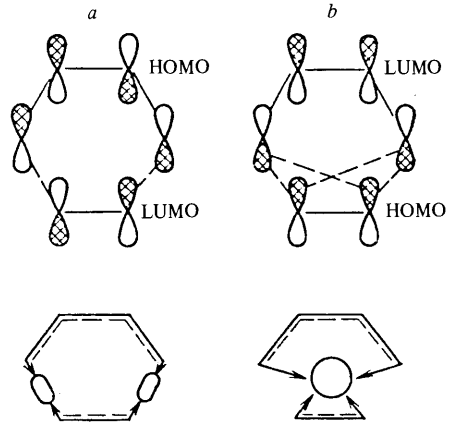

Figure 22. Schematic representation of the interaction of antisymmetric (*a*) and symmetrical (*b*) frontier orbitals of the addends in Diels–Alder reactions.

The change in the electronic character of the reactant and the associated change in sensitivity to the localisation effects can alter also the periselectivity of the reaction. It is well known that electron-donating dienes react with tetracyanoethylene at a carbon–carbon bond[98–100]. However, this dienophile reacts with electron-accepting dienes under mild conditions to form products of addition to the cyano-group[101,102]. Acrylonitrile behaves analogously[103]. Such behaviour corresponds to the lower stability (lower delocalisation energy) of the C≡N bond compared with the C=C bond.

---o0o---

The above discussion shows that many characteristic features of the reactivities of the addends in diene synthesis can be explained if the donor–acceptor properties and stabilities of the reactants, described by the delocalisation energies or enthalpies of reaction, are adopted as the principal electronic factors determining the reactivities of dienes and dienophiles. The enthalpies of reaction make it possible to take into account also the differences between the energies of the *s-trans–s-cis* conformational transitions, which influence the reactivities of open-chain dienes. On the other hand, the

geometrical factor, such as the 1,4-distances in dienes, needs to be taken into account as well. It is noteworthy that the above conclusion has been reached on the basis of the study of reactions of the "diene (donor)–dienophile (acceptor)" type. In order to answer the question to what extent this conclusion is valid for reactions of other types, special studies are necessary. Data indicating the possible qualitative differences between the effects of the interaction of the antisymmetric and symmetrical orbitals make it particularly necessary.

Conformations of Six-membered Carbon Rings with Planar Groups

A.N.Vereshchagin

A systematic account is given of experimental and theoretical data on the steric structures of six-membered rings containing groups with a coplanar disposition of three consecutive bonds within the ring—a fragment with a double bond, a condensed rigid ring, or a bridged bicyclic system. We shall consider rings containing one such fragment, namely cyclohexane, bicyclo-[4.1.0] heptane, and its analogues, as well as rings with two fragments of this kind in the 1,4- or 1,3-positions. Data are presented on the structure of the rings, their inversion, and the orientation of the substituents in various positions. The principal characteristics of the conformational structures of such compounds are described and the possibility of the assumption of the boat form and the relative preferences for the axial and pseudoaxial orientations of the substituents and the condensed planarising fragments are discussed.
The bibliography includes 272 references.

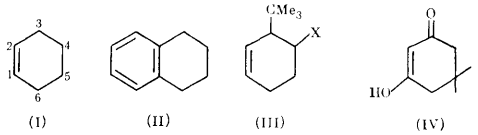
I. INTRODUCTION



Cyclohexane and its derivatives are classical objects of conformational analysis. Much less attention has been devoted to six-membered carbon rings with planar groups of atoms formed by a double bond or by condensation with a rigid system ensuring an eclipsed conformation of the common bond. The ring may also contain two planar groups in the 1,3- or 1,4-positions. Variation of the nature and positions of such groups and of the configurations of the condensed rings and substituents creates a wide variety of possible types of compounds. Studies on such compounds have been far from uniform; the available reviews concern individual conformational relations for the cyclohexane[1,2] and cyclohexa-1,4-diene[3,4] series.

The stereochemistry of both unsaturated six-membered rings and cyclohexanes or cyclohexenes condensed with three-membered rings or other rigid systems has developed vigorously during the last decade. A theoretical basis for the known facts is being developed and a number of common features have been discovered. This permits a survey and analysis of the results obtained.

II. PRINCIPAL CHARACTERISTICS OF THE CONFORMATIONAL STRUCTURE OF CYCLOHEXENES

1. Ring Conformation

It is known that cyclohexene (I) and its derivatives exist in the half-chair conformation (Fig.1).[5,6] The endocyclic torsional angles ϕ(for the half-chair conformation the angle of twist ψ) serve as a measure of non-planarity. The structure of cyclohexene has been determined by gas electron diffraction[7-11] and microwave spectroscopy[12,13]:

(I) (II) (III) (IV)

The angles ϕ vary within narrow limits: $\phi(23) = 15.2-15.7°$, $\phi(34) = 44.8-46.0°$, $\phi(45) = 60.2-62.6°$, and $\psi = 25.4°$ (Chiang and Bauer[10]) or 30.1° (Scharpen et al.[13]). The value $\phi(45) = 63°$ was also established by ^{1}H NMR.[14] Theoretical conformational analysis using various computational methods leads to a good agreement with experiment[8,9,15-23]. Ring structure is retained when the substituents are located only at the olefinic atoms in cyclohexene, in tetralin (II), and in its heteroaromatic analogues; a number of data have been published for tetralin derivatives[24,25] and for their solutions[26].

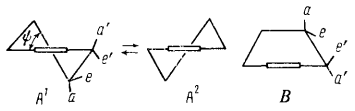


Figure 1. The conformations of cyclohexene and its derivatives; A^1, A^2—half-chair; B—boat.

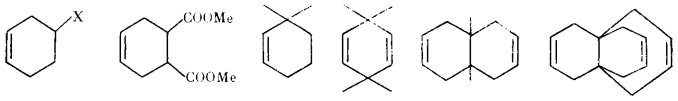


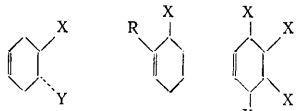
Asymmetric substitution can distort the half-chair, i.e. can lead to different deviations of the C(4), and C(5) atoms from the plane of the double bond, which has been demonstrated by calculation[18,27] and structural studies[24,25]. Marked distortions are observed under the conditions of steric hindrance due to bulky substituents. For example, the angle ϕ(23) in the *trans*-isomers of 4-substituted 3-t-butylcyclohexenes (III) and the angle ϕ(56) in the *cis*-isomers diminish to 7°.[28,29] Further distortion of the half-chair leads to the boat conformation, which has been observed for certain polycyclic compounds[32].

An additional conformational effect, namely conjugation of the C=O bond with the π-electron system, is observed in cyclohexanones and tetralinones. This effect stabilises the 1,2-diplanar form (the envelope conformation); thus the C(5) atom in dimedone (IV) is displaced from the plane of the ring by 0.6 Å.[30,31] The structure of 1-tetralinone is also close to the envelope conformation[32].

2. Ring Inversion

The barrier $\Delta G^{\neq}$ to the transition between two half-chairs A^1 and A^2 in cyclohexene (Fig.1) amounts to 5 kcal mol^{-1} [33] or 7.6 kcal mol^{-1}. [34] The calculated data correspond to the maximum energy of the boat conformation. A point on the sloping section of the energy curve corresponds to the envelope conformation; the energy gain compared with the half-chair conformation is 1.5–2.5 kcal mol^{-1}. [17,22,35,36]

Data concerning the influence of substituents are contradictory. Energy barriers not exceeding 5.1 kcal mol^{-1} have been measured by the ultrasonic method for 4-substituted cyclohexenes (V): [37]



(V) (VI) (VII) (VIII) (IX) (X)

However, ^{1}H NMR studies of compounds (V) and (VI) have shown that the introduction of each substituent increases the barrier by 1 kcal mole^{-1}, which indicates inversions via the boat form[38]. This is confirmed by the increase of $\Delta G^{\neq}$ by 2.2 kcal mol^{-1} on passing from (VII) to (VIII)—the 3,6-flagstaff ("prow") interaction creates a considerable steric hindrance in the intermediate boat form[39]. Finally, the barrier for compound (IX) is approximately twice as high and that for compound (X) three times as high as the usual value, since two or three rings pass simultaneously through the boat form in the inversion process[40].

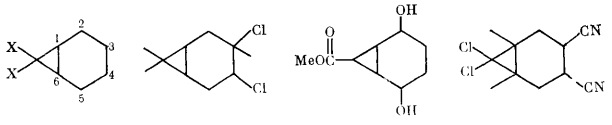
3. Conformations of the Substituents

The introduction of a double bond into a six-membered ring alters the orientation of the exocyclic bonds, particularly in the allylic positions, where they have a pseudoequatorial (*e'*) or pseudoaxial (*a'*) orientation (Fig.1). The dihedral angles between the planes in which these bonds are located (τ) differ appreciably from the angles in cyclohexane derivatives: $\tau(e'a) = 51°$, $\tau(e'e) = 62°$, $\tau(a'a) = 151°$, $\tau(a'e) = 53°$, $\tau(ea) = 64°$, and $\tau(aa) = 168°$. The bonds between the olefinic atoms form dihedral angles of 46° and 65° with the *e'*- and *a'*-substituents respectively[41]. The introduction of a double bond is responsible for the disappearance of one *syn*-axial interaction and a marked weakening of the second (*aa'*). The conformational energies of 4-substituents are therefore much lower than in the cyclohexane series. For halogen atoms, they are close to zero[38,42–46], and for iodine the *a*-orientation is actually preferred (ΔG = −0.05 kcal mol^{-1}). [38] The same may be noted for the cyano- and nitro-groups[46–48]. The methyl group[49] and the carbonyl functional groups[47,50–52] exhibit a somewhat greater tendency towards an equatorial orientation (but not exceeding 1 kcal mol^{-1}). The stabilisation of the axial position compared with the saturated analogues increases by 0.7 kcal mol^{-1} on passing from atom to atom in the series of halides, in conformity with their polarisabilities[38].

The $ee \rightleftharpoons aa$ equilibrium is possible for *trans*-4,5-disubstituted cyclohexenes (XI). In the case of dichlorides and dicyanides the proportions of different forms are virtually the same[53–56], while for X = Y = Br the repulsion of the equatorial substituents leads to a greater stability of the diaxial conformation[57–59]. On the other hand, *trans*-4,5-dimethylcyclohexene has a preferred diequatorial conformation (ΔG = 1.1 kcal mol^{-1}) [60,61] like the analogous acids and esters[62]. In contrast to compound (XI), *trans*-2,3-dihalogenotetralins are characterised by a greater proportion of the *aa*-form (up to 80% for X = Cl and 95% for X = Br. [26,57,63]

(XI) (XII) (XIII)

An extensive investigation of cyclohexane with various *trans*-substitutents in the 4,5-positions has been undertaken [47,50,64–68]. It has been established that compounds with carboxy-groups are fully diequatorial, while others are almost so. An appreciable shift is observed when one of the substituents is CCl_3 (up to 66% of the *aa*-conformer for X = CCl_3 and Y = CH_2OH). [66,67]. This resembles the behaviour of iodocyclohexene. The large bulk of the substituent is not an obstacle to its axial orientation; even the t-butyl group can occupy the *a*-position to a large extent[69].



Pseudoequatorial substituents in the 3- and 6-positions are located close to the plane of the double bond, which is sterically unfavourable, particularly in the presence of substituents at the nearest olefinic atom, as in compound (XII). Such interaction is called 1,2-allylic ($A^{1,2}$). [1] The pseudoaxial position is therefore preferred for chlorine and bromine [43,70] and for certain oxygen-containing functional groups[71]. Qualitative analysis of the available data has shown that the proportion of the *e'*-conformer is greater only for 3-methylcyclohexene[72]. The *trans*-3,6-disubstituted derivatives can be fully diaxial[73]. 2,3-Disubstituted cyclohexenes are almost entirely pseudoaxial[74]. There is evidence that such orientation is caused not only by steric factors but also by hyperconjugation[72].

The different conformational conditions for the substituents in the 4(5)- and 3(6)-positions are revealed in the analysis of the structures of molecules of type (XIII), which exist in the form of six-configurational isomers. The *trans*-oriented bonds of the substituents at the atoms in the 4- and 5-positions assume the diequatorial position with the exception of the $a'eea' \rightleftharpoons e'aae'$ equilibrium, but even the latter is 80–90% displaced towards the first form[24,25,41,75–77]. Concordant results have been obtained by calculation for 3,4-dimethylcyclohexene: $ee' > ea' > ae' > aa'$. [21]

III. CONFORMATIONS OF CYCLOHEXANE FRAGMENTS IN BICYLIC SYSTEMS

1. Bycyclo[4.1.0]heptane

The condensation of a six-membered ring with a three-membered ring also gives rise to the coplanarity of four atoms and the loss of a plane of symmetry by the planar group leads to the presence of two different boat conformations (*syn*- and *anti*) and, in the presence of different substituents, also to two half-chair forms (Fig.2). Theoretical calculations predicted the maximum stability of the half-chair conformation of bycyclo[4.1.0]heptane (XIV, X = H), [78,79] but the energy of the boat form is not higher by more than 3.3 kcal mol^{-1}. An electron diffraction study yielded the same results[80] as for the 7,7-dichloro-derivative (XIV, X = Cl) [81,82] and *trans*-3,4-dichorocarane (XV): [83]

(XIV) (XV) (XVI) (XVII)

The half-chair conformation has been found by X-ray diffraction for many compounds, for example, for compound (XVI)[84] and a series of cyclosteroids[24,25]. As a rule, the half-chair is somewhat asymmetric and approaches the envelope form in polysubstituted compounds of type (XVII).[85] This has also been observed after the introduction of an sp^2-atom into the six-membered ring[86].

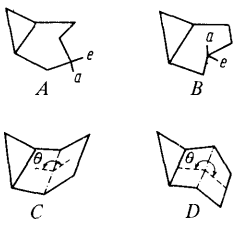


Figure 2. The possible conformations of bicyclo[4.1.0]-heptane; *A*, *B*—half-chair; *C*—*syn*-boat; *D*—*anti*-boat.

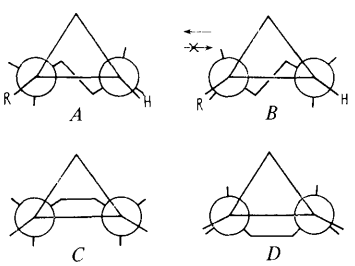

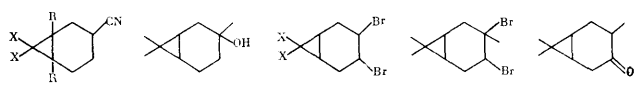

Figure 3. The orientation of the bonds in bicycloheptane systems; for legend, see Fig. 2.

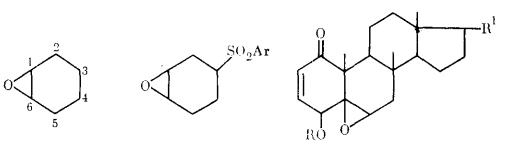
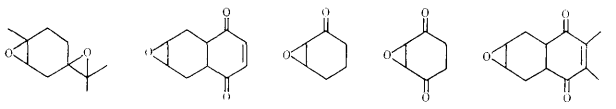
Substituents in the 1-positions stabilise the half-chair form, in which they are less eclipsed (Fig. 3*A*). This has been demonstrated[87] for 1-t-butylbicycloheptane. The equatorial *cis*- and *trans*-substituents in the 3- and 4-positions do not interact with the ring, but the *cis*-axial substituent can be strongly destabilised, particularly for bulky *syn*-7-substituents. In the *trans*-isomers of compound (XVIII, R = H or Me, X = Cl or Br), the cyano-group is therefore 8% axial, while in the *cis*-isomers it occupies only the equatorial position[88,89]; similarly in both caranol (XIX) isomers the *cis*-substituent is equatorial[90,91]. Only the methoxycarbonyl group retains the equatorial position whatever the configuration[92,93].



In *trans*-3, 4-disubstituted bicycloheptanes, the unsubstituted three-membered ring does not hinder the diaxial conformation; at any rate, in dibromocycloheptane the latter predominantes significantly[94]. In 1,6-disubstituted derivatives the steric hindrance experienced by the *trans*-axial substituent results in a diequatorial structure of the 3,4-diesters[89,92,95] and the corresponding dinitriles[89].

The introduction of substituents into the *syn*-7-position increases the conformational possibilities. The distortion of the ring in compound (XVII) in the direction of the envelope form in the crystalline phase has been noted. The tetrahalogeno-compounds (XX, X = Cl or Br) exist in solution mainly in the *anti*-boat conformation with the angle $\theta = 200$ to 215 °C.[96] The same form appears in the equilibrium involving dibromocarane (XXI) although the dichloro-derivative consists of a mixture of the *ee*- and *aa*-half-chair conformations: the smaller chlorine atom can be in the *cis*-axial position relative to the *gem*-dimethyl group[97,98]. The *anti*-boat conformation appears also in caranols and caramines with the *cis*-orientation of two substituents in the 3- and 4-positions[99,100]; the conformation of compounds of this type is greatly influenced by the possibility of the formation of hydrogen bonds[101–104].

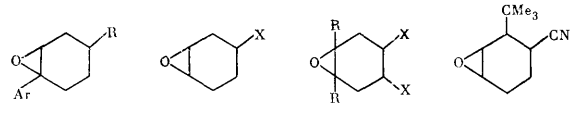
The half-chair conformation is retained when sp^2-atoms are introduced into the ring[105,106] and in the isomeric caranones (XXII) the carbonyl group approaches the three-membered ring regardless of the orientation of the 3-methyl group[105].



2. 7-Heteroanalogues of Bicycloheptane

Epoxycyclohexane (XXIII) has been investigated by gas electron diffraction[7,107,108] and microwave spectroscopy[109]. The six-membered ring has the half-chair conformation with the endocyclic dihedral angles $\phi(12) = \phi(65) = 16.3°$, $\phi(23) = \phi(54) = 48.8°$, $\phi(34) = 63.9°$,[108] and $\psi = 34.4°$.[109]

The results of calculations by the method of molecular mechanics are consistent with these findings[79]. The half-chair conformation has been established for many epoxycyclohexanes, for example, the isomers of compound (XXIV)[110] and polysubstituted and polycyclic compounds[24,25], including steriods. It is noteworthy, firstly, that the half-chair is usually asymmetric and, secondly, that its form depends to a large extent on the strength of the crystal field. Thus withafevin A (XXV) crystallises in two conformations differing in the direction and degree of bending of the *B* ring[111].

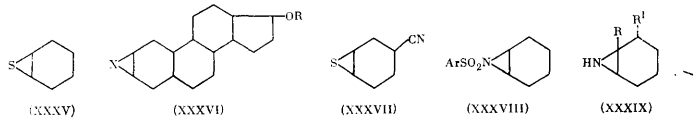


In certain epoxides the cyclohexane ring has the boat conformation. The electrical parameters of the molecule of terpinolene dioxide (XXVI) can be described only in terms of the presence of this form[112]. The boat conformation is to some extent stabilised by the other six-membered ring: for this reason, 10–20% of the *syn*-boat conformation is involved in the equilibrium in the case of compound (XXVII).[113]

The fact that the *syn*-boat form obtains is readily understood from the standpoint of the orientation of the bonds (Fig. 3). According to a calculation[113], the contribution of the torsional interaction energy in the case of the half-chair and the *syn*-boat amounts to ~3 kcal mol^{-1}, while for the anti-boat form it is more than 7 kcal mol^{-1}.

The envelope or highly distorted half-chair conformation is typical for epoxycyclohexanones (XXVIII). If carbonyl groups have been introduced into both α-positions, as in compound (XXIX) then, compared with the chair form, the *syn*-boat form has a more favourable orientation of the dipoles and conditions for the conjugation of the carbonyl groups with the oxiran ring; ultimately, simple calculation predicts the highest stability of compound (XXIX) in the *syn*-boat form. Compound (XXX) has precisely this structure[114]. The substituent in the 1(6)-position is responsible for the "uneclipsed" half-chair conformation being preferred, as in bicycloheptanes (Fig. 3). This has been demonstrated in compound (XXXI) with R = H; however, when R = t-C_4H_9, the ring conformation is determined by the bulky substituent [115].

The orientation of the substituents in the other positions of 7-oxabicycloheptane is determined to a large extent by the direction of their dipoles relative to the epoxy-group. Apart from the general preference for the equatorial orientation, electrostatic repulsion destabilises the *cis*-axial positions of the polar substituents. It has been shown[110] that the *cis*- and *trans*-isomers of compound (XXXII, X = SO_2Ph, NO_2, or CN) exist preferentially in the equatorial form, but the fraction of the axial form of the *cis*-isomers is systematically lower, so that the values of ΔG for these compounds are smaller by 0.7 kcal mol^{-1} than for the *trans*-isomers[110,116];

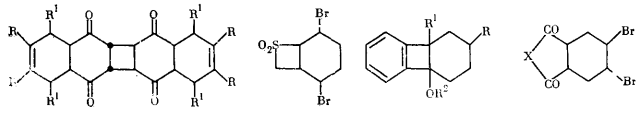


(XXXI) (XXXII) (XXXIII) (XXXIV)

the ratio of the values of ΔG mentioned above holds also for these compounds. Since the *cis*-substituent does not tend to occupy the axial position, the *trans*-3,4-dicyanides and the *trans*-3,4-diesters (XXXIII) exist preferentially in the *ee*-form[116,117].

The substituents in 2- and 5-positions to some extent retain the features of the conformational behaviour of cyclohexanes. This is indicated by the axial orientation of the 3-*cis*-t-butyl group in compound (XXXIV).[116] On the other hand, in general the ring conformation is determined mainly by the substituents in the 3,4- and not 2,5-positions (see, for example, Tadwalkar et al.,[118] Watanabe et al.,[119] and Jackson and Zurqiyah[120]).

The 7-heteroanalogues of bicycloheptane with other heteroatoms have been scarcely investigated. Cyclohexenothiiran (XXXV) has been found to have the half-chair conformation with the angle $\psi = 27.6°$.[121] A similar analogy with the corresponding epoxides has been observed in the structure of epithioandrostanes (XXXIV) with X = S (a) and SO (b).[122,123]



(XXXV) (XXXVI) (XXXVII) (XXXVIII) (XXXIX)

The *A* ring has the distorted half-chair conformation. The similarity of the dipole moment of cyanocyclohexenothiiran (XXXVII) to that of the epoxide has in fact led to the conclusion that the former is involved in an analogous conformational equilibrium with participation of about 40% of the equatorial half-chair conformation[48].

A typical half-chair conformation has been observed in an X-ray diffraction study of 7-(*p*-iodobenzenesulphonyl)-7-azabicyclo[4.1.0]heptane (XXXVIII).[124] Substituted compounds of type (XXXIX) have been investigated by ^{13}C NMR.[125] The substituent R^1 in the *trans*-position relative to the nitrogen atom is pseudoaxial, while that in the *cis*-position is pseudoequatorial, i.e. only one half-chair conformation with an uneclipsed substituent R is realised (Fig. 3).

3. Compounds of the Bicyclo[4.2.0]octane Series

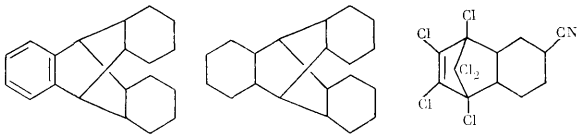
A planar group arises only in the *cis*-condensation of the plane of the four-membered ring with the six-membered ring. Two groups of compounds have been investigated in fair detail. The first comprises the photodimers of hydrogenated naphthoquinones (XL).[126] The central four-membered rings in these compounds are planar and the cyclohexanedione rings have the half-chair conformation distorted to different extents, up to the envelope conformation, depending on the nature of the substituents R and R^1.

(XL) (XLI) (XLII) (XLIII)

The half-chair conformation has also been observed for compound (XLI); the C–Br bonds occupy the pseudoaxial positions, as in cyclohexene[127].

The compounds of the second group contain a six-membered ring condensed with the benzocyclobutene fragment, as in structure (XLII).[128,129] In all the molecules the cyclohexane ring has a fairly symmetrical boat conformation: the atoms in the 2- and 5-positions deviate from C(1)–C(3)–C(4)–C(6) by 0.55 and 0.62 Å respectively[128]. It is of interest that this is the *syn*-boat conformation, i.e. the bonds in the four-membered ring are axial.

4. The Anhydrides and Imides of *Cis*-cyclohexenedicarboxylic Acids



The tendency towards the formation of the boat form is manifested also in those cases where the cyclohexane ring is *cis*-condensed with a planar five-membered ring—anhydride or imide ring, as in compounds (XLIII, X = O or NAr). Compounds of this type have been investigated in solutions by various methods and it has been definitely established that there is an equilibrium between the diaxial half-chair and *syn*-boat conformations in proportions of 4 : 1 for anhydrides and 3 : 2 for *N*-arylimides[130].

The NMR spectra of the methyl-substituted anhydrides were interpreted as evidence for the twist-boat conformation; the possibility of an equilibrium was not taken into account[131].

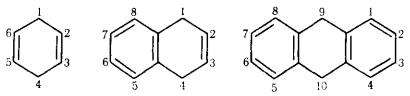
5. The Cyclohexane Ring Condensed with a Bridged System

The limiting case in the series of bicyclo[4.*n*.0]alkanes considered consists of a cyclohexane ring *cis*-condensed with a similar ring incorporated in a rigid bicyclic system ensuring the coplanarity of the three consecutively arranged C–C bonds. A series of X-ray diffraction studies have been made of the possible isomers of the hydrogenated triptycenes (XLIV) and (XLV).[132–137]. All the *cis*-condensed rings have the boat conformation owing to the necessity for the optimum blending of the "rigid" and "mobile" halves of the ring.

When the contributions of different energy components are considered it is seen that the *cis,cis,cis*-form (three boats) involves a torsional energy loss of ~10 kcal mol^{-1} relative to the *trans,trans,trans*-form (three chairs), but there is a gain of the same amount of energy due to the Baeyer strain, since the overall destabilisation of the molecule in the "three boat" conformation does not exceed 2.5 kcal mol^{-1}.[136] The boat forms in compound (XLV) are somewhat distorted: the endocyclic dihedral angles formed by the common bond reach 17° for a very small inversion barrier between two directions of twist.

(XLIV) (XLV) (XLVI)

The observation of the stability of the boat conformation of the classical cyclohexane ring is an important achievement in the development of conformational analysis, because it necessitates a review of the structures of many compounds. It is appropriate to mention here that the preference for the boat conformation over the half-chair conformation has been demonstrated by calculations for the inversion of cyclohexane[138].



The C-C bonds in the bicyclic systems of compounds (XLIV) and (XLV) occupy an equatorial position in the cyclohexane ring, which is quite understandable from the standpoint of steric factors, although it conflicts with some of the data presented above for the bonds in three-, four-, and five-membered rings.

Substituted derivatives have been hardly investigated. The structure of the isomeric cyano- derivatives (XLVI) with the *cis*- and *trans*-dispositions of the cyano-group and the bicyclic system has been determined by the dipole moment method[139].

IV. 1,4-DIPLANAR SIX-MEMBERED RINGS

1. Aromatic 1,4-Dihydro-compounds

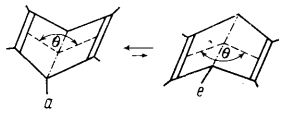
The series considered includes three main types of molecules—cyclohexa-1,4-diene (XLVII), 1,4-dihydronaphthalene (XLVIII), and 9,10-dihydroanthracene (XLIX).

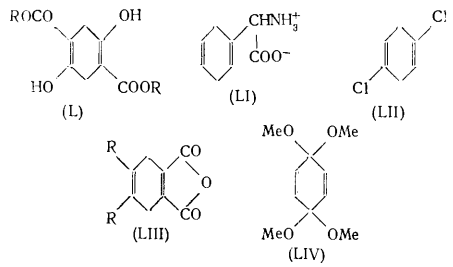
(LXVII) (XLVIII) (XLIX)

The only possibility for a change in conformation involves the bending of the molecule along the C(1)-C(4)-C(9)-C(10) line, so that the ring always assumes the boat conformation specified by the angle θ between the planes of the π-electron systems (Fig.4).

(a) Cyclohexa-1,4-diene and its Derivatives

The planar structure of the molecule of compound (XLVII) is indicated by vibrational spectroscopy[140-143], rotational spectroscopy[144], gas phase electron diffraction[145], and NMR spectroscopy (in a nematic solvent)[146], the potential well being very flat[143], so that the effective angle θ is 167°.[147] This is apparently why it was concluded that the cyclohexa-1,4-diene molecule is non-planar[148]. Theoretical calculations by various methods confirmed the planar structure of compound (XLVII).[23,36,149-154]. Even though calculations indicated an energy barrier at θ = 180°, its height was found to be only ~0.1 kcal mol^{-1}.[155]





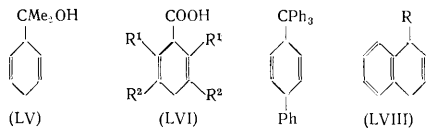


Figure 4. The structure of cyclohexa-1,4-diene and its derivatives.

Substituents at the olefinic atoms do not influence the ring conformation; this was established in an X-ray diffraction study of compounds (L) and (LI),[24,25] although the physical properties of solutions of compounds such as (LII) and (LIII) indicate an appreciable bending of the molecules, which may be effective[156,157]. The 1,1-disubstituted derivatives are also planar, since the bending increases the $A^{1,2}$ strain. An example may be provided by the diketal of the quinone (LIV).[158]

(L) (LI) (LII) (LIII) (LIV)

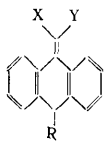
The conformations of 1-substituted cyclohexadienes are very interesting. When the substituents are not unduly bulky, the NMR spectra indicate the planarity of the ring[159-161]. With increase of the bulk of the substituent, there is an increase of the $A^{1,2}$ strain, so that a pseudoaxial boat conformation was observed for compound (LV).[162] The influence of the substituent on the ring conformation is reflected in the results of the calculation[150]: with increase of the bulk of the 1-substituent, the angle θ changes from 180° to 160° for t-butylcyclohexadiene; there are no energy minima at all corresponding to the pseudoequatorial orientations.

(LV) (LVI) (LVII) (LVIII)

The $A^{1,2}$ strain is equally enhanced after the introduction of substituents at the nearest sp^2-atoms.[163] In particular, in the molecule of compound (LVI), the ring is almost planar for $R^1 = H$ and $R^2 = Me$, but, when $R^1 = Me$ and $R^2 = H$, it is bent at an angle of 8.4°.[164]

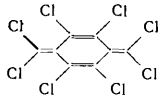
1,4-Disubstituted derivatives with the *trans*-configuration have a planar ring (see the data published by Kitaigorodskii et al.[25]) or the more bulky substituent occupies the pseudo-axial position, as in compound (LVII).[165] It is of interest that the *cis*-isomer is diequatorial and not diaxial as might have been expected[166]: the deviation in the opposite direction would not alter appreciably the $A^{1,2}$ strain but would lead to the appearance of the prow-interaction.

(b) 1,4-Dihydronaphthalenes



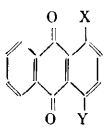
Condensation of cyclohexa-1,4-diene with an aromatic ring increases the $A^{1,2}$ strain and in addition there is a decrease in the torsional barriers in the $C_{sp^2}-C_{sp^3}$ bonds[23]; all this leads to an increase of conformational mobility. Although calculations, predicted a planar structure of compound (LVIII) for R = H,[150,151] experiment indicated a bend, albeit small, in the molecule[167]. Substituents in the 1-position are usually pseudoaxial[161,168-170]. The angle θ depends on the bulk of the substituent[171] and, in the presence of the bulky t-butyl substituent, there is a possibility that the ring form changes completely[172]; however, calculation for all the 1-alkyldihydronaphthalenes indicates the boat conformation with the sole difference that two energy minima correspond to the t-butyl group, with the corresponding angles θ = 132° (*e'*) and 149° (*a'*).[150]

(c) The 9,10-Dihydroanthracene System



Numerous X-ray diffraction data indicate an appreciable bend in the molecules of 9,10-dihydroanthracene (XLIX) and its derivatives[24,25], which, incidentally, is poorly described by the theory[150,154]. For the two bonds in which the atom in the 9(10)-position is involved, that carrying the larger substituent is predominantly pseudoaxial[161,173] and there is a possibility of equilibrium between two forms[174]. The behaviour of 9-alkyldihydroanthracenes has been satisfactorily accounted for by calculation[150].

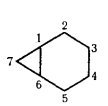
The *trans*-9,10-disubstituted dihydroanthracenes are largely planar, but, in the presence of very bulky substituents, there is a possibility of distortion of the ring[175]; naturally, if the substituents are different, the conformation is determined by the larger substituent. The central ring in symmetrical 9,9,10,10-tetrasubstituted compounds and compounds with condensed benzene rings is also planar[24]. The *cis*-configuration of the 9,10-substituents ensures the possibility of the energetically favourable diaxial conformation. Indeed, it has been observed for a number of dialkyl [25,175] and bis(trimethylsilyl)[176] derivatives. The angle θ is almost constant, varying in the range 150-155.7°. The same conformation is maintained in solutions[177].



The sterically hindered molecules of type (LIX) with an sp^2-atom in the 9-position constitute a special group. An extremely pronounced 1,3-allylic ($A^{1,3}$) strain[1] between the substituents in the methylene group and the nearest hydrogen atoms of the hydroanthracene system is present in these compounds. The molecule therefore assumes that boat conformation, although sterically unhindered compounds of this type are planar[178]. The substituent R in the 10-position assumes the pseudoaxial orientation[179]. The $A^{1,3}$ interaction destabilises the planar structure so much that the height of the inversion barriers exceeds 15 kcal mol^{-1} [178-180] when X,Y ≠ H or for an unsubstituted methylene group and chlorine atoms in the 1- and 8-positions. Even in a quinonoid structure there is a possibility of the breakdown of planarity as a consequence of steric hindrance. Thus compound (LX) has a distinct boat conformation, in which the angle between the directions of the exocyclic double bonds is ~110°.[181]

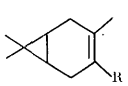
(LIX)

(LX)



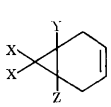
(LXI)

Even the molecules of aromatic compounds, for example, anthraquinones (LXI), can be non-planar as a result of steric hindrance. The bending of the ring requires at least two substituents in the 1,4- or 1,8-positions. For example, the 1,8-dichloroanthraquinone molecule is bent along the C(9)–C(10) line with θ = 168°.[182] The degree of non-coplanarity is still greater if X is a nitrogen atom incorporated in a 1,2-condensed aromatic heterocycle: the atoms in the 9- and 10-positions can be displaced from the plane by 0.2–0.4 Å [183,184].

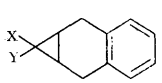


2. Bicyclo[4.1.0]hept-3-ene and Its Analogues

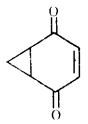
(a) Bicycloheptenes and Epoxycyclohexenes



When the cyclohexene ring is condensed with a three-membered ring in the 4,5-positions, there is a possibility of two different boat conformations–*syn* and *anti* (Fig. 5). Bicyclo[4.1.0]hept-3-ene (norcarene) (LXII) and its homologues exist in the *syn*-boat form[185], like 3-carene (LXIII, R = H), whose structure has been determined most reliably by gas-phase electron diffraction[186], NMR spectroscopy[187,188], and the Kerr effect[189]. The angle θ is 165°.[82] The possibility of the involvement of the *anti*-form in the equilibrium in an amount of 5–10% ($\Delta G = 1.48$ kcal mol^{-1}) has been indicated[187]. The structure of 4-methylcarene (LXIII, R = Me) with θ = 172° is even closer to planarity[190]. Steric interactions have been suggested as a factor stabilising the *syn*-form[187], but calculations[189,191] have demonstrated that the torsional term plays the decisive role.



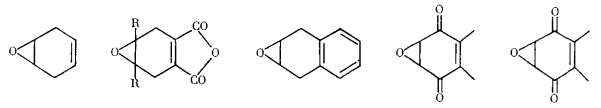
(LXII)



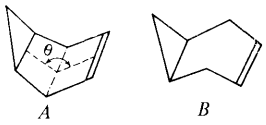
(LXIII)

(LXIV)

(LXV)



(LXVI)



The data for norcarenes with polar substituents in the cyclopropane ring are contradictory. 7,7-Dihalogeno-derivatives exist in the *syn*-boat conformation with θ ≅ 165°.[192] The NMR spectra of the polyhalogeno-compounds (LXIV, X, Y, Z = F, Cl, or Br) indicate the *anti*-structure[193]. Just as contradictory results have been obtained for tetralin derivatives (LXV). If there is no substituent in the *syn*-7-position, the *syn*-boat conformation obtains[191,194]. However, the *anti*-structure with θ = 222° has been established with the aid of various methods for molecules with dichlorocyclopropane and dibromocyclopropane fragments[191,195].

The introduction of carbonyl groups in the 2,5-positions as in compound (LXVI) gives rise to the possibility of conjugation which flattens the ring. On the other hand, the torsional energy minimum retains its position, since the configuration with eclipsed carbonyl groups and C_{ring}–H bonds is favourable. The *syn*-conformations therefore obtain for compounds of type (LXVI) in crystals[24,25] and in solutions[196]. The angle of the bend remains the same as in analogues without carbonyl groups, so that the torsional term is decisive.

The oxygen analogue of norcarene-7-oxabicyclo[4.1.0]-hept-3-ene (LXVII)—has been investigated in fair detail in the gas phase[197,198]. The molecule has the *syn*-boat conformation with the angle $\theta = 160°$.[197] According to Durig et al.[198], the *anti*-boat conformation has an energy greater by 2.33 kcal mol^{-1}, i.e. is hardly involved in the equilibrium; the energy barrier separating the two forms is only 2.81 kcal mol^{-1}. Compound (LXVIII) has a fairly distinct *syn*-boat conformation, but its dipoles are directed to one side[157]. On passing to the tetralin analogue (LXIX), an inversion of conformation takes place, as for compound (LXV) and the *anti*-boat form with the same angle of bend of 219° becomes stable[196].

(LXVII) (LXVIII) (LXIX) (LXX) (LXXI)

A *B*

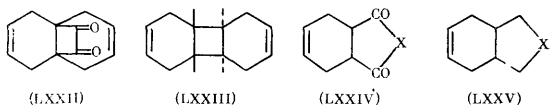


Figure 5. The possible conformation of bycyclo[4.1.0]-hept-3-enes; *A*—*syn*-form; *B*—*anti*-form.

Theoretical calculation[191] predicted the stability of the *anti*-boat form for the 7,7-dihalogeno-derivatives as a consequence of the repulsion of the π-electron systems and electron pairs of the *syn*-halogens. However, at the present time this conformation has been established reliably only for the benzo-derivatives, while the cyclohexene analogues (LXIV, Y = Z = H) and (LXVII) exist in the *syn*-form.

The introduction of carbonyl-containing groups stabilises additionally the *syn*-boat conformation not only as a result of the decrease of the torsional energy but also as a result of the most favourable orientations of the dipoles[199]. It is not surprising that this conformation is characteristic of epoxyquinones (LXX)[196,199] and hydroxyketones (LXXI).[24,200]

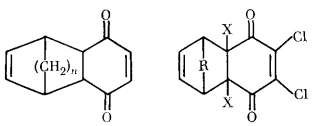
(b) Derivatives of Bicyclo[4.2.0]oct-3-ene

The planarity of the four-membered ring condensed with the cyclohexane ring, which is necessary for a fixation of all three bonds of the latter, is by no means always manifested; even the cyclobutene fragment is strongly bent in many instances[24]. The cyclobutane-1,2-dione ring is planar, as a result of which the molecule of compound (LXXII) exists in the crystal with the cyclohexene ring having the *syn*-boat conformation. The four-membered ring then occupies the axial position and the bonds in the second cyclohexene ring are equatorial[201]. Spectroscopic data[202] permit the same conclusion for solutions.

(LXXII) (LXXIII) (LXXIV) (LXXV)

The cyclobutane ring exhibits planarising properties in polycyclic molecules with the skeleton of compound (LXXIII) (but not in all cases)[25]. The degree of bending of the cyclohexene ring can be greater than in the bicycloheptene series—up to $\theta = 142°$.

(c) The Bicyclo[4.3.0]non-3-ene System



The five-membered anhydride and imide rings are planar in all cases, as a result of which the derivatives (LXXIV) exist in the boat conformation. The view has been frequently expressed that this is the *anti*-boat conformation, but experimental data have shown that the *syn*-form predominates ($n = 90 \pm 10\%$) for anhydrides[203,204], while the imides (LXXIV, X = NAr) exist as a mixture of approximately equal amounts of molecules in the *syn*- and *anti*-boat conformations[192].

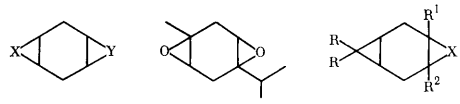
Spectroscopic data on the basis of which the equilibrium in solutions might have been inferred unambiguously became available only recently and yielded ambiguous results. According to Larter et al.[205], the anhydride (LXXIV) and its homologues are equilibrium mixtures of the *syn*- and *anti*-forms in proportions of 9:1, in excellent agreement with other data[203]; the degree of bending of the ring was then assumed to be the same as that found in the X-ray diffraction study of cyclohexene *cis*-condensed with a five-membered ring[206]. The study of the temperature variation of the ^1H NMR spectra of compounds (LXXIV)[62] confirmed the *syn*-boat conformation at the usual temperatures, but characteristic signs of equilibrium were observed only on heating above 450 K, which should correspond to an unusually high barrier to inversion.

In the series of bicyclonon-3-enes the *cis*-junction between the cyclohexene ring and the saturated five-membered heterocycle is rigid, as in compound (LXXV). When $X = N^+Me_2$, the degree of bending is very marked: $\theta = 139.7°$.[206] The substance crystallises in the *anti*-boat form, although the *syn*-form is permissible in solution according to NMR data. The equilibrium has been studied in detail for X = O[207] and it has been established that the fraction of molecules in the *anti*-boat conformation is 60–80%.

(d) Adducts of Quinones with Cyclic Dienes

All the compounds investigated in which cyclohexene ring is *cis*-condensed with a bicyclic system can be obtained as adducts in the diene synthesis of *p*-quinones with cyclodienes. The cyclohexenedione ring in compound (LXXVI) with $n = 1, 2$ has the *syn*-boat conformation with an angle of bend close to the canonical value[114,208]: even bulky bicyclic systems can occupy the axial position.

(LXXVI) (LXXVII)



The same conformation has been established for adducts of quinones with hexachlorocyclopentadiene and even with anthracene, although in the latter case the ring is flattened[114,196]. The *syn*-boat conformation has been noted for quinoxalinedione adducts[209].

The adducts of substituted quinones of type (LXXVII) crystallise in the *syn*-boat form[210], but in solution there is a possibility of equilibrium, since in the boat form both the axial and equatorial positions are occupied by the C–C or C–X bonds[114].

3. 1,4-Diplanar Systems Formed by Condensation with Two Rings.

(a) Tricyclo[5.1.$0^{3,5}$]octanes

Mainly compounds (LXXVIII) with a *trans*-junction have been investigated, while only a few data have been obtained for the *cis*-isomers.

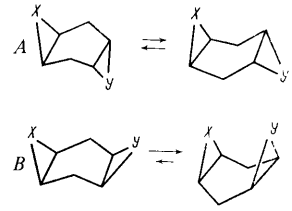
(LXXVIII) (LXXIX) (LXXX)

For the symmetrical derivatives (LXXVIII), the main problem was that of the degree of bending of the central ring. It was established ultimately that, for X = Y = CCl_2, CBr_2, or O,[211] and also for the *trans*-dioxide of γ-terpinene (LXXIX)[192], the angle θ between the C(1)–C(2)–C(5)–C(6) and C(2)–C(3)–C(4)–C(5) planes is ~160°. X-Ray diffraction study of compound (LXXX, R = R^1 = Me, R^2 = H, X = CBr_2) showed, however, that the degree of bending varies in the range 0.5–6.1°:[212] similarly, electron diffraction study of the analogous dichloride showed that it is best described by a planar structure[213]. Nevertheless, NMR study of compounds of type (LXXX) demonstrated in all cases the existence of conformational equilibria, which are possible only for a fairly high degree of bending of the molecules[214,215]. The determination of the structure of oxatricyclooctanes methylated to different extents (R = R^2 = H, R^1 = Me; R = H, R^1 = R^2 = Me;[216] R = R^1 = Me, R^2 = H;[217] R = R^1 = R^2 = Me)[187] showed that it depends on the degree of substitution, but the central ring is always significantly non-planar.

In the series of bicyclene oxides, X-ray diffraction data have been obtained for compound (LXXVIII, X = CBr_3, Y = O) and its 1,6-dimethyl derivatives[218]. Extremely small angles of bend of the ring were obtained—7.6° and 6.4° respectively. However, in solutions the polarity and polarisability of the *trans*-oxides of 7,7-dichloro-, and 7,7-dibromonorcarenes cannot be described in terms of a planar conformation; they can be treated only in terms of an equilibrium mixture of two boat forms[208]. The symmetrisation of molecules of this kind in the crystal is encountered fairly frequently.

According to electron diffraction data, the *trans*-oxide of 3-carene (LXXX, R = R^1 = Me, R^2 = H, X = O) has a pseudoaxial cyclopropane fragment and a pseudoequatorial epoxide ring (Fig.6, *syn*-boat)[219] with θ = 160°.[82] Studies in solutions by the NMR [220,222] and Kerr effect[223] methods revealed a conformational equilibrium in which the *syn*-boat form predominates (2:1).[223] The same ratio of conformers obtains for compound (LXXX, R = R^1 = Me, R^2 = COMe, X = O).[224] Equilibria in solutions have been discovered for a number of homologues of 3-carene oxide, the ratio of the conformers depending on the degree of methylation[190,225–227], and for 3-carene *trans*-sulphide (LXXX, R = R^1 = Me, R^2 = H, X = S)[228]. The only exception is a study[218] in which the NMR spectra of the *trans*-oxides of norcarene (LXXVIII, X = CH_2, Y = O) and its 7,7-dimethyl derivative were interpreted as evidence for the planar structure of the central ring.

The *cis*-isomers of compounds (LXXVIII) can exist in the *anti,anti*- or *syn-syn*-conformations (Fig.6), which are significantly different. The *anti,anti*-conformation is doubly destabilised by torsional interactons, while for the *syn,syn*-conformer one may expect stronger interactions between three-membered rings, particularly when these are polar or carry bulky substituents. Studies on the *cis*-oxide of 3-carene (LXXX, R = R^1 = Me, R^2 = H, X = O) by various methods revealed the presence of the *syn,syn*-boat form with θ = 160°,[219,223,229] as for its various homologues[226,227] and 3-carene *cis*-sulphide[228]. The dipole moment of the *cis*-dioxide of γ-terpinene (LXXIX) shows that the oxiran rings have a parallel or nearly parallel orientation, which is possible only for the *syn,syn*-boat conformation[192]. Only certain NMR studies led to the unambiguous conclusion that the *anti,anti*-form is possible or even more stable or that the planar structure obtains[218,221,222,225,228].



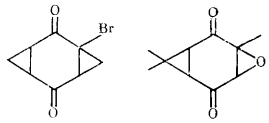


Figure 6. The conformations of 1,4-diplanar tricyclic systems with the *trans*-configuration (*A*) and the *cis*-configuration (*B*).

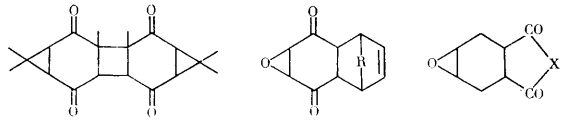
Ketones of the tricyclopropane series, investigated from the conformational standpoint, have the *trans*-disposition of two three-membered rings. The virtually symmetrical molecule of compound (LXXXI) has an almost planar six-membered ring in the crystal with θ = 175°.[230]

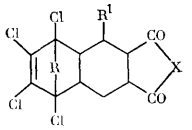


(LXXXI) (LXXXII)

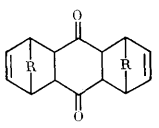
If one of the rings is an epoxide ring, as in compound (LXXXII), it has a pseudoaxial orientation with favourable directions of the dipoles of the carbonyl groups and of the epoxide ring[196].

(b) Conformation of the Cyclohexane Ring in Certain Polycyclic Systems

The number of structures which can be formed on 1,4-condensation of the cyclohexane ring with various rigid fragments is very large; the available data concern only some types of compounds.



If one of the planarising fragments is a three-membered ring, it occupies the pseudoaxial position, i.e. in relation to this fragment the cyclohexane ring has the *syn*-boat conformation for reasons indicated above. Compound (LXXXIII) in the crystal[25] and the epoxy-derivatives (LXXXIV) in solutions[114,231] have such a structure. This angle of bend of the molecule of compound (LXXXIV) is approximately 150°.



(LXXXIII) (LXXXIV) (LXXXV)

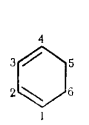
The epoxy-derivatives of the anhydrides and imides of cyclohexenedicarboxylic acids have the *cis*-configuration and exist in the *syn,syn*-boat form[192,203] like the *cis*-tricyclo-octane compounds, although the stabilising role of the torsional interactions is reduced by a factor of two compared with compound (LXXVII), while the electrostatic interactions are clearly unfavourable. These facts have no simple explanation and must be regarded as the manifestation of a specific conformational effect (the Pangolin effect).

In polycyclic anhydrides and imides of the type (LXXXVI, $R = CCl_2$ or CO, X = O or NAr, R^1 = H or Me) the cyclohexane ring has the *syn*-boat conformation in relation to the five-membered ring, so that the more bulky bridge system occupies the equatorial positions[232,233].

(LXXXVI)

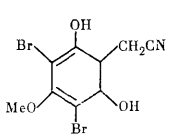
(LXXXVII)

The exceptions to this rule are due to the equatorial location of the substituent R^1 *trans*-oriented relative to the five-membered ring.



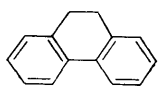
The bisadduct of quinone and cyclopentadiene (LXXXVII, $R = CH_2$)[234] and its tetrahydro-derivatives[235] have been investigated by X-ray diffraction. In the former case the carbonyl carbon atoms are displaced from the plane of the sp^3-atoms of the central ring by 0.37 Å, which corresponds to the classical boat conformation; a planar structure has been obtained by Norment[235]. This shows that small changes in the crystal lattice can give rise to a powerful conformational effect. In solutions the molecules have the boat conformation[208], which undergoes inversion at a high rate[236].

V. 1,3-DIPLANAR SYSTEMS



1. Cyclohexa-1,3-diene and Its Analogues

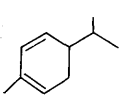
(a) The Ring Conformation



If two planar systems in the ring have a common bond, the only possibility for conformational movements is rotation about this bond [C(2)–C(3) in cyclohexa-1,3-diene (LXXXVIII)] until the distance between the C(5) and C(6) atoms becomes equal to the length of the C–C bond.

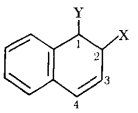
(LXXXVIII)

(LXXXIX)



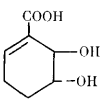
(XC)

In the molecule of compound (LXXXVIII) the angle ω between the planes of the double bonds is 17°,[237] 17.96°,[238] or 18.34°[148] according to electron diffraction data. A microwave study yielded 17.5°.[239] Spectroscopic data confirm the C_2 symmetry[142,240]. Two mirror-isomeric forms are separated by a fairly high inversion barrier, amounting to 3.15 kcal mol^{-1},[142] although a transition can be induced by rotation by only 35°. Theoretical calculations reproduce satisfactorily the height of the barrier and the positions of the potential energy minima (ω = 17–18°);[148,149,155] it is of interest that this angle has been obtained from the analysis of Dreiding models[241]. An X-ray diffraction study of compound (LXXXIX) yielded an angle of 17.3°;[242] in polycyclic systems the angle can diminish to 15° in steroids, 14° in glyotoxin, and 11.8° and 9.1° in laevopimaric acid[24,25].

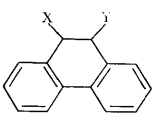


Calculation for the 9,10-dihydrophenanthrene fragment of compound (XC) yielded almost the same value as for cyclohexa-1,3-diene, namely ω = 15.3°.[243] The values of ω found for the crystalline phases of dihydrophenanthrenes[244,245], their benzo-derivatives[25], and their analogues with heteroaromatic rings[246,247] vary in the range 9.3–21°. Thus the cyclohexa-1,3-diene system exhibits a unique conformational constancy associated with the rigidity of its structure.

(b) The Conformation of the Substituents in the 5(6)-Positions



Since both sp^3-atoms are allylic, they are characterised by a pseudoaxial orientation of the substituents. Such orientation of the isopropyl group is in fact preferred for phellandrene (XCI):[248,249] $\Delta G = -0.42$ kcal mol^{-1}.[249]



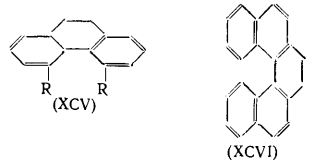
(XCI)

(XCII)

(XCIII)

(XCIV)

A comparison for a series of 5-alkyl derivatives has been carried out by an indirect method based on the ratio of the ring opening products; the pseudoaxial position was found to be energetically more favourable by an amount ranging from 0.24 kcal mol^{-1} for methyl to 2.98 kcal mol^{-1} for t-butyl[250]. The calculation[153] for the 5-methyl derivative predicted a greater stability of the pseudoequatorial form, but only to the extent of 0.025 kcal mol^{-1}. The two possible orientations of substituents such as the fluoro-, cyano-, and nitro-groups were also almost equivalent and the pseudoaxial position is appreciably preferred only for the hydroxyl and amino-groups: $\Delta G \cong -0.6$ kcal mol^{-1}.



The substituents in the 2-position in the 1,2-dihydronaphthalene system (XCII, X = COR, Y = H) behave in the same manner: $\Delta G = -0.6 \pm 0.1$ kcal mol^{-1} for carbonyl functional groups, while for chlorine the two orientations are energetically equivalent[251]. On the other hand, the substituents in the benzyl 1-position in compound (XCII, X = H, Y = COR) are appreciably more axial[252,253] as a consequence of the $A^{1,3}$ strain. The *trans*-1,2-disubstituted dihydronaphthalenes are also preferentially diaxial and the introduction of a further substituent at the atom in the 8-position renders this form anancomeric [?enantiomeric][253–256]. The *trans*-5,6-derivatives of cyclohexa-1,3-diene have been scarcely investigated. It has only been observed that the conformational composition of dihydroxydihydrobenzoic acid (XCIII) varies sharply as a function of the solvent[257].

The substituents at the C_{sp^3} atoms of 9,10-dihydrophenanthrene (XCIV) are also preferentially pseudoaxial: the methyl, carbonyl, and dimethyl amino-groups are 75–80% pseudoaxial, and bulky substituents such as the t-butyl and trimethylsilyl groups are fully pseudoaxial; the cyano-group is as usual conformationally indifferent[258,259]. The *trans*-9,10-disubstituted derivatives are diaxial[258,260].

(c) Ring Inversion in 9,10-Dihydrophenanthrenes

Unsubstituted compounds with the cyclohexa-1,3-diene fragment have small inversion barriers[253], in agreement with calculation[261]. Their increase to a value measurable by NMR is acheived by the introduction of *cis*-substituents in the 9- and 10-positions in the dihydrophenanthrene

(XCIV) molecule[262], as in the cyclohexene series. The increase of steric hindrance in compounds of types (XCV) and (XCVI) gives rise to the possibility of the separation of the conformers, i.e. the barriers are more than 20 kcal mol^{-1}.

(XCV)

(XCVI)

The racemisation of bridged biphenyls has been the subject of numerous studies[259,263,264].

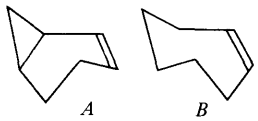


Figure 7. The relative positions of the bonds in the bicyclo[4.1.0]hept-2-ene molecule: *A*) *syn*-form; *B*) *anti*-form.

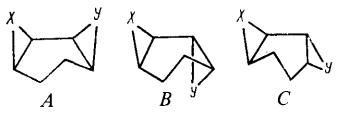

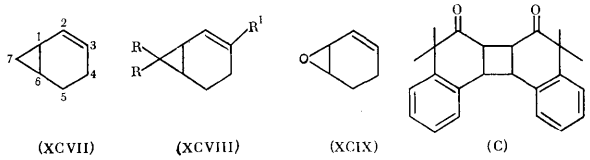

Figure 8. The steric structures of 1,3-diplanar compounds of the tricyclooctane series: *A*) *cis*-form; *B*) *trans,syn,syn*-form; *C*) *trans,anti,anti*-form.

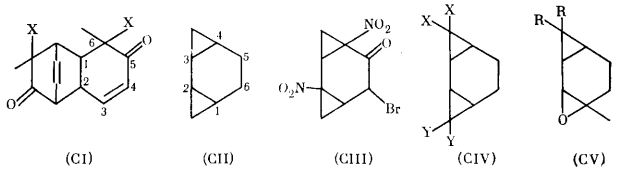
2. The Bicyclo[4.1.0]hept-2-ene Series



When a three-membered ring is introduced, two directions of the relative movement of the planar groups become non-equivalent. The atom in the 4-position in the (XCVII) system moves towards the three-membered ring (*syn*) or in the opposite direction (*anti*) (Fig.7). The study of compound (XCVII) by gas electron diffraction showed that the dihedral angle of the C(1)–C(2) bond is 15.4°, i.e. it hardly changes compared with cyclohexa-1,3-diene. The ratio of the *syn*- and *anti*-forms is 3:7. The *anti*-form has also been found for 2-carene (XCVIII; R = R^1 = Me) [265] and its 7,7-dihalogeno-derivatives with R = Cl or Br and R^1 = H. [266] The opposite conclusion concerning the stability of the *syn*-boat form has been reached on the basis of the NMR spectrum for R = H and R^1 = Me. [267]

(XCVII) (XCVIII) (XCIX) (C)

The internal rotation potential energy curve has been investigated for the 7-oxa-derivative (XCIX); [198] it has two minima with an energy difference of 1.09 kcal mol^{-1}, also in favour of the *anti*-form. The inversion barrier is the same as in cyclohexadiene (3.82 kcal mol^{-1}). The flattening of the ring has been observed in some derivatives[268].

The tetralin fragment in the molecule of compound (C) has an analogous *anti*-conformation[269]. Among the molecules containing the cyclohexane ring 1,3-condensed with a bicylic system, the keto-derivatives (CI) have been studied.

(CI) (CII) (CIII) (CIV) (CV)

According to the conjugation conditions, they exist in the envelope form with displacement of the C(6) atom from the plane of the ring by 0.70 ± 0.13 Å: [270] the isomer in which the attractive interactions stabilise the *syn*-conformation is an exception[271].

3. Tricyclo[5.1.0.0^{2,4}] Octane and Its Heteroanalogues

As for the 1,4-diplanar analogues, the conformational behaviour of the tricyclic compounds (XCII) depends on their configuration. As a result of the rotation about the C(2)–C(3) bond in the *cis*-isomer, one of the three-membered rings acquires an environment of the *syn*-type while the other acquires one of the *anti*-type (Fig.8). On the other hand, the two conformations of the *trans*-isomer differ. Electron diffraction study of the two isomers of compound (XCII) yielded the angles ω = 17.87–18.20° (*cis*-isomer) and 15.75–16.68° (*trans*-isomer). [272] The *trans*-isomer consists of a mixture of conformers, but, in contrast to compound (XCVII), the *syn,syn*-conformer proved to be more stable (87 ± 5%). Evidently, the direction of the bend in the 1,3-diplanar system depends on very fine structural details. Furthermore, the *syn,syn*-form has been discovered for compound (CIII). [24] The *syn*-orientation is impossible for a three-membered ring with large substituents and for this reason the *anti,anti*-form of all the compounds (CIV, X,Y = Cl, Br, or Me) is stable[266]. The *trans*-oxide of 2-carene (CV, R = Me) exists in the same form[265]. The removal of the *gem*-dimethyl group leads to inversion to the same *syn,syn*-form as for the *trans*-isomer of compound (CII), [226]

The *cis*-isomers have been scarcely investigated. In the *cis*-dioxides of the terpene series the angle ω = 15–16° is retained[25]. If the rings are different, as in the *cis*-oxide of 2-norcarene (CV, R = H), the *syn*-conformation relative to the oxygen atom, which has less stringent steric requirements than the methylene group, is the most stable[226,267].

---oOo---

The data examined show that six-membered carbon rings with planar groups of atoms are characterised by certain common features in their conformational behaviour despite the wide variety of their structures. These include the tendency of the cyclohexane ring to assume the boat conformation on condensation with rigid rings, which may be due to torsional or electrostatic factors, as in the *syn*-boat form of bicyclo[4.1.0]heptane systems, the steric interactions, as

in the *anti*-boat form of polysubstituted bicycloheptanes, and the ring closure conditions, as in perhydrotriptycenes. Next, it is necessary to note the relative stability of the axial and pseudoaxial positions of the substituents, including bonds belonging to planarising cyclic groups. The preferential pseudoaxial orientation of the condensed three-membered rings is responsible for the stability of the *syn*-conformers even in the presence of pronounced steric hindrance.

The extents to which the different types of compounds have been investigated from the conformational standpoint are by no means the same; in a number of instances it is still impossible to speak of rigorous rules. However, the interest aroused by the conformational studies in this field, including the analysis of the stereochemical reactions, gives rise to the hope that considerable advances will be achieved in the immediate future.

P-Hetero-substituted Phosphorus Ylides

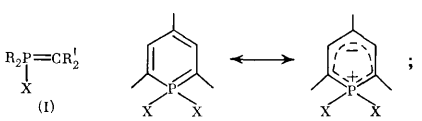
O.I.Kolodyazhnyi and V.P.Kukhar'

The literature data on the methods of synthesis and properties of ylides containing various heteroatoms at the phosphorus atom in the P = C group are surveyed and described systematically.
The bibliography includes 134 references.

CONTENTS

I. Introduction 1096
II. Methods of synthesis 1096
III. Properties 1102

I. INTRODUCTION



The interest in the chemistry of phosphorus ylides is due to the great theoretical and practical importance of these reactive compounds[1,2]. Phosphonium ylides are widely used in the laboratory and industrial Wittig synthesis of olefins and are employed in the synthesis of strained cycloalkanes, macrocyclic compounds, cyclic dienes and heavy metal complexes[3-10].

Structurally phosphorus ylides are carbanions stabilised by the neighbouring phosphonium group[1]:

$$R_3P{=}CR'_2 \longleftrightarrow R_3\overset{+}{P}{-}\overline{C}R'_2 .$$

The stability and reactivity of phosphorus ylides depend to a large extent on the substituents R' at the carbanionic centre. By varying these substituents, it is possible to obtain all possible types of *C*-substituted phosphorus ylides with exceptionally varied properties[1-10]. However, the substituents R at the phosphonium centre also exert a significant influence on the properties of ylides. Ylides containing heteroatoms attached to the phosphorus atom have especially interesting and frequently unusual properties; the chemistry of these compounds began to be investigated only in recent years. The principal results achieved in the synthesis and investigation of the properties of *P*-hetero-substituted phosphorus ylides (I) and published up to 1983 are the subject of the present review.

The review deals with acyclic *P*-hetero-substituted phosphorus ylides. Ylides containing a P=C bond in the ring, particularly λ^5-phosphorins, are not discussed in detail, since these compounds have specific chemical properties which resemble little those of acyclic phosphorus ylides:

(I)

X = Cl, Br, RS, R_2P, R_3Si, RO, HO, R_2N, RNH, H .

Electrophilic substitution reactions in the C(4)-position, comparable to the analogous reactions of other electron-enriched aromatic systems, for example, dimethylaniline, are characteristic of *P*-hetero-substituted λ^5-phosphorins. Their basicity and nucleophilicity are very low, they form stable radicals, give rise to stable π-complexes with heavy metal salts, etc.[11] Physicochemical studies confirming the unusual electronic structure of λ^5-phosphorins nevertheless make it possible to regard them as ylides in which the negative charge of the carbanionic component is delocalised over the ring[12,13].

II. METHODS OF SYNTHESIS

There exist several methods for the synthesis of *P*-hetero-substituted ylides. These compounds are usually obtained by the "oxidative ylidation" of phosphorus(III) compounds. The term "oxidative ylidation" implies reactions as a result of which the coordination number of the tervalent phosphorus atom increases and a P=C bond with a tetracoordinate phosphorus atom is formed[14]. Depending on the structure of the initial tervalent phosphorus compounds, their ylidation can proceed via two pathways: either a substituent X is introduced at the phosphorus atom of compound (II) with simultaneous deprotonation of the α-carbon atom or an alkylidene group is introduced in some way at the phosphorus atom of an X-substituted phosphine:

$$\underset{(II)}{R_2P{-}CHR'_2} \xrightarrow[-H^+]{[X]} \underset{(I)}{R_2P(X){=}CR'_2} \xleftarrow{I\diagdown\!\!\diagup CR'_2I} R_2PX .$$

The remaining methods of synthesis, especially the dehydrohalogenation of phosphonium salts and the conversion of one *P*-hetero-substituted phosphorus ylide into another, are used only in individual instances, but they sometimes have an advantage over "oxidative ylidation".

1. "Oxidative Ylidation" of Tervalent Phosphorus CH Acids

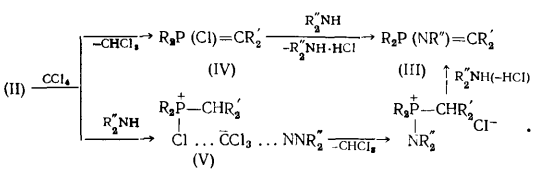
The "oxidative ylidation" of tertiary phosphines and phosphonites (II), containing a mobile hydrogen atom at the α-carbon atom and behaving as CH acids of tervalent phosphorus, must be regarded as the most flexible and general approach to the synthesis of *P*-hetero-substituted ylides[14-16]. Compounds (II) containing at the α-carbon atom only electron-accepting substituents R', enhancing the mobility of the hydrogen atoms and stabilising the ylide function, are ylidated most readily. However, in many instances it is possible to ylidate successfully also weak CH acids, such as, for example, trialkylphosphines. The phosphorus(III) CH acids are carbon analogues of the phosphorus(III) OH acids[14-20] and can be converted into ylides in the same way as the OH acids of tervalent phosphorus form compounds with a P=O group. In particular, the phosphorus(III) CH acids undergo reactions resembling the Atherton–Todd, Michaelis–Becker, etc. reactions characteristic of dialkyl phosphites. Certain alkylphosphines of type (II) isomerise to ylides with a P–H bond, analogous to the prototropic P(O)H forms of the phosphorus(III) OH acids, which emphasises still further the similarity of these types of organophosphorus compounds[18]:

$$R_2P{-}CHR'_2 \rightleftarrows R_2P(H){=}CR'_2 \quad R_2P{-}OH \rightleftarrows R_2P(H){=}O .$$

(a) Reactions of Compound (II) with Carbon Tetrahalides

Tertiary phosphines and phosphonites (II) containing electron-accepting substituents at the α-carbon atom are ylidated on interaction with carbon tetrachloride and alkylamines, aniline, or ammonia[15,16,19-22]. The reaction models the Atherton–Todd reaction, according to which dialkyl phosphites react with CCl_4 and alkylamines to form phosphoric acid amides[23]. The interaction of compound (II) with CCl_4 and alkylamines and also ammonia proceeds readily in ether at 0 °C, but the reaction with aniline must be carried out, in view of the low basicity of the latter, in the presence of triethylamine. The method employs readily available starting materials and makes it possible to vary widely the substituents at the phosphorus and carbon atoms of the P=C group:

$$R_2P{-}CHR'_2 \xrightarrow[-CHCl_3,\ -R''_2NH\cdot HCl]{CCl_4+R''_2NH} R_2P(NR''_2){=}CR'_2 \quad ;$$



(II) (III), (50–70%)

R = Et, iso-Pr, Ph, EtO, iso-PrO; CR'_2 = $CHCO_2Et$, $CPhCO_2Me$, $C(CO_2Me)_2$, $CHSO_2CF_3$, $C(SO_2Ph)_2$; NR''_2 = NH_2, NHMe, NHPr-iso, NMe_2, NEt_2 ;

$$(iso\text{-}PrO)_2P{-}CH(CO_2Et)_2 \xrightarrow[-CHCl_3,\ -Et_3N\cdot HCl]{CCl_4+PhNH_2+Et_3N} (iso\text{-}PrO)_2P(PhNH){=}C(CO_2Et)_2 \ .$$

Compounds (II) are converted into ylides (III) via the intermediate formation of *P*-halogenoylides (IV)[15,20] or via the complex (V)[21]. Depending on the reaction conditions, the first or second pathway is followed (Scheme 1).

Scheme 1

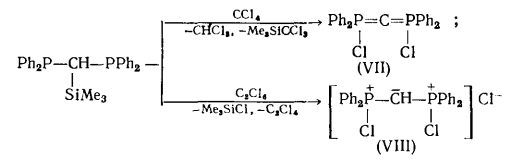
In the absence of amines, compounds (II) react with $CHal_4$ to form ylides with a halogen atom attached to the phosphorus atom[14,16,24-30]:

$$R_2P{-}CHR'_2 + CHal_4 \rightarrow R_2P(Hal){=}CR'_2 + CHHal_3 \ ;$$

(II) (VI)

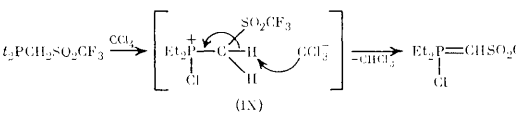
R = Et, iso-Pr, t-Bu, Ph, EtO, iso-PrO, Me_2N, Et_2N;

CR'_2 = CH_2, CHMe, CHPr, CHPr-iso, $CHSiMe_3$, CHSMe, CPh_2, fluorenylidene, cyclopentadienylidene, $C(SiMe_3)_2$, $CPhSiMe_3$, $C(CO_2Me)_2$, $C(CO_2Et)_2$, $C(SO_2Ph)_2$, $CHSO_2CF_3$;



Hal = Cl, Br

The interaction of trialkylphosphines with carbon tetrachloride takes place readily on cooling to a temperature below 0 °C; less nucleophilic phosphonites react with carbon tetrachloride and are converted into *P*-chloroylides at an appreciable rate only in the presence of triethylamine, which exhibits a catalytic activity[14]:



$$(EtO)_2P{-}CH(CO_2Et)_2 \underset{+H^+}{\overset{B,\ -H^+}{\rightleftharpoons}} \left[(EtO)_2P{-}\bar{C}(CO_2Et)_2 \rightleftharpoons (EtO)_2\bar{P}{=}C(CO_2Et)_2\right] \xrightarrow[-CHCl_3]{CCl_4} (EtO)_2P(Cl){=}C(CO_2Et)_2 \ .$$

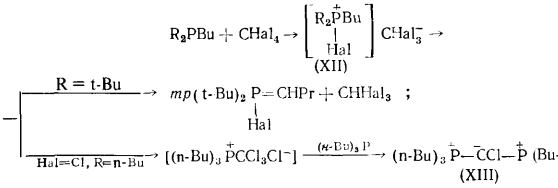
However, phosphonites react with the very reactive carbon tetrabromide to form *P*-bromoylides even in the absence of triethylamine at −70 °C.[14] The yields of *P*-halogenoylides (VI) are usually high.

Interesting possibilities appear after the introduction of the trimethylsilyl group at the α-carbon atom in compound (II). Thus trimethylsilylbis(diphenylphosphino)methane gives rise to carbodiphosphorane (VII) on interaction with carbon tetrachloride as a result of the elimination of tribromotrimethylsilylethane and chloroform, while the reaction with hexachloroethane results in the formation of the ylide (VIII)[31,32]:

Compounds (II) are converted into *P*-halogenoylides owing to the presence of a mobile hydrogen atom at the α-carbon atom, as a result of which the anion $CHal_3^-$ readily deprotonates the quasi-phosphonium salt (IX) formed in the intermediate stage. Electron-accepting substituents at the α-carbon atom, which increase the mobility of the hydrogen atom, promote the formation of *P*-halogenoylides[14]:

However, weak CH acids such as trialkylphosphines can also be converted into *P*-halogenoylides, provided that there are bulky substituents at the phosphorus atom[28,29]:

$$t\text{-}Bu(R)PCH_2R' \xrightarrow[-CHHal_3]{CHal_4} t\text{-}Bu(R)P(Hal){=}CHR' \ ;$$



(X) (XI)

R = t-Bu, n-Bu, Et_2N, Me_2N; R′ = H, Me, n-Pr, iso-Pr; Hal = Cl, Br .

The "unstabilised" *P*-halogenoylides (XI) formed under these conditions are extremely reactive and are used for the synthesis of many interesting organophosphorus compounds.

Sterically unhindered tertiary phosphines, for example Me_3P or $n\text{-}Bu_3P$, do not form *P*-chlorides on interaction with CCl_4 but give rise to phosphoranylphosphonium salts (XIII)[33]. On the other hand, tertiary phosphines containing the t-butyl group are converted quantitatively into *P*-halogenoylides on interaction with carbon tetrahalides[28]. The influence of the steric shielding of the phosphorus atom on the pathway followed in the reactions of tertiary phosphines with carbon tetrahalides can be accounted for by Scheme 2 below:

Scheme 2

The interaction of a tertiary phosphine with $CHal_4$ results in the formation of the ion pair (XII), whose further reaction can proceed via two pathways: via the nucleophilic attack by $CHal_3^-$ on the phosphonium cation (anion exchange) or via the deprotonation of the α-carbon atom. The steric hindrance at the phosphorus atom generated by the t-butyl group is an obstacle to the interaction of $CHal_3^-$ with the phosphonium cation, as a consequence of which the deprotonation of the α-carbon atom becomes the dominant process. The mechanism has been confirmed by experimental observations[28].

The interaction of sterically hindered tertiary phosphines with carbon tetrabromide at −120 °C results in the formation of bright orange solid substances–bromophosphonium tribromomethanides (XIV)[28]. They exist at a very low temperature and, on increasing the latter to −90°– −60 °C, they are converted quantitatively into *P*-bromoylides. The stability of these unusual compounds is undoubtedly determined by the steric influence of the t-butyl groups at the phosphonium cation. Ion pairs of this type are also formed on interaction of sterically unhindered tertiary phosphines with carbon tetrahalides. However, in this case they behave as short-lived intermediates and can be "captured" by the proton-donating reagents only at the instant of their formation[34].

A conclusion concerning the structure of bromophosphonium tribromomethanides was reached on the basis of the study of their chemical reactions[28]. The reactions with deuterium chloride and chlorotrimethylsilane convincingly demonstrate the presence of the CBr_3^- anion:

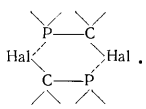
$$(t\text{-Bu})_2PR + CBr_4 \xrightarrow{-120^\circ} (t\text{-Bu})_2\overset{+}{P}(Br)RCBr_3^- \ ;$$

R = t-Bu, n-Bu, Et_2N (XIV)

$$(XIV) \xrightarrow{-60^\circ,\ R=n\text{-Bu}} (t\text{-Bu})_2P(Br)=CHPr + CHBr_3 \ ;$$

$$(XIV) \xrightarrow{-120^\circ,\ DCl} (t\text{-Bu})_2(R)\overset{+}{P}ClBr^- + CDBr_3 \ ;$$

$$(XIV) \xrightarrow{-120^\circ,\ Me_3SiCl} (t\text{-Bu})_2(R)\overset{+}{P}ClBr^- + Me_3SiCBr_3 \ .$$



(b) The α-Halogenoalkylphosphine–P-Halogenoylide Rearrangement

The α-halogenoalkylphosphines (XV), formed on interaction of phosphinochloridous acids with halogenosulphonylmethanes, readily rearrange to *P*-halogenoylides (VI)[21,35]:

$$R_2PCl \xrightarrow[Na^+[HalCR'_2]^-]{HalCHR'_2+Et_3N} R_2P{-}\underset{(XV)}{CR'_2}{-}Hal \rightarrow \underset{(VI)}{R_2P(Hal)=CR'_2} \ ;$$

R = Et, iso-Pr, Ph; $CR'_2 = CHSO_2CF_3$, $C(SO_2Ph)_2$; Hal = Cl, Br .

The migration of the halogen atom from the α-carbon atom to the phosphorus atom (the C → P halogenotropic shift) increases the coordination number of the phosphorus atom and results in the formation of a P=C bond, i.e. "oxidative ylidation" takes place. The α-halogenoalkylphosphine (XV) contains a "positively charged" halogen to which the nucleophilic attack by the tervalent phosphorus atom may be directed, resulting in the abstraction of the halogen from the carbon atom. It is entirely likely that the transfer of the halogen from the carbon atom to the phosphorus atom proceeds via a six-membered transition state:

Electron-accepting substituents at the phosphorus atom, particularly halogen atoms, which make it less nucleophilic, prevent the rearrangement[36]:

$$Cl_3P + ClCH(CO_2Et)_2 \xrightarrow[-Et_3N\cdot HCl]{Et_3N} Cl_2P{-}\underset{Cl}{C}(CO_2Et)_2 \not\rightarrow Cl_3P{=}C(CO_2Et)_2 \ .$$

The α-halogenoalkylphosphine–*P*-halogenoylide rearrangement was first observed in a number of compounds containing sulphonyl groups at the α-carbon atom[21,35]. However, it was shown subsequently that certain silicon-containing α-chloroalkylphosphines also readily rearrange to *P*-chloroylides[37,38]:

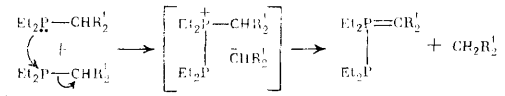
$$Me_2PLi + Cl_2C(SiCl_3)_2 \rightarrow Me_2P{-}\underset{Cl}{C}(SiCl_3)_2 \rightarrow Me_2P{=}\underset{Cl}{C}(SiCl_3)_2 \ ;$$

$$R_2PCl + LiClC(SiMe_3)_2 \rightarrow R_2P{-}\underset{Cl}{C}(SiMe_3)_2 \rightarrow R_2P{=}\underset{Cl}{C}(SiMe_3)_2 \ ;$$

R = Ph, Me_2N .

(c) Disproportionation of Tertiary Phosphines with a Mobile Hydrogen Atom at the α-Carbon Atom

Tervalent phosphorus compounds with a mobile hydrogen atom at the α-carbon atom exhibit a distinct tendency to be converted into phosphorus ylides. Thus diethylbis(alkoxycarbonyl)methylphosphines and diethyltrifluoromethanesulphonylmethylphosphine disproportionate on heating with formation of the ylides (XVII) containing a phosphorus–phosphorus bond[14,39]:



$$\underset{(XVI)}{2Et_2P{-}CHR'_2} \xrightarrow{120^\circ} \underset{(XVII)}{Et_2P{-}PEt_2{=}CR'_2} + CH_2R'_2 \ ;$$

$CR'_2 = CHSO_2CF_3$, $C(CO_2Me)_2$, $C(CO_2Et)_2$.

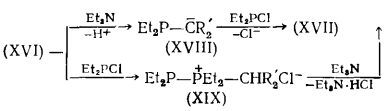
The disproportionation of compounds (XVI) is a reversible process. On heating with the simultaneous removal from the reaction sphere of the non-phosphorylated component $CH_2R'_2$, the equilibrium is fully displaced in the direction of the P–P ylides (XVII). Without heating and the removal of $CH_2R'_2$, the disproportionation of compounds (XVI) does not take place.

Scheme 3, taking into account the high lability of the P–P bond in compounds (XVI), explains the formation of P–P ylides (XVII).

Scheme 3

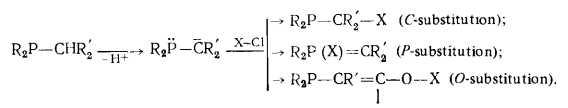
This lability is due to the effective stabilisation by the electron-accepting substituents R', formed on dissociation of the P–C bond of the carbanion CHR'_2, which becomes capable of playing the role of a readily eliminated group. Compounds (XVI) are cleaved at the P–C bond by alcohols, water, ketoenols, thiols, etc.[14]

The structure of the P–P ylides (XVII) is confirmed by spectroscopic data. The ^{31}P NMR spectra of the ylides (XVII) contain a double doublet of signals due to the tricoordinate and tetracoordinate phosphorus atoms. The constant $^1J_{PP}$ = 270–280 Hz corresponds to the spin–spin coupling of the phosphorus nuclei in the tetracoordinate phosphorus–tricoordinate phosphorus bond.



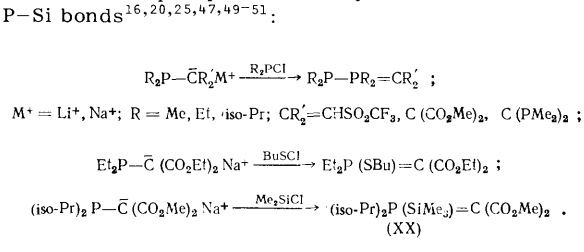
(d) Reactions of Tervalent Phosphorus CH Acids and Their Carbanions with Chlorine-containing Electrophiles

Tervalent phosphorus compounds (XVI) containing a mobile hydrogen atom at the α-carbon atoms form P–P ylides (XVII) also on interaction with chlorodiethylphosphine in the presence of triethylamine[14,20,40]. The reaction is carried out in ether at 0–10 °C:

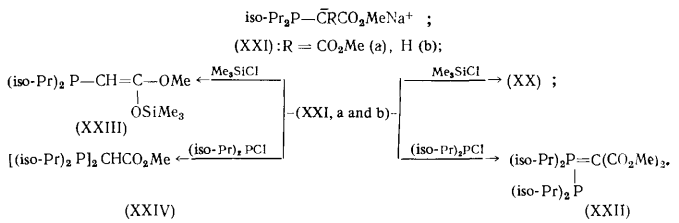


$$(XVI) + Et_2PCl \xrightarrow[-Et_3N\cdot HCl]{Et_3N} (XVII) \ .$$

A convenient method of synthesis of the P–P ylides (XVII) involves the reaction of malonic ester or trifluoromethanesulphonylmethane with two equivalents of chlorodiethylphosphine in the presence of an excess of triethylamine[14,39]. The tertiary phosphines (XVI), formed in the intermediate stage, can be obtained in high yields when the starting reactants are taken in proportions of 1:1.[14,25,40,41]

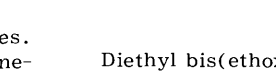


The P–P ylides (XVII) are apparently formed as a result of the *P*-phosphorylation of the α-phosphinocarbanion (XVIII) However, one cannot rule out also the electrophilic attack by chlorodiethylphosphine on the tervalent phosphorus atom of the tertiary phosphine (XVI) with subsequent dehydrochlorination of the phosphonium salt (XIX) (formed under these conditions) under the influence of triethylamine:



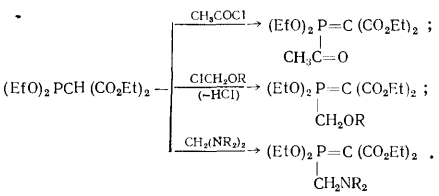
The α-phosphinocarbanions (XVIII), which are obtained by deprotonating alkylphosphines by various bases [lithium alkyls[20,42–45], sodium bis(trimethylsilyl)amide[46], sodium hydride[47], and even alkylamines[48]], can be converted in many instances into *P*-hetero-substituted phosphorus ylides. In principle, α-phosphinocarbanions can react with chlorine-containing electrophiles to form products substituted both at the carbon atom and at the phosphorus atom and, when the C=O group is present at the carbanionic centre, also products substituted at the oxygen atom:

The mode of reaction of ambident α-phosphinocarbanions with chlorine-containing electrophiles (alkyl halides, tervalent phosphorus chlorides, sulphene chlorides, and chlorotrimethylsilane) is determined by kinetic and thermodynamic factors and depends primarily on the structure of the initial reactants. The presence of the electron-accepting groups CO_2R, SO_2R, and Me_2P at the α-carbon atom stabilises the ylide functional group, favouring the formation of products substituted at the phosphorus atom—ylides with P–P, P–S, and P–Si bonds[16,20,25,47,49–51]:



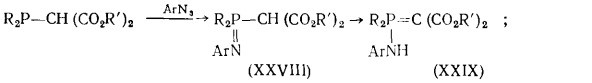
The influence of electron-accepting groups with substituents on the mode of reaction of α-phosphinocarbanions with chlorine-containing electrophiles is demonstrated by the following example. The carbanion (XXIa), containing two methoxycarbonyl groups, reacts with iso-Pr_2PCl and Me_3SiCl to form the ylides (XX) and (XXII)[47], while the carbanion (XXIb), with a single methoxycarbonyl group, gives rise to only the products (XXIII) and (XXIV) substituted at the C and O atoms[52]. The stabilisation of the *P*-substitution products by only one MeO_2C group in the latter case is insufficient:

When bis(diphenylphosphino)methyl-lithium reacts with chlorodialkylphosphines at −78 °C, a P–P ylide (XXV) is formed and, on raising the temperature to 20 °C, rearranges to triphosphinomethane (XXVI)[49]. Evidently, under the conditions of kinetic control, the less stable *P*-substitution product is formed and is then converted into the thermodynamically more favourable *C*-substitution product:



Steric hindrance is an obstacle to the rearrangement to triphosphinomethane, as a result of which the P–P ylide (XXVII) is isolated in a pure state[49]:

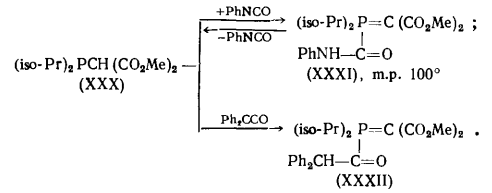
Diethyl bis(ethoxycarbonyl)methylphosphonite readily forms ylides by interaction with acetyl chloride in the presence of bases[53,54], with α-chloroethers under the conditions of the Arbuzov reaction[55], and also with aminomethylenes under the conditions of the Kabachnik–Fields reaction[56] (Scheme 4):



Scheme 4

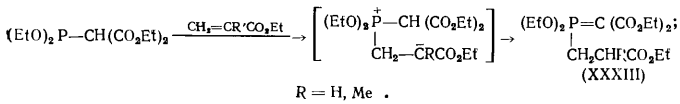
(e) Prototropic Transformations of Phosphorylated CH Acids

The use of tervalent phosphorus compounds containing a mobile hydrogen atom at the α-carbon atom makes it possible to realise the extensive possibilities for their conversion into ylides as a result of reactions involving prototropic rearrangements.



The Staudinger imination of bis(alkoxycarbonyl)methylphosphines and the analogous phosphonites by aryl azides yields the phosphazo-compounds (XXVIII), which readily rearrange to the ylides (XXIX) with the RNH group at the phosphorus atom[41,57–59] (for the phosphazo-ylide tautomerism, see Section III.4):

The driving force of this rearrangement is the endeavour by the system to form the least "acid" tautomeric form.



Phenyl isocyanate and diphenylketen readily add to the tertiary phosphine (XXX). The reaction proceeds with formation of the *P*-acyl-substituted ylides (XXXI) and

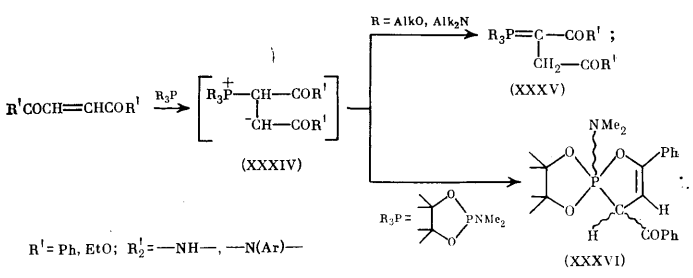
(XXXII)[25]:

The ylide (XXXI) is stable in the crystalline state, but in solutions it dissociates into the initial compounds. On cooling or removal of the solvent, the ylide (XXXI) is recovered from the solution in the crystalline form.

Diethyl bis(ethoxycarbonyl)methylphosphonite reacts with acrylic and methacrylic acid esters under the conditions of the Pudovik reaction with formation of the ylides (XXXIII)[60]:

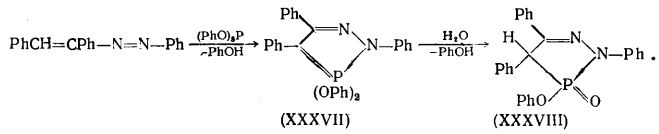
It has been noted that in the presence of alkaline catalysts the yields of the ylides increase and the reaction is accelerated.

2. Introduction of an Alkylidene Group into Tervalent Phosphorus Compounds



P-Hetero-substituted phosphorus ylides are formed when tervalent phosphorus acid derivatives interact with various compounds serving as sources of a substituted methylene fragment. Such sources can be carbenes, carbenoids, and various compounds with activated multiple bonds.

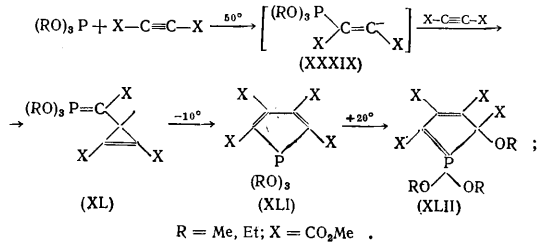
(a) Reactions of Tervalent Phosphorus Compounds with Alkenes and Alkynes



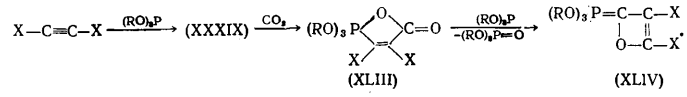
Compounds with an activated multiple bond readily react with tervalent phosphorus compounds and give rise to phosphorus ylides in many instances. Nucleophilic attack by the tervalent phosphorus atom on the electron-unsaturated carbon atom in the activated double bond produces a very reactive betaine (XXXIV), which readily rearranges to an ylide. An adequate mobility of the α-hydrogen atom is a condition which must be fulfilled for such a rearrangement. In the presence of the electron-accepting carbonyl group, the rearrangement of the betaine (XXXIV) to its less "acid" prototropic form, namely the ylide (XXXV), takes place readily. Thus the amides and esters of tervalent phosphorus acids add to maleimides[61-63], fumaric acid esters[64], and *trans*-dibenzoylethylene[65] with formation of the ylides (XXXV).

However, the presence of the five-membered dioxaphospholan ring favours the cyclisation of the betaine (XXXIV) to the phosphorane (XXXVI)[64] (Scheme 5).

Scheme 5

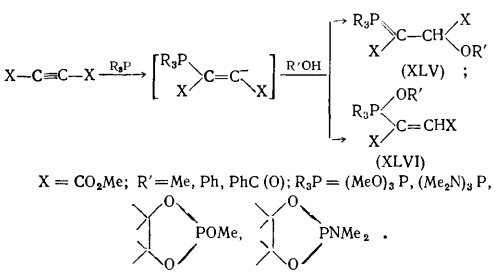


The ylides (XXXVII) with phenoxy-groups at the phosphorus atom have been obtained as a result of the [1 + 4]-cycloaddition of triphenyl phosphite to a conjugated azoalkene[66]. The chemical shift $\delta p = +43.7$ p.p.m. rules out a structure of the compound with a pentacoordinate phosphorus. The ylide (XXXVII) is very hygroscopic and is formed as a colourless solid product only after the complete removal of traces of moisture from the reaction mixture. In the presence of moisture, the ylide is instantly converted into the diazophosphole (XXXVIII):



The reactions of acetylenedicarboxylic acid derivatives with tervalent phosphorus esters and amides proceeds in an interesting fashion. Thus the interaction of the methyl ester of this acid with trialkyl phosphites leads to the formation of the cyclic ylides (XLII) containing alkoxy-groups at the phosphorus atom[67,68]. NMR study of the reaction at a low temperature showed that the betaine (XXXIX) is formed initially and then its interaction with a second acetylenedicarboxylate molecule gives rise to the ylide (XL) with the cyclopropenyl group at the α-carbon atom. This ylide exists at −50 °C but, on raising the temperature to −10 °C, rearranges to the phosphorane (XLI), whose structure has been confirmed by the ^{31}P NMR spectrum ($\delta p = -37.4$ p.p.m.). At 20 °C the phosphorane is converted into the cyclic ylide (XLII)[67,68] via Scheme 6.

Scheme 6



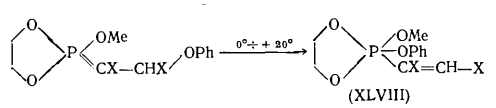
The ylides (XLII) have been obtained in the form of a crystalline substance and their structure has been convincingly confirmed by spectroscopic studies.

The betaine (XXXIX) interacts with carbon dioxide to form the phosphorane (XLIII) ($\delta p = -53.8$ p.p.m.), which is stable at a low temperature, but at 20 °C reacts with a second trialkyl phosphite molecule, gives up an oxygen atom to the latter, and is converted into the ylide (XLIV)[69]:

In the presence of hydroxylated reagents, the reaction of acetylenedicarboxylate ester with phosphites leads to the formation of ylides or phosphoranes. Acyclic phosphites give rise to the ylides (XLV), while five-membered cyclic phosphites yield the phosphoranes (XLVI)[70-72] (Scheme 7):

Scheme 7

(XLVI)



$X = CO_2Me$; $R' = Me$, Ph, PhC (O); $R_3P = (MeO)_3P$, $(Me_2N)_3P$,

Interesting transitions between the ylide and phosphorane structures, whose direction depends on the substituent R at the phosphorus atom and on the nature of the proton-donating reagent, have been observed with the aid of ^{31}P NMR. The rearrangement of the ylide to the phosphorane was observed in the interaction of trimethyl phosphite with acetylenedicarboxylate ester in the presence of a "trapping reagent"–methanol. At −40 °C the phosphorane can be detected in the reaction mixture, while at 20 °C it is converted into the ylide[73]:

$$(MeO)_4P{-}CX{=}CHX \xrightarrow{+20^\circ} (MeO)_3P{=}CX{-}CH\langle^{X}_{OMe} \quad .$$

(XLVII)

Conversely the reaction of acetylenedicarboxylate with cyclic phosphites and phenol at a low temperature gives rise to an ylide, which rearranges to the phosphorane (XLVIII) above 0 °C:

(XLVIII)

(b) Other Methods for the Introduction of the Methylene Group into Tervalent Phosphorus Compounds

A unique example of the synthesis of the ethoxycarbonyl ylide (XLIX) by displacing trimethylamine by an aminophosphine from a quaternary ammonium salt has been described[74]:

$$(Me_2N)_2PPh + Me_3\overset{+}{N}CH_2CO_2Et\ Cl^- \xrightarrow[-Me_3N\cdot HCl]{} (Me_2N)_2P{=}CHCO_2Et \quad .$$

Ph

(XLIX)

The formation of the trimethoxyphosphonium ylide (L) as a result of the interaction of tri(phenylthio)methyl-lithium with trimethyl phosphite has been reported[75]. The ylide (L) could not be isolated in a pure state, but its formation was demonstrated with the aid of the Wittig reaction. Under analogous conditions, the triphenylphosphonium ylide (LI) was obtained in the form of a pure crystalline substance:

$$(PhS)_3CLi + P(OMe)_3 \xrightarrow{-PhSLi} [(MeO)_3P{=}C(SPh)_2] \xrightarrow[-(MeO)_3P=O]{p\text{-}O_2NC_6H_4CHO}$$

(L)

$$\rightarrow p\text{-}O_2NC_6H_4CH{=}C(SPh)_2 \quad Ph_3P{=}C(SPh)_2 \quad .$$

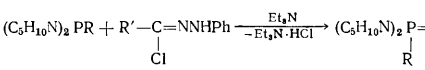
(LI)

Compounds of tervalent phosphorus react with certain thioketones and their dimers to form the ylides (LII). The formation of a carbene in an intermediate stage, which then reacts with the second phosphite molecule, has been postulated. The ylides (LII) are stable liquids which can be vacuum-distilled[76]:

$$(CF_3)_2C{=}S + P(OR)_3 \xrightarrow{-(RO)_3P=S} [(CF_3)_2C{:}] \xrightarrow{P(OR)_3} (RO)_3P{=}C(CF_3)_2 \ ;$$

(LII, a–c)

R = Me (a), Et (b), iso-Pr (c);



(LII) .

It has been shown recently that the epoxy-derivatives of perfluorinated alkenes give rise to ylides on interaction with trialkyl phosphites[77]:

$R = CF_3$, CO_2R'

The amides of tervalent phosphorus acids react with *C*-ethoxycarbonyl- and *C*-acetyl-*N*-arylnitrile imines to form stable azomethylenephosphonium ylides (LIII)[78]:

(LIII)

$R = C_5H_{10}N$, Ph; $R' = CO_2Et$, C (O) CH_3 .

3. The Synthesis of Ylides from Phosphonium Salts

The simplest method of synthesis of phosphorus ylides is the "salt method", which is widely used, particularly in the preparation of dialkylaminophosphonium ylides.

The phosphonium salts (LIV) are dehydrobrominated by sodium amide to form the ylides (LV) containing the unsubstituted methylene group; they are colourless, comparatively stable liquids which can be vacuum-distilled[79]. The benzylides (LVI) have been obtained by treating a phosphonium salt with butyl-lithium or sodium ethoxide[80,81]:

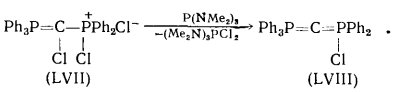
$$\underset{(LIV)}{(Me_2N)_n(Me)_{4-n}\overset{+}{P}Br^-} \xrightarrow[-NaBr]{NaNH_2/NH_3} \underset{(LV)}{(Me_2N)_n(Me)_{3-n}P{=}CH_2} \ ;$$

$$\underset{(LVI)}{(R_2N)_3\overset{+}{P}CH_2PhHal^-} \xrightarrow[(-HHal)]{BuLi;EtONa} (R_2N)_3P{=}CHPh \ ;$$

$R = Me$, Et; $n = 1 - 3$.

Stable ylides containing alkoxycarbonyl or diethylaminocarbonyl groups at the ylide carbon atom and primary or secondary amino-groups at the phosphorus atom have been obtained by treating the corresponding phosphonium salt with an aqueous solution of alkali, sodium ethoxide, or potassium t-butoxide[80–82].

The dehalogenation of trihalogenomethylphosphonium salts by triphenylphosphine or phosphorous acid tris(*N*,*N*-dimethylamide) constitutes a preparative method for the synthesis of dialkylaminophosphonium ylides containing a dihalogenomethylene group[83–85]:

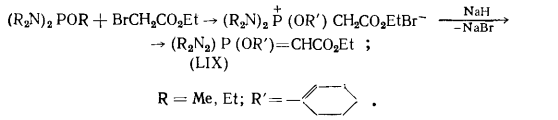


$$(Me_2N)_3\overset{+}{P}CHaI_3Hal^- \xrightarrow[-R_3PHal_2]{R_3P} [(Me_2N)_3P{=}CHal_2] \xrightarrow{R'_2C=O} R'_2C{=}CHal_2 \ ;$$

$R = Me_2N$, Ph; Hal = Cl, Br, F .

Ylides are usually obtained, without the isolation of the phosphonium salts, by treating the phosphorous acid tris(*N*,*N*-dimethylamide) with carbon tetrahalide. This results in the formation of extremely reactive ylides, which are readily converted into ketones and olefins[86–88]:

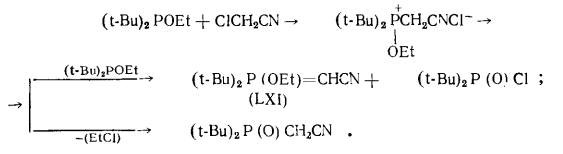
$$2(Me_2N)_3P + BrCCl_3 \xrightarrow[-20^\circ \div -10^\circ]{} [(Me_2N)_3P{=}CCl_2] + (Me_2N)_3PClBr \quad .$$



Carbodiphosphorane (LVIII) has been obtained by treating the ylide (LVII) with phosphorous acid triamide[89]:

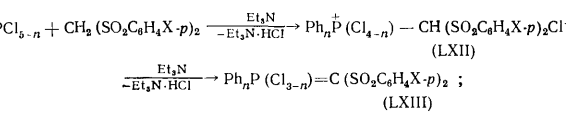
(LVII) (LVIII)

The "salt method" is hardly used for the synthesis of ylides with alkoxy-groups at the phosphorus atom in view of the instability of the alkoxyphosphonium salts.



A rare example of this kind has been described recently[90]. The formation of the ylides (LIX) proved to be possible as a result of the unique stability of vinyloxyphosphonium salts:

(LIX)

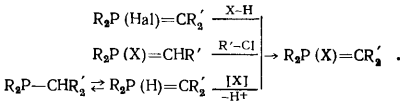


R = Me, Et; R′ = .

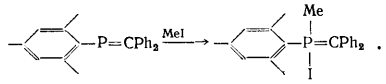
The ylide (LXI) with the ethoxy-group at the phosphorus atom was detected among other products after the reaction of ethyl di-t-butylphosphinite with chloroacetonitrile. It has been suggested that the intermediate phosphonium compound (LX) is dehydrochlorinated by the phosphinite in the reaction. The Arbuzov dealkylation of the phosphonium salt (LX) takes place simultaneously[91]:

(LXI)

Polychlorophosphoranes react readily with bis(arenesulphonyl)methanes in the presence of triethylamine. The phosphonium salt (LXII) formed initially is dehydrochlorinated by triethylamine and is converted into the *P*-chloroylide (LXIII) with a high yield[92]. The reaction is preparatively very simple and makes it possible to obtain ylides with both one and two chlorine atoms at the phosphorus atom:



(LXII) (LXIII)



$n = 1,2$; X = H, Cl, Me, OMe .

4. The Conversion of Phosphorus Ylides of one Type into Phosphorus Ylides of Another Type

The conversion of ylides of one type into those of another provides extensive possibilities for the synthesis of *P*-hetero-substituted ylides. Thus *P*-halogeno-ylides readily exchange their mobile halogen atom for different groups in their reactions with nucleophiles, which makes it possible to introduce virtually any substituents at the phosphorus atom[14]. The hydrogen atoms at the ylide carbon atom are also readily substituted by other groups on interaction with chlorine-containing electrophiles[28,79]. The oxidative ylidation of tervalent phosphorus CH acids can be regarded to some extent as conversion of ylides of one kind into those of another. The CH acids are regarded as tautomeric forms of PH ylides[26,27]:

The synthesis of *P*-hetero-substituted ylides of one type into those of another type is discussed below in the section devoted to the properties of these compounds. The synthesis of *P*-hetero-substituted ylides from tervalent phosphorus compounds with a P=C bond is extremely interesting, although this method has been hardly developed further. A single example of the conversion of the acyclic phosphene (LXIV) into the ylide (LXV) with an iodine atom at the phosphorus atom is known[93]:

(LXIV) (LXV)

III. PROPERTIES

The properties of *P*-hetero-substituted phosphorus ylides are quite varied. The heteroatoms at the phosphorus atom of the P=C group alter the positive charge on the phosphonium cation and influence the nucleophilic properties of the ylides. In many instances, as a consequence of their mobility, the heteroatoms alter significantly the behaviour of ylides in chemical reactions. *P*-Hetero-substituted ylides therefore acquire properties which are lacking in triphenylphosphonium ylides. *P*-Hetero-substituted ylides are very reactive, are involved in many interesting reactions, and are valuable starting materials for the synthesis of many organic compounds.

1. Physical and Physicochemical Properties

In a pure state, the *P*-hetero-substituted phosphorus ylides are liquid or crystalline substances. Their stabilities differ greatly. Ylides having electron-accepting groups at the α-carbon atom capable of delocalising the negative charge of the carbanion are particularly stable. For example, the ylides (LXIII) with arenesulphonyl groups can be stored indefinitely and withstand heating to 200 °C.[14,21] However, unstable ylides, which exist only in solutions, are encountered. The "unstabilised" ylides, containing an unsubstituted methylene or alkylidene group, are oxidised very readily and hydrolysed in air[28,79,81].

P-Hetero-substituted phosphorus ylides have been investigated by various spectroscopic methods. The P=C group vibration frequencies have been observed in the infrared spectra of *P*-hetero-substituted ylides in the range 1000–1080 cm^{-1}.[18,28] A characteristic feature of ylides stabilised by carbonyl groups is the bathochromic shift of the absorption bands of these groups as a consequence of the conjugation with the negative charge of the ylide carbon atom[14,15,28,94,95]. The $\nu_s(SO_2)$ and $\nu_{as}(SO_2)$ absorption bands also undergo a bathochromic shift of approximately 70–80 cm^{-1} under the influence of the negative charge of the ylide carbon atom[14,21].

The ^{13}C and ^{31}P NMR spectra of *P*-hetero-substituted phosphorus ylides agree with their dipolar structure. The chemical shifts of the ^{31}P signals (Table 1) are located in a

weak field in direct proximity to the values of δp characterising the phosphonium cation $R_3\overset{+}{P}$ in phosphonium salts[28, 95,96]. On the other hand, the chemical shifts of the ^{13}C signals (relative to tetramethylsilane) are observed in a strong field in the region characteristic of the corresponding carbanions.

Table 1. The chemical shifts of the ^{31}P signals in the NMR spectra of *P*-hetero-substituted phosphorus ylides $RR'P(X)=CR''_2$.

2. Ylides with a P—H Bond

Alkylphosphines containing an α-hydrogen atom can be regarded as carbon analogues of tervalent phosphorus OH acids. Almost all the known OH acids of this kind exist in the tetracoordinate prototropic P(O)H form[102], which can be explained by the high energy of formation of the P=O bond ($E_{P=O}$ = 140 kcal mol^{-1}). On the other hand, the majority of alkylphosphines exist in the tricoordinate CH form owing to the inadequate thermodynamic stability of the PH ylide form. The ylide form can be stabilised by introducing two alkoxycarbonyl groups at the α-carbon atom as a consequence of the effective delocalisation of the negative charge of the ylide carbon atom over the conjugated bond system[18,25].

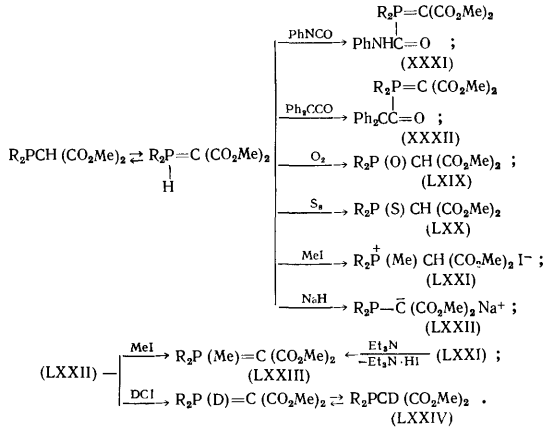
Thus dialkylbis(methoxycarbonyl)methylphosphines isomerise completely or partly to ylides with a P—H bond (Table 2):

$$\underset{(A)}{RR'P{-}CH(CO_2Me)_2} \rightleftarrows \underset{(B)}{RR'P(H){=}C(CO_2Me)_2}\ .$$

Dialkylbis(methoxycarbonyl)methylphosphines are stable substances which can be vacuum-distilled without decomposition and can be stored satisfactorily at the usual temperature. Some of them [compounds (LXVI)—(LXVIII)] have been obtained in the pure crystalline PH ylide form (B)[18,25]:

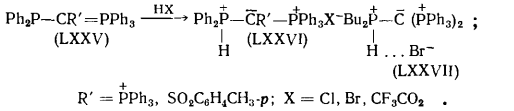
$$\begin{array}{c} t\text{-Bu}(R)P{=}C(CO_2Me)_2 \\ | \\ H \end{array}$$

R= iso-Pr (LXVI), t-Bu (LXVII), Me_3SiCH_2 (LXVIII)



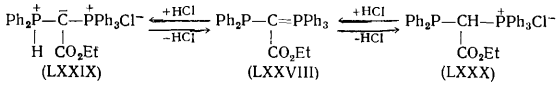
Dialkylbis(methoxycarbonyl)methylphosphines exist in solution as tautomeric mixtures of the prototropic forms (A) and (B), which has been demonstrated by spectroscopic studies. The signals of the protons of the CH and PH groups have been detected in the ^1H NMR spectra of these compounds. The signal of the proton of the PH group is split owing to the interaction with the phosphorus atom ($^1J_{PH}$ = 440 Hz). The signals of the CH form (singlet) and the PH form (doublet) with a coupling constant of 440 Hz are present in the ^{31}P NMR spectra. When the spin—spin coupling of the phosphorus nuclei with the protons is suppressed, the doublet is converted into a singlet, which confirms unambiguously the presence of a bond between the phosphorus atom and the hydrogen atom.

The tautomeric equilibrium (A) ⇌ (B) depends on the temperature and on the nature of the solvents and substituents at the phosphorus atom. The study of the thermodynamics of the tautomeric equilibrium led to the conclusion that the ylide form has a higher formation energy than the phosphine form [$\Delta H = -2.4 \pm 0.2$ kcal mol^{-1}, $\Delta S = -7.4 \pm 0.7$ e.u. for compound (LXVI) in chloroform][18].



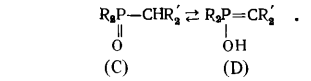
The results presented in Table 2 show that bulky and branched alkyl substituents stabilise the PH ylide form and displace the tautomeric equilibrium towards it. Examination of the Stuart—Briegleb models has led to the conclusion that bulky alkyl substituents are more favourable for the tetracoordinate PH ylide form, since the latter is sterically less hindered than the tricoordinate CH form[18,25]. It is quite evident that the influence of branched alkyl substituents on the position of the tautomeric equilibrium is associated with steric and not polar effects. According to modern ideas, alkyl groups (Me, Et, iso-Pr, t-Bu, etc.) are electrically neutral and differ only by their steric characteristics[103].

The chemical properties of ylides with a P—H bond are similar to those of other tervalent phosphorus CH acids as a consequence of the involvement of the tricoordinate form (A) in the tautomeric equilibrium[18,25,96]. They are oxidised, combine with sulphur, and are alkylated by alkyl halides with formation of phosphine oxides (LXIX), phosphine sulphides (LXX), and phosphonium salts (LXXI). At the same time dialkylbis(methoxycarbonyl)methylphosphines readily enter into oxidative ylidation reactions. The interaction with phenyl isocyanate and diphenylketen yields the *P*-substituted ylides (XXXI) and (XXXII). On interaction with sodium hydride, PH ylides are converted into the α-phosphinocarbanions (LXXII). The reaction of α-phosphinocarbanions with methyl iodide takes place at the phosphorus atom with formation of the ylide (LXXIII) (the "ylide variant" of the Michaelis—Becker reaction), while their reaction with deuterium chloride results in the formation of deuterated dialkylbis(methoxycarbonyl)methylphosphines (LXXIV), which consist of a tautomeric mixture of the CD and PD forms[18,25,96] (Scheme 8).



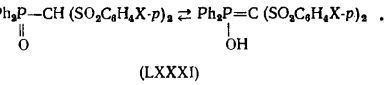
Scheme 8

The phosphinophosphonium ylides (LXXV), containing electron-accepting substituents at the α-carbon atom, are protonated by strong acids at the phosphorus atom[104-107]. X-Ray diffraction analysis of compound (LXXVII) not only confirmed the presence of the P–H bond but also showed that the proton retains to some extent its bond with the halogen[108-110]:



Detailed studies of the protonation of phosphinophosphonium ylides established that compound (LXXVIII) reacts with an excess of hydrogen chloride in methylene chloride at −80 °C with formation of the PH and CH forms of compounds (LXXIX) and (LXXX), between which equilibrium is established[109-112]:

These forms are unstable and exist only in solution at a low temperature, decomposing fully with cleavage of the P–C bond at −20 °C. The position of the tautomeric equilibrium (LXXIX) ⇌ (LXXX) depends on the temperature and the polarity of the solvent. The ratio of the CH and PH forms also depends on the concentration of hydrogen chloride, whence it follows that the interconversion of the forms occurs as a result of the reversible addition of HCl to and its elimination from the phosphinophosphonium ylide (LXXVIII). The involvement of hydrogen chloride in the prototropic equilibrium constitutes a significant difference between the tautomerism of the protonated phosphinophosphonium ylides and the phosphine–PH ylide tautomerism of dialkylbis(methoxycarbonyl)methylphosphines. The nature of the anion is also very important in this instance. For example, when hydrogen chloride is replaced by trifluoroacetic acid, protonation takes place only at the phosphorus atom of the phosphinophosphonium ylide (LXXVIII), the PH form is produced, and the CH form disappears[110].

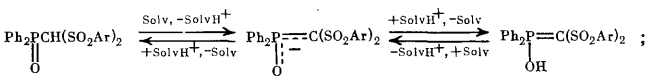


3. Ylides with a P–O Bond

Ylides with an OH group are tautomeric forms of alkylphosphine oxides:

The majority of alkylphosphine oxides exist in the CH form (C) as a consequence of the high basicity of the ylide carbon atom. The tautomeric equilibrium (C) ⇌ (D) is displaced towards the OH form (D) in the case of diphenylbis(arenesulphonyl)methylphosphine oxides (LXXXI), which contain substituents with strong electron-accepting properties[97,98,113].

In the crystalline state these phosphine oxides exist in the pure CH phosphine oxide form while in solutions they consist of a tautomeric mixture of the OH ylide and the CH phosphine oxide forms (Table 3)[97,98]:



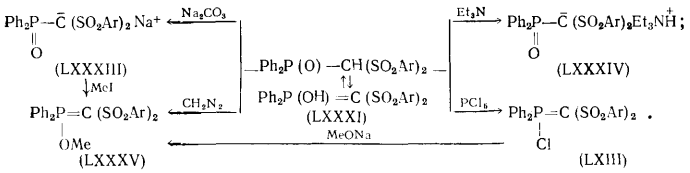
(LXXXI)

Table 3. The tautomeric composition of diphenylbis(benzenesulphonyl)methylphosphine oxides (LXXXI) (tetrahydrofuran at 25 °C)[96-98].

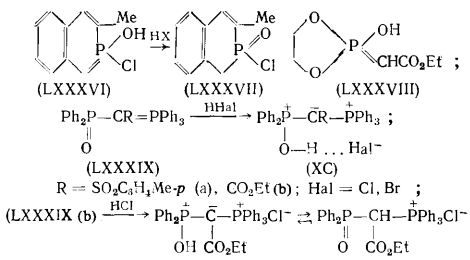
X	C, %	D, %
Cl	45	55
H	80	20
Me	90	10
MeO	96	4

The OH and CH forms can be readily detected by spectroscopic methods (infrared, ^{1}H, NMR, and ^{13}P NMR spectroscopy). The study of the process with the aid of dynamic NMR indicates a high rate of the interconversion of the tautomeric forms (the temperature at which the ^{31}P signals merge for the system in chlorobenzene is 100 °C for an external magnetic field strength of 81 MHz)[96]. The tautomeric equilibrium (C) ⇌ (D) is mobile and depends on the temperature and nature of the solvents and the substituents. The content of the ylide form increases with decrease of temperature and this form is evidently energetically more favourable. Electron-accepting substituents in the *para*-positions in the arenesulphonyl groups increase the content of the ylide form, because they enhance the delocalisation of the negative charge of the ylide carbon atom.

The study of the prototropic equilibrium in aqueous alcoholic solutions showed that a two-stage mechanism of the tautomeric transformation, with formation of the common anion (LXXXII), operates in these solvents, which have a high dissociating capacity:

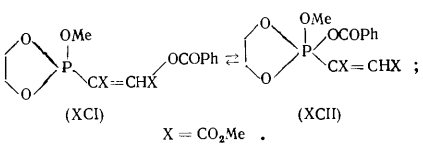


(LXXXII)



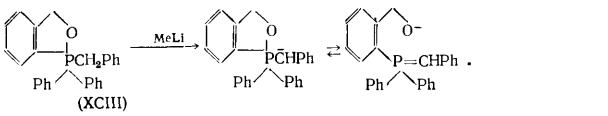
Solv = solvent.

Diphenylbis(arenesulphonyl)methylphosphine oxides have interesting properties, resembling those of the OH acids of tetracoordinate phosphorus. These extremely stable compounds are comparatively strong acids (pK_a = 3.55–3.68 in 50% alcohol). They readily dissolve in an aqueous solution of sodium carbonate, from which they can be recovered quantitatively on acidifying the solution; they react with triethylamine to form the stable triethylammonium salts (LXXXIV). The reaction of phosphine oxide with diazomethane leads to the formation of an *O*-methylated product—the ylide (LXXXV). The formation of the product (LXXXV) substituted at the oxygen atom is accompanied by the interaction of the sodium salt (LXXXIII) with methyl iodide. The reaction of compounds (LXXXI) with phosphorus pentachloride gives rise to the *P*-chloro-derivatives (LXIII) (Scheme 9).

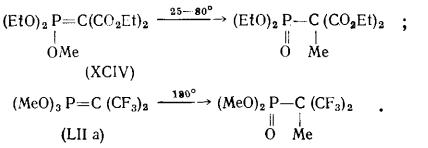


Scheme 9

The phosphine oxide–ylide tautomerism was first discovered and investigated in relation to diphenylbis(arenesulphonyl)-methylphosphine oxide[97,98,113]. Subsequently other OH ylides were also described. The cyclic *P*-hydroxy-λ^5-phosphorin (LXXXVI), which is stable in the crystalline state and which rearranges irreversibly to the more stable isomer (LXXXVII) with a P=O group in the presence of proton-donating reagents, has been synthesised[114]. It has been established[115] that the five-membered dioxaphospholan ring effectively stabilises the OH ylide form (LXXXVIII). The phosphine oxide phosphonium ylides (LXXXIX) are protonated by strong acids at the oxygen atom of the P=O group[106,116,117]. X-Ray diffraction analysis of compound (XCa) showed that the OH form is stabilised by a strong O–H...Br bond and that the H...Br distance is 2.24 Å, which is much less than the sum of the van der Waals radii (3.11 Å)[116]. The hydrochloride salt of the ylide (LXXXIXb) exists in the crystalline state in the OH form, while in solutions it is a mixture of the CH and OH forms in proportions of 1:1.8 (Mastryukova et al.[117]):

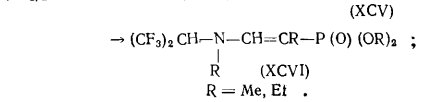


The tautomeric equilibrium between the ylide and phosphorane structures (XCI) ⇌ (XCII), which has been investigated by ^{31}P NMR,[71] is of considerable interest:



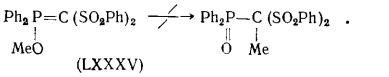
The position of the tautomeric equilibrium (XCI) ⇌ (XCII) depends on the nature of the solvent in the following way:

Solvent	(XCI)	(XCII)
CCl_4	18%	82%
CH_2Cl_2	37%	63%

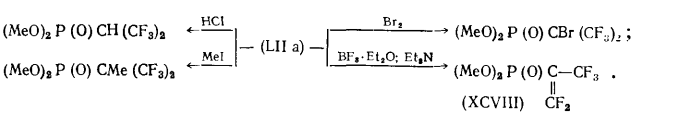


Another example of the ylide–phosphorane tautomeric equilibrium was found in the metallation of the phosphorane (XCIII) with a benzyl group[118]:

The ylides containing alkoxy-groups at the phosphorus atom are readily dealkylated and converted into phosphonates. Thus the alkoxyphosphonium ylides (LIIa) and (XCIV) rearrange on heating to phosphonates with migration of the alkyl group to the ylide carbon atom (the ylide version of the Pishchimuka reaction)[15,77]:



The ylides (XCV) are converted into the phosphonates (XCVI) already in their preparation reaction[119]:



The ylides (XCVII) with ethoxy- or isopropoxy-groups at the phosphorus atom are more stable than the corresponding ylides (XCIV) with methoxy-groups. They are converted into phosphonates only on heating to 150–180 °C and the rearrangement is complicated by the elimination of an alkene[14]:

Electron-accepting substituents, which reduce the nucleophilicity of the ylide carbon atom, hinder the rearrangement. The ylide (LXXXV), containing the powerful electron-accepting benzenesulphonyl groups at the α-carbon atom, is stable and does not change on heating to 200 °C[14]:

Alkoxyphosphonium ylides are dealkylated on interaction with hydrogen chloride, bromine, and alkyl halides[14,16,76]. When the ylide (LIIa) was treated with boron trifluoride etherate, the "phosphorus analogue" of the perfluoromethacrylic ester (XCVIII) was obtained as a result of the simultaneous dealkylation and the elimination of a fluorine atom[120,121]:

Hydrolysis of ylides containing alkoxy-groups at the phosphorus atom proceeds both with elimination of one of the alkyl groups and with cleavage of the P=C bond[63,120].

Alkoxyphosphonium ylides normally undergo the Wittig reaction and their reactivities are probably comparable to those of triphenylphosphonium ylides. However, there are

very few data on this question[95]:

$$(\text{iso-PrO})_2(Et_2N)P{=}CHCO_2Et \xrightarrow{ArCHO} ArCH{=}CHCO_2Et + (\text{iso-PrO})(Et_2N)PO \ ;$$
$$Ar = Ph,\ p\text{-}O_2NC_6H_4 \ .$$

4. Ylides with a P–N Bond

Ylides with dialkylamino-groups at the phosphorus atom are available and are very reactive, which aroused much interest in these compounds by investigators. The reactivity and stability of dialkylaminophosphonium ylides depend on the substituents at the ylide carbon atom. Dialkylaminophosphonium ylides stabilised by electron-accepting substituents are indeed very stable. The azomethylenephosphonium ylide (LIII) hydrolyses only after prolonged refluxing in aqueous alcoholic solution. This involves the cleavage of the P–N and not the P=C bond and the amine formed converts the ethoxycarbonyl group into a carbamoyl group[78]:

$$(C_5H_{10}N)_3P{=}\underset{\underset{CO_2Et}{|}}{C}{-}N{=}NPh + H_2O \rightarrow (C_6H_{10}N)_2P(O){-}\underset{\underset{CO_2Et}{|}}{C}{=}NNHPh + C_5H_{10}NH \rightarrow$$
(LIII)
$$\rightarrow (C_5H_{10}N)_2P(O){-}\underset{\underset{C(O)NC_5H_{10}}{|}}{C}{=}N{-}NHPh + EtOH \ .$$

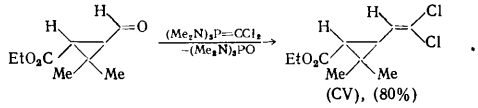
The ylide (XCIX) does not change even after heating at 140 °C for 4 h in 50% KOH, but it is reactive in the Wittig reaction[81]:

$$(Et_2N)_3P{=}CHCONEt_2 \xrightarrow{p\text{-}O_2NC_6H_4CHO} p\text{-}O_2NC_6H_4CH{=}CHCONEt_2 \ .$$

On the other hand, the unstabilised dialkylaminophosphonium ylides or the same ylides stabilised by weak electron-accepting substituents hydrolyse very readily and are oxidised by atmospheric oxygen. The ease of the reaction of the benzylide (LVIa) with atmospheric oxygen, in which it is converted into stilbene in a high yield, is so great that it actually interferes with its isolation in a pure form[81]:

$$[(Et_2N)_3P{=}CHPh] \text{ (LVI a)} \begin{cases} \xrightarrow{p\text{-}O_2NC_6H_4CHO} p\text{-}O_2NC_6H_4CH{=}CHPh \ ; \\ \xrightarrow{O_2} PhCH{=}CHPh + (Et_2N)_3PO \ . \end{cases}$$

The ylide (LV) having a methylene group reacts with chlorine-containing electrophiles, being converted in high yields into new types of dialkylaminophosphonium ylides (C) and (CI). The reaction is carried out with a reactant ratio of 2:1, since one ylide molecule is consumed in the dehydrochlorination of the intermediate phosphonium salt[79]:



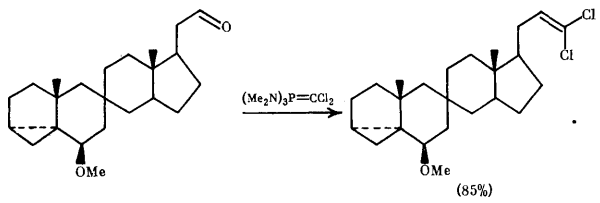
$$(Me_2N)_3P{=}CH_2 \begin{cases} \xrightarrow[-(Me_2N)_2(Me)\overset{+}{P}Cl^-]{PCl_3} [(Me_2N)_3P{=}CH]_3P \ ; \\ \xrightarrow[-(Me_2N)_2(Me)P^+Cl^-]{R_2PCl} (Me_2N)_3{=}CHPR_2 \ ; \end{cases}$$
(C) (CI)
$$R = Me, Et, OEt, NMe_2$$

Diazonium salts couple directly with dialkylaminophosphonium ylides. Phenyldiazonium fluoroborate reacts with the ylide (CII) to form the phosphonium salt (CIII), which can be converted into a new ylide (CIV) by treatment with sodium ethoxide[78]:

$$(C_5H_{10}N)_2P(Ph){=}CHCO_2Et \xrightarrow{PhN_2^+BF_4^-} (C_5H_{10}N)_2\overset{+}{P}(Ph)\underset{\underset{CO_2Et}{|}}{CH}{=}NPhBF_4^- \rightarrow$$
(CII) (CIII)
$$\xrightarrow{C_2H_5ONa} (C_5H_{10}N)_2P(Ph){=}\underset{\underset{CO_2Et}{|}}{C}{-}N{=}NPh \ .$$
(CIV)

As reactants in the Wittig reaction, dialkylaminophosphonium ylides are more reactive than triphenylphosphonium ylides. The electron-donating dialkylamino-groups weaken the electron-accepting properties of the phosphonium group, as a result of which the negative charge on the ylide carbon atom increases. Under the influence of strongly nucleophilic dialkylaminophosphonium ylides, even inactive ketones are converted into olefins and in the reactions with reactive carbonyl compounds there is a significant increase in the yields of olefins. The use of dialkylaminophosphonium ylides frequently yields satisfactory results in those cases where the triphenylphosphonium ylides are unsuitable. The compounds $(Me_2N)_3P{=}CF_2$[83] and $(Me_2N)_3P{=}CCl_2$,[86] generated *in situ* from $(Me_2N)_3P$ and carbon tetrahalides, are good sources of the trifluoromethylene and dichloromethylene groups for reactions with inactive ketones. The conversion of the ethyl ester of *cis,trans*-caronaldehydic acid into an olefin with the aid of $(Me_2N)_3P{=}CCl_2$ made it possible to obtain a high yield of a chrysanthemic acid derivative (CV)—an analogue of the natural insecticide permethrin (NRDC 143)[87] (Scheme 10).

Scheme 10



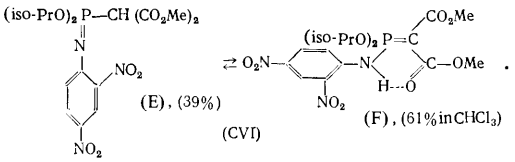
(CV), (80%)

Under analogous conditions, $Ph_3P{=}CCl_2$ gives a low yield of a highly contaminated compound (CV)[87].

It has been noted that the use of dimethylaminophosphonium ylides increases the stereospecificity of the Wittig reaction. It is significant, especially in studies with natural products, that, on treatment with these ylides, the optically active centres in the molecule are not involved and the compounds are not racemised[12,83] (Scheme 11).

Scheme 11

(85%)



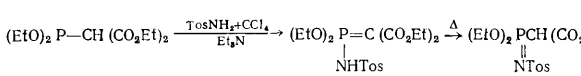
The ylides (F) containing NHR groups at the phosphorus atom are in a tautomeric equilibrium with the phosphazo-compound (E)[57,99]:

$$R_2P(O){-}CHR'CO_2R'' \rightleftarrows R_2P{=}CR'CO_2R''$$
$$\underset{\underset{NR'''}{\|}}{} \qquad \underset{\underset{NHR'''}{|}}{}$$
(E) (F)

The phosphazo-ylide tautomerism (E) ⇌ (F) obeys the rules of the acid–base prototropic equilibria and shifts towards the form which is a weaker acid under the given conditions. The introduction of more electron-accepting substituents at the nitrogen atom of the $-N-\underset{|}{P}-C\diagup\diagdown$ triad increases the content of the phosphazo-form (E) and, conversely, electron-accepting substituents at the carbon atom favour the formation of the ylide form (F)[57,99].

Depending on the substituents at the nitrogen and carbon atoms, the phosphazo–ylide equilibrium (E) ⇌ (F) can be displaced towards the preferential formation of one of the tautomeric forms or the forms (E) and (F) are present in comparable amounts (Scheme 12).

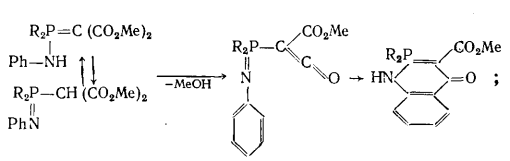
Scheme 12



(E), (39%) (F), (61% in $CHCl_3$)

(CVI)

Thus compound (CVI) exists in the ylide form in the crystalline state, while in solutions it is present as a mixture of two tautomers. The ratio of the forms (E) and (F) depends on the temperature and the solvent. The study of the thermodynamics of the phosphazo–ylide tautomerism showed that the tautomeric equilibrium (E) ⇌ (F) is influenced by two opposed factors. On the one hand, the conversion of the phosphazo-form into the ylide form with its conjugation chain results in an energy gain $\Delta H = -6 \pm 0.6$ kcal mol^{-1}. On the other hand, this entails an increase of the rigidity of the molecule (since the ylide form is fixed by a strong intramolecular hydrogen bond) and the entropy diminishes ($\Delta S = -21 \pm 2$ e.u.). According to the equation $\Delta G = \Delta H - T\Delta S$, the equality of ΔH and $T\Delta S$ determines the equilibrium position. The presence of a strong intramolecular hydrogen bond has been confirmed by infrared and ^{1}H NMR spectra[57, 99, 124]. The migration of the proton between the nitrogen and carbon atoms in the $-N-\underset{|}{P}-C$ triad takes place readily and the interconversion of the tautomers (E) ⇌ (F) takes place comparatively rapidly.



It has been reported[125] that the ylide with the tosylamide group at the phosphorus atom rearranges to the phosphazo-compound during the vacuum distillation of the reaction mixture formed in accordance with the equation

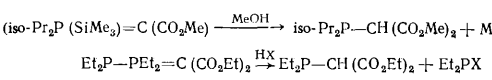
The conclusion that an ylide is formed and undergoes a rearrangement was reached on the basis of the presence in the infrared spectrum of the reaction mixture of an absorption band at 1650 cm^{-1}, which disappears on heating. The energy barrier to the prototropic rearrangement is unusually high, bearing in mind the high mobility of the NH proton of the tosylamide group, and apparently requires additional study and confirmation.

Anilinophosphonium bis(alkoxycarbonyl)methylides, which are stable under the usual conditions, evolve alcohol on heating to 150–180 °C and are converted into 2-phospha-4-quinolones (CVIII)[124]. The elimination of the alcohol results in the formation of the keten (CVII), whose cyclisation at the *ortho*-position of the benzene ring gives rise to 2-phospha-4-quinolone (Scheme 13).

Scheme 13

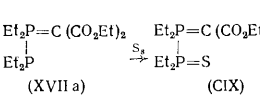
(CVII) (CVIII)

R = EtO, iso-PrO, iso-Pr .



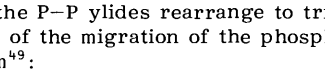
Under analogous conditions, the thermolysis of dialkylbis(methoxycarbonyl)methylphosphine oxides and phosphine sulphides leads to the formation of stable ketens[25]:

R = iso-Pr, t-Bu; X = O, S .



5. Ylides with P–Si, P–S, and P–P Bonds

The ylides containing the P–Si, P–S, and P–P bonds are stable liquids, capable of being vacuum-distilled, or crystalline substances. The P–P and P–Si ylides are readily cleaved at the phosphorus–element bond by various proton-donating reagents:

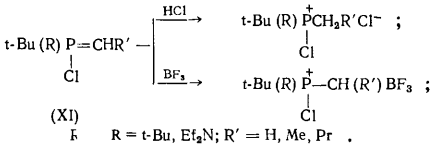


X = Cl, MeO, HO .

The P–P ylides are readily oxidised by atmospheric oxygen. The ylide (XVIIa) combines with sulphur via the tervalent phosphorus atom and is converted into the ylide (CIX) with the P(S)–P group; the P–P bond is then retained[14,48]:

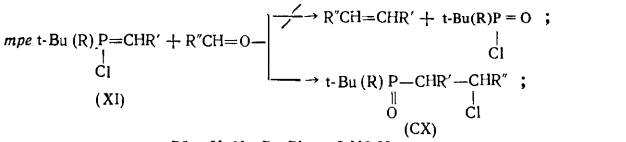
(XVII a) (CIX)

In certain cases, the P–P ylides rearrange to triphosphinomethanes as a result of the migration of the phosphino-group to the α-carbon atom[49]:



6. Ylides with Halogen Atoms at the Phosphorus Atom

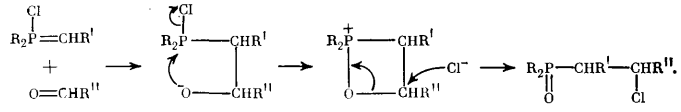
P-Halogenoylides are promising reagents for organophosphorus synthesis. They are very reactive. The combination in one molecule of two active reaction centres (the nucleophilic centre consisting of the negatively charged carbon atom and the electrophilic centre consisting of the phosphonium carbanion to which the labile halogen atom is attached) is responsible for the wide variety and the specific features of the properties of these compounds:



P-Halogenoylides react readily with both electrophiles and nucleophiles. Their reactivity in relation to electrophiles depends on the substituents at the carbanionic centre. The nucleophilicity and basicity of the *P*-halogenoylides containing powerful electron-accepting substituents R′ are low. Some of them (R′ = SO_2Ar) do not even give rise to stable phosphonium salts on interaction with hydrogen chloride. On the other hand, the "unstabilised" *P*-halogenoylides (XI, R′ = H or alkyl) are extremely reactive in relation to electrophiles. They combine with hydrogen chloride and boron trifluoride

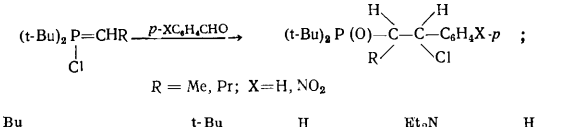
via exothermic reactions and interact with carbonyl compounds, acid chlorides, etc.[27,28]:

(XI) R = t-Bu, Et_2N; R′ = H, Me, Pr .



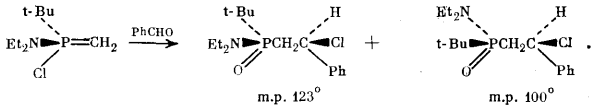
In contrast to triphenylphosphonium ylides, *P*-halogenoylides react with carbonyl compounds without the dissociation of the P=C bond, which results in the formation of organophosphorus products. *P*-Chloroylides do not form olefins on reaction with aldehydes, but give rise to β-chloroalkylphosphine oxides (CX)[101]. The reactions of *P*-chloroylides (XI) with aldehydes having different structures proceed at a low temperature and are accompanied by the evolution of heat. The yields of β-chloroalkylphosphine oxides (CX) are very high:

(XI) (CX)



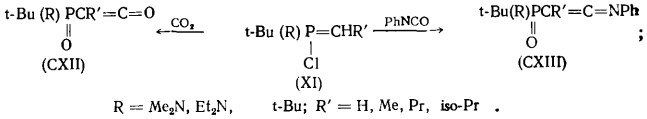
R″ = H, Me, Pr, Ph, *p*-$O_2NC_6H_4$.

The anomalous course of the reaction of *P*-chloroylides with aldehydes is due to the presence of the labile chlorine atom. As a consequence of the ability of the chlorine atom to ionise, an intermediate oxaphosphetanium salt (CXI) is formed. In contrast to the pentacoordinate intermediate compound in the Wittig reaction, this salt does not decompose into an olefin and a compound containing the P=O group, but is converted into a β-chloroalkylphosphine oxide as a result of the attack by Cl^- on the β-carbon atom via the mechanism of the Arbuzov rearrangement:



(CXI)

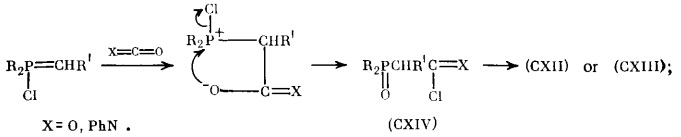
The reactions of *C*-alkyl-substituted *P*-chloroylides with aldehydes are stereoselective and lead to the formation of a single diastereoisomer of a β-chloroalkylphosphine oxide. However, the reactions of *P*-chloroylides having an asymmetrically substituted phosphorus atom are not distinguished by a high stereoselectivity and give rise to a mixture of diastereoisomers (in proportions of 1:2–2:3)[96,101]:



R = Me, Pr; X = H, NO_2

m.p. 123° m.p. 100°

The *P*-chloroylides (XI) react with carbon dioxide and phenyl isocyanate to form phosphorylated ketones and *C*-phosphorus-containing keten imines (CXII) and (CXIII)[27]:



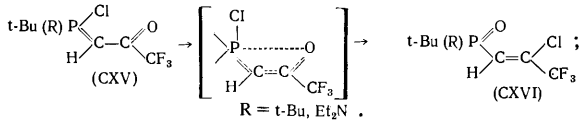
(CXII) (XI) (CXIII)

R = Me_2N, Et_2N, t-Bu; R′ = H, Me, Pr, iso-Pr .

The reaction is carried out with an initial reactant ratio of 2:1, since one molecule of the ylide is consumed in the dehydrochlorination of the acid chloride (CXIV) formed at an intermediate stage (the reaction stops at the stage involving the formation of this acid chloride in the presence of a large excess of CO_2) (Scheme 14).

Scheme 14

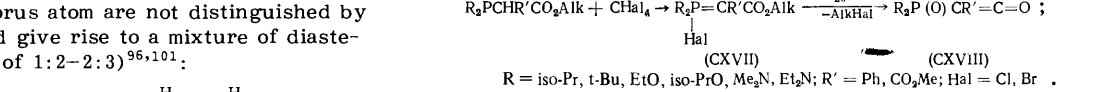
X = O, PhN . (CXIV)



This method of synthesis of phosphorylated ketens and keten imines is preparatively fairly convenient. The initial *P*-chloroylides are formed from the tertiary phosphines (X) and CCl_4 and it is not obligatory to isolate them. The ketens (CXII) can be obtained directly from the tertiary phosphine (X) by treating it with CCl_4 and CO_2; the yields of the ketens are high:

(X)

The reactions of *P*-chloroylides containing a carbonyl group at the ylide carbon atom proceed via an analogous mechanism. The *P*-chloroylides (CXV), where there is a trifluoroacetyl group at the carbon atom, rearrange on heating to 120–150 °C to β-chlorovinylphosphine oxides (CXVI). The rearrangement takes place via a four-membered transition state, formed as a consequence of the intramolecular attack by the negatively charged oxygen of the C=O group on the positively charged phosphorus atom[126] (Scheme 15).

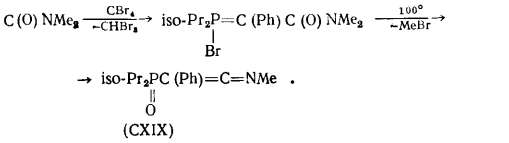


Scheme 15

(CXV) (CXVI)

R = t-Bu, Et_2N .

The *P*-halogenoylides (CXVII), containing an alkoxycarbonyl group, are converted into the phosphorylated ketens (CXVIII) even at room temperature and an alkyl halide is formed[25,127–129]:



(CXVII) (CXVIII)

R = iso-Pr, t-Bu, EtO, iso-PrO, Me_2N, Et_2N; R′ = Ph, CO_2Me; Hal = Cl, Br .

The *P*-halogenylides (CXVII) are comparatively stable at 0 °C. They have been isolated in a pure state and characterised by the usual physical and chemical methods[14,25].

Diisopropyl-α-(*N*,*N*-dimethylcarbamoyl)benzylphosphine reacts with carbon tetrabromide to form a *C*-phosphorus-containing keten imine (CXIX) via the intermediate *P*-bromoylide[126]:

(CXIX)

The labile halogen atom attached to the $\overset{+}{P}$–C group in combination with the highly basic negatively charged ylide carbon atom determines the unusual "chlorinating" dehydrating

properties of *P*-chloroylides. Thus the reaction of the *P*-chloroylides (XI) with *N*-monosubstituted carboxylic acid amides results in the formation of imidoyl chlorides and phosphine oxides. The reactions take place in ether at a temperature below 0 °C and is accompanied by the evolution of heat[131]:

$$(XI) + PhC(O)NHR'' \rightarrow \begin{matrix} t\text{-Bu}(R)P(O)CH_2R' \\ + \\ PhC(Cl)=NR'' \end{matrix};$$

$R = t\text{-Bu}, Et_2N$; $R = H, Pr$; $R'' = Ph, p\text{-}ClC_6H_4$.

It has been suggested that the deprotonation of the amide by the ylide results in the formation of an ion pair containing the mesomeric anion $O-\overset{-}{C}-NR'$. The attack by the phosphonium cation on the oxygen atom of this anion gives rise to a quasi-phosphonium salt, which decomposes into an imidoyl chloride and a phosphine oxide[131] via Scheme 16.

Scheme 16

$$PhC(O)NHR' + R_2P(Cl)=CH_2 \rightarrow R_2\overset{+}{P}(Cl)-CH_2Me \; O=CPh(R'N) \rightarrow R_2\overset{+}{P}(Me)-O-C(Ph)=NR' \; Cl^- \rightarrow R_2P(O)Me + PhC(Cl)=NR' .$$

The primary amides of carboxylic acids are dehydrated by *P*-chloroylides (XI) and are converted into nitriles. Imidoyl chlorides are formed as intermediates and are dehydrochlorinated by the ylides to nitriles:

$$R''C(O)NH_2 \xrightarrow[-t\text{-}Bu(R)P(O)CH_2R']{(XI)} [R''CCl=NH] \xrightarrow[-t\text{-}Bu(R)(R'CH_2)PCl_2]{(XI)} R''C\equiv N .$$

The anilides of diphenylacetic and α-phosphorylated carboxylic acids react similarly with the *P*-chloroylides (XI) to form keten imines, while *N*,*N'*-disubstituted ureas are dehydrated by *P*-chloroylides to carbodiimides. The reaction of *P*-chloroylides (XI) with phosphaureas, providing a pathway to the synthesis of the heterocumulenes (CXX) with a dicoordinate phosphorus atom, are of special interest[96,131-133]:

$$R_2CHC(O)NHPh \xrightarrow{(XI)} R_2C=C=NPh ;$$

$R_2 = Ph_2$, t-Bu$_2$P(O)C(Me) ;

$$R-NHC(O)NH-Ph \xrightarrow{(XI)} R-N=C=N-Ph ;$$

$R = Ph$, t-Bu ;

$$RPHC(O)NHBu\text{-}t \xrightarrow{(XI)} RP=C=NBu\text{-}t .$$

(CXX)

P-Halogenoylides serve as the starting materials for the synthesis of a wide variety of organophosphorus compounds containing P=C bonds, including those which are difficult to obtain in other ways. Thus bis(methylene)phosphoranes (CXXII), the first compounds of quinquevalent tricoordinate phosphorus with two P=C bonds, have been obtained with the aid of the *P*-chloroylide (CXXI)[134]:

$$R-P(Cl)-C(SiMe_3)_2 \xrightarrow[-LiCl,-Cl_2C(SiMe_3)_2]{LiCCl(SiMe_3)_2} R-P[C(SiMe_3)_2]_2 ;$$

(CXXI) (CXXII)

$R = C_6H_{11}$, Ph, Me_2N .

In the reactions of *P*-chloroylides (XI) with chlorine-containing electrophiles (chlorotrimethylsilane, carboxylic acid chlorides, and tervalent phosphorus chlorides), the hydrogen atoms attached to the carbon atom of the P=C group are substituted and the new *P*-chloroylides (CXXIII)–(CXXVI), containing various substituents at the α-carbon atom, are formed[28] (Scheme 17).

Scheme 17

$$t\text{-Bu}(R)P(Cl)=CH_2 \rightarrow \begin{cases} \xrightarrow{R'C(O)Cl} mpe\ t\text{-Bu}(R)P(Cl)=CHC(=O)R' \ (CXXIII)\ (R'=CCl_3, CF_3) \\ \xrightarrow{Me_3SiCl} t\text{-Bu}(R)P(Cl)=CHSiMe_3 \ (CXXVI) \\ \xrightarrow{mpem\text{-}BuPCl_2} t\text{-Bu}(R)P(Cl)=CHP(Cl)Bu\text{-}t \ (CXXV) \\ \xrightarrow[(R=Et_2N)]{(Me_2N_2)PCl,CCl_4} t\text{-Bu}\,P(Cl)\,Cl\,P(NMe_2)_2\,CH\,NEt_2\;Cl^- \ (CXXVI) \end{cases} ;$$

$R = t\text{-Bu}$, Et_2N .

The halogen atom at the phosphorus atom in *P*-halogenoylides is exchanged for different substituents on interaction with nucleophiles containing a mobile hydrogen atom. The *P*-halides stabilised by electron-accepting groups are converted with high yields into all possible types of *P*-substituted ylides on interaction with alkylamines, aniline, ammonia, lithium phosphides, alcohols, phenols, thiols, and lithium alkyls[14,16,20,21,35,37,130]. These reactions are preparatively very simple and lead to extensive prospects for the synthesis of ylides containing virtually any substituents at the phosphorus atom in the P=C group (Scheme 18).

Scheme 18

$$R_2P(OAlk)=CR'_2 \xleftarrow{AlkOH+Et_3N\ (AlkONa)} R_2P(Hal)=CR'_2 \xrightarrow{NH_3} R_2P(NH_2)=CR'_2 ;$$

$$R_2P(OPh)=CR'_2 \xleftarrow{PhCNa} \qquad \xrightarrow{AlkNH_2} R_2P(NHAlk)=CR'_2 ;$$

$$R_2P(SAlk)=CR'_2 \xleftarrow{AlkSH+Et_3N} \qquad \xrightarrow{Alk_2NH} R_2P(NAlk_2)=CR'_2 ;$$

$$R_2P(R_2P)=CR'_2 \xleftarrow{R_2PLi} \qquad \xrightarrow{PhNH_2+Et_3N} R_2P(NHPh)=CR'_2 ;$$

$R = Alk, AlkO, Ph, Alk_2N$; $R' = CO_2R, SO_2Ph, SiMe_3, SiCl_3, Ph$; $Hal = Cl, Br$.

On the other hand, the unstabilised *P*-halogenoylides (XI) are converted with high yields into the phosphonium salts (CXXVII)–(CXXX) on interaction with compounds containing a mobile hydrogen atom (alcohols, phenols, ketoenols, alkylamines, hydrazoic acid, etc.)[130]. The CH acidity of the phosphonium salts is low and they are not dehydrochlorinated under the reaction conditions and are not converted into ylides. The reaction therefore stops at the stage involving the formation of addition products and not substitution products, as in the case of the stabilised *P*-halogenoylides:

Scheme 19

$$t\text{-Bu}(R)\overset{+}{P}(NHMe)MeCl^- \xleftarrow{MeNH_2} t\text{-Bu}(R)P(Cl)=CHR' \xrightarrow{AlkOH} t\text{-Bu}(R)\overset{+}{P}(OAlk)CH_2R'Cl^- \ (CXXVIII) ;$$

(CXXIX)

$$t\text{-Bu}(R)\overset{+}{P}(OAr)CH_2R'Cl^- \xleftarrow{ArOH} (XI) \xrightarrow{HN_3} t\text{-Bu}(R)\overset{+}{P}(N_3)MeCl^- \ (CXXX) ;$$

(CXXVII)

$$(XI) \xrightarrow{ArOH} t\text{-Bu}(R)\overset{+}{P}(Cl)CH_2R'OAr^- \rightarrow (CXXVII) .$$

(CXXXI)

The reactions of unstabilised *P*-chloroylides with compounds containing a mobile hydrogen atom take place in two stages. Initially the ylide carbon atom is protonated and the chlorophosphonium salt (CXXXI) is formed, after which the anion attacks the phosphonium cation to produce the phosphonium chloride (CXXVII). The chlorophosphonium salts (CXXXI) can be detected by spectroscopic methods[96,130].

It follows from the data examined here that the *P*-hetero-substituted phosphorus ylides can be used successfully in organic and organophosphorus synthesis. They successfully complement and significantly extend the applications of ylides as a whole. The introduction of various substituents not only at the carbon atom but also at the phosphorus atom of the P=C group makes it possible to control flexibly the properties of these reactive compounds.

The Properties and Use in Catalysis of Zeolites of the Pentasil Type

Kh.M.Minachev and D.A Kondrat'ev

Progress in the study of the structure, physicochemical, and catalytic properties of high-silica zeolites of a new structural type—pentasils— has been reviewed. The bibliography contains 289 references.

V.	The use of pentasils in other catalytic reactions	1137

I. INTRODUCTION

In recent years in the field of zeolite catalysis, there has been intensive development of studies of the physicochemical and catalytic properties of zeolites of a new structural type—pentasils. These zeolites are characterised by an unusually high SiO_2 content, and are therefore sometimes called "super-high-silica" (SHS) zeolites. The best known of these materials are the Mobil Oil ZSM zeolites[1-6], for which x, the molar ratio SiO_2/Al_2O_3, usually lies in the range 12–100, but may reach much higher values. The final member of this series is silicalite[7], which does not contain any aluminium ($x = \infty$) and consists of crystalline silicon dioxide. Analogues of the ZSM zeolites have also been synthesised and are being extensively studied in the Soviet Union; in the Soviet scientific literature they are usually called SHS zeolites.

Interest in the new generation of zeolites increased after the publication, by Mobil Oil in 1974-75, of a large number of patents which showed that ZSM zeolites are much more effective catalysts for a number of processes of practical importance in petroleum refining and petroleum chemistry than their predecessors (faujasites, mordenite, etc.). Processes based on the use of ZSM zeolites include, for example, the catalytic dewaxing of petroleum fractions[8,9], the alkylation of aromatic hydrocarbons by alkenes[10], the aromatisation of individual C_2–C_4 alkenes and their mixtures[11-13], the cracking of gas oil fractions, giving a higher yield of aromatic hydrocarbons[16,17], the isomerisation of xylenes[18-21], and the conversion of synthetic gas into petrol[22]. In 1975, a number of patents[23-31] were published on the production of high-octane petrols (octane number ≥95) from various oxygen-containing and other heteroatomic compounds in the presence of ZSM zeolites.

A unique place among these processes is occupied by the production of high-octane petrol from methanol on ZSM zeolites[28,32-37]. This process, which at the time of the energy crisis and the search for new sources of energy revealed a realistic way of obtaining high-quality motor fuels without using petroleum raw materials, stimulated the study of the properties and potential use of the new zeolites as catalysts.

Although only slightly more than ten years have passed since the appearance of the first papers on pentasils, extensive information has accumulated in the literature on

the structure, physicochemical, and catalytic properties of these zeolites. These data have to some extent been reflected in a number of reviews of problems in zeolite catalysis[38-51]. Some of the reviews were published a comparatively long time ago, however, and they do not include recent results. The authors of other reviews either restricted themselves to an examination of data on the use of pentasils as catalysts of one single reaction, or use these data to illustrate the current state and trends in the development of zeolite catalysis. Thus in the compilation of the present review an attempt has been made, as completely as possible, to survey, systematise, and analyse data available in the scientific literature on zeolites of the pentasil family, with the exception of patents, although in a number of cases reference to these has been necessary.

II. SYNTHESIS, STRUCTURE, AND PHYSICOCHEMICAL PROPERTIES OF PENTASILS

The synthesis of zeolites is an independent and very specific field at the boundary between inorganic and physical chemistry. The main characteristics of the method of preparing pentasils will therefore be examined only briefly, and the conditions for their crystallisation and the regular features, kinetics, and mechanism of this process will not be discussed in detail. A large number of published papers have been devoted to these questions[52-61].

The synthesis of pentasils is based on the hydrothermal crystallisation of alkali aluminosilicate gels in the presence of the cations of organic bases. This method has been described in Mobil Oil patents dealing with the production of various representatives of the ZSM zeolite family[2-6]. At the present time this family alone includes more than fifteen different zeolites (ZSM-4, -5, -8, -10, -11, -12, -20, -21, -34, -35, -38, etc.), which are synthesised by varying the temperature of the process, the ratio of the components in the reaction mixture, and other conditions, and also using different organic compounds as additives.

The addition of organic bases (tetramethylammonium compounds) was first used in 1961 by Barrer[62,63] in the synthesis of the first generation of zeolites. The zeolites obtained in this way (zeolites of type A, erionite, chabasite, offretite, faujasite) were characterised by higher values of the ratio SiO_2/Al_2O_3 than the same zeolites synthesised in the absence of organic cations. In a development of this method, Mobil Oil studied the possible use in zeolite synthesis of tetraethyl-, tetrapropyl-, and tetrabutylammonium and tetrabutylphosphonium cations and the cations of pyrrolidine, ethylenediamine, and other organic compounds. This led to the preparation of the high-silica zeolites of the large ZSM family.

The study of these zeolites[5,6] showed that some of them, for example ZSM-21 and -34 zeolites, have a familiar structure (ferrierite and erionite–offretite respectively). At the same time, the zeolites ZSM-5, ZSM-11, and apparently ZSM-12 belong to a previously unknown pentasil structure[2-4] which has no natural analogues. The same structure is shown by silicalite and fluorosilicalite (analogues of ZSM-5), obtained in the presence of the tetrapropylammonium cation[64,65]; silicalite-2 (analogue of ZSM-11), synthesised using tetrabutylammonium cations[66]; and tetraethylammonium silicate (analogue of ZSM-12), which was crystallised in the presence of tetraethylammonium cations[67]. It is now known that zeolites with a pentasil structure can be synthesised using as organic additives, for example, lower aliphatic alcohols, or without using any organic additives[68].

In the ZSM zeolite family, the most detailed studies have been carried out for ZSM-5 and ZSM-11 zeolites[69-73], which show unusual catalytic properties, and also silicalite[48], the structural analogue of ZSM-5 zeolite. The ZSM-5 zeolite crystallises in the orthorhombic system with crystal lattice parameters $a \cong 20.1$, $b \cong 19.9$, and $c \cong 13.4$ Å, and the ZSM-11 zeolite crystallises in the tetragonal system with lattice parameters $a = b = 20.12$ Å and $c = 13.44$ Å. The composition of the unit cell of both zeolites in the Na form is given by the formula $Na_nAl_nSiO_{96-n}O_{192}\cdot\sim 16H_2O$, where $n < 27$ for ZSM-5 and $n < 16$ for ZSM-11. The densities of the crystal lattice of the zeolites ZSM-5 and ZSM-11 are 17.9 T and 17.6 T per 1000 Å^3 respectively (T = Si + Al).

The crystal lattice of ZSM-5 and ZSM-11 zeolites is based on structural elements (Fig. 1*a*) which consist of five-membered rings. Because of the low Al concentration (which can be determined with a high accuracy in the pentasil framework by X-ray diffraction[74]), these five-membered rings are formed chiefly by silicon–oxygen tetrahedra[69-72]. Chains of these elements (Fig. 1*b*) are connected in layers (Fig. 1*c*), and each chain in the layer is the mirror image of its neighbours. The layers of chains of structural elements can be connected in pairs in two ways. If the connection of two neighbouring layers is accompanied by their inversion relative to one another, a crystal lattice of the ZSM-5 zeolite type is formed, whereas with mirror arrangement of neighbouring layers, a crystal lattice of the ZSM-11 type is formed.

It has been suggested[70] that structurally, ZSM-5 and ZSM-11 zeolites are the extreme members of a very extensive series of mixed structures formed as a result of the large number of possible combinations of chains and layers of structural elements. All these structures belong to the pentasil family, which also includes silicalite, whose crystal lattice is made up of only silicon–oxygen tetrahedra[64].

The production of the crystal lattice of pentasils involves the formation of a system of channels which intersect one another at right angles and which in cross-section have the form of ten-membered rings (Fig. 1*c*). For ZSM-5 zeolite this system consists of straight and "sinusoidal" channels (Fig. 2*a*).[69,70,72] The straight channels in cross-section have the form of an almost regular circle (5.4 × 5.6 Å), and the cross-section of the sinusoidal channels has the form of an ellipse (5.1 × 5.5 Å). An analogous system of channels has been detected in silicalite, which differs from ZSM-5 zeolite only in the fact that the straight channels have an elliptical cross-section (5.0 × 5.6 Å), and the cross-section of the sinusoidal channels has the form of a circle with diameter 5.3 Å.[64] In contrast to ZSM-5 zeolite and silicalite, the system of pores in ZSM-11 is formed only by straight channels, which in cross-section have the form of an ellipse (5.4 × 5.6 Å) (Fig. 2*b*).[71,72] In a number of cases, the synthesis may be accompanied by the formation of zeolites of the pentasil family, having a mixed pore system (for example 2*c*).[47]

The unusual structures and composition of the pentasils give them characteristic catalytic and adsorption properties, which make them different from the first generation of zeolites. This raises the question of the reasons for the high catalytic activity of pentasils, which are characterised by a low aluminium content. According to existing ideas[1], the activity of zeolites in a whole series of catalytic reactions involving carbenium ions is due to the presence on their surface of acidic OH groups, joined to the Al atoms of the crystal lattice.

Of particular importance in this connection is the question, not yet fully resolved, of the localisation and distribution of Al atoms in the framework of pentasils. In the opinion of some authors[69-71], the small number of Al atoms is distributed

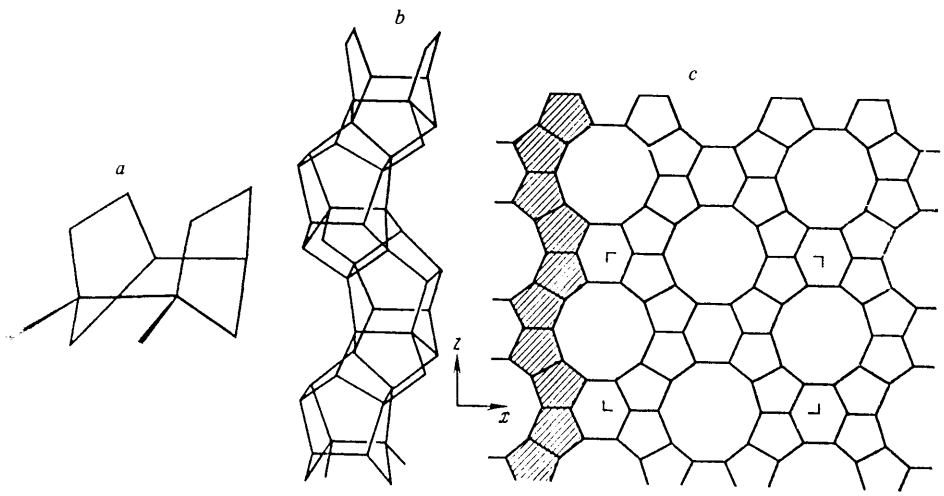

Figure 1. Schematic representation of the structural element (*a*), chains (*b*) of these elements, and the layer (*c*) formed by these chains, for ZSM-5 and ZSM-11 zeolites[69-72].

uniformly through the volume of the crystallites, as confirmed for ZSM-5 zeolites by Auger spectroscopy[75] and secondary ion mass spectrometry[76]. X-Ray photoelectron spectroscopy (XRPES), however, established[77] that the surface of specimens of the Na- and H-forms of ZSM-5 zeolite are enriched in silica. According to the data of other authors, obtained by the same method for ZSM-5 zeolite[78], and also for its analogues of the TsVK and TsVM type[79], the surface layers of the crystallites are enriched in alumina. This is also indicated by the results of a study of large (60–200 μm) crystallites of ZSM-5 zeolite by scanning electron microscopy and scanning X-ray microanalysis[53]. The conclusion that Al is uniformly distributed in pentasil crystallites was also reached in Refs.80–83.

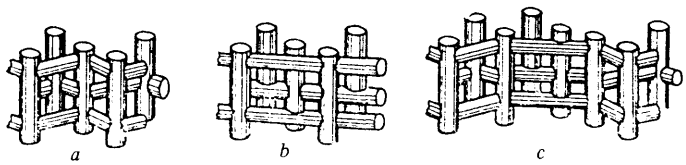

Figure 2. Schematic representation of the structure of the pores in zeolites of different types: *a*) ZSM-5 and silicalite, *b*) ZSM-11, *c*) mixed type[44,64,69-72].

The reasons for this are not completely clear. It is considered[53], for example, that enrichment of the surface layers of pentasil crystallites in aluminium is related to the characteristic features of the final stage of crystallisation. It is pointed out, however, that in small crystallites, the concentration of Al may be the same on the surface and in the volume. It is also known that the nature of the distribution of Al in pentasil crystallites may change with change in the conditions of thermal treatment and treatment with acids (see below).

Because of the low aluminium concentration, zeolites of the pentasil family have a much higher thermal stability than the zeolites of the first generation, whose structure in most cases breaks down at temperatures of 700–800 °C. In contrast to this, X-ray diffraction shows that heating ZSM-5 and TsVK zeolites at temperatures up to 1000° does not lead to breakdown of their crystal structure[2,78,84,85], and the structure of silicalite begins to become amorphous only at 1300°.[64] At the same time, according to XRPES,[78] high-temperature treatment apparently leads to the migration of ~15% of the Al atoms from the framework of the ZSM-5 zeolite. This may indicate slight breakdown of the zeolite structure at the points where aluminium is localised. The possibility of slight changes in the structure of pentasils on high-temperature treatment is also indicated by data on the change in the catalytic activity and selectivity of TsVK zeolite after its activation at 900–1000°.[84,85]

The ion-exchange properties of zeolites of the zeolite family are determined by the characteristic features of their composition. The presence of small quantities of aluminium in these zeolites determines the low value of the negative charge on their lattice and hence the low concentration of cations compensating these charges[57,86]. The latter include both Na^+ cations and the bulky non-exchangeable cations of organic bases (R_4N^+), used in the synthesis of the zeolite. The Na^+ cations, whose concentration in the original Na-form of the pentasils usually does not exceed 1.0–1.5% (calculated as Na_2O), can readily be replaced by NH_4^+ cations or protons by ion exchange with NH_4Cl or HCl. The organic cations are readily decomposed by heating the zeolite in air (350 to 450°), and are removed as ammonia, amines, and the corresponding hydrocarbons. The decationated or proton H-forms of the zeolites produced by this treatment have a higher sorptive capacity[2,86,87] and a higher catalytic activity[86-88] than the original Na form.

When caesium cations are introduced into the H-forms of a series of ZSM-5 zeolites with different compositions ($SiO_2/.Al_2O_3$ = 89–8660), a very good correlation is observed between the concentration of exchangeable caesium and the concentration of Al in the zeolite framework (Fig.3).[89] Thus the ability of pentasils to undergo ion exchange shows the

same dependence on the Al concentration in the crystal lattice as in the case of zeolites of the first generation. Moreover, the protons of the H-forms of ZSM-5, TsVK, and TsVM pentasils can be replaced by the cations of Na, Ca, Ag, the lanthanides, Pt, and Pd,[2,90,91] and this opens up new possibilities for the directed control of the catalytic properties of these zeolites.

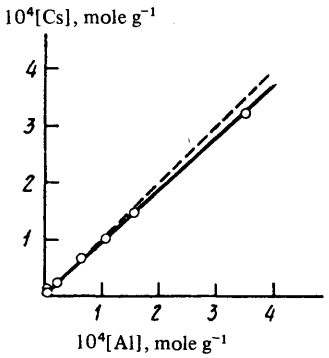

Figure 3. Influence of the Al concentration in the framework of H-ZSM-5 zeolite on its ability to undergo exchange with caesium[89]; the broken line corresponds to a ratio [Cs]/[Al] = 1.

Pentasils are much more hydrophobic than first-generation zeolites[2,64,89,92-95]. For ZSM-5 zeolite heated in air at 550°, the ratio of the quantities of sorbed n-hexane and water is ~1.5, whereas for zeolites of types A, X, and Y, the ratio is ~0.5.[2] According to other data[93], the same ratio (which for zeolites of types A, X, and Y, and mordenite is 0.4–0.9) increases to 1.4–2.4 for ZSM-5 and ZSM-11 zeolites. The water adsorbed by ZSM-5 zeolite occupies only 20–25% of the total volume of its pores[64,89]. For different ZSM-5 zeolite specimens in which the ratio SiO_2/Al_2O_3 varied from 75 to 8660 [89] and from 50 to 900,[95] with decrease in the Al concentration of the zeolite, the quantity of water sorbed by it decreased linearly to a very low value, corresponding to the adsorption of water by silicalite (~15 H_2O molecules per unit cell[64]). A similar result was obtained[96] for a number of ZSM zeolite specimens and their analogues with different Al concentrations.

These data on the hydrophobic properties of pentasils are in good agreement with the suggestion that there is a relationship between the affinity of the zeolites for water and the concentration of aluminium in them, and also that a bond is formed between the molecules of sorbed water and the protons joined to $[AlO_2]^-$ groups in the zeolite structure[94].

The hydrophobic character of the zeolites is combined with an ability to adsorb small molecules of various inorganic compounds. O_2, N_2, CO_2, and H_2S molecules easily penetrate into the channels of ZSM-5 and ZSM-11 zeolites[72], and the sorptive capacity of the latter is slightly lower, because of the characteristic features of its porous structure (see above). A significant contribution to the sorptive capacity of pentasils is apparently made by the cavities which are formed at the points of intersection of the channels and which have different shapes in ZSM-5 and ZSM-11. The H-form of ultrasil (an analogue of ZSM-8 zeolite) has a high sorptive capacity for hydrogen, equal to ~80% of its capacity for nitrogen[97].

A study of the adsorption of substances of different chemical character (inorganic compounds, hydrocarbons, methanol) on a zeolite of the ultrasil type[98,99] showed a definite relationship between the quantity of the substance sorbed by the zeolite and the volume of the sorbate molecules (Fig. 4). The curve giving this relationship shows a maximum in the region of n-heptane, whose existence was attributed to steric hindrance, preventing the diffusion into the pores of the zeolite of molecules with a chain length of more than seven carbon atoms. In contrast to this, for NaX zeolite, the quantity of adsorbed substance is independent of the volume of the adsorbate molecule.

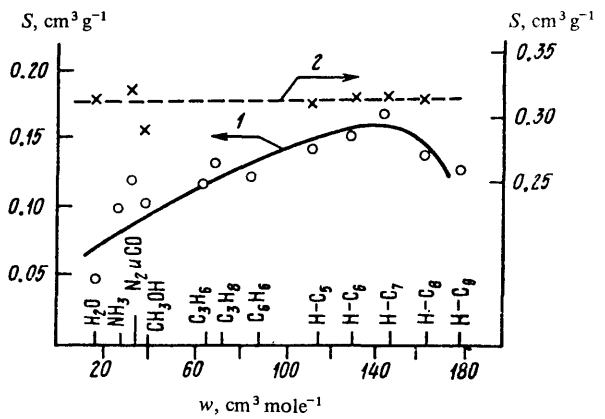

Figure 4. Change in the volume (S) of substances adsorbed by ultrasil (*1*) and NaX zeolite (*2*) on the volume of their molecules (w) (from published data[99]).

Pentasils readily adsorb normal alkanes[2-4,64,70,72,87,95,98-103]. The adsorption of branched alkanes and alkylaromatic and other hydrocarbons is limited considerably by the size and shape of the pores in the pentasils. For example, ZSM-5 zeolites readily adsorb n-hexane (4.3 Å)†, but sorb the isomeric methylpentanes (5.5 Å) and dimethylbutanes (6.1–6.3 Å) to a much smaller extent, and the extent of the sorption of these hydrocarbons decreases with increase in the degree of branching of the adsorbate molecules. H-ZSM-5 zeolite selectively adsorbs 2-methylpentane from its mixture (1:1) with 2,2-dimethylbutane[104,105]. Benzene, toluene, and *p*-xylene (which all have a diameter of 5.8 Å) are the aromatic hydrocarbons most readily adsorbed. An interesting feature is that the volume of benzene sorbed by H-ZSM-5 zeolite is much smaller than the volume of *p*-xylene. This is apparently because of the closer packing of the *p*-xylene molecules in the pores, and the interaction of the hydrogen atoms of this isomer with the surface of the walls of the zeolite pores[70,72].

The pore volumes occupied by adsorbed hydrocarbons with different structures are different, and always less than the true volume of the entire system of channels in the pentasil[72]. The system of pores in these zeolites is evidently not equally accessible to adsorbate molecules with different structures.

---

†The figures in brackets give the values of the kinetic diameter of the molecules from Refs. 1 and 70.

The accessibility of the porous structure of pentasils (ZSM-5, ultrasil) to molecules of different hydrocarbons has been studied in detail[100,101,106]. The sorptive capacity of ZSM-5 zeolite for n-hexane is greater by approximately 30% and 50% than its capacity for 3-methylpentane and benzene respectively[72]. The sorptive capacity of pentasils depends to a significant extent on the nature of the adsorbate[107].

In the examination of sorption processes in zeolites, it is desirable to take account of the rate of penetration of the molecules into the pores of the adsorbent[108]. There are as yet, however, very few published data on the kinetics of sorption and diffusion for pentasils. The diffusion coefficients of benzene and *p*-xylene in ZSM-5 zeolite are approximately 10^3 times that for *o*-xylene, and 10^5 times those for 1,3,5-trimethylbenzene and pentamethylbenzene[70,109]. The initial rates of the adsorption of the xylene isomers in TsVK zeolite decrease in the following order[84]: *p*-xylene > *m*-xylene > *o*-xylene.

Thus pentasils whose maximum pore diameter is ~5.8 Å show clearly defined molecular-sieve properties. Unlike the first-generation zeolites, they can sorb molecules whose kinetic diameter exceeds the width of their channels by ~1 Å.[100] At the same time, in the pentasil pore system there is steric hindrance to the diffusion of molecules whose shape does not correspond to the shape of the zeolite channels[110,111].

Molecular-sieve properties of this kind, requiring correspondence between the size and shape of the adsorbate molecules and the pores of the adsorbent, were previously observed for various first-generation zeolites (zeolite of type A, erionite, mordenite, etc.).[110-112] As with these zeolites, the molecular-sieve properties of the pentasils have a significant influence on their catalytic properties. This influence is revealed as the so-called "configurational selectivity" (shape selectivity)[110] of catalytic reactions with respect to the original reagents, the products, or the transition state. These effects have made it possible to use pentasils as catalysts for dewaxing petroleum fractions[8,9], for the selective production of *p*-xylene[18-21,109], and for other processes[113].

The sorptive properties of pentasils depend both on the diameter and on the shape of the channels forming their porous structure. The straight and sinusoidal pores of ZSM-5 zeolite differ in relation to the adsorption and diffusion of hydrocarbons[70,72,102]. ZSM-5 zeolite has a higher sorptive capacity for hydrocarbons than ZSM-11 zeolite[114]. The geometry of the pores of ZSM-5 zeolite evidently corresponds more effectively to the shape of the molecules of the hydrocarbons being sorbed. A relationship has been established between the length of adsorbate molecules, the length of the channels in the pentasils, and their sorptive capacity, and it has been shown that the cavities which are formed by the intersection of the channels and which have different shapes in ZSM-5 and ZSM-11 zeolites play a part in the processes of sorption and diffusion[72,102]. In ZSM-11 zeolite, in which all the pores are straight, the molecules of normal and branched C_3–C_{10} hydrocarbons can be adsorbed in channels passing through the crystallite in only one crystallographic direction. In contrast to this, in ZSM-5 zeolite, small n-alkane molecules (C_3–C_5) are adsorbed in all the pores. Higher n-alkanes (C_6–C_8), C_4 and C_5 isoalkanes, and *p*-xylene are adsorbed only in the straight channels, and C_9 and C_{10} n-alkanes only in the sinusoidal channels. For the isomers of decane (methylnonanes), depending on the position of the methyl group in the chain, the adsorption of the isomers may take place only in the straight channels (4-methylnonane) or only in the sinusoidal channels (5-methylnonane) of ZSM-5 zeolite[72].

Published data on the adsorption of hydrocarbons on ZSM-5 zeolites[102] indicate that the movement of the molecules inside the crystallites is controlled by the pentasil pore system itself (molecular traffic control). According to this hypothesis, which has been questioned[115,116], in catalytic processes (for example the transformation of methanol into hydrocarbons), reagent molecules with a definite size diffuse into the crystallites along channels of one type, and the molecules of products with a different size are removed from the zeolite through channels of the other type. This should stop back-diffusion, which lowers the reaction rate.

The influence of the pore structure of pentasils on their molecular-sieve and catalytic properties is also revealed in the high stability of zeolites of this type with respect to coke formation, compared with first-generation zeolites. The restricted diameter of the channels in the pentasils, and the absence of large cavities, apparently prevent the formation, in the crystallites, of large molecules of polycondensed aromatic compounds, which cannot diffuse out of the pores and which provide one source of the coke which deactivates the catalyst[78,112,117-120]. In H-ZSM-5 zeolite, in contrast to mordenite and offretite, coke is formed on the outer surface of the crystallites, and not inside the pores, where the most strongly acidic centres, responsible for the catalytic activity of the pentasils, are situated[119]. In the transformation of C_3 and C_4 alkanes (450–550 °C), TsVK pentasils shows practically no loss of activity for 6–8 h, whereas zeolites of types A, X, and Y, and mordenite under the same conditions are rapidly deactivated as a result of intensive coke formation[121].

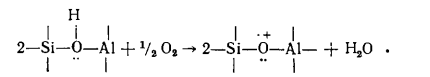
The shape and diameter of the pentasil channels evidently are not the only factors determining their adsorption and catalytic properties. For example, the study of the sorption of a series of hydrocarbons, methanol, and dimethyl ether on different specimens of H-ZSM-5 zeolite has shown[107,108] that the extent and kinetics of the sorption depend on the $SiO_2/.Al_2O_3$ ratio and on the size of the crystallites. It is suggested that the sorptive properties of the pentasils may be influenced by various other factors which cannot be estimated by a simple analysis of the structure and composition of the zeolite, since they are determined by the previous history of the specimen[107]. They apparently include the nature of the localisation of the Al atoms in the crystal lattice, the phase purity of the zeolite, and the structural type to which it belongs (ZSM-5, ZSM-11, or a mixed structure).[70]

The chemical character of the adsorbate also has a significant influence on the nature of the sorption processes on pentasils. For example, ethylene and propylene, unlike ethane and propane, are adsorbed irreversibly and in larger quantities on the H-forms of ZSM-5 zeolites[103,107,122,123]. Infrared spectroscopy and other methods have shown that on pentasils, ethylene molecules are chemisorbed, activated, and react with other molecules of this alkene from the gas phase, forming a linear oligomer, which fills the pores of the zeolite[103,107,123]. When propylene is adsorbed, molecules of non-branched macromolecular compounds again accumulate in the pores of the pentasil. It is suggested that propylene undergoes conjugated polymerisation, and not oligomerisation, which leads to the formation of oligomers with quaternary carbon atoms, whose formation is prevented by the small diameter of the channels in the pentasil[122].

The formation of macromolecular compounds in the pores was also observed in a study of the adsorption of C_4–C_6 alkenes and cycloalkenes (cyclopentene, cyclopentadiene, and cyclohexene) on HZ-79 zeolite, an analogue of ZSM-5 zeolite[123]. In contrast to this, an infrared spectroscopic study of the adsorption of hex-1-ene, hept-1-ene, and cyclohexene on H-ZSM-5 zeolite detected only the interaction of the alkenes with the active (acidic) centres of the zeolite[124].

Because of the low concentration of Al atoms, the centres active in catalysis and adsorption are evidently situated at comparatively large distances from one another, and this lowers the probability of interaction between the sorbed molecules.

With increase in temperature, the oligomers or polymers filling the pores of the pentasil undergo cracking, and their decomposition products are readily removed as various hydrocarbons from the channels by a stream of inert gas[122,123]. In this way it has been possible, for example, to regenerate TsVK zeolite modified by added vanadium, which had been completely deactivated in experiments with ethylene by its oligomerisation products[125].



The sorption and catalytic properties of zeolites are due to the presence of active centres on their surface. It is therefore necessary to examine the question of the nature of these centres in pentasils and to determine whether there are any differences in this respect between pentasils and first-generation zeolites. Studies by infrared spectroscopy, mass spectrometry, and various other methods have shown[78,126-129] that the surface of pentasils, like that of first-generation zeolites[130], is covered by OH groups of two types. In the infrared spectra these correspond to two bands in the hydroxyl group stretching region at 3720 cm^{-1} and 3600 cm^{-1}.

The band at 3720 cm^{-1} is assigned to silanol or terminal OH groups (Si–OH), which do not have acidic properties and play no part in catalysis[78,130]. It is suggested[78] that these groups may also be joined to the amorphous SiO_2 present as impurity in pentasils. A recent study of the infrared spectra of a series of carefully prepared specimens of H-ZSM-5 zeolite with a high purity and different concentrations of Al atoms in the lattice (from 0 to 47 Al atoms in the unit cell) showed that the band at 3720 cm^{-1} is in fact due to a small quantity of structureless silicon dioxide, and also a very small quantity of terminal OH groups. Thus the presence or absence of this band in the infrared spectra of pentasils can be used as an indicator of the degree of crystallinity and the phase purity of the zeolite[131].

The band at 3600 cm^{-1} is due to acidic groups formed by the decationation of the Na- or NH_4-forms of the zeolites. It is usually assumed that they act as Brönsted acidic centres and are responsible for the catalytic activity of zeolites in acidic reactions[78,126-130]. These groups are joined to three-coordinate Al atoms in the zeolite framework (Si–OH–Al); the number of groups should therefore correspond to the concentration of Al in the crystal lattice. The infrared spectra of very pure specimens of H-ZSM-5 zeolite contain only the band at 3600 cm^{-1}.[131] Its width indicates that the acidic OH groups are apparently localised in cavities formed by the intersection of the channels of the pentasil.

The activation of zeolites at increased temperatures (T_{act}) is accompanied by the removal of both terminal and acidic (bridging) OH groups. As a result of dehydroxylation, the Brönsted acidic centres are converted into Lewis centres[130]. In first-generation zeolites, Brönsted centres can be regenerated by hydrating the dehydroxylated zeolites. In contrast to this, repeated hydration of an H-ZSM-5 zeolite activated at $T_{act} = 800°$ does not lead to regeneration of the Brönsted centres[78]. At a high T_{act}, apparently, a certain fraction of the Al atoms is removed from the zeolite framework and prevents the hydration of the Lewis centres, localised in the depth of the channels of the pentasil. This migration of aluminium as Al^{3+} cations from the framework of zeolites of type Y, and, to a lesser extent, mordenite was observed by ^{27}Al NMR spectroscopy after thermochemical treatment of the specimens[129,132]. It is assumed that the strong electron-acceptor properties of the Al^{3+} cations and the possibility of the heterolytic ionisation of water molecules in the field of these cations lead to the production in zeolites of type Y and mordenite of strong proton-donor centres of the type $[Al-O-Si]_3^-[O-Si].Al_3^+(OH)^-...H^+$. Since in zeolites of the TsVK type and erionite the migration of Al could not be detected, the authors cited[129,132] assumed that in these zeolites such centres are either absent or present at very low concentrations. It should also be noted that there are no published data confirming the existence of proton-donor centres of this type in zeolites.

Recent EPR data[133] indicate that the activation of pentasil at $T_{act} \geq 500°$ is accompanied by the conversion of Brönsted acidic centres into "solid state defects":

In the opinion of the authors[133], organic molecules adsorbed on a pentasil surface and capable of ionisation can react with these defects to form radical-cations, which undergo subsequent transformations. The reactions of this kind examined include the isomerisation of 3,3-dimethylbut-1-ene to 2,3-dimethylbutene, and the cyclotrimerisation of 1,2-dimethylacetylene.

As already noted, the quantity of Al atoms in the pentasil framework is much smaller than that in first-generation zeolites. Thus the concentration of Brönsted (and correspondingly Lewis) acidic centres in pentasils should be appreciably lower[78]. This is confirmed by data obtained by H–D exchange and from the infrared spectra of pyridine adsorbed on the zeolites (Table 1),[128] and also by ^{27}Al NMR spectroscopic data[129].

Table 1. Comparison of the acidic properties of H-ZSM-5 and HNaY zeolites[128].

Parameters	H-ZSM-5	HNaY
T_{act}, °C	400	500
Concentration of OH groups*	$2.2 \cdot 10^{20}$	$8.7 \cdot 10^{20}$
Concentration of Brönsted centres**	$3 \cdot 10^{19}$	$3 \cdot 10^{20}$
Concentration of Lewis centres	$2 \cdot 10^{19}$	$3 \cdot 10^{20}$

*Calculated for 1 g of zeolite (from H–D exchange data).
**The concentration of acidic centres in 1 g of zeolite was calculated from the infrared spectra of adsorbed pyridine.

The number of Brönsted acidic centres in the unit cell should correspond exactly to the number of Al atoms in the crystal lattice of the zeolite[131,132]. The calculation of the number of these centres in pentasils from the heats of adsorption of NH_3 (q), however, gives low values, and this has been attributed to the existence in the pentasils of very weak acidic centres ($q \leq$ ~60 kJ $mole^{-1}$), which cannot be detected by this method[78].

At the same time, the high acidity of the pentasils is combined with a comparatively low concentration of acidic centres. This suggested that these zeolites contain centres having an anomalously strong acidity. The microcalorimetric determination of the heats of adsorption of NH_3 revealed the existence in pentasils of acidic centres of different strength (acidity spectra);[132,134-137] however, only a very small proportion of the centres adsorbed ammonia with q ~150 to

160 kJ mole^{-1}, which was slightly greater than the corresponding value for zeolites of type Y and mordenite (120 to 140 kJ mole^{-1}).[132-137] Zeolites of the ultrasil and mordenite type showed practically no difference from one another in the heats of adsorption of NH_3 on the strongest centres (q ~ 150 kJ mole^{-1}).[134]

The infrared spectra of pyridine adsorbed on H-ZSM-5 showed that with increase in T_{act} from 500° to 800°, the intensity of the bands at 1550 cm^{-1} and 1460–1450 cm^{-1} in these spectra decreases, that is there is a decrease in the concentration of both the Brönsted and the Lewis centres[78]. An EPR study of the adsorption of NO, however, indicated that the number of the strongest Lewis centres, capable of adsorbing nitric oxide, begins to increase sharply at T_{act} > 500°.[78] The discrepancy in the data obtained by the two methods is apparently due to the greater accessibility of the strongly acidic centres of the zeolite for NO molecules, compared with pyridine. Moreover, these data also indicate that such centres are localised inside the pores of the zeolite[72,80,119,137]. Data on the acidic properties of ZSM-5 zeolite are also given in Ref. 138.

The published data on the hydroxyl covering and the acidic properties of Soviet pentasils of the TsVK type and ultrasil[84,134,139-147] agree with and supplement available data for ZSM-5 zeolites. For example, the highly sensitive infrared diffuse reflectance spectroscopy[145] confirmed the above data[78] on the existence of two types of OH group on the pentasil surface, and showed that high-temperature activation leads to the removal of OH groups from the zeolite surface, and that at T_{act} ≅ 900–1000°, some Al atoms migrate from the pentasil framework. These results[145] show good agreement with data obtained by H–D exchange[84], which show that there is an almost two-fold decrease in the concentration of the surface OH groups in a TsVK zeolite with increase in T_{act} from 300° to 700° (curve *1* in Fig. 5). It should be noted that the removal of this quantity of OH groups had practically no influence on the catalytic properties of the zeolite in the transformations of lower alkenes (isobutene): both the total yield of liquid products and the yield of aromatic hydrocarbons remained unchanged (curves *2* and *3* respectively in Fig. 5). Even the activation of the zeolite at 900 to 1000° has little influence on its total activity, although the ability of the zeolite to bring about dehydrocyclisation decreased appreciably. The catalytic activity of TsVK pentasil is apparently due to a small quantity of OH groups present in the active centres, which may break down only at T_{act} > 800°. After high-temperature treatment, the zeolite also showed a significant increase in selectivity in the formation of *p*-isomers of dialkylbenzenes, and this was attributed[84] to slight changes in the zeolite structure at high temperatures. These changes possibly involve the removal of Al atoms from the zeolite framework[145], lead to a decrease in the pore diameter, and create hindrance for the diffusion of molecules larger than *p*-dialkylbenzene molecules.

A number of other studies have established a relationship between the acidity and catalytic activity of pentasils[135,142,143,148,149]. For example, it has been shown[143] that a decrease in the number of strongly acidic centres in a zeolite of the ultrasil type by dehydroxylation is accompanied by a sharp decrease in the activity of this zeolite in the cracking of n-octane and iso-octane. According to Ref. 148, the rate constant for the transformation of methanol into hydrocarbons increases linearly with increase in the acidity (that is the number of acidic centres) of a catalyst based on a ZSM-5 zeolite. A correlation has been established between the acidity and the catalytic activity of H-ZSM-5 pentasil in the cracking of cumene, the isomerisation of *o*-xylene, and the decomposition of methanol and ethanol[149]. The number and strength of the acidic centres in the H-form of this zeolite depend on the conditions of its preparation from the NH_4-form.

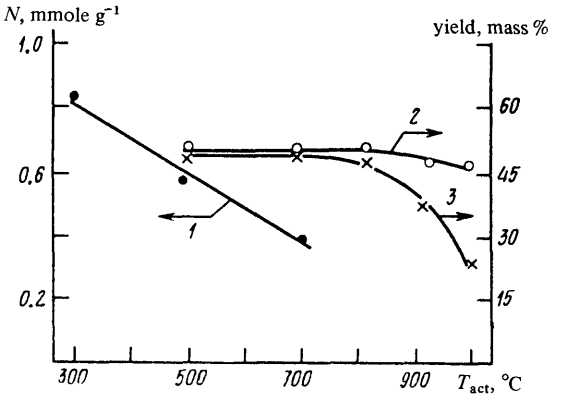


Figure 5. Dependence of the concentration of OH groups (N) in TsVK zeolite (*1*) and the yield of liquid catalysate (*2*) and aromatic hydrocarbons (*3*) from isobutene (500 °C) on T_{act}.[84]

Thus the composition and structure of the pentasils determine a number of specific properties which distinguish them from first-generation zeolites. These properties include, in particular, their hydrophobic nature, high thermal stability, and configurational molecular-sieve selectivity. The surface of the pentasils, like that of zeolites of any other type, carry hydroxyl groups, some of which show acidic properties, and apparently act as the source of the catalytic activity, playing the part of Brönsted acidic centres. The concentration of these centres in pentasils is appreciably lower than that in first-generation zeolites. Nevertheless, they show a high activity as catalysts in a whole series of reactions, and differ from zeolites of other types in their high stability. Data on the use of pentasils as catalysts in various reactions are examined below.

III. TRANSFORMATIONS OF OXYGEN-CONTAINING COMPOUNDS ON PENTASILS

1. Transformations of Methanol

The transformations of various oxygen-containing compounds, including methanol, on first-generation zeolites (chiefly of types X and A) have been the subject of a number of studies and reviews[38,40,42,150,151]. On these zeolites, methanol decomposes to give water, dimethyl ether, and small quantities of lower alkenes and alkanes; the catalysts rapidly lose their activity as a result of coke formation. In contrast to this, on ZSM-5 pentasils, methanol at 350–400° is completely converted into water (~56%) and a mixture of hydrocarbons (~44%).[28,32-37]

According to Ref. 152, the mixture of hydrocarbons formed from methanol contained propane (~16%), n-butane and isobutane (~25%), isopentane (~8%), aliphatic C_6–C_{10} hydrocarbons (~4%), and also toluene (~10%), xylenes (~17%), and

C_9 and C_{10} alkylbenzenes (~11%). The fact that the reaction products did not contain molecules with more than 10 carbon atoms was attributed to the influence of the porous structure of the zeolite, responsible for its molecular-sieve selectivity, as discussed above. This selectivity was also revealed in an increased concentration in the products, compared with the equilibrium concentration, of durene and isomers of tri- and tetramethylbenzenes, whose molecular size enabled them to diffuse comparatively easily from the pores of the zeolite into the gas phase.

The compositions of the products of the transformations of methanol on pentasils have also been studied in detail by other authors[87,138,149,153–167]. In addition to the hydrocarbons indicated above, these products contained small quantities of C_5–C_7 cyclanes and cyclenes, naphthalene, and alkylnaphthalenes[154,156,157]. Data on the composition of the products of the transformations of methanol on pentasils under similar conditions are given in Table 2.

Table 2. Characteristics of the transformations of methanol on ZSM-5 zeolite and the composition of the products.

Parameters of the process[1]	[152]	[153–154]	[155]	[156][3]	[87][3]	[157][4]	[158]	[159]

[3] Pilot plant, stationary catalyst layer, H_2 carrier gas.

[4] After 73 h catalyst use without regeneration in a pilot plant.

[5] Temperature at reactor inlet; temperature at outlet 404°.

[6] Calculated for the pure zeolite, mixed in the catalyst with SiO_2 (1:1).

[7] Including C_5 naphthenes.

[8] Including C_6 and C_7 naphthenes.

[9] Including naphthalene and alkylnaphthalenes.

In spite of the significant differences in the conditions of these reactions (in laboratory[87,152–154,158] or pilot-plant[155–157] assemblies with stationary or fluidised-bed[156] layers of catalyst) and the fact that different ZSM-5 zeolite specimens were used, the data in Table 2 show considerable agreement. Thus in all cases the conversion of the alcohol is ~100%, the yield of hydrocarbons is stoichiometric (~44%), and the products contain 1–3% methane and an appreciable quantity of alkanes, in which iso-alkanes predominate. At the same time, appreciable differences are observed in the distribution of individual products and in the ratio of the quantities of aliphatic and aromatic hydrocarbons formed. Thus the composition of the products of the transformation of methanol depends on the reaction conditions (temperature, volume rate, pressure) and on the composition of the catalyst (the SiO_2/Al_2O_3 ratio).

In a flow reactor with a stationary catalyst layer (H–ZSM-5), the conversion of methanol increased rapidly with temperature, and reached 100% at 340–375°.[152] Below 300°, methanol was converted chiefly into dimethyl ether with the formation of small quantities of C_2–C_5 alkanes and alkenes (7–10%) and aromatic hydrocarbons (~1–3%). At 300–400° the products contained only aliphatic and aromatic hydrocarbons (60% and 40% respectively). Increase in temperature to 450–500° led to the formation of methane and lower alkanes by secondary cracking reactions, and above 500°, methanol decomposed directly to CO and H_2.

Analogous results were obtained when other H-ZSM-5 zeolite specimens were used[153–155,158], including specimens with added phosphorus[158]. With a fluidised-bed catalyst based on ZSM-5 zeolite[156], the reaction rate increased by a factor of 1.5 for each increase in temperature by ~27–30 K. The influence of temperature on the distribution of the products of the transformation of methanol on H-ZSM-5 zeolite was studied in detail[124], and the results showed good agreement with earlier data[152].

The transformations of methanol on ZSM-5 zeolites at different volume rates have been studied[152,154,156,160,163,168]. Increase in the volume rate (v) by a factor of more than 1000 (from 1 h^{-1} to 1080 h^{-1}) lowers the conversion of methanol (370°, p_{CH_3OH} = 1 atm) by a factor of approximately 3 (from 100% to ~30%) and has a significant influence on the direction of the transformations of the alcohol[152]. The change in the composition of the products of the transformations of methanol with change in the volume rate for different partial pressures of alcohol (p_{CH_3OH}) is shown in Figs. 6*a* and 6*b*.[152,160] These data also indicate that p_{CH_3OH} influences the composition of the products formed from methanol on ZSM-5 zeolites. Increase in p_{CH_3OH} leads mainly to an increase in the selectivity of the process with respect to the formation of polyalkylbenzenes, in particular durene[155,156,160]. Thus the aromatic fraction of the products formed from CH_3OH on H-ZSM-5 zeolite at p_{CH_3OH} = 1 atm (370°, v = 1 h^{-1}) contains only ~2 mass % durene[152], whereas at p_{CH_3OH} = 50 atm under the same conditions, the durene concentration increases to ~60 mass %.[160] It is suggested[160] that polyalkylbenzenes are formed by alkylation taking place with simultaneous dehydration of the oxygen-containing compounds and aromatisation of the hydrocarbons (hatched region in Fig. 6*a*). With increase in p_{CH_3OH}, this range broadens considerably (Fig. 6*b*), leading to an increase in the range of conditions favouring the formation of polyalkylbenzenes. With decrease in p_{CH_3OH} to 0.04 atm, the range corresponding to simultaneous dehydration and aromatisation practically disappears, and polyalkylbenzenes are formed in very small quantities.

The degree of transformation of methanol and the composition of the reaction products depend to a significant extent on the SiO_2/Al_2O_3 ratio and the concentration of Na in the pentasil. In the transformation of methanol (400°, v = 3 h^{-1}) on the original form of silicalite (0.22 mass % Na,

SiO_2/Al_2O_3 = 1125), the initial conversion of alcohol was ~50%, and the reaction products contained chiefly dimethyl ether and a small quantity of propane[87]. With decrease in the concentration of Na in the silicalite, the conversion of methanol gradually increased to 100%, and the resulting mixture of aliphatic and aromatic hydrocarbons showed an increased concentration of arenes (up to ~45 mole %). The original and decationated forms of ZSM-5 zeolite were much more active in the transformations of methanol, although the concentration of Na in them (2.03 mass % and 0.38 mass % respectively) were much higher than in the original form of silicalite. In both cases the conversion of the alcohol was 100%. As with silicalite, decrease in the concentration of Na in the zeolite was accompanied by an increase in the concentration of aromatic hydrocarbons in the reaction products (from 20 mole % to 78 mole %).

Thus to obtain silicalite specimens active in the transformation of methanol, it is necessary to have much more extensive decationation than with ZSM-5 pentasil, which is active even in the Na-form. Thus the lower the Al concentration in the zeolite, the greater the extent to which its catalytic activity is suppressed by sodium.

The influence of the SiO_2/Al_2O_3 ratio on the catalytic properties of H-ZSM-5 zeolite in the transformations of methanol can be judged from the published data[161] in Table 3. For the zeolite specimens *1* and *2* with SiO_2/Al_2O_3 ratios of 38 and 54.5 respectively, the conversion of the alcohol and the composition of the reaction products were practically the same, in spite of the difference in the Na concentration in the zeolites and the difference in the reaction temperatures. Increase in this ratio to 158 (specimen *3*), however, decreased the conversion of the alcohol by a factor of almost 2, and in this case the alcohol was converted chiefly into dimethyl ether. Thus the activity of ZSM-5 zeolites in the transformation of methanol into hydrocarbons depends on the concentration of Al atoms in the zeolite framework. Below a definite concentration of these atoms (~0.5%), the number of active centres in the zeolite evidently becomes insufficient for the formation of hydrocarbons from methanol.

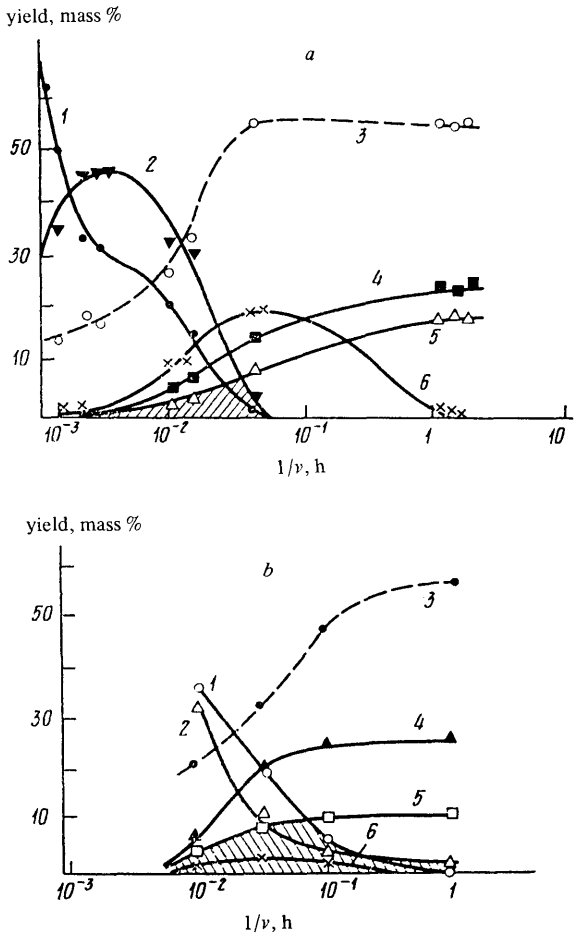

Figure 6. Dependence of the composition of the products of the transformation of methanol on H-ZSM-5 zeolite (370 °C) on the reciprocal of the volume flow rate at $p_{CH_3OH} = 1$ atm (*a*) and 50 atm (*b*): [*1*) CH_3OH; *2*) $(CH_3)_2O$; *3*) H_2O; *4*) alkanes; *5*) aromatic hydrocarbons; *6*) C_2–C_5 alkenes].[160]

including: aromatic	9.1	5.4	0.5
aliphatic	90.9	94.4	99.5

In an examination of the relationship between the composition of pentasils and their activity in the transformations of methanol, mention must be made of patent data[23,24,28,30,169,170], according to which modification of ZSM-5 zeolites by the addition of various elements (Mg, B, Zn, Cd, Sb, Ni, Pd, P, etc.) leads to an increase in the yield of liquid products from methanol and to an increase in the concentration of aromatic hydrocarbons in them. Treatment of a ZSM-5 zeolite with various phosphorus compounds (for example trimethyl phosphite) lowers slightly its activity in transformations of methanol, but increases the selectivity of the reaction with respect to the formation of ethylene and other lower alkenes, particularly at low temperatures[158]. After this treatment, the zeolite showed an increase in the quantity of acidic centres, but these centres were weaker than the centres of the non-modified pentasil[158].

An increase in the selectivity of the transformations of methanol with respect to C_2 and C_3 alkenes was also detected[171] on MnNa-ZSM-5 and MgNa-ZSM-5 zeolites prepared by cation exchange. These zeolites are more stable than MnNaY and MnNaX zeolites.

The production of ethylene and propylene from methanol with a good selectivity (more than 75%) was observed on non-modified ZSM-34 pentasil[6]. This catalyst rapidly lost its activity, however, as a result of coke formation. Improvement of the method of synthesis of ZSM-34 zeolite by using seed crystallites led to a significant change in its catalytic properties. The total yield of hydrocarbons from methanol at 400° increased by a factor of ~2, the selectivity with respect to C_2 and C_3 alkene formation increased to ~80%, and the time of service of the catalyst increased by a factor of 2.2.[172,173] These positive effects are due to the high uniformity of the size and shape of the zeolite crystallites formed in the presence of the seed crystals. Detailed information on the influence of the nature and quantity of added seed crystals on the structural, catalytic, adsorptive, and other properties of ZSM-34 zeolite has been published[174,175]. On the basis of this zeolite, synthesised using a seed crystal, a technical process has been proposed for converting methanol into C_2–C_4 alkenes with a selectivity of more than 86%.[176]

Comparison of the products of the transformation of methanol on H-ZSM-5 and H-ZSM-11 pentasils[113] showed that on H-ZSM-5, aromatic C_8 hydrocarbons are formed preferentially, whereas on H-ZSM-11, more C_9 hydrocarbons are obtained. These results[113] were attributed to differences in the volume of the cavities formed at the intersections of the pores in zeolites of these two types. It was also established that the products of the transformations of CH_3OH on large crystallites of H-ZSM-11 zeolite have approximately the same composition (more aliphatic C_1 and C_2 hydrocarbons, less C_6 hydrocarbons and aromatic C_9 hydrocarbons), as on H-ZSM-5 crystallites with the same size.

The low degree of coke formation characteristic of pentasils, and the corresponding high stability of operation as catalysts, also depend on the composition of the zeolite. Na silicalite and Na-ZSM-5 zeolite are deactivated completely after use for 5 h under the conditions of methanol transformation at 400°.[87] Under the same conditions, the activity of decationated silicalite remains unchanged for ~6 h, and H-ZSM-5 zeolite is not deactivated after ~12 h.

It should be emphasised again that the high stability of pentasils is due primarily to their unusual porous structure[112,117,118]. A study of the transformations of methanol on H-ZSM-5 zeolites, H-offretite, and H-mordenite[119] showed that the maximum quantity of coke deposited on these catalysts after use for 12 h at 380° increased in the order H-ZSM-5 < H-mordenite < H-offretite, and amounted to 2.2, 8.7, and 16.8 mass % respectively. H-mordenite and H-offretite are almost completely deactivated after 30 min and 55 min respectively, whereas the activity of H-ZSM-5 zeolite decreased only slightly after this catalyst had been used for 1.5 h. For all three zeolites, increase in the quantity of coke formed was accompanied by various changes in the distribution of the hydrocarbons formed. For example, for H-ZSM-5 zeolite the ratio C_4H_{10}/C_4H_8 gradually decreased, approaching a constant value. Simultaneously, the products showed an increase in the already high concentration of *p*-xylene. Overall, the ratio of the concentrations of *p*-xylene and *o*-xylene for H-ZSM-5 zeolite reached values >40, whereas for the other two zeolites it was 0.5–2.0 and remained unchanged throughout the experiment. EPR showed that the coke deposited on H-ZSM-5 has a low hydrogen content, and is similar to graphite in character. In contrast to this, the coke on H-mordenite, and H-offretite corresponds more to polynuclear atomatic systems. It was suggested[119] that as a result of the size and shape of the channels in H-ZSM-5 zeolite, coke formation takes place chiefly on the outer surface of the zeolite and does not influence the strongly acidic centres which are localised within the pores and which are responsible for the catalytic activity. The surface coke may partly block the entry to the pores, however, increasing the molecular-sieve properties of the pentasil, as revealed by the change in the selectivity of the process during the operation of the catalyst.

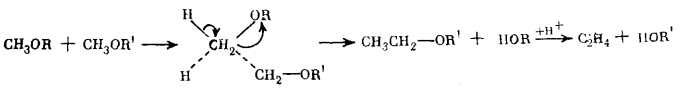
H-ZSM-5 zeolite has a high stable activity under the conditions of the formation of aromatic hydrocarbons from methanol under pulse conditions (450 °C), whereas the new SHS zeolite Nu-1 ($SiO_2/Al_2O_3 \cong 53$), whose structure does not correspond to the pentasil family, is rapidly deactivated by coke formation[177].

Considerable attention has been paid to the study of the stability of catalysts based on H-ZSM-5 zeolite in the development of a technical process for producing petrol from methanol in pilot plant[155–157]. By carrying out the stage of alcohol dehydration and the stage of the production of a mixture of hydrocarbons from the dehydration products in two different reactors with a stationary layer of zeolite catalyst[155], it was shown that the deactivation of the latter takes place predominantly in the second stage as a result of coke formation. The period of use of this catalyst in the second stage without regeneration reached 167 h, and after this period a significant change in the selectivity of the process was observed: the yield of C_3 and C_4 alkenes and hydrocarbons containing five and more carbon atoms decreased. The results were confirmed under prolonged testing conditions, in which ten working cycles with a total duration of ~207 d were carried out without replacing the catalyst. Under fluidised-bed conditions, a catalyst based on ZSM-5 zeolite functioned for more than 50 d. During this time it was regenerated six times using air[156]. In each working cycle the high initial activity of the catalyst gradually decreased with time, and after each regeneration the activity of the catalyst at the start of the next cycle was lower than that at the start of the previous cycle.

2. Mechanism of Formation of Hydrocarbons from Methanol

The intensive study of the transformations of methanol to hydrocarbons on the new generation of zeolites has led to the development of earlier[178–180] suggestions about the mechanism of this process.

From the ideas of Venuto and Landis[179] on the mechanism of the decomposition of methanol on zeolites of type X, it was suggested[152] that on ZSM-5 zeolites, methanol or its decomposition product dimethyl ether can decompose to give carbene-like methylene biradicals



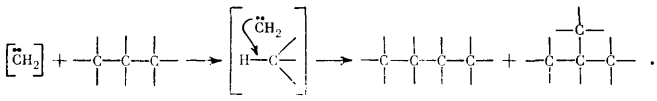
These biradicals may then either dimerise

$$2\,[\ddot{C}H_2] \rightarrow C_2H_4$$

or react with molecules of methanol or dimethyl ether

$$[\ddot{C}H_2] + CH_3OR \rightarrow CH_3CH_2{-}OR \xrightarrow{+H^+} C_2H_4 + HOR \quad (R = H,\ CH_3)$$

Since the molecules of alcohol or ether act as both donors and acceptors of methylene biradicals, this mechanism can be represented as a conjugated bimolecular reaction



R and R' = H, Alk.

After the formation of the first molecules of alkene (ethylene), the carbene biradicals can add on across the double bond, giving hydrocarbons with higher molecular weight.

Later, on the basis of this mechanism, a kinetic model was developed[181] for the transformation of methanol to hydrocarbons on ZSM-5 zeolites, making it possible to determine with satisfactory accuracy the extent of the conversion of alcohol and the selectivity of the process over a wide range of pressures.

Because of the doubts expressed by various authors about the correctness of the carbene mechanism, data were published[182], which in the author's opinion proved that carbene biradicals are formed from methanol on ZSM zeolites. According to these data, in the transformations of $^{13}CH_3OH$ on H-ZSM-5 zeolite (370°, 1 atm, $v = 0.4\ h^{-1}$), dilution of the alcohol by propane (whose conversion under these conditions is ~0.3%) decreases by a factor of more than three the ratio of isobutane to n-butane in the reaction products compared with experiments in which methanol was diluted with helium. The data on the distribution of the ^{13}C isotope between the butane isomers formed made it possible to attribute this effect to the direct methylation of the "inert" propane by carbene biradicals. The reaction can take place by the introduction of this biradical at one of the sp^3 C–H bonds of propane

This reaction should give 75% n-butane and 25% isobutane, which corresponds to the results obtained.

One objection to the carbene mechanism is that it does not explain the formation from methanol of methyl ethyl ether and large quantities of isoalkanes, and the increase in the yield of alkenes with decrease in the conversion of alcohol[153,154]. The authors cited suggested that on ZSM-5 zeolites, whose surface has strong Brönsted acidic centres, methanol may undergo dehydration, being converted successively to dimethyl ether and ethylene[178,180]

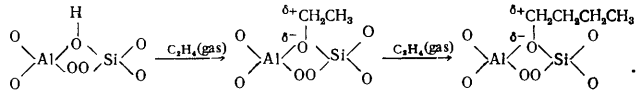
$$2CH_3OH \xrightarrow[-H_2O]{} CH_3OCH_3 \xrightarrow[-H_2O]{} CH_2{=}CH_2 .$$

According to this scheme, methanol should be converted chiefly to ethylene, which does not agree with data on the composition of the products on the transformation of this alcohol, which contain only small quantities of ethylene (see Table 2). It was therefore suggested that ethylene is highly reactive and readily forms carbenium ions by reacting with Brönsted acidic centres

$$CH_2{=}CH_2 + HOZ \rightarrow CH_3\overset{+}{C}H_2 \cdots \bar{O}Z .$$

The reaction can then proceed in two directions

$$CH_3\overset{+}{C}H_2 \cdots \bar{O}Z \left\{ \begin{array}{l} \xrightarrow[a]{CH_3OH} CH_3CH_2{-}O{-}CH_3 + HOZ \\ \xrightarrow[b]{CH_2=CH_2} CH_3CH_2CH{=}CH_2 + HOZ . \end{array} \right.$$



Path *a* gives methyl ethyl ether, which can be dehydrated to give propylene

$$CH_3CH_2{-}O{-}CH_3 \rightarrow CH_3CH_2{=}CH_2 + H_2O .$$

Propylene ether is converted into propane by redistribution of hydrogen, or, like ethylene, reacts with Brönsted acidic centres (path *a*) giving a more stable secondary carbenium ion, leading to the formation of iso-alkanes.

The linear hydrocarbons which are formed according to path *b* by polymerisation, and which contain not less than six carbon atoms, can then undergo cyclisation to give aromatic hydrocarbons. According to the proposed mechanism, the development of the process in the system requires the continuous presence of unconverted methanol. It is therefore suggested that in addition to the forward reaction of alcohol dehydration, the back reaction of alcohol formation also takes place, and both of these reactions compete with the processes of polymerisation, cyclisation, and aromatisation.

To confirm the carbenium-ion mechanism, the adsorption of ethylene on dehydrated H-ZSM-5 zeolite was studied[103]. Thermogravimetric and ^{13}C NMR and infrared spectroscopy indicated that on the strong Brönsted acidic centres of the zeolite, low-temperature chemosorption and activation of ethylene can take place according to the scheme

The addition of ethylene to OH groups corresponds to the formation of carbenium ions, which take part in chain growth giving macromolecular aliphatic hydrocarbons capable of undergoing isomerisation and aromatisation at higher temperatures (300–400°).

In a study of the transformations of methanol on H-ZSM-5 zeolite in the presence of carbon monoxide[183], ^{13}C NMR spectroscopy showed that the products contained saturated and unsaturated aliphatic (and aromatic) aldehydes and ketones. Their formation is attributed only to the reaction of CO with carbenium ions present on the surface

$$CH_3\overset{+}{C}H_2 + CO \rightarrow CH_3CH_2{-}\overset{+}{C}O \xrightarrow{\text{alkane}} CH_3CH_2CHO ,$$
$$CH_3CH_2CHO + C_2H_4 \rightarrow CH_2{=}CH{-}CHO + C_2H_6 .$$

These data also indicate the impossibility of the formation of carbenium biradicals, which in the reaction with CO should give ketene, capable of reacting with the water, methanol, and ethylene present in the system. No products of these reactions (acetic acid, its methyl ester, and cyclobutane) were detected.

These results[103,153,154,183] made it possible to develop a detailed scheme for the transformations of methanol to various hydrocarbons on pentasils with the participation of carbenium ions[166]. According to this scheme, the reaction of carbenium ions with various components of the reaction system can give a broad spectrum of aliphatic and aromatic C_6–C_{10} hydrocarbons, including appreciable quantities of xylenes, ethylbenzene, and 1,2,3-trimethylbenzene. It was subsequently shown[184] that aromatic hydrocarbons are formed predominantly on centres localised in the cavities formed at the intersection of the channels in the pentasils. Since the geometry of the pores in these zeolites permits the simultaneous dehydrocyclo-oligomerisation of only two aliphatic C_5 molecules, the aromatic hydrocarbons formed cannot contain more than ten carbon atoms.

A slightly different mechanism has also been proposed[185], according to which not ethylcarbenium but methylcarbenium (CH_3^+) ions, differing from carbenium biradicals, are formed from methanol on pentasils.

The presence of small quantities of ethylene in the products of the transformation of methanol on pentasils, and also the low degree of conversion and poor reproducibility of the results in experiments with this alkene, led to the suggestion[87] that ethylene is not highly reactive on these zeolites. Thus the role of active intermediate species in the formation of hydrocarbons from methanol is played not by ethylcarbenium ions but by "unsaturated C_3 and C_4 residues", as

shown in the scheme

$$CH_3OH \xrightarrow{H^+_{surf}} (\text{unsaturated } C_3 \text{ and } C_4 \text{ residues})_{surf} \begin{cases} \longrightarrow C_3 \text{ and } C_4 \text{ alkenes} \\ \longrightarrow \text{aromatic hydrocarbons} \end{cases}.$$

Here, H^+_{surf} is an acidic centre on the zeolite surface. To obtain more details of this scheme, the transformations of methanol and various hydrocarbons on H-ZSM-5 zeolite were studied using deuteriated compounds[186]. The results, with allowance for the reaction of methanol on Brönsted acidic centres, indicated that in the first stage of the reaction, activated species $(CH_3)\overset{+}{R}OH$ (R = H, CH_3) are formed on the zeolite surface. Simultaneously, methanol is dehydrated to give alkenes, in which the number of carbon atoms ≥3. This is followed by growth of the carbon chain according to the scheme

$$(CH_3)\overset{+}{R}OH_{surf} + R'R''C{=}CH_2 \rightarrow R'R''\overset{+}{C}{-}CH_2CH_3{}_{surf} \xrightarrow{+ROH} R'R''C{=}CHCH_3 + H^+_{surf}$$
$$R', R'' = H, Alk$$

Isomerisation and dehydrocyclisation, and also the rupture and formation of C=C bonds, can take place, depending on the temperature.

To supplement this mechanism, a scheme was proposed for the transformation of methanol to alkenes with the intermediate formation of methyl isopropyl ether with the subsequent elimination of methanol and the formation of propylene[187]. This scheme has been considered unlikely, however, since the size of the molecule of the intermediate compound is much greater than the diameter of the pores of the zeolite[188].

The formation of hydrocarbons from methanol on H-ZSM-5 zeolite, modified by phosphorus, has also been represented by a general scheme giving only the possible routes and the sequence of transformations of the alcohol[158]. In addition, it was suggested[158] that with a zeolite containing phosphorus, a significant part begins to be played by reactions, catalysed by the acidic centres, involving the alkylation of methanol by methanol (to give dimethyl ether), of ether by ether (to give methyl ethyl ether, which by the removal of an alcohol molecule gives ethylene), and of alkenes by methanol (chain growth). Oligomerisation of alkenes, cracking of oligomers, cyclisation, and hydrogen transfer may also take place.

The mechanism proposed in[189] assumes the formation of intermediate alkyloxonium ions $[R_3O]^+$, where R = H, CH_3, C_2H_5, etc., which can undergo intramolecular rearrangements. According to this mechanism, methanol is dehydrated to dimethyl ether, which on Brönsted acidic centres may be converted into the dimethyloxonium ion $[(CH_3)_2HO]^+$. The reaction of this ion with a dimethyl ether molecule gives an intermediate compound, and the removal of a methanol molecule from the latter gives the stable trimethyloxonium ion $[(CH_3)_3O]^+$. The C–H bonds in this ion may be polarised on the basic centres of the zeolite, formed by the deprotonation of the Brönsted acidic centres. The trimethyloxonium ion can then undergo rearrangement to the methylethyloxonium ion, which can give up a methanol molecule to form ethylene and regenerate the Brönsted acidic centre.

Simultaneously, the dimethyloxonium ion formed at the start of the process can react in six directions with the molecules of water, methanol, and dimethyl ether present in the system. This should lead to the predominant formation of ethylene, whose subsequent transformations give a whole spectrum of hydrocarbons, detected in the reaction products. In spite of its complexity, the mechanism involving alkyloxonium ions explains many experimental facts. Some authors suggest that the formation of hydrocarbons from methanol is autocatalytic[138,148,168]. In an isothermal system on catalysts containing 1.4–10% H-ZSM-5 zeolite and an inert diluent (γ-Al_2O_3 or metallic copper powder), it was shown[148] that at low CH_3OH concentrations the rate of consumption of alcohol is very low, but increases rapidly with increase in the concentration of the alkenes formed. The increase in the reaction rate is apparently due to the autocatalytic reaction of the original alcohol with the alkene (propylene) formed. Kinetic calculations showed that the rate constant of this autocatalytic stage of the process is 50 times the rate constant for the formation of the alkene from the alcohol[148].

The conclusion that the transformations of methanol on ZSM-5 zeolites is autocatalytic was also reached from data which showed a sharp increase in the rate of transformation of the alcohol when an alkene was introduced into the system[138] and data which showed an abrupt increase in the yield of hydrocarbons for a comparative small increase in the temperature of the reaction (from 280° to 300°).[168] It was suggested that the first stage of the process involves the reaction of methanol with a Brönsted acidic centre to give the methylcarbenium ion. The reaction of this ion with an alcohol molecule gives a proton and an ether, which decomposes to give ethylene

$$\overset{+}{C}H_3 + CH_3OH \rightarrow \left[\begin{matrix} H \\ CH_3 \end{matrix} \!\!>\!\! CH_2OR \right]^+ \rightarrow CH_3CH_2OR + H^+ .$$

Thus there is still lack of agreement about the mechanism of formation of hydrocarbons from methanol on zeolites of the new generation. At present, apparently, there is agreement only on the first stage of the process, involving the dehydration of the alcohol to dimethyl ether. There is lack of agreement about the mechanism of all the other stages, because of the lack of convincing proof. Up to the present, no unambiguous answers have been obtained to the questions of how the first C–C bond is formed from methanol (or dimethyl ether), and what is the nature of the resulting compound, which is the precursor of all the other hydrocarbons detected in the reaction products. The nature of the intermediate compounds involved in the development of the transformation of methanol into hydrocarbons is also not clear. According to existing ideas, these compounds may be carbene biradicals, carbenium ions, or alkyloxonium ions. The suggestion that intermediate carbenium biradicals are formed has been criticised[153,154,187,191], and these criticisms have been answered, and the suggestion clarified[188,192]. Thus it has been shown[188] that the decomposition of dimethyl ether or methanol can be represented by a scheme involving both carbenium biradicals and carbenium ions. It was concluded that the carbenium mechanism is to some extent provisional, and does not assume the existence of free carbenium biradicals.

It is at present difficult to give preference to any of the proposed mechanisms. The most reliable mechanisms, however, agreeing with current ideas on catalysis, are those involving carbenium ions.

3. Transformations of Other Oxygen-Containing Compounds

Alcohols. In addition to methanol, the transformations of various other alcohols, primarily ethanol, on pentasils have been studied. Comparison of the results of the most detailed study[154] of the products formed from ethanol on H-ZSM-5 zeolite (SiO_2/Al_2O_3 = 43.6; 0.05 mass % Na_2O) with the analogous data for methanol shows that C_2H_5OH undergoes transformations more readily than CH_3OH. Even at 250°, its conversion reached more than 99% (85% methanol), and the reaction products contained more than 98% hydrocarbons (2 to 11% in the case of methanol). At high rates of supply, ethanol is almost completely converted into ethylene[154]. Beginning at 300°, the formation of aromatic hydrocarbons

is observed, and the quantity decreases with increase in the rate of supply of the alcohol, but increases with increase in the reaction temperature. More ethylbenzene and ethyltoluene are formed from ethanol than from methanol. The start of the formation of aromatic hydrocarbons in the gaseous reaction products is accompanied by a sharp decrease in the ethylene concentration, but the concentration of C_4 alkanes and alkenes increases[154].

The formation of aromatic hydrocarbons from ethanol on H-ZSM-5 zeolite has also been observed[193]. The yield of aromatised products increases with increase in temperature (>260°), with decrease in the rate of supply of alcohol, and with the addition of water to the reaction mixture. Water prevents deactivation of the zeolite catalyst[193]. Unlike pentasil, dealuminated Y and M zeolites in the H-form showed only dehydrating properties, and H-mordenite rapidly lost its activity even in the presence of water.

H-ZSM-5 zeolites are deactivated more rapidly in the transformations of ethanol than in experiments with methanol[194]. In addition, ethanol gave more trimethylbenzenes and aromatic hydrocarbons with higher molecular weights, the quantity of which in the reaction products increased with deactivation of the zeolite. A study of the adsorption of n-hexane and toluene on H-ZSM-5 before and after the experiments showed that during use with ethanol, the sorptive capacity of the zeolite decreases, but it can be restored by regeneration in a stream of oxygen.

Ethanol has been transformed into ethylene with a high selectivity on the Na- and H-forms of ZSM-5 zeolite at 200 to 250°.[195] The products contained almost no diethyl ether, but contained acetaldehyde, the quantity of which increased with temperature.

Table 4. Composition (mass %) of the products of the transformations of various alcohols and dimethyl ether on H-ZSM-5 zeolites (for all compounds, $\alpha \cong 100\%$).

Products	Original compound					
	CH_3OH[1]	C_2H_5OH[2]	$t\text{-}C_4H_9OH$[1]	$C_7H_{15}OH$[1]	$(CH_3)_2O$[3]	$(CH_3)_2O$[3]

C_9–C_{11} alkylbenzenes	11.0	10.1	7.1	8.8	3.4	—

[1]From published data[152] at 370°.
[2]From published data[189] at 310° after zeolite use for 28 min.
[3]From published data[159] under pulse conditions; 550°, TsVK zeolite.
[4]Only ethylene.
[5]Only xylenes.

At 350° under a pressure of 50 atm, ethanol on H-ZSM-5 zeolite gave quantities of durene smaller by a factor of 65 than those obtained from methanol, but the quantities of various alkylbenzenes (ethyl-, methylethyl-, dimethylethyl-, and diethylbenzenes) were ~7 times greater[160].

Thus the transformations of ethanol on pentasils show characteristic features, although the products of the transformations of ethanol and methanol have approximately the same composition (Table 4), in spite of the significant difference in the conditions of the reactions and in the pentasil specimens used[149,152,189]. The similarity in the products formed from the two alcohols has been noted by other workers[160,195]. It was therefore suggested[154,195] that the mechanisms of the transformations of ethanol and methanol on pentasils are the same, and involve the formation of carbenium ions on Brönsted acidic centres with the participation of ethylene, as the primary unsaturated hydrocarbon. According to another view[194], the ease of formation of C_9–C_{12} aromatic hydrocarbons from ethanol indicates that its molecules are split into C_2 fragments, whereas CH_3OH gives mainly C_1 fragments.

The transformations of alcohols with higher molecular weights than ethanol on pentasils have been described in only two papers[152,196]. The data for t-butyl, heptyl, and methyl alcohols (Table 4) show that the composition of the products is approximately the same in all cases[152]. Irrespective of the original alcohol, these products contain less than 1% methane, and the main products are propane, isobutane, toluene, and xylenes. The data for heptan-1-ol, however, were obtained at a lower volume rate ($0.7\ h^{-1}$), and this may indicate that this alcohol is less reactive than t-butyl alcohol and methanol.

A study of the transformations of 2-methylbutan-2-ol on TsVK pentasil and on zeolites of type Y (NaY, CaY, HY) [196] showed that at 120–200°, the alcohol decomposes to give 2-methylbut-1-ene, 2-methylbut-2-ene, and 3-methylbut-1-ene. The Na-form of the TsVK zeolites was more active than NaY, but less active than CaNaY and HNaY.

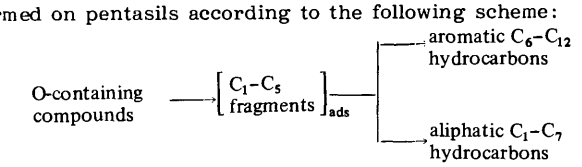
Simple ethers. Among these compounds, the transformations of dimethyl ether—the intermediate product in the formation of hydrocarbons from methanol on pentasils—have been studied in greatest detail. In most cases the experiments with dimethyl ether were carried out to investigate the mechanism of formation of the hydrocarbons from the alcohol[107,152,158,189]. In addition, the transformations of dimethyl ether have been used as a model reaction in the study of the influence of various factors on the catalytic properties of ZSM-5 zeolites[159,197] and in their comparison with the properties of amorphous aluminosilicate, prepared using organic bases[166].

Table 4 shows that the transformations of dimethyl ether on pentasils give (in addition to water and methanol) the same hydrocarbons as in the products of the transformations of methanol and other alcohols. In contrast to alcohols, the decomposition of dimethyl ether on ZSM zeolites gives considerable quantities of ethylene. It was therefore suggested[189] that it is ethylene that is the primary hydrocarbon in this process, and that its rapid methylation gives propylene. Data on the composition of the products of the transformation of dimethyl ether formed the basis of the mechanism, examined above, for the formation of hydrocarbons from methanol involving alkyloxonium ions[189].

The influence of the reaction conditions on the composition of the products formed from dimethyl ether has been studied[152,189]. At a temperature below 300°, the products contain chiefly C_2–C_5 alkenes, whereas at 350°, the formation of appreciable quantities of aromatic hydrocarbons (~20 mass %) and also C_2–C_5 alkanes (~20 mass %) is observed. The nature of the dependence of the conversion of dimethyl ether and the composition of its transformation products on the reciprocal of the volume rate agrees satisfactorily with the

analogous data for methanol (see Fig.6). Similar results were obtained on H-ZSM-5 zeolite modified with phosphorus[158].

Pentasils show a slightly lower stability under the conditions of the transformations of dimethyl ether than when used with methanol. For example, after the operation for 1.5 h of a catalyst based on H-ZSM-5 zeolite (SiO_2/Al_2O_3 = 55) mixed with SiO_2 (1:1), the conversion of dimethyl ether into hydrocarbons decreased by 30%.[189] Simultaneously, the reaction products showed a marked increase in the concentration of ethylene and propylene, and a decrease in the concentration of C_3 and C_4 alkanes. The low stability of the catalyst in these experiments[189] was apparently partly due to the extensive dilution of the pentasil by silicon dioxide. On H-ZSM-5 zeolite in the pure form, the conversion of dimethyl ether at 350° decreased by only ~10% in the first 9 h, and after use for 100 h it decreased by ~40%.[197]



Comparison with first-generation zeolites showed that the conversion of the ether on HY after 9 h decreases by 92%, and erionite and mordenite in the H-forms are almost completely deactivated after use for 6–7 h under the same conditions.

The deactivation of all the zeolites is due to the formation of coke, the quantity of which in the H-ZSM-5 zeolite amounted to only ~2.5 mass % after 9 h, whereas in other zeolites it amounted to ~7–9 mass %.[197] After 100 h, the concentration of coke in the H-ZSM-5 zeolite increased to ~7%. It is suggested that during use, coke formation in the pentasil takes place chiefly on its outer surface, since the small diameter of the zeolite pores prevents bimolecular reactions in them between large molecules, leading to coke precursors (see section II). The coke deposited on the outer surface has little influence on the pentasil activity, which is apparently suppressed by oligomers (or polymers) of ethylene and propylene, which accumulate in the pores on prolonged catalyst use.

The method of preparation of the pentasil has a slight influence on the nature of the transformations of dimethyl ether. Thus ether is converted to a greater extent into ethylene on H-ZSM-5 specimens synthesised in the presence of tetrapropylammonium cations than on specimens obtained using 1,2-diaminohexane[198].

The rate of formation and composition of the products of the transformations of dimethyl ether on H-ZSM-5 pentasil are practically independent of the size of the zeolite crystals and the concentration of Al in them, but change significantly with change in the diameter of the zeolite catalyst pellets[107]. From this and the results of a study of the kinetics of the diffusion and transformations of dimethyl ether on these zeolites, it was concluded[199] that in catalyst pellets with a diameter >2 mm, the rate of the reaction and its selectivity are limited by the diffusion of the molecules in the secondary porous structure. For a smaller pellet diameter, diffusion between the crystallites plays almost no part[107,199]. It was also shown[199] that diffusion in the pores of the pentasil also have very little influence on the rate and selectivity of the transformations of dimethyl ether.

In addition to dimethyl ether, the transformations of diethyl, di-isopropyl, and dibutyl ethers on pentasils have been studied[159]. Since there are no significant differences in the compositions of the products formed from these ethers and also from dimethyl ether, methanol, and acetone, it was concluded that all oxygen-containing compounds are transformed on pentasils according to the following scheme:

Other oxygen-containing compounds. In contrast to alcohols and simple ethers, there have been almost no published studies of the transformations of oxygen-containing compounds of other types (ketones, aldehydes, acids, etc.) on zeolites of the pentasil family. For example, the transformations of acetone have been described only in Refs.152 and 159. Of the total quantity of hydrocarbons formed at 250°, ~60% corresponds to mesitylene, apparently formed on the outer surface of the zeolite by the condensation of three acetone molecules[152]. In addition, the products contain ~19% isobutene and ~19% C_6 and higher aliphatic hydrocarbons. The oxygen-containing products consist chiefly of mesityl oxide (~27%)—the product of the condensation of two acetone molecules—and also C_4 alcohols. At 320°, the total conversion of acetone increases to only ~25%, but the composition of the products changes significantly: among the hydrocarbons, the chief product is isobutene (~83%), and the concentration of mesitylene is only ~2.5%. Approximately 10% of the acetone reacting is converted into CO and CO_2. Increase in temperature to ~400° leads to the almost complete conversion of acetone into C_1–C_{10} hydrocarbons, among which the chief components are xylenes (~22%), C_9 alkylbenzenes (~20%), toluene (13%), a mixture of propylene and propane (~10%), and C_{6+} alkanes and alkenes (~8%).

Table 5. Composition (mass %) of the products of the transformations of aldehydes, esters, and acetic acid on H-ZSM-5 zeolite (371°, 100% conversion).[152]

[1]Conversion 29.9%.
[2]Including 66.5 mass % isobutene.

Published data[152] on the composition of the products of the transformations of various other oxygen-containing compounds on H-ZSM-5 zeolite are summarised in Table 5. All the compounds studied (except acetic acid) are readily transformed into mixtures of hydrocarbons, whose composition depends on the nature of the starting material. Thus propionaldehyde gives products whose composition is extremely close to the products of the transformations of alcohols (see Table 4). Acetaldehyde and n-butyl acetate, in addition to hydrocarbons, give appreciable quantities of CO and CO_2. The transformation of these compounds into

aromatic hydrocarbons is more selective than the transformation of alcohols. The products of the transformation of n-propyl acetate, in addition to a large quantity of aromatic hydrocarbons (~50%), contain more than 30% propylene.

The most stable compound under these conditions is acetic acid, whose conversion amounts to less than 30%, and only ~58% of the quantity of acid reacting is converted into hydrocarbons. The latter consist chiefly of butenes (66.5% isobutene + 5% butenes) and C_9 and C_{10} alkylaromatic hydrocarbons (~25%).

Thus zeolites of the pentasil family are effective catalysts for the transformations of methanol, dimethyl ether, and other oxygen-containing compounds to give mixtures of C_1–C_{10} hydrocarbons with approximately identical compositions; most of the work in this field has been devoted to the transfromations of methanol. The importance of these studies is not limited to the accumulation of data which can be used to develop the important practical process of motor fuel production. They have developed to a considerable extent the study of the structure and physicochemical properties of zeolites of the new generation and have made a significant contribution to the development of ideas about the catalytic activity of zeolites. They have also initiated studies of the possible application of pentasils in other catalytic processes, in particular the transformations of various hydrocarbons.

IV. TRANSFORMATIONS OF HYDROCARBONS ON PENTASILS

The ability of first-generation zeolites (faujasites, mordenite) to catalyse the transformations of various hydrocarbons was established by a large number of studies, reviewed earlier[40,130]. Thanks to this property, these zeolites have found extensive application as catalysts of a number of processes in petroleum refining and petroleum chemistry. The reactions of hydrocarbons carried out on first-generation zeolites include, for example, cracking, isomerisation, oligomerisation, disproportionation, etc. These and various other reactions of hydrocarbons also take place on zeolites of the pentasil family.

1. Transformations of Alkenes

The possibility of using pentasils to catalyse the transformation of individual C_2–C_5 alkenes and their mixtures into aliphatic and aromatic hydrocarbons with higher molecular weights was shown in the first Mobil Oil patents in 1973–74. In the scientific literature, the first reports of the study of these reactions appeared only in 1979.[87,128,200] In the last two or three years, the number of papers on this topic has increased considerably, and most have been devoted to the study of the transformations of ethylene and other lower alkenes on pentasils.

Transformations of ethylene. The large number of studies of the transformations of ethylene on pentasils[87,103,107,122,125,128,159,161,166,184,186,189,200–205] differ considerably in the reaction conditions and in the types and compositions of the catalysts used. There is therefore often lack of agreement between the data obtained by different authors. For example, in Ref.87 it is reported that on H-ZSM-5 zeolite (SiO_2/Al_2O_3 = 59; 0.38 mass % Na) at 400° and a rate of supply of hydrocarbons of 1.2×10^{-2} mole h^{-1}, ethylene usually shows a low reactivity, but sometimes its conversion reached high values. A low degree of conversion of ethylene on zeolites of the same type was also observed by other workers[122,158,161]. At the same time it is reported that under selected (usually milder) conditions, the conversion of ethylene exceeds 90%.[125,159,189,200–202,204] The available data show that the extent of the conversion of ethylene depends on the rate of supply of the alkene, the temperature of the reaction, and the presence of modifying additives in the zeolite. The influence of these factors on the degree of transformation of ethylene and the composition of the reaction products has not been studied in detail, however.

Experiments with ethylene on different TsVK zeolites with approximately equal SiO_2/Al_2O_3 ratios (~80–82) [200] showed that decrease in the quantity of Na_2O in the zeolite from 1.2 mass % to 0.6 mass % not only increases the conversion of the alkene (from 72% to 98%) but also changes significantly the composition of the reaction products: the gases show a decrease in the concentrations of C_3 and C_4 hydrocarbons by factors of 2 and 5 respectively, and the liquid catalysate, whose yield remains almost unchanged, is enriched in aromatic hydrocarbons, with the simultaneous disappearance of C_4–C_6 alkanes and alkenes. Approximately the same influence on the composition of the gaseous and liquid reaction products is shown by an increase in temperature from 350° to 530°. A significant increase in the concentration of benzene and toluene in the catalysate was observed, however.

The activity, stability, and selectivity of pentasils in the transformations of ethylene depend to a significant extent on the SiO_2/Al_2O_3 ratio[205]. For ultrasil zeolites, at values of this ratio in the range 26–80, the conversion of ethylene at 350° is ~97%, and remains practically unchanged during the experiment. At SiO_2/Al_2O_3 = 190, however, the degree of transformation of C_2H_4, which at the start of the experiment is ~53%, decreases to ~18% in 80 min. Moreover, with increase in this ratio from 29 to 190, the concentration of alkanes in the reaction products decreases considerably. It was therefore suggested[205] that the reactions involving the redistribution of hydrogen take place on the strong acidic centres produced in the pentasils with decrease in the concentration of Al and the total quantity of acidic centres. As already noted in section II, however, no anomalously strong acidic centres have been detected in pentasils. With decrease in the Al concentration, the total number of active centres in the zeolite apparently decreases, and below a certain limit it becomes insufficient for the competing reactions to take place simultaneously on them. The secondary processes, including, for example, the reactions involving the redistribution of hydrogen, should evidently be suppressed to a greater extent.

A comparative study of the transformations of ethylene on H-ZSM-5 and HNaY zeolites by infrared spectroscopy and mass spectrometry also showed[128] that unsaturated hydrocarbons predominate in the products of the reaction on pentasil. Depending on the temperature, the products on this zeolite are either aliphatic C_3–C_7 hydrocarbons (at 100 to 200°) or C_5–C_7 cyclanes and cyclenes (at 200–300°), or C_6 to C_{10} aromatic hydrocarbons (at 320–430°), and the pentasil had a much higher aromatising power than HNaY zeolite. In Refs.204 and 205, no mention was made of the formation of aromatic hydrocarbons in the transformations of ethylene on pentasil.

In the discussion of the products of the transformations of ethylene on pentasils, it should be noted that according to infrared spectroscopy, thermogravimetric analysis, and ^{13}C NMR spectroscopy, ethylene even at 20° is adsorbed on the Brönsted acidic centres of these zeolites and is activated and oligomerised to give long unbranched molecules[103,189,202,203]. It is suggested[103,184] that the oligomerisation of ethylene takes place by a carbenium-ion mechanism, and also that

above 300° the ethylene oligomers may undergo cracking and dehydrocyclisation.

In attempts[103,122,128,189] to model the conditions of the transformation of methanol (and dimethyl ether) into hydrocarbons, the decomposition of ethylene on pentasils in the presence of water was studied. The study of the combined sorption of ethylene and water on H-ZSM-5 zeolite[103] showed that at 20°, the strong Brönsted centres of this zeolite adsorb water preferentially, suppressing the activation and oligomerisation of the alkene. Above 250°, some of the centres become accessible for the adsorption of ethylene, which undergoes transformations to give chiefly alkenes with higher molecular weight, and also aromatic hydrocarbons. The poisoning by water of the acidic centres of H-ZSM-5 zeolite, responsible for the oligomerisation and aromatisation of ethylene, was also observed at a higher temperature (370°).[122] At the same time, water increased the stability of the zeolite and the degree of conversion of ethylene, facilitating cracking reactions. In spite of the suppression by water of the aromatisation of ethylene, the formation of the products of this reaction was observed at lower temperatures in the presence of water than in experiments with the dry alkene. It was suggested[122] that water facilitates the desorption of aromatic hydrocarbons from the zeolite channels by lowering their boiling point, as in steam distillation. The ability of water to increase the rate of desorption of the reaction products was confirmed in a study of the thermal decomposition of ethylene oligomers formed on H-ZSM-5 zeolite[198]. At the same time it was shown that water apparently acts as an additional source of protons, since in its presence there is an increase in the proportion of alkanes in the reaction products.

A fairly complete picture of the influence of water on the transformations of ethylene on ZSM-5 zeolites and on the composition of the products of this reaction is given in a paper[189] which mainly confirms data obtained by other workers[122,198]. According to Ref.189, however, water not only does not decrease the selectivity of the formation of aromatic hydrocarbons from ethylene, but increases it significantly, although this effect becomes slightly weaker on prolonged zeolite use.

Transformations of C_3 and C_4 alkenes. These alkenes are more reactive than ethylene in transformations on pentasils. On three specimens of H-ZSM-5 zeolites at 285–310°, propylene was transformed much more rapidly than ethylene[107].

In a study of the transformations of propylene on ZSM-5 zeolites and silicalite (SiO_2/Al_2O_3 = 59 and 1125 respectively) at 400°, the conversion of the alkene reached 85–94%. The reaction products contained aliphatic and aromatic hydrocarbons with a predominance of C_4 (~40%) and C_6 (~25%) alkanes and alkenes, and also xylenes (~30%).[87] With decrease in temperature to 370°, the conversion of propylene decreased to ~55%, and the reaction products contained ~30% butenes and only ~3% aromatic hydrocarbons[122,167]. Approximately the same results were obtained for but-1-ene.[167] In the transformations of propylene on H-ZSM-5 at 285° and 310°,[107] the predominant formation of C_4 and C_6 aliphatic hydrocarbons and the almost complete absence of aromatisation products were observed.

The transformations of C_3 and C_4 alkenes on TsVK zeolites have been studied in detail[84,88,121,125,206,207]. On the Na-form of this zeolite, propylene at 230–240° and isobutene at 140 to 150° gave liquid products containing C_6–C_9 alkanes and alkenes with normal and *cis*-structures. The yield of these products increased sharply with temperature, reached a maximum (>80%) at 310–320°, and then gradually decreased (broken lines in Figs.7*a* and 7*b*). An increase in the yield of gaseous products, consisting of C_2–C_5 alkanes and alkenes and small quantities of methane (not more than 5–7% at 580°) was observed. Above 320°, the liquid catalysates from both alkenes contained aromatic hydrocarbons (mainly benzene, toluene, and xylenes), whose concentration gradually increased with temperature to 91–93% at 550–580°.

Similar results were obtained on a more active decationated TsVK zeolite (<0.1% Na_2O).[88,207] Comparison with the data for Na-TsVK shows that on H-TsVK (continuous lines in Figs.7*a* and 7*b*), the formation of liquid products begins at lower temperatures; at 320° the catalysates contain not only aliphatic but also aromatic (~15–20%) hydrocarbons, and beginning at 450°, both the yield of liquid catalysate and the concentration of aromatisation products in it remain practically constant (up to 580°). The differences between the Na- and H-forms of TsVK are revealed most clearly under the conditions of the transformations of isobutene (Fig.7*b*), which are characterised by distinct temperature ranges corresponding to different reactions: up to 200°, only dimerisation and trimerisation of isobutene take place; at 200–300°, isomerisation of the resulting oligomers is also observed; and above 300°, aromatisation of aliphatic hydrocarbons begins, and this process predominates at 450–550°. These processes are accompanied by reactions involving

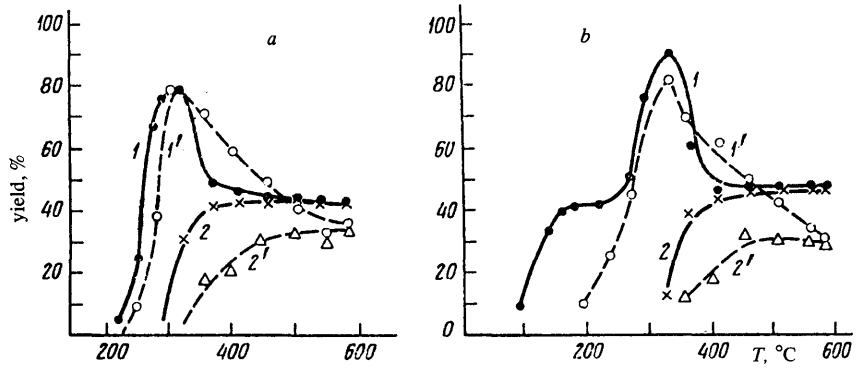

Figure 7. Temperature dependence of the yield of liquid catalysates (*1*, *1'*) and aromatic hydrocarbons (*2*, *2'*) from propylene (*a*) and isobutene (*b*) on the Na-form (broken line) and the H-form (continuous line) of TsVK zeolite[88].

the redistribution of hydrogen, cracking, and interconversion of aromatic hydrocarbons. For propylene, a distinct range corresponding to only oligomerisation was not observed, since significant quantities of the liquid catalysate appeared only at temperatures above 200°, that is under conditions in which intensive isomerisation took place. The small quantities of liquid products formed below 200°, however, contained isomeric hexenes, that is dimers of propylene.

The influence of temperature on the yield and composition of the gaseous products of the transformations of isobutene on H-TsVK zeolite[88] is shown in Fig.8.

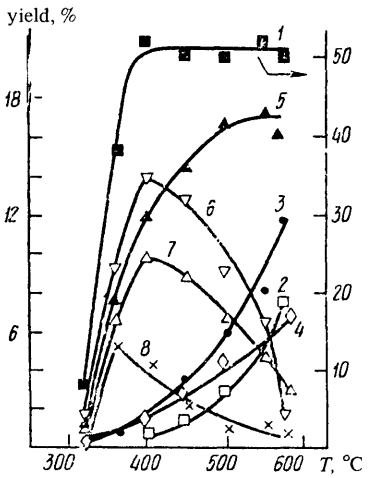

Figure 8. Temperature dependence of the yield of gaseous hydrocarbons from isobutene on H-TsVK zeolite: *1*) total yield of gaseous products, *2*) methane, *3*) ethane + ethylene, *4*) propylene, *5*) propane, *6*) isobutane, *7*) n-butane, *8*) C_5 hydrocarbons.[88]

Comparison with first-generation zeolites (types A, X, Y, and mordenite) [121] showed that the original and decationated forms of TsVK zeolites are much more active in the aromatisation of lower alkenes (450–550°). Neither change in the reaction conditions nor modification of the zeolites by decationation, cation exchange, or the introduction of additives, in the case of first-generation zeolites, led to the production of the high yields of aromatic hydrocarbons reached on pentasil. In addition to high activity in aromatisation, TsVK zeolites were stable and retained their activity for 6–9 h, since coke formation was slight. In contrast to this, first-generation zeolites and catalysts based on them were almost completely deactivated in the first 1–1.5 h of use, as a result of the deposition of coke, the quantity of which reached 10–20%, calculated for the propylene passed. On the TsVK pentasil, the quantity of coke deposited was ~10 times smaller, because of the characteristic features of its porous structure.

A study of the transformations of C_3 and C_4 alkenes on TsVK pentasil containing different quantities of Na and activated at different temperatures (T_{act}) revealed the relationship between the catalytic properties of the pentasil, its composition, and the activation conditions[84]. Increase in the concentration of Na_2O in the zeolite from 0.1 mass % to 1.1 mass % decreased slightly the conversion of the alkene and the yield of liquid catalysate, and also suppressed the aromatisation considerably. The lowest activity was shown by the zeolite specimen containing 1.3 mass % Na_2O, and also 0.25 mass % iron oxide impurity. The complete removal of this impurity and almost all the sodium by decationation gave the most active catalyst specimen, which brought about the greatest conversion of the original alkene and the highest yields of liquid catalysate and aromatic hydrocarbons[84].

Activation at 900–1000° had the greatest influence on the catalytic properties of TsVK zeolite[84]. This thermal treatment led to a decrease in the yield of liquid catalysate and the overall yield of aromatic hydrocarbons from isobutene at 320° and 500°, but at the same time the selectivity of *p*-xylene formation increased considerably. Moreover, with increase in T_{act} from 500 to 1000°, the gaseous reaction products showed a decrease in the concentration of alkanes and an increase in the concentration of alkenes (Fig.9), indicating a decrease in the activity of the zeolite in hydrogen redistribution reactions. These reactions apparently take place on Brönsted acidic centres, the quantity of which decreases on high-temperature treatment as a result of dehydroxylation of the surface (see section II). These data provide another example of the existence of a relationship between the intensity of hydrogen redistribution reactions and the quantity of Brönsted acidic centres in the pentasils, also observed in the transformations of ethylene on ultrasil zeolites[205].

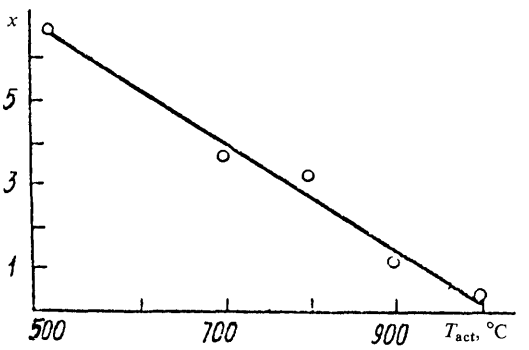

Figure 9. Influence of T_{act} on the ratio of the concentrations (x) of C_2–C_4 alkanes and alkenes in the products of the transformations of isobutene (500 °C) on TsVK zeolite[84].

The addition of vanadium (2.8 mass %) to the Na-form of TsVK zeolite (SiO_2/Al_2O_3 = 70.5, 0.7 mass % Na_2O) decreased considerably the conversion of C_3 and C_4 alkenes (and ethylene), the yield of liquid catalysate, and the total yield of aromatic hydrocarbons[125]. For the more active H-form of this zeolite, the influence of the additive depends on its concentration and on the reaction temperature[208]. The addition of 0.3 mass % vanadium to H-TsVK not only did not decrease, but even increased by a factor of ~1.5, the total yield of aromatic hydrocarbons from isobutene at 320°. Approximately the same effect was observed at 500°, but in this case it was reached at a vanadium concentration of 0.9 mass %. At both temperatures, the conversion of the original alkene remained at 100% throughout the entire range of vanadium concentrations studied (0.3–10.3 mass %).

It was also found[125,208] that the modification of TsVK zeolites by vanadium increases sharply the selectivity of the formation of *p*-xylene (and *p*-ethyltoluene) from lower alkenes, estimated from the ratio of the concentrations of *p*- and *m*-xylenes ([PX]/[MX]) in the reaction products. For the non-modified zeolite[209], the ratio [PX]/[MX] did not exceed 0.44, corresponding to the concentration of these isomers in the equilibrium mixture. In the presence of vanadium, however, this ratio increases by a factor of not less than ~19. For the decationated zeolite, the addition of V led to a slightly smaller increase in the selectivity of the formation of the *p*-isomers of dialkylbenzenes, and this effect increased with increase in the concentration of the additive and with decrease in the reaction temperature (Fig. 10).[208] The results were attributed[125,208] to the influence of the added vanadium on the molecular-sieve and diffusion properties of the TsVK zeolites (see section II). The reasons for the selective formation of the *p*-isomers of dialkylbenzenes will be discussed later, since this phenomenon was observed not only in the transformations of lower alkenes but also in other reactions.

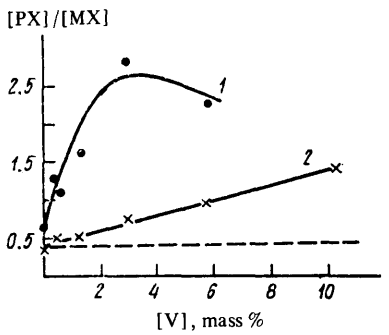

Figure 10. Dependence of the selectivity of formation of *p*-xylene ([PX]/[MX]) from isobutene on the vanadium concentration in H-TsVK zeolite at 320 °C (*1*) and 500 °C (*2*); the broken line gives the ratio at equilibrium[207].

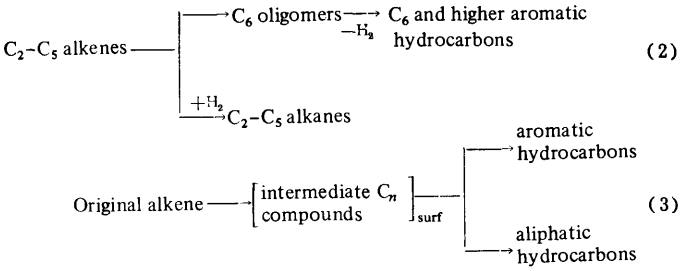
Apart from these studies, only a comparative kinetic study of the isomerisation of but-1-ene and *cis*-but-2-ene on H-ZSM-5 and H-Fu-1 zeolites (SiO_2/Al_2O_3 = 60 and 22 respectively), and also on an amorphous aluminosilicate, at 0° in a static system, has been carried out[210]. The results indicated that the isomerisation of butenes on these catalysts takes place by a carbenium-ion mechanism on the Brönsted acidic centres, which are much more stable in H-ZSM-5 than in H-Fu-1 or in the amorphous aluminosilicate.

The transformations of alkenes with higher molecular weights on pentasils have been described in only a few papers. The transformations of oct-1-ene on the Na-form of TsVK zeolite at 175–550° have been studied in most detail[212]. Only the reaction involving the movement of the double bond in octene took place intensively below 250° on this zeolite. At 250 to 300°, structural isomerisation of the octene began, and the yield of linear isomers decreased to 10%. Under these conditions, appreciable cracking of oct-1-ene and its isomers was observed, leading to a decrease (to ~75%) in the yield of liquid catalysate, in which aliphatic C_6 and C_7 hydrocarbons appeared. At 400°, oct-1-ene gave appreciable quantities of aromatic hydrocarbons, the concentration of which in the catalysate increased sharply with increase in temperature and when the zeolite was modified by added V, Pt, and Rh.[212] Thus as with lower alkenes, the introduction of added vanadium increased to a considerable extent the selectivity of the formation of the *p*-isomers of xylene and ethyltoluene from oct-1-ene, but this selectivity decreased with increase in temperature. These effects were not observed on the catalysts prepared by modifying the pentasil by added Pt and Rh.

The studies have included not only oct-1-ene but also the transformations of 3,3-dimethylbut-1-ene, which on H-ZSM-5 zeolite at 370° readily underwent isomerisation to 2,3-dimethylbut-1-ene and 2,3-dimethylbut-2-ene, and also cracking to give appreciable quantities of propane and butane. The reaction products contained a small quantity of C_6–C_9 aromatic hydrocarbons[161].

Thanks to the molecular-sieve properties of ZSM-5 zeolite, the rate of the isomerisation of C_6–C_8 alkenes on this catalyst (150–175°) decreases with increase in the degree of branching of the molecule (hex-1-ene > 6-methylhept-1-ene ≫ 3-ethylpent-1-ene ≫ 4,4-dimethylhex-1-ene).[113] The selective hydrogenation (at 275°) of hex-1-ene in its mixtures with 4,4-dimethylhex-1-ene on a Pt-ZSM-5 ion-exchange zeolite catalyst is also possible[113].

The transformations of cycloalkenes on pentasils has not been specially studied. Infrared spectroscopy has shown[212], however, that even at 40–45°, cyclopentene, cyclopentadiene, and cyclohexene are strongly adsorbed on HZ-79 zeolite (an analogue of ZSM-5 zeolite) with the formation of the same oligomers as with the linear alkenes. Partial transformation of the cycloalkenes into aromatic hydrocarbons was observed. With increase in temperature to 200–360°, the infrared spectra of the adsorbed cyclenes show an increase in the strength of the bands corresponding to the formation of aromatic structures. The mechanism of formation of linear oligomers and aromatic hydrocarbons from cycloalkenes has not yet been determined.

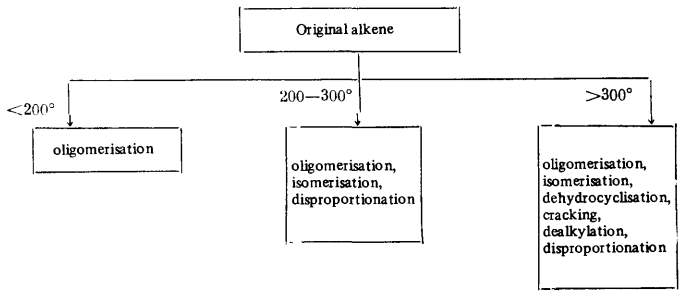


2. Mechanism of the Transformations of Alkenes on Pentasils

As already noted in section II, the nature of the catalytic activity of zeolites of the pentasil family and first-generation zeolites is the same and is determined by the presence of surface OH groups, which act as Brönsted acidic centres. Thus the mechanism of the transformations of alkenes on pentasils apparently corresponds to present-day ideas, according to which these reactions on zeolites involve the formation of carbenium ions as a result of the protonation of the reacting molecules on the acidic OH groups[130]. There are very few published papers, however, specially devoted to the study and examination of the mechanism of the transformations of alkenes on pentasils. In most cases, this question is discussed in direct relation to the mechanism of formation of hydrocarbons from methanol and dimethyl ether (see section III), which assumes the participation of molecules of oxygen-containing surface compounds either in the growth of the hydrocarbon chains or in the regeneration of the Brönsted acidic centres.

The transformations of lower alkenes in mixtures of various hydrocarbons in the absence of oxygen-containing compounds is usually represented by the general schemes (1),[186] (2),[184] and (3):[87,159,20]

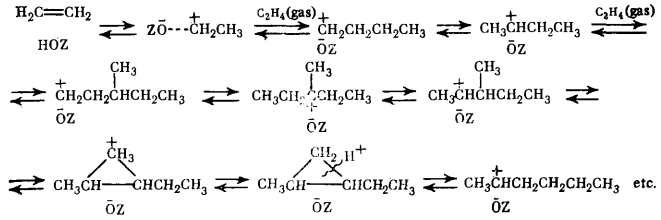
$$C_nH_{2n} + HOZ \rightleftarrows [C_nH_{2n+1}OZ \leftrightarrow C_n^+H_{2n+1}\,\bar{O}Z] \rightarrow C_mH_{2m} + HOZ \quad (1)$$



Z = zeolite, $m \gg n$

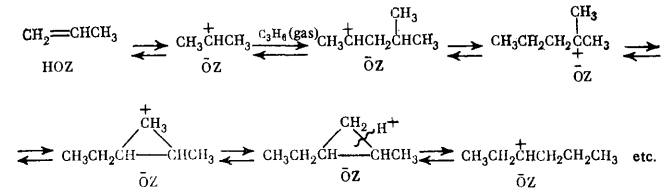
In Eqn.(3), the intermediate compounds are either "unsaturated residues" of the original molecules[87] or C_1–C_4 fragments of these molecules, adsorbed on the zeolite surface[159, 200].

From the composition of the products formed from lower alkenes on TsVK pentasils of different temperatures, a sequence of transformations of the original hydrocarbons and the products formed from them was proposed[88,207] (scheme 1).



Scheme 1

Although this scheme says nothing about the mechanism of the transformations of the alkenes, all the reactions in it can take place on the acidic centres of zeolite catalysts by a carbenium-ion mechanism[130]. Moreover, this scheme shows good agreement with the conclusion that there are three temperature ranges of transformations of C_2–C_4 alkenes on ZSM-5 zeolites, reached on the basis of thermogravimetric analysis and high-resolution ^{13}C NMR spectroscopy[189,201,202]. According to these data, the alkenes below ~30° readily undergo oligomerisation to give long unbranched molecules, and the rate of this reaction for ethylene is lower than that for other alkenes. These oligomers are formed and strongly adsorbed inside the pores of the zeolites, filling them completely. With increase in temperature, the rate of oligomerisation, calculated for one active centre, increases for all the alkenes. At ~130°, slight cracking of the oligomers is observed, and above 230° the rate of cracking begins to exceed the rate of oligomerisation. Thus above 230 °C, blocking of the pores of the zeolite by oligomers does not take place, and the reacting molecules diffuse freely through the channels of the pentasil, which at these temperatures is an active catalyst for the transformations of lower alkenes. An infrared spectroscopic study of the sorption of alkenes on HZ-79 zeolite indicated that the alkene oligomers formed apparently act as the source of aromatic hydrocarbons[197], whereas on HNaY zeolite they are mainly transformed into coke[212].



The mechanism of the oligomerisation of ethylene with the formation of hydrocarbon chains containing an average of 25 carbon atoms is represented by scheme 2 [201,202] involving carbenium ions formed on the Brönsted acidic centres of the pentasil:

Scheme 2

The last stages of this scheme explain the formation of linear molecules from propylene and other alkenes, whose oligomerisation should give only branched molecules (scheme 3).

Scheme 3

The oligomers formed from propylene and isobutene contain an average of 6–8 carbon atoms. The differences in the rates of the oligomerisation of ethylene and the C_3 and C_4 alkenes were attributed to a difference in the stability of the primary, secondary, and tertiary carbenium ions formed from these alkenes[201,202].

Similar schemes have been used to represent the transformations of alkenes with higher molecular weights (3,3-dimethylbut-1-ene), including not only oligomerisation but also other reactions such as the aromatisation of lower alkenes[161].

These ideas on the mechanism of the reactions of alkenes on pentasils, together with data on the specific molecular-sieve properties of these zeolites, have made it possible to explain the predominance of certain hydrocarbons and the absence of others in the products of the transformations of alkenes[184].

Thus the mechanism of formation of carbenium ions on Brönsted acidic centres has been successfully applied to the transformations of alkenes on zeolites of the pentasil family. At the same time there are a number of unsolved problems, related to the nature of the catalytic action of these zeolites, which can be solved only by further studies.

3. Transformations of Saturated Hydrocarbons

The ability of zeolites of the pentasil family readily to adsorb and bring about the selective cracking of alkanes with the normal structure has made these zeolites promising catalysts for processing high-alkane petroleums and petroleum products[8,16,17,213]. It will be shown below that pentasils can apparently catalyse not only cracking but also other transformations of saturated hydrocarbons of practical importance. The reactions of alkanes on pentasils have been insufficiently studied, however.

Transformations of alkanes. Recently published data[214] on the possibility of transforming methane and ethane into C_6–C_{10} aromatic hydrocarbons on TsVM zeolites are of considerable interest. In a pulse reactor on this zeolite ($SiO_2/.Al_2O_3$ = 33.3), containing added group VIII metals (0.2 to 1.0%), methane at 600° in the absence of oxidising agents gives benzene in >6% yield, calculated on the hydrocarbon passed. The yield of aromatic hydrocarbons from ethane on the non-modified zeolite was ~10%, and on the zeolite containing added metal the yield reached 20%, but the reaction was less selective.

The formation of benzene, toluene, xylenes, and trimethylbenzenes from methane has also been observed under the conditions of its oxidative dehydrogenation on pentasils modified by added transition metal compounds[215]. In this case the selectivity of the reaction corresponds to 10–20% of the transformed methane.

Pentasils can bring about the aromatisation of alkanes with higher molecular weights—hexane, 3-methylpentane, 2,2-dimethylbutane, and iso-octane[87,159,216]. The liquid catalysates formed from n-hexane, 3-methylpentane, and iso-octane on TsVK zeolite (flow reactor, 450°), in addition to the non-transformed alkane and cracking products, contained 50, 42, and 10% aromatic hydrocarbons respectively. Similar results were obtained on the same zeolite under pulse conditions, and also in a flow system on H-ZSM-5 zeolite at 400°.[87] According to these data[87], the conversion of the hexane isomers decreased with increase in the kinetic diameter of their molecules. Together with the results of sorption measurements, these data indicated that the rate of the transformations of the alkanes is limited by the rate of their diffusion into the zeolite pores. Thus n-hexane penetrates rapidly into the pores and is readily transformed on the active centres localised in them. 2,2-Dimethylbutane, however, must apparently first undergo isomerisation on the outer surface to give isomers which can more readily diffuse into the zeolite channels, where they undergo further transformations. These suggestions were confirmed in experiments using 4-methylquinoline and ammonia, introduced into the reactor together with the hydrocarbons. The addition of 4-methylquinoline, which can be adsorbed only on the outer surface of the zeolite, had practically no influence on the conversion of n-hexane, but suppressed almost completely the transformations of 2,2-dimethylbutane. The addition of ammonia, which readily penetrates into the pores, deactivated the catalyst for the transformations of both hydrocarbons. When the supply of ammonia was stopped, the catalytic activity of the pentasil was gradually restored as desorption took place.

The acidic properties of the pentasils indicate that they may be active in the isomerisation of alkanes. In fact, n-butane, n-pentane, and n-hexane undergo isomerisation on TsVK zeolites (SiO_2/Al_2O_3 = 33.3, 47, and 83) at 250–400° under a pressure of 30 atm.[91] Extensive hydrocracking and disproportionation of these alkanes took place simultaneously. The relative extent to which these last reactions took place decreased sharply when the zeolites were modified with palladium. The greatest activity and selectivity in the isomerisation of n-pentane was shown by the 0.5% Pd/TsVK catalyst prepared by ion exchange, on which the yield of isopentane at 330° reached ~60 mass %, and the yield of the products of hydrocracking and disproportionation amounted to only 2.8 mass % and 1.3 mass % respectively[91].

It should be noted that n-decane, which has a higher molecular weight, underwent hydrocracking preferentially on the 0.5% Pt/H-ZSM-5 ion-exchange catalyst, and underwent isomerisation to only a slight extent[90]. The composition of the products of the isomerisation of n-decane, in which 2-methylnonane predominated, differed considerably from the equilibrium composition. The results were attributed[90] to the influence of the molecular-sieve properties of the zeolite, which prevents the formation of highly branched isomers.

The isomerisation of isobutane on H-ZSM-5 zeolite ($SiO_2/.Al_2O_3$ = 100; 0.01 mass % Na; 350°) took place much more intensively than that of n-butane, and the rate of reaction on pentasil was ~70 times slower than that on H-mordenite.[217] Moreover, the pentasil showed almost no activity on the disproportionation of isobutane to propane and pentanes, accompanying the isomerisation. Since the isomerisation and disproportionation of isobutane are bimolecular reactions, the low activity of the pentasil in these reactions was attributed to the difficulty of formation of bulky intermediate compounds in the narrow pores, that is to the molecular-sieve selectivity with respect to the transition state (see below).

The cracking of alkanes on pentasils has been studied in much more detail than isomerisation. H-ZSM-5 zeolite is more active in the cracking of n-hexane than H-mordenite.[217] The activity of both zeolites in this reaction is much greater than that of other zeolites (NaY, LaY, HY, MgX, and Na-ZSM-5), industrial cracking catalyst (ICC), and amorphous aluminosilicate (AAS).[101] The relative activity ($\alpha = k_X/k_{ICC}$, where k_X and k_{ICC} are the rate constants of the cracking on the catalyst being studied and on ICC respectively) for H-ZSM-5 and HM were more than 10^5, whereas for the other catalysts the values of α did not exceed 10^3.[101] The ZSM-5 zeolites showed a high resistance to treatment with steam at a high temperature, and a high stability due to the low degree of coke formation in these catalysts. The products of the cracking of n-hexane on these zeolites at low degrees of conversion of the hydrocarbon (5–20%) contained chiefly propane, n-butane, and isobutane. With increase in the conversion of the original alkane to ~90% at higher temperatures, the formation of aromatic hydrocarbons and an increase in the concentration of ethylene in the reaction products were observed[101].

The cracking of n-octane on TsVK pentasil and zeolites of type Y, mordenite, and erionite can be represented by the following general scheme[134]:

Alkane → "unsaturated fragments" → alkanes and aromatic hydrocarbons → polycyclic hydrocarbons (coke)

The reactions involving the redistribution of hydrogen and secondary transformations of alkenes apparently take place at a lower rate on pentasil than on other zeolites[134]. Moreover, for pentasil the rate of desorption of monocyclic aromatic hydrocarbons is much greater than the rate of their transformation into polycyclic systems, which act as coke precursors. These characteristic features were attributed[134] to the unusual geometry of the pentasil pores and the low density of hypothetical proton-donor centres (see section II), whose existence in zeolites has not yet been proved.

The activity of pentasils of different type (ZSM-5, TsVK, TsVM, ultrasil) in the cracking of alkanes decreases with decrease in the Al concentration in the zeolite framework[89,101,218], with increase in T_{act},[85] and with decrease in the quantity of acidic OH groups on treatment of the zeolite with ammonia[143].

The relative rate of the cracking of alkanes decreases with decrease in the length of the carbon chain of the molecules ($n\text{-}C_7 > n\text{-}C_6 > n\text{-}C_5$) and with increase in the degree of branching of the alkane (n-alkane > 2-methylalkane > 3-methylalkane > dimethylalkane > ethylalkane).[100] The rate of transformation of the different molecules is apparently limited by the rate of their diffusion into the zeolite pores, which is determined by the size and shape of the

molecules; the length of the molecules is slightly less important than the kinetic diameter[100]. A decrease in the reaction rate with increase in the degree of branching of the molecules was also observed in the cracking of n-octane and iso-octane on ZSM-5 pentasils and ultrasil[101,141,143,164]. With increase in temperature, the differences in the rate of cracking of alkanes with different structures on these zeolites decreased considerably[100,143]. It was suggested[100] that in contrast to the first-generation zeolites, pentasils have a "dynamic" molecular-sieve selectivity with respect to the reacting molecules, as a result of which the molecules whose kinetic diameters differ by more than 1 Å can diffuse into the pores of these zeolites at approximately equal rates. Unfortunately, no explanation for the reasons for this phenomenon was given[100].

A number of papers have been devoted to the cracking of individual alkanes or high-alkane petroleum fractions on complex catalysts containing pentasils as one of the components. For example, the cracking of n-hexane has been studied on zeolites of the ultrasil type mixed with 30–90% of a binding agent (Al_2O_3, Al_2O_3–SiO_2, etc.).[219] The high cracking activity of these catalysts was combined with good isomerisation properties. The cracking products contained chiefly C_4 and C_5 hydrocarbons, including the iso-compounds. The addition of 1% Pd to these catalysts increased their isomerisation activity considerably, but decreased significantly the yield of cracking products. Increase in the quantity of binding agent and in the ratio SiO_2/Al_2O_3 in the zeolite had a similar effect.

A number of papers deal with the preparation and study of two-zeolite ("hybrid") cracking catalysts containing TsVM zeolites or ultrasil, and also first-generation zeolites (types X, Y, and Ln-Y).[220–225] The study of the catalytic properties of these systems in the cracking of individual alkanes (n-heptane) and petroleum fractions (gas oil, kerosene–gas oil fraction) showed that the yield of unsaturated hydrocarbons increases considerably in the presence of pentasil.

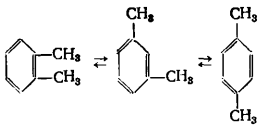
The possibilities provided by the use of zeolites of the pentasil family as industrial cracking catalysts, and the present state of the production of these zeolites in the Soviet Union have been examined in detail[226].

The transformations of cycloalkanes on zeolites of the pentasil family are described in very few papers. The possibility of obtaining high yields of aromatic hydrocarbons (benzene, toluene, xylenes, and other alkylbenzenes) from cyclopentane, cyclohexane, and methylcyclohexane on TsVK zeolite at 450° under flow and pulse conditions has been reported[159,216]. The same products in approximately the same proportions were formed in all cases, irrespective of the original hydrocarbon. Comparison with corresponding data for ethylene and n-hexane indicated that the reactions of the lower alkenes, alkanes, and cycloalkanes take place according to the same scheme involving the initial splitting of the original hydrocarbon into C_1–C_4 fragments, which are adsorbed on the zeolite surface.

In addition to these data, it has been reported[227] that decalin is transformed to a very slight extent on an experimental industrial cracking catalyst containing 20% H-ZSM-5 zeolite in a kaolin matrix.

4. Reactions of Aromatic Hydrocarbons

The interconversion and alkylation of aromatic hydrocarbons, which are of considerable practical importance, have been studied in detail on first-generation zeolites[130,209]. An important contribution to these studies has been made by Soviet scientists[40]. Pentasils have also been recommended as extremely effective catalysts for these reactions[18–21,228–239].



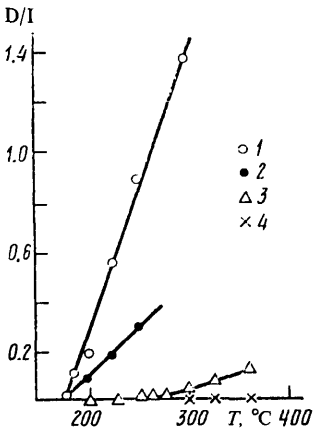
The primary reaction of aromatic hydrocarbons on pentasils is the *selective isomerisation* of *m*- and *o*-xylenes to give the *p*-isomer. In some countries, this process, based on ZSM-5 pentasil, has been carried out on the industrial scale in recent years[38,110].

A number of scientific papers deal with the study of this reaction on pentasils[149,240–245]. For example, the isomerisation of *m*- and *o*-xylenes on the Na- and H-forms of TsVK zeolite, on H-mordenite (HM), and on dealuminated mordenite (DM) was studied in detail[240] to determine the reasons for the high selectivity of the formation of *p*-xylene from different alkenes on pentasils[84,88,125]. The activity of the catalysts studied in this reaction increased in the order Na-TsVK < H-TsVK < HM < DM. With the exception of HM, whose activity decreased by a factor of 2 after 70 min, all the catalysts showed stable operation for 1.5–2 h. The TsVK zeolites catalysed practically only the isomerisation of xylenes, whereas on HM and DM, appreciable disproportionation of xylenes took place to give toluene and trimethylbenzenes (Fig.11). A significant difference was also observed in the ratio of the products of the isomerisation of *m*- and *o*-xylenes on TsVK zeolites and mordenite. For Na- and H-TsVK, the values of the ratio of the concentrations of the isomers formed from *o*-xylene ([PX]/[MX]) were the same, were appreciably greater than the corresponding values for HM and DM, and approached the equilibrium value more rapidly with increase in the degree of conversion (Fig.12*a*). In the isomerisation of *m*-xylene on H-TsVK, the values of the corresponding ratio [PX]/[OX] were greater than the equilibrium value throughout the entire range of degrees of conversion, and with decrease in the conversion from 50% to 15%, this ratio increased from 1.5 to 3.6. In contrast to this, for DM the values of the ratio [PX]/[OX] practically corresponded to the equilibrium value for all degrees of conversion of the original isomer (Fig.12*b*).

Similar results were obtained in experiments with *m*-xylene on H-TsVK and HY zeolites[241]. The data given in Ref.240 were completely confirmed in a comparative study of the transformations of all three xylene isomers on H-ZSM-5, HY, and HM zeolites[242]. The H-ZSM-5 zeolite showed a high activity in the isomerisation of the xylenes, which took place selectively to give the *p*-isomer. This zeolite also showed a very low activity in the disproportionation of dialkylbenzenes, and was completely inactive in the transformations of 1,2,4-trimethylbenzene. All these date made it possible to reach conclusions about the size of the zeolite channels and the cavities formed by the intersection of these channels. It was suggested[242] that the isomerisation of xylene could be used to estimate the porous structure of pentasils instead of the method widely used at present, involving the determination of the "permeability index" (constraint index)[243] $\omega = k_{nh}/k_{2mp}$, where k_{nh} and k_{2mp} are the rate constants for the cracking of n-hexane and 2-methylpentane respectively.

The activity of pentasil in the isomerisation of *m*-xylene and the selectivity of this reaction under pulse conditions are influenced considerably by the composition of the zeolite, its degree of decationation, and the activation conditions, and also by the extent of the poisoning of the acidic centres by ammonia, pyridine, or quinoline[244]. The selective poisoning of the pentasil NiH-ZSM-5 by ammonia suppresses the activity of the acidic centres responsible for dealkylation and disproportionation side reactions, leading to an increase in the selectivity of the isomerisation of *m*-xylene to the *o*- and *p*-isomers.[245]

In contrast to these studies[240-242], other studies[246] reported the selective formation of *p*-xylene from the *m*- and *o*-isomers on H-ZSM-5 zeolite only after its modification by added phosphorus and magnesium. In other respects, the data[246] agreed with the data obtained by other workers. The rates of isomerisation of the xylenes decrease in the order *p*-xylene > *m*-xylene > *o*-xylene in the ratio 5 : 2.5 : 1. Since bimolecular reactions in the channels of the zeolites of the pentasil family are difficult, it was suggested[246] that the isomerisation of xylenes can apparently take place by the intramolecular successive displacement of the methyl group:



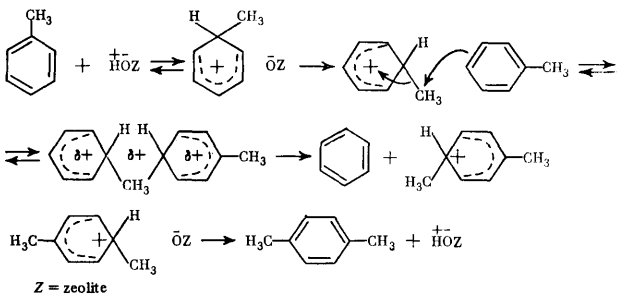


Figure 11. Temperature dependence of the ratio of the concentrations of disproportionation and isomerisation products (D/I) of *o*-xylene for the zeolites DM (*1*), HM (*2*), H-TsVK (*3*), and Na-TsVK (*4*).[242]

In addition to the isomerisation of xylenes, the *disproportionation of toluene* to benzene and xylenes takes place selectively on pentasils. It should be noted that this reaction takes place on pentasils less intensively than isomerisation, and the selective formation of *p*-xylene is observed only when the zeolite is modified by various additives, or when the conversion of toluene is decreased by changing the reaction conditions.

With increase in temperature from 400° to 600° (at a mass rate of supply of toluene of ~3.5 h^{-1}), the conversion of toluene to benzene and xylenes on H-ZSM-5 zeolite increased from 8% to 52%, but the ratio of the xylene isomers in the reaction products remained almost unchanged and practically corresponded to the equilibrium value[109,246,247]. A significant increase in the yield of *p*-xylene was observed only at 550°, when as a result of an increase in the rate of supply of toluene to 30 h^{-1} its conversion decreased from 40% to ~13%. The xylene fraction contained 35, 46, and 19% of the *p*-, *m*-, and *o*-isomers respectively[109,246]. Approximately the same effect was observed on large (~3 μm) crystallites of H-ZSM-5 zeolite at a high rate of supply of toluene. The greatest selectivity of *p*-xylene formation was achieved on zeolite specimens modified by the addition of various elements, in particular magnesium and boron[246,247]. As in the modification of TsVK zeolite by vanadium (see above), however, the introduction of these additives decreased considerably the conversion of the original hydrocarbon. The rate of the disproportionation of toluene on modified H-ZSM-5 zeolite specimens was 10^2 times lower than the rate of isomerisation of xylenes[246]. It was suggested that the mechanism of disproportionation involves the reaction of the toluene molecule with the proton of a Brönsted acidic centre and subsequent transfer of a methyl group (scheme 4).[247]

Scheme 4

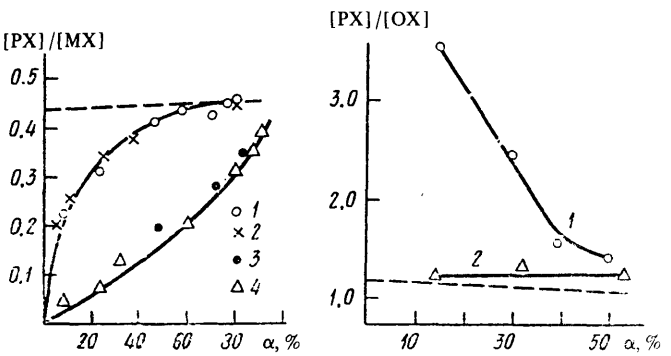

Figure 12. Dependence of the ratio of the concentrations of the products of the isomerisation of *o*-xylene (*a*) and *p*-xylene (*b*) on their conversion (α) on the zeolites H-TsVK (*1*), Na-TsVK (*2*), HM (*3*), and DM (*4*); the broken lines give the ratio at equilibrium[242].

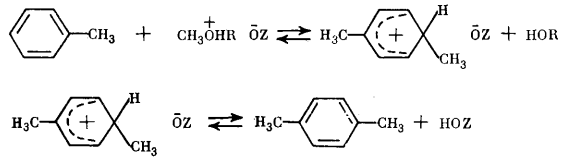
In experiments with toluene (420° and 500°) in the absence of a carrier gas, HY zeolites, HM, omega, and offretite showed a much higher initial activity than H-ZSM-5 zeolite, catalysing both disproportionation and other reactions[248,249]. The pentasil, however, was distinguished by its high stability and ability to bring about the selective conversion of toluene into benzene and a mixture of xylene isomers with the equilibrium composition. An increased concentration of *p*-xylene in this mixture, relative to the equilibrium concentration, was obtained only in experiments with H-ZSM-5 zeolite in which the toluene was diluted with a carrier gas (Ar or H_2), accompanied by a decrease in the conversion of the original hydrocarbon[250]. The greatest yield of *p*-xylene was observed in the presence of H_2, although the side reaction of toluene demethylation simultaneously increased.

Under the conditions of the disproportionation of toluene without a carrier gas (350°), HY zeolites and HM are rapidly deactivated as a result of coke formation, and with increase in their deactivation there is a significant increase in the concentration of *p*-xylene in the reaction products[248]. This was also observed for HY and H-ZSM-5 zeolites when the reaction was carried out in a stream of nitrogen[251]. An increase in the selectivity of *p*-xylene formation was not observed in a stream of H_2.

A study of the disproportionation of toluene on H-ZSM-5 and H-ZSM-11 zeolites showed a slight difference in the behaviour of these pentasils: H-ZSM-11 was slightly less active but more stable than H-ZSM-5, on which *p*-xylene is formed with a greater selectivity than on H-ZSM-11.[251]

The disproportionation of ethylbenzene takes place selectively on HNa-ZSM-5 zeolite, and its total conversion at 200° is 4.4%.[252]

The alkylation of aromatic hydrocarbons, which has been studied in detail on first-generation zeolites[209], is another reaction which takes place on pentasils. Considerable attention has been paid to the study of the reaction of pentasils between toluene and methanol, which may give considerable quantities of *p*-xylene. On different cation-exchange forms of Y zeolite, this reaction gives products containing up to 40–50% *p*-xylene.[253,254] The conversion of methanol on pentasils in this reaction was usually 100%, and the reaction products, in addition to unreacted toluene, contained a mixture of xylene isomers and small quantities of benzene and C_9 and C_{10} alkylbenzenes[109,246,255]. The proportion of aromatic hydrocarbons formed from methanol was very low. Under the mildest conditions (t < 300°, short contact time), the products also contained traces of methanol, dimethyl ether, formaldehyde, CO, and CO_2.[255] The conversion of toluene, the yield of xylenes, and the concentration of the *p*-isomer in them depended on the reaction conditions and the catalyst composition.



On non-modified H-ZSM-5 and H-ZSM-11 zeolites, this reaction gave a mixture of xylene isomers with a composition close to the equilibrium composition[246,255,256]. The selectivity of *p*-xylene formation on H-ZSM-11 was slightly higher than that on H-ZSM-5. This conclusion requires verification, however, because of the marked differences in the reaction conditions on these zeolites[255].

As in the case of the disproportionation of toluene, a significant increase in the concentration of *p*-xylene in the products of the alkylation on pentasils was observed when large crystals (~3 μm) were used[109,246], and also after an interval from the start of the catalyst operation at high temperatures (550° and 700°).[246,255,256] The selective formation of *p*-xylene in the alkylation of toluene by methanol was also observed not under flow conditions but under pulse conditions[257,258].

A sharp increase in the selectivity of this reaction with respect to *p*-xylene, as in the case of other reactions, was observed when H-ZSM-5 zeolite was modified by various additives[109,246,255,256]. For example, when not less than 16% MgO was introduced by impregnation into H-ZSM-5, the alkylation products showed an increase to ~90% in the concentrations of xylenes, of which more than 90% corresponded to the *p*-isomer. The cation-exchange Mg-H-ZSM-5 zeolite, in which the quantity of Mg was ~13 times lower than that in MgO-H-ZSM-5, at 400° showed approximately the same activity as the non-modified zeolite, but the selectivity of the reaction with respect to *p*-xylene was slightly greater.

The alkylation of toluene by methanol on H-ZSM-5 zeolite with added P, B, Mg, and other elements has been studied in detail at different temperatures, pressures, reagent ratios, and reagent supply rates[246,255]. The greatest effects were obtained on H-ZSM-5 modified using phosphorus (~3–8%), introduced by impregnating the zeolite with solutions of phosphoric acid, diphenylphosphinic acid, methyl phosphite, chlorodiphenylphosphine, or dichlorophenylphosphine. On these catalysts, by varying their composition and the reaction conditions, it was possible to obtain alkylation products containing up to 80–90% xylenes, of which 50–80% corresponded to the *p*-isomer.

In an examination of the possible mechanism of the alkylation of toluene by methanol on pentasils with allowance for the presence of Brönsted acidic centres on these zeolites, it was suggested[186,255] that this reaction takes place according to the following scheme:

R = H, CH_3; Z = zeolite.

According to the rules of electrophilic substitution in aromatic compounds, the chief products of this reaction should be *o*- and *p*-xylenes. The formation of a mixture of all three isomers is due to the isomerisation of the alkylation products formed initially. On non-modified pentasils, the rate of isomerisation of xylenes (w_i) is 10–15 times greater than the rate of alkylation (w_a), whereas on the modified specimens, w_a is 7–15 times smaller than w_i.[246] At the same time, the isomerisation of xylenes takes place preferentially on the strongest Brönsted acidic centres of the pentasils[256]. Thus the selective formation of *p*-xylene in the alkylation of toluene by methanol on pentasils should apparently take place in those cases where these centres are suppressed either by a modifying additive or as a result of treatment with water vapour at high temperature.

In the alkylation of benzene by ethanol on ZSM-5 zeolites (in the pure form or forms modified by phosphorus or boron), the ethyl group is introduced into benzene directly from the alcohol without the intermediate formation of ethylene[186,258].

Like first-generation zeolites, zeolites of the pentasil family are effective catalysts for the alkylation of aromatic hydrocarbons by alkenes. A process was recently developed for obtaining ethylbenzene by the alkylation of benzene by ethylene on ZSM-5 pentasils[238,239]. Pilot-plant and large-scale industrial experimental tests of this process demonstrated a number of advantages of the new catalyst, particularly its high stability and ease of regeneration.

The alkylation of aromatic hydrocarbons by alkenes can take place during any process on pentasils if alkenes and aromatic compounds are present in the system as starting materials or final products. For example, this reaction has been observed[100] under the conditions of the cracking of mixtures of alkanes, accompanied by the formation of a small quantity of benzene and toluene. The ratio of the rates of the alkylation of toluene and benzene by the fragments of molecules undergoing cracking is ~0.7, whereas for the usual heterogeneous or homogeneous systems this ratio is 1.4.

In the alkylation of benzene by ethylene on TsVK zeolites[259], in addition to ethyl and diethylbenzene, the reaction products contained cumene and s-butylbenzene, the yields of which decreased with increase in temperature (Table 6). The formation of these products is evidently due to the

ability of the temperatures to catalyse the oligomerisation of ethylene with the subsequent splitting of the oligomers and disproportionation of the fragments formed. The products of these transformations can then alkylate benzene.

Table 6. The alkylation of benzene by ethylene on ultrasil zeolites ($v = 1.2\ h^{-1}$, molar ratio $C_6H_6 : C_2H_4 = 3:1$).[259]

T, °C	C_2H_4 conversion, %				S, A/B	T, °C	C_2H_4 conversion, %				S, A/B
	to EB (A)	to IPB	to SBB	total (B)			to EB (A)	to IPB	to SBB	total (B)	
	H-TsVK ($x = 60$)						H-TsVK ($x = 172$)				
250	20.2	12.2	6.4	55.0	36.7	250	18.6	9.5	7.3	34.0	54.6
300	53.6	3.5	0.7	80.2	67.0	300	41.7	7.4	1.2	68.4	61.1
350	81.0	1.3	traces	99.0	81.8	350	73.0	1.6	traces	95.0	76.9

Note: EB = ethylbenzene, IPB = isopropylbenzene, SBB = s-butylbenzene, x is the molar ratio SiO_2/Al_2O_3, and S is the selectivity.

The formation of "anomalous" alkylation products was also observed in a study of the reaction of benzene with propylene on ultrasil zeolites[260–262]. These products contained s- and n-butylbenzenes, s- and n-pentylbenzenes, and s- and n-hexylbenzenes. Unlike zeolites of type Y, ultrasil did not give polyalkylbenzenes, and the formation of monoalkylbenzenes with a branched side chain was hindered. The temperature dependence of the composition of the products is complex[260,261], since change in temperature leads to a change in not only the rate of alkylation but also the rate of the transformations of propylene and its oligomers, taking place by a carbenium-ion mechanism. With increase in the degree of decationation of the pentasil there is an increase in its activity and an increase in the selectivity of the reaction with respect to the formation of n-propylbenzene and "anomalous" alkylation products. There is a simultaneous decrease in the stability of the zeolite, probably as a result of the blocking of the active centres by condensation products.

Published information on other reactions of aromatic hydrocarbons on pentasils is limited to data[113] on the selective hydrogenation of styrene in its mixtures with 2-methylstyrene on Pt-ZSM-5 ion-exchange catalyst (400°) and the selective oxidation of *p*-xylene in its mixtures with the *o*-isomer on 1% Cu-ZSM-5 catalyst (390–450°). These reactions provide a good illustration of the molecular-sieve mechanism of the action of zeolites of the pentasil family, examined below.

5. Molecular-sieve Properties of Pentasils and the Selectivity of Reactions Taking Place on Them

Many examples of the molecular-sieve action of pentasils and the consequent high selectivity of the reactions are now known. These include the selective cracking of alkanes, the transformation of alcohols and lower alkenes to hydrocarbons containing not more than 10 carbon atoms in the chain, the absence in the products of these reactions of polyalkylbenzenes with branched side chains, condensed aromatic systems, etc. The most striking example is the selective formation of *p*-xylene in the isomerisation of xylenes, the disproportionation of toluene, and its alkylation by methanol.

It is possible to distinguish three types of molecular-sieve selectivity of zeolites[110,111], each of which is due to one of the following factors: 1) the size of the molecules of the original reagent, that is their ability to penetrate into the zeolite pores to the active centres localised in them; 2) the size of the molecules of the products, that is their ability to diffuse from the zeolite pores into the gas phase; and 3) the size of the intermediate complex, that is the possibility of the formation of this complex in the restricted space of the pores and cavities of the zeolite.

When the diameter of the zeolite channels is commensurate with the diameter of the molecules of the starting materials and the products, the reaction apparently takes place under internal-diffusion conditions, which may have a significant influence on the selectivity of the process[263]. The rate of diffusion of the molecules depends both on their size and on their shape or their ability to adopt a configuration which corresponds more closely to the size and shape of the zeolite channels. Under these conditions, which have been called "configurational diffusion" conditions[110], the selective formation of a definite reaction product may take place, that is there is "configurational selectivity".

The transformations of xylenes on pentasils take place under these conditions. Data on the composition and distribution of the reaction products, and also on the rate of the transformation of different xylene isomers[240,242,246] have shown that in this case all the above types of molecular-sieve selectivity are observed. Steric hindrance leads to a very marked decrease in the rate of the disproportionation of xylenes, but does not prevent their isomerisation, in which *p*-xylene is formed with a high selectivity. The molecules of this isomer, which has a smaller kinetic diameter (6.4–7.0 Å) than the molecules of *m*- and *o*-xylenes (6.9–7.6 Å), diffuse into the pentasil channels at the highest rate and readily migrate from the pores into the gas phase[70,84,87,110]. The molecules of *m*- and *o*-xylenes, which are present in the zeolite channels for a longer time, may undergo additional isomerisation into *p*-xylene, increasing the concentration of the latter in the reaction products. For zeolites with wider pores (for example mordenite[240]), the selective formation of *p*-xylene does not take place, since the molecules of all three isomers diffuse in the channels of this zeolite at approximately equal rates[240,242].

The influence of diffusion factors on the reaction rate is estimated using the dimensionless parameter $Q = [k(R^2/D)]^{1/2}$, where k is the reaction rate constant, R the radius of the zeolite crystallites, and D the effective diffusion coefficient of the molecules[110,263]. This parameter is related to the efficiency factor (η—the degree of utilisation of the internal surface of the catalyst) and to the configurational selectivity of the reaction ($S = D_p/D_a$, where D_p and D_a are the diffusion coefficients of the molecules p and a, which respectively diffuse easily and with difficulty into the zeolite pores).[111,263] A mathematical theory was recently developed for the selective formation of *p*-xylene in the isomerisation of xylenes, the disproportionation of toluene, and its alkylation by methanol under conditions of configurational diffusion on catalysts showing molecular-sieve properties[264].

The concept of the limiting role of the diffusion of the molecules in the pores of the zeolite makes it possible to explain the increase in the selectivity of *p*-xylene formation in various reactions on pentasils when partial coke formation takes place in the zeolite, when it is modified by various additives, or when the size of the crystallites increases. For example, the introduction of additives or partial coke formation in the zeolite during its operation leads to a decrease in the effective diameter of the channels and creates additional steric hindrance for the diffusion of molecules.

The modification of TsVK pentasil by vanadium decreases the sorptive capacity of the zeolite and the initial rate of adsorption for all three xylene isomers[211]. The sorption characteristics of the pentasil change to the smallest extent for *p*-xylene, however. In the alkylation of benzene by propylene on ultrasil pentasil[264], the change in the selectivity of the reaction with time is due to the accumulation in the zeolite channels of "condensation products" (that is coke or its precursors), which apparently restrict the access of the reacting molecules to the active centres.

It is also possible that when coke is formed in the pentasil or when various additives are introduced into it, the acidic properties of its surface may change, with a consequent change in the selectivity of the reactions. For example, when H-ZSM-5 zeolite is treated with phosphorus compounds, there is a marked increase in the number of surface acidic centres[158], and selective formation of *p*-xylene takes place on these zeolites[247,255]. According to data obtained by H–D exchange[208], however, modification of TsVK pentasil by vanadium does not lead to a change in the concentration of the surface OH groups, that is it has no influence on the acidic properties of the pentasil surface.

These data indicate the existence of a definite relationship between the selectivity of the reactions on pentasils, the nature of their porous structure, and the rate of diffusion of the molecules of the reagents and products in the zeolite pores. The question of the relationship between the acidity of zeolites and the selectivity of the reactions which they catalyse, and the influence of modifying additives on the acidic properties of the pentasils, is still not clear. A significant part in this relationship may be played by the nature of the additive, its localisation in the system of zeolite pores, and the state in which this additive may exist under the reaction conditions. Further studies are required in order to solve these problems, which are important for the directed control of the catalytic properties of zeolite catalysts.

V. THE USE OF PENTASILS IN OTHER CATALYTIC REACTIONS

A number of studies have shown that pentasils can be used as catalysts not only in the above transformations of oxygen-containing compounds and hydrocarbons, but also in various other reactions. Among these, an important place is occupied by processes directed towards the production of motor fuels from non-traditional raw materials, capable of replacing the petroleum products used for these purposes. A promising raw material in this respect is biomass (the waste products from the processing of agricultural products, the timber and timber-processing industries, etc.), on the basis of which a technological process has now been developed for the production of various synthetic fuels by thermochemical and fermentation processes[265–267]. The possibility in principle of using pentasils for the catalytic transformation of various components of plant raw materials into high-quality motor fuel was demonstrated[268] in a study of the transformations of polyisoprene latex, corn oil, castor oil, and other plant oils on ZSM-5 zeolite. At 450–500°, a high conversion of the starting materials was achieved, and the composition of the products was close to that of the hydrocarbon mixtures obtained from methanol, although they usually contained more benzene, toluene, and xylene.

The availability of zeolites of the pentasil family has provided a realistic solution to the problem of the production of motor oils from the products of the treatment of coal, including the conversion of synthesis gas[266,267,269–271]. Two versions of this process are usually considered:

$$\text{coal} \xrightarrow{+H_2O} CO + H_2 \begin{cases} \longrightarrow CH_3OH \rightarrow \text{petrol}; & (4) \\ \longrightarrow \text{petrol}. & (5) \end{cases}$$

Process (4) includes the intermediate formation of methanol, which can then be converted on a ZSM-5 zeolite into petrol, by the process developed by Mobil Oil (see section III). Method (5) is more attractive, since it makes it possible in principle to obtain petrol or individual hydrocarbons directly from synthesis gas without the intermediate stage. This process is complicated by the absence of catalysts giving a higher selectivity of the conversion of synthesis gas into hydrocarbons than the familiar catalysts of the Fischer–Tropsch process. Considerable progress has already been made in this direction, by using catalysts based on first-generation zeolites[272,273] and zeolites of the pentasil family[22,41,45,266,267].

The study of the conversion of synthesis gas on Fe-, Zn-Cr-, Zr-, or Co-zeolite catalysts of the ZSM-5 or ultrasil type, prepared by mixing or impregnation, showed that in the presence of a zeolite of the pentasil family there is a significant increase in the conversion of the original mixture and an increase in the yield of hydrocarbons, and aromatic hydrocarbons are formed[274–277]. In contrast to the usual versions of the Fischer–Tropsch process, the reaction products contained much smaller quantities of alkenes; the normal chains of the aliphatic hydrocarbons formed contained not more than 11 or 12 carbon atoms, and the aromatisation products consisted chiefly of benzene, toluene, and xylenes[274–277].

On a catalyst based on H-mordenite, but not pentasil, a decrease in the concentration of alkenes in the reaction products and the formation of aromatic hydrocarbons was also observed[276]. The conversion of synthesis gas, which was partly converted into CH_3OH and $(CH_3)_2O$, was ~4 times lower, however, than in the presence of pentasil. The nature of the metallic component has a significant influence on the catalyst properties. For example, the Zr- and Zn-Cr-ZSM-5 catalysts showed a much lower ability to give methane and a much higher aromatising power than the Fe-ZSM-5 catalyst[275].

The activity at 240° of the Co-ultrasil catalyst obtained by mixing depends on the SiO_2/Al_2O_3 ratio in the pentasil[276]. Increase in this ratio from 42 to 190 led to a decrease in the conversion of the synthesis gas, the total yield of hydrocarbons, and their concentration in the reaction products. At 190°, only a decrease in the proportion of hydrocarbons in the liquid catalysates was observed. The activity of the Co-ultrasil catalysts increased sharply when 3% MgO was added, but this led to a significant change in the composition of the reaction products, which contained C_1–C_{22} hydrocarbons. Increase in the concentration of the additive to 12% lowered the yield of the light C_5 and C_6 hydrocarbon fractions, increased the yield of C_7 and higher hydrocarbons, and suppressed the aromatisation. These additives had approximately the same effect on less active catalysts with the same composition (Co-ultrasil), prepared by impregnating the zeolite with cobalt carbonyl[276].

It is suggested[275] that on catalysts containing a zeolite of the pentasil family, the conversion of synthesis gas takes place according to the following scheme:

$$2H_2 + CO \xrightarrow{\text{metal}} [CH_3OH \rightleftarrows {}^1/_2 (CH_3)_2O + {}^1/_2 H_2O] \xrightarrow{\text{pentasil}} (CH_2) + H_2O .$$

The composition of the reaction products is determined both by the ability of the pentasil to transform the intermediate compounds (alcohol and ether) into hydrocarbons and also by its molecular-sieve properties, which prevent the formation

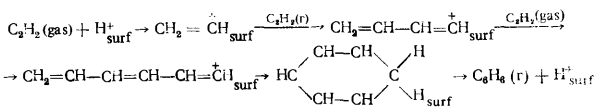
of long or bulky molecules. The influence of diffusion factors on the selectivity of the conversion of synthesis gas was studied with decrease in the size of the particles of the components of the Zn-Cr-ZSM-5 catalyst, that is with decrease in the path length of the molecules diffusing in the pentasil pores[275]. It is considered[274] that the active centres of the pentasil in the catalyst can interrupt the growth of the hydrocarbon chains by converting the α-alkene molecules into molecules which are inert with respect to the active centres of the metallic component (for example into aromatic hydrocarbons, branched and internal alkenes, etc.).

CO can be adsorbed on ultrasil-containing Co-catalysts of the Fischer–Tropsch synthesis in several forms, characterised by different temperatures of desorption (T_{des}).[276] With decrease in the Al concentration in the ultrasil there is a decrease in the total sorption of CO and an increase in the concentration of carbon monoxide adsorbed in a form with $T_{des} = 400°$, which apparently has the lowest activity in the synthesis of hydrocarbons. The lowest concentration of this form of adsorbed CO was detected for the most active catalyst containing Co-ultrasil + 6% MgO.

A catalyst based on ZSM-5 zeolite has been developed for transforming liquid oxidation products and various side products of the Fischer–Tropsch synthesis into more valuable aliphatic and aromatic hydrocarbons[278]. It has been shown possible to increase considerably the profitability of the Fischer–Tropsch process.

Mixed Co-ultrasil catalysts show a high activity in the carbon monoxide-initiated hydropolymerisation of ethylene, which gives mixtures of C_3–C_{22} hydrocarbons and ethane[279]. The activity of these catalysts decreased with decrease in the Al concentration in the zeolite. Unlike catalysts based on mordenite and zeolites of type Y, they retained their activity over a wide temperature range (190–310°) and gave products with a large proportion of C_5 and higher fractions. The products also contained aromatic hydrocarbons, and this was attributed to the influence of the pentasil. It was suggested[279] that the hydropolymerisation of ethylene is activated by carbon monoxide adsorbed on the zeolite surface.

One of the ways of using the products of the gasification of coal involves the use of carbon monoxide for the carbonylation of hydrocarbons to obtain carboxylic acids and their esters. It was previously shown that it is possible to carry out this reaction on heterogeneous non-zeolite catalysts containing Pd.[280–282] This reaction has also been studied on mordenite and TsVK pentasil containing group VIII metals[283,284]. The Pd-containing pentasils can be used as active catalysts for the production of propionic and butyric acids by the carbonylation of ethylene and propylene respectively.



In the carbonylation of ethylene and propylene on catalysts based on pentasils, the formation of considerable quantities of esters such as ethyl propionate, isopropyl isobutyrate, and isopropyl n-butyrate has been observed[283, 284]. An interesting feature is that the H-form of a ZSM-5 pentasil showed no activity in the liquid-phase esterification of acetic acid by ethanol and isopropy alcohol[285].

The gas-phase chlorination of benzene (175°) on pentasils (NaH-ZSM-5, H-ZSM-5, Ce-ZSM-5, NaH-ZSM-11, and silicalite), and also on mordenite and amorphous SiO_2, gives chiefly chlorine addition products—a mixture of stereoisomers of hexachlorocyclohexane[286]. In contrast to this, the reactions on L and Ln-Y zeolites, and also on Al_2O_3, involved chiefly substitution to give chlorobenzenes containing up to 5 or 6 Cl atoms. It was suggested[286] that catalysts with a low Al concentration initiate the homolytic dissociation of chlorine, which is followed by its radical addition. Because of the large diameter of the molecules formed (~8 Å), this reaction apparently takes place only on the outer surface of the zeolite particles or in the openings into its pores.

In the hydrolysis of ethyl acetate (60°), it was shown possible to use pentasils, which have a hydrophobic surface, as catalysts for reactions in an aqueous medium[287]. In this reaction, H-ZSM-5 zeolite showed an activity equal to ~40% of the activity of a cation-exchange resin. Dealuminated mordenites were less active, and the original mordenite, zeolite Y, and amorphous aluminosilicates had a very low activity in this reaction. With increase in the atomic ratio Si/Al, the activity of all the zeolites studied increased, reached a maximum, and then decreased. Decrease in the quantity of Al in the zeolite is evidently accompanied by an increase in the hydrophobic character of its surface and an increase in its affinity for organic compounds. At a very low Al concentration, the zeolite loses its activity as a result of a decrease in the quantity of surface active centres on which the reaction takes place.

A zeolite of the pentasil family ($SiO_2/Al_2O_3 \cong 29$; 0.2 mass % Na_2O), not containing transition metals, can decompose ammonia at 550°.[288] Before the reaction, the zeolite was heated at a high temperature. The degree of dissociation of ammonia was ~42 mass %.

Data on the transformations of alkynes on pentasils are of interest[133,221,289]. For example, on Na- and H-ZSM-5 zeolites at temperatures above 300°, acetylene is very readily transformed (to the extent of more than 99%) into a mixture of C_6–C_{13} aromatic hydrocarbons[221]. Pure acetylene rapidly deactivates the catalyst, so that the reaction is carried out with dilution by an inert gas (He). The composition of the products depends on the volume rate of supply of acetylene. It is suggested[221] that the reaction involves the Brönsted acidic centres, with the intermediate formation of the vinyl cation and its homologues:

1,2-Dimethylacetylene readily undergoes cyclotrimerisation to hexamethylbenzene on ZSM-5 zeolite[133].

Examination of the above material shows that high-silica zeolites of the pentasil family in many respects are similar to the zeolites of the first generation. Because of their characteristic composition and structure, however, they are more stable to high temperatures, water vapour, and mineral acids, have a lower tendency to undergo cation exchange, and exhibit specific adsorption and catalytic properties.

Pentasils as catalysts are distinguished from zeolites of other types by their high stability, which is due to their low tendency to form coke, and their clearly defined molecular-sieve properties, which are responsible for the high selectivity of various reactions taking place on these zeolites. A characteristic feature of pentasils is their ability to transform methanol (and other oxygen-containing compounds) into hydrocarbon mixtures forming a high-octane petrol, to aromatise lower alkenes, and to catalyse various other reactions of practical interest. It may be expected that in the near future, zeolites of the pentasil family will provide a basis for the production of effective catalysts which will make it possible to solve the problem of producing motor fuels without using petroleum raw material, and also to obtain valuable chemical products from accessible and inexpensive starting materials.

The Equilibrium NH Acidity of Organic Compounds

E.S.Petrov

The literature data of the last decade on the acidity of the N-H bond in organic compounds in aprotic solvents and in the gas phase are examined. The influence of structural factors on the equilibrium NH acidities of arylamines, carboxamides, sulphonamides, polyfluoroaryl compounds, and heterocycles, as well as the acidifying effects of the electron-accepting substituents at the NH acid centre are discussed on the basis of the results of studies of protolytic equilibria in dimethyl sulphoxide. The question of the influence of the *N*-anion stabilisation factors in solution (specific solvation and ion association) on the relative strengths of NH acids is also considered. Data obtained in studies of the NH acidity in the gas phase are presented.
The bibliography includes 103 references.

I. Introduction 1144
II. The equilibrium NH acidity of organic compounds in dimethyl sulphoxide 1144
III. The influence of the medium on the strength of NH acids 1150
IV. NH acidity in the gas phase 1152

I. INTRODUCTION

Organic compounds whose N–H bonds are involved in a protolytic equilibrium can be regarded as NH acids. They belong to the most common types of Brønsted acids in organic chemistry, like the CH and OH acids. However, in contrast to the latter, which have become the objects of numerous quantitative investigations[1–5], until recently few studies were made on NH acids[6]. Measurements of NH acidity have been used mainly to investigate the cationic forms, i.e. to estimate the basicity of nitrogen-containing compounds. The expansion of the sphere of preparative applications of NH acid anions (*N*-anions)[6] stimulated interest in the structural characteristics which determine the acidity of amino- or imino-group in organic compounds. In many respects they have been discovered in the course of systematic researches carried out during the last decade and to which this review is devoted.

The measure of the acidity of compounds in solution is the p*K*.[1,3] The acidity data are usually referred to the aqueous p*K* scale (pK_a), but, as a consequence of the hydrolysis of the *N*-anions, it is impossible to measure the p*K* of the majority of NH acids in aqueous solution and for this reason studies of the equilibrium NH acidity in non-aqueous media have acquired primary importance.

Considerable advances in the study of NH acids are associated with the application of the method based on the H_- function for media such as mixtures of water with hydrazine[7,8], sulpholan[9], and dimethyl sulphoxide[8–11] and also for alcohols[12,13]. The equilibrium NH acidities of many compounds have been investigated by the indicator method in liquid ammonia[14,15]. The results of these and other studies published up to 1972 have been included in a review[6] and will therefore not be considered here. We shall only mention that the differences between the properties of the solvents employed, their differentiating influence on the relative strengths of the NH acids, have been a serious obstacle to the establishment of a unique NH acidity scale. It was established in the course of studies of NH acids in aprotic polar solvents, in particular, in dimethyl sulphoxide.

II. THE EQUILIBRIUM NH ACIDITY OF ORGANIC COMPOUNDS IN DIMETHYL SULPHOXIDE

The first data on the equilibrium NH acidity of organic compounds in dimethyl sulphoxide (DMSO) were obtained as early as the second half of the 1960's,[10,16,17] while systematic studies of NH acids in DMSO have been carried out, starting from the middle 1970's, by Shatenshtein and co-workers[18–30] and Bordwell and co-workers[31–37]. Both groups of investigators have used the indicator method, based on the spectrophotometric determination of the equilibrium constant K_p of the proton transfer reaction from the NH acid (NH) to the indicator acid AH anion:

$$\rangle NH + A^- \rightleftharpoons \rangle N^- + AH \quad . \qquad (1)$$

The values of K_p, the p*K* of the indicator (pK_{AH}), and the p*K* of the test acid (pK_{NH}) are related:

$$\lg K_p = pK_{AH} - pK_{NH} \quad . \qquad (2)$$

The relation is used to calculate the pK_{NH} from the known values of pK_{AH}.

In the studies of Shatenshtein and co-workers the strengths of NH acids were estimated in terms of the relative acidity scale[38], on which the p*K* for 9-phenylfluorene, established[9] in aqueous sulpholan (18.5), served as a reference, while Bordwell and co-workers used in their studies an absolute scale[39] based on potentiometric data[40,41], on which p*K* = 17.9 corresponds to 9-phenylfluorene. Comparison of the two p*K* scales in dimethyl sulphoxide (DMSO) revealed the following discrepancies between them[42]: on average 0.3 of a logarithmic unit in the range p*K* > 20, 0.6 in the range 14 < p*K* < 20, and ~1.1 in the range p*K* < 14. We took into account these differences in comparing the data of the two groups of investigators. In the Tables below the p*K* are listed in terms of a scale on the basis of which the acidities of the majority of compounds of the given series have been established; together with the recalculated p*K*, the initial values are indicated in brackets.

The reaction centre in all NH acids (we have in mind neutral or anionic forms) is known to contain an unshared electron pair capable of conjugation with the π-electron system of the molecule. Evidently the greater the degree of conjugation and of the delocalisation of the electrons of the unshared pair, the stronger the resonance effects of the substituents at the nitrogen atom on the energy state of the second unshared pair liberated in the heterolytic dissociation of the N–H bond. At the same time, their role in the stabilisation of *N*-anions, one of the unshared pairs in which occupies the σ orbital, is apparently less pronounced than the role of the inductive effects and is not as great as in the stabilisation of carbanions having an analogous structure. Bearing in mind this preliminary remark, we shall consider the influence of structural factors on the equilibrium NH acidity of organic compounds. In the case of acyclic NH acids of the type ArNHR, we shall discuss mainly the effect of substituents in the aryl group Ar and of the groups R directly linked to the acid centre. In the case of heterocyclic NH acids attention will be concentrated on the influence of the structure of the heterocycle and of the substituents in the latter or in the annelated benzene ring.

1. Aniline, Diphenylamine, and Their Substituted Derivatives

Substituted anilines and diphenylamines, particularly the nitro-derivatives, are widely used as indicators in the study of acid–base equilibria and it is therefore useful to quote the full compilation of their p*K* determined in DMSO. The majority of data (Table 1) have been obtained by Bordwell and co-workers, who were the first to measure directly the p*K* of aniline [compound (II)] in DMSO. The acidities of certain other compounds, namely (VIII), (XVIII), (XXII), and (XXIII), were measured in other investigations[43,44] in a buffered system containing phenylacetylene as the proton-donating additive in DMSO. The p*K* found for the NH acids (IV), (IX), (XIII), (XVI), and (XX) are smaller by 1–3 logarithmic units than the values established by Bordwell (see Bordwell et al.[35] concerning the discrepancy) and there is a satisfactory linear relation between the two sets of data ($r = 0.999$), which we used to recalculate in terms of the absolute scale the p*K* determined in a buffer solution. p*K* values similar to those quoted in Table 1 have been obtained for diphenylamine (XXI) (24.8 on the absolute scale[19]) and compounds (XVI), (XVII), (XX), and (XXIV) (potentiometric titration with tetrabutylammonium hydroxide[45]). At the same time, for certain substituted anilines [compounds (XVI), (XVII), and (XX)], Bordwell and co-workers found higher p*K* values than in previous studies[10,16,17,40], in which unduly high estimates were apparently obtained for these and a number of other NH acids in DMSO.

An excellent correlation of the p*K* of aniline and its *meta*-substituted derivatives [compounds (I)–(VII)] and the Hammett σ constants has been obtained ($\rho = 5.67$; $r = 0.9996$),[33] and it is satisfied also by the p*K* of compounds (VIII), (X), (XI), and (XV) (for the last three compounds, values of $\sigma^- = 1.05$, 1.00, and 1.65 respectively must be used[46]). However, the p*K* of 4-benzoyl- and 4-nitro-anilines deviate significantly from the linear relation towards higher acidities even when nucleophilic constants are used.

The available information about the acidities of substituted diphenylamines in DMSO is so far extremely scanty. An approximate estimate of the sensitivity of the NH group of diphenylamine to the electronic influence of the substituents in one benzene ring, based on the three compounds (XXI) to (XXIII), yields $\rho = 4.60$ for the Hammett relation when a nucleophilic constant is used for the nitro-group.

The relative acidities of a large series of polynitrodiphenylamines (17 compounds) have been measured in dimethylformamide (DMF) by potentiometric titration (using tetrabutylammonium hydroxide in methanol as the titrant)[47]. The p*K* found vary in the range from 11.3 for 4′-methoxy-2,4,2′-trinitrodiphenylamine to 1.28 for 2,4,6,2′,4′,6′-hexanitrodiphenylamine. The acidity of 2,4-dinitrodiphenylamine was estimated by extrapolating the relation between the p*K* and Σσ for certain polynitrodiphenylamines and p*K* = 12.65 was obtained. It differs little from the p*K* measured in DMSO [cf. compound (XXIV) in Table 1], which justifies the assumption that the data of Sharnin et al.[47] are a good approximation to the absolute p*K* scale for NH acids in DMSO. For a series of 4′-substituted 2,4,2′-trinitrodiphenylamines, there is a satisfactory correlation between the p*K* and the Hammett σ constants ($r = 0.999$; $n = 5$). The specificity of the effect of the *ortho*-nitro-groups has also been noted; whereas the first is somewhat inferior in its acidifying influence to the *para*-nitro-group, the second appreciably surpasses the analogous *para*-substituent in this respect.

Table 1. The equilibrium NH acidities of aniline, diphenylamine, and their substituted derivatives in DMSO (absolute p*K* scale[39]).

2. Aminoazines

The data on the acidities of aminoazines in DMSO (Table 2) and aniline made it possible to estimate reliably the acidifying effects of the aza-groups in various positions in the heterocycle (these positions are designated by a numeral in brackets): 3.1 (2), 2.4 (3), and 4.5 (4) logarithmic units (within the limits of ±0.2 of a logarithmic unit)[28]. As a rule, in the presence of several groups, their effects are additive except for two aza-groups in the *ortho*-positions relative to an amino-group in a side chain [compounds (XXIX) and (XXXIV)]; their combined effect is smaller by 0.8–1.0 of a logarithmic unit than the value calculated assuming additivity[28]. It has been suggested that the deviation from additivity is due to the destabilising influence of the free electron pairs of the *ortho*-nitrogen atoms, which cannot be located simultaneously in the *trans*-positions relative to the electron pair of the imino-nitrogen atom, liberated when the proton of the N–H bond is abstracted.

For a series of NH acids, including the aminoazines (XXV) to (XXVIII) and (XXX)–(XXXIII) and aniline, a correlation equation ($r = 0.998$), linking the p*K* to the relative values of

the σ constants of the aza-groups (σ_N), found from the acidifying effects, has been found[28]. Using the ratio of ρ for the given correlation (4.16) to that for substituted anilines (see above), the relative constants σ_N were adjusted to the scale of the Hammett constants: 0.55 (σ_{2N}), 0.44 (σ_{3N}), and 0.78 (σ_{4N}).[48] They are smaller than the corresponding values of σ_N established in water[49,50], because in DMSO there is no possibility for the specific solvation of aminoazines and their *N*-anions (for the formation of a hydrogen bond with the endocyclic nitrogen atoms), which could enhance the electron-accepting properties of the azine ring in a proton-donating medium.

Table 2. The equilibrium NH acidities of aminoazines in DMSO [28] (relative scale[38]).

Compound	Name	p*K*
(XXV)	3-Aminopyridine	28.9
(XXVI)	2-Aminopyridine	28.0
(XXVII)	4-Aminopyridine	26.7
(XXVIII)	5-Aminopyrimidine	26.4
(XXIX)	2-Aminopyrimidine	25.9
(XXX)	2-Aminopyrazine	25.8
(XXXI)	3-Aminopyridazine	25.7
(XXXII)	4-Aminopyridazine	24.1
(XXXIII)	4-Aminopyrimidine	23.9
(XXXIV)	2-Amino-*sym*-triazine	21.5

The influence of substituents in the heterocycle on the NH acidity of aminopyrimidines has been studied in fair detail[23]. It has been established that π-donor groups as a rule deviate from the linear relation between the p*K* and the Hammett constants. The results of a two-parameter correlation analysis (with subdivision of the σ into σ_I and σ_R) have shown that, when the endocyclic nitrogen atom is located between the substituent and the amino-group [the 4-substituted derivatives of compound (XXIX) or the 2-substituted derivatives of compounds (XXXIII)], the electronic effects are transmitted via the pyrimidine ring to a greater extent than via the benzene ring. For the *para*-positions of the substituent and the amino-group, there are conditions for direct polar conjugation (σ_R^- is used in the correlation instead of σ_R), but, if the substituent is then in the *ortho*-position relative to both aza-groups [2-substituted derivatives of compound (XXVIII)], then the best correlation between the p*K* and the Hammett constants is achieved for resonance components represented by the sum $0.6\sigma_R + 0.4\,\sigma_R^-$.

In conclusion, we may note that it is possible to obtain a unique correlation equation describing the dependence of the p*K* on the sum of the Hammett constants (including the values of σ_N presented above) and embracing the 3- and 4-substituted anilines (I)–(VIII), (X), (XI), and (XV), the aminoazines (XXV)–(XXVIII) and (XXX)–(XXXIV), and the majority of the substituted derivatives of compounds (XXVIII) and (XXXIII):[48]

$$pK = 31.0 - 5.38\Sigma\sigma \quad (S = 0.36;\ r = 0.993;\ n = 44)\ .$$

3. Carbonyl Compounds

Data for the equilibrium NH acidities of carbonyl compounds of the type RCONHR′ in DMSO are listed in Table 3. Comparison of the p*K* for carboxamides and arylamines with a similar structure shows that the CO group has a considerable acidifying effect [cf., for example, the p*K* of aniline (II) and compounds (XL)–(XLV)] and appreciably reduces the sensitivity of the acid centre to the electronic effect of the second α-substituent (R′). Thus, whereas the acidities of aniline and 4-aminopyridine exceed the acidity of ammonia (p*K* = 41 in DMSO [34]) by 10 and 14 logarithmic units respectively, the acidities of acetamide (XXXVII) and its phenyl- and 4-pyridyl-substituted derivatives (XL) and (XLVIII) differ by only 4 and 6.5 logarithmic units respectively. The influence of the CO group is manifested also by a weakening of the transmission of the effects of substituents via the benzene ring to the N–H bond. Thus the following values of ρ have been obtained for the three series of NH acids of the type $RCONHC_6H_4X$ in DMSO for the relations between the p*K* and the Hammett constants of the substituents X (the number of the compound corresponding to X = H is indicated in brackets; in all the series $r = 0.995$): −3.22 (XLIV);[26] −3.16 (XLIII);[19] −2.96 (XLVII);[18] in absolute magnitude, they are all smaller than ρ for substituted anilines (see above).

*Recalculated[17] taking into account the difference between the p*K* of urea (XXXV) and diphenylamine.
**19.4 (18.8).[31]
***4-Pyridyl.

In connection with the study of the effects of substituents in the benzene ring, we may point out that the p*K* of 4-fluoro-derivatives of acetanilide and formanilide (21.3 and 19.4)[27] and of a series of 2′-substituted benzanilides[18] have also been determined in DMSO. In particular, it has been shown that the influence of the 2′- and 4′-nitro groups on the NH acidity of benzanilide (XLVII) is virtually the same (the p*K* of the substituted derivatives are 15.5 and 15.4 respectively[18]); this has also been observed for *N*-phenylcarbamate (XLIII).

The nature of the substituent R at the carbon atom of the CO group also has appreciable influence on the strength of the carbonyl NH acids [cf., for example, the p*K* of compounds (XL), (XLV), (XLVII), (XLIX), (LI), and (LII)]. The correlation between the p*K* and the Taft σ* constants (ρ* = 4.69; $r = 0.997$) for substituents R, which are mainly alkyl and chloroalkyl groups, has been obtained for the chloralamides $CCl_3CH(OH)NHCOR$ whose acidity has been measured

potentiometrically in a mixture of benzene and methanol[51]. The inductive influence of R is a decisive factor also in the NH acidity of dichlorovinylamides $CCl_2 = CHNHCOR$ (R = alkyl, chloroalkyl, phenyl, or substituted phenyl; potentiometric measurements in DMF; $\rho^* = 2.36$; $r = 0.996$).[52] A linear relation of a similar kind has also been established for the carboxamides $R''CH_2CONH_2$ (R'' = H, F, C_6H_5O, CH_3O, C_6H_5, C_6H_5S, etc.; $\rho^* = 2.8$; $r = 0.908$),[32] but, for R'' = alkyl, no correlation is observed between the pK and σ^*.[32]

On the other hand, certain data in Table 3 also cannot be interpreted from the standpoint of the predominant inductive influence of the substituent R on the acidity. If that were so, urea (XXXV) should be a more acid compound than acetamide (XXXVII) and *N*-phenylcarbamate (XLVII) should be more acid than formanilide (XLV). Since the actual relative strengths of the above NH acids are the reverse of expectation, the hypothesis that the π-donor capacity of the substituents R (for example, NH_2 and CH_3O) also plays an appreciable role suggests itself. A confirmation of this may be seen in the two-parameter correlations

$$pK = 24.3 - 9.1\sigma_I - 4.7\sigma_R^- \quad (S = 0.4;\ r = 0.971),$$
$$pK = 20.1 - 9.7\sigma_I - 4.9\sigma_R^- \quad (S = 0.12;\ r = 0.999),$$

deduced for the $RCONH_2$ [compounds (XXXV)–(XXXIX)] and $RCONHC_6H_5$ [compounds (XL), (XLIII), (XLV), (XLVII), and (LII)] series respectively, from which it follows that, apart from the inductive contribution to R to the stabilisation of *N*-anions, account must be taken also of its resonance effect.

The influence of substituents in the benzene ring attached to the CO group on the NH acidity has been investigated in relation to benzanilides. The relative pK of compounds having the general formula $4\text{-}XC_6H_4CONHC_6H_4OCH{=}CH_2$ were determined potentiometrically in DMF, pyridine, and other solvents and linear relations between the pK and the Hammett constants of the substituents X were established (the values of ρ vary from −6.18 to −7.85 depending on the medium)[53].

The replacement of the oxygen atom in the CO group by sulphur entails an increase of the NH acidity by 4–6 logarithmic units, which follows from a comparison of the pK of urea[15,17] or *N*-phenylcarbamate[19] and their thio-analogues. The acidities of certain thiocarbonyl compounds have been investigated potentiometrically in DMF, in which the pK of the thioamides $4\text{-}XC_6H_4NHCSR$ (R contains a CH group linked to powerful electron acceptors—the CN, $C_6H_5SO_2$, etc. groups)[54] and the acylthioureas RCONHCSNHR′ (R = 2-furyl substituted in the 5-position or 4-substituted phenyl; R′ = phenyl or 4-substituted phenyl) were determined[55,56]. In the case of thioamides the second dissociation constant corresponds to the ionisation of the N–H bond (the first refers to the C–H bond); the range of variation is small: from 0.8 to 1.6 logarithmic units on passing from X = H to $X = NO_2$ for different R.

In the series where $R = CH(SO_2C_6H_4Cl\text{-}4)CONH_2$ the pK are correlated with the σ^0 constants of the substituents X ($\rho = -1.95$). Only one dissociation step, attributed to the N–H bond between the CO and CS groups, has been noted for acylthioureas (the terminal NH group forms a hydrogen bond with the oxygen atom of the CO group[55]). The influence of the nature of the substituents in the furan or benzene ring (for $R' = C_6H_5$) on the NH acidity of acylthioureas is more appreciable than in the thioamides indicated above: the values of ρ in the Hammett relations are respectively −6.8 and −5.3. In the series where R = 2-furyl and $R' = C_6H_4X$ the sensitivity of the acid centre to the effects of the substituents X is fairly low: the pK vary in the range 8.9–11.3 [$X = 2\text{-}NO_2$ and $4\text{-}(C_2H_5)_2N$ respectively] and for the 3- and 4-substituted derivatives it was not possible to discover a dependence of pK on the Hammett constants.

4. Sulphonamides

The equilibrium NH acidity of sulphonamides (Table 4) is lower by 6–7 logarithmic units than that of their carbonyl analogues (cf. Table 3). This large difference is due to the fact that, in terms of the negative inductive effect $-I$, which plays the most important role in the stabilisation of *N*-anions, the SO_2 group is significantly superior to the CO group. Accordingly, the acidifying influence of the substituents R at the sulphur atom in the RSO_2 group on the N–H bond is apparently also even more inductive in its character than the influence of the analogous substituents on the N–H bond in carboxamides. In particular, we may note that the pK of sulphonamides of the type RSO_2NH_2 [compounds (LIV), (LVII), and (LXI)] vary linearly with the Taft constants of the substituents R, including the phenyl group:

$$pK = 18.3 - 2.86\sigma^* \quad (r = 0.998).$$

Alkyl substituents at the nitrogen atom of benzenesulphonamide reduce the NH acidity in conformity with their inductive effects[27] [see compounds (LIII) and (LV)–(LVIII)].

Table 4. The equilibrium NH acidities of the sulphonamides RSO_2NHR' in DMSO (relative scale.

(LXI)	CF_3	H	10.8 (9.7)	[31]
(LXII)	CF_3	C_6H_5	6.8 (5.7)	[36]

*pK = 16.7 (16.1) has been quoted[37] for compound (LVIII).
**4-Pyridyl.

The acidities of benzenesulphonanilides substituted in the benzene ring attached to the nitrogen atom are described by a linear correlation between the pK and the Hammett constants ($\rho = -2.7$ and $r = 0.990$ for the *meta*- and *para*-substituents and $\rho = -2.53$ and $r = 0.998$ for the *ortho*-substituents[27]).

5. Polyfluoroaryl-substituted Compounds

The complete substitution of hydrogen atoms by fluorine in the aryl groups of arylamines or carboxamides is accompanied by an increase of the equilibrium NH acidity by 6–8 logarithmic units [cf. the pK of compounds [LXIII)–(LXVII) in Table 5, compounds (II), (XXVII), (XXI), (XL), and (XLVII) in Tables 1–3, and compounds (LXV) and (LXVIII) in Table 5]. The high electron-accepting capacity of the polyfluoroaryl groups is due to the negative inductive effect of fluorine atoms[57]. Like the sulphonyl group, they therefore activate the N–H bond to a greater extent than the carbonyl group and are superior in this respect also to the *p*-nitrophenyl group[24].

The equilibrium NH acidity of compounds C_6F_5NHAr is described satisfactorily by a two-parameter correlation equation, where the chemical shift δ_F of the signal of the *para*-fluorine atom of the C_6F_5 group in the ^{19}F NMR spectra has

been suggested as a measure of the resonance influence of the aryl group Ar: [24]

$$pK = 20.0 - 3.88\sigma^* + 0.36\delta_F \quad (r = 0.988) .$$

Table 6. The acidifying effects (ΔpK) of the substituents R in NH acids.

R	I	II	III
C_6H_5	10.3	5.8	3,9
CH_3CO	15.5	9.2	7,6
HCO	17.5	11.6	—
C_6H_5CO	17.6	11.9	10.1
C_6F_5	18.2	11.8	10.5
CN	24.0	—	—
$C_6H_5SO_2$	24.9	19.2	—
$2,4\text{-}(NO_2)_2C_6H_3$	25.1	18.3	12.9
CF_3SO_2	31.3	25.0	—

Note. The ΔpK were found as the differences between the pK of ammonia [~41 (Algrim et al.[34]), series I], aniline [30.7 (Bordwell and Algrim[31]), series II], and pentafluoraniline [22.8 (Vlasov et al.[24]), series III], on the one hand, and the pK of the corresponding *N*-substituted derivatives on the absolute scale; apart from the data in Tables 1–5, $pK = 17.0$ for cyanamide[37] has been used.

Satisfactory linear relations ($r = 0.988–0.998$) between the pK and the Hammett constants for the substituents X have been obtained for four series of NH acids of the type $4\text{-}XC_6F_4NHR$ (dialkylamino-groups, which exhibit an extremely weak electron-donating effect in the above series, were not included in the correlation). The constants ρ vary as follows (the substituents R are indicated in brackets)[29]: -6.43(H); -3.93(C_6F_5); -3.23(C_6H_5CO); -3.01[$2,4\text{-}(NO_2)_2C_6H_3$]. The differences between them and the ρ in the correlations for the analogous series of non-fluorinated compounds (see above) are insignificant, i.e. the degree of transmission of the electronic effects of the *para*-substituents via the benzene ring to the NH acid centre changes little when the *ortho*- and *meta*-hydrogen atoms are replaced by fluorine[29]. This is also supported by the results of a quantum-chemical calculation (by the CNDO/2 method) of the parameters of the highest occupied molecular orbital in the *N*-anions containing the phenyl or pentafluorophenyl group at the nitrogen atom[29].

6. The Acidifying Effects of the Substituents in Acyclic NH Acids

In conclusion of the discussion of data for the equilibrium NH acidity of acyclic compounds in DMSO, it is useful to compare the acidifying effects of α-substituents, which provide a clear idea about the relative strengths of NH acids of different types. Table 6 presents the values of ΔpK characterising the acidifying influence of a series of groups on the N–H bonds of ammonia, aniline, and pentafluoroaniline.

The sequence in which the ΔpK vary is virtually the same in all three series and there is a linear relation between the ΔpK for series I and II:

$$\Delta pK_I = 1.06\Delta pK_{II} + 5.1 \quad (S = 0.6;\ r = 0.996) .$$

On the other hand, the absolute magnitude of the acidifying effect of a given substituent decreases from series I to series II and further to series III. This can be partly due to the increased steric hindrance to the conjugation of the substituent R with the nitrogen atom on replacement of a single hydrogen atom in ammonia by the phenyl (series II) and pentafluorophenyl (series III) groups. However, this is not the only cause and apparently not the main cause of the inconstancy of the ΔpK noted above. For example, the steric environments of the acid centres in aniline and 4-aminopyridine are identical and yet the acidifying effects of the CH_3CO, C_6H_5CO, and $C_6H_5SO_2$ groups in aniline are greater by 1–3 orders of magnitude than in aminopyridine [cf. the differences between the pK of compound (XXVII) and compounds (XLVIII), (L), and (LX) with the corresponding ΔpK in series II]. Furthermore, the steric hindrance should not be reflected in the stabilisation of the *N*-anions via the inductive mechanism and yet the tendency towards a decrease of the ΔpK can be distinctly traced also for substituents which exert a predominantly inductive influence on the N–H Bond (C_6F_5, $C_6H_5SO_2$, and CF_3SO_2).

An analogous situation has been observed for the CH acidity[58,59] and has been interpreted as a consequence of the mutual weakening of the electronic effects of the substituents at the acid centre[34,42]. Evidently this phenomenon is of a general character and must be taken into account also in the consideration of the NH acidity†.

7. Nitrogen-containing Heterocycles

The principal data on the acidity in DMSO of heterocycles containing the imino-group in the ring are presented in Table 7. The majority of the NH acids of this type are azoles and their derivatives. The equilibrium NH acidity of azoles increases with increase in the number of aza-groups in the ring and the influence of such groups in the β-positions on the N–H bond is greater than that of those in the α-positions [cf. the pK of compound (LXXIX) and those of (LXXXII) and (LXXXIV) or the pK of the last two compounds and (LXXXIX), Table 7].

† New values of the constants σ^-, whereby one can take into account the influence of the substituents in CH acids, have been proposed recently[60], but it is not possible to obtain even a satisfactory linear relation between these constants and the pK of NH acids measured in DMSO.

The influence of the ring substituents on the acidity of azoles is predominantly inductive. Thus a linear relation has been obtained between the pK of 2-substituted and 2,3-disubstituted pyrroles and the sum of the inductive constants σ_I of the substituents ($\rho = -17.4$; $r = 0.994$) and the transmission of the effect of the substituent from the 3-position is twice as weak as the transmission of the effect from the 2-position[22]. The acidity of substituted pyrazoles and imidazoles can be described by correlations between the pK and the sum of the constants σ_m regardless of the number of substituents and their positions in the ring ($\rho = -8.8$ and -9.5 and $r = 0.987$ and 0.999 respectively)[21].

Table 7. The equilibrium NH acidities of nitrogen-containing heterocycles in DMSO (relative scale).

Compound	Name	pK	Refs.
(LXXIII)	1,2,3,4-Tetrahydroquinoline	32.1	[20]
(LXXIV)	1,2,3,4-Tetrahydroquinoxaline	32.1	[20]
(LXXV)	Indoline	30.5	[20]
(LXXVI)	2,2-Pentamethylenebenzimidazoline	29.3	[20]
(LXXVII)	3,4-Dihydro-2*H*-benzo-1,4-thiazine	28.8	[20]
(LXXVIII)	Acridan	25.2	[30]
(LXXIX)	Pyrrole	23.3	[21]
(LXXX)	Phenothiazine	22.8	[21]
(LXXXI)	Indole	21.3	[21]
(LXXXII)	Pyrazole	20.4	[21]
(LXXXIII)	Carbazole	19.6	[21]
(LXXXIV)	Imidazole	18.9	[21]
(LXXXV)	Indazole	18.8	[21]
(LXXXVI)	Phenanthridinone	18.3	[30]
(LXXXVII)	Benzimidazole	18.1	[21]
(LXXXVIII)	9-Acridone	16.4	[30]
(LXXXIX)	1,2,4-Triazole	15.4	[21]
(XC)	Benzotriazole	12.6	[21]
(XCI)	Tetrazole	9.3 (8.2)	[36]

Note. The statistical correction for two NH groups has been introduced for compounds (LXXIV) and (LXXVI). For compounds (LXXIX) and (LXXXI), Bordwell et al.[37] obtained similar pK values, equal to 23.35 (23.05) and 21.25 (20.95) respectively, while for compound (LXXXIII) a higher pK, amounting to 20.5 (19.9), was obtained.

When the azole ring is annelated to the benzene ring, the NH acidity increases on average by two logarithmic units. A satisfactory linear relation ($r = 0.995$) has been established between the pK of compounds (LXXIX), (LXXXI), (LXXXII), (LXXXIV), 2-phenylimidazole, and their benzo-derivatives; with its aid, the acidity of 1,2,3-triazole (pK = 14.7) has been estimated from the pK of benzotriazole[21]. The influence of the benzo-group should apparently be attributed to the strengthening of the delocalisation of the unshared pair of the electrons of the "pyrrole" nitrogen atom over the π-electron system of the molecule, although one cannot rule out the possibility that the inductive effect of the sp^2-hybridised carbon atoms of the benzo-group also plays an appreciable role. In this connection one may note that the inductive effect of the phenyl group in the 2-position of pyrrole increases the NH acidity by 1.7 logarithmic units[22].

However, the role of conjugation in the stabilisation of the N-anions of certain heterocycles is apparently nevertheless greater than in the case of acyclic NH acids. Structural changes which affect the p,π-conjugation system in the molecules of azoles can lead to an appreciable weakening of the NH acidity. Thus the rupture of the o,o'-C–C bond between the benzene rings of carbazole (LXXXIII) or its replacement by a methylene bridge, is accompanied by a decrease of acidity by more than 5 logarithmic units [cf. with diphenylamine (XXI) in Table 1 or with acridan (LXXVIII)]. The consequences of a decrease in the size of the π-electron system of benzoheterocycles and of the "dearomatisation" of the heterocyclic ring following its partial hydrogenation at the C=C or C=N bond are even more appreciable (10–12 logarithmic units) [cf. the pK of compounds (LXXV) and (LXXXI) and of (LXXVI) and (LXXXVII)]. On the other hand, the annelation of the benzoheterocycles (LXXIII) and (LXXVII) to a second benzene ring with simultaneous replacement of the aliphatic C–C bond by an aromatic bond leads virtually to a doubling of the size of the π-electron system and the consequent increase in the NH acidity by 6–7 logarithmic units [cf. with compounds (LXXVIII) and (LXXX)]. The analogous structural change in the case of a five-membered heterocycle is accompanied by an increase of the NH acidity by 11 logarithmic units [cf. compounds (LXXV) and (LXXXIII)].

When the methylene group of acridan is replaced by the carbonyl group, the NH acidity increases by ~9 logarithmic units [cf. with 9-acridone (LXXXVIII)], which is close to the acidifying effect of the acyl groups in aniline (9–12 logarithmic units—see Table 6, series II). In view of the considerable remoteness of the acid centre of 9-acridone from the CO group, presumably the contribution of its inductive effect to the stabilisation of the given N-anion is smaller than in acyclic carbonyl-containing N-anions. The planar conformation of the 9-acridone molecule apparently favours the manifestation of the resonance effect of the CO group, which is the maximum possible for NH acids. It has been suggested that this is the reason why the sensitivity of the acid centre of 9-acridone to the resonance influence of substituents in the 2-position (the *para*-position relative to the nitrogen atom) is weakened[30].

The benzoheterocyclic compounds (LXXIII)–(LXXVII) with a partially reduced heterocyclic ring can be regarded by convention as the corresponding *ortho*-substituted N-alkylanilines. It is not therefore surprising that their acidities are similar to that of aniline. It is remarkable that the acidity of compounds with a five-membered heterocycle is appreciably higher than that of their six-membered analogues [cf. compounds (LXXIII) and (LXXV), (LXXIV), and (LXXVI)]. This difference persists also for their p-nitro-substituted derivatives (when the nitro-group is introduced, the acidity increases by 10–12 units)[20]. This behaviour was first observed in a potentiometric determination of the NH acidities of anthraquinones containing the imino-group in the annelated five- or six-membered heterocycle (the range of the pK for the compounds investigated is from 11.4 to 20.7).[61] The increase of acidity following a decrease in the size of the heterocycle has been explained by the increase of the s character of the orbital of the N–H bond as a consequence of the endeavour of the nitrogen atom to rehybridise due to the tendency of the five-membered ring annelated to the benzene ring to weaken the strain.

The above data exhaust the information currently available about the influence of the structure of organic compounds on the acidity of the N–H bond in DMSO. Measurements of the pK of NH acids in other aprotic solvents (mainly in dimethylformamide[47,52–54], nitromethane[62,63], and a number of others) covered a much smaller number of compounds and did not yield fundamentally new information about the influence of the structure of the compounds on their equilibrium NH acidity compared with data for solutions in DMSO.[64] On the other hand, the relative strengths of the NH acids frequently change significantly on passing from proton-donating to relatively non-polar solvents, which is due primarily to

factors stabilising *N*-anions such as specific solvation or association with the counterion[42,65].

Studies of NH acids using proton-donating media (water, alcohols, mixtures of DMSO with hydroxylated components, etc.) are being prosecuted at the present time. Thus a number of investigations of the NH acidities of arylamines[50,66,67], derivatives of guanine[68] and barbituric acid[69], and certain azoles[70,71] in the above solvents have been published during the last 5–7 years. The equilibrium NH acidities of certain heterocycles and carbonyl compounds have been measured also in a weakly polar aprotic solvent—1,2-dimethoxyethane[18,19,21,72]. It is therefore of interest to consider to what extent the differences between the proton-donating capacities or polarities of the solvents are reflected in the strength of the NH acids.

III. THE INFLUENCE OF THE MEDIUM ON THE STRENGTH OF NH ACIDS

The overall pattern in the change of the equilibrium NH acidity of organic compounds when DMSO is replaced by water is illustrated in Fig.1, where the p*K* for NH acids of different structural types, determined relative to the corresponding standard states in both solvents, are compared. The pK_a employed (the subscript *a* indicates the assignment of the p*K* to the acidity scale in aqueous solutions[3]) were either measured directly in water or were obtained by the authors[50,73] by recalculating the values for mixed solvents using methods taking into account the activities of the species involved in the protolytic equilibrium. It has been shown for a large number of CH and NH acids that the results of the recalculation by two such methods[78,79] are in good agreement[80].

Analysis of the relation between the p*K* of NH acids in both solvents shows easily that the equilibrium NH acidities of the majority of compounds in DMSO are lower than in water—the circles in Fig.1 are distributed mainly above the dashed straight line passing through the origin of coordinates at an angle of 45°. This difference has come to be explained by the fact that, by virtue of the specific character of the solvation in water (the formation of hydrogen bonds), the *N*-anions are stabilised in this solvent to a greater extent than in DMSO. The reduced NH acidity in DMSO is partly, but apparently to a lesser extent, caused by the formation of stronger hydrogen bonds between the molecules of the NH acids and the solvent (see Trofimov et al.[22] and Karjalainen and Ruostesno[81] concerning this topic) whose basicity is higher than that of water[39]. For *N*-anions with a highly delocalised charge, the degree of specific solvation in water is diminished, while the solvation of the anion in DMSO via the dispersion interaction mechanism is actually enhanced[40,41]. This is probably why the NH acidities of the corresponding compounds, for example, of 2,4-dinitrodiphenylamine (see point 14 in Fig.1), are higher in DMSO than in water.

The data presented in Fig.1 also show that, when the solvent is changed, the strengths of the NH acids change unequally: the differences between the pK_{DMSO} and pK_a vary from 2.5 to 6 logarithmic units, i.e. a differentiating effect of the medium on the equilibrium NH acidity is observed. At the same time, linear relations between both parameters can be found for structurally similar NH acids (see the straight line in Fig.1 and the data in Table 8).

The pK_{DMSO} and the pK_a of anilines and unsubstituted aminoazines (Table 8, series I and II) are correlated most effectively and the form of the linear relation I hardly changes when aniline and diphenylamines are combined into a single series (cf. series I and II). The considerable scatter of the points in the case of azoles (see points 21–28 in Fig.1) precludes a conclusion concerning a distinct linear relation between pK_{DMSO} and pK_a. One can only speak of a parallel variation of these quantities. Relations with a satisfactory correlation coefficient and standard deviations greatly superior to the accuracy of the determination of the p*K*, which is to within 0.1, can be obtained for monocyclic azoles (series IV) and benzazoles (series V). The excellent linear correlation obtained for benzenesulphonanilides (series VI) is appreciably impaired when benzenesulphonamide (series VII) is included in the above series. On the basis of the foregoing, one can conclude that the solvation effects responsible for the shift of the protolytic equilibrium on replacement of an aprotic solvent by a proton-donating solvent depend specifically on the structure of the NH acid. At the same time their contributions to the energetics of the acid dissociation process vary in proportion in a series of NH acids of a given structural type.

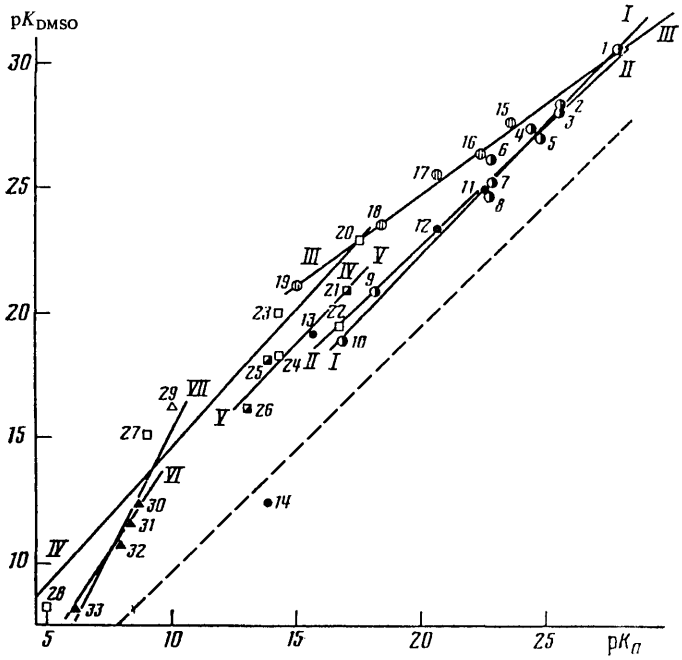

Figure 1. The equilibrium NH acidities of organic compounds in dimethyl sulphoxide (pK_{DMSO}) and in water (pK_a) (the pK_a are indicated in brackets); aniline and its substituted derivatives[73] (the substituents are indicated): 1) H (27.8); 2) 3-Cl (25.5); 3) 3-CF_3 (25.4); 4) 3-CN (24.3); 5) 3,4-Cl_2 (24.6)l 6) 2,4-Cl_2 (22.6); 7) 4-CN (22.7); 8) 2,6-Cl_2 (22.6); 9) 4-NO_2 (18.1); 10) 4-Cl, 2-NO_2 (16.8); diphenylamine and its substituted derivatives[73]: 11) H (22.4); 12) 3-Cl (20.6); 13) 4-NO_2 (15.5); 14) 2,4-$(NO_2)_2$ (13.8); aminoazines[50]: 15) 2-aminopyridine (23.5); 16) 4-aminopyridine (22.3); 17) 2-aminopyrimidine (20.5); 18) 4-aminopyrimidine (18.4); 19) 2-amino-*sym*-triazine (14.9); azoles: 20) pyrrole (17.5);[74] 21) indole (17.0);[75] 22) carbazole (16.7);[76] 23) pyrazole (14.2);[74] 24) imidazole (14.2);[74] 25) indazole (13.8);[75] 26) benzimidazole (12.9);[75] 27) 1,2,4-triazole (8.9);[70] 28) tetrazole (5.0);[70,71] 29) benzenesulphonamide (10.0) [77] and benzenesulphonanilides[77] (the substituent in the 4'-position is indicated); 30) CH_3 (8.7); 31) H (8.3); 32) Cl (7.9); 33) NO_2 (6.2).

It is also of interest to note the following factors. The regression coefficient *b* in the correlation equation (Table 8) shows that, when the solvent is replaced, the sensitivity of the acid centre in compounds of the given structural type to the electronic effects of the substituents is altered. In particular, for phenyl-substituted NH acid (series I, II, and VI), the coefficient *b* is determined by the ratio of the constants ρ of the Hammett relations between the p*K* and σ in DMSO and in water (it has been assumed that the Hammett σ constants are identical for the two solvents). In the majority of the series of NH acids considered the coefficient *b* exceeds unity, which indicates a smaller sensitivity of the NH acidity to structural factors in the aqueous solution (cf., for example, the values of ρ for substituted anilines—$\rho = 5.20$ in water[50] and $\rho = 5.67$ in DMSO [34]). As a result of this, the replacement of DMSO by water entails a smoothing out of the differences between the NH acid strengths within a given series.

Table 8. Correlations of the type $pK_{DMSO} = a + bpK_a$ for NH acids in different structural series.

Series	Compound	*a*	*b*	*S*	*r*	*n*
I	Anilines (Nos. 1-10)	1.5±1.3	1.05±0.06	0.4	0.994	10
II	Anilines and diphenylamines (Nos. 1-13)	3.0±0.9	0.99±0.04	0.5	0.991	13
III	Aminoazines (Nos. 1 and 15-19)	10.1±0.4	0.74±0.02	0.2	0.998	6
IV	Azoles (Nos. 20, 23, 24, 27, and 28)	3.6±1.7	1.12±0.13	1.3	0.979	5
V	Benzazoles (Nos. 21, 25, and 26)	2.6±3.5	1.09±0.24	0.7	0.976	3
VI	Benzenesulphonanilides (Nos. 30-33)	−2.2±0.8	1.65±0.1	0.2	0.996	4
VII	Benzenesulphonamides (Nos. 29-33)	−5.3±0.7	2.07±0.08	0.7	0.979	5

Note. The numbers of the series correspond to the numbers of the straight lines in Fig.1, while the numbers of the compounds correspond to the numbers of the points in the same Figure.

Such levelling of the acidity in a hydroxylated solvent can be explained by the specific solvation of *N*-anions. The higher the basicity of the *N*-anion (the greater the p*K* of its conjugate NH acid), the stronger the hydrogen bond between it and the solvating molecules of the hydroxylated solvent and the greater the decrease of the p*K* on passing from DMSO to a proton-donating medium. Thus the coefficient *b* can be regarded also as a measure of the sensitivity of *N*-anions to the stabilising effect of specific solvation. Judging from the data in Table 8, it is a maximum for sulphonamides (series VI and VII), which is probably due to the involvement of the oxygen atoms of the SO_2 group in the formation of hydrogen bonds.

Series III, in which the regression coefficient is significantly less than unity, attracts attention in this connection. This implies that an "anomalous" tendency is observed for unsubstituted aminoazines—the levelling of acidity on passing from water to an aprotic medium. The most probable cause of this anomaly is specific solvation of the aminoazine anions at the endocyclic nitrogen atoms, which enhances the electron-accepting influence of the latter on the acid centre (indeed, as mentioned earlier, the Hammett constants for the aza-groups in water are larger than for the same groups in DMSO [48]). This factor is apparently more important than the decrease of the sensitivity of the anionic centre to the effects of the aza-groups in water (decrease of ρ) and the difference between pK_{DMSO} and pK_a therefore increases with increasing sensitivity of the aminoazines, in contrast to what is observed for other NH acids.

An analogous phenomenon can probably occur also for azoles. For example, the difference between pK_{DMSO} and pK_a (i.e. ΔpK) increases with increase of acidity in the sequence pyrroles (5.5) < pyrazole (5.8) < triazole (6.2) (Fig.1). However, there is no doubt that the actual situation may be more than complex because the pyrazole and triazole anions each contain two equivalent nitrogen atoms, which function as both anionic centres and substituents simultaneously.

We shall now consider how the change from a polar to a weakly polar medium is reflected in the relative strengths of NH acids. In a weakly polar medium the protolytic equilibrium involves species resulting from the association of the free anions with the counterion (M^+), in particular ion pairs, and not the free ions themselves (Eqn.(1)):[42,82]

$$\rangle NH + A^-M^+ \rightleftharpoons \rangle N^-M^+ + AH\,. \qquad (3)$$

The pK_{NH} calculated by Eqn.(2) from the equilibrium constant of reaction (3) characterises the so-called "ion-pair" acidity (pK_p) and is related to the "free-ion" (pK_i) value of pK_{NH} determined for equilibrium (1):

$$pK_p = pK_i - \lg (K_{AM}/K_{NM}) \qquad (4)$$

where K_{AM} and K_{NM} are the dissociation constants of the ion pairs A^-M^+ and $\rangle N^-M^+$ into free ions. Evidently the stronger the association of the *N*-anion with the counterion (other conditions being equal) the greater the displacement of equilibrium (3), the greater the difference between pK_p and pK_i, and the greater the relative strength of the conjugate NH acid.

The effectis of ion association have been investigated in detail for CH acids[83-86], for which appreciable differences between the pK_i, measured in DMSO, and the pK_p, determined relative to the same standard in 1,2-dimethoxyethane (DME), have been established in many instances. The difference is particularly large (up to 8 logarithmic units) when the CH acid molecule contains a heteroatom (nitrogen or oxygen) to which there is a partial transfer of the anionic charge on ionisation of the C–H bond. The coordination of the counterions to such "hard" nucleophilic centres takes place with formation in DME of very stable contact ion pairs (for the varieties of the latter, see Szwarc[87]).

An analogous study has been carried out also for NH acids: the pK_p have been determined in DME for ~20 compounds, incorporating the Li^+ or Cs^+ counterions, relative to 9-phenylfluorene ($pK = 18.5$).[72] It has been shown that they are appreciably smaller than the corresponding pK_p, measured in DMSO and for Li^+ the difference between the pK values is greater than for Cs^+, since in the contact ion pair the anion is stabilised to a greater extent than the cation with a smaller radius. Since a "hard" nucleophilic centre (the nitrogen atom) is already present in *N*-anions, the introduction of other heteroatoms into such species is not accompanied by such an appreciable differentiation of the equilibrium "ion-pair" acidity as for the CH acids with analogous structures. Furthermore, satisfactory linear relations have been obtained for the entire set of NH acids investigated in DME:

$$pK_p(Li^+) = 0.89\,pK_i - 2.6 \quad (S = 1.0;\ r = 0.971)\,,$$
$$pK_p(Cs^+) = 1.01\,pK_i - 1.5 \quad (S = 0.6;\ r = 0.992)\,.$$

In the first equation the regreession coefficient is significantly less than unity, which indicates an enhancement of the stabilising effect of the lithium cation with increase of the intrinsic basicity of the *N*-anions. In the case of a

weaker interionic interaction (with the caesium cation), the stabilising effect of the counterion hardly changes in the acidity range investigated (18 logarithmic units).

The K_{NM} (M = Cs) in DME have been determined conductimetrically for a series of compounds (diphenylamine, carbazole, nitrophenyl-substituted NH acids, and certain others) and the pK_i in DME have been calculated by Eqn.(4).[72] The majority of the constants are slightly (by 0.3–0.5 of a logarithmic unit) smaller than the corresponding pK_i in DMSO, but the differences for the nitro-derivatives reach 1.4–1.9 logarithmic units. Such an appreciable difference can be a consequence both of the marked stabilisation of the nitrophenyl-substituted NH acids in the more basic DMSO and of the relatively less effective solvation of the corresponding *N*-anions in this solvent. At any rate, these results show that differentiation of the NH acid strengths is observed in protic solvents, but it does not occur for the analogous CH acids[42,82].

Thus our comparison of the quantitative data for the equilibrium NH acidities of organic compounds in media differing in their polar and proton-donating properties shows that specific solvation and ion association have a differentiating effect on the stability of their *N*-anions in solution. As a result of this, the available information about the NH acid strengths in a hydroxylated or weakly polar solvent can give rise to a distorted idea about the true structural rules governing the equilibrium NH acidity. In order to discover such rules, one can employ the NH acidity scale in DMSO or a similar p*K* scale established in a weakly polar solvent (for example in DME) with a counterion having a large radius (Cs^+). The most reliable information about the influence of the structure of compounds on their acidity is provided by the results of studies of protolytic equilibria in the gas phase.

IV. NH ACIDITY IN THE GAS PHASE

Studies of equilibria involving proton transfer in the gas phase have been prosecuted quite vigorously during the last decade. The usefulness of such research is undoubted because it gives rise to the possibility of separating the purely structural effects in acidity from the solvation effects[88]. However, as in the condensed phase, the main objects of investigations have been OH and CH acids. Data concerning the gas phase NH acidities of organic compounds are so far scanty and studies have been made mainly on the cationic forms of NH acids: alkylamines[89–92] and substituted pyridines[93] and anilines[94]. The results of such investigations have been analysed in fair detail in two reviews[88,95], which have been supplemented by an extensive communication by Taft and co-workers[96].

The relative strengths of the neutral forms of NH acids in the gas phase were first compared by Brauman and Blair[97], who established the following sequence in which acidity varies in the series of primary and secondary aliphatic amines: Et_2NH > t-$BuCH_2NH_2$ ≧ t-$BuNH_2$ ≧ Me_2NH ≧ iso-$PrNH_2$ > $PrNH_2$ > $EtNH_2$ > $MeNH_2$ > NH_3. Later Mackay et al.[98] determined the free energies ΔG of abstraction of a proton from the N–H bond in certain amines (Table 9) and showed that the acidity of amines is higher than that of ammonia. Thus it follows from the data presented that alkyl groups, which are usually regarded as electron donors, exhibit electron-accepting properties in the gas phase, stabilising amide anions. According to the above investigators[97,98], the stabilisation is due to the interaction between the negatively charged nitrogen atom and the polarisable alkyl group.

The ΔG for a series of other NH acids have been found by Kebarle and co-workers[100,101]. Having observed that the acidity of diacetamide is lower than that of its CH analogue, namely acetylacetone, the above investigators suggested that the ΔG found for barbituric acid (327.3 kcal mol^{-1})[100] characterises the acidity of the CH_2 group, while the energy of the deprotonation of the N–H bond should be somewhat higher (by ~2 kcal mol^{-1}). McIver and co-workers[99,102] determined the difference $\delta\Delta G$ in the gas phase between the ΔG for *p*-xylene (adopted as the standard acid), on the one hand, and pyrrole, aniline, and phenyl-substituted anilines, on the other. According to their estimate, $\delta\Delta G$ for the pair of NH acids methylamine and aniline is 35.9 kcal mol^{-1}, which makes it possible to calculate the ΔG indicated for aniline in Table 9 (we may note that ΔG = 353 kcal mol^{-1} has been obtained for pyrrole by an analogous procedure; cf. Table 9).

Table 9. The free energies of the deprotonation (ΔG) of certain NH acids in the gas phase.

Compound	ΔG, kcal mol^{-1}	*T*, K	Refs.
Ammonia	396.1	298	[98]
Methylamine	395.7	298	[98]
Ethylamine	391.7	298	[98]
Dimethylamine	389.2	298	[98]
Aniline	359.8	320	[99]
Pyrrole	351.8	300	[100]
Acetanilide	345.8	300	[100]
Acetylurea	341.1	300	[100]
Diacetamide	339.8	300	[100]
Succinimide	338.0	300	[100]

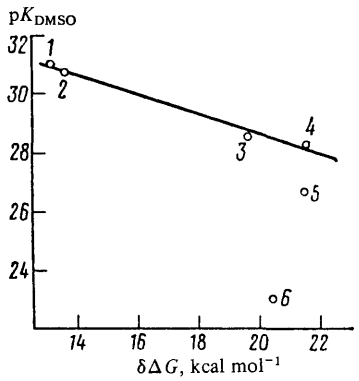

Figure 2. The equilibrium NH acidities of compounds in the gas phase (the relative deprotonation energies $\delta\Delta G$) and in DMSO (pK_{DMSO}): 1) 3-methylaniline; 2) aniline; 3) 3-chloroaniline; 4) 3-trifluoromethylaniline; 5) acetanilide; 6) pyrrole (according to the data in Tables 1, 3, 7, and 9).

It has been shown[99] that the $\delta\Delta G$ for *meta*- and *para*-substituted anilines are satisfactorily correlated with the Hammett σ constants (ρ = 10.4), but the points for the 3-F, 4-MeO, and 4-CF_3 substituents then deviate significantly from the straight line (r = 0.948). On the other hand, the two-parameter relations obtained for both series of substituted

anilines using the σ_I and σ_R^- constants are characterised by a high correlation coefficient (0.991). Bartmess et al.[99] note that the effects of the substituents are greater in the gas phase than in solutions. For example, in liquid ammonia and DMSO the parameters ρ of the Hammett relations (5.3 and 5.7 respectively) are smaller almost by a factor of two than in the gas phase (10.4). Furthermore, the ratio ρ_R^-/ρ_I for *meta*-substituted compounds decreases and that for *para*-substituted compounds increases on passing from the gas phase to the condensed phase.

For substituted anilines, a satisfactory agreement is observed between the acidities in the gas phase and in DMSO,[99] while in other cases there is an inversion of the acidity sequence (cf., for example, acetanilide and pyrrole in Fig. 2). Consequently an appreciable superposition of solvation effects on structural effects cannot be ruled out even in an aprotic solvent. The view according to which the rules governing the variation of the "intrinsic" acidity (i.e. the acidity determined only by the molecular structure) of compounds can be established only by methods for the investigation of gas-phase proton-transfer processes is therefore apparently quite valid[88].

---o0o---

In conclusion we may note that the expansion of studies on protolytic equilibrium in the gas phase and in an aprotic medium is in our view quite promising. The result of such investigations not only make it possible to obtain the correct idea about the relation between NH acidity and the structure of a compound but also one can solve the practically important problem of the quantitative estimation of solvation effects, including the effect of specific solvation, in acid–base interactions. The study of processes involving the transfer of a proton in the N–H bond in the excited states of acid and conjugate base molecules is of both theoretical and practical interest[103].

Conformational Analysis of Phosphoryl Compounds with Phosphorus-Carbon Bonds

O.A.Raevskii and T.I.Ignat'eva

The literature data on the conformational analysis of phosphoryl compounds containing one or several phosphorus-carbon bonds are analysed. Attention is concentrated to the steric orientation of the phosphoryl group and the substituents at the α-carbon atom. Data concerning different phase states of the compounds are discussed. The necessity for a combined application of various physicochemical methods to the solution of conformational problems involving complex phosphoryl compounds in solution is emphasised.
The bibliography includes 121 references.

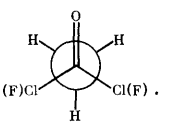
I. INTRODUCTION

Organic compounds containing the phosphoryl group have found extensive applications as complex-forming agents. In particular, such derivatives are used to synthesise new medicinal drugs effective in the elimination of toxic metal ions from the organism and in technological processes for the separation and concentration of the most valuable metals[1]. Phosphates and their derivatives play a key role in biochemical processes as structural elements in many biological components and as energy transferring agents, which is associated with their ability to form complexes with the so-called "metals of life"[2,3].

The importance of the class of compounds under consideration can be explained in the first place by the significant electron-donating capacity of the oxygen atom in the phosphoryl group—an effective centre for the formation of complexes with various metal ions. Data on the steric structures of the ligands, characterised by the bond length and the valence and dihedral angles, as well as information concerning the changes in the potential energy of the system occurring as a result of internal rotations are very important for the elucidation of the complex formation reaction mechanisms. These factors are in fact responsible for the growing interest in the stereochemical properties of phosphoryl compounds. We may note that the approaches to the theoretical analysis of the steric effects in complex formation and the results of the study of the complex-forming properties of polydentate ligands containing phosphoryl groups have been discussed in a number of communications[4-6].



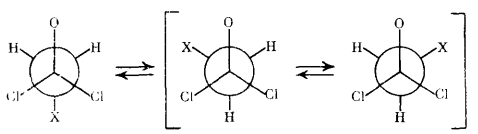
During the last decade vigorous studies have been made on the conformational analysis of phosphoryl compounds, but the complete analysis of the results obtained has not yet been carried out. The earlier reviews[7,8] include data obtained up to the end of the 1960s. In the monograph of Vilkov et al.,[9] the available data on the properties of phosphoryl compounds are described in an extremely concise form. The review of Bokii et al.[10] discusses only data obtained by X-ray diffraction while that of Arshinova[11] deals with data secured by the dipole moment and Kerr effect methods.

In the present review an attempt has been made to summarise the results of experimental and theoretical studies on the conformational properties of phosphoryl compounds with phosphorus–carbon bonds carried out in recent years. The review presents a logical analysis of the steric structures of compounds as a function of the character of the substituents at the phosphorus and carbon bonds.

II. HINDERED INTERNAL ROTATION ABOUT A SINGLE P–C_{sp^3} BOND

1. Alkylphosphonic Acid Dihalides

We shall discuss initially the conformational properties of compounds of the $\begin{matrix}R_1\\ \\ R_2\end{matrix}\!\!>\!P(O)Alk$ series using as examples the dichloride $Cl_2P(O)CH_3$ (I) and difluoride $F_2P(O)CH_3$ (II) of methylphosphonic acid. Reliable structural data, obtained by electron diffraction, are available for compound (I) in the gas phase[12]. According to these results[12], the angles at the phosphorus atom deviate significantly from tetrahedral values: $\angle O{=}P{-}C = 117.4° \pm 1.0°$, $\angle O{=}P{-}Cl = 114.5° \pm 0.5°$, $\angle CH_3{-}P{-}Cl = 103° \pm 0.5°$, and $\angle Cl{-}P{-}Cl = 101.8°$ (calculated). Because all three atoms attached to the carbon atom are identical, the hindered internal rotation involves the formation of only one triply degenerate staggered conformation:



No information whatever has been published[12] concerning the character of the hindered internal rotation.

An effective method for conformational analysis is that of vibrational spectroscopy, which can yield information about the conformation mobility and the character of the changes in potential energy as a result of internal rotation. There have been a number of publications on the vibrational spectra of compounds (I) and (II) in different states of aggregation[13-22]. Thus, Durig and co-workers[18,19] analysed in detail the infrared and Raman spectra of compound (I) in gaseous, liquid, and solid states. The identification of the bands in the vibrational spectra was based on the available

literature assignments for related compounds. However, Durig et al.[18] were unable to isolate the torsional vibrations. Using improved infrared and Raman spectroscopic techniques, Durig and Casper[19] obtained clear-cut spectra of compounds (I) and (II) in the range 33–300 cm^{-1}. Having assigned specific lines and bands in this part of the spectra to torsional frequencies, the authors calculated the potential barriers to the rotation of the methyl groups in both compounds. Since this information is very important for the characterisation of intramolecular interactions, we shall consider in greater detail the interpretation of the experimental data obtained in the above study.

Eight bands were observed in the far infrared spectrum of a crystalline specimen of compound (I)[19]. Since five of these bands did not undergo any changes in frequency on raising the temperature from −190° to −80°C, the authors assigned them to intramolecular vibrations. Four of them, split into doublets (for specimens in the crystalline state), were assigned, by analogy with earlier studies[18,20], to different deformation vibrations. The "superfluous" fifth band at 264 cm^{-1} was assigned to a torsional vibration and the potential barrier was estimated from its frequency. Evidently, this approach is not rigorous without calculations for the vibrations. Furthermore, when torsional frequencies are employed, the correspondence between the mode of the observed vibration and that of the purely torsional vibration[21] and an exact estimate of the inertial parameters of the torsional vibration[22] are important. Finally, even for a correct estimate of the barrier, it is not clear to what type of interactions the characteristic obtained should be assigned. The neglect of the intermolecular interactions and of the crystal field effects can lead to a significant distortion of the true intramolecular component.

The replacement of even one hydrogen atom in the CH_3 group by some other substituent can lead to the appearance of different conformers and to equilibrium between them. Assuming that the presence of the barrier corresponds to conformations with eclipsed bonds, three stable staggered conformations can be put forward for compounds having the formula $Hal_2P(O)CH_2X$ (where X = alkyl):

The vibrational spectra of the compound $CH_3CH_2P(O)Cl_2$ (III, X = CH_3) have been discussed in a whole series of publications. Infrared absorption bands and Raman lines in the spectra of a liquid specimen of compound (III) were first interpreted by Gerding and Maarsen[13]. Analysis of the causes of the appearance of the $\nu_s(PCl_2)$ doublet led to the conclusion that a mixture of isomers is produced. The doublet in the range 1250–1300 cm^{-1} was assigned to the resonance of the Fermi stretching vibration of the phosphoryl linkage and the deformation vibration of the C–H bond. Although the above study[13] was in fact quoted in subsequent reports[23–25], the cause of the appearance of a doublet in the range 1250–1300 cm^{-1} was not discussed; the question of equilibrium between the conformers is interpreted in the same way as in the earlier investigation[13]. Steger and Kuntze[24] indicated a specific structure of the conformers (*gauche*- and *trans*-orientations of the P=O and C–C bonds). The available data concerning the assignment of the bands and lines to specific type of vibrations are extremely contradictory.

In later communications[26–28] there are no references to the earlier data[13,25]. It has been stated[26] that the study of the infrared spectra of compound (III) confirmed the conclusions reached by Steger and Kuntze[24]. Shagidullin et al.[27] estimated the thermodynamic parameters of the equilibrium involving the conformers of compound (III) in a non-polar medium (solvent—carbon tetrachloride, temperature 298 K). An estimate of ΔH for compound (III) has also been published by Fishman and Remizov[28], but it refers to a liquid specimen and the energy of the conformers includes in this instance intermolecular interactions. The above workers[28] estimated the height of the barrier to the internal rotation of compound (III) from the torsional frequency quoted by Steger and Kuntze[24]. $\Delta H_{trans\text{-}gauche}$ = 0.1 kcal mol^{-1} has been obtained for compound (III).[27]

The initial data concerning the structure of the compound $Cl_2P(O)CH(CH_3)_2$ (IV) were contradictory. Thus, in their study of the vibrational spectra of compound (IV), Gerding and Maarsen[13] did not observe signs of a conformational equilibrium. Christol and Christol[23] postulated equilibrium between two conformers on the basis of the doublet band assigned to the antisymmetric vibrations of the PCl_2 group.

Comparison of the infrared and Raman spectra of compound (IV) in various media and at different temperatures[29,30] permitted a more specific conclusion concerning its structure. It was found that equilibrium between two conformers is characteristic of this compound, as for the ethyl derivative. The thermodynamic parameters of the equilibrium were calculated from the temperature variation of the spectra of compound (IV) in solution (solvent—n-hexane, temperature 182–298 K): $\Delta H_{gauche,gauche/trans,trans} = -0.5$ kcal mol^{-1}, $\Delta F = -0.2$ kcal mol^{-1}, and $\Delta S = -1.0$ kcal mol^{-1} K^{-1}.[30]

The substitution of all three hydrogen atoms at the α-carbon atom by CH_3 groups to give the compound $Cl_2P(O)C(CH_3)_3$ (V) also results in the stabilisation of the triply degenerate conformation by the hindered internal rotation. The barrier to the hindered internal rotation about the P–C bond in compound (V) is then greater than in compound (I) owing to the increased repulsion between the non-bonded atoms. The ^1H NMR spectra of compound (V) have been analysed[31,32]. Nixon and Schmutzler[32] did not observe any signs of hindered internal rotation about the P–C bond, but, on the basis of the broadening of the signals of the methyl protons on cooling the specimen, Bushweller and Brunelle[33] postulated the possibility of a barrier having a height of 7 ± 1 kcal mol^{-1}.

The dipole moment (DM) and Kerr effect methods and vibrational and ^1H NMR spectroscopic data were used in the identification of the steric structures of the conformers of compounds (III)–(V) formed[30] [the ^1H NMR spectra of the liquid compound (III), (IV), and (V) have also been published by Siddall and Prohaska[34]]. It was established on the basis of the Kerr constants that equilibrium between conformers with the *trans*- and *gauche*-dispositions of the P=O and C–CH_3 groups in proportions of 0.35:0.65 is characteristic of compound (III) in solution in CCl_4 at 298 K, while equilibrium with the *trans,gauche*- and *gauche,gauche* dispositions in proportions of 0.4:0.6 is characteristic of compound (IV). ^1H NMR spectroscopic data obtained under the same experimental conditions have led to the conclusion that there is equilibrium between the above conformers in proportions of 0.25:0.75 and 0.45:0.55. Thus the conclusions concerning the structure of the conformers and the quantitative estimates of the equilibrium positions for compounds (III) and (IV) obtained on the basis of infrared and ^1H NMR spectroscopic measurements agree, the latter to within 5%.

The NQR spectroscopic method has been resorted to in order to reach a conclusion about the conformations of compound (I), (II), and (IV) in the crystalline phase. It was established that symmetrical and asymmetric conformations are stabilised in the crystal cells of compounds (III) and (IV) respectively[35,36], which agrees with vibrational spectroscopic data for compound (III)[27] but conflicts with other results[30]. The NQR frequencies quoted[35,36] apparently do not allow in the given instance a reliable identification of the structure of the compound. In particular, a splitting of the signal by approximately 0.3 Hz has been observed for compound (I), which has a symmetrical structure, i.e. the splitting is of the same order of magnitude as that which has been attributed to the non-equivalent states of the two chlorine atoms owing to their different environments in other derivatives.

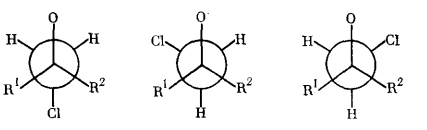
Spectroscopic data indicating a considerable structural similarity of phosphoryl, thiophosphoryl, and selenophosphoryl derivatives are also available for the analogous compounds with P=S and P=Se bonds. In particular, detailed studies have been made of the compounds $Cl_2P(S)C_2H_5$ (VI)[30,37,38] and $Cl_2P(S)C_3H_7$ (VII)[37], which led to the detection of conformational equilibria for these compounds in the liquid state.

The spectra of compound (I), (III)–(V), and $Cl_2P(O)Bu^i$so (VIII) in the range 400–700 cm^{-1}, in which infrared absorption bands and Raman lines assigned to the stretching vibrations of the P–Cl bond are observed, have been compared[29,30]. Only two bands or lines (symmetrical and antisymmetric vibrations of the PCl_2 group) are observed for compounds (I), (V), and (VIII) in the above range under the experimental conditions (solutions of different polarity, temperature 180–300 K), which indicates the absence of a dynamic equilibrium between two conformers of compound (VIII) and the existence of a conformer with the *gauche*-disposition of the bulky substituent at the α-carbon atom relative to the P=O bond. The authors[29,30] explained this by the increase of the energy of the *trans*-orientation of the P=O and isobutyl groups owing to steric interactions. The conclusion reached has also been confirmed by the agreement between the frequencies ν_s and ν_{as} of the vibrations of the PCl_2 group in the spectrum of compound (VIII), on the one hand, and the components of the ν_s and ν_{as} doublets of the PCl_2 group in the thoroughly investigated compound (III), on the other. The character of the infrared and Raman spectra of compounds (I) and (V) is consistent with the existing view concerning their structure; the infrared spectra of compound (V) have also been published by Holmes and Fild[39].

In order to elucidate the character of the intramolecular effects, Raevskii et al.[30] carried out calculations for non-valence interactions within the framework of the atom–atom approximation. The calculations yielded somewhat high interaction energies. Thus the height of the barrier to internal rotation in compound (V) proved to be twice as high as in the study of Bushweller and Brunelle[33]. However, the character of the change in energy in the course of internal rotation was determined correctly[30]: the potential energy minima correspond to the *gauche*- and *trans*-dispositions of the $C-CH_3$ and P=O groups; a deeper minimum corresponds to the *gauche*-conformer of compound (III) and the *gauche*, *gauche*-conformer of compound (IV). It is noteworthy that, from the standpoint of steric non-valence interaction, the preference for the *gauche*-position compared with the *trans*-position in the case of the hindered internal rotation about the P–C bond is partly due to the deviations of the valence angles involving the phosphorus atom from the tetrahedral value[7]. On passing from compound (III) to compound (IV), there is an increase in the energy difference between the conformers, which has also been observed experimentally. A slight increase of energy compared with the skewed structure results from the CH_3 group being eclipsed by the oxygen atom of the phosphoryl group. The barrier corresponding to the conformation with eclipsed P–Cl and $C-CH_3$ bonds is found to be fairly high.

Thus the steric interactions of the non-bonded atoms determine the character of the changes in the potential energy curves in the course of internal rotation about the $P-C_{sp^3}$ bond in compounds (I)–(VI).

2. Phosphoryl and Thiophosphoryl Compounds with a Single Halogen or Cyanoalkyl Group



The phosphoryl compounds with a single halogen or cyanoalkyl group attached to the phosphorus atom can be regarded as more complex than compounds (I)–(VIII). Apart from the steric interactions, additional intramolecular effects may be manifested in derivatives of this series.

Fairly detailed spectroscopic studies have been made for the compounds $Cl_2P(O)CH_2Cl$ (IX)[40,41], $Cl_2P(S)CH_2Cl$ (X)[40,42], $F_2P(O)CH_2Cl$ (XI), $F_2P(S)CH_2Cl$ (XII), and $Cl_2P(O)CH_2CH_2Cl$ (XIII)[24].

The number of observed absorption bands in the infrared spectra and lines in the Raman spectra of compound (IX) in the liquid state is greater than 18, which is inconsistent with the concept of a conformationally rigid eight-atom non-linear molecule. Comparison of the spectra of liquid and solid specimens of compound (IX) revealed a tendency towards a simplification of certain parts of the spectrum on crystallisation, which also indicates the existence of a mixture of conformers in the liquid phase. An analogous picture has been observed also for compounds (X)–(XIII). It has been established by the dipole moment and Kerr effect methods that, in a non-polar medium, there is equilibrium between the *trans*-conformer (80%) and the *gauche*-conformer of compound (XI)[43]. Certain considerations concerning the structures of the conformers produced in a given series of compounds have been put forward[24,40]. Special conformational studies on compounds of the type $R_1R_2P(O)CH_2Cl$ undertaken to discover the influence of the nature of the substituents R_1 and R_2 on the hindered internal rotation about the $P-C_{sp^3}$ bond have been made by infrared spectroscopic and dipole moment methods[44], Raman spectroscopy, differential thermal analysis[45], and ^1H NMR.[46] Compounds with $R^1 = R^2 = Cl$ (IX), $R^1 = R^2 = CH_3$ (XIV), $R^1 = Cl$ and $R^2 = CH_3$ (XV), $R^1 = R^2 = C_6H_5$ (XVI), $R^1 = C_6H_5$ and $R^2 = Cl$ (XVII), and $R^1 = C_6H_5$ and $R^2 = CH_3$ (XVIII) were investigated.

The joint examination of Raman spectroscopic and differential thermal analysis data yielded additional evidence for the conformational inhomogeneity of compounds (XV) and (XVII) in different phase states. The joint analysis of the vibrational and ^1H NMR spectra made it possible to explain the changes in the geminal constants for the interaction of the phosphorus and proton nuclei in media of different polarity and to estimate the parameters for individual conformers. The results of an electron diffraction study of compound (IX)[47] are comparable with those obtained elsewhere[44–46].

The possibility of the existence of three conformers or their equilibria was examined for compounds (IX) and (XIV)–(XVIII):

The equilibrium between several conformers has been observed in a non-polar medium for all the compounds (Table 1)[44].

Table 1. The percentages of conformers in solutions of compounds (IX) and (XIV)–(XVIII) in CCl_4 at 298 K[44].

No.	Compound	*trans*-Conformer	*gauche*-1-Conformer	*gauche*-2-Conformer
(IX)	$Cl_2P(O)CH_2Cl$	60	20	20
(XIV)	$(CH_3)_2P(O)CH_2Cl$	90	5	5
(XV)	$Cl(CH_3)P(O)CH_2Cl$	60	10	30
(XVI)	$(C_6H_5)_2P(O)CH_2Cl$	10	45	45
(XVII)	$Cl(C_6H_5)P(O)CH_2Cl$	30	10	60
(XVIII)	$C_6H_5(CH_3)P(O)CH_2Cl$	30	35	35

The influence of the nature of the substituents at the phosphorus atom on the relative stabilisation of the conformers involved in the equilibria has been elucidated on the basis of conformational analysis: when the chlorine atoms in compound (IX) are replaced by methyl groups as in compound (XIV), the equilibrium shifts significantly towards the *trans*-form. Calculation of the energies of the steric and electrostatic interactions of the non-bonded atoms showed[44] that steric factors do not play a significant role in the displacement of the equilibrium for compound (IX) and that the greater stability of the *trans*-form is due to the mutual repulsion of the C–Cl dipole and the most polar P=O group. The role of steric interactions in compound (XIV) increases (there is some stabilisation of the *gauche*-form), but the interaction of the dipoles remains the decisive factor.

Analogously allowance for the steric and dipole–dipole interactions in compound (XV) permitted an explanation of the existing conformational equilibrium with satisfactory accuracy. As in compounds (IX) and (XIV), the electrostatic interaction plays the main role in compound (XV). Even for the two *gauche*-conformers, where the orientations of the C–Cl bond and of the P=O bond, which is the most polar of the bonds involving the phosphorus atom, are the same, the energy difference is wholly determined by the polar interactions involving the P–C and P–Cl dipoles which are weaker but their orientations are opposed.

When the methyl groups are replaced by phenyl groups [compounds (XVI)–(XVIII)]. the relative stabilities of the conformers change and the *gauche*-conformer predominates. This can be explained by the steric hindrance due to the aromatic rings. The *trans*-orientation of the chlorine atom is unfavourable even in the presence of only one phenyl group. There is an approximately 30% content of the *trans*-conformer of compound (III), while the proportion of the corresponding conformer of the methyl analogue (XV) is 60%.

An analogous investigation of thiophosphoryl derivatives has been carried out[48]. The infrared spectroscopic and dipole moment data and conformational calculations on compounds having the general formula $R^1R^2P(S)CH_2Cl$, where $R^1 = R^2 = Cl$ (X), $R^1 = Cl$ and $R^2 = C_2H_5$ (XIX), $R^1 = Cl$ and $R^2 = C_6H_5$ (XX), and $R^1 = Cl$ and $R^2 = p\text{-}ClC_6H_4$ (XXI), indicate the existence of conformational equilibrium. The content of the less polar *trans*-form is 80% for compound (XIX) and 40% for compounds (XX) and (XXI). As for the phosphoryl derivatives the *gauche*-conformers are not identical. Comparison of the experimental dipole moments of compounds (XIX)–(XXI) and the corresponding dipole moments calculated within the framework of Exner's method[49] permitted the conclusion that the *gauche*-1 form is involved in the equilibrium, i.e., of the two possible *gauche*-forms, that in which the C–Cl bond is in the *trans*-position relative to the most bulky substituent at the phosphorus atom is actually produced.

Thus the replacement of the phosphoryl oxygen by a sulphur atom hardly leads to any serious changes in the intramolecular interactions.

The energy of rotation about the $P-C_{sp^3}$ bond can change when the substituents are varied not only at the phosphorus atom but also at the carbon atom, as already noted for alkylphosphonic acid dichlorides examined in the previous section.

A series of recent publications describe a detailed conformational analysis of dichloromethylphosphonic acid dichloride $Cl_2P(O)CHCl_2$ (XXII)[50], dichloromethylphosphonothioic acid dichloride $Cl_2P(S)CHCl_2$ (XXIII)[51], the dichloride of α-chloroethylphosphonic acid $Cl_2P(O)CH(CH_3)Cl$ (XXIV)[52], and the dichloride of α-chloroethylphosphonothioic acid $Cl_2P(S).CH(CH_3)Cl$ (XXV)[53] by means of a combined application of infrared, Raman, and NMR spectroscopic, dipole moment, and Kerr effect methods as well as theoretical conformational calculations.

The effectiveness of the vibrational spectroscopic method in the estimation of the conformational inhomogeneity of the specimens has been clearly demonstrated[51] in relation to the vibrational spectra of compound (XXIII) in the liquid and crystalline states: conformational pair equilibrium is manifested by the doublet structures of seven pairs of bands and lines due to the stretching and deformation vibrations of the P–Cl, P=S, C–Cl, P–C, and C–H bonds (Table 2).

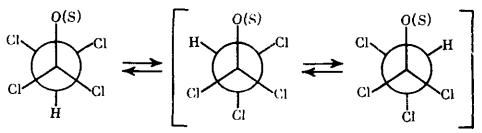


Table 2. Vibrational spectra of the compound $Cl_2P(S)CHCl_2$ (XXIII) (ν, cm^{-1})[51].

It must also be emphasised that the "combined application of methods" is understood as the joint processing of information obtained independently by different physical methods using either analytical or graphical procedures. This principle was first proposed by Exner and Jehlicka[49] and Altona

et al.[54] and was subsequently developed by Vereshchagin and co-workers[55,56]. Thus graphical analysis of the squares of the dipole moments and Kerr constants (Fig. 1*a*), the squares of the dipole moments and the spin–spin coupling constants (Fig. 1*b*), and the Kerr and spin–spin coupling constants (Fig. 1*c*), and finally the joint analysis of all the three physicochemical characteristics indicated (Fig. 1*d*) led to an unambiguous identification of the conformational state of compound (XXIV)[56]. The following conformational pair equilibria have been observed for compounds (XXII)–(XXV) in a non-polar medium (dilute solutions in CCl_4):

(XXII) and (XXIII)

(XXIV) and (XXV).

As in the systems examined previously, the steric structures formed are influenced by two intramolecular effects: the steric and electrostatic interactions of the substituents at the phosphorus–carbon bond. However, allowance for only these effects in compounds (XXII) and (XXIV) is insufficient to account for the observed picture. Comparison of quantitative data on the thermodynamic parameters of the conformational equilibria of compounds (III), (IV), and (XXII) (Table 3) can be of definite assistance in this instance. In the absence of specific intramolecular interactions, the difference between the entropies of the conformers usually corresponds to their statistical weighting factors within the limits of the error of the measurements (~ 0.5 cal mol^{-1} K^{-1}), which has in fact been observed for compounds (III) and (IV), in the molecules of which there are no electronegative substituents at the α-carbon atom. The replacement of the hydrogen atoms of the alkyl fragment by chlorine atoms leads to a significant deviation from this relation. This is also accompanied by the stabilisation of the conformers with the C_1 symmetry. These changes can be explained by the formation of a weak intramolecular hydrogen bond. Its existence in one of the conformers of compound (XXII) has been demonstrated by an estimate[50] of the ratio of the absolute integral ν_{CH} band intensities due to different conformers. Thus, in the presence of protons, which have appreciable electron-accepting properties, at the α-carbon atom, the intramolecular hydrogen bond can influence the hindered internal rotation about the phosphorus–carbon bond.

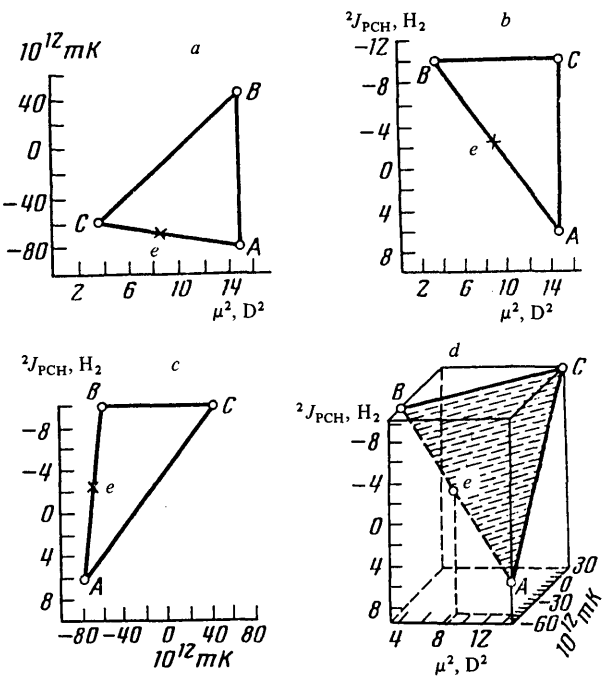

Figure 1. Graphical comparison of the squares of the dipole moments μ^2, the spin–spin coupling constants $^2J_{PCH}$, and the Kerr constants *mK* for the possible conformations of the compound $Cl_2P(O)CH(CH_3)Cl$ (XXIV): *a*) graphical comparison of μ^2 and *mK*; *b*) graphical comparison of μ^2 and $^2J_{PCH}$; *c*) graphical comparison of *mK* and $^2J_{PCH}$; *d*) graphical comparison of μ^2, *mK*, and $^2J_{PCH}$; *e*) experimental points[52].

Table 3. Thermodynamic parameters of the conformational equilibria in solutions of a number of compounds in CCl_4 at 298 K[57].

No.	Compound	$\Delta H_{C_1-C_S}$, kcal mol^{-1}	$\Delta S^{exp}_{C_1-C_S}$, cal mol^{-1} K^{-1}	$\Delta S^{theor}_{C_1-C_S}$, cal mol^{-1} K^{-1}	$\Delta\Delta S$, cal mol^{-1} K^{-1}
(III)	$Cl_2P(O)CH_2CH_3$	0.00	1.65	1.40	−0.25
(IV)	$Cl_2P(O)CH(CH_3)_2$	0.50	1.00	1.40	0.40
(XXII)	$Cl_2P(O)CHCl_2$	−1.32	−2.30	1.40	3.70
(XXIII)	$Cl_2P(O)CH(CH_3)Cl$	−1.00	−2.50	0.00	2.50
(XXV)	$Cl_2P(S)CH(CH_3)Cl$	0.10	1.30	1.40	0.10

Note: $\Delta H_{C_1-C_S}$ and $\Delta S_{C_1-C_S}$ are the differences between the enthalpies and entropies respectively; $\Delta\Delta S$ are the differences between the experimental entropies and the entropies calculated from the statistical weights of the conformers.

The hindered internal rotation in a compound with a single bromomethyl group at the phosphorus atom has been investigated in relation to the dibromide of bromomethylphosphonic acid $Br_2P(O)CH_2Br$ (XXVI)[41]. The authors[41] suggested that the bands in the infrared spectra of these compounds, whose intensity increases with decrease of temperature, are associated with the conformer having a plane of symmetry (i.e. a *trans*-disposition of the P=O and C–Br bonds). However, this initial hypothesis cannot be regarded as correct. Comparison of the spectra of compounds (IX) and (XXVI)[57] showed that the replacement of substituents [in the given case of chlorine atoms at the phosphorus atom and in the chloromethyl group of compound (IX) by bromine atoms, as in compound (XXVI)] can entail a redistribution of the contributions of different intramolecular interactions. Therefore, in some cases the *trans*-conformation can be stable, while in others the *gauche*-conformation is stable.

The incorrect hypothesis put forward by Nyquist[41] led to his assignment of the high-frequency component of the doublet ν(P=O) band in the spectrum of compound (IX) to the conformer with the C_1(*gauche*) symmetry and of the corresponding component in the spectrum of compound (XXVI) to the conformer with the C_s(*trans*) symmetry. Spectroscopic studies of a large series of phosphoryl compounds have shown[44] that the high-frequency component of the ν(P=O) vibration corresponds to the more polar conformer in the given series. It is therefore more logical to assume that the high-frequency component of the ν(P=O) band in the spectrum of compound (XXVI) corresponds to the *gauche*-isomer. Comparison of the spectra of compounds (IX) and (XXVI), obtained under identical conditions, reveals a redistribution of the intensities of the ν(P=O) and $\nu_{as}(PX_2)$ bands on passing from the chloromethyl to the bromomethyl derivative. This is apparently due to the displacement of the conformational equilibrium and not to a change in the ratio of the absolute integral intensities, since a parallel behaviour of absorption bands of different types has been observed. Temperature measurements have shown that, with decrease of temperature, the intensities of the low-frequency component of the ν(P=O) band in the spectrum of compound (IX) and of the high-frequency component in the spectrum of compound (XXVI) increase.

Thus a greater stability of the *trans*-conformer is characteristic of the dichloride of chloromethylphosphonic acid in a non-polar medium, while the *gauche*-conformer of the dibromide of bromomethylphosphonic acid is the more stable, which can also be explained primarily by the intensification of the influence of steric interactions on the energetic stabilities of the conformers. The significant increase in the bulk of the substituents at the phosphorus atom and in the halogenomethyl group led to an increase of the energy of the molecule in the *trans*-conformation (the bromine atom of the bromomethyl group is located in the projection between the two bulky bromine atoms) compared with the *gauche*-conformation (the bromine atom of the bromomethyl group is located between the bromine atom and the small oxygen atom).

The conformations of bromomethyldimethylphosphine oxide $(CH_3)_2P(O)CH_2Br$ (XXVII) and iodomethyldimethylphosphine oxide $(CH_3)_2P(O)CH_2I$ (XXVIII) have been investigated[58,59] by infrared and ^1H NMR spectroscopy and the dipole moment and Kerr effect methods. The agreement between the estimates of the conformational composition obtained by each of the above physical methods is to within 5%. It has been established that the *trans*-conformation predominates in compounds (XXVII) and (XXVIII) in a non-polar medium. This emphasises the decisive role of the electrostatic interaction of the polar group (namely P—O and C—Hal).

The steric structures of phosphoryl compounds with cyanomethyl groups, namely cyanomethyldiethylphosphine oxide $(C_2H_5)_2P(O)CH_2CN$ (XXIX) and cyanomethyldiphenylphosphine oxide $(C_6H_5)_2P(O)CH_2CN$ (XXX), have been investigated by the dipole moment and infrared spectroscopic methods[60,61]. The ratio of the *trans*- and *gauche*-conformers (0.8:0.2) of compound (XXIX) proved similar to the experimental ratio determined under the same conditions for compound (IX). The estimation of the contributions of the intramolecular effect showed that the repulsion of the dipoles leads to a relative energy gain for the *trans*-conformer by 1.3 kcal mol^{-1}. The equilibrium position for compound (XXX) is also somewhat displaced towards the *trans*-form. Comparison of the proportions of the conformers of compounds (XIV) and (XVI) (Table 1), on the one hand, and compounds (XXIX) and (XXX), on the other, has shown that for the latter pair of compounds the bulk of the substituents at the phosphorus atom no longer plays a significant role. The dipole–dipole interactions (the differences between the interaction energies of the dipoles of the *gauche*- and *trans*-conformers calculated theoretically virtually agree with the experimental values) have a greater influence in this case. Even a small decrease in the bulk of the substituents at the α-carbon atom probably weakens appreciably the steric interactions with the substituents at the phosphorus atom. The experimental difference between the free energies for compound (XXIX) is greater by 0.2 kcal mol^{-1} than for compound (XXX). The electrostatic interaction energies for these compounds differ similarly.

Thus the electrostatic factor can explain not only the observed ratio of the conformers but also the influence of the nature of the substituents at the phosphorus atom on the position of the conformational equilibrium.

Summarising the data discussed above concerning the hindered internal rotation about a single P—C_{sp^3} bond, the following observations may be made. Despite the availability of only a small amount of direct reliable quantitative data for the magnitudes of the potential barriers, detailed conformational studies of the series of compounds (I)–(XXX) which we selected suggest that the hindered internal rotation about the given bond obeys all the rules known for non-conjugated compounds and can be described satisfactorily with the aid of simple models[62,63]. This conclusion is confirmed by the results of calculations on steric and electrostatic interactions mentioned above. A distinctive feature of the group of compounds considered is the presence of the polar P=O bond, which can exert a significant influence on the orientation of the polar substituents at the α-carbon atom.

III. HINDERED INTERNAL ROTATION ABOUT A P—C_{sp^2} BOND

1. Derivatives of Vinylphosphonic Acid

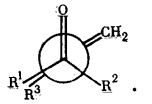
The dichloride $Cl_2P(O)CH=CH_2$ (XXXI) can be regarded as the simplest derivative of vinylphosphonic acid. Its vibrational spectra in the gaseous, liquid, and crystalline states and in solutions of different polarity have been discussed[64]. The infrared spectra of the liquid compound (XXXI) and of its solutions show a doublet ν(C=C) band. The ratio of the intensities of the components of this doublet varies with the polarity of the medium and temperature. The spectrum simplifies on crystallisation: only the high-frequency component of the ν(C=C) band remains and the band at 485 cm^{-1}, which has not been assigned to a specific type of vibrations, disappears. All these factors enabled the authors[64] to postulate that the existence of two conformers is characteristic of the liquid state and solutions of compound (XXXI): the *S-cis*- and *S-trans*-conformers, analogously to the esters of acetyl- and benzoyl-phosphonic acids, vinylphosphonates, and vinylphosphine oxides whose conformations had been investigated previously by the dipole moment method[65,66]. Remizov et al.[64] also present data for the difference between the internal energies (0.6 kcal mol^{-1}) and the potential barrier (4.0–5.0 kcal mol^{-1}), which can be regarded as approximate in view of the narrow experimental temperature range and the uncertainty of the approximations used in the calculation of the heights of the barriers, which was already mentioned above.

Another paper[67] presents data obtained in an electron diffraction study of compound (XXXI). Comparison of the geometrical parameters of the molecules of compounds (XXXI) and (I) reveals insignificant differences between the corresponding bond lengths and in the valence angles. The bond lengths in compounds (I) and (XXXI) are respectively as

follows (Å): l_{P-C} = 1.800 ± 0.025 and 1.817 ± 0.033, l_{P-Cl} = 2.032 ± 0.009 and 2.016 ± 0.004, and $l_{P=O}$ = 1.448 ± 0.005 and 1.455 ± 0.011, while the valence angles in compound (XXXI) are ∠O=P—Cl = 116.8° ± 1.5°, ∠O=P—C = 119.5° ± 3.3°, and ∠Cl—P—Cl = 101.6° ± 1.2°. Electron diffraction studies[67] established that the *cis*-conformer predominates in the gas phase. Taking into account the data of Remizov et al.,[64] Naumov and Shaidullin[67] refined the geometrical parameters of the molecule for 10, 20, and 30% of the *trans*-conformer (assuming that the bond lengths and valence angles are the same in both conformations). The best agreement with experiment was achieved for the equilibrium with a 20% content of the *trans*-conformer. The revised bond lengths and valence angles thus obtained differ only slightly from those indicated above. The characteristic feature discovered in this system is that the O=P and C=C bonds in the dominant *cis*-conformation are not located in a single plane; the dihedral angle between them is 12°.

The photoelectron spectrum of vinylphosphonic acid dichloride (XXXI) has been investigated and calculated by the CNDO/2 method[68,69]. According to the calculations, the dependence of the total energy of the molecule of compound (XXXI) on the dihedral O=P—C=C angle has an absolute minimum for the *cis*-orientation of the P=O and C=C bonds and a relative minimum for the *trans*-orientation. The total energy minimum in the case of the *cis*-conformation is due to the non-valence interactions, while the minimum in the case of the *trans*-conformation arises as a consequence of the electrostatic interactions of the polar group, which are related to the effective charges on the corresponding atoms. The infrared spectra quoted by Zverev et al.[69] (see also Remizov et al.[64]) showed signs of a conformational equilibrium for compounds in the liquid state and in solutions and the stabilisation of one of the structures in the gas phase. According to Zverev et al.,[69] the photoelectron spectra make it possible to interpret, to a first approximation, the experimental ionisation potentials as the ionisation energies of the orbitals of individual fragments. The high π(C=C) ionisation potential for compound (XXXI) can be explained by the inductive effect and not the specific manifestation of the π—π interaction.

The study of vinylphosphonic acid difluoride $F_2P(O)CH=CH_2$ (XXXII) by electrical methods showed[43] that equilibrium between the *cis*- and *trans*-conformers, with an appreciable predominance (70%) of the former, is characteristic of compound (XXXII) in a non-polar medium, i.e. the replacement of Cl atoms by F atoms has an insignificant influence on the conformational equilibrium.



According to Remizov et al.,[64] the replacement of the hydrogen atom at the α-carbon atom in compound (XXXI) by a methyl group as in the compound $Cl_2P(O)C(CH_3)=CH_2$ (XXXIII) or of the phosphoryl oxygen atom by a sulphur atom to give the compound $Cl_2P(S)CH=CH_2$ (XXXIV) influences significantly the hindered internal rotation about the $P-C_{sp^2}$ bond. No signs of conformational equilibrium were observed in the infrared spectra of these compounds. The stabilisation of a single structure of compound (XXXIV) can be explained, according to Remizov et al.,[64] by the fact that the replacement of the phosphoryl oxygen atom by a sulphur atom should entail a significant decrease of the P=X bond order as a result of the weaker π-bonding between the *p* orbital of the sulphur atom and the vacant 3*d* orbitals of the phosphorus atom. Consequently a higher electron density deficiency should be obtained at the phosphorus atom with increase of the P—C bond order. In order to explain the observed phenomenon, it is evidently also necessary to take into account the steric effects, since the steric factor should influence the conformational equilibrium following the replacement of the oxygen atom of the phosphoryl group by a sulphur atom or of the hydrogen at the α-carbon atom by a CH_3 group.

Substituted styrylphosphonates have been investigated by NMR using lanthanide shift reagents[70]: $Cl_2P(O)CH=CH(C_6H_5)$-*trans* (XXXV), $Cl_2P(O)CH=C(CH_3)C_6H_5$-*trans* (XXXVI), $Cl_2P(O)CH=CH(C_6H_5)$-*cis* (XXXVII), $Cl_2P(O)CH=C(Cl)C_6H_5$-*trans* (XXXVIII), and $(CH_3)_2P(O)CH=CH=CH(C_6H_5)$-*trans* (XXXIX). According to Berkova et al.,[70] in solutions of compounds (XXXV), (XXXVI), and (XXXIX) in carbon tetrachloride there is an equilibrium between the *S-cis*- and *S-trans*-conformers, while the stabilisation of the *S-trans*-conformer is characteristic of compounds (XXXVII) and (XXXVIII). On the other hand, under identical experimental conditions, it has been assumed that the *S-trans*- and *S-cis*-structures predominate for compounds (XXXV) and (XXXIX) respectively, which is due to the influence of the nature of the substituent at the phosphorus atom on the hindered internal rotation about the $P-C_{sp^2}$ bond.

In order to solve the problem of the conformational equilibria in complex compounds such as (XXXV)—(XXXIX), it would be desirable to apply also the vibrational spectroscopic method. It is then essential to carry out a series of spectroscopic studies in order to assign reliably the set of bands in the infrared spectra or lines in the Raman spectra to rotational isomers, because the existence of a complex pattern in any one part of the spectrum does not alone constitute a confirmation of the existence of conformational equilibrium. Thus, in the study of the Raman spectra of the compounds $ROCH=\underset{\displaystyle Cl_2\overset{|}{P}(O)}{C}-CCl=CH_2$ (XL), Batuev et al. [71] noted a splitting of the ν(P=O) band into four components, and, without quoting any additional evidence, they assigned each component to a particular conformer; such interpretation of the spectra cannot be regarded as well founded.

Patanovskii et al.[43] investigated the compound $F_2P(O)CH=CH(C_6H_5)$ (XLI) by the dipole moment and Kerr effect methods. The experimental data obtained agree with the hypothesis of equilibrium between the *S-cis*-conformer (10%) and the *S-trans*-conformer (90%).

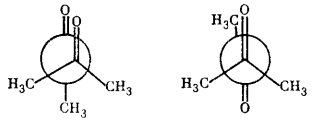
Data obtained as a result of the investigation of the steric structures of a small series of compounds (XXXI)—(XLI) provide only initial ideas concerning the character of the rotation about a single $P-C_{sp^2}$ bond. In order to reach specific conclusions, it is necessary to obtain additional data for a large number of phosphoryl compounds with a single vinyl group and a wide variety of other substituents at the phosphorus atom. Nevertheless, within the framework of the concept of conformational energy as the sum of the contributions by the simplest intramolecular effects, it is already possible to postulate that the role of the steric non-valence interactions in the stabilisation of the conformers as the molecules of the compounds investigated is decisive. The absence of appreciably skewed forms in the series of derivatives with the vinyl bond, in contrast to the alkylphosphonic acids (I)—(XXX) for which these forms are energetically stable, can apparently be explained by the geometry of the bonds involving the α-carbon atom. The sp^2-hybridisation of the orbitals of the α-carbon atom in compounds (XXXI)—(XLI) is responsible for the disposition of all three bonds in a single plane. In the skewed conformation with the dihedral angle φ(O=P—C=C) = 60° the third bond associated with the α-carbon atom therefore eclipses one of the substituents at the phosphorus atom:

This apparently results in the loss of the energy of the steric interaction compared with the *S-cis*- and *S-trans*-conformations in which the CH_2 group or the substituent R^3 accepts the phosphoryl oxygen atom whose steric repulsion energy is minimal.

2. Derivatives With a Single Aryl Substituent at the Phosphorus Atom

The geometrical parameters of the molecule of phenylphosphonic acid dichloride $Cl_2P(O)C_6H_5$ (XLII) are fairly close to those of compound (XXXI)[72]. Only some shortening of the $P-C_{sp^2}$ bond in the phenol derivative (l = 1.76 Å) compared with the vinyl derivative (l = 1.82 Å) should be noted. The conformation in which the phosphoryl bond and the benzene ring are located in a single plane has been assigned to compound (XLII) in the gas phase. The steric interactions between the non-bonded atoms have been analysed[72] in terms of the scheme developed by Magnasco[73]; the analysis showed that this type of interaction together with conjugation can influence the stability of the structure presented above. The spectroscopic study of compounds (XLII) and $Cl_2P(S)C_6H_5$ (XLIII) demonstrated, according to Remizov and Kuramshi[74], the existence of only one isomer in the liquid phase.

Certain derivatives of arylphosphine oxides have been investigated by the dipole moment and Kerr effect methods. Data have been obtained for solutions in carbon tetrachloride of the oxides of dimethyl-*p*-tolylphosphine $(CH_3)_2P(O)(p\text{-}CH_3).C_6H_4$ (XLIV), di-t-butyl-*p*-tolylphosphine $(t\text{-}C_4H_9)_2P(O).(p\text{-}CH_3)C_6H_4$ (XLV), and *p*-cyanophenyldimethylphosphine $(CH_3)_2P(O)(p\text{-}CN)C_6H_4$ (XLVI)[75], as well as the oxides of dimethylphenylphosphine $(CH_3)_2P(O)C_6H_5$ (XLVII), *p*-chlorophenyldimethylphosphine $(CH_3)_2P(O)(p\text{-}Cl)C_6H_4$ (XLVIII), and *m*-chlorophenyldimethylphosphine $(CH_3)_2P(O)(m\text{-}Cl)C_6H_4$ (XLIX).[76] However, the conclusions of various investigators concerning the orientation of the benzene ring in compounds (XLIV)–(XLIX) do not entirely agree. Thus alternative structures have been proposed for compound (XLIV): the bisector structure[75] and the conformation in which the angle between the $C_{sp^2}-P=O$ plane and the plane of the benzene ring is 46°.[76] This discrepancy between the conclusions reached in the two investigations[75,76] cannot be explained solely by the discrepancy between the experimental molar Kerr constants. Evidently, the differences between the initial parameters used by the authors to calculate the anisotropy of the polarisability can also be a cause.



Since there are at present no rigorous criteria for the selection of the electro-optical parameters within the framework of an additive scheme, theoretical conformational calculations have been carried out in terms of the atom–atom approximation[77]. The energies of the non-valence interactions have been calculated for different conformations of the oxides of ethylphenylphosphine $C_2H_5(H)P(O)C_6H_5$ (L), diethylphenylphosphine $(C_2H_5)_2P(O)C_6H_5$ (LI), and di-t-butylphenylphosphine $(t\text{-}C_4H_9)_2P(O)C_6H_5$ (LII), in addition to compounds (XLII) and (XLVII). The results of the calculation showed that, in the presence of symmetrical substituents, the bisector orientation of the benzene ring is the most favourable from the standpoint of non-valence interactions. The barrier to internal rotation increases with the bulk of the substituents. It is noteworthy that the form of the calculated potential curves permits the possibility of torsional vibrations of the benzene ring relative to the P–C bond with an amplitude of ±15°.

When the methyl groups of one of the ethyl substituents in compounds (XL) and (LI) are in the *trans*-positions relative to the P=O bond, the benzene ring deviates from its bisector position towards one in which it eclipses the P–H bonds in the molecules of compound of (L) or one in which it eclipses the substituent with the *gauche*-conformation of the methyl group in compound (LI). Since there is no such possibility for compound (LII), it assumes a stable bisector conformation requiring considerable deformations of the valence angles at the phosphorus atom to the tetrahedral values. In the presence of identical substituents at the phosphorus atom, the benzene ring probably tends to assume the bisector position. Attention should also be drawn to the considerable similarity between the steric structures of phosphoryl compounds with vinyl and phenyl groups. The *S-cis*- and *S-trans*-conformations or their equilibrium mixture are characteristic of the first group. The bisector conformation of the benzene ring can be regarded as the *S-cis,trans*-form. Evidently, the non-valence steric interactions are decisive factors for the stabilisation of such orientation of the vinyl and phenyl groups. In agreement with Bochvar et al.,[78] no evidence has been found for the influence of conjugation of the $\pi-\pi$ or $p\pi-d\pi$ type on the stereochemistry of these molecules.

3. Derivatives with a Carbonyl Group at the Phosphorus Atom

Compounds containing the P(O)–C(O) fragment are convenient objects for investigation from the standpoint of vibrational spectroscopic and dipole moment methods in view of the presence of two polar bonds (phosphoryl and carbonyl). However, in the vast majority of cases the molecules investigated contain stereochemically irregular substituents at the phosphorus and carbon atoms and in a rigorous study must be treated as systems with several different axes of rotation. Only two compounds having fixed dispositions in space of the groups adjoining phosphorus and carbon have so far been investigated: the compounds $(CH_3)_2P(O)C(O)CH_3$ (LIII) and $[(CH_3)_3C]_2P(O)C(O)C(CH_3)_3$ (LIV).

Compound (LIII) has been studied by Kostyanovskii et al.,[79,80] by infrared and ^1H NMR spectroscopic methods. The infrared spectra of the liquid compound (LIII) have been found to contain two bands, assigned to $\nu(C=O)$ vibrations, with maxima at 1723 and 1760 cm^{-1}. Apart from the equilibrium between two conformers, the authors of these studies discussed also other possible causes of the appearance of doublet absorption bands in the range 1700–1800 cm^{-1}. In particular the hypothesis of the occurrence of the Fermi resonance of the vibrations in the given range was considered and ruled out, since both bands remained intense in different solutions. The ^1H NMR data also agree with the hypothesis of equilibrium between two conformers. Structures with the *cis*- and *trans*-disposition of the P=O and C=O bonds were proposed as the possible conformers.

Laskorin et al.[81] noted a unique and symmetrical character of the absorption in the spectrum of compound (LIII) at the $\nu(C=O)$ frequency and, although they do not discuss a specific structure of compound (LIII), comparison of the results of the above investigations[79–81] throws doubt on the initial conclusion concerning the conformational equilibrium.

A subsequent study by Laskorin et al.[82] was undertaken to solve the problem of the possible steric structure of ketophosphoryl derivatives. Only one $\nu(C=O)$ band was

observed in the infrared spectra of the compounds, including (LIV). Considering the possibility of the existence of compound (LIV) as the *cis*-, *trans*-, and *gauche*-isomers, the authors[82] assumed that the *trans*-conformation is the most probable having resorted to the Stuart–Briegleb model. The inadequate information about the structure of the group of compounds considered so far precludes a conclusion concerning the specific features of the steric orientation of the P=O and C=O bonds in the absence of internal rotation of other fragments.

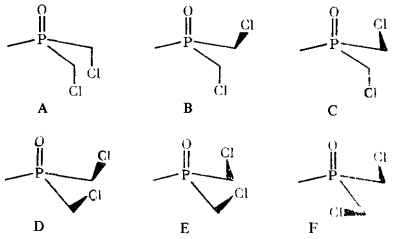
IV. THE STERIC STRUCTURES OF COMPOUNDS WITH TWO AND THREE IDENTICAL IRREGULAR FRAGMENTS

1. Derivatives with Alkyl Groups

It is evident from the data described above (Section II) that a skewed position relative to the bonds adjoining the phosphorus atom is characteristic of alkyl fragments. There exist three such positions for each alkyl group. The number of possible different steric structures in the case of two and three alkyl fragments therefore increases as a result of internal rotation about the P–C_{sp^3} bonds, which leads to additional problems in the conformational analysis of such systems. X-Ray diffraction data for the compounds $(C_2H_5)_3$.P(S) (LV) and $(C_2H_5)_3P(Se)$ (LVI) confirm that the skewed disposition of the alkyl fragment is preferred[83,84]. The vibrational spectra of such compounds in the crystalline state have been interpreted[84].

Solutions of trialkylphosphine oxides having the general formula $Alk_3P(O)$, where Alk are normal unbranched hydrocarbons in which the number of carbon atoms ranges from one as in the compound $(CH_3)_3P(O)$ (LVII) to 16 as in the compound $[(CH_3)(CH_2)_{15}]_3P(O)$ (LXXII), have been investigated[85–87].

The steric structures of the conformers of compounds (LVII)–(LXXII) have not been described accurately but the possibility of rotations about the P–C_{sp^3} and C_{sp^3}–C_{sp^3} bonds, which lead to a disposition of the alkyl fragment in the vicinity of the phosphoryl linkage, has not been ruled out.



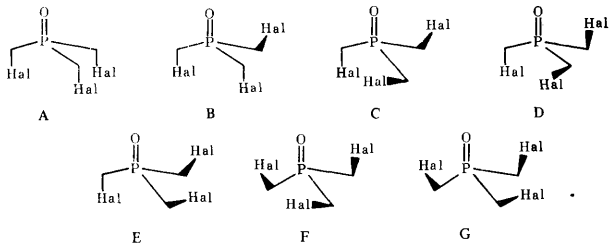
There exist definite data in the literature concerning the conformational equilibria of compounds with two alkyl groups at the phosphorus atom. Thus detailed analysis of the infrared spectra of compounds of the type $ClP(O)Alk_2$, where Alk = CH_3 [compound (LXXIII)], C_2H_5 [compound (LXXIV)], C_3H_7 [compound (LXXV)], iso-C_3H_7 [compound (LXXVI)], C_4H_9 [compound (LXXVII)], s-C_4H_9 [compound (LXXVIII)], or C_5H_{11} [compound (LXXIX)],[88] made it possible to isolate a single ν(P–Cl) band in the spectrum of compound (LXXIII) and a doublet in the spectra of compounds (LXXIV)–(LXXIX). The disappearance of one of the components of the doublet from the spectrum of the solid compound (LXXIV) and the redistribution of the band intensities in the spectra when the temperature of the liquid compounds (LXXIV)–(LXXVIII) is altered indicate the existence of a mixture of conformers; the differences between the internal energies should be of the order of magnitude of ~ 0.4 kcal mol^{-1}.

Electrical methods proved to be fairly effective in the determination of the structures of such complex systems. Thus the application of the dipole moment and Kerr constant methods to diethylpropynylphosphine oxide $(C_2H_5)_2P(O)C{\equiv}C(CH_3)$ (LXXX) showed that the C–CH_3 bonds in the ethyl groups are only in the *gauche*-positions relative to the P=O bond[89].

In view of the large number of possible conformational equilibria and the small amount of reliable data available, one cannot at present reach unambiguous conclusions concerning the conformational composition of the group of compounds considered.

2. Derivatives with Two and Three Halogenomethyl Groups

The structures of dichloromethyl(methyl)phosphine oxide $CH_3P(O)(CH_2Cl)_2$ (LXXXI) and the chloride of di(chloromethyl)phosphinothioic acid $ClP(S)(CH_2Cl)_2$ (LXXXII) have been discussed[90] on the basis of data obtained by the vibrational spectroscopic, dipole moment, and Kerr effect method. It was established that each of the C–Cl bonds in the molecules of these compounds can have the *trans*-orientation or one of the two possible *gauche*-orientations (g_1–in the direction of the methyl group, g_2–in the direction of the chloromethyl group), i.e. altogether there is a possibility of six sterically incompatible conformations:



Equilibrium between two conformers, with the less polar conformer predominating (0.7:0.3), has been observed in a dilute solution of compound (LXXXI) in CCl_4. The measured dipole moments and Kerr constants led to the conclusion that the weakly polar form A and also one or several forms (B, C or D) having positive Kerr constants are involved in the equilibrium. This conclusion was confirmed by plotting the square of the dipole moment against the Kerr constant. The equilibria A ⇌ B and A ⇌ C agreed best with these spectroscopic data. The structure thus discovered proved comparable to the structure described previously for the analogue of this compound with a single chloromethyl group, i.e. the *trans*-orientation of the P=O and C–Cl bonds proved to be preferable.

Substitution of the phosphoryl oxygen atom by sulphur and of the CH_3 group by chlorine, as in compound (LXXXII), leads to a considerable stabilisation of one of the least polar forms (A or B); the fraction of the more polar structure (most probably the C structure) does not then exceed 10%.

In order to follow the variation of the steric structures of compounds when the halogen atom in the halogenomethyl group is replaced, a study was made of dibromomethyl(methyl)phosphine oxide $CH_3P(O)(CH_2Br)_2$ (LXXXIII) and di-iodomethyl(methyl)phosphine oxide $CH_3P(O)(CH_2I)_2$ (LXXXIV) by means of a combined study of the infrared, Raman, and ^1H NMR spectra, the dipole moments, and the Kerr effect[91]. It was established that substitution of chlorine atoms by bromine and iodine atoms in the halogenomethyl groups leads to a fairly appreciable alteration of the molecular structure. For compounds with two bromo- and iodo-methyl groups, the conformation with the *trans*-orientation of both C-Hal bonds is not involved in the equilibrium. The most stable proved to be the form with the *trans–gauche* disposition of the C–Hal bonds, where the halogen atoms are remote from one another, which rules out steric hindrance and, as a consequence of the electrostatic interaction, one C–Hal bond is in the *trans*-position relative to the P=O group.

Molecules in which three conformationally irregular groups are attached to the phosphorus atom are the most interesting and at the same time most complex. In the molecules of tri(halogenomethyl)phosphine oxides each C–Hal bond has either the *trans*-orientation or one of the *gauche*-orientations relative to the phosphoryl group, i.e. there is a possibility of seven conformations:

The conformational equilibrium of tri(chloromethyl)phosphine oxide $(CH_2Cl)_3P(O)$ (LXXXV) has been analysed[92]. The infrared spectra of this compound indicated equilibrium between two conformers in non-polar solutions (in proportions of 0.7:0.3), the less polar component predominating. Comparison of the experimental dipole moments and Kerr constants with the corresponding quantities evaluated by a graphical method established that all three C–Cl bonds in the dominant conformer are in the *trans*-positions relative to the P=O bond (structure A), while in the energetically less favourable conformer they are in the *gauche*-positions, all being rotated to one side (structure F). In principle, this result agrees with data obtained for phosphine oxide with one or two chloromethyl groups. It was of interest to note that the equilibrium found for tri(chloromethyl)phosphine oxide corresponds to a cooperative transition of all three chlorine atoms from the *trans,trans,trans*-positions to the *gauche,gauche,gauche*-positions.

The predominance of the B structure in the case of three bromomethyl groups was observed in an analogous study of tri(bromomethyl)phosphine oxide $(CH_2Br)_3P(O)$ (LXXXVI) and tri(iodomethyl)phosphine oxide $(CH_2I)_3P(O)$ (LXXXVII), which indicates an appreciable role of not only steric but also electrostatic interactions of the strong P=O and C–Br dipoles in the conformational equilibrium. The subsequent replacement of bromine atoms by iodine atoms led to the displacement of the conformer having the *trans,trans*-orientations of the P=O and C–Hal bonds from the equilibrium. The *gauche, gauche,gauche*-structure F was found to predominate in this case.

Thus the influence of two intramolecular effects (those of the steric and electrostatic interactions of the non-bonded atoms) on the structures of compounds with several halogenomethyl groups has been clearly followed. The equilibrium which obtains in the case of tri(chloromethyl)phosphine oxide indicates the approximately identical influence of two of the factors indicated above: the *trans,trans,trans*-structure is a result of the Coulombic repulsion of the dipoles of the P=O and C–Cl groups, while the *gauche,gauche,gauche*-structure is determined by steric interactions. Steric interactions predominate for compounds with iodomethyl groups, so that the *gauche,gauche,gauche*-disposition of the P=O and C–I bonds is observed in the preferred conformation.

3. Two and Three Vinyl or Phenyl Groups at the Phosphorus Atom

The structure of the compound $ClP(O)(CH=CH_2)_2$ (LXXXVIII) has been investigated by electron diffraction[67]. Complete agreement between the experimental and calculated data was not obtained in the above studies, but the authors concluded that the conformer in which the C=C and P=O groups have a disposition intermediate between *cis* and *gauche* (which corresponds to the model with C_S symmetry and dihedral angles close to 35°) predominates. The deviation from the rigorously eclipsed disposition of these groups may be associated with the interaction of the *p* orbitals of the vinyl groups. Evidently, the solution of the problem of the structure of compound (LXXXVIII) requires its more detailed investigation using other independent methods.

The data for the steric structures of compounds containing two and three benzene rings at the phosphorus atom can be divided into three groups: the results of X-ray diffraction analysis, the results of studies in solutions, and the results of theoretical conformational calculations.

X-Ray diffraction analysis was used to investigate diphenylphosphinic acid $(C_6H_5)_2P(O)OH$ (LXXXIX)[93,94], the diphenylphosphoryl alcohols $(C_6H_5)_2P(O)(CH_2)_3OH$ (XC)[95], $(C_6H_5)_2P(O)(CH_2)_2OH$ (XCI)[96], and $(C_6H_5)_2P(O)CH_2(o\text{-}OHC_6H_4$ (XCII)[97], triphenylphosphine oxide $(C_6H_5)_3P(O)$ (XCIII)[98–100], *p*-chlorophenyldiphenylphosphine oxide $(p\text{-}ClC_6H_4)P(O).(C_6H_5)_2$ (XCIV)[101], tri(*o*-tolyl)phosphine oxide $(o\text{-}CH_3C_6H_4)_3.P(O)$ (XCV), tri(*o*-tolyl)phosphine sulphide $(o\text{-}CH_3C_6H_4)_3.P(S)$ (XCVI)[102,103], tri(*m*-tolyl)phosphine sulphide $(m\text{-}CH_3C_6H_4)_3P(S)$ (XCVII)[103], and tri(*o*-tolyl)phosphine selenide $(o\text{-}CH_3C_6H_4)_3P(Se)$ (XCVIII)[102,103]. A disposition of the planes of the benzene rings relative to the X=P–C plane (X = O, S, or Se) skewed to different extents has been established for all the derivatives listed above, but the cause of this has not been elucidated. The results of the X-ray diffraction analysis of the two crystalline modifications of compound (XCIII) show that the polymorphic transformation involves a fairly appreciable alteration of the conformation, i.e. the crystal packing has an effect. However, the extent to which the crystal field effects are responsible for the non-equivalence of the benzene rings is difficult to determine without reliable information about the molecular structure in the liquid phase and in solutions. In virtually all the studies which have yielded data for the structures of the above compounds in solutions, it was assumed that each of the three benzene rings attached to the phosphorus atom has been rotated by the same angle[104,105]. It has been found by the dipole moment and Kerr effect methods that their angle of rotation is 60°[104] or 55°[105] for compound (XCIII) and 62° for the compound $(C_6H_5)_3P(S)$ (XCIX)[104]. Analogous results have been obtained also for several substituted triarylphosphine oxides having the general formula $(XC_6H_4)_3P(O)$, where X = *p*-Cl [compound (C)], *m*-Cl [compound (CI)], $p\text{-}CH_3$ [compound (CII)], or $m\text{-}CH_3$ [compound (CIII)][105]. However, a broadening of the signals due to the fluorine atoms in the *meta*-position has been observed in the NMR spectra of the fully fluorinated triphenylphosphine oxide[106], which disagrees with the results of Aroney et al.[104] and Bulgarevich et al.[105]

The same problems arise also in the study of compounds with two benzene rings at the phosphorus atom. According to the measurements of the dipole moments and Kerr constants for methyldiphenylphosphine oxide $(C_6H_5)_2P(O)CH_3$ (CIV)[76], the dihedral angle of the benzene rings and the P=O group is 58°. Somewhat different results have been obtained for analogous compounds in other investigations[89,107,108]. Ishmaeva et al.[107] examined two types of rotations for $(C_6H_5)_2P(O)CCl_3$ (CV), $(p\text{-}CH_3C_6H_4)_2P(O)CCl_3$ (CVI), and $(p\text{-}ClC_6H_4)_2P(O)CCl_3$ (CVII): the symmetrical rotation ($\phi_1 = -\phi_2$) and the antisymmetric rotation ($\phi_1 = \phi_2$). The dihedral angles obtained are 15°, in agreement with the symmetrical rotation. The dipole moment and Kerr constant data for the compound $(C_6H_5)_2P(O)CN$ (CVIII) indicated a

structure in which the planes of the benzene ring are almost parallel to the P=O bond[108]. Thus, according to the above workers[108], the addition of the strongly electron-accepting cyano-group to the phosphorus atom does not affect the conformational behaviour of the phenyl groups and is not manifested in the intramolecular electronic interactions involving the phosphorus atom. On the other hand, the experimental Kerr constants for the compound $(C_6H_5)_2P(O)C\equiv C-CH_3$ (CIX) agree with the conformation in which the planes of the phenyl groups are close to the arrangement in which the ethynyl group is eclipsed. In this case the authors[108] concluded that the interaction of the conjugated systems of the aromatic fragments with the triple bond is a stabilising factor.

An attempt has been made[109] to estimate the stereochemical properties of compound (CIV) and the compound $(C_6H_5)_2$.P(O)H (CX) with the aid of the relation found[110] between the ratio of the intensities of the symmetrical and asymmetric vibrations in the infrared spectra and the angle between the polarisation vectors of the out-of-plane vibrations. Relations of this kind may be useful in the study of the steric structures of complex compounds, but, so long as their universality has not been tested, they must be treated with caution.

Apart from the experimental studies on individual examples of the group of compounds considered, theoretical conformational calculations have been carried out. The calculation for compound (CIV) has been performed within the framework of the method of atom–atom potential functions and it was shown that the skewed state of the benzene rings attached to the phosphorus atom relative to the O=P–C–C plane is preferred[111].

The dependence of the conformational energy on the angles of internal rotation of the benzene rings relative to the $P-C_6H_5$ bonds has been investigated for the chloride of diphenylphosphinic acid $(C_6H_5)_2P(O)Cl$ (CXI) also within the framework of the atom–atom approach with simultaneous optimisation of the bond lengths and valence angles at the phosphorus atom[77]. The calculation showed that the two conformers for which the difference between the internal energies is 0.3 kcal mol^{-1} are the most stable in terms of the given approximation. The angles $\phi_1 = 10°$ and $\phi_2 = 76°$ were obtained for one conformer and $\phi_1 = 30°$ and $\phi_2 = 15°$ were found for the other conformer. It is noteworthy that the conformations with identical angles of rotation of the benzene rings ($\phi_1 = \phi_2$), in the range 10°–40°, have energies slightly different from those of the structures indicated above (~ 0.5 kcal mol^{-1}). The possibility therefore remains that a whole series of states obtains for the molecule of compound (CXI) with both identical and different angles of rotation of the planes of the benzene ring in the range from 10° to 40°.

On the basis of experimental data for compounds containing two or three phenyl groups at the phosphorus atom, one must conclude that it is difficult to obtain reliable results concerning the orientation of the plane of the benzene ring in such compounds when the latter are in solution. The employment of the vibrational spectroscopic method in this instance is complicated by the presence in the spectra of a large number of bands of the benzene ring. On the other hand, data obtained with the aid of electrical methods (in particular the Kerr effect methods) cannot be regarded as sufficiently accurate, despite their satisfactory sensitivity, owing to the limited amount of available information about the type of variation of the anisotropy of the polarisability of the benzene rings under the influence of electronic effects in the hindered internal rotation about the $P-C_{sp^2}$ bonds.

V. THE STERIC STRUCTURES OF COMPOUNDS WITH DIFFERENT IRREGULAR SUBSTITUENTS AT THE PHOSPHORUS ATOM

The conformational analysis of compounds with different irregular substituents at the phosphorus atom is undoubtedly even more complex than the study of compounds with identical groups. This is associated both with the removal of degeneracy, and hence the increase of the number of conformers having different properties, and with the possibility, in principle, of the stabilisation of those structures which might be disregarded in the case of derivatives with identical groups in view of their instability. The employment of any one physical method in the conformational analysis of compounds of the given series can therefore lead to erroneous conclusions.

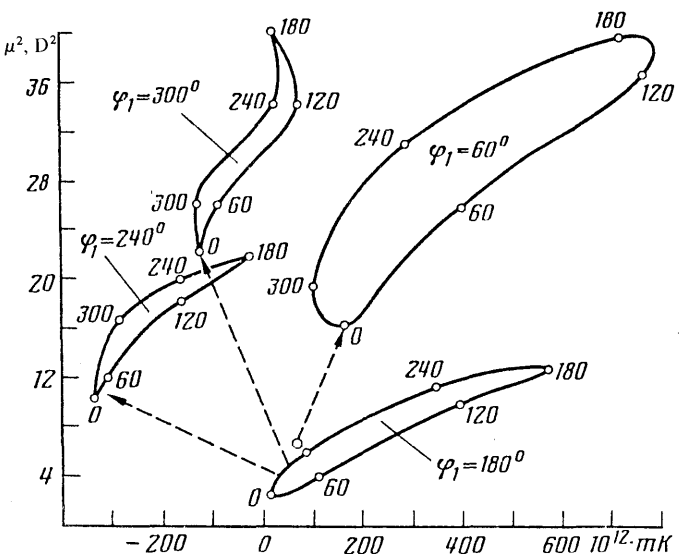
For example, the ^{1}H NMR spectra of compounds (I) and (III)–(V), $CH_3(C_6H_5)P(O)Cl$ (CXII), $C_2H_5(C_6H_5)P(O)Cl$ (CXIII), and iso-$C_3H_7(C_6H_5)P(O)Cl$ (CXIV) have been discussed[34]. In contrast to compounds (CXII) and (CXIII), in the spectrum of compound (CXIV) a doublet is observed at the $\nu(CH_3)$ frequency. The authors[34] explained this finding by the conformational equilibrium, but the merging of the signals did not occur even following an appreciable increase of temperature. The observed spectroscopic pattern cannot apparently be explained by rotational isomerism and is in fact due to the manifestation of the magnetic non-equivalence, giving rise to spectra of type ABX and A_2X for the methyl groups of compound (CXIV), which the authors[34] failed to take into account. The same interpretation has been given[112] for the protons of the chloromethyl group in the compound $(CH_3)_2NP(O)Cl(CH_2Cl)$ (CXV).

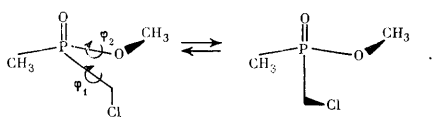
In a stereochemical study of ketophosphonate compounds, the vibrational spectroscopic method was mainly used. It has been stated[113] that there is only a single $\nu(C=O)$ band in the spectra of compounds having the general formula $(C_2H_5O)_2P(O)C(O)(CH_2)_nCH_3$, where n = 10 [compound (CXVI)], 12 [compound (CXVII)], 14 [compound (CXVIII)] and 16 [compound (CXIX)]. Analogous conclusions were reached on the basis of the Raman spectra of the compound $(C_2H_5O)_2P(O)C(O)C_6H_5$ (CXX)[114] and the infrared spectra of the compound $(C_2H_5O)_2P(O)C(O)CH_3$ (CXXI)[115], as well as a whole group of compounds having the general formula $(R'O)_2P(O)C(O)R$, where R = CH_3 and R' = C_2H_5 [compound (CXXII)], R = C_2H_5 and R' = C_2H_5 [compound (CXXIII)], R = iso-C_3H_7 and R' = C_2H_5 [compound (CXXIV)], R = t-C_4H_9 and R' = C_2H_5 [compound (CXXV)], R = C_6H_5 and R' = C_2H_5 [compound (CXXVI)], R = C_5H_9 and R' = C_2H_5 [compound (CXXVII)], R = C_6H_{11} and R' = CH_3 [compound (CXXVIII)], R = C_6H_{11} and R' = C_2H_5 [compound (CXXIX)], and R = C_6H_{11} and R' = iso-C_3H_7 [compound (CXXX)][116]. However, two ranges of variation of $\nu(C=O)$ (1656–1666 and 1698–1700 cm^{-1}) have been indicated[117] for 33 different compounds having the general formula $R(R''O)$.P(O)C(O)R', where R = C_2H_5, C_6H_5, p-$CH_3C_6H_4$, or p-ClC_6H_4, R' = C_6H_5, CH_3, p-$CH_3C_6H_4$, or p-ClC_6H_4, and R'' = CH_3, C_2H_5, C_3H_7, or iso-C_4H_9.

Detailed infrared and ^{1}H NMR spectroscopic data for the compounds $(CH_3O)_2P(O)C(O)CH_3$ (CXXXI), $(C_2H_5O)_2P(O)$.C(O)CH_3 (CXXXII), and $(CH_3O)_2P(O)C(O)C_6H_5$ (CXXXIII) have been published[118]. The infrared spectra of compounds in different phase states, in solutions of different polarity, and at different temperatures have been obtained. The type of the band characterising the absorption by the carbonyl group has led to the conclusion that conformational pair equilibrium obtains for compounds (CXXI) and (CXXXII) and that one conformer of compound (CXXXIII) is stabilised. However, only a single $\nu(C=O)$ band has again been noted[81]

for compound (CXXXI). In a special investigation[82] it has been stated that the manifestation of the second ν(C=O) band with a maximum at 1710 cm^{-1} is apparently due to an admixture of decomposition products. In the infrared spectrum of a freshly prepared and purified specimen of compound (CXXXI), the splitting of the ν(C=O) band is not observed for a liquid film and for a solution in CCl_4, while the addition of traces of acetic acid to the specimen leads to the appearance of a second absorption band at 1710 cm^{-1}. Preference has been given[82] to the *trans*-orientation of the P=O and C=O bonds.

However, in a number of instances the high sensitivity of individual physical methods to hindered internal rotation makes it possible to obtain fairly definite results even when only one method is used to study the conformations of complex compounds. Thus the considerable polarity of the P=O and C≡N bonds makes it possible to identify their relative positions in space[61]. The dipole moment method has been used[119] to investigate the steric structures of compounds having the general formula $XC_6H_4CH{=}C(CN)P(O)OC_2H_5$, where X = H [compound (CXXXIV)], *p*-NO_2 [compound (CXXXV)], *p*-Cl [compound (CXXXVI)], *p*-OCH_3 [compound (CXXXVII)], *p*-$N(CH_3)_2$ [compound (CXXXVIII)], and *m*-NH_2 [compound (CXXXIX)]. The rigidity of the $XC_6H_4CH{=}C(CN)$ fragment made it possible to infer the orientations of the phosphoryl and vinyl bonds and hence their electronic interactions. A number of other examples of this approach to conformational studies have been described in a review[120].





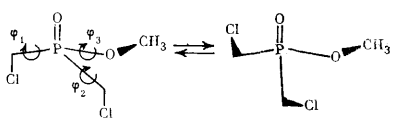


Figure 2. Graphical comparison of the dipole moments and Kerr constants for the compound $CH_3(CH_3O)P(O)CH_2Cl$ (CXL)[121].

Nevertheless, a combined physicochemical investigation is required to a greater extent than in other cases for the identification of the steric structures of organophosphorus compounds with different substituents. Such a study has been carried out of the ester of chloromethyl(methyl)phosphinic acid $CH_3(CH_3O)P(O)CH_2Cl$ (CXL)[121]. Vibrational and ^1H NMR spectroscopic data have been used in studies by the dipole moment and Kerr effect methods have been carried out. When account is taken of the possible rotations of both groups in steps of 60°, one can imagine the occurrence of 36 structures. However, all the structures in which the P=O and C—Cl, P—C and C—Cl, and P—C and O—CH_3 pairs of bonds are eclipsed can be excluded from consideration according to the data presented above in the present review and the conclusions reached by Raevskii[63]. Vibrational spectra have shown that in dilute solutions in CCl_4 compound (CXL) exists as a mixture of two conformers in which the less polar form predominates appreciably (~ 90%).

Experimental dipole moment and Kerr effect data have been assessed under the same conditions[121]. Fig. 2 compares the calculated squares of the dipole moments and Kerr constants with complete internal rotation relative to the P—O bond and four fixed positions of the P=O and C—Cl groups (the angles between the P=O and C—Cl bonds are 60°, 180°, 240°, and 300°). The experimental point is located in the vicinity of a closed curve corresponding to the set of conformations with the *trans*-orientation of the P=O and C—Cl bonds, which shows that the conformer with the *trans*-disposition of the C—Cl bond predominates in the equilibrium. The orientation of the O—CH_3 bond of this conformer can correspond to the *cis*- or *gauche*-disposition. The steric structure of the second conformer, the partner in the equilibrium in the given instance, cannot be determined with much reliability in view of its small amount. However, ^1H NMR data suggest the existence of equilibrium between the following conformers:

An analogous study has been carried out for a series of alkyl esters di(chloromethyl)phosphinic acid having the general formula $(CH_2Cl)_2P(O)OR$, where R = CH_3 [compound (CXLI)], C_2H_5 [compound (CXLII)], $CH_2CH{=}CH_2$ [compound (CXLIII)], iso-C_3H_7 [compound (CXLIV)], or C_4H_9 [compound (CXLV)].[121] The combined employment of various physical methods made it possible to identify the steric structures of these complex compounds for which the following equilibrium obtains in a non-polar medium:

Comparison of the steric structures of the series of compounds considered in this section with the simpler related compounds (IX)–(XXVIII) having the P—C_{sp^3} bonds shows that the *trans*-orientation of the P=O and C—Cl bond predominates in all the phosphoryl compounds investigated having the CH_2Cl group (groups) and small substituents at the phosphorus atom. The "cisoid" (60° ≥ φ ≥ 300°) orientation of the P=O and O—Alk bonds which has been established is common to phosphoric acid esters. Thus the steric structures of the compounds investigated having different substituents at the phosphorus atom correspond fully to the structures of related derivatives with a single irregular group and do not exhibit any new intramolecular effects.

Consequently, the features discovered previously for molecules with identical groups account fully for the structure of phosphoryl compounds with different substituents.

---o0o---

The data presented in this review lead to the conclusion that fairly extensive and quite definite information has now been accumulated on the hindered internal rotation about the phosphorus–carbon bond. Modern ideas concerning the nature of various intramolecular effects frequently permit an *a priori* determination of the preferential conformation of a compound which has not yet been studied. However, for subsequent successful conformational investigation of the given class of compounds, containing the P=O group, it is necessary to concentrate attention on the following problems: (1) the determination of quantitative data for the barriers to internal rotations; (2) the improvement and extensive employment of a scheme involving the combined application of the maximum possible number of independent physicochemical characteristics; (3) the estimation of the steric structures of compounds in aqueous media.

Quantitative information about the barriers to internal rotation can be obtained by employing microwave and NMR spectroscopy. However, experimental and theoretical difficulties significantly limit the application of these methods to the class of compounds under discussion. In this case the combination of vibrational spectroscopic and gas-phase electron diffraction methods, which make it possible to draw inferences about the nature of the change in the potential energy in the course of the hindered internal rotation from the torsional frequencies in the spectra and the geometrical parameters of the molecules determined, acquire special importance in this instance.

Analysis of data referring to the group of compounds with different irregular substituents shows that in the case of complex organic compounds the application of any one method cannot lead to a reliable solution of the conformational problem. The increase of the number of physicochemical parameters employed permits the analysis of the compatibility of the characteristics of the conformational equilibria with experimental data. When the number of equations relating the experimental and theoretical physicochemical characteristics corresponds to the number of the possible conformers, one can obtain a rigorous solution of the conformational problem[52]. The employment of the possibilities inherent in the NMR spectroscopic method involving different nuclei is evidently extremely promising for complex systems in this instance.

One should also note that the results presented in this review refer to gaseous, liquid (including solutions in non-polar and polar solvents), or crystalline states of the molecules. In order to assess the problem of the physiological activities of compounds, it is essential to have information about their steric structures in aqueous solutions. Such data are not available for the class of compounds discussed in this review. The present authors have recently obtained the infrared spectra of aqueous solutions of a phosphoryl compound with a halogenomethyl group using an IFS-113 Fourier spectrometer. It was found that in water the ratio of conformers with the *trans*- and *gauche*-orientations of the P=O and C–Hal bonds (0.4:0.6) differs significantly from the ratio in a non-polar medium (CCl_4, 0.9:0.1). The example presented indicates the necessity for a detailed study of the conformational state of compounds in an aqueous medium. At any rate, the neglect of the influence of the aqueous medium on the stereochemistry in the selection of structural elements responsible for the physiological activity of compounds of a given class can lead to erroneous constructions.

The Macrokinetics of the Thermal Decomposition of Polymers

N.A.Khalturinskii and A.A.Berlin

The kinetics of the thermal decomposition of thermoplastic polymers have been reviewed. The influence of the external medium—inert and chemically active gases - on the rate of thermal decomposition has been discussed. Heat and mass exchange at the surface of a polymer undergoing degradation, and the influence of the rate of heating and the thermal flux power, have been examined.
The bibliography contains 67 references.

I. INTRODUCTION

In connection with the continuous increase in the production and use of polymeric materials, their stability to various external factors, including thermal fluxes of different intensities, is acquiring exceptional importance. When a thermal flux acts on a polymer surface, heating and thermal degradation take place, and this is important from a number of viewpoints.

Many polymers are designed for use at high temperatures of the surrounding medium, and may also be subjected to powerful thermal fluxes from flames and other sources. A knowledge of the mechanism of the thermal decomposition of polymers can therefore be used to change their properties to create fire-resistant synthetic polymers.

Thermal degradation processes can be divided into two categories, according to the nature of the heat acting on the polymer (the thermal flux power and the temperature of the surrounding medium). The first corresponds to bulk processes of isothermal degradation of the polymer, and the second to surface degradation of the polymer, usually called linear thermal decomposition.

Detailed discussion of the isothermal degradation of polymers, examination of the theoretical aspects, and attempts to establish the dependence of the mechanism of the decomposition of polymers on their structure have been carried out by a number of workers, and comprehensive monographs on these topics have been written by Jellinek[1], Grassie[2], Madorsky[3], and others[4,5].

The extrapolation of data on isothermal kinetics in a block to the range of rates of degradation usually encountered in surface thermal degradation and combustion is apparently unjustified[6].

To determine the macrokinetic characteristics of combustion, the efficiency of ablation heat protection, the efficiency of fire-resistant polymer coatings, and the parameters of other processes characterised by high temperatures and high thermal fluxes, it is necessary to know the regular kinetic features of the thermal decomposition and the influence of the surrounding atmosphere, the rate of heating of the polymer surface or the thermal flux power, the structure of the polymer, the thermochemical and thermophysical properties of the polymers, etc.

According to existing ideas[5], polymers can be divided into three classes, according to the type of thermal degradation: the first undergo complete degradation with rupture of the main chain; the second type includes the removal of lateral fragments, and these polymers give volatile gaseous products and a coke residue; and the third type consists of cross-linked polymers which give small quantities of volatile products and a large quantity of coke.

Without going into the details of the mechanism of thermal degradation, the main task today is to establish the limiting stage of the thermal decomposition of polymers at high temperatures and the relationship between the macrokinetics of this process and the kinetic characteristics of the low-temperature "isothermal" degradation. This problem can be solved only by analysing published experimental data on high-temperature thermal decomposition.

The simplest case is the thermal degradation and thermal decomposition of thermoplastic polymers, when the polymer is completely converted to gases, without leaving a residue. In this case it is possible to study the phenomenon of high-temperature degradation and thermal decomposition under quasi-stationary conditions. With polymers of the second and third types, however, a carbonised residue will gradually accumulate on the surface of the condensed phase, leading to a continuous change in the conditions of heat and mass transfer at the interface between the gas and condensed phases. The present paper analyses published experimental data on the thermal decomposition of thermoplastic polymers.

II. PROCEDURES FOR STUDYING THE THERMAL DECOMPOSITION OF POLYMERS

A number of methods have now been developed for studying the macrokinetic characteristics of thermal decomposition in the range of temperatures and rates of thermal decomposition not accessible to classical isothermal methods. They are based on the measurement of the rate of mass loss by the specimen being studied, and on the analysis of the volatile products[3]. An important problem is the measurement of the temperature of the surrounding medium, the temperature of the surface of the polymer undergoing thermal decomposition, and the thermal flux at the surface of the specimen.

The composition of the degradation products under the conditions of high-temperature thermal decomposition characterises not only the processes taking place in the condensed phase but also the secondary reactions taking place in the heating zone. Analysis of the dependence of the degradation products of polymers on the temperature of the sur-

rounding medium[7] showed that increase in the temperature of the surrounding medium leads to a significant decrease in the yield of monomer as a result of secondary reactions for polymethyl methacrylate (PMMA), poly-α-methylstyrene, polystyrene (PS), polypropylene (PP), and other polymers (see Table 1). The yield of monomer in the thermal decomposition is strongly influenced by the conditions of the experiment[7].

Table 1. Yield of monomer (mass % of the total quantity of volatile products) in the thermal decomposition of various organic polymers in a vacuum at elevated temperatures[7].

Polymer	T, °C		
	500	800	1200
Polyethylene	0.03	5.5	26.4
Polypropylene	0.4	17.9	15.8
Polyisobutene	36.5	69.0	13.0
Polystyrene	51.0	10.5	0.6
Polymethyl methacrylate	94.2	91.8	12.9
Polytetrafluoroethylene	96.6	91.2	78.1
Poly-α-methylstyrene	100	88.5	37.7

In the methods developed for studying thermal decomposition, the polymer is heated in different ways: 1) by the heat flux from a heated plate[8-13]; 2) by the heat flux from a massive heat-conducting block[14-16]; 3) by a radiant thermal flux[17-19]; 4) by convective heating in a stream of hot gas[20-24]; 5) by the thermal flux from a diffusion flame formed close to the surface of the polymer specimen, which is swept by a stream of gaseous oxidising agent[25-33], etc.

The first studies of the thermal decomposition of polymers were carried out by Schultz and Dekker[8]. The essential feature of their method is that the polymer specimen is pressed with a constant force by means of a load against the flat surface of a metal plate heated by an electric current. The junction of a platinum–platinum/rhodium thermocouple with a diameter (d) of 50 μm was welded to the centre of the plate above the specimen being tested. The heated-plate method was subsequently developed by other workers[9,10,12,13].

Other workers[34,35] used a porous plate instead of a continuous plate to heat the specimens. In their opinion, the use of a continuous plate to study the thermal decomposition leads to an increase in the rate of the thermal decomposition as a result of the elution (erosion) of the molten liquid layer of polymer from the gap between the specimen and the heater by the flux of thermal decomposition products. Many of the data which they obtained, however, show a marked scatter even for materials which sublime. It is possible that in the thermal decomposition of thermoplastic polymers, the liquid layer flowed into the pores of the plate before volatilising, so that the porous-plate technique has not found application in thermal decomposition studies.

The use of massive copper or aluminium blocks instead of a plate heater has been proposed[14] to obtain linear thermal decomposition with the highest possible levels of thermal flux and rate of thermal decomposition. A heater and a thermistor are mounted on the lateral surface of the block. The junction of a microthermocouple is stamped into the lower end face. The system used to supply the specimen and record the rate of linear thermal decomposition was the same as in Ref.8. The instruments with a heating block solved extremely simply the problem of measuring the thermal flux q_s. Thus placing two Constantan junctions separated by a distance l in the lower part of the copper block having a cross-section close to the area of the end fact (S) of the specimen undergoing thermal decomposition makes it possible, from the readings of the resulting differential Constantan–copper–Constantan thermocouple ΔT_{bl}, to find

$$q_s = \lambda_m \Delta T_{bl}/l$$

where λ_m is the thermal conductivity of copper.

In contrast to previous methods in other studies[21,22,24] etc., the surface of the polymer specimen was heated by a flow of heated gases.

In Ref.22, the temperature of the heated gases was varied from 500 °C to 950 °C, and the flow rate was varied in the range 30–60 cm s^{-1}. The temperature of the polymer surface and the temperature profile along the axis of the specimen were measured by introducing Chromel/Alumel thermocouples with a wire diameter of 50 μm.

In Ref.21, the surface of the specimen undergoing thermal decomposition was swept with the exhaust gases from a small laboratory rocket motor—the products of the combustion of a C_3H_8–O_2–N_2 mixture —and the rate of the thermal decomposition was measured. The concentration of oxygen in the surrounding atmosphere varied from 12 mole % to 83 mole %. The temperature of the stream at the end of the rocket motor jet was 1100 °C. The density of the thermal flux was ~20 cal cm^{-2} s^{-1}. The rate of thermal decomposition was determined by the change in the length of the specimen undergoing thermal decomposition when it was swept by the combustion products for 9 s.

In Ref.24, a method for studying the high-temperature thermal decomposition of polymers in a stream of heated gases was proposed, which made it possible to record the mass rate of thermal decomposition, the temperature of the polymer surface, and the temperature of the stream of gases.

Polymer specimens with an initial mass of ~$(2-3) \times 10^{-3}$ g and initial diameter d_0 = 1–1.5 mm were taken for the study of the thermal decomposition. The specimen was placed on the junction of a Pt–Pt/Rh thermocouple (wire diameter 20 μm), the ends of which were brought through a two-channel sheath with diameter 1 mm and through an amplifier to the recording apparatus. The thermal decomposition was carried out in a stream of gases, heated by an electric furnace, and the rate of flow was kept constant (4 cm s^{-1}). When introduced into the furnace, the polymer specimen melted, covered the junction of the thermocouple, and hung from it as a liquid drop. The thermocouple junction was then in the surface layer of the specimen, and recorded a temperature close to the temperature of the surface of the polymer. The change in the mass of the specimen was recorded using an electronic microbalance based on an MKh-1S mechano-electronic device—an electronic valve with a moveable anode. The signal from the mechano-electronic device was passed through an electronic transformer and amplifier and recorded by an N-115 oscillograph. Typical curves giving the change in the mass of the specimen and temperature are shown in Fig.1. When the specimen is introduced into the stream of heated gases, in the first period (I) the specimen is heated to a temperature T_s, which changes little during the thermal decomposition of the polymer specimen. When the thermal decomposition is complete, the thermocouple records the temperature of the stream T_∞.

The degradation of small polymer specimens in a stream of heated gases under the conditions of thermal decomposition and combustion has been studied[26]. The experimental assembly included two electrical heating coils, between which the polymer specimens (diameter 1–2 mm) were placed, at the

end of a horizontal glass fibre. The coils were heated to ~1000 °C. The diameter of the specimen was measured photographically during the thermal decomposition and combustion to within 1.27×10^{-3} cm. The temperature of the polymer surface was estimated using a thermocouple, on which the polymer specimen was placed. As in the previous case, the temperature of the specimen increased rapidly in the first period, after which it remained practically constant until the specimen disappeared completely, when it increased sharply, recording the temperature of the external medium. The moment of complete volatilisation of the polymer was recorded photographically.

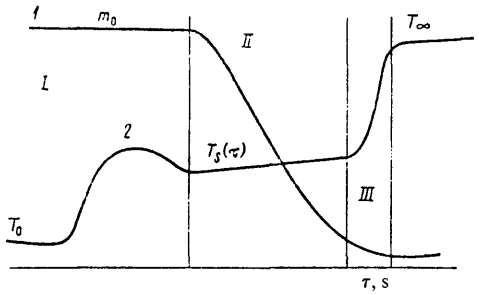

Figure 1. Change in mass (m) (*1*) and temperature (*2*) during thermal decomposition: *I*) heating of the polymer, *II*) thermal decomposition, *III*) recording of the flow temperature T_∞.

To increase the thermal flux at the polymer surface under conditions in which the polymer was swept by a stream of heated gases, a method was developed[25] in which a planar diffusion flame was established above the surface of the polymer. The temperature profile in the condensed phase was measured by a thermocouple placed inside the specimen. Cylindrical PMMA specimens with diameter 1.9 cm and length 3.71 cm were studied. The rate of linear thermal decomposition was determined in the stationary region by measuring the time required for the thermal decomposition of a specimen with a thickness of 1.27 cm. In addition to the thermocouple method, the temperature of the surface was measured using spectral methods, by recording the emission spectra of PMMA at a wavelength of 5.8 μm (the characteristic band of the C=O bond in the monomer), and determining T_S from their intensity. The optical measurements of the temperature of the surface (T_{SO}) gave a reproducible dependence of the temperature on the concentration of oxygen in the stream. The values of T_{SO} obtained were only a few degrees higher than the values measured by other methods.

The thermocouple measurements were carried out using Pt–Pt/Rh thermocouples with diameter 15 μm. In all cases, a region of relatively slow increase in temperature was observed before the thermocouple came out on to the surface. The extent of this region decreased sharply with increase in the rate of thermal decomposition. From the change in the nature of the thermocouple noise, it was concluded that there is a liquid layer on the surface of the PMMA undergoing thermal decomposition. The temperature profile in the condensed phase under the conditions of "quasi-stationary" thermal decomposition was assumed to obey Mikhel'son's equation[36]

$$T_{(x)} - T_0 = (T_s - T_0)\exp(-Ux/a) \quad (1)$$

where x is the distance from the surface, $T_{(x)}$ the current temperature, T_0 the initial temperature, T_S the temperature of the surface, a the coefficient of temperature change in the polymer, and U the rate of linear thermal decomposition. The authors[25] found the temperature of the surface by analysing their temperature profile data using the semilogarithmic relationship of Eqn.(1).

Other authors[34,37] studied combustion processes using an apparatus similar to that developed in Ref.25. An optical device was used to keep the surface of the specimen at the same distance from the front of the jet through which the oxidising agent was passed. In Ref.38 the polymer specimen was swept not by a counter stream but by a stream in the same direction, and "candle combustion" took place. All the measurements of the mass rate of thermal decomposition under the conditions of candle combustion were carried out when stationary conditions had been reached.

In Ref.19, thermal decomposition under combustion conditions was studied using planar polymer discs with thickness 3–5 cm and thermal decomposition surface area from 60 cm^2 to 100 cm^2. The specimen was placed in a quartz tube of length 61 cm and diameter 17 cm. A nitrogen–oxygen mixture with a given O_2/N_2 ratio was passed through the tube at a rate of 50–70 litre min^{-1}. The apparatus was fitted with two additional powerful sources of thermal radiation, which were directed on to the surface of the polymer being studied. The mass rate of thermal decomposition was measured continuously by an electronic balance. To investigate the influence of various factors on the rate of thermal decomposition ($\dot{m}$), the influence of the thermal decomposition surface area on the value of $\dot{m}$ was first studied. Extrapolation of the data on the dependence of $\dot{m}$ on S gave different values of the surface area at which $\dot{m}$ no longer depends on S; 3.0 m^2 for polystyrene, 2.5 m^2 for polymethyl methacrylate, 0.5 m^2 for polyethylene, and 0.3 m^2 for polypropylene.

To exclude completely the influence of heat losses from the specimen to the surrounding medium, that is to eliminate the influence of the surface area of the heated specimen on the mass rate of thermal decomposition, a method was proposed[33] for studying thermal decomposition under the conditions of the diffusion combustion of a spherical specimen completely surrounded by a flame. The polymer specimen with diameter 10 mm was fixed by a quartz capillary-holder on a vertical ceramic tube with outer diameter 1–1.5 mm. This ceramic tube was firmly connected to the horizontal rod of a mechano-electronic device, which recorded the change in the mass of the specimen undergoing thermal decomposition under combustion conditions. The power of the thermal flux to the surface of the polymer was controlled by changing from 20% to 100% the proportion of oxygen in the $N_2 + O_2$ mixture, supplied through a quartz tube with diameter 70 mm. The specimen was ignited by a gas burner, which was switched off immediately after the specimen began to burn. The thermal flux to the polymer surface was measured using a thermocouple probe, the shape of which coincided with the shape of the isothermal surface of the specimen. The temperature profile in the specimen and the temperature of the thermal decomposition surface were measured by a thermocouple placed inside the specimen at a distance of 1 mm from the surface. The diameter of the Pt–Pt/Rh wire used for the thermocouples was 0.02–0.03 mm. The external thermocouple probe was firmly connected to the linear displacement meter, whose readings were recorded on an oscillograph film. The moment when the outer thermocouple probe touched the polymer surface was recorded from the

response of the mechano-electronic device on the oscillograph film, and also visually using a KM-6 cathetometer and time recorder. An advantage of this method is that the change in the mass of the specimen undergoing thermal decomposition and the temperature profile in the gas and condensed phases are recorded on the same time coordinates.

The values of the maximum temperature of the flame (T_f), the temperature of the surface (T_S), and the temperature gradient (dT/dr), determined using the external thermocouple probe, are given in Table 2.

Table 2. Temperature measurements during the combustion of spherical PMMA specimens in an $N_2 + O_2$ atmosphere[33].

O_2, %	T_f, °C	T_S, °C	dT/dr, K cm^{-1}*
20	1350	460	5050
25	1520	480	6200
30	1660	500	7400

*Radius of the specimen in the measurements 4.5 cm.

The temperature of the surface and the temperature gradient at high oxygen concentrations (greater than 30 mass %) were measured by means of an internal thermocouple which emerged into the gas phase; this moment was recorded optically and determined from the sharp break on the curve giving the change in temperature. In Ref.30, an apparatus was proposed for determining the rate of degradation under conditions of thermal decomposition and combustion, in which a cylindrical reaction vessel with diameter 0.8 cm and height 1 cm was connected to a quartz rod, acting as the rod of an electronic balance. In this apparatus it was possible to carry out the thermal decomposition in a stream of air and inert gas. The planar heater, with diameter 0.9 cm, was placed at a distance of 0.8 cm from the specimen surface. The instrument developed makes it possible to record simultaneously the temperature of the specimen undergoing thermal decomposition and the change in its mass.

III. MEASUREMENT OF THE TEMPERATURE OF THE SURFACE OF POLYMERS DURING THERMAL DECOMPOSITION

Data on the kinetics of the degradation of polymers are usually correlated using the Arrhenius expression for the rate of thermal decomposition

$$\dot{m} = A \exp(-E/RT_s) . \qquad (2)$$

If the kinetic data are described by this relationship, the data obtained in one temperature range can be used to predict the behaviour of the polymer in other temperature ranges.

Success in correlation has been restricted to the knowledge of such quantities as T_S and the thermodynamic properties of a specific polymer[6]. When the experiments are carried out in the low-temperature range up to 300 °C, and when the degradation takes place in the "kinetic range", that is when the characteristic heating time of the specimen is much less than the chemical reaction time, the temperature of the polymer is equal to the temperature of the reaction vessel or the temperature of the surrounding medium.

Shteinberg[15] examined the physical picture of the endothermic bulk decomposition (gasification) of a sphere of substance whose kinetics corresponded to Eqn.(2). By introducing characteristic time scales, namely the heating time of the sphere

$$\tau_h = \frac{r^2}{a}$$

where r is the characteristic dimension of the specimen, and a is the thermal conductivity, and the decomposition time of the substance at a temperature T_S

$$\tau_r = [K_0 \exp(-E/RT_s)]^{-1}$$

he estimated the relative thickness of the reaction layer Δ.

At comparatively low temperatures T_S (Fig.2*a*), $\tau_h \ll \tau_r$, and all the substance can be heated to a temperature $T \cong T_S$ (the temperature gradient along the thickness of the specimen is practically zero) long before any significant fraction of it decomposes, $\Delta = r$. With increase in T_S (Fig.2*b*), the decomposition time τ_r becomes commensurate with the heating time τ_h, and $\Delta < r$. In the limit when $\tau_h/\tau_r \gg 1$ (Fig.2*c*), the thickness of the reaction layer is much less than the thickness of the material $\Delta/r \ll 1$, that is degradation takes place close to the hot surface, and moves together with the heating wave. The temperature profile in the condensed phase is determined by the ratio between the rate of movement of the heating wave and the thermophysical characteristics of the polymer specimen in accordance with the Mikhel'son equation[36]. When the degradation is carried out under thermal decomposition conditions, the temperature measurement involves considerable difficulties. In early studies of linear thermal decomposition by the heated-phase method[8–13], and also in thermal decomposition by a heated metal block[14–16], the thermocouple designed to record the surface temperature was fixed in the metallic heater. The temperature of the heater was taken as the temperature of the surface.

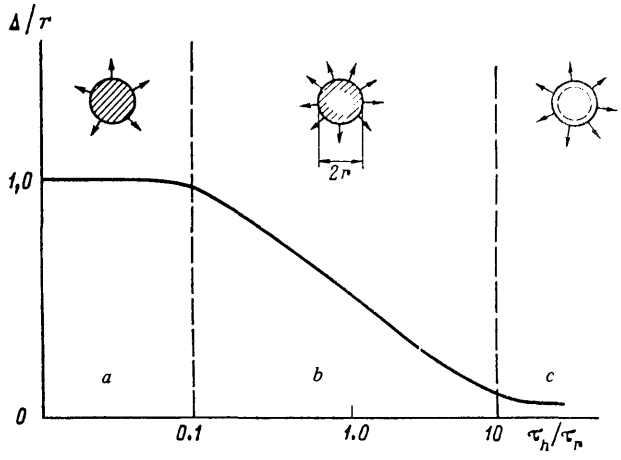

Figure 2. Dependence of the relative thickness of the reaction layer on the ratio of the characteristic times of thermal relaxation τ_h and decomposition τ_r.[15]

Cantrell[10] was the first to draw attention to the fact that the temperature of the surface undergoing thermal decomposition was different from the temperature of the heated block.

With change in the temperature of the heater T_0 from 8 °C to 60 °C, the rate of the linear thermal decomposition of solid carbon dioxide increased by a factor of less than 2, and the temperature of the surface T_S increased from −52 °C to −42 °C. An interesting feature is the appreciable superheating of the surface of dry ice compared with the temperature of equilibrium sublimation, corresponding to a pressure of gas in the film of ~1 atm. It was pointed out that for small T_0, $T_S \cong T_0$, and at high T_0 and high rates of linear thermal decomposition, the effect of the film may be significant, and $T_S < T_0$. Cantrell examined the problem of the transfer of heat in the gas gap formed by the linear thermal decomposition between the heater plate and the polymer, and obtained an equation relating the thickness of the gap (z) to the geometric dimensions of the specimen (r), the rate of linear thermal decomposition (U), the density of the substance (ρ), the viscosity of the thermal decomposition products (γ), and the force (W) pressing the polymer against the heated surface

$$z = \frac{3}{2}(\pi r^4 \gamma \rho U / W)^{1/3} . \quad (3)$$

In his experiments on the linear thermal decomposition of PMMA, Shteinberg[16] recorded the linear rate of decomposition and the thermal flux to the specimen surface q_1, which is given by:

$$q_1 = \lambda (T_0 - T_s)/z \quad (4)$$

where T_0 is the temperature of the heater. Eqns.(2)–(4) were used to calculate the values of ΔT, which are given in Fig.3.

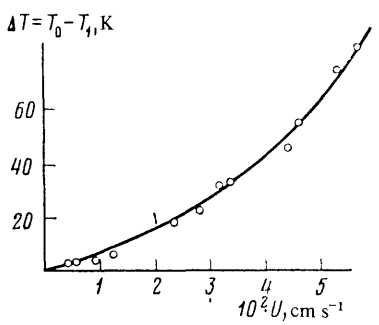

Figure 3. Change in the temperature drop through the gas film with increase in the rate of thermal decomposition of PMMA.[14]

The values of the thermophysical constants of the gas in the calculations were taken for the heavy hydrocarbon octane at the temperature of the plate. For the highest rates of thermal decomposition achieved in the experiments, the calculated thickness of the gas gap did not exceed 30 μm.

Tkachenko and co-workers[14] studied the thermal decomposition of linear and cross-linked PMMA. The temperatures of the surface of the material undergoing thermal decomposition at medium rates of thermal decomposition were calculated as in the previous case, but for high rates, assuming that T_S is constant, the temperature was found graphically from the equation:

$$\frac{mr}{W^{1/3}} = \left(\frac{32}{\pi}\right)^{1/3} \frac{\lambda (T_0 - T_s)}{\nu^{1/3} [c (T_s - T_\infty) + Q]} .$$

The values of T_S obtained were 450 °C for linear PMMA, and 475 °C for cross-linked PMMA.

In a study of the linear thermal decomposition of PE and PMMA,[23] the dependence of the temperature of the surface of the polymers undergoing thermal decomposition on the temperature of the surrounding medium was measured, and it was shown that they gradually increase.

A study of linear thermal decomposition in a stream of heated gases in the temperature range 500–950 °C [22,39] showed that the temperature of the surface and the temperature profile in the condensed phase are the same, irrespective of the conditions of the experiment.

Table 3. Temperatures of the surface (T_S) in the combustion of various polymers[25,40].

Polymer	λ, μm	T_s, °C	
		in air	in oxygen

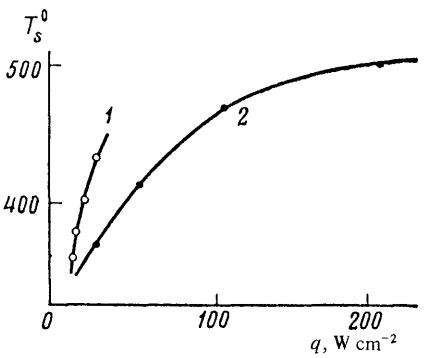

Figure 4. Influence of the thermal flux on the temperature of a PMMA surface during thermal decomposition: *1*) data from Ref.17, *2*) data from Ref.18.

The increase in the rate of linear thermal decomposition was attributed to the increase in the rate of volatilisation of the degradation products from the surface.

Infrared radiation has been used[40] to measure the temperature of the surface of burning fuels and polymer binding agents. This method was used to measure the temperatures of the surface of polymers during combustion in air and in an oxygen atmosphere.

The data in Table 3 show that for combustion in oxygen, T_S is 40–60 K greater than for combustion in air. The same method has been used[25] to determine the temperature of the surface in the thermal decomposition of PMMA during combustion.

Published data[17,18] on the influence of the thermal flux on the temperature of thermal decomposition show that with increase in the thermal flux to a surface, its temperature

increases (Fig.4). The dependence is more marked at low thermal fluxes. The lack of agreement in the published data[17,18] is due either to the inaccuracy of the determination of the thermal flux to the polymer surface or to the inaccuracy of the temperature determination.

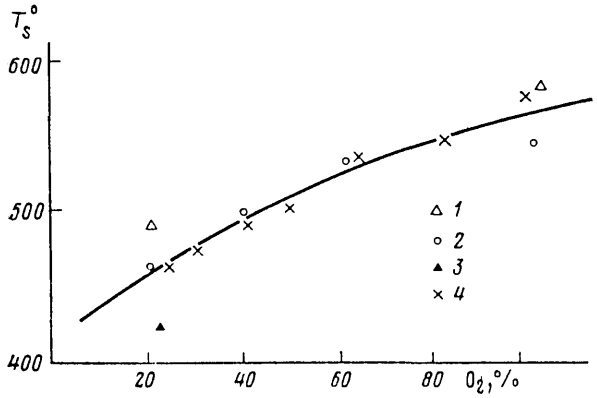

Figure 5. Dependence of the surface temperature of a PMMA specimen undergoing thermal decomposition under combustion conditions on $[O_2]$: *1*) Ref.25, *2*) Ref.26, *3*) Ref.33, *4*) Ref.44.

* —[43], ** [42].

The influence of the oxygen concentration on T for the surface of a burning PMMA specimen was studied by other workers[34,41], and the results are given in Fig.5.

The experimental values of the temperatures of the surface and the rates of combustion for a number of polymers are given in Table 4.

Systematic studies of the influence of the temperature of the surrounding medium on the temperature of the surface of thermoplastic polymers undergoing thermal decomposition in a stream of heated gases have been carried out[24], and the results are given in Table 5.

IV. INFLUENCE OF OXIDISING AGENTS AND CHEMICALLY ACTIVE GASES ON THE THERMAL DECOMPOSITION OF THERMOPLASTIC POLYMERS

Studies carried out by many authors on the influence of oxygen on the rate of "bulk" degradation, studied thermogravimetrically, have shown that the presence of oxygen in the surrounding atmosphere usually leads to a marked increase in the rate of the bulk degradation of thermoplastic polymers[44,45]. In thermal decomposition, however, we are dealing with much higher temperatures, thermal fluxes, rates of heating of the specimen, and rates of degradation, so that it was necessary to determine the role of chemically active gases and oxygen in this range.

Table 5. Values of T_s (°C) in the thermal decomposition of thermoplastic polymers in a stream of heated gases[24].

Polymer	T_s					
	500	600	700	800	900	1000
PMMA	410	440	460	470	480	485
POM	450	490	515	530	535	540
PS	465	500	525	545	555	565
PE	485	535	570	595	610	620
PP	480	525	560	585	600	610

In Ref.21, the surface of a porous polymer was heated in the exhaust from a laboratory jet motor—the combustion products of a C_3H_8–O_2–N_2 mixture. The concentration of oxygen in the surrounding atmosphere was varied from 12 mole % to 83 mole %. A study of the rates of the thermal decomposition of PS and PMMA showed that the rate of the thermal decomposition is not sensitive to oxygen. In another series of experiments, a porous specimen was used and the concentration of any test gas passed through it was accurately controlled. The influence of N_2, O_2, ClO_3F, NO, NO_2, Cl_2, HCl, NH_3, and SO_2 on the thermal decomposition of PS and PMMA was studied. The rate of the thermal decomposition of PMMA and PS decreased with increase in the rate of supply of the test gases, but the introduction of NO_2 and Cl_2 led to a slight increase in the rate of the thermal decomposition of PS. The decrease in the rate of degradation with increase in the supply of test gases was related to the increase in the proportion of heat used up in heating the gas, and the decrease in the heat used to heat the polymer.

The influence of the concentration of oxygen on the thermal decomposition of PS and PMMA in a stream of gas heated to a temperature of 700 °C has been studied[22]. Increase in the O_2 concentration has no influence on the rate of the linear thermal decomposition of PS, and leads to a slight increase in the rate for PMMA.

A study of the influence of oxygen on the rate of the linear thermal decomposition of polystyrene, styrene–butadiene copolymers, and mixtures of polystyrene with o-phthalic acid, maleic acid, and propylene glycol[46] showed that at rates of thermal decomposition comparable with the rates observed in the combustion of polymers, oxygen has no influence on the rate of the linear thermal decomposition.

In Ref.24, the influence of the composition of the surrounding atmosphere was investigated by studying the thermal decomposition of PMMA in a stream of helium, nitrogen, and air. The values of the "volatilisation" constants for spherical specimens in a stream of heated gases, and their thermal conductivities, are given in Table 6.

At medium temperatures of the surrounding medium, the volatilisation constant is greater in helium, in which the thermal conductivity is almost ten times that for nitrogen and air. With increase in T_∞, this difference decreases, as a result of the increase in the contribution of radiation from the heating furnace to the total thermal flux. Thus at a temperature of ~1000 °C, the radiative thermal flux to the polymer surface is ~0.1 cal cm^{-2} s^{-1}, and the convective thermal flux ~0.05 cal cm^{-1} s^{-1}.

Table 6. Volatilisation constants 10^3 K, cm^2 s^{-1} for PMMA.

Gas streat	10^6 λ, cal $cm^{-1}s^{-1}K^{-1}$*	T_∞°					
		400	500	600	700	800	900
Nitrogen	98	0.5	2.5	4.8	7.0	9.6	13.0
Air	99	0.4	2.2	4.2	6.2	—	—
Helium	670	1.5	3.0	5.0	7.5	11.0	15.5

*The values of λ were taken for the gases at a temperature of 500 °C.[47]

From the neutron activation analysis of hot molten polypropylene[38], it was concluded that oxygen from the surrounding atmosphere is sorbed in the molten polymer layer. Examination of the thermal balance showed that an appreciable proportion of the heat is liberated in oxidation at the surface. It was concluded that if the contribution from external parameters is excluded, the combustion of the polymer is determined by its stability towards thermal oxidation.

On the basis of the results of Ref.29, the authors of Ref.48 examined the propagation of a flame over a polypropylene surface. They found that the temperature of the polymer surface increases from 350 °C to 500 °C with increase in the concentration of oxygen in the stream from 21% to 28%. As in the previous study, they found that the temperature of the flame remains constant at 1308 °C. This was taken as proof of the participation of oxygen in the thermal decomposition of polypropylene and the heating of the surface. Although analogous data were obtained for PMMA, it was stated that in the case of PMMA, surface oxidation does not take place.

The ^{13}C NMR spectra of molten PMMA formed during the combustion of a specimen coincide with the spectra of the original specimen[49]. This confirms indirectly that oxygen does not take part in the reaction in the condensed phase. The combustion of PMMA and MMA in a stream of oxidising agent has been studied, and the temperature profiles and the profiles of the products of the thermal decomposition of the polymer and their subsequent transformation obtained[50]. From an analysis of the profiles of the concentrations of the products in the gas phase and the temperature profiles, it was concluded that the earlier suggestion[29,37,48] that oxidation processes take place on the surface of the condensed phase is not justified. Other conditions being equal, the escape of oxygen through the diffusion flame is the same for the polymer and the monomer, and amounts to 0.5 mole %. This quantity of oxygen is too small for an exothermic reaction to take place on the surface. Oxygen can catalyse only the thermal oxidation of the gaseous thermal decomposition products, but cannot have any significant influence on the thermal decomposition of the condensed phase, since there is a fairly powerful stream of monomer from the surface.

V. MACROKINETICS OF THE THERMAL DECOMPOSITION OF THE POLYMERS

As shown in section I, in the thermal decomposition of polymers, the supply of heat to the surface can take place by one single mechanism or by several mechanisms simultaneously (radiation, convection, conduction, etc.).

Thermal decomposition usually takes place under "quasi-stationary" conditions, when the heat absorbed by the chemical degradation reaction is equal to the heat supplied to the polymer. To determine accurately by formal kinetics the dependence of the mass rate of degradation on the external conditions in each specific case it is necessary to solve the non-stationary thermal conductivity equation, after which the familiar temperature distribution $T(x, \tau)$ within the specimen can be used to determine the mass rate of degradation as

$$\frac{dm(x,\tau)}{d\tau} = K_0 \int_V \rho \exp\left[-\frac{E}{RT(x,\tau)}\right] dV$$

where ρ is the density of the material, K_0 the pre-exponential factor, and E the activation energy of degradation.

The analytical solution of the non-stationary thermal conductivity equation with a sufficient accuracy, even in the spherically symmetrical case for the bulk thermal degradation in a molten polymer and varying thermal flux over the surface of a sphere represents an extremely complex problem, and can be carried out only in particular cases. For many thermal decomposition problems, however, it is sometimes sufficient to examine only the thermal balance equation:

$$q_1 + q_2 + q_3 = \frac{dm}{d\tau} \cdot L + q_4$$

where q_1 is the radiation thermal flux, q_2 the convection or conduction thermal flux, q_3 the thermal flux through the specimen holder, $\frac{dm}{d\tau} \cdot L$ the absorption of heat as a result of the chemical degradation reaction (L is the heat of gasification), and q_4 is the heat used to heat the specimen. The thermal flux of the radiation from the surrounding non-isothermal cavity with an emissivity different from unity is determined in accordance with the geometry of the surroundings and the arrangement of the specimen relative to the surroundings, and is proportional to the emissivity of the material ε.

For an isothermal cavity with a surface area much greater than the surface area of the spherical specimen, the surface absorption is given by[51]:

$$q_1 = 4\pi r^2(\tau)\varepsilon\sigma(T_1^4 - T_s^4)$$

where $r(\tau)$ is the current radius of the sphere, and T_1 and T_S the temperatures of the cavity and the polymer surface.

If the thermal decomposition is carried out in a laminar stream of hot gas, the convective thermal flux to the polymer surface is given by[52]

$$q_2 = \frac{\overline{Nu} \cdot \lambda_f}{d(\tau)} (T_2 - T_s) \cdot S$$

where $d(\tau)$ is the diameter of the sphere, S the area of the sphere, T_2 the temperature of the gas, λ_f the thermal conductivity of the gas at a temperature $(T_2 + T_3)/2$, $\overline{Nu}$ the Nusselt number, which is determined by the geometric dimensions of the specimen and the physical conditions of flow, and $\overline{Nu} = f(Re, Pr)$ is a function of the Reynolds and Prandtl numbers.

For a sphere swept by a gas stream $Pr \approx 1$, and for small $Re \to 0$, $\overline{Nu} \to 2$, and for intermediate values $Re = (0-100)$, $\overline{Nu} = 2(1 + 0.08Re^{2/3})$.[53]

For the thermal decomposition of a polymer specimen in a stationary heated atmosphere, the parameter describing the nature of the motion is not *Re* but another dimensionless quantity—the Grashof number[53]

$$Gr = gd^3\gamma\Delta T/\nu^2$$

where g is the acceleration due to gravity, ν the kinematic viscosity, γ the coefficient of volume expansion of the medium, and ΔT the temperature difference responsible for the convection. For gases, $\gamma \sim 1/T$ and

$$Gr = \frac{gd^3}{\nu^2} \cdot \frac{\Delta T}{T} .$$

For heat exchange by conduction, the thermal flux to the surface of a sphere will be given by the equation

$$q_2' = \lambda_f \left.\frac{dT}{dr}\right|_{r=r(\tau)} \cdot S$$

where $S = 4\pi r^2(\tau)$ is the area of the surface of the sphere.

The thermal flux q_3 must be determined or calculated in each specific case, depending on the type of holder (quartz capillary, support, thermocouple wire, etc.). In thermal decomposition experiments it is desirable to decrease the flux q_3, since it is difficult to estimate its magnitude with sufficient accuracy, as it may show a complex dependence on the geometric dimensions. q_3 can be estimated for the thermal decomposition of a specimen on the junction of a Pt–Pt/Rh thermocouple with diameter $\delta = 0.02$–0.05 mm. The emissivity of platinum is assumed to be zero[47,54]. The purely convective heating of the wire is examined under the most favourable conditions, when its axis of symmetry is perpendicular to the thermal flux. The thermal conductivity equation for the temperature distribution along the axis of the wire from the surface of the specimen has the form

$$\lambda_{Pt} \cdot \frac{\partial^2 T(x)}{\partial x^2} = \frac{\overline{Nu}\lambda_f}{2\delta} [T_2(x) - T_3(x)] \frac{dS}{dV} \qquad (5)$$

with boundary conditions

$$T_3(x)|_{x=0} = T_s,\ T_3(\infty) = T_2(\infty)$$

where $T_3(x)$ and $T_2(x)$ are the temperatures of the wire and the gas at a distance x along the axis of the thermocouple, $dS/dV = 2\pi\delta\Delta x/\pi\delta^2\Delta x = 2/\delta$; and λ_{Pt} the thermal conductivity of platinum. For the gas it will be assumed that $Pr = 1$. The temperature fields and the flux rate fields at the polymer surface are then similar

$$\frac{T_2 - T_3}{v_0} = \frac{T_2(x) - T_s}{v(x)} \qquad (6)$$

where v_0 and $v(x)$ are the flux rates at a sufficient distance from the specimen and at a distance x from the specimen.

For small values $1 < Re < 4$, the following equation is applicable[52]

$$Nu \approx 0.891 \cdot \left(\frac{v_0 2\delta}{\nu}\right) \cdot 0.33 \qquad (7)$$

From Eqns.(6), (7), and (5),

$$\lambda_{Pt}\left[\frac{\partial T_3(x)}{\partial x}\right]^2 = \int_0^\infty \frac{2\lambda_f}{\delta^2}\left[\frac{T_2(x) - T_s}{T_2 - T_3}\right]^{0,33} \cdot 0.891\,[T_2(x) - T_3(x)]\left(\frac{v_0 2\delta}{\nu}\right)^{0,33} dT_3(x) .$$

The maximum value of the integral is obtained for $T_2(x) = T_2$

$$\left.\frac{dT_3(x)}{dx}\right|_{x=0} = \sqrt{\frac{\overline{Nu}}{\delta^2} \cdot \frac{\lambda_f}{\lambda_{Pt}}} \cdot (T_2 - T_3)$$

$$q_3 = 2\lambda_{Pt} \cdot S \left.\frac{dT_3}{dx}\right|_{x=0} = 2\lambda_{Pt}\pi\delta \sqrt{Nu\frac{\lambda_f}{\lambda_{Pt}}} (T_2 - T_s) .$$

The maximum value of q_3 for the thermal decomposition of a polymer drop on a Pt–Pt/Rh thermocouple ($d = 0.02$–0.05 mm, $\lambda_f = 0.6 \times 10^{-4}$ cal cm^{-1} s^{-1} K^{-1}, $Nu = 0.5$, $\delta = 0.0025$ cm, $\lambda_{Pt} = 0.8$ cal cm^{-1} s^{-1} K^{-1}, ($T_2 - T_S \cong 250°$) is ~0.5×10^{-2} cal cm^{-2} s^{-1}.

To estimate q_4, the heat used to heat the specimen, it is necessary to solve the non-stationary thermal conductivity equation. For the thermal decomposition of a uniformly heated specimen, however, this term can be neglected. For large values of *Bi*, the surface degradation of a spherical specimen should take place with a quasi-stationary temperature profile, and q_4 will decrease with decrease in the current radius of the sphere, since *Bi* decreases. For high initial radii of a spherical specimen and high values of *Bi*, the temperature profile in the condensed phase will tend to the Mikhel'son distribution.

The heating term tends to the value $q_4 = c\rho U(T_S - T_0)$ or

$$q_4 = \frac{dm}{d\tau} \cdot c \cdot (T_s - T_0)$$

and this term can be combined with $L \cdot \frac{dm}{d\tau}$ to give:

$$q_1 + q_2 + q_3 = \frac{dm}{d}[L + c(T_s - T_0)] = \frac{dm}{d\tau} L_{eff} .$$

Thus depending on the diameter of the sphere, different effective heats of gasification of PMMA are obtained, from ~200 cal g^{-1} [55] for the completely heated specimens (diameter up to 1–2 mm), to ~400 cal g^{-1} [19,26] for linear thermal decomposition (large diameters).

For a heated drop of polymethyl methacrylate, the radiation flux for a drop diameter of about 1 mm and a temperature of the wall of the heater of 1000 °C is ~0.10 cal cm^{-2} s^{-1}. The degree of blackness of the polymer is 0.9.[42,54] The convective flux in this case is ~0.05 cal cm^{-2} s^{-1}. The value of q_3 is always smaller than 0.5×10^{-2} cal cm^{-2} s^{-1}, so that q_3 can be neglected, compared with the thermal flux. The thermal decomposition of the heated drop for a constant temperature throughout its volume is proportional to the mass of the specimen, that is

$$\frac{dm}{d\tau} = mK_0 \exp(-E/RT_s) .$$

The thermal balance equation with allowance for convection and radiation can be written as:

$$\frac{dm}{d\tau} = mK_0 \exp(-E/RT_s) = \frac{1}{L_{eff}} \cdot \sum_i q_i = \frac{S}{L_{eff}}\left[\varepsilon\sigma(T_1^4 - T_s^4) + \frac{Nu\lambda_f}{d}(T_2 - T_s)\right] \qquad (8)$$

where L_{eff} is the heat of gasification of the polymer.

The kinetic curve for the thermal decomposition of PMMA in Fig.1 gives the mass loss and the change in the temperature of the polymer specimen. Fig.1 shows that in the first period before the polymer specimen has melted, the thermocouple records the mean temperature between T_S and T_∞, but when the specimen has been heated and melted, it covers the junction of the thermocouple, which records the temperature of formation of the drop T_S.

In this period there is a considerable change in the density of the polymer sphere from 1.19 g cm^{-3} to ~0.8 g cm^{-3}, after which the density remains practically constant. The decrease in the density is due to the increase in the volume[26] (surface area) as a result of the formation of bubbles of the degraded monomer in the bulk. The monomer formed cannot leave the polymer surface immediately, since the rate of formation of the gas phase is greater than the rate of diffusion of the

bubble to the surface. With increase in the temperature of the specimen, the viscosity decreases, and the size of the bubbles reaching the surface is stabilised, and in this range (region II) it may be assumed that ρ is constant and equal to ~0.8.

Region III is characterised by small dimensions of the polymer drop, and in this region it is not possible to neglect the supply of heat through the holder (in the present case through the thermocouple) in the thermal balance equation.

Region II, in which the main mass loss takes place during thermal decomposition, is characterised by a constant smooth increase in the temperature of the drop from T_{s1} to T_{s2} (here we are dealing with the temperature of the entire drop, and not its surface, since all the specimen "boils" vigorously and there is good heat exchange within it, $dT/dr \to 0$).

To understand the increase in temperature in region II, Eqn.(7) is transformed, with the assumption that ρ = const, to the form:

$$L_{\text{eff}} K_0 \exp(-E/RT_s) = \frac{7{,}5\varepsilon\sigma(T_1^4 - T_s^4)}{d} + \frac{7{,}5\lambda_f Nu(T_2 - T_s)}{d^2} \quad (9)$$

It is obvious that with change in T_S by 30–40 K, the difference $(T_1^4 - T_S^4)$ remains practically unchanged, but the difference $(T_2 - T_S)$ decreases by ~5–7%. Thus by introducing the symbols

$$75\varepsilon\sigma(T_1^4 - T_s^4)/L_{\text{eff}}K_0 = A,\ 75\lambda_f Nu(T_2 - T_s)/L_{\text{eff}}K_0 = B_0$$

Eqn.(9) can be transferred to:

$$\exp(-E/RT_s) = \frac{A}{d} + \frac{B}{d^2} \quad (10)$$

Eqn.(10) shows that with decrease in the diameter during the experiment, both terms in the right-hand side increase, leading to an increase in T_S. To follow the dependence of the temperature of the heated drop T_S on the magnitude of the thermal flux, the diameter of the drop in Eqn.(9) is fixed:

$$d = \text{const};\ \frac{75\varepsilon\sigma}{dL_{\text{eff}}K_0} = C;\ \frac{75\lambda_f Nu}{d^2 L_{\text{eff}}K_0} = D$$

$$\exp(-E/RT_s) = C(T_1^4 - T_s^4) + D(T_2 - T_s). \quad (11)$$

Fig.6 gives the graphical solution of Eqn.(11), the intersection of curves *1* and *4*, and gives the required "quasi-equilibrium" temperature of the polymer specimen during thermal decomposition. It is obvious that with increase in the thermal flux to the polymer at a fixed diameter, the temperature of the specimen increases. For thermal fluxes which are not too large, there is only a slight change in the value of T_S.[56]

A number of papers[18,23,24,29,33] give data on the dependence of T_S for various thermoplastic polymers on either the thermal flux power or the temperature of the stream and the temperature of the radiant source, confirming the above conclusions.

Published data[24] on the mass rates of thermal decomposition and the corresponding temperatures were used to obtain graphically (Fig.7) the values of the kinetic parameters for the thermal decomposition of various polymers, given in Table 7.

Data on the thermal decomposition of small and large spherical polymer specimens under combustion conditions have been published[26,33]. The flame zone in the combustion of spherical particles lies close to the polymer surface, and heat exchange between the flame and the surface of the sphere takes place by conduction[33]. According to the theory developed[57–60] for the combustion of hydrocarbon liquids from porous spheres and the combustion of single droplets, the mass rate of combustion can be represented as

$$\frac{dm}{d\tau} = \frac{4\pi\lambda_f r}{c_p} \ln\left[1 + \frac{c_p(T_f - T_s)}{\Delta H - a}\right] \quad (12)$$

where c_p is the heat capacity, $\Delta H = (L + c_p\Delta T)$ the enthalpy of gasification of the polymer, $a = Ra/\frac{dm}{d\tau}$ defines the contribution of the radiation from the flame, and T_f is the temperature of the flame. Eqn.(12) was obtained assuming conductive heat transfer by integrating the thermal flux from the flame over the surface of the specimen. Since the flame of thermoplastic polymers is transparent, the term *a* can be neglected, so that the integration of (12) with respect to time gives the law governing the change in the dimensions of the specimen during thermal combustion

$$d^2 = d_0^2 - \frac{8\lambda_f}{c_p\rho} \ln\left(1 + \frac{c_p\Delta T}{\Delta H}\right) \cdot \tau$$

Introducing the symbol

$$\frac{8\lambda_f}{c_p\rho} \ln\left(1 + \frac{c_p\Delta T}{\Delta H}\right) = K$$

gives

$$d^2 = d_0^2 - K\tau$$

the law obtained for the volatilisation of a drop of liquid[61].

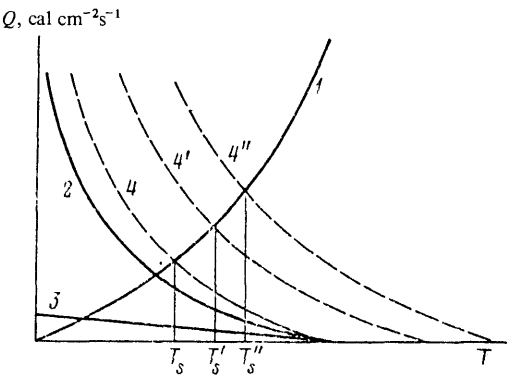

Figure 6. Graphical solution of Eqn.(11).

The change in the diameter of the polymer specimen with time is given in Fig.8.[26]

In this case and in the case of the combustion of large specimens (diameter up to 10 mm),[33] a linear time dependence of the surface area of the sphere is formally observed, since

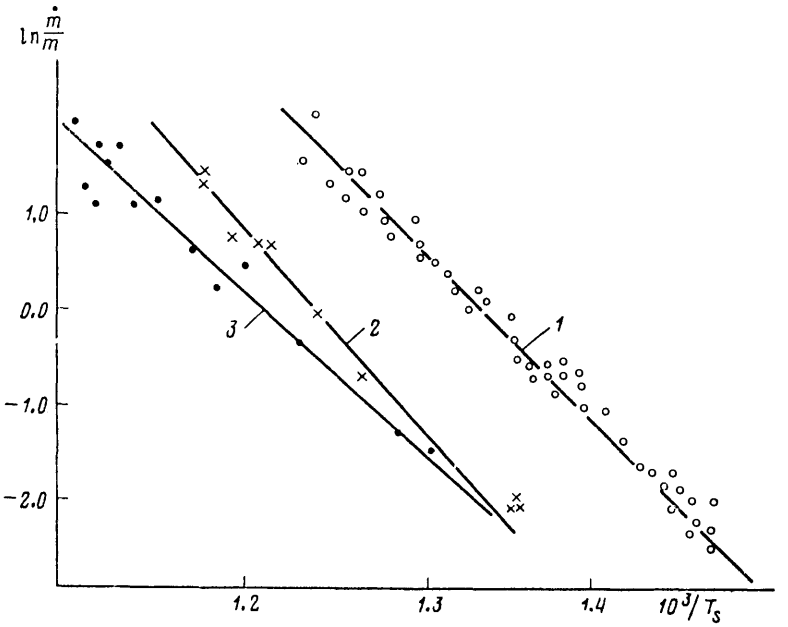

Figure 7. Plot of $\ln \dot{m}/m$ against $10^3/T$ during thermal decomposition: *1*) polymethyl methacrylate, *2*) polystyrene, *3*) polyethylene.

the rate of the process is determined by the rate of heat transfer from the flame to the polymer surface. The exact calculation of the kinetics of the thermal decomposition in the combustion of specimens with a large diameter is an extremely complex problem, because the process is non-stationary. Here, the situation is intermediate between bulk and linear thermal decomposition. In fact, the dependence of $\ln \dot{m}/m$ on $1/T_S$ for a fixed diameter and temperature within the sphere[33] gives a straight line with slope smaller than E but greater than $E/2$.[62] As with bulk thermal decomposition, the absolute values of the mass rates of thermal decomposition are determined by the power of the thermal flux to the polymer surface.

Research workers have paid most attention to the linear thermal decomposition of thermoplastic polymers[8–16]. In this case the temperature distribution in the condensed phase will be determined by Eqn.(2), as confirmed by the data in section II and Ref.43, obtained in a study of heat transfer during the combustion of polymers, and the rate of linear thermal decomposition can be calculated from the relationship[63]

$$U = K_0 \int_0^\infty \exp\left[-E/RT\,(U, x)\right] \mathrm{d}x \,. \qquad (13)$$

The integral was calculated[64] using the Frank-Kamenetskii expansion of the exponent[53] to give

$$U^2 = aK_0 \exp(-E/RT_s) \frac{RT_s^2/E}{T_s - T_0 - \frac{1}{2}\frac{Q}{c\rho}} \,. \qquad (14)$$

The equation obtained is applicable for the model of the linear thermal decomposition of a semi-infinite mass. The effective energy of activation is equal to half the true activation energy. Linear thermal decomposition is usually studied using round rods of finite dimensions, for which heat losses from the lateral surface of the specimen may be significant[65]. Shteinberg[66] examined the regular features of linear thermal decomposition with heat losses, and determined the criterion for the change to the region in which external heat losses can be neglected. By assuming that the temperature field was one-dimensional, that is that the length of the specimen l was much greater than its diameter $d = 2r$, and that the heat losses are limited by external heat exchange between the lateral surface of the specimen and the surrounding medium, the thermal conductivity equation can be written in the form:

$$\frac{\mathrm{d}^2T}{\mathrm{d}x^2} + \frac{M}{\delta}\frac{\mathrm{d}T}{\mathrm{d}x} - \frac{QK_0}{ac}\exp(-E/RT_s) - \frac{Bi}{\delta^2}-(T\ T_\infty)$$

with boundary conditions

$$T|_{x=0} = T_s$$
$$T|_{x\to\infty} = T_\infty$$

where δ is the half-thickness of the plate (or radius of the cylinder), $M = U\delta/a$ is the Mikhel'son (Peclet) number, $Bi = \alpha\delta/\lambda$ the Biot number, and Q the heat of the reaction.

The expression obtained by Shteinberg for the rate of linear thermal decomposition has the form

$$U^2 = \frac{2aK_0T_s^2 \exp(-E/RT_s)}{E\left[(T_s - T_\infty)\left(1 + \sqrt{1 + 4Bi/M^2}\right) - \frac{Q}{C}\right]} \,.$$

For high rates of linear thermal decomposition and relatively small external heat losses, that is for $4Bi/M^2 \ll 1$, the limiting case of the thermal decomposition of a semi-infinite continuum of Eqn.(14) is obtained, and $U \sim \exp(E/2RT_S)$. For low rates, that is $4Bi/M^2 \gg 1$

$$U = \frac{K_0\delta RT_s^2 \exp(-E/RT_s)}{E(T_s - T_\infty)\sqrt{Bi}} \,. \qquad (15)$$

Eqn.(14) shows that with increase in the relative heat losses there is a qualitative change in the nature of the dependence of the rate of linear thermal decomposition on the temperature of the surface, $U \sim \exp(-E/RT_S)$. This is related to the fundamental difference in the dependence of

the width of the reaction zone on the parameters of the process. In the first case, $\Delta \cong a/U$, that is Δ increases without restriction with decrease in the rate of the process. In the second case, $\Delta = \delta\sqrt{Bi}$, that is it is practically constant, since it depends only on the defining dimension of the specimen and the heat exchange criterion Bi. Fig.9 gives the dependence of the rate of the linear thermal decomposition of polymethyl methacrylate on the reciprocal of the temperature of the surface on semilogarithmic coordinates.

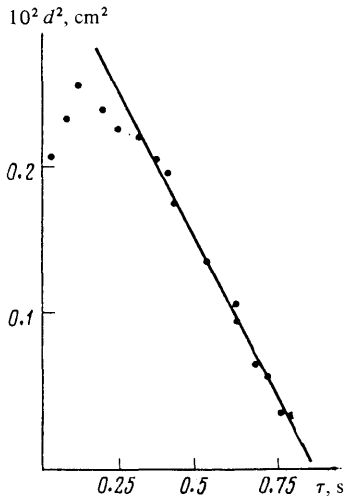

Figure 8. Change in the square of the drop diameter with time.

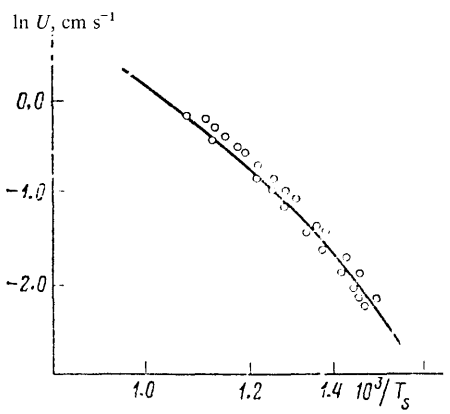

Figure 9. Dependence of the rate of the thermal decomposition of PMMA on $1/T_S$.[16]

Fig.9 shows that in the high-temperature range for large thermal fluxes, the effective value of the activation energy is $E/2$, and the pre-exponential term is equal to K_0. With decrease in the rate of linear thermal decomposition, there is a clearly defined change to the second range, where $U \sim \exp(-E/RT_S)$, that is the activation energy and the pre-exponential term acquire their true values.

It should be noted that the temperature distribution in the condensed phase during thermal decomposition will be more complex than the relationship given by Eqn.(2). Thus the distribution (2) was obtained from the solution of the thermal conductivity equation without a source or sink, with a boundary moving at a rate U. The true temperature distribution in the condensed phase can be obtained only with allowance for the chemical degradation reaction taking place in the surface layer of the condensed phase. In the surface layer of the molten polymer, where intensive degradation is taking place, the bubbles of gaseous degradation products lead to intensive mixing of the melt ("boiling"), and the heat transfer process differs considerably from conduction. The temperature gradient in this layer is $dT/dx \to 0$. For the second zone, where it is possible to neglect the chemical reaction, the temperature distribution along the x axis should be obtained from the solution of the thermal conductivity equation without a source, as in Ref.36, but only with allowance for the temperature dependence of the thermal conductivity coefficient, which increases markedly with increase in T in the range of temperatures produced during linear thermal decomposition on the surface of a polymer.

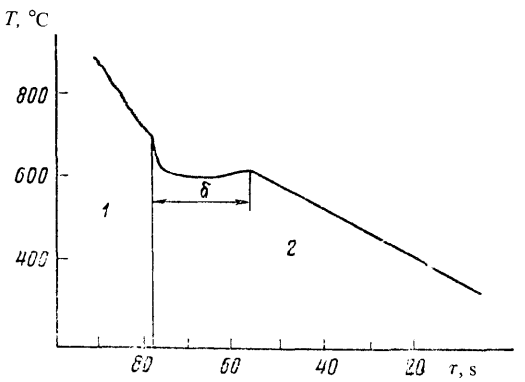

Figure 10. Temperature profile in the condensed phase in the thermal decomposition of thermoplastic polymers[67]; δ is the "boiling layer"; *1*) gas phase; *2*) condensed phase.

The existence of a boiling layer on a polymer surface during linear thermal decomposition was observed by a number of workers[25,67]. Fig.10 gives the temperature profile in the condensed phase obtained in Ref.67 for the thermal decomposition of PMMA. The thickness of the heated layer and the layer of melt in the thermal decomposition of polystyrene is inversely proportional to the rate of the thermal decomposition[43]. The same conclusion was reached in an analysis[25] of data on the thermal decomposition of polymethyl methacrylate Since the temperature distribution, as a result of intensive, heat exchange in the layer δ, is analogous to that shown in Fig.10, the rate of the linear thermal decomposition, in accordance with Eqn.(13), can be written as

$$U = K_0 \int_0^\infty e^{-E/RT(x)}\,dx = K_0 \int_0^\delta e^{-E/RT(x)}\,dx + K_0 \int_\delta^\infty e^{-E/RT(x)}\,dx . \quad (16)$$

Under the conditions of extensive heat exchange in the "boiling" layer, $T(x) \cong$ const in the range $0 \leq x \leq \delta$. Assuming that the reaction takes place at an appreciable rate only in the layer δ, the second integral in Eqn.(16) can be neglected,

and the rate of linear thermal decomposition is

$$U = K_0 e^{-E/RT_s} \int_0^{\delta} dx = K_0 \delta e^{-E/RT_s}$$

and the condition $\delta \sim 1/U$ gives $U^2 \cong K_0 e^{-E/RT_s}$, that is the same dependence of the rate of linear thermal decomposition on the reciprocal of the temperature as in Eqn.(14).

The kinetic characteristics of the degradation of PMMA, K_0 and E, obtained by the study of high-temperature thermal decomposition coincide with the values of K_0 and E obtained for "bulk isothermal" degradation[1,3]. This agreement indicates that on going from the low-temperature to the high-temperature range, the mechanism of the degradation apparently remains unchanged. The conclusions reached by various authors that the mechanism changes may be due chiefly either to the inaccuracy of the measurement of the temperature of the polymer surface during thermal decomposition or to the neglect of the complex macrokinetics in each specific case (the complex temperature profile, which changes with time and with change in the external conditions). Thus to reach final conclusions about the mechanism, it is necessary to carry out new studies with accurate allowance for all factors.

Enzymic Conversion of Racemates into Aminoacid Enantiomers

V.Švedas and I.U.Galaev

The present state of the art and prospects for further development in the employment of enzymes for the resolution of aminoacid racemates or the conversion of racemates of a series of chemical compounds into optically pure aminoacids are considered. A comparative survey of studies involving the use of aminoacylases, proteases, hydantoinases, α-aminocaprolactam hydrolase, and a number of other enzymes for the preparation of L- and D- aminoacids has been carried out. Examples are presented of processes involving the enzymic resolution of racemates on an industrial scale. The kinetic and thermodynamic features of the enzymic reactions employed have been analysed in detail and the limits in the employment of a particular enzyme for the conversion of racemates into optically pure aminoacids are accounted for.
The bibliography includes 288 references.

I. INTRODUCTION

The synthesis of optically pure aminoacids has become an increasingly urgent problem of modern biotechnology in recent years. Its solution by purely chemical means involves many difficulties. The chemical synthesis of optically active aminoacids has been achieved so far only in the manufacture of L-3,4-dihydroxyphenylalanine (L-DOPA) by the enantioselective hydrogenation of an α,β-unsaturated derivative in the presence of rhodium complexes of chiral phosphines[1]. The manufacture of L-DOPA is a rare example of a process in which the cost of an extremely expensive catalyst can be neglected in the synthesis of an expensive final product. The industrial chemical synthesis of the remaining aminoacid enantiomers remains at the present time no more than a theoretical possibility.

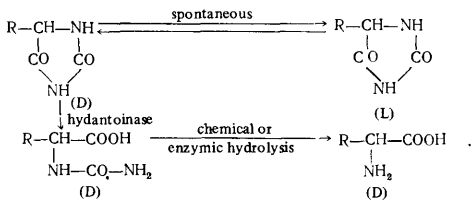
The manufacture of L- and D-aminoacids by the physicochemical resolution of racemic mixtures of aminoacids obtained by large-scale chemical synthesis (for the chemical synthesis of aminoacids, see the review of Safonova and Belikov[2]) is also not free from disadvantages. Thus the preparation of an enantiomer by the selective crystallisation of a supersaturated solution of the racemate has been achieved only for glutamic acid[3]. The highly effective enantioselective chromatography, which is being activity developed at the present time, has so far found practical applications only in the preparation of optically active compounds labelled by radioactive isotopes[4]. The available methods for the selective crystallisation of the diastereoisomers of aminoacids and any other optically active compounds require the search for and synthesis of the latter, which limits the practical application of this method.

New possibilities for the synthesis of aminoacids have arisen in connection with the development of genetic engineering methods which have given rise to the highly effective industrial production, in the first place of L-lysine, L-histidine, L-arginine, L-threonine, L-isoleucine, and L-valine[5]. The difficulties involved in the employment of this technology are associated primarily with the isolation of the required compond from the culture liquid containing other metabolic products, including many physiologically active compounds, and also with the establishment and maintenance of the properties of the producing agent.

One of the promising ways of obtaining optically pure aminoacids involves the use of individual enzymes. There are two fundamental possibilities for the enzymic preparation of aminoacid enantiomers. The first involves the synthesis, catalysed by many enzymes (aspartate ammonia-lyase, L-tyrosine phenol-lyase, L-tryptophan indole-lyase, phenylalanine ammonia-lyase, etc.), of L-aminoacids from optically inactive precursors, for example, of L-tryptophan and L-tyrosine from ammonia, pyruvate, indole, or phenol[6]. In the present review we shall not discuss the possibility of the employment of this approach to the synthesis of aminoacids, since it has already been considered in detail[7,8].

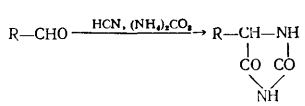
The second possibility of employing individual enzymes consists in the enzymic conversion of the simplest racemic aminoacid derivatives into the optically pure L- and D-aminoacids. Such enantioselective enzymic reaction results in the formation of a single unreacted optical isomer and the other optical isomer which has undergone chemical modification. The resulting differences between chemical properties make it possible to separate them readily. The presence of two fairly reactive groups in the aminoacid molecule (the carboxy- and amino-groups), linked to the asymmetric carbon atom, permits a large number of similar enantioselective modifications of the aminoacid molecule by various enzymes.

The first attempts at the employment of living organisms for the separation of aminoacid racemates were based on the ability of animals to assimilar only one optical isomer. When an animal was fed or administered a racemic aminoacid, the D-enantiomer, which had not been assimilated, could be isolated from its urine[9,10]. Despite its evident disadvantages (the permanent loss of half of the starting material, the difficulty of isolating the product from a mixture containing a whole series of all possible organic compounds, and the consequent formation of the aminoacid D-enantiomer which is usually physiologically less active and hence less valuable), this method has still not lost its importance. Thus a patent was taken out in 1976 in Japan for the preparation of D-aminoacids and their esters by treating the racemic aminoacid with the cells of the micro-organisms *Mycoplasma*, *Protaminobacter*, *Acetobacter*, *Pseudomonas*, *Aeromonas*, *Xanthomonas*, and *Bacillus*[11]. As a result of this procedure,



the L-isomer was assimilated by the bacteria, while the D-isomer was isolated from the culture medium after separating the cells by centrifugation.

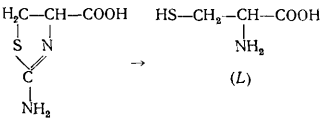
A much greater success was achieved by employing separate enzyme preparations purified to different extents. In this case only one chemical reaction takes place and it is possible to isolate both aminoacid enantiomers. At the present time all enzymic methods for the resolution of aminoacid racemates can be divided into the following groups, which are listed in order of their increasing practical value and the extent to which they are used: (1) specific methods for the resolution of racemates suitable only for individual aminoacids (lysine, cysteine, and aromatic aminoacids); (2) stereoselective oxidation and decarboxylation of aminoacids; (3) enantioselective synthesis of the amide bond; (4) stereoselective hydrolysis of aminoacid amides and esters; (5) enantioselective hydrolysis of *N*-acylated aminoacids.



II. ENZYMIC CONVERSION OF CYCLIC AMINOACID DERIVATIVES

1. 5-Substituted Hydantoins

When enzymes are used for the resolution of aminoacid racemates into optical isomers, the problem of the utilisation of the enantiomer which has not reacted arises. It is usually solved by its chemical racemisation and the return of the resulting racemate to the resolution process. However, in the case of hydantoin derivatives of aminoacids the racemisation takes place spontaneously at fairly high rates even under the conditions of enzymic enantioselective hydrolysis. Thus the half-racemisation time of 5-phenylhydantoin at pH 8.5 and 30 °C in 0.25 M solution is 19 min[12]. This made it possible to put forward the following scheme for the enzymic resolution of aminoacid racemates using hydantoinase (dihydropyrimidinase, EC 3.5.2.2) which hydrolyses 5-substituted D-hydantoins stereoselectively:



Although the formation of *N*-carbamoylaminoacids from hydantoins in the organism was observed in 1926 [13] and the possibility of the enzymic resolution of racemates was demonstrated as early as 1930,[14] the preparation of optically active aminoacids by this procedure has acquired practical importance only recently. 5-Substituted DL-hydantoins can be synthesised in a single stage from the corresponding aldehydes by the Bucherer reaction[15]:

Calf liver dihydropyrimidinase cleaves the ring of dihydropyrimidines with formation of *N*-carbamoyl-β-aminoacids[16] and is identical with the enzyme which converts hydantoin into *N*-carbamoylglycine[17]. It is of interest to note that the opening of the dihydropyrimidine or hydantoin ring is a reversible process and that the reverse reaction can be achieved under acid conditions[16,18]. The bovine liver hydantoinase catalyses the enantioselective hydrolysis of D-hydantoin derivatives of α-aminophenylacetic α-amino-*p*-chlorophenylacetic acids, leucine, alanine, methionine, and valine. The D-derivatives of glutamic and aspartic acids and tryptophan are resistant to the action of the enzyme[12,19]. Hydantoinase has been found in a whole series of microorganisms: *Klebsiella*, *Corynebacterium*, *Agrobacterium*, *Pseudomonas*, and *Bacillus*[20]. The strain *Pseudomonas striata* IFO 12 996 has proved most suitable for practical applications. The hydantoinase is induced by DL-5-methylhydantoin (a hydantoin derivative of alanine). Other hydantoins are inert or actually suppress the biosynthesis of the enzyme[21]. The hydantoinase from *Ps. striata* was purified to a homogeneous state and was obtained in a crystalline form. Its molecular weight is 190 000 and it consists of four identical subunits[22]. Tables 1 and 2 indicate the substrate specificity of the hydantoinase from *Ps. striata*. 5,5-Disubstituted hydantoins are not cleaved by the enzyme. The hydantoinase from *Corynebacterium sepedonicum* and *Aerobacter cloacae* differs somewhat in its substrate specificity from the enzyme obtained from *Ps. striata*[23]. Thus the best substrate for the latter is DL-5-*m*-chlorophenylhydantoin, while for the former the best substrate is DL-5-*p*-chlorophenylhydantoin. A hydantoinase which effectively hydrolyses the hydantoin derivatives of various substituted 5-phenylhydantoins, particularly 5-thienylhydantoin, has been isolated from the micro-organisms *Bacillus sp.* 121-3.[24,25] The strains of the soil micro-organisms T-524, T-639, and especially T-523 effectively convert 4,5-indolylmethylhydantoin into tryptophan, exhibiting not only the hydantoinase but also the N-carbamoylhydrolase activity. The optical purity of the L-tryptophan obtained in this way from the racemic hydantoin reaches 99.1%.[26] L-Glutamic acid can be obtained from DL-5-β-carboxyethylhydantoin with the acid of the micro-organism *Bacillus brevis* ATCC 8185. When it is cultured in a weakly alkaline medium containing 1.0% of DL-5-β-carboxyethylhydantoin, it is possible to convert 90% of the racemate into L-glutamic acid. The enzyme system responsible for this reaction is induced by the addition of the initial substrate to the medium[27]. A reactor capable of processing up to 3 kg of hydantoin per day has been devised on the basis of calf liver hydantoinase incorporated in triacetate fibres. The half-life of the catalyst at pH 8.5 at 30 °C was 20 days[12].

2. 2-Amino-Δ^2-thiazoline-4-carboxylic Acid

L-Cysteine can be obtained from DL-2-amino-Δ^2-thiazoline-4-carboxylic acid using *Pseudomonas* cells[28]:

The reaction yield is close to 100% because the hydrolysis of the thiazoline ring of the L-isomer is accompanied by the racemisation of the D-enantiomer of the substrate in the reaction mixture. The strain *Pseudomonas thiazolinophylum* AI3854 showed the highest activity among the 463 strains of the 37 species tested. The enzyme (or enzyme system) responsible for the conversion is an induced intracellular enzyme closely associated with cell growth. Further degradation of cysteine (or cystine) can be prevented by introducing hydroxylamine or semicarbazide into the reaction medium and inhibiting thereby the pyridoxal 5'-phosphate-dependent cysteine desulphhydrase. The addition of Mn^{2+} (5 mM) and Fe^{2+} (25 mM) ions increases the overall activity of the enzyme

system by a factor of 5–7 and in addition the presence of Mn^{2+} ions at a concentration of 1–10 mM has a stabilising effect on the activity. When intact cells of *P. thiazolinophylum* AI3854 were used, a sigmoid time variation of the accumulation of L-cysteine was observed, but treatment of the cells with ultrasound eliminated this effect and led to a linear relation[29].

Table 1. The substrate specificity of the hydantoinase from *Ps. striata*[20].

D-substrate 

R	Relative rate of hydrolysis*	R	Relative rate of hydrolysis*
H	13	*p*-HO—C_6H_4	16
CH_3	45	*m*-HO—C_6H_4	5
$(CH_3)_2CH$	15	*p*-Cl—C_6H_4	19
CH_3—S—CH_2—CH_2	48	*m*-Cl—C_6H_4	10
$(CH_3)_2CH$—CH_2	48	*p*-CH_3O—C_6H_4	7

3. α-Aminocaprolactam

A very promising method of preparation of L-lysine from DL-α-aminocaprolactam (DL-ACL), proposed by the Japanese company Torrei Industries[30,31], is based on the use of the L-aminocaprolactam hydrolase–α-aminocaprolactam racemase two-enzyme system:

Caprolactamase has been isolated from various micro-organisms: *Bacillus circulans, Bacillus firmas*[32], *Cryptococcus laurentii, Candida humicola, Trichosporon cutaneum, Achromobacter cycloclastes, Achromobacter obae, Flavobacterium arborescens*, and *Alcaligenes faecalis*[33,34]. The strains of *Cryptococcus laurentii, Candida humicola*, and *Trichosporon cutaneum*, whose properties have in fact been studied in detail, proved to be the most promising[35]. Caprolactamase was purified to a homogeneous state. The enzyme consists of two subunits with a molecular weight of 67 000, a sedimentation constant of 4.4 S, and an isoelectric point $pI = 5.7$.[36,37] Caprolactamase is a metalloenzyme and its activity is fully suppressed in the presence of 7 mM *o*-phenanthroline but can be restored in the presence of Mg^{2+}, Mn^{2+}, or Zn^{2+} ions (but not Co^{2+} and Ni^{2+}) up to 30–70% of the initial value[31,37]. At pH 8.5 and 37 °C the catalytic constant of the enzyme hydrolysis of L-α-aminocaprolactam is 750 s^{-1}.[31] The enzyme hydrolyses L-α-amino-δ-valerolactam three times less effectively and D-α-amino-ε-caprolactam twenty times less effectively than L-α-aminocaprolactam and does not exhibit activity in relation to γ-butyrolactam, δ-valerolactam, ε-caprolactam, cyclic oligomers of ε-caprolactam, α,α-dichloro-ε-caprolactam, and DL-pyrrolidinone carboxylic acid[30]. Caprolactamase has recently been found to show activity in relation to L-lysinamide which is hydrolysed by the enzyme twice less effectively than L-α-aminocaprolactam[36,37]. The Michaelis constant for the hydrolysis of L-α-aminocaprolactam is 2.6 mM and that for the hydrolysis of L-lysinamide is 14 mM.[37] At high substrate concentrations the enzyme is inhibited both by the substrate and by the L-lysine formed. The reaction can be described by the equation[39]

$$\frac{d[S]}{dt} = \frac{k_{cat}[E][S]}{\left(K_M + [S] + \frac{[S]^2}{K_S}\right)\left(1 + \frac{[P]}{K_i}\right)} ,$$

where E, S, and P are respectively caprolactamase, L-α-aminocaprolactam, and L-lysine, $K_M = 0.023$ M, the substrate inhibition constant $K_S = 1.54$ M, and the product inhibition constant $K_i = 3.23$ M.

By selecting micro-organisms capable of growing on media containing only L- or D-α-aminocaprolactam as the only source of nitrogen and the main source of carbon, micro-organisms producing α-amino-ε-caprolactam racemase were selected: *Achromobacter obae, Achromobacter cycloclastes, Alcaligenes faecalis*, and *Flavobacterium arborescens*. The *Achromobacter obae* strain showed the highest activity[30]. The racemase was isolated and partly purified. Its molecular weight was 54 000 and the pH optimum of its activity was 7.5–9.0. The activity of the racemase is fully inhibited by hydroxylamine (10^{-4} M), but is restored following the addition of pyridoxal 5′-phosphate. At higher concentrations (>10^{-4} M) pyridoxal 5′-phosphate is a racemisation inhibitor[40]. Substrate inhibition is characteristic of the racemisation reaction catalysed by lyophilised cells. In addition L-lysine, inevitably present when the hydrolysis of L-α-aminocaprolactam and the racemisation of D-α-aminocaprolactam are carried out in a single reactor, is a powerful non-competitive inhibitor of this reaction. In the real process one must take into account also the inactivation of the racemase in the course of the reaction[39].

The optimum process pH depends on the ratio of the catalytic amounts of racemase and caprolactamase and shifts towards the pH optimum of the enzyme limiting the rate of the entire process. For a periodic reactor, in which the enzyme ratio can be varied during the process, the principal characteristic is the ratio

$$f = \frac{[\text{racemase}]}{[\text{racemase}] + [\text{caprolactamse}]} \quad (0 \leqslant f \leqslant 1) \ .$$

If the concentration is expressed in mole fractions, and k_1 and k_2 are the rate constants for the racemisation and hydrolytic reactions, then the composition of the reaction medium as a function of time can be described by the following system of equations:

$$\frac{d[D\text{-ACL}]}{dt} = fk_1([L\text{-ACL}] - [D\text{-ACL}]);$$

$$\frac{d[L\text{-ACL}]}{dt} = fk_1([D\text{-ACL}] - [L\text{-ACL}]) - (1-f)k_2[L\text{-ACL}];$$

$$[L\text{-ACL}]_0 = [D\text{-ACL}]_0 = 0.5 \ .$$

Initially the optimum condition is that the processes occur at $f = 0$, i.e. when the racemase is absent. Subsequently the optimum condition involves the occurrence of the reaction when [D-ACL]/[L-ACL] = 1 + α, where $\alpha = (k_2/k_1)^{1/2}$. Under these conditions, the optimum enzyme ratio is defined by the expression

$$f = \frac{\alpha(1+\alpha)}{1+(1+\alpha)^2} \ .$$

The optimum composition of the biocatalyst depends only on the ratio α. If the latter remains constant during the reaction, the process can be carried out by the optimum procedure[39].

III. ENANTIOSELECTIVE OXIDATION AND DECARBOXYLATION

Strictly speaking the enantioselective oxidation and decarboxylation of aminoacids does not constitute the resolution of aminoacid racemates because such reactions lead to the loss of half of the starting material. This is the reason why these methods have not found extensive application in the preparation of aminoacid enantiomers from their racemates.

As early as the beginning of this century, it was possible to obtain 60–70% yields of the D-isomers of alanine, leucine, valine[41], norvaline, serine, phenylalanine[42], alloisoleucine, glutamic acid, and histidine[43] by treating the aminoacid racemates with yeast, whose action was due to its decarboxylases. Later this method was employed to obtain the D-isomers (of methionine with the aid of *Proteus vulgaris*[44] and of glutamic acid[45] and lysine[46] with the aid of *E.coli* and *Bacillus cadaveris* respectively). On the other hand, the monoaminodicarboxylic acid decarboxylase, specific exclusively to the D-enantiomers and isolated from *Aspergillus ustus*, makes it possible to obtain their L-enantiomers[47].

The stereoselective oxidation of aminoacids by means of the D-aminoacid oxidase from mammalian kidneys and the L-aminoacid oxidase from snake venom has found a somewhat more extensive application:

$$\text{aminoacid racemate} + O_2 \xrightarrow{\text{oxidase}} \text{unreacted optical isomer} + \alpha\text{-ketoacid} + H_2O_2 + NH_3.$$

The L-enantiomers of alanine, methionine[48], and proline[49] were obtained by treating their racemates with D-aminoacid oxidase.

The possibility of obtaining aminoacid D-enantiomers by treating the racemates with snake venom L-aminoacid oxidase is limited by the specificity of the enzyme. Thus L-threonine, L-proline, L-alanine, L-lysine, and L-ornithine are resistant to the action of the oxidase from *Crotalus adamentus*[50,51]. However, L-alanine is readily oxidised by the enzyme from the venom of *V. libetina*[52] and L-lysine is oxidised by the enzyme from the venom of *Bothrops atrox*[53]. The acylation of the ω-amino-groups of L-lysine, L-ornithine, and L-citrulline also renders them susceptible to oxidation by the enzyme from the venom of *Crotalus adamentus*[50,51]. The reaction products do not inhibit L-aminoacid oxidase, but the α-ketoacids obtained in the oxidation of aromatic aminoacids inhibit D-aminoacid oxidase. The addition of cyanide to the reaction mixture inhibits the catalase usually present as an admixture in preparations of D-aminoacid oxidase. The hydrogen peroxide formed during the reaction under these conditions is no longer decomposed by catalase and is consumed in the oxidation of the α-ketoacid to its nearest lower aliphatic acid homologues, which are much weaker inhibitors of the D-aminoacid oxidase[53].

The ease with which the reaction can be monitored from the evolution of ammonia or the peroxide and also the exceptionally low affinity of oxidases for the uncleaved isomer makes it possible to employ stereoselective oxidation as a method for the analysis of the optical purity of aminoacid stereoisomers. By means of this procedure, it is possible to determine 0.1–0.01% of the admixture of the other isomer[54,55].

The resolution of racemates by stereoselective oxidation and also by stereoselective decarboxylation has not found extensive application, firstly owing to the loss of half of the starting material in the reaction and, secondly, owing to the high cost of snake venom—the source of L-aminoacid oxidase.

IV. ENZYMIC SYNTHESIS OF THE AMIDE BOND

An interesting method for the resolution of aminoacid racemates is the enantioselective synthesis of the amide linkage catalysed by various proteolytic enzymes. It is well known that the hydrolysis of the amide linkage formed by *N*-acylated aminoacid derivatives proceeds until the attainment of equilibrium and under certain conditions the reverse synthetic reaction can be achieved[56–58]. If aniline or phenylhydrazine is used as the amino-group donor for the synthesis of the amide linkage, then the anilides or phenylhydrazides of the *N*-acylated aminoacids, which are sparingly soluble in water and crystallise from the reaction mixture, are formed as a rule. This shifts the equilibrium in the direction of synthesis and makes it possible to carry out the stereoselective synthesis almost quantitatively. Attention was drawn to the enantioselectivity of such synthesis, catalysed by papain, for the first time in a study of the synthesis of acetyl-DL-phenylalanylglycine anilide[58].

A similar method was used to resolve the racemate in benzyloxycarbonyl-DL-glutamic acid[59] and the diastereoisomer of acetyl-DL-phenylalanyl-L-leucine[60]. Later the method was improved[61] and it was possible to resolve by this procedure the racemates of alanine, leucine, isoleucine, norleucine, valine, lysine, serine, threonine, and phenylalanine.

For the synthesis reaction of the anilide to go almost to completion, the *N*-acylaminoacid must be readily soluble and the corresponding anilide must be sparingly soluble. The choice of a suitable *N*-acyl group on the grounds of solubility can entail in its turn difficulties associated with the stereospecificity of the enzyme employed[60]. This question was investigated in greater detail in relation to the papain-catalysed stereoselective synthesis of the phenylhydrazides of *N*-acylated aminoacids[62–64]. The replacement of aniline by phenylhydrazine is dictated by the fact that the phenylhydrazide group can be readily removed by mild oxidation.

The product synthesised was found to have almost fully the *L*-configuration if the acyl group was acetyl or benzoyl. If the acyl group consisted of methoxycarbonyl, ethoxycarbonyl, or benzyloxycarbonyl residues, then a considerable amount of the D-hydrazide, almost comparable to the amount of the L-hydrazide, was formed. This phenomenon was observed regardless of the nature of the aminoacid residue, although the rate of formation of the product is influenced by the nature of both the *N*-acyl group and of the slight change of the aminoacid itself[65-67]. Unfortunately quantitative conclusions as regards this system are hindered by the continuous inactivation of papain by phenylhydrazine[63].

Despite a number of evident advantages, namely the simplicity of the enantioselective synthesis of the anilide or phenylhydrazide and the exceptionally convenient separation of the unreacted D-isomer, this method has not found extensive applications for the resolution of aminoacid racemates into optical isomers and its possible comparative use has been pointed out in only isolated studies[68]. This is associated, firstly, with the difficulty of choosing a suitable acyl derivative of the aminoacid satisfying all the essential requirements, secondly, with the necessity for a careful selection and constant monitoring of the conditions in the resolution process, and, thirdly, with the fact that the starting materials and the reaction products are not aminoacids themselves but fairly complex derivatives of the latter. This necessitates additional synthetic stages followed by the hydrolysis of these compounds. Since the anilides of the acylated aminoacids are fairly stable, refluxing for many hours in 6 M HCl must be used for the preparation of the free aminoacid[59]. This is why, even if the L-compound does not contain initially admixtures of the other isomers, such treatment can lead to partial racemisation[66,69] and in the case of certain aminoacids, for example, methionine[70] and tryptophan[71], to chemical degradation.

Despite the fact that the stereoselective synthesis catalysed by various proteolytic enzymes is hardly used for the resolution of aminoacid racemates into optical isomers, reactions of this type are being vigorously investigated. They have already found applications in the stereoselective synthesis of various *N*-acylated oligopeptides. Apart from papain, the synthesis of the amide linkage can be catalysed by α-chymotrypsin[72], nagarase, pepsin, and thermolysin[73]. The employment of proteolytic enzymes with different specificities makes it possible to incorporate various aminoacids in the oligopeptides synthesised. The kinetics of both the direct synthesis of the amide linkage, for example, the papain-catalysed synthesis of hippurylanilide from aniline and hyppuric acid[74] as well as the formation of the dipeptide from *N*-benzoyl-L-tyrosine and glycineanilide catalysed by α-chymotrypsin[75], and the "synthesis with transfer", where instead of the *N*-acylated aminoacid one uses its more reactive derivative, usually the ester, as the carboxyl donor for the formation of the amide linkage, have been studied in detail. Proteolytic enzymes such as trypsin[76] and α-chymotrypsin[77] are catalysts of reactions of this kind. Since the hydrolysis of amide and ester substrates of these enzymes proceeds via the formation of the acyl-enzyme, it follows that, in accordance with the principle of microreversibility, the synthesis should also proceed via these intermediate states. The use of aminoacid esters as donors of the carboxy-group facilitates the acylation stage compared with the acylation of the free aminoacid, which accelerates the entire process, because the deacylation stage is not rate-limiting[78], and makes it possible to use aminoacid esters with a free amino-group as donors of the carboxy-group[79]. Furthermore, for a specific ratio of the kinetic parameters of the hydrolytic and synthetic reactions, it is possible to achieve yields exceeds the thermodynamic values in "synthesis with transfer"[80,81].

The study of the equilibrium constants of the hydrolytic-synthetic reactions of the amide or peptide linkage[82-85] permitted the conclusion that the free energy of the synthesis, calculated in relation to the unionised forms of the starting materials and reaction products, is as a rule negative, i.e. the equilibrium is displaced towards synthesis. However, when the reactions are carried out in aqueous solutions, the vast majority of one or both starting materials exist in the ionised form (since the p*K* of the carboxy-groups of such compounds are in the range 2–3.5 and the p*K* of the amino-groups are in the range 6–9.5) and the synthesis of the amide and peptide linkages is no longer such a thermodynamically favourable process[56,57].

Various methods whereby the reaction equilibrium can be displaced towards the required product have been vigorously developed recently[86-88]. Such methods are based on the alteration of the ionisation constants of the reactants and the decrease of the concentration of water in the system, the employment of two-phase "water–water-immiscible organic solvent" systems, or the creation of conditions for a kinetically controlled equilibrium as a result of the immobilisation of the enzyme on a charged carrier. Admittedly this entails an appreciable decrease of the rate of synthesis and additional components, hindering the isolation of the required product, are introduced into the system.

Summarising, one may say that, although the stereoselective method of synthesis of amides, hydrazides, or peptides under the influence of proteolytic enzymes has not found applications as a procedure for the resolution of aminoacid racemates into optical isomers, the study of such reactions has made it possible to understand many features of the thermodynamics of the important reaction involving the synthesis of the peptide linkage and provided synthetic chemists with a convenient method whereby one can synthesise various oligopeptides stereoselectively under mild conditions and with a high yield[89-91].

V. ENANTIOSELECTIVE HYDROLYSIS OF AMINOACID ESTERS AND AMIDES

The stereoselective hydrolysis of aminoacid esters was first used for the resolution of racemates into optical isomers in 1906,[92] i.e. it was contemporary with the classical diastereoisomeric crystallisation methods. A common disadvantage of the method described was the long time involved and their laborious nature, since the employment of low-purity enzyme preparations required much time for the hydrolytic reaction and led to contamination by products of side reactions.

Despite these difficulties, tryptophan[93-97], phenylalanine[98-100], norleucine[100], methionine[94], valine[98,99], and a number of benzene ring-substituted phenylalanine[98,99,101,102] racemates have been resolved by the stereoselective hydrolysis of their esters under the influence of pancreatic enzymes.

The studies discussed above were extremely empirical. The isolation of proteolytic pancreatic enzymes in a pure form, the discovery and isolation of numerous proteases from various micro-organisms, and the development of a convenient method whereby the kinetics of reactions of this kind can be followed (pH-stat measurements) renewed the interest in the stereoselective hydrolysis of esters as a method for the resolution of aminoacid racemates into optical isomers.

1. Characteristics of the Action of α-Chymotrypsin on Aminoacid Esters

Despite the fact that α-chymotrypsin is one of the most thoroughly investigated enzymes[103], the mechanism of the hydrolysis by the latter of aminoacid esters has not been

ultimately elucidated. As for the esters of *N*-acylated amino-acids, the formation of an intermediate acyl-enzyme has been postulated in all the investigations for esters with a free amino-group, but the question which stage, acylation or deacylation, is rate-limiting still remains open[104–109].

The hypothesis that in the hydrolysis of aminoacid esters by α-chymotrypsin the reactive form of the Michaelis complex is a complex of the enzyme with the substrate protonated in the amino-group can now be regarded as having been convincingly demonstrated[104,105,109–112]. It is supported by the higher reactivity in hydrolytic reactions of the forms of aminoacid esters protonated in the amino-group[113] and also by the possibility of the formation of a hydrogen bond between the NH_3^+ group and the carbonyl group of Ser[214,112]. The formation of a hydrogen bond in the Michaelis complex would ensure a more favourable binding of the substrate and, in accordance with the "better binding–better catalysis" principle[103], might occur in the catalytic stage of the chymotrypsin catalysis. The results of the crystallographic study of α-chymotrypsin indicate the presence in the active centre of the enzyme, alongside the hydrophobic section, of the aspartic acid residue Asp[194], participating in the formation of a salt bridge, which is necessary for the maintenance of the catalytically active tertiary structure[114,115] and is capable of electrostatic interaction with the protonated amino-group of the substrate. The mechanism of the enzymic (chymotrypsin) hydrolysis of aminoacid esters with a free amino-group, proposed on the basis of these considerations, describes satisfactorily the pH dependence of all the kinetic parameters[109].

A characteristic property of α-chymotrypsin is its high stereospecificity with respect to the L-isomers of aminoacid esters with a free amino-group, which makes it possible to use this reaction for the separation of aminoacid racemates. It is of interest to examine factors determining the high stereospecificity of α-chymotrypsin. The idea that the stereospecificity is determined by the structure of the substrate and is not an invariant property of the enzyme has been confirmed in the study of the hydrolysis of the *p*-nitrophenyl esters of *N*-acetylated aminoacids[116,117]. As the side chains of the substrate becomes more hydrophobic, the deacylation of the L-acyl-enzymes is accelerated, while that of the corresponding D-acyl-enzymes is retarded.

According to the view which has become firmly established at the present time[103], the driving force of the chymotrypsin catalysis is the hydrophobic interaction between the side chain (R^2) of the substrate having the general formula $R^2–CH(NHR^1)–COR^3$ and the groups located in the hydrophobic region of the active centre of the enzyme. The "better binding–better catalysis" rule is then observed. However, it is applicable only to the variation of R^2. It has been shown[118] that, when the *N*-acyl group in ester derivatives of L-aniline is altered, the "better binding–less effective reaction" relation is observed. In order to interpret this effect, the hypothesis of the "unproductive binding" of the substrate molecule by the enzyme was put forward. The binding of the molecules of the L- and D-substrates can be illustrated schematically on the basis of the model involving the three-point binding of the substrate to the active centre of α-chymotrypsin (Fig. 1). Evidently in the case of the L-substrate the "correct" binding is at the same time also productive. Therefore the enhancement of the hydrophobic properties of the aminoacid side chain (the group R^2) leads to an increase of the efficiency of the catalysis (Fig. 1*a*). The unproductive binding can be explained in this instance by the fact that the *N*-acyl group R^1, which is fairly hydrophobic, can itself occupy a site in the hydrophobic section of the active centre and the carbonyl group attached to the bond undergoing dissociation in the substrate will not be correctly oriented in relation to the general nucleophile of the active centre (Fig. 1*b*).

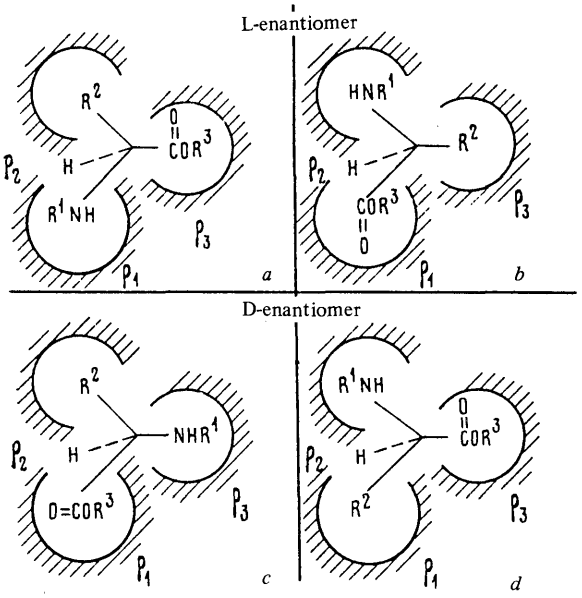

Figure 1. Different versions of the three-point binding of the substrate molecule to the active centre of α-chymotrypsin; ρ_1 = hydrogen bond acceptor; ρ_2 = hydrophobic region of the active centre; ρ_3 = generalised nucleophile of the active centre.

The hydrolysis of D-aminoacid derivatives takes place in exactly the opposite manner: the "correct" binding of the substrate, i.e. binding such that the group R^2 is in the hydrophobic section of the active centre, leads to an unproductive enzyme–substrate complex (Fig. 1*c*), since the formation of the productive complex is in this case sterically hindered and requires that the *N*-acylamide group occupy the site provided in the active centre for the hydrogen centre[119]. On the other hand, the "incorrect" orientation of the *N*-acylamide group in the hydrophobic region ρ_2 is in fact productive (Fig. 1*d*). It is clear from the foregoing that the enhancement of the hydrophobic properties of the aminoacid group R^2 entails an increase of the stereospecificity of the enzyme, while the enhancement of the hydrophobic properties of the *N*-acyl group R^1 should actually reduce it. This conclusion has been confirmed experimentally[120,121].

For the resolution of aminoacid racemates, it is important to know how the stereospecificity of the action of α-chymotrypsin changes on passing to substrates with a free amino-group. It was found that the character of the influence of the hydrophobic properties of the group R^2 on the stereospecificity of the chymotrypsin hydrolysis of the methyl esters of aminoacids is the same for substrates with free and acetylated amino-groups, but the ratio of the second-order rate constants for the enzyme hydrolysis of L- and D-substrates is approximately 10 times greater for acetylated aminoacids than for aminoacids with a free amino-group. The

D-substrate having a free amino-group is hydrolysed by α-chymotrypsin faster than its acylated analogue[112].

2. The Problem of the Spontaneous Hydrolysis of α-Aminoacid Esters

In the stereoselective hydrolysis of aminoacid esters by proteolytic enzymes the spontaneous (non-enzymic) hydrolysis of the aminoacid esters is one of the concomitant processes interfering with the effective resolution of their racemic mixture. It is therefore necessary to seek optimum conditions which correspond both to relatively low rates of spontaneous hydrolysis and to an adequate activity of the biocatalyst employed. The most sensitive parameters of such optimisation are the pH of the solution and the reaction temperature. It is therefore very urgently necessary to compare the pH profile of the catalytic activity of the enzyme and the pH dependence of the rate of spontaneous hydrolysis.

Until recently, the hydrolysis of aminoacid esters has been studied only over a narrow range of alkaline pH (9–12), which did not allow the estimation of the rate of the process in neutral and weakly acid media[122–125]. The following kinetic mechanism has been proposed on the basis of a detailed study of the pH dependence of the hydrolysis of the ethyl ester of DL-tryptophan in the pH range 4.5–10.5:[113]

$$\left.\begin{array}{l}\xleftarrow{k_5[OH^-]}\\ \xleftarrow{k_3[H_2O]}\end{array}\right| -EH^+ \overset{K_E}{\rightleftharpoons} E- \left|\begin{array}{l}\xrightarrow{k_1[H^+]}\ ,\\ \xrightarrow{k_2[H_2O]}\ ,\\ \xrightarrow{k_4[OH^-]}\ ,\end{array}\right. \qquad (1)$$

together with the corresponding equation for the rate of hydrolysis:

$$V = k_1[E][H^+] + k_2[E][H_2O] + k_3[EH^+][H_2O] + k_4[E][OH^-] + k_5[EH^+][OH^-] = k_{abs}[E]_{tot},$$

where EH^+ and E are the form of the aminoacid ester protonated in the amino-group and the non-protonated form and k_1, k_2, k_3, k_4, and k_5 are the rate constants for the acid, neutral, and alkaline hydrolysis. The possibility of the acid hydrolysis of the protonated form of the substrate, which is unlikely in view of the electrostatic repulsion of the interacting species, is not reflected in mechanism (1). Analysis of the pH dependence of k_{obs} obtained and the literature data for the hydrolysis of *N*-acylated aminoacid esters made it possible to find or at least to estimate all the kinetic parameters of mechanism (1):

$$k_1 \cong 10^{-5} \text{ litre mol}^{-1}\text{s}^{-1},\ k_2 \cong 10^{-7} \text{ litre mol}^{-1}\text{s}^{-1},\ k_3 = 2.7 \times 10^{-7} \text{ litre mol}^{-1}\text{s}^{-1},$$
$$k_4 = 1.2 \text{ litre mol}^{-1}\text{s}^{-1},\ k_5 = 79 \text{ litre mol}^{-1}\text{s}^{-1}.$$

The pH dependence of the hydrolysis of the ethyl ester of DL-tryptophan permits certain practically important solutions. Thus, in order to diminish the contribution of the spontaneous hydrolysis as a side process in the enzymic resolution of aminoacid racemates as a result of the stereoselective hydrolysis of their esters, it is necessary to employ proteolytic enzymes with a pH optimum of the catalytic activity in the region of acid and neutral pH (neutral and acid proteases). The possibility of employing alkaline proteases is to a large extent limited, because in the region of the alkaline pH the rate of spontaneous hydrolysis is so high that it is difficult to avoid the contamination of the final product even when high enzyme concentrations are used and the process is carried out over a short time interval.

In the study of the possibility of employing a particular proteolytic enzyme for the resolution of aminoacid racemates by the enantioselective hydrolysis of aminoacid esters, it is important to know the characteristics of the reaction at substrate concentrations close to saturation, i.e. under the conditions of the preparative resolution of aminoacid racemates. It has been shown[126,127] that the full kinetic curves for the enantioselective hydrolysis of the ethyl ester of DL-tryptophan, catalysed by α-chymotrypsin, are described by the mechanism

$$E\cdot D\text{-}S \overset{K_i'}{\rightleftharpoons} D\text{-}S + E + L\text{-}S \overset{K_S}{\rightleftharpoons} E\cdot L\text{-}S \xrightarrow{k_2} EA \xrightarrow{k_3} E + P,$$
$$P \quad (P' \text{ from } E\cdot L\text{-}S), \qquad E\cdot P \quad (K_i)$$

where *E* is α-chymotrypsin, L-S and D-S are the ethyl esters of L- and D-tryptophan respectively, P is L-tryptophan, P′ is ethanol, $K_i' = (1.8 \pm 0.3) \times 10^{-3}$ mol litre^{-1} is the constant of the competitive inhibition by the ethyl ester of D-tryptophan, $K_i = (25 \pm 5) \times 10^{-3}$ mol litre^{-1} is the constant of the competitive inhibition by L-tryptophan, $k_{cat} = k_2k_3/(k_2 + k_3) = 100 \pm 10$ s^{-1} is the catalytic constant, and $K_M = K_Sk_3/(k_2 + k_3) = (2.4 \pm 0.1) \times 10^{-3}$ M is the Michaelis constant (all the constants were determined at 37 °C and pH 6.3).

Summarising the discussion of α-chymotrypsin as a potential catalyst of the enantioselective hydrolysis of aromatic acid esters, one may make the following conclusions: firstly, α-chymotrypsin is highly stereospecific. Secondly, the pH optimum of the catalytic efficiency of the action of α-chymotrypsin on aminoacid esters with a free amino group is in the pH range 6.5–7.0, where the non-enzymic hydrolysis of the substrate proceeds to only an insignificant extent; the rates of the enzymic hydrolysis of the L-isomer of the substrate, of the enzymic hydrolysis of the D-isomer, and of the spontaneous hydrolysis of the racemate at the pH optimum of the α-chymotrypsin activity are approximately 10 000 : 1 : : 0.0001, which leads to a very insignificant contamination of the final product by the other isomer. Thirdly, the optimum pH range from the standpoint of the relative contributions of the enzymic and non-enzymic hydrolytic reactions is in fact also most convenient for the isolation of the reaction product from the reaction mixture, because in this particular pH range aminoacids are least soluble and the substrate hydrolysed is fairly soluble. Fourthly, L-tryptophan and ethanol, formed in the enzymic reaction, have an insignificant influence on the process kinetics, which makes it possible to achieve high degrees of conversion of the substrate.

Thus α-chymotrypsin is an exceptionally convenient catalyst for the resolution of aromatic aminoacid racemates by the hydrolysis of their esters. However, a significant disadvantage of α-chymotrypsin is its animal origin and hence its relatively high cost. A possible way of overcoming this disadvantage may be the use of immobilised preparations of the enzyme with a fairly high stability, which would make possible their repeated employment in the process. The immobilisation of α-chymotrypsin has been thoroughly investigated[6] and there is no doubt that active preparations of the immobilised enzyme with a high stability and effective mechanical properties necessary for practical applications can be obtained. Another solution of the problem is to seek proteolytic enzymes of microbial origin with properties close to those of α-chymotrypsin.

3. The Stereospecificity of Proteolytic Enzymes

Bacterial proteases have been studied only recently from the standpoint of their suitability for the resolution of aminoacid racemates[126–129]. Unfortunately, all the enzymes or

enzyme complexes of bacterial origin investigated are appreciably inferior to their activities and, what is most important, in their enantioselectivity to α-chymotrypsin. The proteases from *Bacillus subtilis* and the extracellular protease from *Actinomyces* are the most suitable for the stereoselective hydrolysis of aminoacid esters. The catalytic constants for the hydrolysis of the ethyl ester L-tryptophan at the pH optimum are 6.5 ± 0.5 and 3.2 ± 0.4 s^{-1} for these enzymes and their enantioselectivities, i.e. the ratios of the catalytic constants for the enzyme hydrolysis of the L- and D-isomers of the ethyl ester of tryptophan, are 200 and 150 respectively. For α-chymotrypsin, these quantities are 100 s^{-1} and 10 000.[126,129] Furthermore, the pH optimum of the catalytic activity of these substrates corresponds to a weakly alkaline region where the solubility of the substrate is low and the contribution of the non-enzymic hydrolysis increases.

The relatively low stereospecificity of the microbial proteolytic enzymes can be associated with the fact that contacts with the aminoacid residues, remote from the bond undergoing cleavage in the hydrolysis of oligopeptide and polypeptide substrates, are exceptionally important for such an enzyme in contrast to, say, α-chymotrypsin[130]. Thus the replacement of an acetylaminoacid amide by an oligopeptide, fully covering the active centre of the enzyme, entails an increase of the efficiency of the action of chymotrypsin by a factor of 4000,[131] of trypsin by a factor of 300,[132] and for the microbial enzymes elastase and the protease from *Streptomyces griseus*, the corresponding increase in the efficiency of hydrolysis is by a factor of 10^7.[130,133–135] Such increase of the efficiency of hydrolysis is apparently due to the stronger binding of the oligopeptide substrates compared with the acetyl aminoacid amide and hence to their more "accurate" orientation, which should lead to an increase of the stereospecificity of the action of these enzymes. However, it is entirely likely that, among the large number of microbial proteases, there is an enzyme corresponding to the highest requirements which must be met by the catalyst of the stereoselective hydrolysis of aminoacid esters for the resolution of the racemate into optical isomers, while the addition of metal ions will make it possible to increase the stereospecificity of bacterial proteases[128,136,137].

The racemates of acetyl-leucine[138], methionine, and α-aminophenylacetic acid[139] have been resolved into optical isomers by the enantioselective hydrolysis of their amides by proteolytic enzymes. However, it is important to note that the stereoselective hydrolysis of aminoacid amides has not found extensive applications owing to the low rates of hydrolysis of the amide substrates compared with the ester derivatives of aminoacids.

VI. THE USE OF ACYLAMIDOHYDROLASES FOR THE RESOLUTION OF RACEMATES

The stereoselective hydrolysis of *N*-acylated aminoacids has come to be most widely used nowadays among all the methods for the resolution of racemates. The application of this method was initiated in 1922, when it was observed that preparations of animal tissues catalyse the hydrolysis of *N*-benzoyl-L-aminoacids only[140]. Subsequently the possibility of the hydrolysis of not only benzoyl derivatives but also of other *N*-acylaminoacids was demonstrated[141–144]. Extensive practical application of the stereoselective hydrolysis of acylated aminoacids became possible only after a series of studies by Greenstein and co-workers who were able to resolve the racemates of virtually all natural and a number of synthetic aminoacids by employing a pig kidney homogenate or partly purified preparations of aminoacid acylase[145].

The enzyme catalysing the hydrolysis of *N*-acylated aminoacids has come to be called aminoacid acylase (EC 3.5.1.14). Aminoacid acylases belong to the group of enzymes hydrolysing non-peptide bonds (EC 3.5..). However, the similarity of the properties of the C–N bond in acylated aminoacids and peptides and also the necessity for a free carboxy-group for the manifestation of the acylase activity indicate that the acylase is related to a number of enzymes hydrolysing the peptide linkage (EC 3.4..), for example, carboxylpeptidases (EC 3.4.2), which split off the *C*-terminal aminoacid from peptides and are capable of hydrolysing *N*-acylated aminoacids with an aromatic side chain. Furthermore, aminoacid acylases exhibit a dipeptidase activity[146], which relates them to the group of dipeptidases (EC 3.4.3.). Such similarity of the substrate specificities of acylases and other enzymes sometimes leads to confusion. Thus in certain studies it has been suggested that the determination of the acylase activity in the liver be used for the diagnosis of virial hepatitis, although in fact this involves the monitoring of the hydrolysis of *N*-butyryl-γ-L-glutamyl-β-naphthylamide and the determination of the β-naphthylamine liberated in the reaction[147,148]. The activity determined is in fact due to an amidase (EC 3.5.1.4) and not an acylase.

Apart from acylase I, at least a further two enzymes capable of hydrolysing *N*-acylated aminoacids have been isolated from animal tissues. The first of these, catalysing the hydrolysis of acyl derivatives of aspartic acid, was called pig kidney acylase II (EC 3.5.1.15). The second enzyme, which hydrolyses *N*-acylated aromatic aminoacids (tyrosine, phenylalanine, tryptophan, and β-phenylserine) has been called acylase III.[149,150] Both these enzymes have been hardly investigated and the existence of acylase (III) has been altogether questioned and its activity has been attributed to carboxypeptidase. Only in recent years studies have been published confirming the presence of a special enzyme hydrolysing the *N*-acyl derivatives of aromatic aminoacids[151,152]. There are indications in the literature also of the presence of a special enzyme responsible for the hydrolysis of *N*-formylmethionine[153].

The biological role of acylases has not been ultimately elucidated. It has been suggested that they are involved in the catabolism of the *N*-acetylaminoacids formed in the hydrolysis of *N*-acetylated proteins[154,155].

1. The Pig Kidney Acylase

The pig kidney aminoacid acylase I has been isolated in a homogeneous state and its physical and chemical properties have been investigated[156–162]. It is a two-subunit enzyme with a molecular weight of 86 000, consisting of 772 aminoacid residues. Each enzyme subunit contains two SH groups, one of which is significantly more active with respect to various SH reagents. The modification of two SH groups per molecule of the enzyme leads to its complete inactivation. Each subunit contains two S–S bonds. The reduction of two S–S bonds per enzyme molecule also results in complete enzyme inactivation[158]. The acylase is likewise fully inactivated by the photochemical oxidation or chemical modification of four histidine residues[160] and two tryptophan residues[159] per enzyme molecule.

It has been recently reported that acylase I is a zinc-dependent metalloenzyme[161] containing one zinc atom per subunit.

Consideration of the substrate specificity of the pig kidney aminoacid acylase makes it possible to isolate two factors: (a) the specificity of the enzyme with respect to the type of aminoacid residue and (b) its specificity with respect to the nature of the acyl group.

Acylase I exhibits a fairly broad specificity and hydrolyses at a high rate the derivatives of the majority of aliphatic aminoacids[161,163]. The catalytic constant of the hydrolysis of acetyl-L-methionine at pH 7.0 and 37 °C is 330 s^{-1} (determined for an electrophoretically homogeneous enzyme)[157]. The Michaelis constants for the majority of acetyl derivatives of L-aminoacids amount to several millimoles. An increase of the chain length in the unbranched aminoacid residue entails an increase of the efficiency of the hydrolysis. If the results are expressed within the framework of the "structure–reactivity" correlation

$$\lg \frac{V_{max}}{K_M} = \alpha\pi + \text{const} \quad ,$$

where V_{max} is the maximum velocity of the enzymic reaction, K_M the Michaelis constant, π the Hansch hydrophobic constant for the substituent which is varied in the given series (π characterises the free energy of the transfer of the hydrocarbon residue from water to a standard hydrophobic phase—1-octanol, amounting to 0.51 for the CH_2 group in the unbranched substituent), and α the proportionality coefficient, it is found that the data obtained are described by a linear relation with a proportionality coefficient $\alpha \cong 0.7$. On passing from a linear aminoacid residue to a branched residue with the same number of carbon atoms (norvaline–valine, norleucine–leucine), the efficiency of the hydrolysis falls by a factor of 5–10. Thus the correlation obtained between the kinetic efficiency and the hydrophobic properties of the substrate shows that the simple "extraction" model of the utilisation of the substrate binding energy in the course of the enzymic reaction is valid for the pig kidney acylase (a detailed explanation of the model of the utilisation of the binding energy in the enzymic reaction has been given, for example, by Berezin and Martinek[103]). The hydrophobic section of the active centre of the acylase is a narrow "slit" whose length corresponds to at least four methylene units[163]. The results obtained agree with data for the inhibition of the acylase by free aminoacids[164] and with the finding that aromatic aminoacid derivatives are hydrolysed 2–3 times more slowly than methionine derivatives. The presence of electron-donating substituents in the aromatic ring of the aminoacid side chain results in a further decrease of the rate of hydrolysis[165]. Acyl derivatives of proline and hydroxyproline are resistant to the action of acylase I.[149] As regards the specificity of acylase I to the nature of the acyl component of the substrate, the enzyme hydrolyses different acyl-aminoacid derivatives. Among derivatives of unsubstituted aliphatic acids, acetylaminoacids are the best substrates[166]. The formyl and propionyl derivatives are hydrolysed less effectively than the acetyl derivatives. The appearance of electron-accepting substituents in the acyl component increases the rate of hydrolysis. The reactivity of the substrates increases in the sequence iodoacetyl < bromoacetyl < chloroacetyl < fluoroacetyl derivatives[149]. The benzoyl derivatives of aminoacids are poor substrates. The presence of electron-accepting substituents in the *para*-position in the benzoyl derivatives of aminoacids accelerates and the presence of electron-donating substituents retards the hydrolysis catalysed by acylase I.[165]

There are data showing that acylase I is capable of catalysing the hydrolysis of dipeptides[146,164,167], although the rate of hydrolysis is lower by 2–3 orders of magnitude compared with the chloroacetyl derivatives of aminoacids. It is of interest to note that the enzyme preparation investigated cleaved dipeptides with the L–L configuration but did not cleave those with the D–D and D–L configurations[146]. It was concluded that, for the manifestation of the catalytic activity of acylase I, it is essential that not only the C-terminal but also the *N*-terminal aminoacids should be in the L-configuration. At the same time, it is known that the acylase hydrolyses equally effectively both diastereoisomers of DL-α-chloropropionyl-L-alanine[167].

However, one should note that commercial preparations of acylase (I) without additional purification were used in the above investigations[146,167]. Presumably the observed activity in relation to dipeptides, which is lower by at least two orders of magnitude than the activity of acylase I in relation to *N*-acetyl-L-methionine, is a consequence of an admixture of another enzyme—a dipeptidase. Kördel and Schneider[164] used an electrophoretically homogeneous preparation of acylase (I), but in this case too the criterion of homogeneity employed can hardly guarantee the absence of less than 1% of an impurity protein. Thus the question of the dipeptidase activity of acylase (I) must be regarded as open.

It has been shown that the Michaelis constants for non-specific substrates (acetyl derivatives of aromatic aminoacids and derivatives of aliphatic aminoacids with a bulky acyl component) are approximately equal to the constants for the competitive inhibition of the hydrolysis of specific substrates in the presence of non-specific substrates[165]. If the three-stage mechanism of the enzymic reaction is valid for acylase I, then in this case such equality would imply that the rates of hydrolysis of non-specific substrates of acylase I are limited by the enzyme acylation stage[165]. However, the validity of the three-stage mechanism of the acylase-catalysed hydrolysis has not so far been in any way demonstrated.

At acid pH it has been possible to observe kinetically and with the aid of sedimentation equilibria the dissociation of acylase I into inactive subunits[168]. The dissociation constant is 2.0×10^{-7} M at pH 7.2 and 1.1×10^{-3} M at pH 5.8. The dissociation into inactive monomers under the influence of the substrate explains the substrate inhibition of the activity of acylase I at acid pH and the fact that there is a "flash" on the product accumulation curve under these conditions[168,165].

The pH optimum of the catalytic activity is in the pH range 7.0–7.5.[164] The Michaelis constant for the hydrolysis of acetyl-L-methionine catalysed by acylase I is independent of pH and the pH dependence of the maximum rate is bell-shaped and can be described in terms of the ionisation of two ionogenic groups having $pK_a = 6.7$ and $pK_b = 8.9$.[170]

One should note that, in the presence of high concentrations of the product of the hydrolytic reaction catalysed by acylase I, namely the acetate ion and the aminoacid, the hydrolysis of *N*-acetylaminoacids proceeds only as far as the attainment of equilibrium in the system and does not go to completion[171–173]. However, only qualitative data were available until recently for the kinetics of the synthesis of *N*-acetyl derivatives of aminoacids catalysed by the pig kidney acylase I.

2. Kinetic and Thermodynamic Characteristics of the Action of Acylase

The application to the study of acylases of a recently developed method for the quantitative determination of aminoacids, based on the spectrophotometric measurement of the product of the interaction of the aminoacid with *o*-phthalaldehyde in the presence of mercaptoethanol[177], permitted a detailed investigation of the kinetics of the hydrolysis-synthesis of acetyl-L-methionine catalysed by the pig kidney acylase I and made it possible to put forward a kinetic mechanism of the action of the enzyme and to determine the

kinetic parameters of the reaction[126,170,178]:

$$E + S \underset{}{\overset{K_M}{\rightleftharpoons}} ES \underset{V_{synth}}{\overset{V_{hydr}}{\rightleftharpoons}} EPP' \leftarrow \left[\begin{array}{l} \xrightarrow{K'_M} EP + P' \xleftarrow{K_i} \\ \xrightarrow{} EP' + P \longleftarrow \end{array} \right] \rightarrow E + P + P' \quad (2)$$

where E is the acylase, S is acetyl-L-methionine, P is sodium acetate, P' is L-methionine, $K_M = (25 \pm 3) \times 10^{-3}$ M and $K'_M = (140 \pm 20) \times 10^{-3}$ M are the Michaelis constants for the hydrolytic synthetic reactions respectively, $K_i = (43 \pm 5) \times 10^{-3}$ M is the acetate ion binding constant, and $V_{hydr} = (17 \pm 2) \times 10^{-5}$ mol litre^{-1} s^{-1} and $V_{synth} = (2.1 \pm 0.3) \times 10^{-5}$ mol litre^{-1} s^{-1} are the maximum rates of hydrolysis and synthesis respectively at an acylase concentration of 1 mg ml^{-1}. The kinetic parameters are linked by the Haldane relation

$$K_{eq} = \frac{K'_M K_i V_{hydr}}{K_M V_{synth}} ,$$

where $K_{eq} = 3.6 \pm 0.4$ is the equilibrium constant of the hydrolytic-synthetic reaction of acetyl-L-methionine. The empirical Eqn.(3) [179] for the description of the action of a membrane reactor with acylase I under conditions where the reaction equilibrium begins to have an effect in essence confirms the kinetic mechanism (2):

$$v = \frac{V_{max}}{1 + (S_L + S_{0D})/K_1} \cdot \frac{S_L - (S_{0L} - S_L)^2/K_{eq}}{K_M [1 + (S_{0L} - S_L)/K_2] + S_L} , \quad (3)$$

where the S_L and S_D are the concentrations of acetyl-L-methionine and acetyl-D-methionine respectively (the symbols with subscript 0 represent the initial concentrations), $K_1 = 1.45 \pm 0.08$ M and $K_2 = (3 \pm 1) \times 10^{-3}$ M are the inhibition constants, $V_{max} = 3.37 \times 10^{-5}$ mol litre^{-1} s^{-1} is the maximum velocity at an acylase (I) concentration of 1 mg ml^{-1}, K_M $(0.8 \pm 0.5) \times 10^{-3}$ M is the Michaelis constant, and $K_{eq} = 2.75$ is the equilibrium constant.

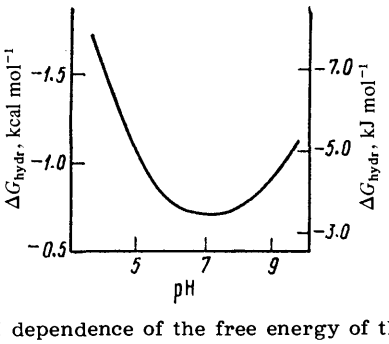

Figure 2. pH dependence of the free energy of the hydrolysis of acetyl-L-methionine.

Since the equilibrium constants of the hydrolytic-synthetic reactions of *N*-acetylaminoacids depend little on the nature of the aminoacid (Table 3), the proposed kinetic-thermodynamic approach is suitable for the description of the interaction of acylases with substrates having different structures.

There is no doubt that the experimental equilibrium constants of the hydrolytic-synthetic reactions of *N*-acetyl derivatives of aminoacids are not thermodynamic constants in the strict sense of the word, because the concentrations of the reactants in the reaction mixture are much higher than in dilute solutions for which the activity coefficient is unity. The lack of literature data for the activity coefficients of compounds of this kind, due to the exceptional difficulty and ambiguity of the measurements of these quantities, resulted in a general employment at the present time of equilibrium constants calculated from the concentrations of the reactants as estimates of the true thermodynamic equilibrium constants[56,57,78,82]. Since the equilibrium constant K_0 calculated in terms of the unionised forms of the reactants is independent of the pH and the entire contribution to the pH dependence of K_{eq} is due to the ionisation of specific ionogenic groups, it follows that, taking into account all the equilibria in system (4), it is possible to calculate the dependence of K_{eq} and hence of ΔG_{hydr} on the pH (Fig.2).[170,178]

Fig.2 shows that the equilibrium in this reaction is displaced towards synthesis precisely at the pH values where the majority of both the native acylases of animal and microbial origin and the immobilised preparations of these enzymes are active. This conclusion has a definite practical importance because the reversibility of the reaction in the stereoselective hydrolysis of the racemic acetylaminoacid reduces the productivity of the process:

$$\begin{array}{l} CH_3{-}CO{-}NH{-}CHR{-}COOH \overset{K_3}{\rightleftharpoons} CH_3{-}CO{-}NH{-}CHR{-}COO^- , \\ \quad \downarrow\uparrow K_0 \\ CH_3{-}COOH \overset{K_4}{\rightleftharpoons} CH_3{-}COO^- , \\ \quad + \\ NH_2{-}CHR{-}COOH \rightleftharpoons NH_2{-}CHR{-}COO^- , \\ \quad \downarrow\uparrow K_5 \qquad\qquad \downarrow\uparrow K_6 \\ NH_3^+{-}CHR{-}COOH \overset{K_1}{\rightleftharpoons} NH_3^+{-}CHR{-}COO^- ; \\ \Delta G = -RT \ln K_{eq} ; \\ K_{eq} = K_0 \dfrac{(1 + K_4/[H^+])(1 + K_1/K_2 + K_1/[H^+] + [H^+]/K_5)}{1 + K_3/[H^+]} ; \quad (4) \\ pK_1\ 2.3;\ pK_2\ 9.2;\ pK_3\ 3.8;\ pK_4\ 4.75;\ pK_5\ 7.4 . \end{array}$$

The search for new microbial acylases or the creation of immobilised enzyme preparations with a pH optimum of their catalytic activity in the pH range where the reversibility of the hydrolytic reaction does not have an effect even at high acetate ion concentrations would make it possible to eliminate this kind of deficiency. A possible method for the creation of immobilised acylase preparations with a modified pH optimum of their activity involves their incorporation in the structure of polyelectrolyte complexes.[180]

It is also of interest to note that the free energy of the hydrolysis of acetyl-L-methionine, calculated relative to the unionised forms of the starting materials and reaction products, is 7.46 kcal mol^{-1} (31.0 kJ mol^{-1}), i.e. the synthesis is a thermodynamically favourable process. The virtual failure to observe the synthesis of the acetamide linkage under the usual conditions is due to the fact that both the starting materials and the reaction products are present in the reaction mixture in the form of ions and the concentration of the unionised forms is negligible. The ΔG_0 obtained for acetyl-L-methionine exceeds somewhat the free energy of hydrolysis calculated relative to the unionised forms, usually obtained for the peptide bond[82], and shows that the synthesis of the acetamide linkage is thermodynamically even more favourable than the synthesis of the peptide linkage. Analogous results have been obtained also in the study of the reversible hydrolysis of *N*-phenylacetyl derivatives of aminoacids catalysed by penicillin amidase from *E. coli*[181,182].

The pig kidney acylase I exhibits a high stereospecificity. Among the large number of acetylaminoacids, only the D-isomer of acetylmethionine is appreciably hydrolysed by this enzyme; the ratio of the rates of hydrolysis of acetyl-L-methionine and acetyl-D-methionine, taken separately, is 10 000 : 1.[52] In the presence of L-methionine, the action of acylase I and acetyl-D-methionine is appreciably inhibited

and in the hydrolysis of the racemic acetyl-DL-methionine the ratio of the rates of hydrolysis of the L- and D-isomers is close to 40 000 : 1. A similar if not slightly greater ratio of the rates of hydrolysis of the optical isomers obtains for the acyl derivatives of other aminoacids. However, it has been observed that, when the acyl group is trifluoroacetyl, then a marked decrease of the stereospecificity of acylase I is observed for certain aminoacids[183].

The high stereospecificity of acylase I in the hydrolysis of acetyl and chloroacetyl derivatives of various aminoacids made it possible to resolve the racemates of many natural and synthetic aminoacids into optical isomers. On the other hand, it is necessary to note that acylase I is unsuitable for the resolution of the racemates of aspartic acid, proline, hydroxyproline, and aromatic aminoacids.

3. Microbial and Plant Acylases

Acylase activity (mainly in the hydrolysis of acetylmethionine) has been detected in tobacco leaves[184], in potato tubers, in many fruits (it is particularly high per unity weight in the radish and the pumpkin), in virtually all gramineous and leguminous plants (with the exception of polished rice whose treatment may lead to the breakdown of the enzyme system), and in the peel of mandarins, oranges, and figs[185,186]. An appreciable activity has been observed in the seeds of all the plants investigated and has been found to increase in the course of their growth[186,187].

Among all the plant acylases, only three enzymes have been partly purified and investigated: from rape seeds[188], from tobacco leaves[184], and from the seeds of palo verde (*Parkinsona Aculeata L.*).[189]

The enzyme from rape seeds hydrolyses enantioselectively the acetyl derivatives of aromatic and aliphatic aminoacids and methionine, the D-form not only not undergoing enzyme cleavage but also showing no influence on the hydrolysis of the L-form. The acetyl derivatives of glycine, glutamic acid, and proline as well as the benzoyl and benzyloxycarbonyl derivatives of aminoacids are resistant to the action of the enzyme. The pH optimum of the catalytic activity is in the range 7.2–8.8. Cobalt(II) ions activate the acylase approximately by a factor of 50, but those of calcium(II), iron(II), magnesium(II), nickel(II), and zinc(II) are 10 times less effective. The enzyme activity is inhibited by *p*-chloromercuribenzoate (PCMB), but *o*-phenanthroline , 8-hydroxyquinoline, or *N*-ethylmaleimide do not influence the catalytic activity[188].

An enzyme with a much narrower substrate specificity, which hydrolyses only *N*-acetyl-L-arginine, *N*-acetyl-L-cysteine, *N*-acetyl-DL-methionine, and, significantly less effectively, *N*-formyl-DL-methionine, has been partially purified from tobacco leaves. The pH optimum of its catalytic activity is displaced to the alkaline region compared with the pig kidney acylase I and depends on the nature of the substrate hydrolysed. Cobalt(II) ions activate the tobacco leaf acylase, the degree of activation increasing during purification. PCMB fully inhibits the enzyme activity at a concentration of 0.5 mM, but iodoacetate (1.5 mM) and EDTA (20 mM) do not influence the catalytic properties of tobacco leaf acylase[184].

The acylase activity in the palo verde seeds is concentrated mainly in the embryo and in the cotyledons. The acylase has been purified by a factor of 75 and its properties have been found to resemble closely those of the acylase isolated from rape seeds[189]. The acylase from the palo verde seeds effectively cleaves a wide set of acetyl and formyl derivatives of aromatic and aliphatic aminoacids, *N*-formyl-L-methionine being the best substrate. The acyl derivatives of D-aminoacids are hydrolysed to only a very slight extent. The pH optimum of the catalytic activity depends on the nature of the substrate hydrolysed and is located in the range 7.0–9.0. Cobalt(II) ions activate the enzyme approximately by a factor of 1.5 and greatly increase its stability during isolation. On the other hand, it has been noted that the acylase retains its activity after dialysis and electrophoresis, i.e. it is most probably not a metalloenzyme, because the metal ion is bound very firmly to the protein globule. The acylase from the palo verde seeds is inhibited by SH reagents like the other acylases considered[189].

The properties of the acylases under examination are close to those of the pig kidney acylase I. Like acylase I they exhibit a high stereospecificity (methionine derivatives are hydrolysed most effectively), are activated by cobalt(II) ions, and are sensitive to the action of SH reagents. A characteristic difference between plant acylases and acylase I is the displacement to the alkaline region of the pH optimum of the catalytic activity and the fact that the plant acylases are capable of hydrolysing the derivatives of not only aliphatic but also aromatic aminoacids. Such broad substrate specificity makes possible the employment of plant acylases for the resolution of aminoacid racemates. However, one should note that even greater prospects, which have already been embodied in practice, are associated with the acylases isolated for various micro-organisms (see Table 4).

4. ε-*N*-Acyl-L-lysine Amidohydrolase

Their exists an enzyme capable of hydrolysing only the L-isomer when it acts on racemic ε-*N*-acyl-DL-lysine (ε-*N*-acyl-L-lysine amidohydrolase, EC 3.5.1.17). It is of interest to note that in this case ε-lysine acylase exhibits stereospecificity in the hydrolysis of a bond which is comparatively remote from the asymmetric centre in the substrate molecule. The ε-lysine acylase activity was first detected in the KT 83 soil bacteria[190]. Later the ε-lysine acylase activity was found in a number of micro-organisms: moulds (particularly *Aspergillus*), the *Rhodotorula glutinis* yeast[191], and the *Achromobacter* and *Pseudomonas* bacteria (particularly *Achromobacter pestifer*[192]). The optimum conditions for the growing of *A. pestifer* as a producer of ε-lysine acylase activity have been elucidated[193] and the enzyme itself has been purified as far as the electrophoretically homogeneous state[194]. The enzyme hydrolyses all possible ε-acyl derivatives of lysine: acetyl, chloroacetyl, di- and tri-chloroacetyl, iodoacetyl, n-butyryl, caproyl, caprylyl, glycyl, benzoyl, phenylacetyl, benzyloxycarbonyl, *p*- and *m*-nitrobenzoyl, and naphthoyl derivatives, but neither α-acyl- nor diacyl-L-lysine undergoes enzymic hydrolysis. The replacement of a hydrogen atom by an alkyl group in the ε-NH_2 group also renders the substrate non-hydrolysable[195]. The Michaelis constants for the hydrolysis of the ε-chloroacetyl, ε-acetyl, and ε-benzoyl derivatives of L-lysine are respectively 0.29×10^{-3}, 0.5×10^{-3}, and less than 0.1×10^{-3} M.[196] The enzyme is inhibited by silver(I), mercury(I), and mercury(II) ions, PCMB, chloroacetone, and iodoacetate. The inhibition by PCMB is fully removed by the addition of cysteine. EDTA has little effect, while iron(III) and aluminium(III) ions (at a concentration of 1 mM) and nickel(II), cobalt(II), manganese(II), calcium(II), strontium(II), and cadmium(II) ions (at a concentration 10 mM) activate ε-lysine acylase to the extent of 20–30%. The pH optimum of the activity of the enzyme from *A. pestifier* is 4.8–5.2, which differs from that of the ε-lysine acylases from *Pseudomonas* and *Aspergillus oryzae*, for which the pH optima are respectively 6.0 and 8.2–8.4.[197]

An enzyme which hydrolyses stereoselectively the *N*-δ-acyl derivatives of ornithine, has been detected in the cells of the *Pseudomonas* KT 80 strain[198], but it has been scarcely investigated.

Table 4. The acylase activities of various micro-organisms.

Micro-organisms	Substrate specificity		Enzyme inhibitors and activators	pH optimum of activity	Refs.
	hydrolyses	does not hydrolyse			
Str. caespitosus	Ac-L-aminoacids	D-isomers	NI : bivalent cations, EPTA	7.0—8.0	[199]
Bact. cadaveris	Form-Gly, -Tyr Ac-Tyr	Ac-, Clac-Asp		7.0—8.0	[200]
Micrococcus n. sp.	ditto	ditto	—	7.0—8.0	[200]
Hydrocarbon oxidising micro-organisms	Ac-Leu, -norLeu, -Val, -Met, Bz-Leu	Ac-Trp, Bz-Asp	—	—	[201]
Bacillus brevis *Bacillus subtilis* *Bacillus megaterium* Micrococcus lysodeckticus	Ac-*L*-Met	Ac-*D*-Met	—	—	[202]
Corynebacterium glutamicum	Ac-*L*-Glu	Ac-*D*-Glu	—	—	[203]
E. coli B	Form-L-Met, Ac-L-Met, Ac-L-aminoacid		A : Co(II)(5×10^{-5}M), Ni(II)(10^{-5}M), Fe(II)(10^{-2}M), Mn(II)(10^{-2}M); I : Zn(II), EDTA	6.5—6.6	[204]
E. coli 160-37	Form-L-aminoacids		EA : Mn(II)(10^{-3}M), Co(II) (10^{-4}M)	7.2	[204]
E. coli ATCC 9637	Ac-Met, -Orn	Ac-Ala, -Leu, -Val, -Glu, Clac-Tyr, Bz-Arg	A : Co(II); I : Cu(II), Zn(II), Ni(II), EDTA	7.0	[205]
E. coli	Phac-*L*-Ala, -*L*-Val, -*L*-Ambut, -*L*-Leu, -*L*-Phe	D-isomers	—	—	[206, 207]
Ditto	Ac-*L*-Ala, -*L*-Met, Clac-*L*-Ala, -*L*-Met, -*L*-Asp, -*L*-Leu, -*L*-Phe	D-isomers Clac-L-Tyr, -L-Trp	A : Co(II)	—	[208]
Neursopora crassa	Phac-L-aminoacids				[209]
Mycobacterium smegmatis	Palmityl-L-Asp, -L-Val, L-Phe, decanoyl-L-Asp, lauryl-L-Asp	Ac-, butyryl-, hexanoyl-, octanoyl-L-Asp	A : alkali metal ions; I : Cu(II), Hg(II)	5.7—7.3	[210, 211]
Ditto	Ac-*L*-Val, -*L*-Asp, Clac-*L*-Phe		A : bivalent cations; I : Cu(II), Hg(II)	—	[210, 211]
Mycobacterium avium	palmityl-L-Asp, -L-Val, -L-Phe		NI : Cu(II), Hg(II)	6.2	[212]
Ditto	Ac-*L*-Val, *L*-Asp, Clac-*L*-Phe	—	I : Cu(II), Hg(II)	7.4	[212]
Mycobacterium phei	lauryl-L-Phe, -L-Ala, -L-Ambut, -L-Met, -L-Glu, Bz-L-Ala, -L-Ambut	—	—	—	[213]
Staphylococcus oureus	Bz-Gly, -Phe	—	—	—	[213]
Brewer's yeast	Ac-*L*-Met, Clac-*L*-Ala, -*L*-Leu, -*L*-Phe, -*L*-Trp, Gly-*L*-Met	—	—	—	[214]
Pseudomonas ATCC 11299B	Form-Asp, Clac-Asp	Ac-Met, Form-Leu	EA : Co(II); A : Fe(II)	7.0	[215]
Ditto	Form-, Ac-, Clac-Asp	Ac-Met, Form-Leu	EA : Co(II); A : Fe(II)	8.0	[215]
Soil pseudomonads	Ac-L-Asp, -L-Asn, Bz-L-Asp, dipeptides with L-Asp or L-Asn at the C-end	D-isomers, Ac-, Bz-aminoacids	Ea : Co(II), Zn(II)	—	[216, 217]
Ditto	Ac-*L*-Ala, Bz-*L*-Ala	ditto	Ditto	—	[218]
»	Ac-L-Glu, -L-Gln, Bz-L-Glu, -L-Gln, dipeptides with L-Glu or O-Gln at C-end	—	—	—	[219]
Pseudomonas KT83	Bz-D-Phe, -D-Phg, -D-*p*-nitro-Phe, -D-β-phenylSer, aromatic diClac-D-aminoacids	L-isomers	—	—	[220, 221]
Pseudomonas KT 84	diBz-*L*-Lys **, Bz-*L*-Ser, -*L*-Thr, -*L*-Orn, -*L*-Met, -*L*-Glu, -*L*-Asp, -*L*-Leu, -*L*-Val	D-isomers	—	—	[222, 223]

Pseudomonas KT 224	Ac-*L*-Met	Ac-*D*-Met	—	—	[229]
Pseudomonas KT 230, KT 231, KT 232, KT 233	diBz-L-Lys**; Bz-L-Phe, -L-Thr, -L-aminoacids (aliphatic)	D-isomers	—	—	[230, 235]
Pseudomonas KT 251, KT 256	Ac-*L*-Trp	Ac-*D*-Trp	—	—	[235]
Pseudomoans KT 301	diBz-*L*-Lys **	diBz-*D*-Lys	—	—	[236]
Pseudomonas KT 303 KT 305	Bz-*L*-Trp	Bz-*D*-Trp	—	—	[233]
Pseudomonas KT 313	diBz-*L*-Lys **, α-Phac-ε-Bz-*L*-Lys	D-isomers	—	8.0	[237]
Pseudomonas KT 801	Bz-, Phac-, diClac-octanoyl-L-aminoacids*	D-isomers	A : Mg(II)*; I : Co(II), Cu(II), Mn(II), *o*-phenanthroline		[238]
Pseudomonas AAA 6020	Phac-L-Val, -L-Leu, -L-Glu, -L-Ala, -L-Met, -D-aminoacids	Ac-, Bz-aminoacids	I : Hg(II)*, Zn(II)*, Co(II) (10^{-3}M)*	8.0	[239]
Pseudomonas AAA6029	Bz-, Ac-D-Phe-, -D-Met, -D-Leu, -D-Ala, -D-Val	Phac-D- and -L-aminoacids, Bz-, Ac-L-Phe, -L-Met, -L-Leu, -L-Ala, -L-Val, Ac-D-L-amino-acids	A : L-Cys(3×10^{-3}M); I : Hg(II), Zn(II)(10^{-3}M), PCMB(10^{-3}M); NI ; Ca(II), Co(II), Mg(II) (10^{-3}M)	10.5 (Bz-*D*-Phe) 6.8 (Ac-*D*-Phe)	[240]
Micrococcus agilis	Ac-Phe-, -Met, -Val, -Leu, Clac-Phg, -Tyr, -Glu	Ac-Asp, Ac-*D*-Phe	I : Ag(I)*, Mn(II), Pb(II), Cu(II), Cd(II), Hg(II)(10^{-3}M), iodo-acetamide, PCMB, *o*-phenanth-roline, mercaptoethanol	7.0	[241]
Streptomyces tuirus IFO 13418	Ac-*D*-Phg, -*D*-Leu, -*D*-Ala, -*D*-Met, -*D*-Val, -*D*-Phe, -*D*-Tyr, -*D*-Trp, -L-Met	L-isomers	I : Ag(I), Hg(II)(10^{-5}M); NI : NaN_3, NaCN	7.5	[242]
Pseudomonas aeruginosa	Ac-L-Glu, Form-L-Glu, fluoroacetyl-L-Glu, propionyl-L-Gly, Ac-L-Gln, -L-Met, -L-Ala, -Gly	butyryl-L-Glu, Form-L-Met*, Ac-L-Ser*, -L-Asn*, -L-His*, -L-Asp*,	EA : Co(II), Zn(II), Mn(II), Mg(II) (10^{-3}M); I : PCMB (10^{-5}M); NI : *N*-ethylmaleimide	6.5	[243]
Penicillium vinaceous	aromatic Ac, Clac-L-amino-acids	D-isomers	A : Co(II)(10^{-3}M) I : Hg(II), Mn(II)	5.6—5.8 (Ac-amino-acids)	[244—247]
Penicillium oxalicum	diAc-*L*-Lys, Ac-*L*-Met, -*L*-Ala, -*L*-Glu, *L*-Leu *, -*L*-Val *, -*L*-isoLeu *, -*L*-His *, -*L*-Asp *, Clac-*L*-Ser, -*L*-Val *	—	—	7.6-7.8 (Clac-amino-acids)	
Aspergillus oryzae	ε-Bz-α-Ac-L-Lys**, Clac, Ac-aminoacids	D-isomers	A: Co(II), Zn(II) *, Cd(II) *, Mn(II) *, Cu(II) * (10^{-3} *M*)	7.5	[248—251]

Table 4 (cont'd).

Micro-organisms	Substrate specificity: hydrolyses	Substrate specificity: does not hydrolyse	Enzyme inhibitors and activators	pH optimum of activity	Refs.
Aspergillus avamori 78-2 *Streptoverticillium*	Ac-Trp, -Met Ac-*L*-Met, -*L*-Leu, -*L*-Phe, -*L*-Trp, -*L*-Phg	D-isomers	— —	7,0	[252] [253]

Notation: A = activators, I = inhibitors, NI = no influence on activity, EA = essential for activity, Form = formyl, Clac = chloroacetyl, norLeu = norleucine, Ambut = α-aminobutyric acid, Phg = α-aminophenylacetic acid (phenylglycine), and isoLeu = isoleucine.

*Weakly hydrolyses or activates.

**The hydrolysis of the diacyl derivatives of lysine takes place only at the α-amino-group (the hydrolysis of the ε-amino-group was examined in Section VI).

Table 5. The preparation and properties of immobilised acylases.

Methods of immobilisation, enzyme	Retention of activity, %	Change in properties of immobilised enzyme relative to native enzyme	Refs.
Pig kidney acylase I			
Adsorption on A-50 DEAE-sephadex	—	IT	[262]
on silica gel or C-80 silochrome	50	shift of pH optimum by 1 to alkaline region	[263,264]
on silica gel coated by a layer of lecithin, cholesterol, or inosine	25—45	ditto	[264]
on DEAE-cellulose	—	—	[264]
on ceramic carriers based on Al_2O_3, SiO_2, and TiO_2	H	pH optimum becomes very broad (7.5-9.5)	[265]
on silochrome coated with a protein or a synthetic polymer	15	—	[266,267]
Bonding to "Enzacryl-AA"	30	shift of pH optimum to alkaline region by 0.4; IT	[268]
to silochrome by means of γ-aminopropyltriethoxysilane and glutaraldehyde	H	—	[269]
to DEAE-cellulose via triazine dyes	H	—	[269]
to silochrome via diazotised *m*-phenylenediamine	H	—	[269]
to insoluble polyamide (copolymer of acrylamide, methyl acrylate, and *N,N'*-methylenebisacrylamide) via an amide linkage	50—100	IT	[270]
to COOH-containing gels via soluble carbodi-imides	—	—	[271]
to water-soluble dialdehyde-epidex and dialdehyde-dextran	L	—	[272]
Incorporation in polyacrylamide gel by oxidative-reductive polymerisation or photopolymerisation	6—12	—	[266]
Incorporation in polyacrylamide gel by radiopolymerisation	25—45	change in substrate specificity	[273]
Acylase from *Aspergillus ochracens*			
Covalent bonding to cell mycelia with the aid of albumin and glutaraldehyde	80	Increase of resistance to action of inhibitors; IT	[274]
Acylase from *Aspergillus oryzae*			
Adsorption on activated charcoal, acid, neutral, and alkaline alumina, and silica gel	<1		[275]
on tannin bonded to aminohexylcellulose	20—25		[276]
on PAB-cellulose	0	shift of pH optimum to acid region by 0.5-1; IT	[275,277, 278]
on TEAE-cellulose	51.5		
on DEAE-cellulose	55.2		
on C-50 KM-sephadex	0	shift of pH optimum to acid region by 0.5-1; IT	
on A-25 and A-50 DEAE-sephadex	56—59		
on IRC-50, IR-4B, and RI-45 amberlites	0		
Covalent bonding to diazotised PAB-cellulose	5.3		[279,280, 281,282]
to diazotised arylamino-glass	43.5		
to diazotised "Enzacryl-AA"	3.6		
to CM-cellulose azide	0		
to BrCN-activated cellulose	1.0		
to BrCN-activated sephadex	1.2		
to chloroacetycellulose	11.3	shift of pH optimum to alkaline region by 0.5-1; IT	
to bromoacetylcellulose	28 0		
to iodoacetylcellulose	39.0		
to arylamino-glass	20—40	shift of pH optimum to acid region by 0.5; IT	
Cross-linking on carrier (AE-cellulose) by a bifunctional reagent			[283]
1,4-dibromobutene	0.4		
1,4-dichlorobutene	0.4		
dicyclohexylcarbodi-imide	1.2		
di-iodomethane	0.3	—	
glutaraldehyde	0.6		
hexamethylene di-isocyanate	1.6		
tolylene di-isocyanate	0.2		
Cross-linking by a bifunctional reagent			[283]
glutaraldehyde	14.7	—	
tolylene di-isocyanate	1.3		
Incorporation in polyacrylamide gel	52.8	shift of pH optimum to acid region by 0.5; IT	[284]
Incorporation in carrageenan gel	50	IT	[285]
Microencapsulation			
in nylon	36.0	—	[284]
in polycarbamide	15.0		
in ethylcellulose	10.4

Notation. H = high, L = low, and IT = increase of thermal stability.

5. Industrial Utilisation of Microbial Acylases

Utilisation of microbial acylases for the resolution of amino-acid racemates into optical isomers constitutes at present the only method which has found an industrial application. For this reason there is an unusually great interest in micro-organisms capable of hydrolysing *N*-acylated aminoacids. The available literature data on microbial acylases are compiled in Table 4.[199-253]

It is seen from the data in Table 4 that microbial acylases exhibit a virtually no substrate specificity and hydrolyse all possible acyl derivatives of all the natural aminoacids except proline, hydroxyproline, and a number of synthetic α-amino-acids. It is of interest to note that the majority of acylases exhibit a pronounced stereospecificity and hydrolyse selectively only the acyl derivatives of the L-isomers of amino-acids, but, among the mutants of soil micro-organisms, it has been possible to detect an enzyme which catalyses the hydrolysis of acylated D-aminoacids with a fairly broad substrate specificity[220,221,240]. The presence of acylases stereospecific

to both L- and D-isomers gives rise to the hope that it will be possible to select a scheme for the aminoacid racemate resolution process depending on which of the two optical isomers has to be obtained.

However, despite the very large number of studies devoted to the conditions under which the enzyme producers are cultivated, the isolation and partial purification of acylases, the development of methods for the preparative resolution of racemates with the aid of the preparations obtained, the immobilisation of acylases from micro-organisms (the immobilisation of acylases will be considered in detail below), and the action of reactors based on an immobilised enzyme, hitherto neither the acylase from *Aspergillus oryzae* nor the acylase from soil micro-organisms have been obtained in a sufficiently pure form; nothing is also known about the mechanism of the action of these enzymes. Undoubtedly the knowledge of the mechanism of the enzyme action would assist in the search for optimum process conditions and in the selection of the type of catalyst for the industrial resolution of racemates using acylases from micro-organisms.

A whole series of methods for the resolution of aminoacid racemates into optical isomers with the aid of soluble acylases of microbial origin have now been patented[254-261], but there is no doubt that the future in this field belongs to immobilised enzymes or cells.

The extensive technological possibilities for the application of immobilised biocatalysts, in particular aminoacid acylases, have led to numerous studies on the immobilisation of the pig kidney acylase I and particularly the acylases from micro-organisms. The available literature data on the methods of preparation and properties of immobilised aminoacid acylases are compiled in Table 5.[262-285] The table shows that a high retention of the activity of the microbial acylase on immobilisation is achieved in the following methods: adsorption on DEAE- and TEAE-cellulose or DEAE-sephadex, covalent bonding to diazotised arylamino-glass or halogenocellulose, bonding via glutaraldehyde to arylamino-glass, incorporation in a polyacrylamide gel, and microencapsulation using nylon. However, the simplicity of preparation, low-cost, high operational stability, and the possibility of regeneration by the adsorption on the carrier of a fresh portion of enzyme corresponding to the loss of activity[286] (Fig.3) make acylase sorbed on DEAE-sephadex the most suitable biocatalyst for the practical resolution of racemates[287]. An industrial apparatus for the resolution of alanine, methionine, phenylalanine, valine, and tryptophan has been devised on the basis of this biocatalyst (Fig.4).[288] A 0.2 M solution of acetyl-DL-methionine, containing 5×10^{-4} M cobalt(II), is passed through a 1000 litre column containing the acylase from *Aspergillus oryzae* immobilised on DEAE-sephadex at a rate of 2000 litre h^{-1} at 50 °C and pH 7.0. The free L-methionine is precipitated when the eluate is evaporated. The yield is 91% and $[\alpha]_D^{25} = +23.4°$ after recrystallisation from water. The acetyl-D-methionine in the mother liquor is heated at 60 °C with acetic anhydride for racemisation and acetyl-DL-methionine is isolated and reused as the substrate[287].

Fig.5 presents a comparison of the usual method with a soluble acylase and the continuous process based on the immobilised enzyme. Firstly, there is a sharp reduction of the consumption of the biocatalyst and, secondly, there is an appreciable decrease of the amount of labour required and the purification procedure is simplified, which makes it possible to obtain a larger amount of the final product from the same amount of the starting materials. All these factors taken together make it possible to decrease by a factor of 2 the cost of the manufacture of L-aminoacids when an immobilised acylase is used.

The examples presented show that the enzymic conversion of racemates into optically pure aminoacids is already a method which has found technological applications, together with other procedures, for the preparation of these compounds. It is noteworthy that there is at present no universal method for the manufacture of the entire set of essential aminoacids. In each specific instance the procedure for the manufacture of a particular aminoacid must therefore be determined individually as a function of the raw materials, the amount required, the required purity, the availability of the necessary biocatalysts, and many other factors. However, there is no doubt that biotechnological processes employing enzymes capable of achieving the enantioselective conversion of the simplest aminoacid derivatives will find, in combination with the chemical synthesis of the starting materials, still more extensive applications in the immediate future.

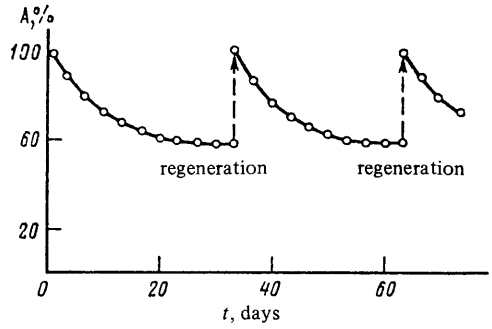

Figure 3. The stability and regeration of a column containing the acylase from *Aspergillus oryzae* immobilised on DEAE-sephapez; A = activity.

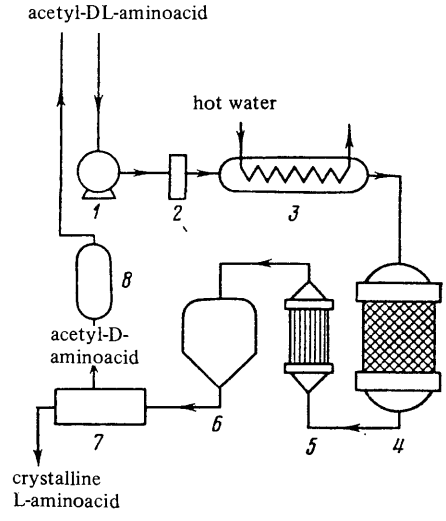

Figure 4. Industrial apparatus for the resolution of aminoacid racemates based on the acylase from *Aspergillus oryzae* immobilised on DEAE-sephadex[283]; 1) pump; 2) filter; 3) heat exchanger; 4) reactor; 5) evaporator; 6) crystalliser; 7) separator; 8) racemiser.

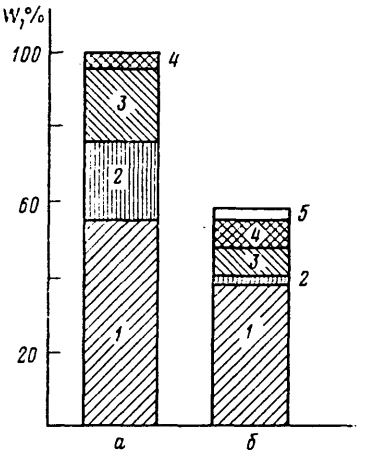

Figure 5. The relative costs W in the industrial resolution of aminoacid racemates with the aid of the acylase from *Aspergillus oryzae*, both soluble and immobilised on DEAE-sephadex: *a*) periodic process (soluble enzyme); *b*) continuous process (immobilised enzyme)[283]; costs of different process components: 1) substate; 2) enzyme; 3) labour; 4) fuel; 5) carrier for immobilisation.

The Debenzhydrylation and Transbenzhydrylation Reactions

P.Buckus

The review describes various reactions involving the cleavage of benzhydrylated compounds and their rearrangements and also the use of the benzhydryl group as a protective group. The lability of the bonds between the benzhydryl group and oxygen, sulphur, nitrogen, carbon, and other atoms is demonstrated.
The bibliography includes 484 references.

CONTENTS

I. Introduction 1203
II. The cleavage of the bonds between the benzhydryl group and oxygen, sulphur, and nitrogen atoms 1203

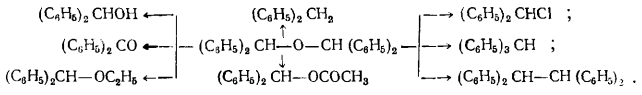
IV. The cleavage of the bond between the benzhydryl group and a carbon atom 1207
V. The cleavage of the bonds between the benzhydryl group and other atoms 1208



I. INTRODUCTION

There are reviews in the literature on the mobility of the benzyl (phenylmethyl) [1] and trityl (triphenylmethyl) [2] groups. The mobility of the benzhydryl (diphenylmethyl) group, which is of both theoretical and preparative interest, has also been known for a long time. However, until recently there have been no surveys in the literature of data on this problem. In the present review an attempt is made to fill this gap. A particularly large number of studies on the debenzhydrylation and transbenzhydrylation reactions have been published during the last two decades.

II. THE CLEAVAGE OF THE BONDS BETWEEN THE BENZHYDRYL GROUP AND OXYGEN, SULPHUR, AND NITROGEN ATOMS

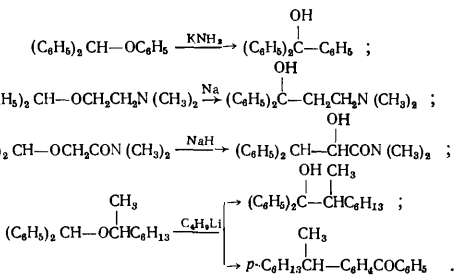
1. The Bond between the Benzhydryl Group and an Oxygen Atom

As early as the end of the past century, Nef[3] showed that the reaction of dibenzhydryl ether with water gives rise to benzhydrol, the reaction with benzene produces triphenylmethane, the reaction with ethanol gives rise to benzhydryl ethyl ether, and the product of the reaction with acetic acid is benzhydryl acetate. When dibenzhydryl ether reacts with hydrogen chloride, it is converted into chlorodiphenylmethane[4], its reaction with nitrogen dioxide converts it into benzophenone[5], it can be hydrogenated to diphenylmethane[6], and on treatment with potassium butoxide it is converted into 1,1,2,2-tetraphenylethane[7]:

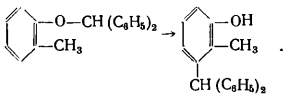
The reversibility of the reaction of chlorodiphenylmethane and its derivatives with ethanol has been demonstrated in a number of studies[4,8-11]. The decomposition of benzhydryl ethers with the following second groups has been described: ethyl[12-15], allyl[16], n-butyl[17], benzyl[18], phenyl[19-22], benzhydryl[7,12,23-26], trityl[18], and others[17,27-29]. The benzhydryl ethers of benzoin[30], hydroquinone[31], and cellulose[32], α-bromo-,[14] 4,4′-dinitro-,[7] and 4,4′-dimethoxy-benzhydryl ethers[15], dixanthydryl ether[33], *O*-benzhydryloximes[34], *O*-benzhydryl-α-aminoperoxides[35], as well as benzophenone ketals[12,36-46] have been decomposed.

Benzhydryl ethers are readily decomposed by liquid potassium–sodium alloy even at room temperature[12]. Shorygin showed[19] that, on treatment with sodium, benzhydryl phenyl ether decomposes with formation of diphenylmethane, *sym*-tetraphenylethane, phenol, and triphenylmethanol. In his survey of extensive researches into the decomposition of ethers by metallic sodium, Shorygin concludes that the cleavage of all the ethers proceeds via one pathway—the oxygen atom always remains bound to the phenyl or tolyl residue, since the benzhydryl, trityl, and naphthylmethyl groups are comparatively weakly bound to oxygen.

On reaction with hydrogen bromide in acetic acid, benzhydryl ethyl ether is converted to bromodiphenylmethane[5]. On direct chlorination of allyl benzhydryl ether, the addition of chlorine atoms to the double bond of the olefin is also accompanied by the dissociation of the bond between the benzhydryl group and the oxygen atom with formation of chlorodiphenylmethane[16]. Catalytic hydrogenation of benzhydryl benzyl ether in the presence of Raney nickel gives rise to diphenylmethane and benzyl alcohol, while hydrogenation of benzhydryl trityl ether produces triphenylmethane and diphenylmethanol, which is converted into diphenylmethane[18]. In the former case the cleavage takes place at the $O-CH(C_6H_5)_2$ bond, while in the latter case dissociation of the $O-C(C_6H_5)_3$ bond has been postulated. Certain benzhydryl ethers undergo thermal decomposition[15,22,32].

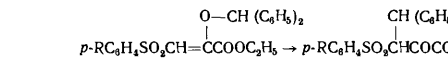


O-Benzhydrylhydroxylamine and its derivatives undergo interesting reactions[47-51]. Their oxidation by lead tetraacetate gives rise to a mixture of substances, including the products of the migration of the benzhydryl group from the oxygen to the nitrogen atom. Treatment of *O*-benzhydryl-*N*-tosylhydroxylamine with sodium hydride or butyl-lithium leads to the formation of the corresponding salts whose pyrolysis gives rise to benzophenone oxime in 100% yield as a result of the loss of the sulphinate group and the migration of the benzhydryl group from the oxygen to the nitrogen atom:



In the presence of a large excess of sodium hydride, diphenylmethanol is formed. Under the same conditions, *O*-benzhydryl-*N*-methyl-*N*-tosylhydroxylamine gives rise to diphenylmethanol, benzophenone, and *N*-methyltoluene-*p*-sulphonamide.

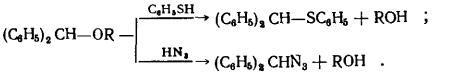
In 1924 Shorygin[52,53] discovered the carbinol rearrangement. He showed that, on heating with sodium wire in a sealed tube, benzyl phenyl ether produces diphenylmethanol.



Subsequently Wittig and Lohmann[36,54] observed an analogous rearrangement of benzhydryl methyl ether, which isomerises to diphenylmethylmethanol on treatment with phenyl-lithium. A rearrangement occurring when the dimethylketal of benzophenone is treated with powdered sodium has been described by Schlenk and Bergmann[36] and was subsequently confirmed by Wittig ahd Happe[36] [Ref.20? (Ed.of Translation)]. An analogous rearrangement involving these and other benzhydryl ethers was achieved still later with the aid of metallic sodium[55], sodium hydride[56], potassium hydroxide[7,30], potassium amide[57], butyl-lithium[58], and lithium dimethylamide[59]. The reaction proceeds in accordance with the following scheme:

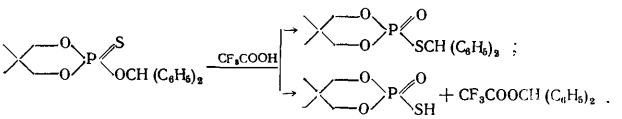
It has been found[60] that the benzhydryl ether of *o*-cresol undergoes a rearrangement with formation of 3-benzhydryl-2-methylphenol on heating for 5 h at 150 °C in the presence of zinc chloride:

It has been observed quite recently[61] that the ethyl esters of β-arenesulphonyl-α-diphenylmethoxyacrylic acids rearrange quantitatively in the temperature range from 160° to 190 °C to the ethyl esters of β-arenesulphonyl-β-diphenylmethylpyruvic acids:



According to the authors, the *C*-alkylation products are apparently formed as a result of suprafacial [1,3]-sigmatropic rearrangement of the benzhydryl group.

The reactions of dibenzhydryl ether with butyl and benzyl alcohols proceed with displacement of one benzhydryl group[62]:

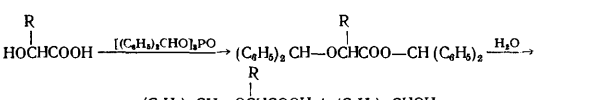


When butyl alcohol reacts with benzhydryl trityl ether, butyl trityl ether is formed together with benzhydryl butyl ether[62]. Yet another instance of the replacement of the benzhydryl group in ethers by the methyl group has been described recently[63]. The yields of the products of all these reactions are high.

It has been shown[28,64] that, on reaction with thiophenol and hydrazoic acid in the presence of trifluoroacetic acid, alkyl benzhydryl ethers are quantitatively converted into the corresponding sulphide and azide:

As early as 1865, Linnemann[65] pointed out the ready decomposition of the benzhydryl esters of acetic, benzoic, and succinic acids. According to Cheeseman's data[5], benzhydryl nitrate decomposes even at room temperature with formation of dibenzhydryl ether and benzophenone.

The hydrolysis of benzhydryl nitrate[5,66], benzhydryl formate[67,68], benzhydryl acetate[67-71], and benzhydryl benzoate[68,71], the ethanolysis of the last compound[72,73], the pyrolysis of the benzhydryl esters of nitric[5,74] and acetic[75,76] acids, the reduction of benzhydryl acetate[77] and benzhydryl benzoate[78], and the cleavage of other benzhydryl esters[79-85] have been described. Many studies have been devoted to the investigation of the kinetics and mechanisms of the above processes[66-73,81]. Thiocarbonates[86,87] and xanthates containing the benzhydryl group[88-90] have also been decomposed. The debenzhydrylation and transbenzhydrylation reactions of benzhydryl esters containing phosphorus[91-95], germanium[96], and silicon[96-100] atoms are of interest. For example[95]:



Chlorodiphenylmethane has been obtained in 90% yield by the reaction of benzhydryl acetate with acetyl chloride[77]. French workers[101,102] showed that, when benzhydryl acetate and benzoate are used in the Reformatskii reaction, the latter proceeds anomalously with formation of diphenylmethane and 1,1,2,2-tetraphenylethane.

Benzhydryl nitrate has been used successfully as the benzhydrylating agent for ammonia, hydrozine, amines, the amides of carboxylic and sulphonic acids, alcohols, mercaptans, urethanes, heterocyclic bases, and other compounds[5]. The kinetics of the benzhydrylation of aromatic hydrocarbons[103] and anisole[104,105] by benzhydryl acetate have been investigated:

Benzhydryl benzoate can be used for the benzhydrylation of thiophenol[64].

Methods for the synthesis of the benzhydryl esters of phosphoric acid and their employment for phosphorylation and the removal of protective groups have been investigated[106-109]. A new method of synthesis of benzhydryl esters based on the reactions of alcohols and carboxylic acids with tribenzhydryl phosphate was published in 1978.[110,111] In the reactions with hydroxyacids two benzhydryl groups are introduced one of which is removed more readily:

The benzhydryl protective group has found applications in the synthesis and the investigation of the properties and structures of nucleosides, nucleotides, and oligonucleotides[106,109,112,113]. In the study of the comparative stabilities under various conditions of the benzhydryl and trityl esters of uridine 3'-phosphate, it was shown that the trityl ester is more resistant to hydrolysis in 80% acetic acid and 50% formic acid than the benzhydryl ester[109].

The protection of the phenolic hydroxyl by the benzhydryl group has found applications in the synthesis of polyesters (including macrocyclic polyesters) containing two dinaphthyl residues[114,115]. The benzhydryl protective group has been used to obtain the esters of phenols and depsides[116-118]. Here one should mention also the protection of phenols and catechols by the diphenylmethylene group[118-126].

The benzhydryl group has found extensive applications for the protection of the carboxy-group in the synthesis and the investigation of the properties and structures of aliphatic

and aromatic carboxylic acids containing from several to several tens of carbon atoms[27,116-118,127-134]. Catalytic hydrogenation is most often employed for the removal of the protective group[27,116,118,127-131,133,134]. The catalyst employed is usually palladium. Furthermore, the benzhydryl protective group can be removed with the aid of trifluoroacetic[128,132] and 80% acetic[117] acids, a saturated solution of hydrogen chloride in acetic acid[132], hydrogen chloride or bromide in nitromethane[133], and basic reagents in ethanol and dioxane[132].

Khorlin and Privalova[135] were the first to describe the protection by the benzhydryl group of the carboxy-group in the most common representative of sialic acids—*N*-acetylneuraminic acid. This protective group and the methods for its removal have been investigated also for various reactions of other carbohydrate derivatives[80,128,131,136-138]. The selective hydrolysis of the protective group has been indicated[80].

The benzhydryl group has found extensive applications for the protection of the carboxy-group in the synthesis and investigation of β-lactam antibiotics, including nocardicin, penicillin, and particularly cephalosporin[134,139-216]. The benzhydryl protective group has been used also in the synthesis of other antibiotics[217] and analogues of the anti-inflammatory agent indomethacin[218] and derivatives of benzofuranone[219]. 4-Chloro-,[106] 2-nitro,[220] and 4-nitrobenzhydryl protective groups[221] have been described in the literature.

The instability of the benzhydryl esters of organic sulphur-containing acids has been pointed out in a number of studies[222-233]. Thus the benzhydryl ester of trichloromethanesulphenic acid rearranges to the corresponding sulphoxide on refluxing in hexane, while in polar solvents it undergoes thermal decomposition to chlorodiphenylmethane and dichlorosulphine[222]. The rearrangements of the benzhydryl esters of aromatic sulphenic[225] and sulphinic[226-228] acids to the corresponding sulphoxides and sulphones, which take place with high yields, have been described:

$$ArS{-}O{-}CH(C_6H_5)_2 \rightarrow ArS(=O){-}CH(C_6H_5)_2 ;$$

$$ArS(=O){-}O{-}CH(C_6H_5)_2 \rightarrow ArS(=O)_2{-}CH(C_6H_5)_2 .$$

A sulphone has been obtained instead of the ester on treatment of the sodium salt of toluene-*p*-sulphinic acid with benzhydryl nitrate[5].

When toluene-*p*-sulphonyl chloride is treated with diphenylmethanol, the product is dibenzhydryl ether (yield 90 to 100%) and not the expected benzhydryl ester of the sulphonic acid[223,224]. Diphenylmethane, diphenylmethanol, and benzophenone are formed on thermal decomposition of benzhydryl toluene-*p*-sulphonate[229-231]. If the latter is refluxed with benzamide in glacial acetic acid for 30 min, transbenzhydrylation takes place with formation of *N*-benzhydrylbenzamide[228]:

$$p\text{-}CH_3C_6H_4SO_3{-}CH(C_3H_5)_2 + C_6H_5CONH_2 \rightarrow C_6H_5CONH{-}CH(C_6H_5)_2 + p\text{-}CH_3C_6H_4SO_3H .$$

The reaction proceeds analogously also with propionamide[228]. The benzhydryl ester of toluene-*p*-sulphonic acid has likewise been used for the benzhydrylation of phenylacetylene[231].

2. The Bond between the Benzhydryl Group and a Sulphur Atom

The decomposition of benzhydryl sulphides with following second organic groups has been described: *N*,*N*-dimethylaminoethyl[55], benzyl[234,235], phenyl[228,236-238], benzhydryl[24,239,240], and others[235,241,242]. Di(benzhydrylthio)acetylene[243] and dibenzhydryl sulphide[244,245] have been decomposed. The oxidation of benzhydrylmethanesulphonyl sulphide by chlorine in an aqueous medium takes place in accordance with the following mechanism[246]:

$$(C_6H_5)_2CH{-}SCH_2SO_2CH_3 \xrightarrow{Cl_2} (C_6H_5)_2CHCl + ClSO_2CCl_2SO_2CH_3 .$$

When an attempt was made at the α-chlorination of benzhydryl benzyl sulphoxide by sulphuryl chloride, only the decomposition products were isolated: chlorodiphenylmethane and benzylsulphinic acid[247]. 1,1,2,2-Tetraphenylethane, dibenzhydryl ether, and debenzhydrylation products were detected among the products of the thermal decomposition of benzhydryl methyl and benzhydryl *p*-tolyl sulphoxides[233]. The following rearrangement has been described:

$$p\text{-}CH_3C_6H_4S(=O){-}CH(C_6H_5)_2 \rightleftarrows p\text{-}CH_3C_6H_4S{-}O{-}CH(C_6H_5)_2 .$$

Benzhydryl sulphides have been used to synthesise asymmetric disulphides. The *S*-benzhydryl protective group can then be removed with the aid of sulphenyl thiocyanates or thiocyanogen without affecting the disulphide bond[126,234,248,249]. Certain benzhydryl sulphides undergo very interesting reactions[126,234,248]. For example:

$$\begin{array}{c} (C_6H_5S{-}SCH_2CH_2CONHCH_2CH_2S{-})_2 \\ \uparrow S(CN)_2 \\ C_6H_5S{-}SCH_2CH_2CONHCH_2CH_2S{-}CH(C_6H_5)_2 \\ \downarrow S(CN)_2 \\ C_6H_5S{-}CH(C_6H_5)_2 \end{array} ;$$

$$(C_6H_5)_2CH{-}SCHCH_2COOH \rightarrow C_6H_5S{-}SCHCH_2COOH .$$

The thermal decomposition of benzyl diphenylmethanethiosulphonate yields a mixture of products[250]:

$$\begin{array}{c} (C_6H_5)_2CH{-}SCH_2C_6H_5 \quad SO_2 \quad (C_6H_5)_2CH{-}CH(C_6H_5)_2 \\ \uparrow \qquad\qquad \uparrow \qquad\qquad \uparrow \\ \hline \qquad\qquad\qquad | \end{array}$$

$$(C_6H_5)_2CH_2 \leftarrow (C_6H_5)_2CH{-}SO_2SCH_2C_6H_5 \rightarrow (C_6H_5)_2CS .$$

This can apparently explain the failure of the attempt to oxidise the above thiocyanate to the corresponding disulphone[251].

When di-*p*-methoxybenzhydryl *p*-tolyl sulphone is heated with ethanol in the presence of potassium hydroxide, the alcohol undergoes di-*p*-methoxybenzhydrylation with formation of the corresponding ether[15].

Benzophenone thioketals have also been subjected to decomposition[36,38,44,45,252,253].

3. The Bond between the Benzhydryl Group and a Nitrogen Atom

The decomposition of dibenzhydrylamine in the presence of alkali metal amides in liquid ammonia[254,255] and by photolysis[24,256] has been described. One of the products of the reduction of benzhydryl(benzyl)methyl amine[257,258], benzhydryl(methyl)-*p*-phenylbenzylamine[259], and other *N*-benzhydrylated compounds[260] is diphenylmethane. *sym*-Tetraphenylethane has been obtained from *N*,*N*-dibenzhydrylhydrazine[5]. The methylation of *N*-benzhydryl-*N*′,*N*′-dimethylethylenediamine by formaldehyde takes place with the removal of the benzhydryl group and the formation of the tetramethyl derivative of ethylenediamine[261]. The cleavage of benzhydrylguanidines in 80% sulphuric acid has been indicated[262]. *N*-Benzhydryl derivatives of acetamide[263], hydroxylamine[34,43,264-267], nitrosohydroxylamine[268], benzylideneamine[269], oxides[270,271], urethanes[272], *N*-substituted ammonium salts[273,274], Schiff bases[268,275-277], azo-compounds[278-283], azides[268], and other nitrogen-containing compounds[284] have also been subjected to decomposition.

An instance of the simultaneous elimination of the *O*-benzyl and *N*-benzhydryl groups is known[260].

When chlorodiphenylmethane is heated with aminoalcohols (for example with *N*,*N*-di-isopropylethanolamine), the hydrochlorides of the corresponding aminoethers are formed[285]. A mechanism has been proposed for this reaction, according to which the N atom is initially alkylated with formation of an ammonium salt; the subsequent N–O transbenzhydrylation leads to the formation of sterically hindered benzhydryl aminoethers[285]. The possibility of this mechanism has been confirmed by other studies[286,287], which showed that at 175 °C benzhydryl(β-hydroxyethyl)dimethylammonium chloride undergoes a thermal rearrangement via a similar mechanism:

$$(CH_3)_2\overset{+}{N}(Cl^-)CH_2CH_2OH \rightarrow (CH_3)_2NHCH_2CH_2O{-}CH(C_6H_5)_2 \quad .$$
$$\qquad\qquad\qquad\qquad\quad |$$
$$\qquad\qquad\qquad\qquad\quad CH(C_6H_5)_2$$

The dimethylaminoalkyl ethers of diphenylmethanol are also formed on rearrangement under these conditions of other compounds of the type $[Ar_2CH\overset{+}{N}(CH_3)_2(CH_2)_nOH]Cl^-$, where $n = 2–7$. Diphenylmethanol, chlorodiphenylmethane, *sym*-tetraphenylethane, and dibenzhydryl ether have been detected as side products in this process[286,287].

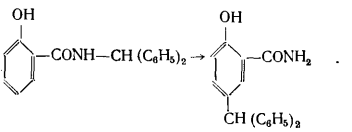
There are indications in the literature of the possibility of the rearrangement of benzophenone *N*-benzyloxime to *N*-benzhydrylbenzaldoxime[34,288]:

$$(C_6H_5)_2C{=}\overset{+}{N}(O^-){-}CH_2C_6H_5 \rightarrow C_6H_5CH{=}\overset{+}{N}(O^-){-}CH(C_6H_5)_2 \quad .$$

When α,α-diaryl-*N*-benzhydrylnitrones, i.e. the *N*-benzhydryloximes of benzophenone and its derivatives, are heated to 200 °C, the corresponding isomeric *O*-benzhydryloximes are formed[34,50,264,270,271,288–298]:

$$(C_6H_5)_2C{=}\overset{+}{N}(O^-){-}CH(C_6H_5)_2 \rightarrow (C_6H_5)_2C{=}N{-}O{-}CH(C_6H_5)_2 \quad .$$

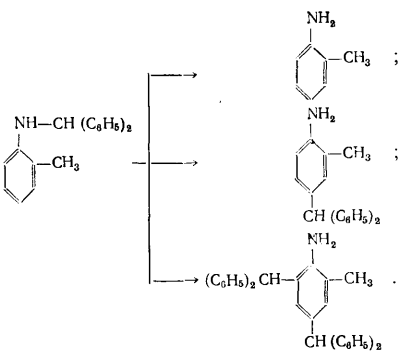
The kinetics and mechanism of this thermal rearrangement as well as the decomposition of *N*-benzhydryloximes have been widely investigated[34,264,270,271,288–297].



The decomposition of benzophenone Schiff bases[266,268,275,298–308], oximes[43,267,309–317], and hydrazones[139,279,318–327] has been described. The oximes have found applications in the synthesis of cycloserine (with removal of the *N*-protective group),[309–311] while the hydrazones have been used as benzhydrylating agents for carboxylic acids[319] and chlorobenzotriazole[326].

On reaction with benzylamine, the acyl derivatives of benzophenone imine give rise to the usual products of the addition of the azomethine group or are cleaved to the amides of the corresponding acids and benzophenone *N*-benzylimine[308]:

$$(C_6H_5)_2C{=}NCOR + C_6H_5CH_2NH_2 \xrightarrow{20°} [(C_6H_5)_2C(NHCH_2C_6H_5)NHCOR] \rightarrow$$
$$\rightarrow RCONH_2 + (C_6H_5)_2C{=}NCH_2C_6H_5 \quad .$$

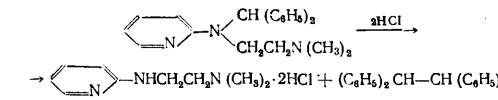


It is extremely likely that in the latter case the *N*-acylimines initially also give rise to addition products, but the latter are unstable and decompose rapidly. In one case the formation of the unstable addition products was demonstrated experimentally. In the reaction of benzylamine with benzophenone *N*-chloroacetylimine in the cold, it was possible to isolate an unstable addition product, which decomposed fully in the course of several days at a temperature as low as 20 °C.[308]

When *N*-benzhydrylsalicylamide is heated with toluene-*p*-sulphonic acid in acetic acid, the benzhydryl group migrates from the nitrogen atom to the carbon atom and 5-benzhydryl-2-hydroxybenzamide is formed[228]:

The same *N*-benzhydryl derivatives of salicylamide undergo debenzhydrylation and not hydrolysis on being refluxed for 3 h with concentrated hydrochloric acid in glacial acetic acid[328].

The lability of the bond between the benzhydryl group and the nitrogen atom in the *N*-benzhydryl derivatives of aromatic amines has been investigated[329–333]. *sym*-Tetraphenylethane was detected among the decomposition products obtained on distilling *N*-benzhydryl-*N'*,*N'*-dimethyl-*N*-phenylethylenediamine[330]. On heating to 150 °C, the hydrochloride of *N*-benzhydrylaniline gives rise to an isomerisation product (*p*-benzhydrylaniline) and also the *N*,*C*-dibenzhydryl derivative of aniline and tetraphenylethylene[331]. When *N*-benzhydryl-*o*-toluidine is heated in a mixture of acetic and hydrochloric acids, the debenzhydrylation and transbenzhydrylation reactions proceed in accordance with the following scheme[332]:



If the reaction is carried out in the presence of *o*-cresol, the *C*-benzhydrylation product of the latter is also formed[332]. It is striking that, on heating to 145 °C with hydrochloric acid, *o*-benzhydrylphenylaniline produces 1-phenylfluorene and aniline[334].

Since the alkylation of 6-azauracil takes place preferentially at the imide group, the latter must be protected in the synthesis of 6-aza-analogues of uridine and related compounds. The benzhydryl group has been used for this purpose. 1-β-D-Ribofuranosyl-6-azauracil[112], 6-azauridine 5'-phosphate[113], and their 5-methyl-derivatives have been synthesised in this way. The *N*-benzhydryl protective group has found applications in the synthesis and reactions of organophosphorus analogues of biologically active compounds[277], β-lactams[335], 1,2-dihydropyridine[336], and 9-amino-9*H*-purines[337].

The debenzhydrylation reaction takes place on hydrogenation of derivatives of *N*-benzhydrylazetidine[338–342]. Protection by the *N*-benzhydryl group has also been described for derivatives of 1,2-diazetidine and the possibilities for its removal have been investigated[343–345]. The possibility of the migration of the benzhydryl group in the benzhydryl derivatives of 2-aminopyridine has been assumed[346]. On distillation and on treatment with dry hydrogen chloride, *N*-benzhydryl-*N'*,*N'*-dimethyl-*N*-(2-pyridyl)ethylenediamine

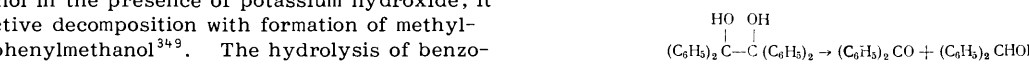
decomposes[330]:

The same derivative of 2-aminopyridine could not be obtained by the reaction of 2-benzhydrylaminopyridine with β-chloroethyldimethylamine, since here too the debenzhydrylation reaction takes place[347]. Because of this, the attempts to synthesise 2-benzhydrylaminomethylimidazoline were also unsuccessful[261]. The hydrogenolysis of the 1-methyl- and 1-benzyl-derivatives of 4-benzhydrylpiperazine has been investigated[348]. When (pyrazinylmethyl)dimethylmethanol is refluxed in ethanol in the presence of potassium hydroxide, it undergoes reductive decomposition with formation of methylpyrazine and diphenylmethanol[349]. The hydrolysis of benzotriazolylchlorodiphenylmethane leads to the formation of benzotriazole and benzophenone, while treatment with methanol leads to benzotriazole and the dimethylacetal of benzophenone[326].

The *N*-diphenylacetyl protective group has been investigated[350–353].

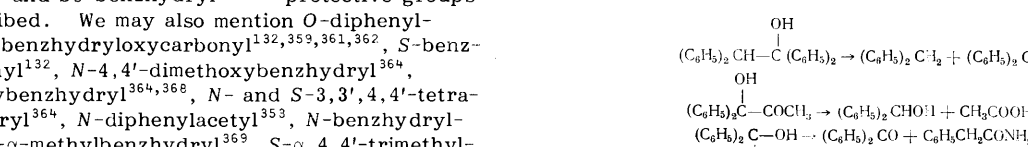
III. THE BENZHYDRYL PROTECTIVE GROUP IN THE SYNTHESIS AND REACTIONS OF AMINOACIDS AND PEPTIDES

The benzhydryl and diphenylmethylene protective groups have found applications in the synthesis and study of the properties and structures of aminoacids and peptides[111,125,126,129,130,132,133,219,234,238,248,249,301,305,317,354–405]. Mention must be made of derivatives of proline[111,129,354,355], histidine[356], hydroxyaminoacids[219,357], tyrosine[357], α-vinyl-α-aminoacids[125], sulphur-containing[132,234,238,248,249,348–382] and selenium-containing[383–386] aminoacids and peptides, glucopeptides[387,388], and individual fragments of the insulin molecule[375,377–380,389].



The benzhydryl group has been usually employed to protect the carboxy-group[111,126,129,130,132,133,219,383–388,390–396]. The *O*-benzhydryl[357], *N*-benzhydryl[301,356], *S*-benzhydryl[234,249,358,360,361,363–382], and *Se*-benzhydryl[384,386] protective groups have been described. We may also mention *O*-diphenylmethylene[125], *N*-benzhydryloxycarbonyl[132,359,361,362], *S*-benzhydryloxycarbonyl[132], *N*-4,4′-dimethoxybenzhydryl[364], *S*-4,4′-dimethoxybenzhydryl[364,368], *N*- and *S*-3,3′,4,4′-tetramethoxybenzhydryl[364], *N*-diphenylacetyl[353], *N*-benzhydrylacrylamide[397], *S*-α-methylbenzhydryl[369], *S*-α,4,4′-trimethylbenzhydryl[369], and other *S*-protective groups for cysteine[369]. The benzhydryl[376], 4,4′-dimethoxybenzhydryl[389,398–403], and xanthyl[404,405] groups have been used to protect the amide group in asparagine, glutamine, and in the amides of other α-aminoacids. The oxime of the *p*-polymer-substituted benzophenone has been proposed quite recently as a protective group in the synthesis of peptides[317].

One of the methods for the removal of the benzhydryl protective group is catalytic hydrogenolysis[129,130,354,355]. In the synthesis of carcinolytic peptides, the complete removal of the benzhydryl group is virtually achieved with the aid of 98% formic acid at room temperature (3 h).[392] Under mild conditions, the benzhydryl protective group can be eliminated with anhydrous hydrofluoric acid[126,376].



For the synthesis of asymmetric (relative to the cysteine residues) cysteine peptides, it is essential that the sulphhydryl groups should be substituted by different protective groups to permit their separate elimination[359,363]. *S*-Trityl-cysteine and *S*-benzhydrylcysteine have been proposed for this purpose. Conditions have been found for the cleavage of *S*-trityl sulphides with retention of the *S*-benzhydryl group[248,358,359,363,372–374]. The *S*-trityl protective group can be readily eliminated at room temperature by treatment with heavy metal salts. The *S*-benzhydryl group is not then affected and can be removed by treatment with trifluoroacetic acid. It has been reported[238] that *S*-trityl sulphides are cleaved by an alcoholic solution of iodine at room temperature, while their *S*-benzhydryl analogues are stable even on boiling.

IV. THE CLEAVAGE OF THE BOND BETWEEN THE BENZHYDRYL GROUP AND A CARBON ATOM

The thermal decomposition of benzopinacol was described as early as 1877:[406]

Phenyltolylpinacol behaves analogously, decomposing at the instant of fusion to phenyl tolyl ketone and phenyltolylmethanol[406]. The conversion of dinitrosotetraphenylethane into benzophenone oxime was later described[407]. Many studies devoted to the cleavage of benzopinacol[14,408–415], its derivatives and analogues[14,20,21,57,411,416,417], phenylbenzoin[39,418–421], α-*C*-substituted derivatives of diphenylmethanol[349,422–425], triphenylethanol[426–430], tetraphenylethanol[7,408,431,432], and benzhydryl phenyl ketone[429,430,432–434] were published subsequently. Less attention has been devoted to DDT,[435] 1,1-diphenylethanediol[436], benzoyldiphenylethanediol[437], benzoyltriphenylethanol[438], 1,1,2-triphenyl-1-propanol[410], 1,1,2-triphenyl-1-butanol[410], 1,1-diphenyl-4-pent-1-enol[439], 1,1,4,4-tetraphenylbuta-1,2-dien-4-ol [40] and its 3-substituted derivatives[441], hexaphenylallene glycol[440], benzhydryl methyl ketone[279], benzhydryl benzyl ketone[442], *p*-anisyl benzhydryl ketone[429], dibenzhydryl ketone[30], benzhydryl α-hydroxybenzhydryl ketone[30], benzoyldiphenylaminomethane[39], 1,2,2-triphenylaminomethane[428], triphenylaminoethanol[254], triphenylacetamide[443], 2-diphenylacetyl-1-methylbenzimidazole[444], and other *S*-benzhydrylated compounds[39,84,85,417,425,445–449]. The products of the cleavage of the above compounds are as a rule diphenylmethane, diphenylmethanol, and diphenyl ketone:

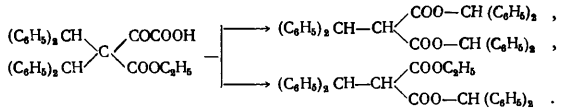
In an early investigation Chichibabin showed[450,451] that pentaphenylethane decomposes at an elevated temperature at the C–C bond of ethane, like hexaphenylethane. In this case the pentaphenylethane molecule decomposes into radicals, which then recombine differently:

According to the observations of Cone and Robinson[452], treatment of this compound with phosphorus pentachloride yields chlorotriphenylmethane. The instability of the central C–C bond in pentaphenylethane was subsequently investigated by other workers[12,453–461]. The dissociation of the carbon–carbon bond in *sym*-tetraphenylethane[12,455,462–464] and *p*-benzhydrylphenyltriphenylmethane[36,465] was indicated.

The photolysis of 1,1,2,2-tetraphenylethane, 1,1,3,3-tetraphenylpropane, 1,1,4,4-tetraphenylbutane, and 1,1,5,5-tetraphenylpentane has been described[24,466,467]. The oxidation of 1,1-diphenylethane, 1,1-diphenylpropane,

1,1-diphenylbutane, 1,1-diphenylpentane, and 1,1,diphenylhexane by oxygen has been investigated[468,469]. It has been shown that tertiary carbon atoms are acted upon by oxygen with formation of hydroperoxides, whose decomposition leads to the formation of benzophenone, its oxidation products, and tarry substances. The product of the electrochemical oxidation of diphenylacetic acid in water is diphenylmethanol, while the same reaction in acetonitrile gives rise to a mixture of diphenylmethane, tetraphenylethane, and the benzhydryl ether of the starting material[470,471].

Attention has been drawn[472] to the anomalous course of the Nef reaction with salts of 1,1-diaryl-2-nitroethanes, in which diaryl ketones are obtained instead of the corresponding diarylacetaldehydes:



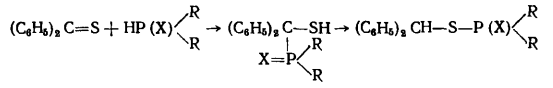
The oxidative hydrolysis of 3,3-diphenylpropionitrile, one of the products of which is diphenyl ketone (yield 22%), has been described quite recently[473]:

Diphenylmethane (yield 49%) and 1,1,2,2-tetraphenylmethane (yield 6%) have been detected and isolated from the products of the thermolysis (250 °C, NaH) of 1,1-diphenylpropanone azine $[(C_6H_5)_2CHC(CH_3)=N-]_2$.[474] The formation of the expected pyrrole derivatives is not observed under these conditions.

When β,β-dibenzhydryl-β-ethoxycarbonyl-α-oxopropionic acid is heated for 20 min at 190–200 °C, the following benzhydryl derivatives of malonic acid are formed[475]:

It has been found[476] that the reaction of trichloroethylene and 2-chloro-1,1-diphenylethylene with benzene in the presence of aluminium chloride results in the formation of polynuclear condensation products, which give rise to anthracene, triphenylmethane, and diphenylmethane on thermal decomposition. These experiments were subsequently repeated[463].

2-Hydroxy-1,4-naphthoquinone and benzophenone are formed in the oxidation and other reactions of 2-benzhydryl-1,4-naphthoquinone[477]. The interaction of 2,3-dibenzhydryl-1-phenylnaphthalene with benzene in the presence of aluminium chloride gives rise to triphenylmethane, 1-phenylnaphthalene, and its isomerisation product—2-phenylnaphthalene[478].



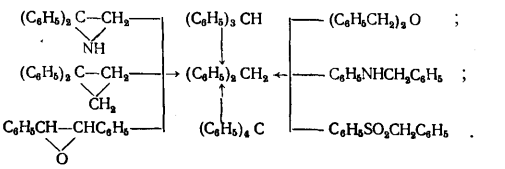
The reaction of 3,3-diphenylpropyl phenyl sulphide under the influence of an organolithium compound proceeds in accordance with the following mechanism[479]:

If the SC_6H_5 group is replaced by the $NHSO_2C_6H_5$ group, the oxidation of the resulting compound with potassium permanganate gives rise to benzophenone[480].

V. THE CLEAVAGE OF THE BONDS BETWEEN THE BENZHYDRYL GROUP AND OTHER ATOMS

It has been shown[481] that dibutylphosphinous and dibutylphosphonothious acids react with thiobenzophenone in the absence of catalysts at room temperature. The main products isolated in all cases were the isomeric *S*-benzhydryl phosphorothioates and their analogues instead of the expected α-mercapto-derivatives of phosphorus acids:

Such isomerisation of α-mercapto-derivatives of phosphorus acids, i.e. the C → S migration of the phosphoryl and thiophosphoryl groups, has been investigated also in relation to other examples[481]. α-Mercapto benzhydrylphosphonites rearrange on heating to benzhydrylphosphonothionates[482].



Benzhydryl acetate has also been obtained in accordance with the following mechanism[483]:

The thermal decomposition of dibenzhydryl diselenide has been described[484]:

Diphenylmethane, diphenylmethanol, and diphenyl ketone have been obtained in various reactions (reduction, oxidation, hydrolysis, thermolysis, and photolysis) of many other compounds containing phenyl groups (usually attached to a carbon atom), for example:

These instances of the formation of the benzhydryl group are not considered in this review, since they can be only formally included among debenzhydrylation reactions.
