In all the industrially developed countries sulphate lignin is used mainly as a fuel in regeneration furnace systems. This application cannot be regarded as normal, because lignin is a valuable chemical raw material and its employment for the generation of power is an example of an uneconomic utilisation of a valuable natural polymer such as sulphate alkali lignin.

Problems concerning the employment of sulphate lignin for the stabilisation of emulsions, in the processing of cement and ceramics, in the dispersion of dyes, pigments, etc., where the surface-active properties of the water-soluble lignin salts are used, and in the preparation of thermoreactive resins in combination with phenols, urea, and other products, have been fairly thoroughly described in the literature. Sulphate lignin can be used to prepare valuable low-molecular-weight products: dimethyl sulphide (the starting material for the manufacture of dimethyl sulphoxide, which is a very valuable solvent), phenolic derivatives more valuable than those obtained from petroleum, vanillin, etc. The possibility, in principle, of using sulphate alkali lignin in the form of liquid self-hardening mixtures in the casting industry, etc. has been demonstrated recently[23–25,48,96,117,118].

Among all the technical lignins, sulphate lignins are chemically the most reactive and have therefore been used for a long time to modify polymers. The majority of investigators believe that chemical bonds may be formed between the lignin macromolcule and the macromolecules of synthetic polymers, although the question of the nature of these bonds

remains open. The oldest and the most familiar application of lignin as a component of polymeric materials involves the reinforcement of raw rubbers. Very extensive studies, published both abraod and in the USSR, have been devoted to this problem[9,15,16,96,119–125].

A distinctive feature of the preparation of lignin-filled rubbers is that, in order to reinforce the latter, lignin is introduced at the latex stage, since the introduction of powdered lignin into dry rubber does not lead to the "reinforcement" effect. It is believed that the reason for this is the binding of lignin particles to one another by hydrogen bonds, which leads to condensation and growth of its particles and prevents the dispersion of the lignin particles during the rolling of rubber[9,119].

The introduction of lignin into rubber at the latex stage greatly complicates and increases the cost of the technology of its manufacture, since the usual method for the preparation of the parent lignin–rubber mixture consists in the dissolution of lignin in an aqueous solution of alkali, mixing of the alkaline solution with the rubber latex, heating the mixture, and the joint coagulation of the rubber and lignin by pouring the mixture into a solution of acid while stirring. The reinforcing effect of lignin is determined by its particle size, which depends on the precipitation conditions and certain other factors[9]. In the parent mixture the lignin is not bound to rubber by chemical bonds. The reinforcing effect of lignin increases appreciably when lignin is precipitated in the presence of sodium silicate[16].

The mechanism of the reinforcement of raw rubbers by sulphate lignin can be accounted for mainly by its surface-active properties and the coagulate is therefore precipitated in the form of fine particles. This leads to the formation of a material with low stress parameters for 300% elongation and a high hardness, so that the lignin-filled vulcanisates exhibit a lower resistance to wear than carbon-black filled rubbers.

In order to eliminate the above defects, the lignin-rubber mixture is treated with polyisocyanates and is used in the manufacture of rubbers for car tyres. The polyisocyanates employed are di- and tri-isocyanates of different chemical structure in amounts ranging from 1 to 10 parts per 100 parts of rubber (dry weight)[126]. The articles obtained from such a composition have improved operating characteristics, in particular the stress corresponding to 300% elongation and the resistance to abrasion increase by a factor of 1.5–2.0 (depending on the content of the additive).

The mechanism of the reinforcement of rubbers by lignin is fairly complex and has not been completely investigated. Apart from the physical explanation, associated with the surface-active properties of lignin, there is a chemical explanation of this phenomenon. The reinforcement of rubbers by alkali lignin can be accounted for by the interaction of the active groups of lignin with the double bonds or active groups of the rubbers—the formation of hydrogen bonds between the hydroxy-groups of lignin and the π electrons of the double bonds of the rubbers[119]. When isocyanates are introduced, the high reactivity of the isocyanate groups promotes the rupture of the hydrogen bonds, which are unable to reinforce the dry lignin and the latter is thus converted into an active series.

Sludge lignin can be used successfully as an active filler and reinforcing agent for polymeric materials[127].

Lignin-filled rubbers can be obtained in two ways: (1) the coprecipitation of lignin and rubber from a lignin–latex mixture by the method indicated above and (2) by introducing hydrated lignin into rubber with the aid of rubber mixing equipment. Both these procedures are technologically complex and uneconomical and have not therefore found extensive industrial applications.

The vulcanisates filled with dry lignin are characterised by a tensile stress σ_t not exceeding 6.0 mN m^{-2}.

Lignin–oil pastes can be used as lignin products isolated from black liquors for the reinforcement of raw and cured rubbers. They are obtained by mixing hydrated lignin, containing approximately 60% of moisture, with a plasticiser (tall oil, pine resin, PN-6 oil), after which moisture is evaporated from the resulting mixture with continuous stirring (the stirring temperature is 60–70 °C). Simultaneously with drying, the lignin is dispersed in the plasticiser, which prevents the agglomeration of the lignin particles and tends to increase the degree of their dispersion. Outwardly, the lignin–oil paste consists of a powder or solid lumps of dark-brown colour, depending on the type of plasticiser. Such a paste can be introduced into rubbers using the normal rubber mixing equipment[123].

Yet another method for the isolation of lignin from black liquors involves its precipitation in the presence of water-soluble additives (low-molecular-weight alcohols, aldehydes, ketones, or emulsifiers) which promote the formation of a highly disperse product. The vulcanisates obtained using these lignins have high values of the tensile stress: $\sigma_t = 16$ and 18 mN m^{-2} respectively.

Dry sulphate lignin is of considerable interest for the filling and modification of thermoplastics in order to obtain frost-resistant polypropylene (PR) compositions and also in the reprocessing of waste from polymeric materials. Studies have been carried out on the creation of composite materials using sulphate alkali lignin based on polyolefins (PO)—materials of the type of poprolin, including preparations based on secondary polyethylene obtained from used articles[17–21,61–67,128–138].

The study of the character of the interaction of the ingredients of the polymer composition under processing conditions is very important for the specific modification of the basic polymer by sulphate lignin (when the content of the latter is up to five parts) and for the determination of the technological regime for the conversion of poprolin materials into articles.

The EPR method is of practical importance for such purposes. It has been established by this method that paramagnetic polypropylene and lignin centres formed at the processing temperatures interact at the interface between the two phases (polypropylene–lignin); it has been shown that the interaction has a radical mechanism[19,64,66,97]. The results agree with data obtained in the study of free radicals in the formation of the carbon black–raw rubber gel. It has been observed that during the rolling of the rubber in the course of its processing, free radicals are formed and interact with the polymer via a radical mechanism[140,141]. An interesting feature of this process is the approximately linear relation between the ratio of the EPR line widths in air and *in vacuo* ($\Delta H_{air}/\Delta H_{vac}$) and the specific surface of the carbon black, which indicates the surface character of the interaction of some of the spins, capable of participating not only in the formation of the carbon black–raw rubber gel but also in the agglomeration of the carbon black particles.

By analogy with data obtained in the study of carbon black by EPR, the concept of c_a/c_0—the relative concentration of the active free radicals on the surfaces of the lignin particles—was introduced for the interpreation of the results in the polypropylene–lignin system and the differentiation of the free radicals present on the surfaces of the lignin particles and responsible for the interaction with the polypropylene; according to the literature[19,129,132], the relative concentration represents the different $c/c_{0\,NaCl} - c/c_{0\,PP}$, where c is the overall concentration of the lignin free radicals at the experimental temperature, c_0 the concentration at room

temperature calculated with a correction for the Curie law, c_0 NaCl the concentration of the radicals R of lignin in the inert NaCl diluent, and c_0 pp the corresponding concentration in the polypropylene matrix. This approach makes it possible to follow the kinetics of the interaction of the paramagnetic centres of lignin and the radicals R of polypropylene at the processing temperatures, to assess its character and to optimise the polymer composition and the optimum lignin content.

In order to improve the operating characteristic of poprolin (to reduce the embrittlement temperature T_{br} and increase the frost resistance), a low-molecular-weight plasticiser dioctyl sebacate (DOS) was introduced into the polypropylene–lignin system, which resulted in the formation of a frost-resistant material—poprolin-1.

It follows from the EPR data that the introduction of DOS into poprolin disrupts the interaction between the paramagnetic centres of lignin and polypropylene, which entails a decrease of c_a/c_0. The attempts to intensify the disrupted interaction by introducing an additional amount of lignin (in excess of the optimum value for the given composition) did not lead to the desired results. Tests showed that the disrupted interaction cannot be restored by introducing fillers of the type of titanium dioxide, which has been stated[24] to be capable of adsorbing lignin, wetting its surface and leading to a more effective dispersion of the plasticiser and lignin in the polymer matrix. Furthermore, the introduction of titanium dioxide prevents the interaction of lignin with DOS, stimulating the interaction of lignin with polypropylene and leading to an enhanced stability of the system[64,65]. These data indicate the possibility of regulating by the above procedures the properties of complex materials important for practical applications.

The study of the rheological characteristics of poprolin-1 showed that the introduction of the optimum amount of lignin (three parts) reduces its fluidity, which entails the transition of the flow curve to the region of the lowest shear stresses compared with the initial polypropylene[19,61,128,139]. This greatly facilitates the processing of poprolin-1, the articles obtained from it being characterised by effective operating characteristics under the conditions of low temperatures (compared with the basic polypropylene) and the range of their utilisation is greatly increased.

One of the procedures in the technology of the processing of plastics designed to increase the quality of the polymeric materials and to increase the useful lifetime of the articles obtained from them is known to involve the introduction of antioxidants in order to suppress oxidation processes occurring under the influence of various factors (high temperatures, solar radiation, etc.). Phenols, as inhibitors absorbing in the ultraviolet, have come to be widely used among antioxidants[142]. The photoreaction of phenols leads to the formation of phenoxy-radicals, which in their turn undergo a photoreaction in the polymer matrix and their subsequent fate depends on their reactivity, temperature, concentration, and the type of polymer matrix[142–144].

In terms of their chemical structure, lignins can be assigned to the class of sterically hindered phenols. On the other hand, the involvement of sterically hindered phenols in radical reactions reduces to the initial abstraction of the hydrogen atom from the hydroxy-group of the phenols with formation of a phenoxy-radical, i.e. the behaviour of the sterically hindered phenol in radical reactions is determined by the properties of the phenoxy-radicals formed. It is known that the O–H bond energy in sterically hindered phenols is somewhat lower than in unsubstituted phenols, which facilitates, on the one hand, the homolytic dissociation of the given bond with formation of phenoxy-radicals, and on the other hand, leads to the formation of thermodynamically more stable species—stable free radicals[144]. The stability of the radicals R formed in the reaction of the antioxidant has a significant influence on the kinetics of the ageing of the polymeric materials, since the probability of the involvement of these radicals, following the enhancement of their stability, in recombination reactions in subsequent processes diminishes, which promotes an increase of the inhibiting effect of the antioxidant. The character of such stability is to a large extent determined both by structure factors (intramolecular stabilisation) and by the interaction of the radicals with the medium (intermolecular stabilisation). The experimental results, showing that lignin or its degradation products can be used as thermostabilisers for polypropylene at its processing temperatures (in excess of 200 °C) and as inhibitors in its photoageing process, may serve as confirmation of the above considerations[64,132,145,146].

However, data have been obtained recently showing that sulphate lignin can be used as a photomodifying additive to polypropylene and that it does not affect its degradation on prolonged irradiation. At the same time it can greatly reduce the efficiency of light stabilisers operating in accordance with an inhibition mechanism, so that, in order to improve the light stability of lignin-containing compositions, it is desirable to introduce additional substances belonging to the class of u.v. absorbers or dyes. Since the ligno-tall product contains simultaneously structure-forming (lignin), reinforcing (aliphatic acid salts), and plasticising (tall oil) substances, it is a complex modifying agent[139].

The application of the ligno-tall substances greatly simplifies the technology of the preparation of frost-resistant polypropylene of the type of poprolin-1 because the necessity for the initial introduction of the scarce and expensive DOS is eliminated.

The application of sulphate alkali lignin in the preparation of compositions based on polyolefins using secondary low-density polyethylene (SLDPE), obtained from worn agricultural sheeting, is of great theoretical and practical interest[20, 21,134–136].

A factor promoting the formation of such composite material (poprolin-2) was the fact that SLDPE is a product activated during use as a consequence of photo-oxidative reactions in the LDPE during the use of the sheeting. The kinetics of the oxidation of the LDPE depend to a large extent on the degree of branching of the polymer and the oxidation proceeds via the formation of polymeric hydroperoxides (POOH) and ketones with the possible occurrence of radical reactions in the photodecomposition of ketones via a Norrish type I mechanism[147,148]. At the same time an additional amount of radicals R are formed in the SLDPE, their concentration being somewhat greater than in LDPE and lower than in polypropylene[19]. As a result of the formation of an additional amount of free radicals in the secondary polyethylene matrix, the effect of the interaction of the polymeric components in poprolin-2 (SLDPE and polypropylene) with lignin is much stronger, which increases the stability of the composition as a result of the improvement of the operating stability of the system.

Materials of the type of poprolin have been successfully converted into articles of extrusion (film materials, including coextrusion films based on moderate-pressure polyethylene, tubes, and sheets), by casting under pressure (transport packing capable of repeated use for branches of industry manufacturing food products), and by mechanothermomoulding and rotation moulding (large packing for various branches of the national economy)[131,133,137].

A distinctive feature of articles made of poprolin materials is their effective physicomechanical and operating characteristics (compared with various polyethylenes and even polypropylene) and the lower intrinsic cost of the articles obtained from them. The poprolin materials are more susceptible to technological procedures and have a better capacity for being worked compared with the basic polymer. The use of poprolin provides the national economy with a significant economic gain by increasing the useful lifetime of articles in the course of their employment, and promotes the rational employment of natural resources, protection of the environment, and the expansion of the reserves of a scarce primary polymeric raw material as a result of the employment of a secondary raw material.

The study of the behaviour of lignin in the modification of wood by synthetic polymers is of interest because it is one of the high-molecular-components of wood. The possibility of radiation grafting onto isolated lignin of various synthetic polymers, for example styrene, methyl methacrylate, and acrylonitrile has been demonstrated[149–154]. It has been established that the radiation-chemical modification of wood with styrene involves the cross-linking of lignin and polystyrene, in which stable free radicals play an appreciable role[155].

Studies of the polymerisation of styrene with hydrochloric acid lignin and Kraft lignin with chemical and radiation initiation have been carried out by non-Soviet workers[150,155,156], who, with the aid of model lignin compounds (guaiacol, 2,6-dimethoxyphenol, and isoeugenol), discovered its inhibiting effect on the polymer. The graft copolymerisation of lignin and styrene takes place as a result of the transfer of the chain of the growing polymer radicals to the lignin units containing phenolic groups, which have an inhibiting effect on the kinetics of the process, resulting in its retardation, which entails the formation of a graft copolymer with a reduced molecular weight.

Sulphate lignin has an analogous effect on the thermal initiation of styrene in dimethyl sulphoxide in the presence of chemical initiators[157]. A considerable increase of the inhibiting effect of lignin in the presence of oxidants (for example, atmospheric oxygen), owing to the formation of quinonoid structures for both chemical and radiation methods of initiation has been noted.

The graft copolymerisation of various monomers with wood lignin leads to a new way of creating mixed composites with a graft structure as a result of the mixed chemical combination of natural and synthetic polymers possessing a valuable set of properties.

According to structural ideas, grafting can occur on the surface of the polymer particle (surface grafting) and within it (block grafting), which depends on the process conditions. By creating conditions for grafting via one procedure or another, it is possible to regulate within wide limits the properties of the resulting composite materials[158].

Like hydrolytic lignin, sulphate lignin can be used for condensation with phenols in order to obtain lignophenol-formaldehyde resins. In the polycondensation reaction the phenol adds to lignin via a ring hydrogen atom but not a hydroxyl hydrogen atom, which follows from the solubility of phenol-lignin in alkali. The introduction of a third component (formaldehyde) makes it possible to obtain fusible and alcohol-soluble resins whose properties are analogous to those of industrial products[25].

Latvian investigators suggested that hydroxypropylated lignins (HPL) be obtained on the basis of modified lignoorganosilicon oligoethers and epoxypropane[159], which constitutes an extremely promising application of technical lignins. A method for the preparation of polyurethane foam materials (on the basis of HPL) has been developed; HPL can be used as fillers (based on technical lignins) for plastics.

There exist data concerning the utilisation of modified sulphate and sulphite lignins for the preparation of a composite friction material with up to 15 wt.% of lignin[160].

A new and promising application of all types of technical lignins in the light of the fulfilment of resolutions concerning the rational employment of natural resources and the protection of the environment involves the development of highly filled polymeric materials based on lignin—lignoplastics. This task is extremely complex and laborious, since it requires very extensive scientific and technological investigations and also the creation of industrial comminuting equipment. However, a realistic basis for its successful fulfilment already exists.

Use of Porous Polymer Sorbents for Concentrating Traces of Organic Compounds from Gases or Liquids

L.D.Glazunova, L.I.Panina, and K.I.Sakodynskii

The advantages and disadvantages of the adsorption method of concentrating organic trace impurities of various types from air or from liquids are discussed. The main types of sorbent currently used are examined, and their adsorption characteristics are compared, with special emphasis on porous polymer sorbents. The special features of these polymers when used as concentrators are stressed, and interrelationships are established between the characteristics of the sorbents and their effectiveness in the sorption of different classes of organic compounds, and between their adsorption capacity (or percentage extraction) and the concentration conditions. Problems in the storage of samples concentrated on polymer sorbents are discussed. Some examples of the practical use of polymer sorbents for concentrating organic trace impurities from air or from liquid media are given. 106 references.

I. INTRODUCTION

The analysis of air contamined by industrial and by domestic waste products and the analysis of natural waters and effluents are among the most important problems in the wide-ranging efforts now being devoted to the protection of the environment. Information on the relative amounts of trace impurities (especially in the case of toxic substances) is needed both in theoretical studies and in the control of industrial practices. Chromatography is now the main method of impurity analysis for air and water[1,2]: its most important advantages are its high selectivity and the wide choice of sorbents and of separation conditions, which make the method ideally suitable for monitoring the composition of the environment.

Because of the relatively low concentration of organic impurities in air, water, and biological fluids most of the chromatographic methods used for impurity detection rely on a preliminary concentration stage. The main steps in the determination of trace impurities† in air and in water are the same: 1) collecting and storing the sample, 2) concentrating the components, and 3) chromatographic analysis. However, depending on whether the sample is air or water, the stages differ in a number of important aspects, discussed (for example) in Refs.1–5.

II. MAIN METHODS OF CONCENTRATING TRACE IMPURITIES OF ORGANIC COMPOUNDS

The following methods have been used for the pre-concentration of organic trace impurities in air: liquid extraction, freezing, chemical trapping of the components, and adsorption of the impurities by sorbents. In the case of water samples additional methods are available, including thermal methods (based on changes in solubility on heating), vacuum and thermo-vacuum methods (based on gas evolution at reduced pressure), and studies of the equilibrium vapour phase.

The extraction method requires high-purity extracting agents and offers only a moderate sensitivity. Liquid–liquid extraction is usually organised as a cyclic process. It is applicable mainly to samples with relatively high concentrations of impurities and relatively low volumes, since large-volume samples make the method excessively laborious. The most commonly used extractants are methylene chloride, chloroform, hexane, and carbon disulphide. The efficiency and speed of the extraction depend on the distribution coefficient of the substance between water and the organic solvent, and on the area of contact between the two phases. The cyclic process is not very effective even when the distribution coefficient is relatively high, and a continuous (or multi-stage) extraction process is now recommended for effective extraction[6]. The main shortcoming of the extraction method is the need to introduce a new solvent, which complicates the subsequent gas-chromatographic analysis. The scrubbing of gas samples with organic solvents has the same disadvantages as liquid–liquid extraction.

When freezing is used as a method of concentrating impurities it is difficult to avoid the incorporation of the wanted impurity in the growing ice crystals. Furthermore, the presence of large amounts of salts in the samples introduces additional complications in the freezing method.

Chemical trapping of the components has only a limited application. The use of thermal and thermo-vacuum methods is difficult in the presence of mechanically entrained contaminants and of surface-active compounds. Decomposition and hydrolysis of the components during desorption (by raising the temperature) must also be guarded against.

Organic compounds dissolved in water are often determined by analysing the equilibrium vapour phase[7,8]. The method involves heating the liquid sample in a closed vessel and studying the composition of the vapour phase in thermodynamic equilibrium with the liquid. Several variants have been described. In the simplest, the equilibrium vapour phase is sampled with a hypodermic syringe, from which the sample is transferred directly to the chromatograph[9]. However, if the organic compound is present in trace amounts in the water, direct sampling of the vapour is seldom adequate, because of the limitations imposed by the sensitivity of the chromatographic detector.

† The trace impurity range corresponds to concentrations between 10^{-1} and 10^{-7} % by volume or weight.

In a method recently proposed[10] for extracting organic impurities from water 5–10 ml samples are forced in air pressure through a special column (called the concentrator) consisting of a glass tube with capillary contructions, which assists the transfer of the impurity to the vapour phase, from which it is injected into the chromatograph by a stream of air. The main shortcomings of this method is its limited application (to high-boiling substances).

The most promising of the methods of concentrating trace impurities listed above is the adsorption method, in which a column packed with a porous sorbent is used as the concentrator. The experimental procedure is the following: a known volume of gas or liquid is passed through a column 2–4 mm in diamter and 2–5 (or up to 50) cm long, packed with the sorbent, under controlled flow-rate and temperature conditions. The organic compounds present in the air (or water) sample are retained and accumulated in the column: the concentrator column acts as a chromatographic column operated at room temperature or below, and the sample of air or water acts as the mobile phase.

The adsorbed substances are recovered from the concentrator by extraction with an organic solvent, or by thermo-desorption. Both these methods are widely used in practice, though the extraction variant causes dilution of the sample with a corresponding loss of analytical sensitivity. The thermo-desorption method is therefore preferred for compounds stable at high temperatures, as it is both simpler and less time-consuming. The choice of the desorption method assumes thermal stability of the sorbent: it should be possible to desorb the impurity completely and without decomposition of any component of the mixture at a temperature chosen according to the boiling points and chemical nature of the components. The thermo-desorption method can form the basis of a simple and fully automated system for concentrating trace impurities from air[11].

However, even in the thermo-desorption method the detection limit may be affected by the spreading of the chromatographic bands of the impurity components being transferred to the analytical column. Therefore, in order to increase the analytical sensitivity, we must optimise the transfer of the concentrated impurities to the analytical column. One way of doing this is to insert an additional trap cooled in liquid nitrogen (capillary loop) after the concentrator; this makes the injection of the concentrated sample even more compact[11–13]. An alternative method is to raise the temperature of thermo-desorption of the impurities, but of course this method makes even more stringent demands on the thermal stability of the chosen sorbent. The desorbed impurities are analysed gas-chromatographically in analytical columns (packed, or capillary). The chromatograph is combined with a mass-spectrometric detector to identify the peaks resolved by the analysis.

Interesting results have been obtained by combining the analysis of the equilibrium vapour phase and the adsorption method. It is found in practice that the sensitivity of the analysis is substantially increased by concentrating the substances present in the vapour phase on columns packed with sorbent. Thus a modification[14] of a system previously described[10] (by inserting a Polisorb-1 column to remove the impurities from the vapour phase) has enabled alcohols, ketones, aldehydes, and esters to be detected in the effluent waters of hydrolysis and alcohol production plant.

One of the variants of the combined method (analysis of the equilibrium vapour and pre-concentration by adsorption) is to examine the vapour over the heated liquid sample swept by a stream of inert gas[15,16] into an adsorption concentrator. Another variant (the gas-phase extraction method[17,18]) relies on bubbling an inert gas through the water sample at a known rate (usually 40–80 ml min^{-1}). The organic impurities pass into the gas phase and are thus gradually removed from the water. The distillation time is 1–3 h, depending on the flow rate of the gas and on the volume and temperature of the sample vessel, controlled by a regulator between room temperature and 70–80 °C. The dynamical nature of this method ensures a high level of extraction at room temperature for substances boiling below 150 °C. If additional concentration of the impurities is needed a water-cooled condenser (to remove the water entrained by the gas flow) and a concentrator filled with adsorbent are inserted into the gas outlet stream[6].

III. CHOICE OF SORBENT FOR PREPARING CONCENTRATOR COLUMNS

The choice of sorbent for the concentrator column depends mainly on the nature of the compound for analysis, and is determined by the intermolecular interactions in the sorbent–sorbate system (as in any other chromatographic process).

The sorbent should have an adequate capacity for the given substance. The adsorption should be reversible, i.e. without chemical changes. Furthermore the sorbent should be thermally stable and its affinity for water should be low (especially for the analysis of solutions and moist gases). If the capacity of the sorbent is insufficient for all the components of the mixture several sorbents can be used instead of a single sorbent[19,20], and placed in the same concentrator.

The sorbents most commonly used for concentrating trace impurities include activated carbon, graphitised thermal black, molecular sieves (including carbon-based sieves), various grades of silica gel and aluminium oxide, sorbents for gas–liquid chromatography[3,21], and porous polymer sorbents.

Activated carbon has a high adsorption capacity, which allows this sorbent to be used in small amounts, and it is also thermally stable. However, it holds the trace impurities very strongly, making them difficult to desorb. Thus the use of carbon may lead to incomplete recovery of the impurities (due to the irreversibility of the adsorption) accompanied by the appearance of spurious peaks (due to impurities already present in the carbon)[22]. Effective removal of low-molecular-weight compounds (for example, ethylene and methylene chlorides) requires strong cooling of the concentrator, which is not always convenient[4]. Furthermore activated carbon reacts with several organic compounds (especially with sulphur compounds). Desorption from carbon usually requires extraction with organic solvents. Transfer of the concentrated substances to the analytical column can be achieved also by thermo-desorption, but often the temperature required is unacceptably high because of the very fine porous structure of carbon.

The use of carbon molecular sieves and graphitised blacks (Carbopaks, Carbochroms, Carbosieves, Spherocarbs) for concentrating traces of organic compounds is limited by the irreversible sorption of many compounds on these sorbents and by the high reactivity of the sorbents. Their main disadvantage, as with the activated carbons, is the need to use organic solvents for the desorption of the concentrated impurities (causing dilution of the sample and loss of analytical sensitivity) or alternatively to use elevated desorption temperatures (causing decomposition of the organic compounds).

Silica gels are used for concentrating hydrocarbons with a C_3 or higher carbon skeleton, as well as organic compounds of other classes. The adsorbed substances are usually

desorbed by extraction of (very unusually) by thermodesorption. Among the shortcomings of silica gel as an adsorbent for concentrating trace impurities we should list incomplete recovery of volatile hydrocarbons, adsorption of water vapour from the air sample for analysis, and a tendency towards irreversible sorption of easily polymerisable unsaturated compounds and of compounds chemically reactive towards silica gel (for example, organic bases).

The sorbents used in gas–liquid chromatography (i.e. carriers coated with a stationary phase) are unsatisfactory in the following respects[23]: 1) possible reaction between the compound and the stationary phase (for example, Dexsil-300 and alkalis), and 2) contamination of the sample for analysis by impurities from the liquid phase.

IV. POROUS POLYMER SORBENTS IN THE ADSORPTION METHOD OF CONCENTRATING TRACE IMPURITIES

The porous polymer sorbents Porapak Q, P, N, Tenax GC, Chromosorb (100 series), Amberlite XAD, Polisorb 1, 10, etc. are now widely used for concentrating impurities from air and water. They offer a high adsorption capacity towards many organic substances and a rapid concentration of the impurities, shortening the analysis time of an air sample (say) to 10–20 s.[24] They have a low sorption capacity for water, which is often present in analytical samples (especially in the analysis of the equilibrium vapour phase), and they are chemically inert and thermally stable. Concentration on porous polymer sorbents can be combined with direct thermal desorption (instead of liquid extraction) to transfer the impurity from the concentrator to the gas chromatograph. This offers an enhanced analytical sensitivity and avoids possible interference by the solvent. The concentration of trace organic impurities on porous polymer sorbents is now widely used in analytical practice including impurity analysis in environment protection studies, in industrial hygiene, and in biochemistry and medicine[15,25–30].

1. Main Characteristics of the Sorbent

The sorbents most commonly used for concentrating trace impurities are listed in Table 1. In most cases the sorbent surface is hydrophobic, but XAD-7, XAD-8, the Spherons, and Amberlyst A-26 are hydrophilic. Dressler has pointed out[5] that hydrophobic non-polar sorbents are more effective for concentrating non-polar compounds, whereas for polar compounds hydrophilic adsorbents should be used: the adsorption capacity of the hydrophobic sorbents increases as the polarity of the compound decreases. The particle size of the polymer sorbents used at present is 25–50 or 35–60 mesh. However, an increased sorption capacity can be achieved[6] by using a smaller fraction (80–100 mesh) of the sorbent particles.

The fairly wide choice of types of synthetic polymer sorbent (differing in structure and in surface-chemical properties) which can be combined within the same concentrator explains the successful use of these materials for concentrating organic trace impurities of different classes, with boiling points covering a wide range. Dynamical enrichment on porous polymer sorbents is subject to the following limitations: 1) incomplete adsorption of molecules of low molecular weight, and 2) the appearance of spurious peaks during desorption, due to impurities in the initial polymer. The first of these shortcomings can seriously limit the application of the method, but it can be overcome by an appropriate choice of polymer sorbent. The influence of the second factor can be lessened by a thorough preliminary purification of the sorbent. Hence the purification procedures applied to the sorbents are among the most important aspects of the practical application of porous polymer sorbents to the concentration of trace impurities.

Table 1. Polymer sorbents for concentrating trace impurities[5,94].

Sorbent	Composition of polymer	S_{sp}	d, Å	t, °C
Amberlite XAD-1	copolymer of styrene and divinylbenzene	100	200	250
Amberlite XAD-2	ditto	290—330	85—90	250
Amberlite XAD-4	"	750	50	250
Amberlite XAD-7	copolymer of methyl methacrylate and divinylbenzene	450	80	150
Amberlite XAD-8	ditto	140	250	150
Amberlyst A-26	anion exchange resin containing trimethylamino groups	25—30	—	—
Ostion SP-1	Copolymer of styrene and divinylbenzene	350	86	250
Polisorb-1	ditto	200—250	130	250
Polisorb-10	polyvinylbenzene	300—350	—	250
Polisorbazol	copolymer of *N*-vinyl-3(5)methylpyrazole and ethylene glycol dimethacrylate	300—400	100	280
Polisorbimid-1	copolymer of pyromellitic dianhydride and diaminodiphenyl ether	40—60	1000	450
PFKh	polyphenylquinoxaline	30—50	1600	300
Porapak N	copolymer of styrene, divinylbenzene, and vinylpyrrolidone	500—550	75	200
Porapak P	copolymer of styrene and divinylbenzene	100—200	—	250
Porapak Q	copolymer of ethylvinylbenzene and divinylbenzene	630—840	75	250
Sinachrom	copolymer of styrene and divinylbenzene	520—620	45	250
Spheron MD 30/70	copolymer of methyl methacrylate and divinylbenzene	320	—	230
Spheron SE	copolymer of styrene and ethylene dimethacrylate	70	—	280
Tenax GC	poly(2,6-diphenylphenylene oxide)	19—30	1400	350—375
Chromosorb-102	copolymer of styrene and divinylbenzene	300—400	85—95	250
Chromosorb-105	copolymer of the polyaromatic type	600—700	—	200
Chromosorb-106	cross-linked polystyrene	700—800	—	250

Symbols. S_{sp} is the specific surface, d is the average pore diameter, t is the upper limit of the working temperature range.

2. Preparation of Sorbents for Concentrating Impurities

Preliminary purification of the sorbents removes the main impurities and improves the reproducibility of the analytical results. The polymer sorbents can be prepared in a form suitable for the experiment by the following methods: conditioning in a stream of oxygen-free carrier gas at high temperature (e.g. for Porapak, heat treatment at 225–250 °C in a stream of carrier gas for 12–24 h is recommended[5]), degassing at high temperature in a vacuum, or extraction with organic solvents. The latter method is used most often with sorbents of the Amberlite type, used for concentrating impurities in water. Thus Junk and co-workers[31] recommend the following pre-treatment of Amberlite XAD-2 and XAD-4: wash the sorbent particles several times with water or 0.1 *N* NaOH solution, decant them from methanol, and extract them in a Soxhlet apparatus with methanol, acetonitrile, and diethyl ether (8 h in each solvent). After this pre-treatment the sorbent is stored in a glass vessel under methanol. The

concentrator trap is prepared by filling the column with the purified sorbent (added as a suspension in methanol) and washing the packed layer several times with distilled water.

Lower levels of detection of organic impurities in drinking water have been acnieved[32] by adopting a method of purification of the XAD-2 resin which includes successive washings with methanol, diethyl ether, and water. It is stressed that this preliminary purification prevents the formation of decomposition products of the sorbent in contact with water, such as alkanes from $n\text{-}C_{10}H_{22}$ to $n\text{-}C_{24}H_{50}$.[32]

When Tenax GC is used as the sorbent in gas chromatography a conditioning treatment in nitrogen (1 h at room temperature and 1 h at 350 °C) is recommended[33]. Tenax samples for packing concentrator columns have been conditioned at 350 °C for 30 min [34] or for 3 h, followed by 12 h at 200 °C.[35]

3. Sorption Capacity of Porous Polymer Sorbents

The most important factor in the successful application of trace impurity concentration processes is an adequate sorption capacity of the sorbent at the concentration temperature. The sorption capacity for each sorbate (g g^{-1} of sorbent) can be determined from measurements of the sorption front[36]:

$$\alpha = \frac{(t - t_M) F}{W_s} \cdot c$$

where α is the dynamical adsorption capacity for the given sorbate (g g^{-1}), t is the time needed to saturate the sorbent to break-through of the sorbate (s), t_M is the retention time of the gas which is not sorbed (s), W_S is the mass of sorbent (g), F is the flow rate of the carrier gas ($cm^3\ s^{-1}$), c is the concentration of sorbate in the carrier gas (g cm^{-3}), and $(t - t_M)F/W_S$ is the volume of carrier gas containing sorbate at concentration c needed to saturate 1 g of sorbent at the chosen concentrator temperature (293 K).

Comparative studies of the adsorption capacity of several polymer sorbents (Tenax, Porapak P and Q, Amberlite XAD, and Chromosorb 101 and 102) towards volatile organic compounds have been reported[15,20,37,38]: alcohols, ketones, organic acids, nitrogen and chlorine compounds, saturated and aromatic hydrocarbons. The capacity of a sorbent for a given compound was shown to be determined by the nature of the sorbate as well as by that of the sorbent. On the whole, polar compounds are sorbed more effectively by polar polymer sorbents, for example XAD-7 and XAD-8 Amberlites. In non-polar polymer sorbents (e.g. Porapak P, XAD-1, XAD-2, etc.) the adsorption increases with the molecular weight of the sorbate and with decreasing polarity of its molecules.

If the chemical nature of the sorbent is kept constant the adsorption capacity is determined by structural characteristics (specific surface area and porosity). Experimental data on the adsorption capacity for volatile organic compounds have led to the classification of the porous polymer sorbents in the following sequence[37].

$$\text{Tenax} \cong \text{XAD-1} < \text{Porapak P} \ll \text{XAD-2} < \text{Porapak Q} < \text{XAD-7} < \text{XAD-4}$$

For Tenax and the XAD-7 and XAD-4 Amberlites[38] the lowest adsorption capacity is observed with cyclohexane, methanol, and ethanol. The concentrator properties of XAD-7 are the most favourable of this group of three sorbents[38], but nevertheless most of the recent work on the concentration of volatile organic compounds (especially from air) has been done with Tenax because of its exceptionally high thermal stability.

The capacity of a sorbent towards a given compound determines the break-through volume, i.e. the volume of gas or liquid which passes through the sorbent before the appearance of the substance of interest. The break-through volume is treated by many workers as synonymous with the retention volume V_R. However, in general the break-through volume can be smaller than the retention volume because of the correction for the concentration conditions[39].

The break-through volume for the polymer sorbent Tenax has been determined[39] by passing a stream of gas containing the impurity through a trap packed with the sorbent and connecting the outlet to a flame-ionisation detector (direct measurement); it has also been calculated theoretically[40] from the retention volumes and the number of theoretical plates in gas-chromatographic measurements (indirect measurement).

The dependence of the break-through volume on the basic concentration conditions (flow rate of the mobile phase, concentrator temperature, concentration of the impurity and of water vapour in the gas stream) has been investigated. The break-through volume in Tenax was found to be strongly dependent on the velocity of the mobile phase. Thus for a stainless steel concentrator (75 mm × 4.5 mm) containing 0.13 g of Tenax which had been pre-heated at 250 °C for 16 h the optimum flow velocity was 50 ml min^{-1}. The impurity concentration and the temperature also have an effect on the break-through volume. To a first approximation V_R increases two-fold for a decrease in temperature of 10 K. The break-through volume in Tenax is almost independent of the water content of the air sample. This is confirmed by measurements[41] of the specific retention volumes of several model compounds (methanol, ethanol, propanol, ethyl acetate, acetone, and benzene) on Tenax in a carrier gas saturated with water vapour. The difference between retentions in the presence and in the absence of water vapour was shown to be ±10%.

Thus Brown and Purnell conclude[39] that a flow rate of the mobile phase of 500–600 ml min^{-1}, a concentration of the impurity vapour of 100 ppm, a concentrator temperature of 20 °C, and a relative humidity of 95% the break-through volume in Tenax is not less than 50% of the measured retention volume of each compound. Hence they recommend determining the retention volume of the organic compounds experimentally at 20 °C and taking 50% of this quantity as the safe volume for a number of stated assumptions (i.e. the volume of contaminated air which can be passed through the adsorbent before break-through). Other workers[42] take the safe volume as 1/3 of the measured retention volume.

The capacity of the packed column is calculated from the parameter V_R at the concentrator temperature (usually room temperature or below). Since V_R is often determined gas-chromatographically at higher temperatures, linear extrapolation of the retention volumes to room temperature[20] is needed. The possibility and the validity of this extrapolation for polymer sorbents have been examined[43] by using $CHCl_3$, CCl_4, and CH_3CCl_3 as sorbates. The retention volumes determined gas-chromatographically at room temperature were compared with those obtained by extrapolation, and in this way the sorption capacity of the column (filled with polymer sorbent) extrapolated from measured retention volumes was shown to differ somewhat from the true value. The discrepancy is different in different systems, and is a characteristic of the particular system. For example, the capacity of Porapak Q columns for all these halogen compounds is higher than the extrapolated value. Nevertheless the extrapolation of V_R to room temperature is often used in practice because of the simplicity of the calculation.

4. Percentage Extraction of the Compounds for Analysis

The parameter which most accurately characterises the ability of a sorbent to adsorb a compound during the concentration stage and to desorb it during treatment with solvents or when heated to a suitable temperature is the percentage extraction, defined as the ratio of the quantity of substance found in the model sample of air or water after concentration to the quantity of the same substance originally present in the sample (expressed as a percentage). At least two effects can cause low percentage extraction: 1) incomplete adsorption, when a substantial proportion of the trace impurity is lost in the stream of mobile phase, and 2) strong adsorption, when the substance is incompletely desorbed by heating the concentrator. When porous polymer sorbents are used to concentrate the trace impurities from water or air the percentage extraction of organic substances is relatively high. Thus for Amberlite XAD-2 and XAD-7 used in concentrating water samples the percentage extraction of most of the common organic substances (including aliphatic and aromatic hydrocarbons, ketones, ethers, organic acids, phenols, nitrogen and halogen compounds, pesticides, and herbicides) is 75–100%, [5] and in the concentration of impurities from air on Tenax the percentage extraction for hexane, light petroleum, biphenyl, acetone, diphenylamine, and *o*-cresol is 90% with a standard deviation of 5%. [44]

It has also been shown[45–49] that the percentage extraction depends on the particle size of the sorbent, on the concentration of the components in the sample, on the flow rate of carrier gas through the layer of sorbent, on the size of the column, and (in the case of water analysis) on the pH of the sample, on the polarity of the eluent, and on the presence of electrolytes. For example, when a finer fraction of XAD-2 Amberlite (85–120 instead of 60–80 mesh) was used for concentrating chlorinated insecticides a higher percentage extraction was obtained[47]. It has been pointed out[46] that the percentage extraction can often be improved by using a 60 mm × 10 mm column instead of a 30 mm × 10 mm column, while the adsorption of herbicides on XAD-2 Amberlite is relatively unaffected by changes in flow rate from 2 to 10 ml min^{-1}. A flow rate of the water sample of 5 ml min^{-1} was found to be the optimum, but increasing the flow rate still further (from 10 to 32 ml min^{-1}) lowered the percentage extraction. It was also shown[46] that the percentage extraction of organic acids and phenols is related to the dissociation of these compounds and therefore depends on the pH of the solution. In an acid medium the percentage extraction of acids and phenols is markedly higher, and acidification of these samples to pH 2 with HCl is recommended.

5. Permissible Storage of the Concentrated Impurities in the Concentrator

Trace impurities from air or water can be concentrated in the field and stored in the concentrator (trap) until they can be taken to the laboratory for analysis. The use of polymer sorbents in concentrators helps to overcome the difficulties presented by the lengthy storage of concentrated compounds. A possible reason is the relative inertness of the surface of these sorbents, which ensures that the composition of the sorbed organic compounds remains constant, as shown by an analytical study[12,50] of a series of volatile compounds concentrated on Tenax. It has also been shown[50] that the percentage extraction of substances from the concentrator is unaffected by one week's storage of the concentrator at 0.4 or at 20 °C. Goldberg and Sandler[12] mention that a previously conditioned Texan column retained its good adsorption properties throughout the investigation (several weeks), and no spurious peaks were noted in the chromatograms. Keeping the concentrator (containing the concentrated impurities) for 90 days gave a chromatogram indistinguishable from that obtained by carrying out the concentration and the desorption on the same day.

The possibility of lengthy storage of concentrated impurities without change in qualitative or quantitative composition has been reported[51] also for polyurethane sorbents and sorbents of the Amberlite type

V. THE USE OF POROUS POLYMER SORBENTS IN SOLVING CONCENTRATION PROBLEMS

1. Concentration on Tenax

Tenax is the porous polymer sorbent most widely used for concentrating trace impurities[24,28,35,52–63]#. Its main advantages over all other similar sorbents are a high thermal stability (up to 375 °C) and a low "noise" level during thermo-desorption.

The sorption capacity of Tenax towards organic compounds of different types has been shown[50,64] to be high: an important attribute in the analysis of biological fluids, perfumes, and atmospheric pollution. Furthermore the sorption of test substances on a Tenax fore-column was found to be unaffected by the presence of water vapour. Losses of trace impurities during concentration from the 10^{-6}–10^{-9} g ml^{-1} level, and the consequent errors in the quantitative determination, were shown[64] to be due in many cases to the irreversibility of the adsorption on Tenax, and to depend on the composition of the mixture and on the concentration conditions. The sensitivity of the determination of trace impurities can be improved by blocking the Tenax active centres. Thus a preliminary injection into the column of a few microlites of octan-1-ol produces a large increase in the peak area (and a corresponding lowering of the detection threshold) for tributylamine, 2-ethylphenol, butyrophenone, etc. [64]

Bunch and Pellizzari[65] examined the possibility of chemical changes in unsaturated compounds (but-2-ene and cyclohexene) during concentration on a Tenax surface in the presence of traces of Br_2 and Cl_2 in the air sample. They showed that under these conditions the sorbent surface can induce reactions leading to the formation of halogenated hydrocarbons. These reactions can be suppressed by inserting a filter of glass wool soaked in sodium thiosulphate in the gas stream before the concentrator. However, in general the Tenax surface is acceptably inert, giving concentration without significant changes in chemical composition[52–63].

The retention volumes of many organic substances on a Tenax column have been determined[66] at 100–200 °C and extrapolated to 25 °C. The conclusion was that Tenax can be used most successfully for concentrating compounds containing more than seven carbon atoms. For lighter molecules the carbon adsorbent Ambersorb XE-340 is recommended[66], though Porapak sorbents are also usable[20].

The sorption characteristics of Tenax and Carbopak in the concentration of trace impurities of different classes from air contaminated with industrial effluent gases[52] has been published. Carbopak B, a graphitised thermal black with a specific surface of 90 m^2 g^{-1}, can be used at practically any

Tenax is a linear polymer of 2,6-diphenylphenylene oxide with a molecular weight of (0.5–1.0) × 10^6, a specific surface of 19–30 m^2 g^{-1}, and an average pore diameter of 1400 Å.

temperature. When compared in terms of the percentage extraction of a series of organic compounds the adsorption characteristics of Tenax and Carbopak B are generally similar, but sorption properties specific to each adsorbent can also be detected. Thus benzene and n-hexane are fully retained by Carbopak B, but they pass through Tenax (in which their percentage extraction is 35 and 20% respectively). Similar effects are observed for the alkanes from n-pentane to iso-octane. Acetone is most effectively retained by Tenax, but butanol and diethylamine should be concentrated on Carbopak B. On average, for all the classes of organic compounds so far examined, the percentage extraction is 83% on Carbopak B and 75% on Tenax. The use of Carbopak B for the absorption of the C_4–C_5 hydrocarbons and of Tenax for organic compounds with a greater number of carbon atoms has been recommended[52].

A concentrator trap containing 2 cm^3 of Tenax of 30–60 mesh particle size has been used[15] to extract impurities for air and water in the analysis of perfumes and biological fluids. The compounds held on Tenax were desorbed at 300 °C, and the sorbent was regenerated at 375 °C. Gas-chromatographic analyses were carried out on a capillary column.

Columns 15 cm long and 1 cm in diameter containing 2.5 g of Tenax (60–80 mesh) have been used[44] to concentrate trace impurities from air. A 5 litre sample was passed through the concentrator at 0.5 cm^3 min^{-1} and 20 °C. The concentrated substances were transferred to traps (stainless steel tubes of 1.6 mm inside diameter) cooled in liquid nitrogen. Desorption from the trap involved heating the tubes to 300 °C. The percentage extraction of individual organic compounds from model mixtures was ~90% on average.

A preliminary concentration of the trace impurities was used to analyse the volatile components in the cabin of the orbital station Skylab-4 at various times during the mission[11]. More than 300 components were detected gas-volumetrically, and 107 0f these were identified on a mass spectrometer (Freons, siloxanes, hydrocarbons, benzene derivatives, and other compounds with molecular weights between 60 and 500). The concentration was carried out in a Pyrex tube (50 mm × 10 mm) filled with Tenax (60–80 mesh). The procedure included thermo-desorption, transfer of the sample by a gas stream to a trap cooled in liquid nitrogen, and temperature-programmed gas chromatographic analysis.

An analysis[67] of cigarette smoke in air relied on a preliminary concentration in a column (115 mm × 5 mm) packed with Tenax (60–80 mesh) and Carbopak BHT, followed by thermo-desorption at 270 °C into a capillary column coated with OV-101 (25 or 55 m × 0.35 mm). The smoke was found to contain a very wide range of compounds, from low-boiling gases to almost involatile polymers and other high-molecular-weight compounds. The main constituents of smoke are aliphatic and substituted aromatic hydrocarbons.

A special study of concentration problems in the analysis of complex mixtures of organic compounds in water at and below the 1 ppm level has been described[12]. The method included direct injection into the system of a 100 μlitre sample of the water, removal of the water in a condenser at 0 °C, concentration of the trace impurities in a small fore-column (2 cm × 1 mm) cooled in solid CO_2 and filled with Tenax (35 to 60 mesh), and gas-chromatographic analysis of the impurities in a capillary column with a flame-ionisation detector. The method gave very good reproducibility (mean standard deviation 5–6%). Only 4 min were needed for the preparation of the sample for analysis.

A recent review[68] is devoted to the apparatus for extracting trace impurities from water or air and to the methods of concentration on Tenax. The following systems are discussed in detail: hexachlorobutadiene in air (at the 20 ppb level), glycol esters in water (500 ppb), chlorobenzenes in water (3–8 ppb), chlorobenzenes in methylene chloride (100 ppb), and phenols and soluble aromatic compounds in water (300 ppb).

An interesting method of analysis for complex mixtures containing low-boiling gases, water, and organic compounds has been described[69]. It relies on the reversibility of the adsorption of the vast majority of organic compounds on Tenax, whereas water and the light gases pass through the column without being sorbed. A short fore-column containing 0.3 g of Tenax, placed in front of the main column, is used to sorb all the organic compounds from the mixture, while water and the gases pass into the analytical column filled with Chromosorb 101 or Porapak QS. After elution of the water and gases the organic compounds are thermally desorbed from the Tenax into a second analytical column filled with 10% XE-60 on Chromosorb WHP. A system of valves allows the two parts of the analysis to be carried out with a single sample injector and a single detector.

2. Concentration on the Porapak, Chromosorb, and Spheron Types of Porous Polymer Sorbent

Porous polymer sorbents other than Tenax has been used[5,38] for concentrating trace impurities from air, water, and organic liquids. Chromosorb-105 was used[70] to concentrate trace impurities from the equilibrium vapour phase of organic liquids, from air, or from water. Volatile compounds from juices, biological fluids, wine, and brandy were concentrated, analysed on a capillary column, and identified mass-spectrometrically. The preliminary activation of the concentrator filled with Chromosorb-105 consisted in heating the tube at 225 °C for 12–24 h in a nitrogen stream (10 ml min^{-1}).

In the determination of trifluorochloromethane, chloroform, and other chlorinated compounds in air from Michigan the samples were pre-concentrated[71] on Porapak N, and sulphur compounds in town gas from Nogai (Japan) were pre-concentrated[72] on Porapak Q.

A method of determining benzene and trace amounts of 1,2-dibromoethane and 1,2-dichloroethane simultaneously in town air contaminated with motor-car exhaust gases (Stockholm) or in garage atmospheres has been described[73]. It is stressed that the sorption capacity of Porapak towards these compounds is greater than that of Tenax or Chromosorb-105.

The content of Halothane (2-chloro-2-bromo-1,1,1-trifluoroethane), an anaesthetic compound present in the air of surgical buildings at the 0.01 ppm level, has been measured[74] by preliminary concentration on Porapak Q and P.

The volatile flavouring agents in brewery products have been concentrated[75] by passing the distillate obtained from beer through an Amberlite column at 25 °C. Other workers[76] used XAD-2 to extract phenols and other compounds which interfere with the chromatographic separation of nucleotides from plant extracts (potato tubers, tomatoes, nuts). The conditions which favour the sorption of phenols on XAD-2 while suppressing the sorption of nucleotides, and those which give preferential sorption of nucleotides, were investigated. An attempt was made to correlate the electronic structure of the nucleotides with their affinity for XAD.

XAD-2 Amberlite has been used also to extract steroids from bile[77], urine[78,79], and milk[80], and morphine[81] and hexachlorophene compounds[82] from urine.

Spheron SE has been used for concentrating aromatic hydrocarbons, phenols, and pesticides from river waters of northern Bohemia[83].

Table 2. Determination of the trace impurities of organic compounds using porous polymer sorbents.

No.	Compound to be determined	Sorbent	Concentration conditions	Conditions and method of extraction	Chromatographic separation conditions	c_{min}	References
1	Amines (b.p. up to 300 °C) from air	Tenax	Glass column, 15 cm × 0.5 cm, air flow rate 1.3 litre h^{-1}	thermo-desorption at 250 °C	glass column, 2 m × 2 mm, filled with 8% Silar 10C on Chromosorb WHP, flame ionisation detector	1 ppb	[28]
2	Aromatic hydrocarbons, alcohols, chlorinated compounds, ketones from town or country air	Tenax	110 mm × 8 mm column, sample volume 3–30 litre, flow rate 100–300 ml min^{-1}	thermo-desorption	capillary column, flame ionisation or electron capture detector	–	[66]
3	Alkanes up to C_{18}, unsaturated and aromatic hydrocarbons, alcohols and ketones in industrial atmospheres	Tenax, Carbopak B	9 cm column with 0.28 g of Tenax and 0.45 g of Carbopak B, flow rate 30 ml min^{-1}	thermo-desorption	combined chromatograph and mass spectrometer	1 ppb	[52]
4	Ethylene from air	Porapak S	copper tube 10 cm × 6 mm containing 0.4 g of sorbent and cooled to −95 °C	concentrator heated rapidly to 100 °C and immersed in boiling water	3 m column filled with Porapak R, 40 °C, flame ionisation detector	0.01–0.1 ppb	[26]
5	Trichlorofluoromethane, chloroform, CCl_4, trichloroethylene, perchloroethylene from air	Porapak N	10 cm × 5 mm stainless steel column, sample volume 0.3–3 litre, flow rate 30–150 ml min^{-1}	thermo-desorption at 200 °C for 15 min	2 m column filled with 20% DC-200 on WAWDMCS Chromosorb, programmed temperature (from −40 to 140 °C, 16 K min^{-1}), electron capture detector	30–130 ppt	[71]
6	1,2-Dibromoethane, 1,2-dichloroethane, benzene from town air	Porapak Q, Chromosorb 105, Tenax	200 mm × 1.8 mm column, sample volume 3 litre, flow rate 50–100 ml min^{-1}	thermo-desorption at 175 °C, 3 min	2 m × 1.8 mm column filled with 6% poly-(*m*-phenyl ether) on Tenax	10–200 ppb	[73]
7	Carbonyl sulphide, CS_2, thiophene, tetrahydrothiophene from natural gas domestic supply	Porapak Q	31 cm × 4 mm column cooled in liquid O_2, sample volume 0.05–0.1 litre	heating from −183 to 100 °C, thermo-desorption at 100 °C	3 m × 3 mm column with Porapak Q 140 °C, flame photometer detector	0.7 ppm	[72]
8	Hydrocarbons, polynuclear aromatic compounds, dibenzofuran, etc., from mains water	XAD-2, –4, –7, –8, and mixtures	40 mm column, flow rate 80 ml min^{-1}	elution with acetone–methylene chloride mixture	analysis on SE-30, SP-2100, or Carbowax 20 M, flame-ionisation detector	1 ng $litre^{-1}$	[22]
9	Fenitrothion from water	XAD-2	10 cm column, sample volume 1 litre	elution with diethyl ether or acetone	column filled with 3% OV-101 on Cromosorb W, 190 °C	50 ppb	[51]
10	Acid food dyes from water	XAD-2	30 cm × 0.5 cm column	elution with methanol	analysis by the TLC method on XAD-2 plates	100 ng ml^{-1}	[86]
11	Fenitrothion and its decomposition products in water from areas treated with insecticides	XAD-2	10 cm × 1.9 cm column, sample volume 1 litre, flow rate 50 ml min^{-1}	elution with ethyl acetate	1.8 m × 4 mm column filled with 4% OV-101 and 6% OV-210 on Chromosorb WAW	10–30 ppb	[88]
12	Carbamate insecticides from water	XAD-2	35 cm × 1.5 cm column, sample volume 1 litre, flow rate 20 ml min^{-1}	elution with ethyl acetate	75 cm × 4 mm column with 3% Carbowax 20 M on Chromosorb WHP	0.01–1 ppm	[101]
13	Pesticides from river water	XAD-2	60 g of sorbent added to 20 litre of water and stirred for 8 h	sorbent stirred with 200 ml of toluene and ethylacetate (1 : 3) for 10 h	analysis by gas chromatography	0.3 ng $litre^{-1}$	[102]
14	Fenitrothion from water	XAD-4	30 cm × 1.9 cm column, sample volume 1 litre	elution with a solvent	analysis by TLC	50 μg $litre^{-1}$	[89]
15	Alcohols, ethers, ketones, aldehydes, alkylbenzenes, phenols, etc. in drinking water and in effluents	XAD-4	25 mm × 1.2–1.8 mm column, sample volume 50–100 μlitre, flow rate 0.8–1.2 ml min^{-1}	elution with 100 μlitre of acetone or acetone–CS_2 mixture	1.8 cm × 3 mm Tenax column	2–10 ppb	[92]
16	*p*-Nitrophenol-glucuronic acid from water	XAD-4	column with 10 g of sorbent flow rate 6 ml min^{-1}	elution with a water–acetone mixture (1 : 1)	analysis by TLC method	–	[103]
17	Fenitrothion and its decomposition products	XAD-7	flow rate 113 ml min^{-1}	elution with ethyl acetate	analysis by TLC method	50 ppb	[90]
18	Organo-chloro and organophosphorus pesticides	Tenax	48 cm × 1 cm column	elution with diethyl ether	gas-chromatographic analysis with electron capture detector	1 ppb	[85]
19	Toluene, *m*-cresol, phenol, pesticides in water	Spheron SE	40 mm × 5 mm column	elution with mixed solvents	120 cm × 3 mm column with Chromosorb-102, 200 °C	10–30 ppm	[83]

Table 2 (continued).

	Compound to be determined	Sorbent	Concentration conditions	Conditions and method of extraction	Chromatographic separation conditions	c_{min}	References
20	Phenol, *p*-nitrophenol, *p*-nitroaniline frow water	Styrene–divinyl-benzene–acrylonitrile	20 cm × 0.5 cm column flow rate 40 ml h^{-1}	elution with acetone	gas chromatographic analysis	—	[91]
21	Volatile metabolic products of micro-organisms	Tenax	–	thermo-desorption	2 m × 3 mm column with 5% Carbowax on Gas-chrome Z	–	[30]
22	Impurities from technical styrene monomer	Tenax	100 mm × 8 mm column	thermo-desorption at 290 °C for 15 min in a stream of helium, 20 ml min^{-1}	100 m × 0.5 mm capillary column, from 60 to 150 °C	–	[56]
23	Benzene and toluene from pentane	Tenax	100 mm × 1 mm column, cooled in water	thermo-desorption at 240 °C	50 m × 1 mm capillary column coated with PEG 20	10^{-5}–10^{-7} vol.%	[104]
24	Phenols from plant extracts	XAD-2	22.5 cm × 1.5 cm column	elution with methanol	–	–	[76]
25	Volatile flavouring agents from beer	XAD-2	60 mm × 7 mm column	elution with diethyl ether	2.8 m × 4 mm column with 10% Carbowax 20M on Chromosorb WAWDMCS, 50–200 °C, 3 K min^{-1}, flame ionisation or flame photometric detector	ppb–ppm	[75]
26	Volatile compounds from juices, wine, brandy, and biological fluids	Chromo-sorb-105	–	thermo-desorption	analysis on a capillary column	–	[70]

Notes. Two types of concentration unit have been recommended[105]: the mass of impurity in unit mass of sample (mass/mass) and the volume of impurity in unit volume of sample (volume/volume). Mass concentration units: 1×10^{-4} % ≡ 1 ppm, 1×10^{-7} % ≡ 1 ppb, and 1×10^{-10} % ≡ 1 ppt. Volume concentration units: 1×10^{-4} % ≡ 1 ppm, 1×10^{-7} % ≡ 1 ppb, 1×10^{-10} % ≡ 1 ppt. The choice of mass or volume units depends on the measurement method and on the practical use made of the results. Concentrations calculated from gas-chromatographic measurements have the dimensions of g ml^{-1}. They can be converted into ppm by using the formula[106] 1 ppm = 1 g $ml^{-1} \times 10^{-6}$ RT/pM, where R is the gas constant, cm^3 atm K^{-1} $mole^{-1}$, T is the temperature, K, p is the pressure, atm, and M is the molecular weight of the compound being analysed.

3. Extraction of Trace Impurities from Water

The use of polymer sorbents for concentrating trace amounts of organic compounds from water has been widely studied. A review paper[5] stresses the importance of a preliminary concentration, lists the requirements on the solvents used for extraction and on the water samples themselves, and discusses the properties and the applications of porous organic sorbents used for concentrating trace impurities.

In the same review[5] Dressler points out the similarity between the liquid extraction of organic impurities from water and the use of a solid sorbent: in both cases the dissolved impurities distribute themselves between the water and the extractant, whether a liquid solvent or a solid sorbent is used.

However, porous polymers offer a number of advantages over liquid extraction, since the adsorption of water on the polymer sorbent is negligibly small and the distribution coefficients of organic compounds in the polymer sorbent–water system tend towards infinity if the choice of sorbent has been optimised for the organic compound being extracted[5]. Sorbents with similar sorption properties can be used interchangeably in the concentrator. Dressler also notes[5] the superiority of Amberlites of the XAD series for concentrating traces of organic compounds from water (in particular, for the determination of biphenyls and poly-chlorobiphenyls in sea water, of chlorinated pesticides in drinking water, and of detergents, herbicides, insecticides, pesticides, hydrocarbons, and polyethoxy compounds in sewage).

The method of sampling the water and preparing the sample for analysis, and the process used for concentrating the impurities, depend on the concentration and on the chemical nature of the compounds in the water. Hydrocarbons (especially aromatic) are present in very small amounts in surface waters; effluents from the petrochemicals industry contain aromatic amines and phenols, and effluents from large-scale organic production plant contain pesticides and by-products of the paper, food, and pharmaceutical production industry. The permissible concentration of some organochloro pesticides in drinking water is 0.1 mg $litre^{-1}$, and a method of concentrating impurities is essential for effective analytical control.

Leoni and co-workers[84] have obtained up to 90% extraction of trace impurities (pesticides and polycyclic aromatic hydrocarbons) present in water at the 1 ppb level with Tenax. However, the capacity of the polymeric sorbents for given organic impurities depends on the other impurities present in water. In particular, mineral oils cause "deactivation" of Tenax[85], with a corresponding decrease in the percentage extraction of the trace impurities. The results obtained in the extraction of pesticides from water on Tenax were equivalent to those of the liquid extraction method in the case of drinking water and surface waters, especially when the sample was free from suspended matter which tend to adsorb some pesticides in large amounts. For waters containing suspended matter the results were equivalent only if the samples had been previously filtered[84]. The main advantages of the adsorption method (using Tenax GC) over liquid–liquid extraction are the long service life of the

sorbent, the ease of automation of the concentration process, and the avoidance of a solvent, which could complicate the subsequent analysis.

Most workers have used Amberlites of the XAD series to concentrate traces of organic compounds from water (see Table 1). The adsorbed impurities are usually extracted with organic solvents (Table 2).

Junk and co-workers[31] sorbed organic impurities from water on a 10 cm × 0.6 cm column filled with XAD-2 and XAD-4 (20–60 mesh) using the following concentration conditions: volume of sample 1000 ml, rate of flow of sample through the concentrator 30–50 ml min^{-1}. The sorbed compounds were extracted with diethyl ether, and the eluate was concentrated by evaporation and analysed by gas chromatography. The method was applied to a large number of model compounds present in water at the 10–100 ppb level (alcohols, aldehydes, ketones, esters, polynuclear aromatic compounds, pesticides, herbicides), and shown to give reasonably accurate and reproducible results. The conclusion was[31] that polymer sorbents are very effective for extracting neutral organic compounds from water. The sorbent was regenerated with methanol.

The use of Amberlite XAD-2 as a sorbent for extracting water-soluble acid dyes in the presence of triethylammonium bicarbonate has been recommended[86]. It is stressed that XAD-2 can selectively adsorb water-soluble organic compounds as a result of the interaction between the non-polar parts of the molecule and the hydrophobic sorbent surface. The use of XAD-2 for extracting polar compounds is limited by the low (or even negligible) affinity of these compounds for the sorbent.

The use of Amberlites of the XAD series (-1, -2, -4, -7, -8) for concentrating fulvic acid from aqueous solutions has been described[87]. The most effective concentration was achieved with Amberlites XAD-7 and -8, acrylate copolymers having an intermediate polarity and a high sorption capacity. The use of styrene–divinylbenzene copolymers (XAD-1, -2, -4) for concentrating fulvic acid is complicated by the slow adsorption of the acid molecule (diffusion-limited), and by the incomplete regeneration of the sorbent.

Amberlites of the XAD series (-2, -4, -7, -8) have been used also to extract impurities from mains water[22]. 13 Organic impurities were detected, including normal hydrocarbons, polynuclear aromatic compounds, and halogenated hydrocarbons. The most favourable sorption characteristics were obtained with a 1 : 1 mixture of XAD-4 and XAD-8.

Extensive studies have been devoted to the analysis of the organophosphorus insecticide Fenitrothion in spring waters. Some workers[51,88] used XAD-2 for this analysis, and showed that the sorbed insecticide is stable for a long time (up to 5 weeks) in a column filled with this sorbent. This is an important advantage of the adsorption method over the chloroform extraction method. Another useful feature of the method is the possibility of repeated regeneration (up to 20 times) of the sorption columns without loss of efficiency. The main disadvantage of the sorption method using XAD-2 is a fairly long analysis time (25–30 min). Increasing the flow rate of water through the adsorbent causes loss of the compounds being concentrated: the use of XAD-4 (which has a greater sorption capacity than XAD-2) is therefore recommended[89] for concentrating Fenitrothion, since it offers a shorter analysis time by allowing the flow rate of water through the adsorbent to be increased (1 lite of water in 2 min). Volpe and Mallet[90] extracted Fenitrothion and its decomposition products from water with XAD-7 Amberlite, which holds Fenitrothion more firmly than XAD-2 and XAD-4.

Ternary copolymers (styrene–divinylbenzene–acrylonitrile) have been used[91] for extracting phenolic compounds from water. The third component was found to improve the mechanical characteristics of the resin and its adsorption capacity for phenol, *p*-nitrophenol, and *p*-nitroaniline. The swelling of these copolymers in water and in acetone is very slight, and therefore the materials are convenient adsorbents for use under dynamic conditions.

As an alternative to the conventional columns for concentrating trace impurities of organic compounds from water, "mini-columns" containing ~80 mg of sorbents have been proposed[92,93]. Columns 25 mm long and 1.2–1.8 mm in diameter are filled with polymeric or hydrocarbon sorbents, the volume of sample is 50–100 μlitre, the adsorbed impurities (alcohols, esters, ketones, aldehydes, etc.) are extracted from the column with 50–100 μlitre of a suitable organic solvent, and 2 μlitre of the eluate are used in the subsequent gas-chromatographic analysis. This procedure avoids the need to evaporate the eluate to a smaller volume, and thus avoids the losses caused by the evaporation. The main shortcoming of the method is the very small size (~100 μlitre) of the water sample which seriously limits the sensitivity. tivity.

4. Use of Porous Polymer Sorbents Produced in the Soviet Union for Concentrating Trace Impurities

The porous polymer sorbents made in the Soviet Union which have been used for concentrating traces of organic compounds include Polisorb-1, Polisorbimid-1, and a sorbent based on polyphenylquinoxaline.

Polisorb-1 is a porous copolymer of styrene and divinylbenzene[94], similar in chemical nature and in structure to sorbents of the Amberlite (in particular, XAD-2) and Chromosorb-102 type. It can be used as an alternative to these sorbents after appropriate pre-treatment[5].

Polisorbimid-1, a polycondensation product of pyromellitic dianhydride and diaminodiphenyl ether, is a thermally stable polymer sorbent (up to 400–450 °C).[94,95] Polisorbimid-1 has been found[96] to retain polar compounds and aromatic hydrocarbons significantly better than Tenax. This sorbent has been used successfully for concentrating traces of oxygen-containing impurities and aromatic hydrocarbons from air. The concentrated impurities were desorbed at 280 °C in a stream of carrier gas, and they were separated and identified gas-chromatographically with a mass spectrometer detector[96].

The sorbent based on polyphenylquinoxaline (PFKh) proposed[97] for the separation and concentration of volatile organic compounds is also thermally stable: its maximum working temperature is 280–300 °C. The gas-chromatographic properties of this sorbent are described in Refs. 98 and 99. The PFKh is pre-conditioned in the concentrator column in a stream of carrier gas by raising its temperature from 100 to 280 °C (in steps of ~50 K) and holding it for 2–3 h at each temperature.

The possibility of using PFKh for concentrating traces of organic compounds from air has been studied in detail[100], and the retention volume was found to be greater than on Tenax for a large number of organic compounds (vinyl chloride, hexene, hept-1-ene, benzene, toluene, ethylbenzene, cumene, pseudocumene, cyclohexanone, and mesitylene) in the effluents from the production and utilisation of structural polymers based on poly(vinyl chloride). For example, at 20 °C the specific retention volume for vinyl chloride on Tenax is 270 ml, as compared with 2250 ml on PFKh. This allows large quantities of the components to be accumulated in the concentrator before break-through, thus increasing the precision of the determination of trace impurities. The impurities are desorbed at 200–280 °C, depending on their chemical nature.

The increasing penetration of these polymer sorbents into analytical practice should hasten the solution of many important problems in the protection of the environment from contamination by toxic trace impurities.

Examples of the determination of traces of organic compounds in gaseous and in liquid media by using porous polymer r sorbents are given in Table 2. The Table also states the conditions used for the concentration, desorption, and gas-chromatographic analysis of the impurities.

---o0o---

This review of published work shows that porous polymer sorbents are now widely used for concentrating trace impurities of organic compounds in gaseous or in liquid media. Their success is due to the great variety of chemical forms and structural characteristics offered by these materials, which allow the choice of the most suitable sorbent for concentrating any given impurity. Another important advantage of polymer sorbents is the associated use of thermo-desorption techniques, which simplify the concentration process and make its automation easier. Polymeric sorbents can be used repeatedly without loss of adsorption efficiency. The continuing expansion of the range of these sorbents, and the penetration of new sorbents into the analytical practice, should result in an increased sensitivity for the determination of trace impurities as well as widening the range of compounds which can be detected.

The use of porous polymer sorbents for concentrating trace impurities will extend the boundaries of gas chromatography as applied to the control of toxic substances in the environment—an essential stage in the fight against the pollution of the atmosphere and hydrosphere of our plant.

Correlation Functions of One-dimensional Systems

V.Ya.Krivnov and A.A.Ovchinnikov

The calculation of correlation functions describing the structure in space of one-dimensional systems is discussed, and various approaches to this problem are analysed. Examples of the use of correlation functions to interpret experimental X-ray and neutron scattering data and to calculate transition temperatures in quasi-one-dimensional systems are given.
The bibliography includes 41 references.

I. INTRODUCTION

In the light of recent advances in the synthesis of interesting quasi-one-dimensional compounds such as electrically conducting donor–acceptor complexes based on tetracyanoquinonedimethane (TCNQ),[1] polyacetylene doped with donors or acceptors[2], etc. the practical importance of one-dimensional physics is now self-evident. We know that one-dimensional system have a number of special attributes which produce a striking difference between one-dimensional and three-dimensional systems. In particular, and in spite of the relative simplicity of the one-dimensional systems, the well tried approximations used in the solution of three-dimensional problems are not always applicable to one-dimensional problems, and advances in one-dimensional physics must await the development of new methods.

Though theoretical studies of one-dimensional quantum systems began before the last war, detailed and organised work only began in the 1960's under the stimulus of successes in the preparation of these materials. During this period, which extends over 10–15 years, theoretical efforts were aimed mainly at the development of methods of calculating the energy characteristics (ground state energy, excitation spectra, etc.) and the thermodynamic parameters of one-dimensional systems. Approximate methods of calculating energies (by the specific variational method) were obtained, and allowed the energy of one-dimensional systems to be calculated very accurately[3]. Furthermore, for some one-dimensional models accurate results were obtained by a method which follows from the work of Bethe[3]. Numerical studies of systems consisting of a finite number of particles have also been very useful[4].

The main outcome of all this work was a realisation of the importance and of the specific features of correlation effects in one-dimensional systems, and the development of accurate methods of allowing for these effects. In spite of the continuing uncertainties in our understanding of some aspects of the energy characteristics (for example, the accurate correction for electron–phonon interactions, and in particular

† This and the following reviews are based on plenary papers presented to the Twelfth All-Union Congress on Organic Semiconductors (October 1982).

for the Peierls transition[5]), the energy problem can be considered (on the whole) to have been solved, and the main focus of attention is now a problem of a different kind: the calculation of the correlation functions of one-dimensional systems.

The correlation functions are different types of average over the wave functions of the system, which characterise its spatial structure as well as determining its response to various external stimuli (in particular, the diffraction of X-rays or neutrons by the system). The information contained in the correlation function is much more profuse than that implicit in a knowledge of the energy spectrum or of the thermodynamics of the system. As an example, we note that the most accurate calculations of the extent of charge transfer in quasi-one-dimensional donor–acceptor crystals of the TTF–TCNQ type (where TTF is tetrathiofulvalene) were based on diffuse X-ray and neutron diffraction spectra[6,7]. However, we should stress that the calculation of correlation functions is a much more complex problem than the calculation of energies. This is mainly because the former requires a knowledge of the wave functions of the system, and whereas the variational method gives acceptable results in calculations of energy it is far from satisfactory when applied to the calculation of wave functions. The method of Bethe, mentioned above, also gives accurate values of the energy but is unacceptable as a method of calculating wave functions. These difficulties are responsible for the lack (until recently) of serious attempts to calculate the correlation functions of one-dimensional systems, although accurate results were obtained[8,9] for a few, isolated model systems. The work done in the first stage has been expertly reviewed (see, for example, Ref.10), and is fully understood by theoreticians as well as by experimental scientists; on the other hand the problem of calculating correlation functions, which has been actively investigated only during the past 6–8 years, is still far from being solved, and has not yet been reviewed in detail. The various approaches to the solution of this problem are based on hypotheses which are difficult to prove and not always well founded, and therefore the acceptance of results from various laboratories is not universal. The aim of this paper is to review recent progress in this field and to discuss the results obtained so far.

II. CORRELATION FUNCTIONS OF THE CONTINUUM MODEL OF A FERMI GAS

We shall examine most closely two specific correlators (or correlation functions): the one-particle density matrix $\rho(R)$, defined by the integral

$$\rho(R) = \rho \int \Psi^*(R, x_2, \ldots x_N)\, \Psi(0, x_2, \ldots, x_N)\, \mathrm{d}x_2 \ldots \mathrm{d}x_N$$

[where $\Psi(x_1, \ldots, x_N)$ is the wave function of the system, depending on the coordinates of the particles $(x_1, \ldots, x_N)$], and the pair correlation function $G(R, t)$,

$$G(R, t) = \langle \rho(0, 0)\, \rho(R, t) \rangle$$

where $\rho(R, t)$ is a density operator depending on the time t, and the angle brackets denote statistical averaging. The function $G(R, t)$ defines the probability of finding any particle of the system at a distance R from the given particle at time t. In particular, for $t = 0$ and zero temperature ($T = 0$) we can write

$$G(R, 0) = \rho^2 \int \Psi^*(0, R, x_3, \ldots, x_N)\, \Psi(0, R, x_3, \ldots, x_N)\, \mathrm{d}x_3 \ldots \mathrm{d}x_N .$$

The correlator $\rho(R)$ is interesting because its Fourier transform $n(k)$ is a function of the distribution of the particles in momentum k at $T = 0$. Also important is the Fourier transform of the correlator $G(R, t)$ (the dynamic form-factor $S(k, \omega)$, where ω is the frequency[11]), which determines the probability of scattering of neutrons and X-rays. We shall be mainly interested in the values of these correlators for large distances and long times.

The most characteristic feature of one-dimensional systems is the lack of long-range order even at $T = 0$, with a few exceptions, which will be mentioned below. This means that the value of the correlators is an inverse function of distance. The determination of this function is one of the theoretical problems facing us. In other words, we have the asymptotic laws $\rho(R) \propto R^{-\kappa}$ and $G(R, 0) \propto R^{-\alpha}$, and we are required to find κ and α (which are sometimes called the critical indices).

It could be useful to dwell briefly on one aspect of the lack of long-range order in one-dimensional systems: the one-dimensional superconductor problem. It is often stated in the literature that one-dimensional superconductivity is impossible owing to the lack of long-range order. These statements rely on the analogy with a Bose gas, in which super-fluidity occurs as a result of a phase transition in the Bose condensate state whose matrix (or, more accurately, the non-diagonal elements of whose matrix) do not vanish for $R \to \infty$. We should stress that there is as yet no strict proof that one dimensional superconductivity is impossible in the absence of long-range order, and furthermore that metastable states with a non-zero current can exist in one-dimensional systems. Though phase transitions at $T \neq 0$ are impossible in one-dimensional systems, and these metastable states do not contribute long-range order, their life-times can be very long because states with a non-zero current and states with a zero current are separated by high activation barriers, and the probability of transitions between the two states is calculated[12] to be very small.

Two main approaches to the calculation of correlation functions are available at present. It has been assumed[13] that the behaviour of the correlation functions of one-dimensional Fermi systems (with which we shall be concerned in this review) at large distances is determined by gap-free long-wave excitations of the acoustic type (which are in fact responsible for the breakdown of long-range order). By allowing for these excitations and ignoring all the others we can obtain explicit expressions for the correlation functions.

The other approach to the calculation of correlators relies on the linearisation of the quadratic Fermion spectrum, i.e. on the replacement of $k^2/2m$ by $v_F k$ (where m is the mass of the Fermion and v_F is the Fermi velocity) and on the definition of two kinds of particle with $k = k_F$ and $k = -k_F$ respectively (where k_F is the Fermi momentum, related to the particle density ρ by the expression $k_F = \pi\rho$). Within the limitations of the "linear model" thus obtained, accurate calculations are possible[14–16].

The correlation functions obtained by these two approaches are qualitatively consistent. Their most characteristic features are the power-law decrease at large distances and the smooth variation of the critical indices with the corresponding electron–electron interaction constant. When evaluating the two approaches we should remember that the hypothesis of the dominant role of acoustic excitations has not been strictly justified. Furthermore, as we shall show below, the asymptotic behaviour of the pair correlation function can be inferred from the properties of the structure factor $S(k)$ at $k = 2k_F$, $4k_F$, etc., and therefore it cannot be associated with excitations of the acoustic type. On the other hand, the approach based on the linearisation of the quadratic Fermion spectrum

also has some weaknesses, the most serious of which is the inadequate symmetry of the complete wave function of the system (due to the introduction of two kinds of particle), which cannot be justified (say) by the expansion of various physical quantities in a power series of a small interaction constant.

Thus both approaches rely on plausible but not strictly justified assumptions. In our calculation[17] of the correlation functions we have developed a variant of perturbation theory which uses a non-interacting Fermi gas as the zeroth approximation, and therefore allows standard corrections to be applied to the correlation function. Our method treats a one-dimensional system of N particles (whose spin is ignored to simplify the problem), distributed over the region $[0, L]$, by the continuum model of a Fermi gas, whose Hamiltonian is

$$\hat{H} = -\sum_{i=1}^{N} \frac{\partial^2}{\partial x_i^2} + g \sum_{i \neq j}^{N} V(x_i - x_j) . \qquad (1)$$

Here $V(x)$ is the interaction potential, assumed to be arbitrary, and g is the interaction constant. As stated above, the most serious difficulty in the calculation of the correlators is our lack of knowledge of the form of the wave functions of this system. We started from the following representation of the wave function of the ground state:

$$\Psi(x_1, \ldots, x_N) = \Psi_0(x_1, \ldots, x_N) \cdot \exp[\Phi(x_1, \ldots, x_N)] \qquad (2)$$

where Ψ_0 is the wave function of the system without interaction (the Slater determinant), which is antisymmetrical with respect to permutation of particle coordinates, and $\Phi(x_1, \ldots, x_N)$ is a symmetric function.

Inserting Ψ into the Schrödinger equation gives an equation for Φ. Since the function Φ is symmetric, the equation obtained is the Hamiltonian of the Bose particles. This "Bosonisation" of the Fermi problem has several interesting consquences, which lack of space prevents us from discussing. It is found that Φ takes the form

$$\Phi = \sum_{i,j} \Phi_2(x_i - x_j) + \sum_{i,j,l} \Phi_3(x_i - x_j, x_j - x_l) + \ldots \qquad (3)$$

i.e. it is made up of functions for two, three, etc. particles. It is also found (even more importantly) that the two-particle function $\Phi_2(x)$ plays the main role in determining the correlation properties. Furthermore, the asymptote of the correlators at large distances is given by the asymptote of the Fourier transform of $\Phi_2(x)$: the function $\sigma_2(k)$ for $k \to 0$.

Thus we have shown that detailed information on the wave function is not essential to the determination of the most important correlation properties of the system, and we have reduced the problem of obtaining the correlators to finding the asymptote of the function $\sigma_2(k)$, followed by suitable averaging. Though each of these problems is fairly difficult, they are much simpler than the initial problem. Our calculations show[18] that the asymptotic form of the function $\sigma_2(k)$ for $k \to 0$ is

$$\sigma_2(k) = \pi(c_0 - c)/2c_0|k| \qquad (4)$$

where c and c_0 are the velocities of sound in the system having interaction and in the system having $V(x) = 0$ respectively. We note that the velocity of sound appears in the expression for the excitation energy: $\varepsilon(k) = c|k|$ for $k \to 0$. The velocity of sound determined in this way is consistent with the value obtained by thermodynamic arguments.

Now let us consider the density matrix $\rho(R)$. In order to evaluate it we developed a special graphical method[17] from which the asymptotic form of the $\rho(R)$ dependence at large distances R can be obtained:

$$\rho(R) = \sin(k_F R)/(\pi R k_F)^{\varkappa}; \quad \varkappa = (c_0^2 + c^2)/2cc_0 . \qquad (5)$$

Since $c = c(g)$, the critical index κ varies continuously as a function of g. This behaviour of κ is typical of one-dimensional quantum systems. As was stated above, the Fourier transform of $\rho(R)$, i.e. the function $n(k)$, is a function of the distribution of the particles in momentum. The most interesting property of the function $n(k)$ is the absence of a discontinuity at $k = k_F$:

$$n(k) = \frac{1}{2}\{1 + \operatorname{sign}(k_F - k)\,|k - k_F|^{\varkappa - 1}\}; \quad \varkappa - 1 = (c - c_0)^2/2cc_0 . \qquad (6)$$

The jump in the momentum distribution of the particles is absent even when the g value is so small that the one-dimensional system behaves very differently from a three-dimensional system. It has been shown[19,20] that in the three-dimensional case the jump persists for $g \neq 0$, though it is no longer equal to 1.

Qualitatively similar results were obtained by the linear model[8]. However, we should note that in the linear model the critical index κ has a different value, and that for some types of interaction potential (in particular, in the case of a δ-function potential) the linear model gives an incorrect value of κ even for $g \to 0$.

We may now consider the other correlator: the pair correlation function $G(R, t)$ and its Fourier transform [the function $S(k, \omega)$]. This correlator is most conveniently discussed by starting with a special case: strong repulsion between the electrons. In this case the correlator of interest to us can be calculated exactly: thus the results can be compared with those of the linear model, and furthermore the form of the pair correlation function can be determined for arbitrary values of the interaction constant.

Let us examine a system defined by the Hamiltonian (1). The potential $V(x)$ which appears in it can be, for example, a power function, or it can have the form $V(x) = \exp(-\gamma|x|)$, where γ^{-1} is the interaction radius. An exact analysis of this system for $g \to \infty$ and low enough temperatures is possible because of the well-known formation of a Wigner crystal with a lattice constant $a = 1/\rho = L/N$.[18] Introducing the new variable

$$x_n = na + \xi_n$$

and truncating the expansion of the potential energy at the term quadratic in ξ_n we obtain the Hamiltonian for a system of harmonic oscillators with long-range effects, which can be reduced in the normal way to the Hamiltonian for a system of non-interacting phonons.

The spectrum of these oscillators defines the energy of the elementary excitations of the Fermi gas. These excitations (Fig. 1) are of the acoustic type at low values of the momentum ($q \to 0$):

$$\omega(q) = c|q|; \quad c = a\left(2g \sum_{n=1}^{\infty} V''(na)\, n^2\right)^{1/2} \qquad (7)$$

and are periodic, with a periodicity of $2k_F$, which is characteristic of one-dimensional systems in general.

In this limit ($g \to \infty$) the wave functions of the initial system reduce to the standard oscillator functions, and the calculation of $G(R, t)$ involves only taking the Gaussian integrals. The expression for $G(R, t)$ is quite cumbersome[18], and will not be reproduced here. We shall examine some

special cases only. For $t = 0$ and $r = 0$ the function $h(R) = G(R, 0) - \rho^2$ becomes

$$h(R) = 2\rho^2 \sum_{s=1}^{\infty} \cos(2k_F sR)\,(R\rho)^{-2\mu s^2};\ \mu = 2k_F/c \quad (8)$$

The asymptotic behaviour of this correlator for $R \to \infty$ is determined by the first term of this sum (for $s = 1$):

$$h(R) = 2\rho^2 \cos(2k_F R) \cdot (R\rho)^{-2\mu} \quad (9)$$

i.e. the critical index is $\alpha = 4k_F/c$. We note from formula (9) that at $T = 0$ the function $h(R)$ decreases with distance by a power law whose index depends on g. For $T \neq 0$ the function $h(R)$ decays exponentially with a correlation radius $\propto T^{-1}$.

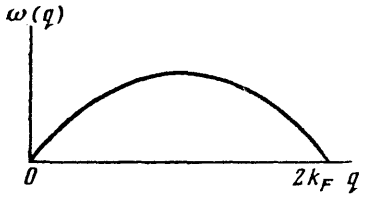

Figure 1. Spectrum of the elementary excitations in a one-dimensional Fermi gas.

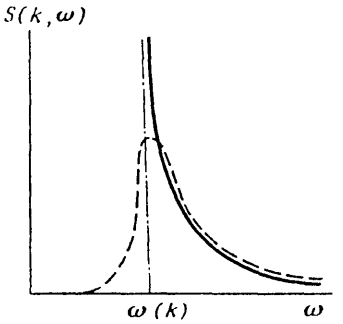

Figure 2. Plots of $S(k, \omega)$ against ω for a fixed k. The full line is for $T = 0$, the broken line for $T \neq 0$.

The following remarks are relevant in connection with the formula for $h(R)$. As stated above, the correlator $h(R)$ has been calculated exactly for some special forms of the potential $V(x)$ and some special values of g (in particular, for the $V(x) = x^{-2}$ potential, used in the Sutherland model[21-24]). The velocity of sound c is also known for these special cases. By inserting these values of c into formula (9) for $h(R)$ we obtain good agreement with all the known exact values. Furthermore, $h(R)$ can be calculated in the limit of small g by the method which we used to calculate the density matrix: comparison of the results[19] shows that the formula for $h(R)$ is valid in this case also. These observations suggest that the expression for $h(R)$ can be used for all $g > 0$ and $T = 0$ if an exact value of the velocity of sound is available for the parameter c which appears in the expression.

Thus the asymptotic behaviour of both $h(R)$ and $\rho(R)$ is known if the velocity of sound c is known. The problem of calculating c is much simpler than the calculation of the correlator, since c is effectively one of the energy parameters of the system, which can be calculated by well tried approximations. For some of the models the c value is accurately known. As g varies from 0 to ∞ the parameter α varies from 2 to 0. It is interesting to compare the expression for $h(R)$ with the corresponding expression of the linear model. The latter also gives a power-law decrease in the correlator as $R \to \infty$, but with a different exponent, except at low values of g.

The Fourier transform of $G(R, t)$—the dynamic structure factor $S(k, \omega)$—defines the probability of scattering neutrons and X-rays. The plot of $S(k, \omega)$ against ω (Fig.2) for a fixed value of k shows a singularity at $\omega \to \omega(k)$ for all $g > 0$ and fixed k ($S(k, \omega)_{g=0} = \text{const.}$), described by a power law with the exponent $1 - \alpha/2$. For $T \neq 0$ this singularity is smoothed out, and a maximum appears in $S(k, \omega)$ at $\omega = \omega(k)$ (broken line in Fig.2).

It is interesting also to consider the correlator $S(k)$, i.e. the static structure factor which determines the probability of elastic scattering of X-rays and is the Fourier transform of the correlator $h(R)$.

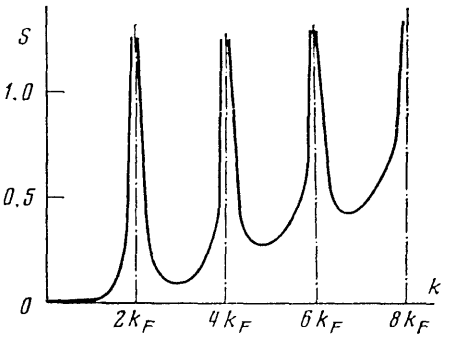

Figure 3. $S(k)$ dependence in the Sutherland model for $g = 2 \times 10^4$ and $T = 0$.[18]

Figs.3 and 4 show plots of the function $S(k)$ at $T = 0$ and at $T \neq 0$ for different values of g in the Sutherland model. At $T = 0$ the function $S(k)$ is discontinuous at the k values $k \to 2k_F n$, and we can write $S(k) = |k - 2k_F n|^{\alpha n^2 - 1}$. The number of peaks, i.e. the number of points n at which the function diverges, satisfies the condition $c > 4k_F n^2$, and therefore the number of peaks increases with g. We also note that the leading term of the asymptote of the function $h(R)$ is determined by the singularity in $S(k)$ at $k = 2k_F$. The effects at $k = \pm 4k_F$, $\pm 6k_F$, etc. correspond to the further terms of the expansion ($s = 2$, 3, etc.) in formula (8). We should note that the singularities of the function $S(k)$ at $k = \pm 2k_F n$ (with $n \geq 2$) are "lost" in the linear model. At $T \neq 0$ the discontinuities in the function $S(k)$ are rounded off, and the value of $S(k)$ is finite for all k, with

$$S(0) = 2k_B T/c^2;\quad S(2k_F n) = \coth(2\pi^2 n^2 k_B T/c^2) \quad (10)$$

As the temperature is raised the height of the peaks decreases. It can be shown that the function $S(k)$ plotted in Fig.4 is valid not only at low temperatures (to which our

discussion applies) but even in the high temperature limit, where the classical approximation can be used. It was found[25,26] that the function $S(k)$ has maxima at $k = 2k_F n$, and the height of the peaks decreases as n increases. These calculations were intended to explain experimental data[26] on the diffuse scattering of X-rays by linear chains of mercury atoms in the quasi-one-dimensional $Hg_{3-\delta}AsF_6$ system. The $S(k)$ dependence obtained experimentally is similar to that shown in Fig.4 and agrees well with the calculations[25,26]. It follows from the expressions for $h(R)$ and $S(k)$ that an interacting Fermi gas is structurally closer to a one-dimensional solid than to a liquid.

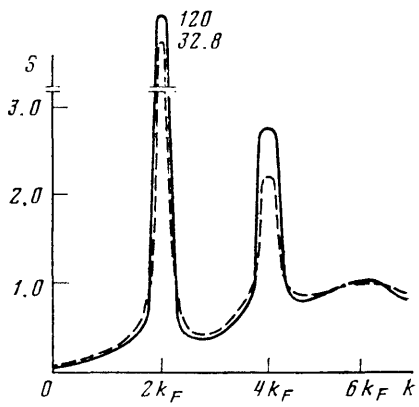

Figure 4. $S(k)$ dependence in the Sutherland model for $g = 200$. Full line $k_B T/\rho^2 = 3/5$; broken line $k_B T/\rho^2 = 3$. The numbers on the curves denote the height of the peak at $k = 2k_F$.[18]

The main conclusions from the above discussion of the correlators for a one-dimensional interacting Fermi gas can be formulated as follows. At large distances and $T = 0$ the correlation functions decrease by a power law, with an exponent expressed simply in terms of the velocity of sound. Reliable methods of calculating the velocity of sound are available, and for some models this parameter is already accurately known. Both methods of calculating the correlators (by linearising the problem or by postulating predominantly acoustic excitation in the formulation of the special features of the correlators) give functionally correct predictions of the asymptotes of the correlators, but the critical exponents are correctly calculated only for small g: evidently, the linearisation procedure as described is valid only in this region of g values.

A new approach to the calculation of correlators has been proposed recently by Haldane[27], who used assumptions basically similar to those of Ref.13 to convert the problem into an oscillator problem and obtained experessions for the correlators identical to ours.

III. LATTICE FERMI GAS

So far our discussion has been confined to the continuum model of a one-dimensional Fermi gas. A more realistic model of the system is provided by the lattice Fermi gas, which describes a system of N interacting electrons located at M centres, with $N \to \infty$ and $M \to \infty$ and $N/M = \rho$. The continuum and the lattice model have a great deal in common both from the electronic structure and from the correlator point of view. Thus, the correlator $\rho(R)$ for the lattice Fermi gas can be calculated as in the continuum case, the steps in the Fermi distribution becomes diffuse[28] however weak the interaction, with a critical index κ for $g \ll 1$ given by

$$\varkappa = 1 + g^2 v^2(0)/32\pi^2\beta^2 \sin^2(\pi\rho/2)$$

where $v(q)$ is the Fourier transform of the function $V(x)$ [$v(0) = v(q = 0)$, and β is the resonance integral].

At the same time, lattice systems offer a number of special features. For example, in contrast to continuum models (for which the elementary excitation spectrum has no gap) the lattice systems can have a gap. Lastly, for stated values of the parameters the lattice systems allow long-range order at $T = 0$.

Let us consider the simplest (but by no means trivial) lattice model: a Fermi gas without spins and with interactions between nearest neighbours. Its Hamiltonian is

$$\hat{H} = -\beta \sum_{n=1}^{N} (a_n^+ a_{n+1} + a_{n+1}^+ a_n) + g \sum_{n=1}^{N} a_n^+ a_n a_{n+1}^+ a_{n+1}; \; \rho = 1/2; \; g > 0 \quad (11)$$

where a_n^+ and a_n are operators for the generation and annihilation of Fermions on the nth centre. This system is interesting also because it is equivalent to the anisotropic antiferromagnetic Heisenberg model. Mathematically, the term "equivalent" postulates the existence of a canonical transformation[29] which converts the Fermi operators into spin operators, so that Eqn.(11) reduces to the Hamiltonian of the Heisenberg model.

An interesting property of this system is the presence of a gap in the elementary excitation spectrum for $g > 2\beta$.[30,31] In this range of g values the system displays long-range order, i.e. the correlator $h(R)$ tends towards a finite limit determined by the ratio g/β at $R \to \infty$. In magnetic systems this implies the existence of non-zero magnetisation of the sublattices. The asymptote of $h(R)$ differs from its limiting value, first calculated by Baxter[32], by an exponentially small quantity. For $g < 2\beta$ the spectrum of the system no longer has a gap, and the long-range order disappears[30,31]. If controlled changes in β (say) are imposed on the system a metal $\to$ dielectric transition is obtained at $\beta = g/2$, when both the gap and the long-range order disappear.

Unfortunately, no strict calculations of pair correlation functions in a metallic phase have been reported yet, and only approximate expressions for this correlatore are so far available. They were obtained[33–35] from the following considerations. The spectrum of elementary excitations of the system is of the form shown in Fig.5.[36] The cross-hatched region is called the two-parameter continuum; its upper and lower limits are the $\varepsilon_2(k)$ and $\varepsilon_1(k)$ curves, given (for $g = 2\beta$, for example) by the expressions

$$\varepsilon_2(k) = \pi g |\sin(k/2)|; \; \varepsilon_1(k) = (\pi g/2)|\sin k|.$$

Against each triangle in Fig.5 is shown the value of $S(k, \omega)$ for the corresponding k and ω obtained[33] in calculations for systems with a finite number of electrons $N = 10$. These calculations show that for the states lying above the two-parameter continuum the $S(k, \omega)$ values are at least an order of magnitude smaller than for the states within the continuum. Assuming that even at $N \to \infty$ the higher states do not contribute significantly, the following expression for $S(k, \omega)$

was obtained[33]

$$S(k,\ \omega) = A\theta[\omega - \varepsilon_1(k)]\,\theta[\varepsilon_2(k) - \omega]\cdot[\omega^2 - \varepsilon_1^2(k)]^{-\lambda_1}\,[\varepsilon_2^2(k) - \omega^2]^{-\lambda_2}$$

$$\theta(x) = \begin{cases} 1, & x > 1 \\ 0, & x \leqslant 0 \end{cases},$$

where A is a constant, and the exponents λ_1 and λ_2 are chosen in relation to known constraints (for example, for $g = 2\beta$, $\lambda_1 = 1/2$ and $\lambda_2 = 0$). The approximate expression for $S(k, \omega)$ thus obtained is functionally similar to the corresponding expression of the continuum model, confirming the similarity between the continuum and the lattice model in the metallic phase.

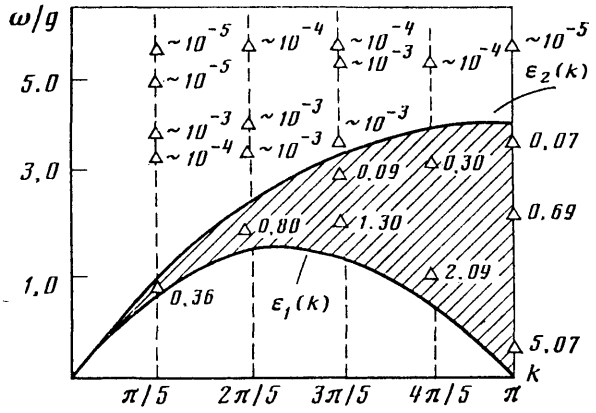

Figure 5. Excitation spectrum of a lattice Fermi gas and $S(k, \omega)$ values for $N = 10$.[33]

IV. EXAMPLES OF THE USE OF CORRELATION FUNCTIONS

We shall illustrate the above discussion by giving two examples of the use of correlation functions: 1) to interpret experimental data on the inelastic scattering of neutrons by a one-dimensional system, and 2) to calculate the critical phase transition temperatures in quasi-one-dimensional systems.

1) The most meaningful experiments on the inelastic scattering of neutrons by one-dimensional systems of the present type were carried out with the one-dimensional antiferromagnetic CPC $[CuCl_2.2N(C_5D_5)]$.[37,38] As was stated above, a one-dimensional antiferromagnetic is equivalent to a one-dimensional lattice Fermi gas with repulsions between particles. Experimental data on the inelastic neutron scattering cross-section of CPC are reproduced in Fig.6a. We note that the asymmetry of the line and the intensity at the maximum increase as the temperature is lowered. The asymmetry was initially thought[37] to be an apparatus effect, but its reality was confirmed by later experiments[38]. The effect is easily explained in terms of the temperature dependence of $S(k, \omega)$, theoretically predicted (see Fig.2) and arising from the properties of the function $S(k, \omega)$ at $\omega = \omega(k)$.

The integral scattering intensity experimentally observed at $T = 1.3$ K (Fig.6b) suggests a singularity in $S(k)$ at $k \to 2k_F$ (in this case $k_F = \pi/2$) and agrees very well with the theoretical expression given by Müller[33].

2) The calculation of the critical transition temperature in quasi-one-dimensional systems. As we have already stated, long-range order is absent in one-dimensional systems at $T \neq 0$ (though it can exist at $T = 0$ in the lattice systems discussed above). In real systems a small but significant lateral interaction between the one-dimensional systems (filaments) is always present. As a result, at low enough temperatures the one-dimensional systems becomes effectively three-dimensional, and they develop long-range order (which disappears at $T = T_{cr}$).

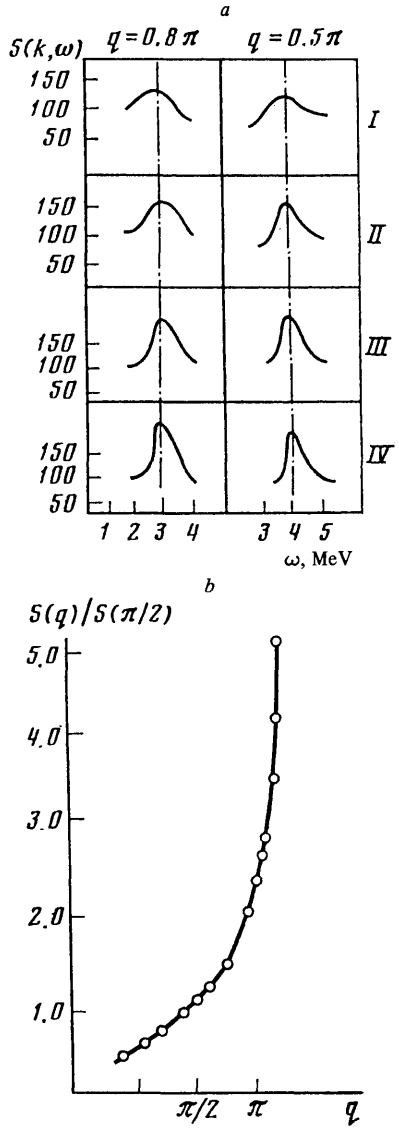

Figure 6. (*a*) Inelastic neutron scattering cross-section for CPC in relative units for two values of q, and (*b*) integral scattering intensity, for different temperatures (T): *I*) 8.0, *II*) 4.0, *III*) 2.0, *IV*) 1.3 K.[37,38]

We shall illustrate the calculation of T_{cr} from a knowledge of the one-dimensional correlators by considering the trivial but very revealing example[39] of a two-dimensional system of

ferromagnetic Eising chains with weak transverse interactions. The Hamiltonian of this system is

$$\hat{H} = -J_{\parallel} \sum_{i,m} S^z_{i,m} S^z_{i+1,m} - J_{\perp} \sum_{i,m} S^z_{i,m} S^z_{i,m+1};\ J_{\parallel} > 0;\ J_{\perp} > 0\ , \quad (12)$$

where $J_{\parallel}$ and $J_{\perp}$ are the exchange integrals for the interaction of nearest neighbours along chains and at right angles to the chains respectively, and $S^z_{i,m}$ is the operator for the z-component of the spin at the lattice point numbered (i, m).

We shall use the self-consistent field approximation and replace one of the operators in the second term by its average value $\langle S^z \rangle$:

$$\hat{H} = -J_{\parallel} \sum_{i,m} S^z_{i,m} S^z_{i+1,m} - 2J_{\perp} \langle S^z \rangle \sum_{i,m} S^z_{i,m}\ , \quad (13)$$

with the self-consistence condition

$$\langle S^z \rangle = \mathrm{Sp}\, S^z_{i,m} \exp(-\hat{H}/k_B T) / \mathrm{Sp} \exp(-\hat{H}/k_B T)\ . \quad (14)$$

At $T \to T_{cr}$ we have $\langle S^z \rangle \to 0$, and by expanding the right-hand side of (15) into a power series in $\langle S^z \rangle$ we obtain the following expression for calculating T_{cr}:

$$k_B T_{cr} = 2J_{\perp} \sum_n \langle S^z_0 S^z_n \rangle\ . \quad (15)$$

The one-dimensional correlation function $\langle S^z_0 S^z_n \rangle$ appears in this expression. Thus, knowing the one-dimensional correlator $\langle S^z_0 S^z_n \rangle = \tanh^n |(J_{\parallel}/4k_B T)/4$, we can calculate T_{cr} by solving Eqn.(15):

$$k_B T_{cr} = 2J_{\parallel} / \ln (J_{\parallel}/J_{\perp})\ .$$

The exact value of T_{cr}, obtained by solving Onsager's equation, is given by

$$k_B T_{cr} = 2J_{\parallel} / \ln (2J_{\parallel}/J_{\perp})\ .$$

These calculations can easily be generalised to include more complex systems[13,40,41]. For example, we can use exactly the same arguments to calculate T_{cr} for a three-dimensional lattice gas with weak transverse interactions[41]:

$$\hat{H} = \hat{H}_0 + \hat{H}_1;\ \hat{H}_0 = -\beta \sum_{i,m} (a^+_{i,m} a_{i+1,m} + a^+_{i+1,m} a_{i,m}) +$$
$$+ g_{\parallel} \sum_{i,m} a^+_{i,m} a_{i,m} a^+_{i+1,m} a_{i+1,m};\quad \hat{H}_1 = g_{\perp} \sum_{i,m} a^+_{i,m} a_{i,m} a^+_{i,m+1} a_{i,m+1}\ .$$

The subscript i gives the number of the site along the filament, whereas m defines the site in the perpendicular direction. For $T < T_{cr}$ we have a long-range order phase (called the phase with a charge density wave), in which three-dimensional effects appear, whereas for $T > T_{cr}$ the system is essentially one-dimensional.

Using the self-consistent field approximation and inserting the self-consistence condition we arrive at the equation

$$1 = 2v \int_0^{(k_B T_{cr})^{-1}} d\tau \sum_n (-1)^n G(n, \tau)\ ,$$

where ν is the number of nearest filaments, and $G(n, \tau)$ is the one-dimensional pair correlation function for imaginary time. As in the previous example we must know the purely one-dimensional correlation function in order to determine T_{cr}. The equation for T_{cr} is more complex than that given by the Eising model because H_0 and H_1 are not commutable in this model (in contrast to the Eising model). The parameter T_{cr} is given by the above equation as

$$k_B T_{cr} = C g_{\perp};\ C \sim 1\ .$$

It is interesting to compare the two models in the light of the fact that the Eising model is the limiting case of the lattice model for $g \gg \beta$, i.e. it aims to model the lattice Fermi gas in the dielectric phase (at $T = 0$) which was discussed above. Thus the two examples considered here describe the three-dimensional ordering of filaments in dielectric or in metallic phases (at $T = 0$). From the corresponding expressions for T_{cr} we note that the transition temperature is substantially higher for filaments in the dielectric phase.

We should stress that the self-consistent method described above can also be used to find approximate expressions for the quasi-one-dimensional correlation functions in an ordered (three-dimensional) phase.

Physical Properties and Applications of Langmuir Monomolecular and Multimolecular Structures

L.M.Blinov

The physicochemical and physical properties of monomolecular and multimolecular structures obtained by the Langmuir-Blodgett method are surveyed. Attention is concentrated on the examination of the microscopic picture of the phenomena underlying the applications of these structures in optoelectronics and micro-electronics.
The bibliography includes 122 references.

I. INTRODUCTION

This review deals with the problem of the creation of complex molecular assemblies by the consecutive transfer of one monomolecular layer of organic molecules after another from the surface of water onto solid supports. A three-dimensional multimolecular structure is thus obtained, whose properties can be specified by the experimenter at will at least along one direction (perpendicular to the plane of the layers). It is striking that with the exception of one translated article[1] which has also become appreciably obsolete, there are apparently no reviews on this subject in the Russian language. Nevertheless, during the last two decades approximately 1000 communications, including several tens of reviews (see, for example, Refs.2–12), a special issue of the journal Thin Solid Films (1980, **68**, No.1) and a monograph[13]† have been published on this question. Molecular or supermolecular construction[9], molecular engineering[11], molecular and biomimetric electronics[8], and the creation of synthetic "organisates"[6]—these apparently constitute what is still an incomplete list of names given to this new branch of research in the field of the physics and chemistry of organic matter. We shall call this branch of science "molecular architectural design" which we believe fully reflects its essential features.

The history of such investigations began with an early study by Franklin[4,14], who carried out numerical estimates of the area of an oil film spreading on the surface of water and observed the suppression of waves in a small lake induced by the film. The results of first systematic studies on the surface tension of water contaminated by organic substances were obtained by Pockels[15]. Subsequently Rayleigh himself carried out a series of studies on the contaminated surface of water and arrived at the following fundamental conclusion[16]: "evidently the observed phenomena are outside the framework of the Laplace theory in which the medium is assumed to be continuous and their explanation requires a molecular approach".

Credit for the determination of the monomolecular nature of the layers at the liquid–gas interface is due to Langmuir. He was the first to establish the possibility of the transfer of monolayers from the surface of water onto solid supports[17]. Subsequently Blodgett perfected this technique and developed a method for the preparation of multilayer structures[18,19]. At the present time the term "Langmuir films" or "Langmuir–Blodgett films" is generally accepted and refers to monomolecular and multimolecular layers transferred from the surface of water onto a solid support.

The idea of molecular architecture, i.e. the creation of complex molecular assemblies with a predetermined architecture in order to obtain specific electrical and optical characteristics, is apparently due to Kuhn. Extensive studies on the optical[2,3] and photoelectric[5–7] properties of the Langmuir multistructures incorporating dye and phosphor molecules were carried out under his supervision in Göttingen in the 1960's–1970's. During very recent years, active studies designed to create molecular assemblies have been prosecuted by the Xerox Company (Canada)[9,12], at a number of English universities[10,11], and also in Japan[8]. There exist also Soviet publications on this topic (see, for example, Refs.20–23).

Nowadays molecular architectural design has aroused the interest of investigators in most varied branches of science. From the standpoint of physics, it gives rise to the possibility of investigating the properties of two-dimensional solid and liquid-crystal structures and microscopic interactions of molecules at rigorously controlled distances from one another and with a rigorously controlled mutual orientation. From the standpoint of chemistry, the possibility of studying the anisotropy of the reactivity of molecules and also of carrying out chemical reactions with molecules fixed in a specially selected matrix are of interest.

For biology, monomolecular and multimolecular structures are primarily systems which model cell membranes. For engineers working in the field of electronics, molecular architecture opens the way to the creation of fundamentally new instruments with spatial resolution at the molecular level by analogy with biological structures[7,8]. The Langmuir method (and also its variant using the adsorption of molecules from solution) is at present one of the most promising ways of creating molecular assemblies and it undoubtedly has a great future.

In the present review, attention is concentrated on the properties of monomolecular and multimolecular layers deposited on solid supports. We shall therefore scarcely discuss the behaviour of monolayers on the surface of water and the general problems of the application of surfactants.

† See also Thin Solid Films, 1983, **99**, Nos.1–3, 1.

These problems have been examined in detail in a monograph[24]. Nor shall we be concerned with the properties of artificial lipid double layers to which an extensive literature has been devoted[25,26]. We have endeavoured to devote much space to the discussion of new ideas having a direct bearing on molecular architectural design avoiding the quotation of numerous specialist investigations. Instead the reviews already mentioned will be widely used[2-12].

II. PHYSICOCHEMICAL ASPECTS AND TECHNIQUE OF THE PREPARATION OF MONOLAYERS AND MULTILAYERS

1. Amphiphilic Compounds

In order to obtain Langmuir films from any one substance, it is in the first place necessary that it should form stable monomolecular layers on the surface of water. This condition is as a rule satisfied by molecules with a polar hydrophilic "head" and a long lipophilic (i.e. soluble in fats or hydrophobic) hydrocarbon "tail". Such molecules are called biphilic or amphiphilic.

Classical examples of amphiphilic compounds are aliphatic acids [see, for example, compound (I) in the Table] or their salts (soaps) [compound (II)]. The polar heads of these molecules are smoothly incorporated in the local water structure (we have in mind the short-range structural order). On the other hand, the hydrophobic hydrocarbon tails are not incorporated in the water structure, since the hydrogen bonds in liquid water would have to undergo a rearrangement to avoid falling within the region occupied by the hydrocarbon tail; such a structural rearrangement decreases the entropy of the system and is therefore unfavourable. Thus the hydrophobic effect does not presuppose the presence of any special repulsion forces between water and hydrocarbon molecules and appears solely due to the mutual attraction of the water molecules leading to the "expulsion" of the hydrocarbon to the outside[27]. As a result, a monolayer of molecules of the amphiphilic substance, whose hydrocarbon tails are "forced out" into the gas phase while the polar heads are in the liquid phase, arises on the surface of water. A small proportion of the molecules are then in the bulk of the liquid, since the solubility of amphiphilic compounds in water is usually 10^{-6}–10^{-10} M depending on the length of the hydrocarbon tail: an increase in the length of the tail by two carbon atoms reduces the solubility approximately by an order of magnitude.

Apart from aliphatic acids and their salts, stable monolayers on the surface of water are formed by ethers[28], the phospholipids used to obtain artificial two-layer membranes[29,30], certain diacetylenes capable of polymerisation[10,11], and also a number of dyes[31–33], aromatic compounds[34], and autocomplexes[35] with a wide variety of structures but virtually always possessing a long hydrocarbon chain (quinquethienyl is an exception[85]). Examples of the corresponding compounds are presented in the Table [see compounds (III)–(XII)].

There exist also a series of biologically active compounds such as cholesterol, chlorophyll, various proteins, etc., which form monomolecular layers capable of being transferred from the surface of water on to solid supports[1]. Many compounds which do not form monolayers themselves are readily incorporated in the structure of Langmuir monolayers of other compounds, in particular aliphatic acids. Examples of dyes of this kind are quoted in a review[2].

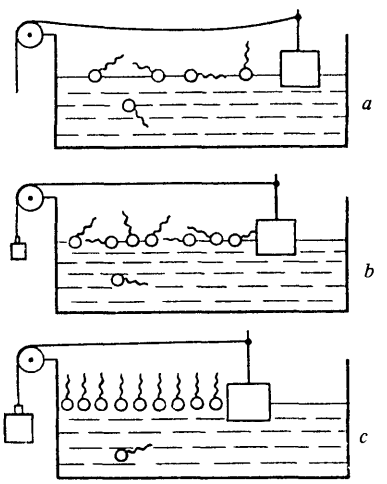

Figure 1. The molecules of an amphiphilic compound on the surface of water: *a*) in the two-dimensional "gaseous" phase; *b*) in the two-dimensional "liquid" phase; *c*) in the two-dimensional "liquid crystal" phase.

2. The Polymorphism of Monolayers

At a low concentration of the amphiphilic compounds on the surface of water the monomolecular layer is not continuous (Fig. 1*a*). Their molecules hardly interact, their tails above the surface of water are oriented at random, and such a phase may be regarded as a two-dimensional gas by analogy with the usual gas phase. If the surface area occupied by the amphiphilic molecules is reduced by means of a floating barrier, they initially approach one another but remain oriented at random (Fig. 1*b*). Such a phase may be called a two-dimensional liquid. With increase of pressure from the

side of the floating barrier, the amphiphilic molecules acquire orientation order but retain the ability to migrate within the plane of the layer. There is then no long-range positional order and the new phase is a two-dimensional liquid crystal (Fig. 1c) equivalent to one (polar) layer of a smectic liquid crystal[36,37]. Further increase of the surface pressure leads to the "puckering" of the monolayer or its collapse. In certain cases after the collapse there is a possibility of two-, three-, or four-layer structures[38].

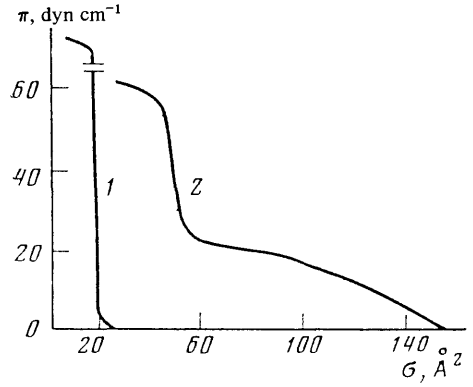

Figure 2. The π–σ isotherms for arachidic acid (curve *1*) and the dye (VII) (curve *2*).[2]

The sequence of phase transitions or the polymorphism of the monolayer can be investigated by following the relation between the surface pressure and the area occupied by the monolayer. Here there is an analogy with the equation of state for a normal three-dimensional substance and one usually measures π–σ isotherms, where π is the surface pressure in dynes per unit length of the floating barrier and σ is the area per molecule. Examples of such isotherms are presented in Fig. 2 for arachidic acid [compound (I) in Table, $n = 18$] and a dye (VII) which has two hydrocarbon chains attached to the side of the chromophore. It is clearly seen from Fig. 2 that from the very beginning the arachidic acid molecules occupy an area approximately equal to the cross-sectional area of the hydrocarbon chain (approximately 20 Å²), i.e. they virtually "stand" vertically on the surface of water. The transition from the "gas" phase to the "liquid crystal" phase takes place almost instantaneously, by-passing the "liquid" phase. For the dye (VII), the situation is different: before the hydrocarbon tails stand at right angles to the surface (to which $\sigma = 50$ Å² corresponds), there is a gradual growth of the surface pressure reflecting the interaction of the molecules which have not yet been oriented ("liquid" phase). In fact the isotherm for the dye (VII) shows two phase transitions, one at $\sigma = 150$ Å², which is approximately equal to the area of the molecule with the hydrocarbon chains lying on the surface of water, and the other at $\sigma = 50$ Å², which corresponds to the cross-sectional area of two vertically oriented chains. Furthermore, curve *2* (Fig. 2) reveals the collapse of the monolayer at $\sigma = 30$ Å².

A more complex example of polymorphism is presented in Fig. 3. According to Heeseman[32], a rearrangement of the conformation of the molecule of the azo-dye (XI) with increase of surface pressure may be observed. The molecular geometries are illustrated schematically in Fig. 3 in the corresponding part of the isotherm.

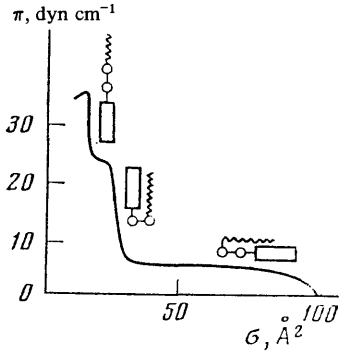

Figure 3. The polymorphism of a surface-active azo-dye (XIII) monolayer. Rectangle—azo-fragment; circles—ester groups; wavy lines—hydrocarbon chains[32].

At a specified temperature it is possible to achieve the required phase state of the monolayer by specifying a particular surface pressure. This can be done automatically by establishing an electrical connection between the motor moving the barrier and the surface pressure measuring device. The latter usually consists of a Wilhelmy balance, which measures the surface tension (the surface pressure is the difference between the surface pressures of the clean water surface and the surface covered by a monolayer of the surfactant).

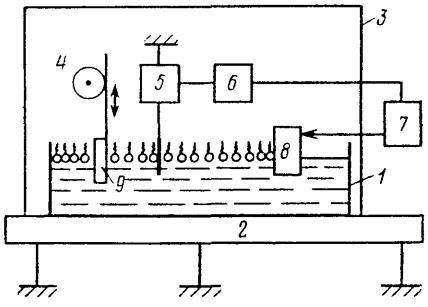

Figure 4. Device for the deposition of Langmuir–Blodgett films: 1) bath; 2) stand on shock absorbers; 3) protecting jacket (transparent); 4) mechanism for the raising and lowering of supports *9*; 5) Wilhelmy electric balance; 6) motor control circuit; 7) motor controlling the mobile barrier *8*.

3. The Langmuir–Blodgett Method

In order to obtain a monolayer, the surfactant is dissolved in a volatile solvent (for example, in chloroform) and is deposited dropwise on the surface of specially purified doubly

distilled water. The solution spreads on the surface and the solvent volatilises. The residual surfactant is compressed by the floating barrier until a continuous film is obtained. The instant of the attainment of the liquid crystal phase state of the monolayer can be detected by means of the Wilhelmy balance; after that one monolayer after another is transferred in succession onto the solid support. This requires the application of a mechanical device, which slowly (at a rate of several mm per minute) lowers or raises the solid support through the surface of the monolayer[17,18]. As the monolayers are deposited consecutively onto the support, the amount of substance on the surface of water naturally diminishes and the floating barrier must be moved automatically to keep the surface pressure constant. The general schematic illustration of the corresponding apparatus is shown in Fig. 4.

Depending on the direction of motion of the support through the monolayer, it is possible to obtain Langmuir films with different orientations. Usually three types of layers are distinguished: two polar layers of types *X* and *Z* and one symmetrical non-polar layer of type *Y* (Fig. 5). In order to deposit the first monolayer of type *X* or *Z*, the support must be hydrophobic or hydrophilic respectively. It is noteworthy that multilayers of type *X* or *Z* cannot always be obtained by the experimenter at will. In many instances, for example, when attempts are made to obtain layers of the *X* type with aliphatic acids, *Y* layers are obtained. This means that the molecules can "capsize" during the deposition of the monolayer. The mechanism of the capsizing process is at present unknown although numerous studies are being devoted to it[1,39]. In general the technique of preparation of Langmuir films still requires much skill from the experimenter, because the quality of the films is influenced by an unduly large number of factors, among which the most important are (a) the purity of water and general cleanliness of the apparatus, (b) the pH of the buffer (i.e. aqueous) solution, (c) the temperature, (d) the preparation of the support, (e) the rate of deposition and variation of the surface pressure, and (f) the absence of mechanical vibrations in the system.

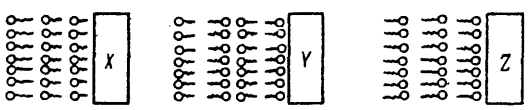

Figure 5. Types of multilayers obtained in accordance with the direction of motion of the plate through the surface of water.

X-Ray diffraction and electron diffraction studies have shown that the Langmuir films frequently have a solid crystal structure[1,40]. This means that, in the course of the deposition of the film, the substance as a rule crystallises although it may be in a vitreous state. However, the orientational order in a liquid crystal phase, including the polar order, persists in the solid crystal phase (with the exception of the case of the capsizing of molecules already mentioned). Thus one obtains ultimately solid multilayer layers with a predetermined composition, thickness, and orientation. This constitutes the uniqueness and value of the Langmuir–Blodgett technique.

In recent years the Langmuir method has been appreciably improved. For example, successful attempts have been made to obtain multilayers of different molecules. Double[41] and also multisector[42] baths, permitting the automatic transfer of supports from one solution to another and conversely, have been developed for this purpose. This increases sharply the productivity of the apparatus and in addition permits the avoidance of the contamination of the specimens.

4. Other Methods of Preparation of Multilayer Structures

Stable monomolecular layers on solid supports can also be obtained by the adsorption of surface-active molecules from the liquid phase[43]. For example, solid films of aliphatic acids or their perfluoro-derivatives are easily adsorbed on glass covered with aluminium or nickel and immersed in a solution of these acids in hexadecane[5]. Monolayers of trichloro-n-octadecylsilane can also be obtained by adsorption. Successive repetition of this procedure can give rise to a multimolecular layer. This method is technically simpler than the Langmuir method but it imposes more stringent requirements on the structure of the corresponding molecules. Monomolecular layers of aliphatic acids on solid supports can be obtained in principle also by the thermal sputtering method[4].

The introduction of surface-active dyes into the solution already containing aliphatic acid molecules can yield mixed monolayers in which the dye molecules are incorporated in the matrix of aliphatic acids. With the aid of another solvent, it is possible "to wash out" the dye molecules selectively from the monolayer leaving behind the so-called skeletised monolayer. Skeletised monolayers possess a "memory" of their initial structure, which can be restored by the readsorption of the same dye or another one with a suitable molecular geometry.

Monolayers and multilayers prepared by the Langmuir technique can be transferred from one solid support to another by the contact method illustrated schematically in Fig. 6[6,7]. For example, a flexible poly(vinyl alcohol) film can be conveniently used as the second support[2]. It is of interest that the information recorded on one support (in the form of, for example, a certain distribution of dimers and monomers) can be "copied" onto another plate[7].

III. ELECTRICAL PROPERTIES OF LANGMUIR FILMS

1. Dielectric Characteristics

Fairly numerous studies have been made for the dielectric properties of multimolecular layers in view of their wide scale employment as calibrated dielectric plates in transistors based on metal–dielectric semiconductor structures[11]. Stringent requirements must be met by the dielectric plates as regards the reproducibility of their capacitance, stability, and resistance to electrical breakdown.

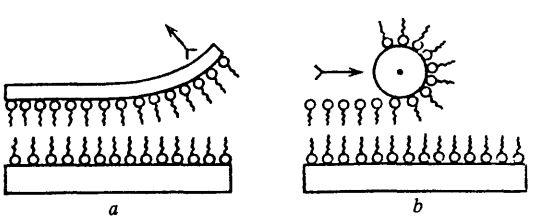

Figure 6. Illustration of the principle of the separation (*a*) and contact deposition (*b*) of a monolayer[7].

The dielectric properties of Langmuir films are usually investigated in sandwich structures with a lower aluminium electrode. The aluminium is deposited by vacuum sputtering onto a glass support, the multimolecular layers are introduced in succession, and then the upper metallic electrode is deposited by vacuum sputtering. The lower electrode can also consist of a sputtered tin film[44] or transparent semiconducting layers of tin dioxide[23], as well as other semiconducting materials[11]. The application of other metals (other than tin and aluminium) frequently leads to non-reproducible results. The Langmuir films exhibit poor adhesion to noble metals.

Carefully prepared (defect-free) sandwich structures usually withstand the application of electric fields up to 5×10^6 V cm^{-1}, which is characteristic of the best of the known dielectrics[45,46]. The reciprocal of the capacitance C^{-1} of the sandwich structures varies linearly with the overall thickness of the multilayer regardless of whether the number of monolayers (Fig.7*a*) or the thickness of each monolayer (Fig.7*b*) are varied.

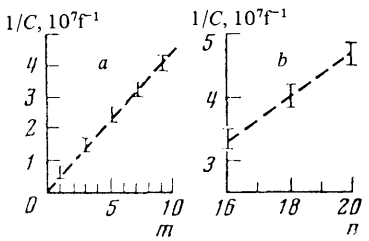

Figure 7. *a*) Dependence of the capacitance of a multilayer palmitic acid structure (number of carbon atoms $n = 16$) on the number of monolayers[8]; *b*) dependence of the capacitance of a seven-layer structure on the length of the aliphatic acid molecule with $n = 16-20$ (frequency 10^{-2} Hz; 300 K)[8].

The absolute dielectric constants of aliphatic acids at low frequencies are $\varepsilon = 2.5-2.9$ at 77–295 K.[43] Dielectric constants close to the above values of ε are expected also for dyes with hydrocarbon tails. For perfluoro-derivatives of aliphatic acids, the dielectric constants are appreciably higher ($\varepsilon = 2.9-3.5$ at $T = 77-295$ K)[43].

As frequency is varied, dispersion of ε is observed, which can be attributed to relaxation processes of different types. At frequencies below 1 Hz the slow movements of the polar COOH groups are apparently responsible for the mechanism of the relaxation of ε for aliphatic acids, while at frequencies in excess of 1 Hz the processes associated with jump movements of electrons from one monolayer to another are responsible for the relaxation[47,48]. The presence of residual water in the multilayer leads to an additional mechanism of dielectric losses[49].

2. Electrical Conductivity

At the present time there are no firmly established ideas about the mechanisms of the flow of electric current through metal–dielectric–metal structures, where the Langmuir film plays the role of the dielectric. At a specified potential at the electrodes, the current depends markedly on the thickness of the multilayer, the material of the electrodes, the temperature, the surrounding atmosphere, and naturally the material of the multilayer itself. In the latter case the presence or absence in the multilayer of molecules with a long chain of conjugated bonds plays a significant role.

The case of extremely thin films, with a thickness equivalent to one or two monolayers (which corresponds to 25–50 Å for aliphatic acids), is apparently simpler. The majority of investigators believe that the dominant mechanism of the conduction of current at temperatures in the range from room temperature downwards is tunnelling of electrons through the monolayer[45,46,50–52]. Fig.8 illustrates instances of the tunnel electron transition from one electrode to another through a potential barrier at a potential applied to the electrodes smaller and greater than the height of the barrier[52]. A characteristic feature of the tunnel mechanism is the absence of a dependence of the current on temperature and the exponential decrease of the current with increase of the thickness of the monolayer; the latter can be varied by passing from the lower homologues of aliphatic acids ($n = 14$) to higher homologues ($n = 20$). The thickness of the monolayer then changes from 21 to 28 Å and the effective conductivity diminishes approximately by 5 orders of magnitude[50]. The tunnel current is influenced significantly also by the presence of an oxide film on the metal surface; allowance for this influence is essential in the calculation of the characteristics of the energy barrier for the tunnelling electrons[46].

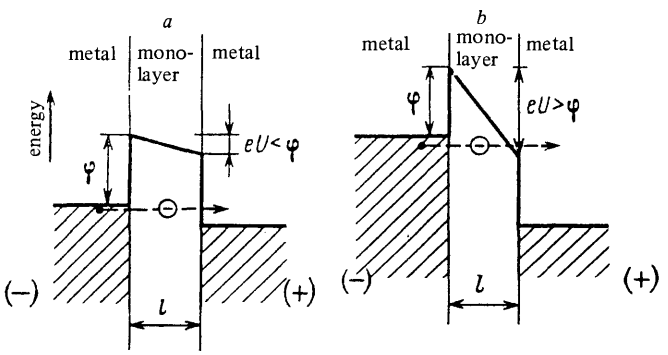

Figure 8. The tunnelling of an electron through a potential barrier at electrode potentials $U < \phi/e$ (*a*) and $U > \phi/e$ (*b*); ϕ = height of barrier; l = thickness of monolayer.

The flow of current through two monolayers in succession is apparently determined also by the tunnel mechanism at least at low temperatures[29]. In the presence of a larger number of monolayers, other processes begin to play an appreciable role. The most probable of these is the jump electron transfer mechanism. Its essential feature is as follows. It is believed that at the boundaries of the monolayers there are large numbers of surface energy states. The electron apparently moves across the multilayer from the negative electrode to the positive electrode not via a single tunnel transition (which would be already extremely unlikely when the number of monolayers exceeds three) but in separate small jumps (a jump constitutes tunnelling accompanied by thermal excitation) through each monolayer in succession (Fig.9). In this model the current decreases exponentially with increase of the thickness of each monolayer separately but with increase in the number of identical monolayers it diminishes merely in accordance with a linear law. This conclusion is in full agreement with experiment[8,53]. The picture illustrated in Fig.9 becomes appreciably more complex when

account is taken of the curvature of the barrier due to the charges bound at the boundaries between the monolayers; this effect has been taken into account[54].

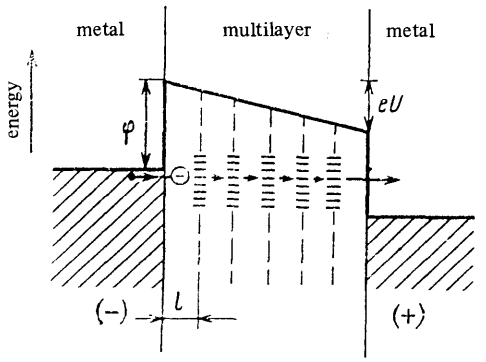

Figure 9. The jump mechanism of the electrical conduction in multilayers (l = thickness of monolayer).

Together with the jump conductivity, injected carriers associated with the emission of electrons from the electrode into the bulk of the multilayer via a contact potential barrier may make an appreciable contribution to the current[52]. This mechanism (the Schottky emission) can apparently explain the marked influence of the material of the terminals on the conductivity of the metal–Langmuir film–metal system. Nor can one rule out the possibility of the ionisation of the impurity molecules in the bulk of the multilayer by the electric field (the Poole–Frenkel mechanism)[52]. The latter effect may play a dominant role in relatively thick multilayers (tens of monolayers).

In the multilayers formed by molecules of substituted anthracene [see, for example, compound (VIII)], a sharp anisotropy of the electrical conductivity is observed. For the same electric field strength, the conductivity in the plane of the multilayer can exceed by 8 orders of magnitude the conductivity measured at right angles. The anisotropy has been explained[55] by a special type of packing of the molecules of compound (VIII) in the monolayer (like a deck of cards), which facilitates the transfer of electrons from molecule to molecule in the plane of the monolayer. However, one should also take into account the possibility of conduction via interlayer surface states, which has also been noted[8]. The passage of the current along the monolayer in the latter case does not require an activated electron jump through relatively wide barriers and the current should be significantly greater for the field directed along the plane of the monolayers.

The introduction of molecules with an extensive chain of conjugated bonds as impurities into the aliphatic acid monolayer increases the tunnel current for the monolayer. Such an experiment has been carried out[56] using carotenoic acid (XIII). Figuratively speaking, the molecules of this acid play the role of thin "conductors" which partially "short circuit" the aliphatic acid monolayer, because they have a free electronic level located below the energy level of an electron *in vacuo*, which facilitates electron tunnelling. In fact the molecules with conjugated bonds lower the height of the potential barrier for the tunnel transition. The molecules of azo-dyes (XII), whose conjugated chain is oriented at right angles to the plane of the monolayer, also influence the conductivity in a similar manner[31]. As stated above, adsorbed monolayers[43,57] can be "skeletised" by desorbing the dye molecules introduced into the monolayer beforehand. The resulting holes are responsible for the marked (approximately by an order of magnitude) increase of the tunnel current through the monolayer[51], although there is no short circuiting as a consequence of the holes being "overgrown" by a layer of the oxidised material of the electrode.

3. Inelastic Tunnelling and Tunnel Spectra

Direct proof of the tunnel mechanism for the flow of current through individual Langmuir layers is provided by the observation of the tunnel spectra of impurity states. Fig.10 illustrates elastic (1) and inelastic (2) electron tunnelling through a dielectric layer. In the latter case the tunnelling electron loses its energy on passing through the film, liberating a molecule of the main substance of the dielectric or impurity. Usually one is dealing with vibrational molecular excitations[58] and $W \cong 0.1$ eV, since the energies of the tunnelling electrons (in eV) do not exceed numerically the potentials (in volts) applied to the electrodes. However, electronic transitions with energies $W \cong 1-2$ eV can also be excited[59]; the loss of energy by the electron under these conditions gives rise to a small (~1%) anomaly on the voltage–current characteristic at an electrode potential $U = W/e$ (Fig.11*a*). If the $I-U$ curve is differentiated twice with the aid of an electronic circuit, the anomaly is revealed extremely clearly (Fig.11*b*). In the presence of a large number of varied energy states within the monolayer, the d^2I/dU^2 curve represents an elaborate spectrum of bands.

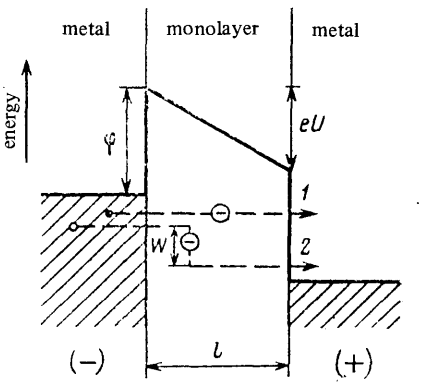

Figure 10. The elastic (curve *1*) and non-elastic (curve *2*) tunnelling of an electron through a monolayer.

The tunnel spectra can reflect the electronic structure not only of the dielectric but also the metal. In particular, the spectra reveal the energy gap characteristic of a superconductor, provided that even only one of the electrodes is a superconductor (the experiment was carried out below the critical temperature). Such observations have been made using the barium stearate monolayer as the dielectric layer[60]. The vibrational spectra of the stearic acid monolayer, obtained recently by tunnel spectroscopy, agree well with infrared and Raman spectra[61]. One cannot rule out the possibility that the method of tunnel spectroscopy will prove

suitable also for the investigation of the electronic spectra of molecules with conjugated bonds forming Langmuir or adsorption monolayers or behaving as impurities in the latter, since at low temperatures such monolayers do not undergo electrical breakdown at potentials up to 4 V,[51,60] while electronic spectra correspond to energies ≥ 1 eV.

A fairly detailed review of the electrical properties of Langmuir layers, including a discussion of the mechanisms of their electrical conduction and breakdown, has been published[62].

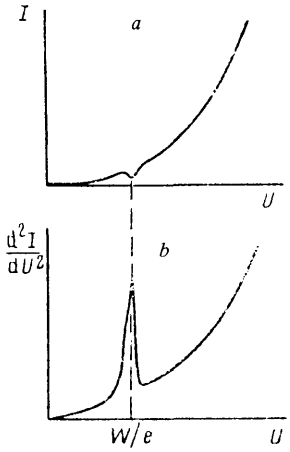

Figure 11. The determination of the characteristics of the tunnel "spectrum" with the aid of the differentiation of the voltage–current characteristic.

4. Asymmetric Structures and a Molecular Rectifier

If the electrodes with a multilayer structure are made from different metals, then in the case of symmetrical multilayers of the *Y* type (see Fig.5), a potential difference appears in the specimen as a consequence of different electronic work functions of the metals. Such a potential difference can arise even in the presence of identical (for example, aluminium) electrodes due to the different properties of the outside film on the lower and upper electrodes[63]. The potential difference due to the difference between the electronic work functions usually amounts to tenths of a volt. If approximately 200 such specimens are connected in series, then a potential of 50 V can be drawn from a battery obtained in this way[60].

It has been claimed[54] that the difference between the electron work functions leads to the electrical breakdown of sandwich structures even in the absence of an external field, provided that they consist of a single aliphatic monolayer between aluminium and barium electrodes.

Another type of asymmetry can be created by the successive deposition of monolayers of different compositions; the material of the electrodes can then be identical. For example, an unusual form of the tunnel voltage–current characteristic, corresponding to the passage of current through a three-layer structure in only one direction, has been predicted theoretically[64]. It is significant that in this case one of the monolayers must be formed by surface-active donor molecules and the other by acceptor molecules, so that the multilayer is in fact an analogue of a charge-transfer complex in which the donor and acceptor are separated by a narrow neutral bridge [the molecules of the autocomplexes (IX) are good models]. The electron current flows along the acceptor–neutral bridge–donor chain from one electrode to the other with non-elastic tunnelling in the neutral bridge. The reverse current is much smaller and the authors[64] thus predict a current rectifying effect.

So far as we are aware, there are no published experimental data concerning the observations of the predicted effect apparently owing to the difficulty of observing the tunnel current in a three-layer, i.e. relatively thick, structure. However, the rectifying effect has been noted for a photocurrent in asymmetric donor-acceptor multilayers[54]. The attempts to create specifically rectifying and subsequently also transistor multistructures may serve as classical examples of molecular architecture.

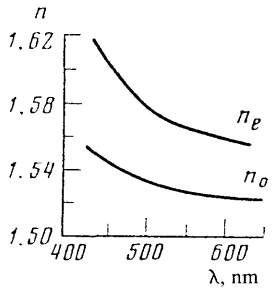

Figure 12. The dispersion curves for the refractive indices of cadmium arachidate[65].

IV. THE OPTICAL PROPERTIES OF MONOLAYERS AND MULTILAYERS

1. Reflective Indices

Langmuir films are specially interesting from the standpoint of the creation of multilayer structures for the investigation of various interference phenomena, because the thickness of a single monolayer is rigorously fixed (it amounts to 24.5 Å for barium stearate, for example[1]). Numerous studies have been made on the optical properties of multimolecular layers formed by aliphatic acid salts[1,3]. The ellipsometric method, measurements of optical transmission and reflection, interferometry and, recently, the integral-optical technique have been widely used for this purpose[10]. The optical anisotropy of multilayers has been reliably established: the refractive index for light with its polarisation vector in the plane of the multilayer (n_o) is always less than the refractive index for polarisation whose direction coincides with the normal to the film (n_e). The optical anisotropy for cadmium arachidate for example, is fairly considerable ($\Delta n = n_e - n_o \cong 0.04$). Virtually no systematic studies of the frequency dispersion of n_e and n_o have been made and reliable data are available only for cadmium arachidate multilayers (Fig.12)[65].

There exist two possibilities of adjusting n_e and n_o to prespecified values at a particular wavelength. Firstly, by varying the composition of the buffer solution, it is possible

to obtain films of salts of different metals (Cd, Ba, Mn) alternatively films made up of aliphatic acid molecules with different lengths of the hydrocarbon chain can be used. The presence of atoms of heavier metals then increases both refractive indices n_o and n_e, while an increased hydrocarbon chain length entails mainly an increase of n_e. The pH of the buffer solution also plays a significant role, determining the concentration of the metal ions in the Langmuir film[10]. It is possible to introduce various dyes into multilayers of aliphatic acids and their salts, which also alters the refractive indices. The second method consists in the skeletisation of Langmuir films. The formation of "holes" on a molecular scale lowers the values of n_e and n_o in proportion to the area occupied by these "holes". Both methods are promising for the specific construction of interference coatings, integrated optical elements, etc.

2. The Waveguide Properties of the Films

It is known that the light beam propagated in any medium with a refractive index n_1 undergoes total internal reflection at the boundary with another optically less dense medium ($n_2 < n_1$) if the angle of incidence exceeds a critical value. A light beam introduced into a thin film at a certain angle is therefore propagated along the film as in a waveguide, undergoing repeated internal reflections at the boundaries of the film with air or another medium satisfying the condition $n_2 < n_1$. This phenomenon makes it possible to achieve extremely compact (film) optical elements used in modern integrated optics[66].

The possibility of the specific variation of the refractive indices and the clear-cut determination of their thickness make Langmuir films extremely convenient materials for such purposes. The main difficulty consists in obtaining defect-free films of high optical quality, since otherwise the light beam propagated along the film is to a large extent scattered by defects, losing its intensity. The best results have been obtained currently on cadmium stearate films[10,21]. Such a film (with the refractive indices $n_o = 1.53$ and $n_e = 1.56$ at a wavelength $\lambda = 633$ nm) is deposited on a quartz support ($n_2 = 1.4571$) and is covered on top by a liquid layer of isostearic acid ($n_3 = 1.4573$). Light is introduced into the film with the aid of a prismatic device and is propagated along it with a decay of 1 dB per cm of the length of the film (i.e. is attenuated by a factor of 10 over a distance of 10 cm).

The introduction of additional monolayers absorbing light in a particular spectral range as a result of the presence of surface-active dyes makes it possible to achieve the isolation of specific spatial[67] or spectroscopic[68] components of the radiation.

Langmuir films are also used as external plates of waveguide films, made, for example of glass or poly(methyl methacrylate)[65]. In this case the geometrical properties of the beam in the waveguide (modal composition) contain information about the refractive indices of Langmuir films consisting of a small number of monolayers. The method based on the measurement of the decay of surface electromagnetic waves propagated along the boundary between dielectric and metal is even more sensitive to the optical characteristic of individual monolayers. Such waves can be excited by visible[68] or infrared[69–71] radiation.

3. Molecules "in front of a Mirror"

Molecular architecture leads to an interesting possibility of investigating a wide variety of optical interference effects. In fact we can achieve the alternation of light emitting, reflecting, and absorbing layers in accordance with a predetermined plan with a rigorous specification of their thickness in each case. If the thicknesses of the corresponding layers are comparable to the wavelength of the light, it is possible to observe a whole range of new phenomena determined by the interference and diffraction of light[3].

Suppose, for example, that a light beam is incident on a metallic mirror surface (Fig.13). The reflected wave interferes with the incident wave, giving rise to a standing wave whose nodes and antinodes are located at fixed points in space. We now imagine that a molecule of a fluorescent dye is placed at different distances from the mirror surface. Then the molecules located at the antinodes of the standing wave will fluoresce strongly, while those which are at the nodes will not fluoresce at all. Such an experiment makes it possible to discover the location of the nodes of the standing wave, which depends on the phase of the beam reflected from the mirror. Classical experiments of this kind were performed as early as the past century by Drude and Nernst using photographic emulsions as indicators of the intensity (i.e. the square of the amplitude) of the standing wave. Using Langmuir films, such experiments can be carried out with a much higher degree of accuracy.

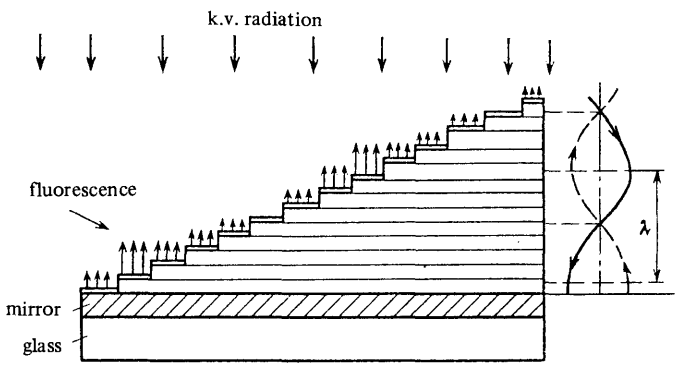

Figure 13. The Kuhn "ladder". Each "step" consists of 20 stearic acid monolayers. One of the monolayers of the fluorescent dye covers all the "steps" at once. The antinodes of the standing light wave (see the scheme on the right) are visualised with the aid of fluorescence; the fluorescence intensity is represented conventionally by the length of the vertical arrows[2].

Fig.13 illustrates the scheme of Kuhn's experiment[2]. Monolayers, for example of cadmium arachidate, were deposited on a silver mirror on a glass support in such a way that each successive monolayer occupied a smaller area than the preceding one; this results in the formation of a "ladder" of monolayers. A single monolayer of a surface-active fluorescent dye [for example, compound (VI)] is then deposited on the entire multistructure. The illumination of the multilayer from above with ultraviolet light at $\lambda = 366$ nm leads to the appearance of a very attractive striped fluorescence pattern of the dye on those sections of the "ladder" which correspond to the antinodes of the standing wave[72].

The light emitted by the fluorescent molecules located at a certain distance from the mirror can also be involved in the interference. The character of the interference then

depends on the nature of the emitter. An electric dipole, a magnetic dipole, an electric quadrupole, etc. are known to be capable of emitting. Each fluorescence band of the dye is associated with its intrinsic emitter so that there is a possibility of the transformation of the complex fluorescence spectrum of the dye as a result of interference effects. An example of such change in the spectrum is illustrated in Fig. 14[3]. The dibenzoyloctane complex of europium (XIV) forms a monolayer separated from a gold mirror by a definite number of cadmium arachidate monolayers. The entire multistructure is immersed in an immersion liquid in order to avoid reflections from its surface. The complex fluoresces on excitation with ultraviolet light. Fig. 14 shows that simple reflection from the mirror alters the form of the spectrum. This implies that the weak fluorescence band with a maximum at 592 nm cannot, in contrast to the band at 615 nm, be attributed to an electric dipole emitter[3]. The proximity of the molecular emitter to the metallic mirror leads to yet another remarkable effect: the fluorescence decay time begins to depend on the distance from the mirror. As a consequence of the interference of the waves, this dependence is oscillatory; when the emitter is in the immediate vicinity of the mirror ($0 < d < 500$ Å), the decay time tends to zero asymptotically.

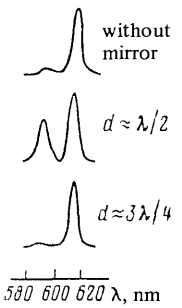

Figure 14. The fluorescence spectrum of a europium complex as a function of the distance d of the molecular emitters from the gold mirror.

By alternating the Langmuir monolayers with metallic mirrors sputtered *in vacuo*, it is possible to create a superlattice having two periods, one of which is equal to the thickness of a single monolayer and the other is equal to an arbitrarily specified distance between the metallic mirrors. The spectroscopic properties of such superlattices agree with theoretical calculations[22].

Numerous other examples of interference effects observed in the optical transmission and interaction of light for different positions of the absorbing or luminescent monolayer in a multimolecular structure have been quoted in reviews[2,3]. The method of specific construction of such multilayers makes it possible to elucidate the nature of the electronic oscillators in molecules.

4. The Dichroism of Dyes

The anisotropy of the refractive indices of Langmuir films was mentioned above. We shall consider the question of the orientation of the chromophoric chains of dye molecules which either form these films or have been introduced into monolayers of aliphatic acids as admixtures. In the usual method of the transfer of monolayers from the surface of water onto a glass or metallised surface, the monolayer or the multistructure on a solid surface is isotropic relative to the rotation of the specimen around the normal z to the layer; the z axis is the only distinct axis. When dyes are introduced into such a multilayer, light is absorbed regardless of the direction of its polarisation if the beam is incident rigorously at right angles to the surface of the multilayer.

On the other hand, chromophoric chains of the dye can be distributed in different ways, being oriented on average either at right angles to the support or in the plane of the support. The situation which is actually realised may be elucidated by studying the anisotropy of the absorption of light for layers placed at a certain angle relative to the incident beam (examples are presented in Fig. 15). In the molecule of the azo-dye (XV) the alkoxy-"tail" is attached to the azo-system in the *para*-position and the entire molecule is oriented at right angles to the plane of the monolayer. Correspondingly light polarised in the plane of incidence (with an electric vector e_1—see the insert Fig. 15) is absorbed more strongly than the light with the vector e_2 in the perpendicular plane, since in the former case there is a component parallel to the conjugation chain of the molecule (Fig. 15*a*). The broad absorption band with $\lambda_{max} \cong 500$ nm in Fig. 15*b* is associated with the polymethine dye (XVI) whose chromophores are located in the plane of the support. In this case the light with the vector e_2, also located in the plane of the support, is absorbed more intensely. The additionally introduced azo-dye (XII), absorbing in the region of $\lambda \cong 415$ nm, has a dichroism with a different sign (the absorption shoulder in the short-wavelength region is weaker), which corresponds to the perpendicular orientation of the chromophore, as in the case illustrated in Fig. 15*a*. The perpendicular orientation of the chromophores has been observed also for other dyes without alkyl tails introduced as admixtures into Langmuir aliphatic acid multilayers[72]. The same orientation of the chromophores of the azo-dyes (XII) in a monomolecular layer on the surface of water (i.e. before its transfer to the support) has also been established[32].

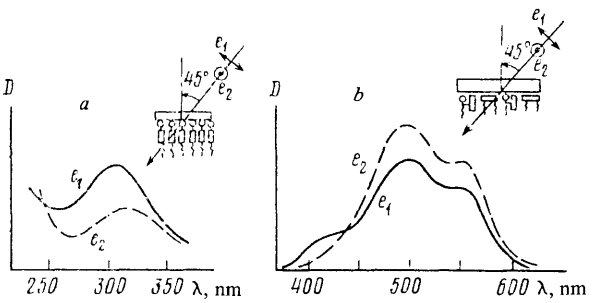

Figure 15. The dichroism of dyes with different orientations of chromophores: a) perpendicular orientation for the azo-dye (XV) with R = SO_2NH_2;[73] *b*) spectra of mixed monolayers of the azo-dyes (XII) and the polymethine dye (XVI) with the chromophore oriented parallel to the support[31]. The inserts illustrate the geometry of the experiment; the rectangles represent molecular chromophores.

A remarkable example of dichroism of another type has been demonstrated in a study[33] where an anisotropic surface (the cleavage plane of crystalline gypsum) was used as the support for the deposition of monolayers. In this case the molecules of the surface-active dyes (VI) and (XVII) are distributed with the chromophores not located simply in the plane of the support but along a specific direction on this plane which coincides with the orientation of one of the crystal axes of gypsum. The dichroism of such monolayers and multilayers can be easily observed also when the beam is incident at right angles to the specimen (Fig.16). The light polarised parallel to the *a* axis of the gypsum crystal is absorbed much more intensely, which indicates the orientation of the chromophore of the dye (XVII) precisely along the *a* axis. The above study[33] thus leads to the possibility of molecular architectural design in all three dimensions.

Theoretical studies of the optical properties of absorbing multilayers require allowance for the anisotropy of the refraction and absorption of light; for monoaxial structures (with an isolated *z* axis), such studies have been carried out[74,75]. For three-dimensional structures, it is necessary to employ the mathematical apparatus of the theory of crystal optics.

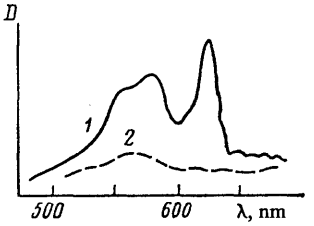

Figure 16. The dichroism of the dye (XIV) on the cleavage plane of crystalline gypsum; the polarisation vector is parallel (curve *1*) and perpendicular (curve *2*) to the *a* axis[33].

5. Spectroscopic Characteristics

Depending on the concentration of the dye in the monolayer of the surface-active substance, the type of packing of the chromophores in the monolayer, and the presence or absence of an influence of the neighbouring monolayers, the absorption and fluorescence spectra of the dye undergo significant changes, which are due primarily to the formation of different associated species. Fig.17 illustrates the transformation of the absorption spectrum of the dye (XVIII) with increase of its molar concentration in the monolayer of cadmium arachidate from 1:100 to 1:1, The increase of the intensity of the absorption band of the dimers (460 nm), associated with the suppression of the absorption band of the monomer, is clearly seen.

A further increase in the concentration of the dye (for example, its employment in a pure form without admixture of aliphatic acids) leads to an even more notable aggregation effect. Fig.16, for example, shows clearly a narrow absorption peak (λ = 625 nm), usually attributed to the parallel packing of the chromophores of the "brickwork" type (J-aggregate). The vibrations of the electronic oscillators of individual molecules take place in phase and are added together ensuring an intense absorption of light in a narrow spectral range.

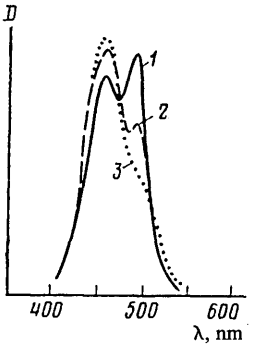

Figure 17. The equilibrium between the monomers (λ_{max} = 490 nm) and dimers (λ_{max} = 460 nm) of the dye (XVIII) in a monolayer of cadmium arachidate for different molar ratios of the two components: 1) 1:100; 2) 1:10; 3) 1:1.[2]

The spectroscopic properties of a dye in a monolayer are influenced by the molecule of the same or another dye in a neighbouring monolayer. The extent of this influence is determined by the distance between the corresponding chromophores. For example, if one monolayer contains the dye (VII) and another the dye (XVIII), mentioned above, and their chromophores are separated by alkyl chains, then the overall absorption spectrum of the two dyes constitutes a simple superposition of their individual spectra. On the other hand, if the chromophores of these two dyes are in contact, the overall spectrum is appreciably modified, i.e. exciton effects arise[2]. In a number of instances the fluorescence spectra of such systems with chromophores in contact show broad long-wavelength bands due to the formation of excited dimers (excimers). The effects of the interaction of the molecules (particularly those of chlorophyll) in neighbouring monolayers are easily observed also in the infrared absorption spectra[76].

An interesting example of the dependence of the absorption spectrum of Langmuir multilayers on the polarisation of light is presented in Fig.15*a*. For light with the polarisation e_1, the absorption maximum is displaced towards shorter wavelengths compared with the maximum for the polarisation e_2. This is caused, on one hand, by the interaction of static molecular dipoles with one another and, on the other hand, by the deviations from the ideal orientation of the molecules of the azo-dye in the multilayer. Then the light with the polarisation e_1 "selects" the molecules oriented on average along the normal to the layer and that with the polarisation e_2 "selects" molecules which have deviated from the ideal orientation. If the static dipole moments of the ground (μ_g) and excited (μ_e) states of the dye molecule are different [for the azo-dye (XV) their difference is $\Delta\mu = \mu_e - \mu_g \cong 3$ D[77]], then the spectral shift is proportional to the product $\mu_g\Delta\mu$ and depends on the angular scatter of the molecular orientations[73].

6. The Transmission of Excitation Energy and the "Photon Funnel"

One of the most impressive achievements of molecular architectural design has been the elucidation of the mechanisms for the transmission of excitation energy from one molecule (of a sensitiser or energy donor) to another (energy acceptor). This question has a long history and is extremely important in practice, because the development of methods for the sensitisation of photographic and other photosensitive materials depends on its solution.

The simplest mechanism for the transfer of energy from one molecule, excited by a light quantum, to another, unexcited molecule involves radiative transfer in which the acceptor molecule simply absorbs the light emitted by the luminescent donor molecule. In thin Langmuir films this mechanism hardly operates because of the weak absorption of light by one or several dye monolayers. The second possible mechanism involves Förster energy transfer; this mechanism operates when the acceptor molecule is at a short distance from the donor molecule. It is known that in the nearest region, i.e. at distances $R \ll \lambda$, the electric field of the emitting dipole decreases in proportion to R^{-3}. In this region the electric wave has not yet been formed, although the energy of the alternating electric field can be transmitted to a neighbouring oscillator. Such energy transfer has come to be regarded as non-radiative, although the probability of this process is proportional to the degree of overlap of the luminescence band of the donor and the absorption band of the acceptor. The third, also non-radiative, mechanism of energy transfer with the aid of exciton excitations is possible only for close packing of the donor and acceptor molecules.

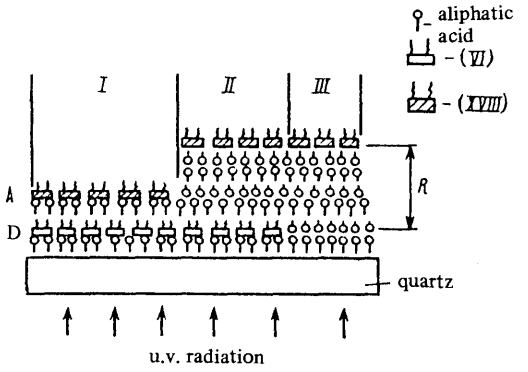

Figure 18. The scheme of Kuhn's experiment[2] designed to elucidate the mechanism of the transmission of excitation energy from the molecules of the sensitiser D to those of the acceptor A.

Fig.18 illustrates the scheme of Kuhn's experiment[2] designed to elucidate the mechanism of energy transfer between monolayers. A monolayer of sensitiser molecules D is deposited on a transparent quartz support (the insulating monolayer of aliphatic acids plays an auxiliary role). The oxacyanine dye (VI) mixed with cadmium arachidate was used for the molecules D. The monolayer of acceptor molecules A [the dye (XVIII) mixed with cadmium arachidate] is separated from the sensitiser layer by several cadmium arachidate monolayers. The number of these monolayers can be varied at will. Illumination of the sensitiser through the support by ultraviolet light leads to the following picture. On the right-hand side (III), where there is no sensitiser, the field of observation is dark, since the acceptors do not absorb the ultraviolet light. In region II, where the acceptor molecules are at a long distance from the monolayer of D molecules, the blue fluorescence from sensitiser molecules absorbing ultraviolet light, is observed. The molecules of the acceptor A absorb little of the fluorescence of the donor D, which is itself weak, and this hardly alters the spectral composition of the latter. In region I the acceptor molecules fluoresce intensely in the yellow part of the spectrum. They clearly receive energy from the molecules of the donor D by a non-radiative process. By altering the number of monolayers separating the D and A monolayers and by measuring the fluorescence intensity of the acceptor A, it is possible to test the theory developed for the Förster mechanism. Fig.19 illustrates the corresponding curve (curve *1*)[3]. Evidently the resonance non-radiative energy transfer is effective over distances of ~ 50–100 Å and less.

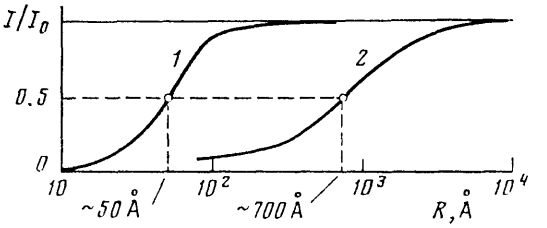

Figure 19. Dependence of the fluorescence intensity of the acceptor molecules on the distance R between the acceptor monolayer and the sensitiser monolayer (in Fig.18) (curve *1*) and between the acceptor molecules within a single monolayer (in Fig.20) (curve *2*).

Extensive studies on the mechanism of the excitation energy transfer through dielectric monolayers, carried out by Kuhn et al.[2] and Drexhage[3], confirm the validity of the Förster mechanism not only for dielectric dipolar oscillators but also for emitters of the type of a magnetic dipole and an electric quadrupole. The non-radiative energy transfer can occur from both singlet and triplet states of the sensitiser[78].

An absolutely different situation obtains when the acceptor molecule, with a structure similar to that of the donor molecule, is introduced into a continuous monolayer formed by the donor molecules. As already stated, the close packed chromophores (in the given instance of the donor molecules) form ordered assemblies which collectively absorb and emit light within narrow spectral ranges (*J*-aggregates). The acceptor molecules introduced into the same monolayer effectively absorb the energy of the *J*-aggregates, transforming it into the emission of their intrinsic luminescence. Fig.20 illustrates the fluorescence spectrum of a mixed monolayer in which there is only one acceptor molecule (trimethine and pentamethine surface-active cyanine dyes[79]) for each 250 sensitiser molecules. Despite the sharp difference between the donor and acceptor concentrations, the fluorescence intensity from the long-wavelength band (acceptor band) is almost the same, while at liquid nitrogen temperature it is

actually higher than from the short-wavelength band of the donor. This demonstrates that the energy of the light absorbed by a large number of donor molecules is concentrated at a single acceptor molecule, i.e. the principle of the "photon funnel" is realised.

Exactly the same experiment has been carried out recently with the dyes (VI) and (VII) as the donor and acceptor respectively[5]; the concentration of the molecules of the dye (VII) in the monolayer of the dye (VI) was varied. The fluorescence intensity of the acceptor molecules was plotted against the average distances between them (see Fig.20 and curve *2* in Fig.19). Fig.19 shows that in this case the characteristic distance from which the acceptor collects energy is ~ 700 Å and the number of donor molecules forming the "photon funnel" is 5×10^4. This figure agreed with the exciton mechanism of energy transfer: during its lifetime (~ 10^{-9} s), the exciton executes ~ 10^4 jumps from molecule to molecule and gives up its energy to the acceptor molecule if the latter is encountered in its path[6].

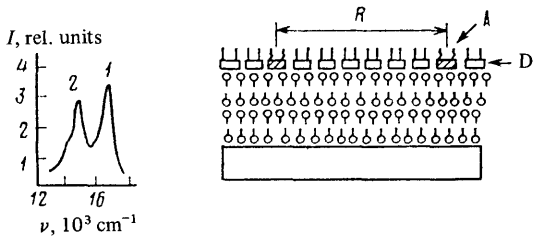

Figure 20. The fluorescence spectrum of a mixed monolayer of donor and acceptor molecules: 1) spectral maximum of the donor; 2) spectral maximum of the acceptor.

Experiments in recent years have shown that the principle of the "photon funnel" discussed above plays a key role in the mechanism of photosynthesis, where one trapping molecule collects the energy from ~ 300 chlorophyll molecules[6].

V. EFFECTS DUE TO "SPONTANEOUS" POLARISATION

1. "Spontaneous" Polarisation#

A completely new trend in molecular architectural design is the creation of asymmetric structures without an inversion centre. A whole series of new properties appear in such structures. We have already spoken of the idea of creating a molecular rectifier; in the next section we shall discuss vectorial electron transfer under the influence of light and now we shall consider the question of the presence of a permanent dipole moment per unit volume of a monolayer or multilayer, i.e. "spontaneous" polarisation *P*.

Turning to Fig.5, we may note that, in the presence of a longitudinal molecular dipole moment μ in the surface-active molecules, layers of type *X* and *Z* should have an overall dipole moment $P = \mu n$, where $n = N_A \rho / M$ is the number of molecules per unit volume (ρ is the density and *M* the molecular weight). In layers of type *Y*, where the overall dipole moments of the monolayers are compensated, $P = 0$. The numerical value of the polarisation for layers of types *X* and *Z* is $P \cong 10^6$ C cm^{-2} for $\mu = 6$ D and $M = 400$ g mol^{-1}.[23] In the experimental determination of the "spontaneous" polarisation, it is necessary to overcome at least two difficulties. Firstly, it is necessary to obtain layers of type *X* or *Z*, which cannot be always achieved; in particular, the molecules of aliphatic acids tend to be arranged in layers of type *Y* whatever the method of deposition. Secondly, the "spontaneous" polarisation, equal to the surface charge density on the multilayer, is usually compensated by the free charges due to the conductivity of the specimen or other leakages. It is therefore possible to measure experimentally not the absolute value of *P* but the changes in it, for example, when the temperature (pyro-effect) or pressure (piezo-effect) is altered. The value of *P* can also be calculated in terms of the molecular dipole, provided that there is an independent method of checking the state of orientation of these dipoles (for example, on the basis of the linear Stark effect—see below). The estimate of *P* quoted above has been obtained[23] by the last method for the azo-compound (XV).

2. The Pyro- and Piezo-Effects

The pyroelectric effect was first observed on *X*- and *Z*-type multilayers of the azo-compounds (XV) and substituted benzenes (XIX)[80]. In order to observe the effect, multilayers consisting of 10–100 monolayers were illuminated by pulses from a laser at a wavelength $\lambda = 1.06$ μm. Light was absorbed in a semi-transparent aluminium electrode and heated the multilayer. A potential pulse then arose on the electrodes, characterised by the pyro-coefficient $\gamma = dP/dT$. The sign of this pulse was the opposite of that for multilayers of the *X* and *Z* types; on layers of the *Y* type, the pyrosignal was not observed. This fact and also the kinetics of the increase and fall of the signal made it possible to establish its pyroelectric nature. The calculated value of γ for a 100-layer structure of the *X* type [compound (XV)] with $R = SO_2NH_2$ is 3×10^{-10} C cm^{-2} K^{-1}, which is lower approximately by an order of magnitude than the pyro-coefficient of film pyroelectrics[114].

The piezoelectric effect can be observed by a very clear procedure using the repeated reflections of a sound wave in a glass support on which a multilayer of the *X* or *Z* type has been deposited[23]. This wave can be obtained by the optoacoustic method, provided that the glass (for example, an SZS-21 light filter) absorbs the pulse of the laser emission at a wavelength $\lambda = 1.06$ μm. The resulting acoustic wave and its frequent repetitions (echo) excite in the multilayer the piezoeffect pulses, which can be observed on an oscilloscope screen using sputtered metallic electrodes, one of which has been deposited on glass (under the layer) and the other on the multilayer. The signs of the piezo-effect are different for layers of the *X* and *Z* types; the effect has not been observed on layers of the *Y* type.

3. The Linear Stark Effect

The observation of the spectral shift (linear in terms of the field) of the electronic absorption band in an external electric field constitutes a powerful quantitative method for the investigation of the polar structures of Langmuir films.

More precisely, we are dealing with macroscopic polarisation due to the process involved in the preparation of the multilayers.

Suppose that a molecule has a dipole moment μ_e in the excited state which does not coincide with the dipole moment in the ground state μ_g, i.e. $\Delta\mu = \mu_e - \mu_g \neq 0$. The ground and excited energy levels in an electric field **E** are then displaced by $\mu_g\mathbf{E}$ and $\mu_e\mathbf{E}$ respectively and the shift of the absorption band is $\Delta h\nu = (\mu_e - \mu_g)E$ (for simplicity it is assumed that the field is directed along the μ_e, μ_g, and $\Delta\mu$ vectors). The direction of the spectral shift is determined by the sign of $\Delta\mu$. If the molecular dipoles in the film lie in one direction, the shift of the absorption band of the film corresponds to the shift of the absorption band of the molecule. Otherwise, the spectral shifts towards long-wavelengths and short-wavelengths are averaged out owing to the scatter of the angles between the directions of the vectors **E** and $\Delta\mu$. The spectral shift of the band in an electric field implies an alteration of the optical transmittance at the specified wavelength. The amplitude of the relative change in the transmittance $\Delta T/T$ is proportional to $\langle\cos\theta\rangle$, where θ is the angle between the vectors $\Delta\mu$ and **E**. In the experimental observation of the linear Stark effect (Fig.21), the electric field vector is usually directed along the normal to the film. If the direction of the vector $\Delta\mu$ coincides with the molecular axis, as happens for the azo-compounds (XV), then the angle θ is the angle of deviation of the molecular axis from the normal. Thus the amplitude $\Delta T/T$ is a measure of the approach of the molecules to the ideal orientation (in which $\langle\cos\theta\rangle = 1$).

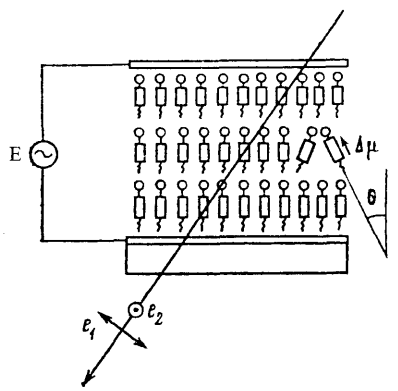

Figure 21. Measurement of the linear Stark effect for a multilayer structure. The molecules of compound (XV) have a chromophoric azo-system (rectangles) and an acceptor group R (circles). There is a transparent SnO_2 electrode on a quartz support and a semitransparent aluminium electrode on top of the multilayer.

Fig.21 illustrates the experimental arrangement designed to observe the linear Stark effect in a multilayer of the *Z* type formed by the azo-compounds (XV)[23]. The polarisation of the light can be of any kind provided that the molecules are scattered at angles θ; otherwise light with the usual polarisation is not absorbed. The changes in the optical transmittance of the film following the application of an external field are illustrated in Fig.22. The $\Delta T/T$ spectrum has the same form as the $dD/d\lambda$ spectrum if one disregards the slight ($\Delta\lambda \cong 10$ nm) mutual shift of these curves due to the different forms of the averaging of the optical and electro-optical contributions by the individual molecules[81]. The value of $\langle\cos\theta\rangle$ is calculated from the $\Delta T/T$ amplitude.

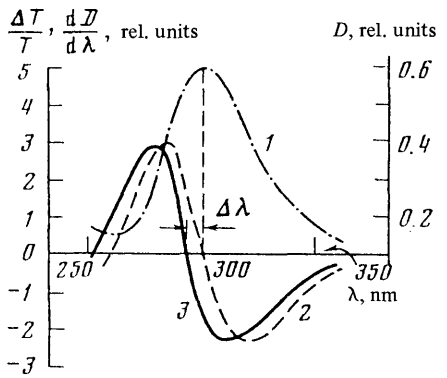

Figure 22. Curves representing the optical density *D* (curve *1*), its first derivative with respect to the wavelength $dD/d\lambda$ (curve *2*), and the $\Delta T/T$ Stark effect signal (curve *3*) for an *X*-type multilayer of compound (XV) with R = $SO_2N.(C_2H_5)_2$.[81]

The $\Delta T/T$ Stark signals for films of the *X* and *Z* types have opposite signs; on *Y* layers, the $\Delta T/T$ amplitude is approximately 30 times lower and is due to the incomplete compensation of the dipole moments of the neighbouring monolayers[23].

We may note that the combination of the dichroism[73] and the linear[81] and quadratic[82] Stark effect methods makes it possible to estimate not only $\langle\cos\theta\rangle$ for Langmuir films but also the next three terms in the expansion of the orientation distribution function of the molecules ($\langle\cos^2\theta\rangle$, $\langle\cos^3\theta\rangle$, and $\langle\cos^4\theta\rangle$)[82]. Measurements of the linear Stark effect together with the pyro- and piezo-effects convincingly demonstrate the polar structure of films of the *X* and *Z* types.

4. Generation of the Second Harmonic of the Light and the Photogalvanic Effect

The polar structure of layers of the *X* and *Z* types must lead to a further two effects which have not so far been observed experimentally. Firstly, symmetry considerations allow in the given instance the generation of the second harmonic of the light via a dipole mechanism (we are dealing with the doubling of the frequency of a powerful light beam). Secondly, intramolecular charge transfer from the donor substituent to the acceptor (for example in azo-compounds) should lead to a potential difference between the electrodes of the multistructure illustrated in Fig.21 when the latter is illuminated (the photogalvanic effect). This potential difference should be proportional to $\Delta\mu$ and to the number of molecules excited by the light with wavelength corresponding to the intramolecular charge transfer band, which is in its turn proportional to the light intensity and to the lifetime of the molecules in the excited state.

VI. PHOTOELECTRIC AND PHOTOCHEMICAL PROPERTIES

1. Electron Transfer

The study of the photoelectric and photochemical properties of artificial multimolecular structures is perhaps the most important trend in molecular architectural design. This concerns the modelling of the processes involved in photosynthesis, the photolysis of water, the creation of solar energy converters, etc. The key factor in all these problems is the achievement of a directed (vectorial) electron transfer from one molecule to another.

The vectorial electron transfer under the influence of a light quantum is modelled by a two-layer structure formed by a monolayer of electron-donating dye molecules and the monolayer of electron accepting molecules (Fig.23)[6]. The thiacyanine dye (VII) can serve as the donor and the bipyridylium salt (XX) (viologen) can serve as the acceptor. When this two-layer system is illuminated by light at wavelengths corresponding to the absorption band of the donor molecules, the excited electron, raised to the highest level of the donor molecule, can tunnel through the dielectric layer to the highest unoccupied level of the acceptor molecule. This transfer can be observed by the quenching of the fluorescence of the donor. The transmission of energy via the mechanisms discussed in the previous section is ruled out in this instance, since compound (XX) has no absorption bands in the spectral region of the fluorescence of the dye (VII). The intensity of this fluorescence depends very markedly on the distance between the chromophoric chains of the donor and acceptor molecules. Thus in case *1* (Fig.23) the fluorescence is quenched completely, in case *2* it diminishes approximately by a factor of two, and in case *3* it hardly changes.

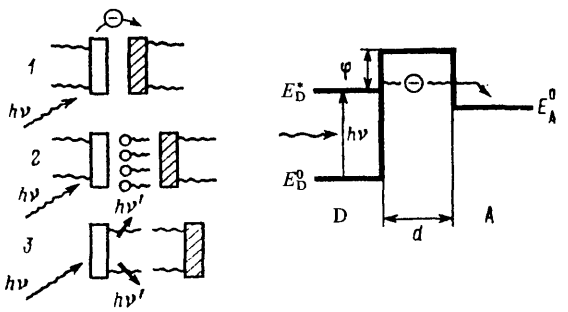

Figure 23. Electron transfer from the photoexcited state of the donor molecule to the highest unoccupied orbital of the acceptor molecule. Open rectangles—electron donor molecules; filled rectangles—electron acceptor molecules; ν' = fluorescence frequencies; in case (2) there is an intervening layer of aliphatic acid molecules[6].

Such a pronounced dependence of the fluorescence intensity on the thickness of the dielectric layer is consistent with the tunnel mechanism of electron transfer through the potential barrier. Experiments in which the width of the tunnel barrier, i.e. the thickness of the aliphatic monolayer, illustrated in scheme *2* (Fig.23), was altered by replacing one aliphatic acid homologue by another (the number of carbon atoms increased from 14 to 22) served as a quantitative confirmation of this postulate[5,6]. The fluorescence intensity diminished exponentially in conformity with the theory of tunnel currents (Fig.24).

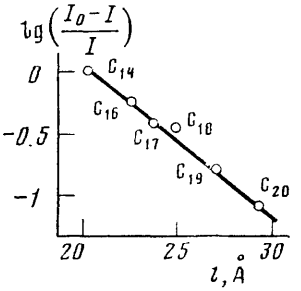

Figure 24. The quenching of the fluorescence intensity of the donor I as a function of the thickness of the tunnel barrier; I_0 = intensity in the absence of a layer of acceptor molecules[6].

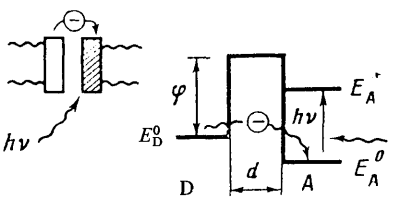

Figure 25. Electron transfer on photoexcitation of the acceptor molecule. Open rectangle—electron donor molecule; filled rectangle—electron acceptor molecule[6].

The degree of quenching of the donor fluorescence depends not only on the width of the barrier but also on the relative positions of the energy levels of the donor and acceptor. In particular, a decrease in the ionisation potential of the donor increases the probability of the electron tunnelling and enhances the quenching effect[83]. The quenching intensifies also on formation of *J*-aggregates by the donor molecules[84].

A second example of photoinduced electron transfer is illustrated in Fig.25. In this case light excites the acceptor molecule and the electron passes from the highest occupied orbital of the donor molecule to a liberated site in the lowest level of the acceptor. Examples of such electron-donating and electron-accepting molecules are provided by compounds (XXI) and (XXII) respectively. In this case the electron transfer from compound (XXI) to (XXII) is monitored by observing the quenching of the fluorescence of the dye (XXII)[2,6].

2. The Electron "Pump"

The photoinduced vectorial electron transfer from the donor to the acceptor molecule, illustrated in Fig.23, is accompanied by the reverse (dark) process, involving the

tunnelling of the electron through the barrier from A to D. However, the two schemes can be combined (Figs.23 and 25) by exciting with light the dye which serves as an electron acceptor in relation to one molecule and at the same time as an electron donor in relation to another. Such a scheme is illustrated in Fig.26. The molecule of the surface-active compound (XXIII) can be conveniently employed as the photosensitive species. The photoinduced electron transfer to the acceptor—the distearylbipyridylium salt (XX)—takes place when a monolayer of these molecules is illuminated. The lost electron is replaced by an electron from the dye-source [the leuco-form of the dye Stearylene Blue (XXIV)].

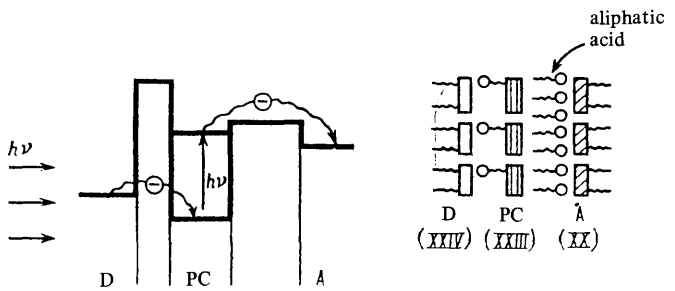

Figure 26. Schematic illustration of the "electron pump"; D = electron source molecule; PC = photocatalyst; A = electron acceptor molecule.

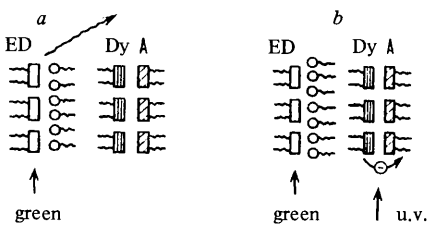

Figure 27. Illustration of the combined effect of the electron phototransfer from the dye Dy to the acceptor A and of the excitation energy transfer from the energy donor ED to A.

Thus the multistructure illustrated in Fig.26 effects a two-stage electron transfer from the source molecule S to the acceptor molecule; the intervening layer plays the role of the photocatalyst PC. As a result of such transfer, the energy of the electron increases. Consequently this structure effects the pumping of electrons from lower energy levels to higher levels, i.e. plays the role of a molecular "pump" for electrons.

The operation of this "pump" can in principle be monitored by the appearance of the oxidised (blue) form of the dye (XXIV) or the reduced form (also blue) of viologen (XX). However, this is difficult to achieve experimentally. A more effective method of detecting the viologen radical involves the observation of the quenching of the fluorescence of special molecules (energy donors) added to the multistructure and chosen in such a way that their fluorescence band coincides with the absorption band of the viologen radical. Then, in the absence of electron transfer in the dye–acceptor (viologen) pair (Fig.27*a*), the energy donor (ED) fluoresces under the influence of visible light, for example, in the red region. Illumination of the dye Dy with ultraviolet light leads to electron transfer from the dye molecule to the acceptor, whereupon viologen is converted into a radical which also absorbs light in the red part of the spectrum. The non-radiative (Förster) mechanism of energy transfer from ED to A begins to operate, which is indeed observed experimentally as the quenching of the red fluorescence of the energy donor[5].

3. Photoconductivity and Photo-e.m.f.

The vectorial phototransfer of an electron can be investigated also by a purely electrical method involving the measurement of the photocurrent in an external circuit for different polarities of the field applied to the specimen or the photo-e.m.f. induced in the electrodes of the specimen.

A fairly large number of studies have been made of the photoconductivity of Langmuir films sensitised by dyes. The physical mechanism of the primary process involving the appearance of a photoelectron in the specimen has been considered[85] in relation to a multilayer structure into which a monolayer containing molecules of quinquethienyl (X), whose electronic oscillators are perpendicular to the plane of the layers (Fig.28), was introduced. The monolayer of quinquethienyl is located among the layers of cadmium arachidate and its position (more precisely its coordinate x) can be varied at will. A potential U, which "inclines" the potential energy diagram for the system, is applied between the mercury and aluminium electrodes. Under the influence of light, electrons pass from the highest occupied orbital of the quinquethienyl molecule to the lowest unoccupied orbital; hence the electrons tunnel across the barrier (or pass through it) and appear in one of the bound energy states on the surface between neighbouring cadmium arachidate monolayers (Fig.9). Next electrons move to the positive electrode via the jump mechanism considered in Section III. The first stage in overcoming the barrier limits the photocurrent. If the ionisation potential of quinquethienyl is ϕ_0 before the application of the external electric field, then it is clear from simple geometrical considerations that in the electric field it falls to $\phi = \phi_0 - eU(L/2d)$, where L is the length of the molecules of compound (X). The current in the external circuit should be proportional to the probability of the escape of electrons from the quinquethienyl molecules to the positive electrode [i.e. to the factor $\exp(-\phi/kT)$] and the time taken to traverse the distance x. Indeed the exponential increase of the current with increase in the potential and the linear dependence on the position of the layer of compound (X) in the multistructure have been observed experimentally[85]. Other results[86] also confirm the model under consideration.

In structures of the type illustrated in Fig.28 it is possible to observe not only a transverse (across the multilayer) but also a longitudinal (in the plane of the layers) component of the photoconductivity. This can be done with the aid of photosensitisers of a new type incorporating the rhodanine fragment (XXV)[87]. The photoconductivity of the longitudinal type exceeds by 2–3 orders of magnitude the transverse component and its temperature variation is of a different type, which agrees with the jump model of the transverse conduction considered previously and the non-active mechanism of the longitudinal conduction[8].

The transverse photoconductivity can be greatly increased by employing, instead of the simple sensitiser shown in Fig.28, a more complex, "photosynthetic" system[88] consisting of monolayers of an electron acceptor and donor and a "molecular conductor" between them[31,54]. Such "construction" of the sensitiser makes it possible to increase the probability of its photoionisation. The corresponding multistructure and energy diagram are shown in Fig.29.

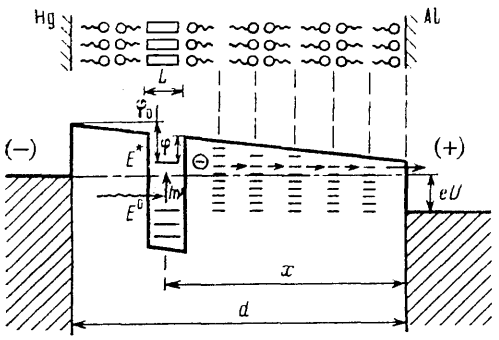

Figure 28. Model elucidating the mechanism of photoconduction in a cadmium arachidate multilayer sensitised by a monolayer of quinquethienyl (X)[85].

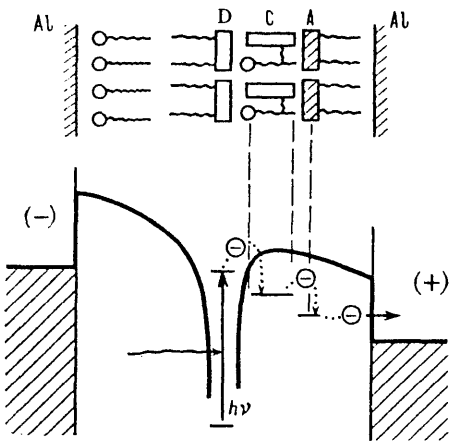

Figure 29. Model elucidating the electronic transitions in the donor D—molecular-conductor C—acceptor A—positive electrode system[54].

In the example given, the rectangular potential well for the electron-donating dye [the indocarbocyanine dye (XXVI)] has been replaced by the more realistic Coulombic potential. The tunnel or thermoactivated electron transfer from the photoexcited state of the donor to the free orbital of the acceptor (XX) is facilitated by the presence of the "molecular conductor" C containing the conjugated chain of the azochromophore of compound (XII). The presence of this chain decreases the width of the potential barrier which must be overcome by the electron tending to enter the acceptor and then the electrode. At any rate, the absence of the molecules of C decreases the photocurrent by an order of magnitude[54]. The change in the polarity of the applied potential results in an appreciable difference in the photocurrent. Since the electrodes are the same in the given instance, this partial "rectification" of the current is caused exclusively by the asymmetry of the "photosynthetic" unit.

The artificially created asymmetry of the multilayer is a necessary attribute required to obtain a photoelectromotive force at the electrodes when the latter are illuminated. Artificial membranes immersed in the solution were used previously to obtain a photo-e.m.f., the opposite surface of the membrane being in contact with solutions of different types. Photo-e.m.f.'s of the order of fractions of a volt were achieved in this way following the illumination of membranes by light from standard light sources[89,90]. Approximately the same photo-e.m.f.'s have been observed also on asymmetric Langmuir multilayers[54,91]. Here an additional factor promoting an increase of the photo-e.m.f. is the use of asymmetric electrodes made, for example, of metals having different electron work functions[54] or using oxide films, the photo-e.m.f.'s reaching several volts in the latter case[92].

4. Photochemical Aspects

There exist fairly numerous publications devoted to the study of the photochemical reactions in monolayers on the surface of water and also in Langmuir multistructures. Their detailed consideration is outside the framework of this review. We shall only note some of the trends which are closest to the idea of molecular architectural design. In particular, photochromic compounds are of special interest for the creation of artificial structures modelling optical memory devices. The surface potential and the area per molecule in monolayers of surface-active photochromic compounds change under the influence of illumination, which can be measured with the aid of the Wilhelmy balance[93,94].

Extensive studies on various photochemical reactions in Langmuir monolayers and multilayers have been carried out in Whitten's laboratory (see, for example, Refs.95—98). The formation of photodimers and excimers, photochemical oxidation and reduction processes (particularly those involving porphyrins), the photoisomerisation of olefins, the photochemical reactions of ketones and surface-active styrene derivatives, and other reactions[12] have been investigated. It was found that the structure of the monolayer has a decisive influence in many instances not only on the rate of reaction but also on the type of final products. As a rule, products whose structure is compatible with the symmetry of their environment are preferred. It has been noted[97,99] that compounds bound in the Langmuir matrix can serve as more effective reagents and also as catalysts of chemical reactions than the compounds in an isotropic solution.

Special mention should be made of polymerisation reactions in solid Langmuir films. Their investigation was begun comparatively recently[100], but important practical results for a whole series of different compounds have already been obtained[10-12]. Ultraviolet radiation, electron beams, and γ-radiation (in particular that from a ^{60}Co source) have been used to initiate polymerisation in multilayers.

The polymerisation of diacetylene derivatives (V) can serve as an example. Under the influence of ultraviolet light, the Langmuir monolayers of compound (V) deposited on a quartz or silicon support react as follows[101]:

$$\mathrm{R{-}C{\equiv}C{-}C{\equiv}C{-}R' \rightarrow \cdots = [=C{-}C{\equiv}C{-}\overset{\displaystyle R'}{\overset{|}{C}}{=}]= \cdots}$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad \mathrm{R}$$

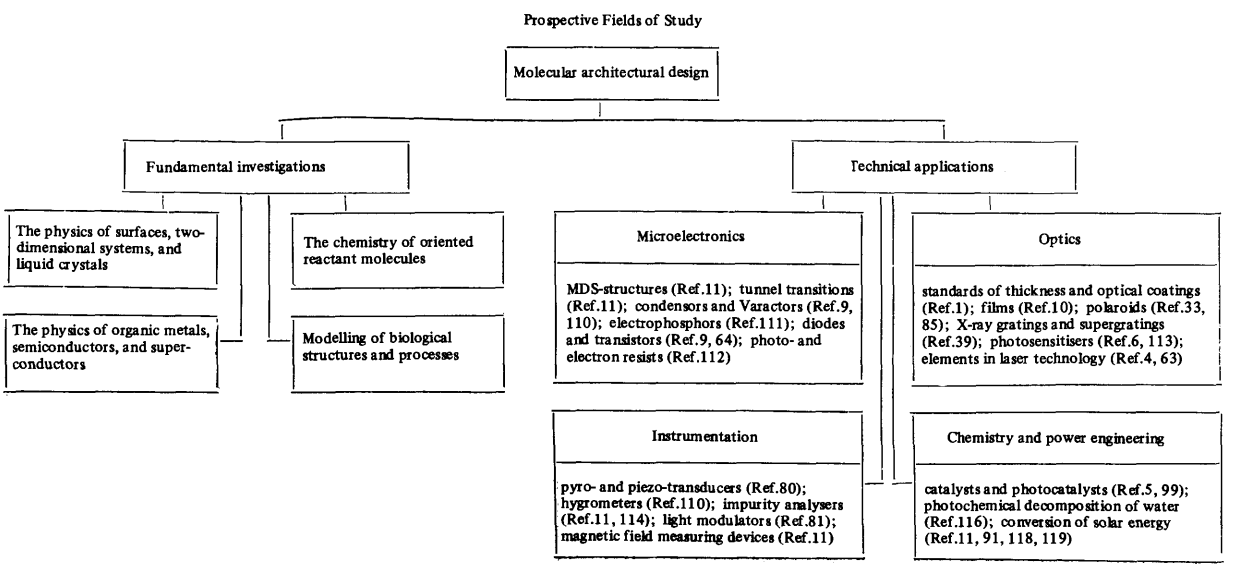
The structure of the monolayer, determined by X-ray diffraction, does not change significantly under these conditions. In general the polymerisation process occurring within the plane of a single monolayer does not as a rule involve the molecules of another layer, which extends the scope of molecular architectural design, permitting the successive deposition of polymer layers made up of different compounds.

An interesting example of a compound which polymerises under the influence of an electron beam is ω-tricosenoic acid. The molecules of this compound in the Langmuir monolayer are oriented at right angles to the support and their cross-linking at the site of the rupture of the unsaturated bond takes place within the plane of the monolayer. The stable multilayers used as electron resists are obtained by this method[102].

A survey of studies of polymerisation in monolayers and of the preparation of monolayers and multilayers directly with the aid of polymer molecules has been published recently[12].

VII. PROBLEMS OF MOLECULAR ARCHITECTURAL DESIGN: REALITY AND PROSPECTS

Molecular architectural design, i.e. the creation of complex molecular assemblies with a predetermined architecture, leads to boundless possibilities for their applications in a wide variety of branches of science and engineering if one disregards technical difficulties. Only some of them are illustrated in the scheme below but the advances in molecular architectural design have already been significant; the corresponding literature sources are indicated in the subsection on technical applications.



1. Fundamental Investigations

Evidently a monolayer resting on the surface of water or transferred onto a solid support can serve as an excellent model of a two-dimensional condensed medium. Studies of the structures of such monolayers have become particularly urgent now that impressive advances have been made in the theory of phase transitions in three-dimensional bodies and the general development of statistical physics of condensed media is directed towards the study of media with a reduced dimensionality. A number of investigations[27,30,122] can serve as examples. The study of the surfaces of solids and liquids also belongs to this field.

Problems concerning the structural organisation of a single monolayer and the correlations in the packing of molecules in neighbouring monolayers, which are in contact with one another, have a direct bearing on the physics of smectic liquid crystals[103] and can be solved with the aid of model systems such as Langmuir layers. On the other hand, a number of ideas in the physics of liquid crystals, concerned, for example, with the explanation of the mechanism of ferroelectricity, can be successfully transferred to the physics of membranes and artificial monolayers and multilayers[104].

In the future molecular architectural design will become a standard procedure for the investigation of a wide variety of processes occurring in organic solids. We have already spoken of the advances in the spectroscopy of complex organic molecules and various associated species, about the mechanisms of the transfer of excitation energy, etc. (Section IV). With the aid of Langmuir films, it is possible to investigate also other exciton processes, in particular, the interaction of excitons with the surface of a crystal, with admixtures, or with metallic electrodes[7,105,106].

It is known that the relative positions of the donor and acceptor fragments of molecules (in the form of stacks, columns, etc.) plays a decisive role in the exciton mechanism of the superconduction in organic crystals. Such structures can be built up in principle on the basis of Langmuir films. Experiments with anthracene derivatives indicate a "stacked" structure of multilayers, leading to a pronounced anisotropy of the electrical conductivity[34]. A similar structure is also characteristic for example, of quinquethienyl layers[85]. Donor–acceptor two-layer systems, formed, for example, by the surface-active analogues of compounds such as tetrathiofulvalene and tetracyanoquinodimethane (TTF–TCNQ complexes), as well as other compounds of this type, which do not form crystals with a suitable structure[9], are of undoubted interest for the physics of organic metals and superconductors.

There is no necessity to mention that chemical and physicochemical reactions involving reactants whose molecules are rigorously oriented in space provide the experimenter with a greater "degree or freedom" than do experiments with isotropic solutions. Clearly in the oriented state it is possible to involve new molecular fragments in the reaction. For such chemical reactions, one can use various boundaries (between the monolayer and the support, between the monolayer and the external environment, and also the boundary between the monolayers)[99]. As already stated, it is thereby possible to alter not only the rates of the reactions but also their products (an example is provided by the formation of a silver mirror at the interface between a monolayer and water[107]).

Molecular architectural design is perhaps of greatest interest for the modelling of various biological processes, in particular the primary stages of photosynthesis. The attempts to model the molecular antenna (or "photon funnel"[5,79]) and also the fundamental photocatalytic electron transfer from a donor to an acceptor[5,6,108] and the replication of information at the molecular level[7] can be regarded as entirely successful. Other model biological studies, including the modelling of the self-organisation of matter[109], are apparently tasks for the immediate future.

2. Technical Applications

The incorporation of molecular architectural design in technology proceeds mainly via four pathways (Fig.30). Microelectronics, where Langmuir films can already be used in commercially produced instruments, can apparently be placed in the first place. This applies primarily to the dielectric layers in metal–dielectric–semiconductor structures, for example, field effect transistors, where the current flowing through the semiconductor is controlled by the electric potential of the metallic electrode separated from the semiconductor by a thin dielectric layer. In field effect transistors based on silicon, the natural oxide layer plays the role of the dielectric. Other semiconductors (for example, InP or CdTe) do not have an oxide film and an additional layer of dielectric with a high electrical strength is essential. Langmuir multilayers, for example, those based on polymerised diacetylenes (a layer with a calibrated thickness and consisting of several tens of monolayers is usually employed) are used as layers of this kind[11].

Ultrathin Langmuir multilayers (with a thickness equivalent to 1–4 monolayers) are also used as tunnel junctions in "cold cathodes" employing the properties of the contact between a photoconductor and a metal. A Schottky potential barrier is usually formed on such contacts. Under the influence of light, a photo-e.m.f. is generated at the site of contact between the semiconductor and the metal and the structure itself becomes an effective converter of light energy into electrical energy. The use of an additional (tunnel) dielectric layer between the metal and the semiconductor improves the efficiency of the conversion of light energy into electrical energy. Thus the efficiency of the "cold cathode" on *n*-type cadmium telluride increases by a factor of 1.4 when two monolayers of the substituted anthracene (VIII) are deposited on the semiconductor[11].

By virtue of their high electrical strength and the possibility of the preparation of films with a rigorously specified and very small thickness, Langmuir monolayers and multilayers are extremely convenient dielectrics for the preparation of high capacitance condensers. The capacitance reaches 0.1 $\mu F\ cm^{-2}$ for the field strength corresponding to breakdown, $\sim 3 \times 10^6\ V\ cm^{-1}$.[110] Condensers whose capacitance is altered under the influence of an external field (Varactors) can also be prepared on the basis of Langmuir films[9].

The unusual type of molecular packing in Langmuir films makes it possible to achieve a high luminescence and electroluminescence (arising from the application of an electric field) quantum yields in them[34,111]. Electrophosphors based on Langmuir films can prove promising for the creation of electroluminescent devices for the reproduction of information (digital displays, panels, flat television screens, etc.). The formation of donor–acceptor multilayers, the employment of surface-active complexes and autocomplexes with charge transfer, and the preparation of solid multilayers based on radical-ion salts will probably lead in the near future to the creation of molecular current rectifiers and more complex transistor structures[9,64].

Quite definite advances have been made in the field of the formation with the aid of Langmuir monolayers of high-resolution photo- and X-ray-resistors.

A sensitivity to an electron beam to within $5 \times 10^{-7}\ C\ cm^{-2}$, for a contrast reaching 2 and a spatial resolution of ~ 600 Å, has been achieved recently on the basis of polymerisable ω-tricosenoic acid films[112]. It was noted that the electron resists obtained by the Langmuir Blodgett technology also exhibit a high resistance to plasma and an effective adhesion to aluminium.

The application of Langmuir films in optics (Fig.30) is based primarily on the possibility of varying their refractive indices for a rigorously specified film thickness. Hence arises the possibility of creating optical thickness standards[1], optical coatings, and interference filters as well as X-ray diffraction gratings[39] and supergratings. It has been noted[9] that X-ray gratings based on multilayers could be particularly useful in the future for the creation of lasers operating in the X-ray range.

The marked dichroism of Langmuir monolayers formed by surface-active dyes, particularly in the aggregated state[33,85,108], makes it possible to employ these structures for the creation of effective film polarizers. The selective absorption of light by dyes can be used also in the development of film layers for the isolation of specific spectral components of radiation (the selection of modes)[63], the generation of ultrashort pulses[4], etc. One may also expect that the non-linear optical properties of polar multilayers will find fairly extensive applications in the immediate future.

Langmuir films are of great interest for integrated optics. They can be used for the creation of both waveguide elements themselves and the outer plates of such devices. The technique of the preparation of multilayers makes it possible to construct the necessary refractive index profile across an integrated optical structure. A fairly high optical quality of such structures (decay of light waves smaller than 1 dB per cm of the path traversed for film thicknesses up to 5000 Å) has already been achieved[10].

The transmission of excitation energy and vectorial electron transfer can be used successfully for the sensitisation of traditional photographic materials. Experiments with silver bromide crystals have shown that AgBr is sensitised as a result of electron transfer from an excited dye monolayer[6,7]. The presence of an electrical acceptor suppresses the sensitisation effect. Specially constructed multilayers on the surface of a photosensitive crystal make it possible to achieve simultaneously the transfer of energy from one dye to another (via the "photon funnel" mechanism), which gives up an electron in its turn to the crystal[113]. This leads to an extremely effective sensitisation of the photographic process.

A new method of recording and replication of information at the molecular level, recently proposed by Kuhn[7], is of

special interest for engineering. Recording on Langmuir films can be achieved with the aid of an electron beam, which induces a photochemical process. The rerecording of information from one monolayer to another is effected by contact procedures similar to the replication of ribonucleic acid in cell chromosomes.

On the other hand, the first attempts to create pyroelectric elements on the basis of polar multilayers led to pyrocoefficients of ~ 10^{-10} C cm^{-2} K^{-1},[80] which is only an order of magnitude lower than the corresponding values for the best film pyroelectrics[114]. In view of the low dielectric constants, which increase the quality factor for pyroelectric materials, one can regard the further development of pyroelectric radiation transducers based on Langmuir multistructures as extremely promising. This applies also to piezoelectric transducers.

There is reason to believe that the linear Stark effect, observed in polar films of surface-active dyes[81], will prove useful in the development of fast acting thin-film light modulators. It has also been suggested that tunnel transitions in Langmuir monolayers be used for the creation of highly sensitive magnetic field measuring devices[11].

Instrument engineering is in acute need of highly sensitive transducers permitting the analysis of low concentrations of admixtures of various gases, water vapour, ionic impurities in solutions, etc. The development of hygrometers based on cadmium behenate multilayers with a gold film electrode permeable to water molecules has been reported[110]. The capacitance of such a structure depends on the amount of water which has diffused through the gold electrode. Selectivity with respect to various impurities can be ensured with the aid of specially constructed multilayers deposited on the open surface of a field effect transistor sensitive to extraneous impurities[115]. The multilayers can also include various biologically active molecules which ensure the selective transport of impurity molecules (for example, via the mechanism of the action of ionophores in membranes).

Reports already exist concerning the creation of instruments detecting gases such as ammonia, carbon monoxide, and hydrogen[11,111].

The possibilities of molecular architectural design in chemistry and power engineering have been assessed very optimistically. The advantages of specific synthesis on Langmuir matrices have already been pointed out. We shall now consider the results of modern studies in the conversion of solar energy into electrical energy. One of the ways of achieving such conversion is photochemical decomposition of water into oxygen and hydrogen; certain surface-active metal complexes can then be used as photocatalysts. A successful attempt at the photochemical decomposition of water with the aid of a monolayer of a ruthenium complex has been reported[116], but subsequent studies[83,117] revealed a number of fundamental difficulties. Another procedure for the conversion of energy consists in the creation of solar batteries by analogy with semiconducting p–n junctions[88]. The Schottky barriers were already mentioned above. In addition, one can employ solid Langmuir multilayers formed by electron-donating and electron-accepting compounds[54,91] as well as electrolytic cells in which the Langmuir monolayers are deposited on a solid support with an optically transparent electrode. In the former case (chlorophyll *a* combined with quinones) the efficiency of the conversion reaches hundredths per cent for a photocurrent quantum yield of the order of several tenths per cent[91]; in the second version (a layer of chlorophyll on an SnO_2 electrode) the photocurrent quantum yield can reach 12–16%.[118,119] The corresponding efficiency of the energy conversion is lower by more than an order of magnitude than the efficiency characteristic of semiconductor solar batteries. However, it is noteworthy that the Langmuir layers are very cheap and technologically convenient. The latter factor is extremely significant when one considers the necessity to "collect" solar energy from large areas. Furthermore, one can employ the principle of the "photon funnel" for the collection of light energy with the aid of a combination of dyes in an energy converter incorporating an electrolytic cell. This should yield an appreciable gain in the efficiency of the conversion[120,121].

In conclusion of the review we emphasise that molecular architectural design is now entering the period of its vigorous expansion and we are justified in expecting from this new field new scientific discoveries and important practical applications.

Organic Metals and Superconductors Based on Tetrathiofulvalene Derivatives

R.N.Lyubovskaya

The latest advances in the synthesis and research into organic metals based on various heterocyclic systems are examined. The influence of the structure of the organic donor and of the size and geometry of the anions on the electrophysical properties of compounds of this series and the conditions governing the appearance of their superconductivity are discussed in relation to compounds of the class of tetrathiofulvalenes.
The bibliography includes 150 references.

I. INTRODUCTION

A new branch of synthetic organic chemistry and the chemistry of coordination compounds (associated with solid state physics), whose task is to synthesise and investigate new materials, which have been called organic metals, has developed vigorously during the last decade. Synthetic organic metals are highly anisotropic and in a certain temperature range behave like "true" metals; on the other hand, they have many unusual electrical, magnetic, and electronic properties[1-4].

The range of compounds on the basis of which synthetic metals can be obtained is fairly wide; further new substances, which are the principal components of organic metals, are being continually synthesised.

Many new studies (their number is increasing rapidly) of square planar transition metal complexes, which also exhibit the properties of one-dimensional synthetic metals under certain conditions have been published[5-8]. The dithiolate complexes of transition metals[9,10] and phthalocyanine[12,14] and porphyrin[11,13] derivatives are being widely investigated. Research into polymeric and electrically conducting materials is developing particularly vigorously. A realistic hope for the creation of fundamentally new technological materials has been a stimulating factor in this field[15-17]. A series of purely inorganic compounds also exhibit metallic conductivity [18,19].

The largest and vigorously developing class of compounds consists of organic metals based on radical-ion salts (RIS) and charge-transfer complexes (CTC) of various electron-donating and electron-accepting compounds. Among numerous thoroughly investigated radical-anion salts based on tetracyanoquinodimethane (TCQM) [20] and other electron acceptors[21], the organic metals which conduct electric current most effectively contain quinolinium, acridinium, and phenazinium cations and are radical-ion salts with a partially reduced TCQM molecule. The conduction in these salts takes place via a stack of TCQM radical-anion species.

Organic metals consisting of compounds with two conducting stacks (electron-donating and electron-accepting) have been thoroughly investigated. In this group of charge-transfer complexes, the salt TTF.TCQM (where TTF = tetrathiofulvalene) and all possible TTF derivatives capable of forming radical-ion salts with TCQM (and other organic acceptors) have been most thoroughly investigated[2,3,23]. CTC or RIS with TCQM have been obtained for the majority of electron-donating compounds listed in Table 1. Many important features characteristic of organic metals have been established precisely on the basis of the study of the radical-ion salts of certain TTF derivatives and other electron donors with TCQM. This has been reflected in a series of review publications[3,4,22,24,25] covering extensive factual data.

The latest advances in the field of organic metals are associated with the study of the radical-cation salts based on tetrathiofulvalenes, tetrathiotetracenes, and other heteroaromatic compounds in which conduction takes place solely via a stack of organic electron-donating molecules. These compounds proved to be the most convenient models for the investigation of the nature of organic metals and their transport properties[3,4,30].

Numerous radical-ion salts of TTT,[26] have been obtained in the series of tetrathiotetracenes TST,[27,28] and TTeT.[29]† The salts $(TST)_2Cl(Br)$ have record conductivities at room temperature ($\sigma = 2\times10^3\ \Omega^{-1}\ cm^{-1}$) and their metallic state is stable down to 1.5 K.[27] These results have been described in a number of reviews[3,30,31].

This review deals with organic metals comprising only tetrathiofulvalenes with inorganic anions. The first organic superconductors based on sulphur- and selenium-containing TTF derivatives have in fact been obtained among compounds of this series[32,33].

II. ORGANIC METALS BASED ON ELECTRON-DONATING COMPOUNDS. CONDITIONS GOVERNING THE EXISTENCE OF ORGANIC METALS

The principal trend in the development of the synthetic chemistry of organic metals is associated with the formation of new heteroaromatic compounds[34,35], with the introduction of various substituents into electron-donating and electron-accepting compounds and the study of the influence of these substituents on the conducting properties[36], and with the replacement of sulphur by selenium[37] and tellurium[38] in compounds of a single series. The endeavour to obtain a series of sulphur-, selenium-, and tellurium-containing compounds

† The abbreviations are defined in Table 1 (Ed. of Translation).

is due to the characteristic features of the structure of organic metals: the possibility of the movement of an electron through a stack of organic molecules is due to the overlap of the wave functions of the unpaired electrons of the heteroatoms and such overlap increases with increase in the size of the heteroatoms in the organic compound.

Both electron-donating and electron-accepting compounds which are components of organic metals have a number of characteristic features[3,39,40], which have been established as a result of the investigation of extensive experimental data; the conditions governing the existence of the stabilised metallic state are constantly being extended and refined.

Table 1 presents the principal classes of heterocyclic electron-donating compounds from which organic metals have been obtained at the present time and are being investigated. The molecular and crystal structures of the components of organic metals must satisfy the following requirements.

(1) Their molecule must be planar in the neutral and ionic states; there is a possibility of a slight deviation (2-4°) from planarity of the ring, which creates conditions for the closest packing of the molecules in the crystal. The intermolecular interaction of the components in the conducting organic stack takes place via the overlap of the molecular π orbitals and is described by the overall wave functions of the unpaired electrons delocalised along the entire molecule.

(2) Their molecules must be symmetrical in order to eliminate the possibility of the appearance of a high random potential which might cause a transition of the system to the dielectric state. A weak electronic or structural disorder may stabilise the metallic state.

(3) The compounds considered must be packed in regular stacks. The movement of electrons takes place along the stack of organic molecules more readily than in the other two directions (the substances are anisotropic in the crystal state).

(4) The distances between the molecules in the stack must be identical and minimal to ensure the non-activated movement of electrons along the stacks.

(5) Apart from the shortened distances between the molecules within the stack, shortened distances between individual stacks are necessary for the stabilisation of the metallic state down to low temperatures and for the occurrence of the superconducting transition.

The electronic structures of the compounds must also have a series of characteristic features.

(1) The presence of unpaired electrons in the system is essential.

(2) Partial charge transfer must take place. Moderately strong electron donors and acceptors satisfy this criterion. The difference between the oxidation-reduction potentials of the electron donor and acceptor must be minimal[39,41].

(3) A minimal Coulombic repulsion energy is necessary to destabilise the transition to the Mott insulator state[39,41].

III. ORGANIC METALS AND SUPERCONDUCTORS BASED ON TETRATHIOFULVALENE DERIVATIVES

1. Organic Metals Based on Unsubstituted Tetrathiofulvalene and Tetraselenofulvalene With Inorganic Anions

The synthesis in 1970 [67] of tetrathiofulvalene, a heterocyclic compound, initiated the study of the enormous class of compounds based on it[2,3]. The crystals of neutral TTF are made up[68] of stacks of its molecules packed in such a way that the character of the structure predetermines the possibility of the insertion of small anions in the channels between the TTF stacks.

Interesting studies have been made on the radical-ion salts of unsubstituted TTF with the halogens. TTF derivatives with the singly charged Cl^-, Br^-, and I^- anions can be obtained by the direct oxidation of standardised TTF solutions in acetonitrile or CCl_4 with standard solutions of Cl_2, Br_2, and I_2 in the same solvents[69,70]. The photochemical reaction

$$TTF + CCl_4 \xrightarrow{h\nu} (TTF)Cl_n$$

can yield TTF chlorides[71]. TTF halides can also be obtained in the electrochemical generation of the TTF^+ radical-cation with subsequent addition of an alkylammonium salt containing Cl^-, Br^-, or I^-.[69] Under certain conditions, there is a possibility of the reverse reduction of the TTF^+ radical-cation with formation of the Br_3^- anion and the initial TTF [72]:

$$TTF^+ + Br^- \rightarrow TTF^0 + Br_3^-.$$

A characteristic feature of the reaction of TTF with the halogen is the formation of the compound $(TTF)X_n$, where $X = Cl^-$, Br^-, or I^- with different values of n. For $n = 1$, one electron is removed from each TTF molecule and the radical cation salt $(TTF^+)X^-$ with complete charge transfer is formed. When $n = 2$, dicationic salts are obtained, two electrons are removed from each TTF molecule on oxidation, and the salt $(TTF)^{2+}X_2$ is produced[69]. However, the number of electrons transferred from an electron-donating TTF molecule to the acceptor is frequently non-integral and is actually less than unity. For $n < 1$, compounds with different stoichiometric compositions are obtained and n can vary continuously within a certain range, while the physical properties of the compound do not change significantly.

The compounds $(TTF)X_n$ where X = halogen and $n < 1$, have been isolated and characterised in detail[69] and the parameters of their unit cell have been published. The phase with n in the range $0.7 < n < 0.8$, obtained for all three halogens indicated, is the most stable[69]. The structure of compounds having this composition [and in general of all the non-stoichiometric compounds $(TTF)X_n$] is characterised by the presence of two independent sublattices: the cationic sublattice consisting of TTF molecules packed regularly in stacks and the anionic sublattice consisting of inorganic anions. The channels between the TTF stacks are filled with the Cl^-, Br^-, or I^- anions distributed with different densities, which determine the non-stoichiometric composition of the compounds $(TTF)X_n$. Fig. 1 presents the structure of the compound $(TTF)Br_{0.76}$;[70] $n = 0.76$ corresponds to the maximum Br^- content on $(TTF)Br_{0.71-0.76}$. The structure contains two separate sublattices; the first consists of stacks of TTF molecules arranged along the conducting axis and the anions Br^- are arranged in the channels between the TTF molecules (second sublattice). The unit cell parameters are constant in the range $n = 0.71-0.76$. The distances between the TTF stacks are regular and equal to 3.57 Å.

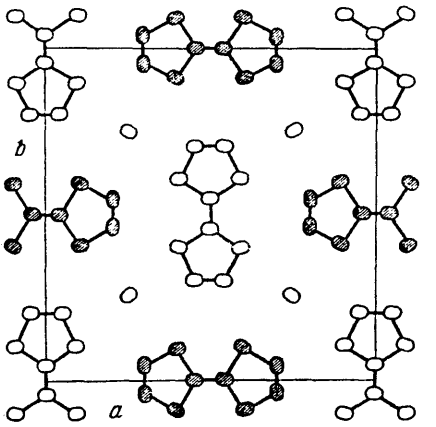

Figure 1. The structure of $(TTF)Br_{0.76}$.[70] Projection along the direction of the radical-cation TTF stacks.

The conductivities of the compounds $(TTF)X_n$ with halide ions are fairly high (Table 2). However, on decrease of temperature, all these compounds undergo the metal-, insulator transition at temperatures in the range 170–270 K and pass to the dielectric state. This is associated with a rearrangement of the structure of these compounds occurring as the temperature is reduced—the so-called Peierls transition takes place[78]. Despite the partial charge transfer, the conductivities of the compounds $(TTF)X_{0.67}$ with $X = ClO_4^-$ or BF_4^- are low, apparently because of the irregular packing of the electron-donating TTF molecules in the stack.

A series of non-stoichiometric TTF derivatives have been isolated electrochemically; one of them, namely $TTF(NO_3)_{0.55}$, has been characterised fairly completely and investigated[80].

Like the $(TTF)X_n$ with halide anions, this non-stoichiometric compound is made up of individual TTF stacks; the NO_3^- anions are distributed in the channels between the stacks of TTF molecules. While the compound has a fairly high conductivity at room temperature ($\sigma = 1200\ \Omega^{-1}\ cm^{-1}$), it undergoes a Peierls type metal → dielectric transition at 180 K.[80]

Apart from the non-stoichiometric compounds indicated in Table 2, radical-cation salts having the composition (TTF)X or $(TTF)_2X^{2-}$, where $X = Cl^-$, Br^-,[69] NO_3^-, BF_4^-, ClO_4^-,[82] $CuBr_3^-$, $AuCl_2^-$, $Cu(NO_2)_2^-$, $TiCl_4^{2-}$, $SnCl_6^{2-}$, or $RuCl_5^{2-}$,[84] the salts (TSF)X, where $X = Cl^-$[88] or I_3^-,[85] and the dicationic salts $(TTF)X_2$ or $(TTF)X^{2-}$, where $X = Cl^-$, Br^-,[69] NO_3^-, BF_4^-, ClO_4^-,[81,82] $CuCl_4^{2-}$, or $AuCl_4^{2-}$,[84] have been obtained.

The conductivities of the compounds (TTF)X with complete charge transfer are low and amount to 10^{-4}–$10^{-7}\ \Omega^{-1}\ cm^{-1}$. The compounds $(TTF)X_2$ are always insulators.

When TTF is oxidised by copper(II) chloride, several products are formed, depending on the solvent employed[81]; compounds with the copper-containing $CuCl_2^-$ anion are obtained (Table 2). Raman spectroscopic studies of these compounds have shown that the compounds $(TTF)_3(CuCl_2)_5$ contain both TTF^+ and TTF^{2+}; the latter is the only example of a compound with a mixed valence incorporating the TTF^{2+} dication. The compound $(TTF)(CuCl_2)$ contains only TTF^+, while $(TTF)(CuCl_4)^{2-}$ contains only the TTF^{2+} dication[81].

Table 2 Characteristics of the radical-ion salts based on unsubstituted tetrathiofulvalene and tetraselenofulvalene with inorganic anions.

Compound	σ, $\Omega^{-1}\ cm^{-1}$	T_t^*, K	Refs.

*T_t = metal–dielectric transition temperature.

**The composition of this compound apparently differs from $(TTF)_2(NO_3)$.

The oxidation of TTF in acetonitrile by the copper(II) salts CuX, where $X = ClO_4$, BF_4, or NO_3, leads to the formation of compounds having three different stoichiometric compositions depending on the reactant ratio: $(TTF)X_n$, (TTF)X, and $(TTF)X_2$[81,82] (Table 2).

Two types of packing of the TTF molecules have been observed[83] in the trichloromercurate radical-cation salts $(TTF)HgCl_3$, while the mercury-containing anions form either the dimers $(Hg_2Cl_6)^{2-}$ or polymer chains made up of $(HgCl_3)_n^{n-}$. The distance between the planes of the TTF molecules is 3.6 Å, which is analogous to the distances in $(TTF)Cl_{0.92}$[76] and $TTFBr_{0.76}$,[70] or 3.45 Å, as in the fully oxidised TTBr.[70] The structural analogies and X-ray diffraction data have led to the conclusion[83] that TTF is present in the $(TTF)HgCl_3$ salt in two different oxidation states. This has also been confirmed by Raman spectroscopy[83,84].

Very few compounds of the selenium analogue, namely the unsubstituted TSF, with inorganic anions have been investigated (Table 2), which is due to the difficulty of synthesising the initial TSF and the low conductivities of the compounds obtained. Thus, while the conductivity of the compound $(TSF)I_{0.8}$ at room temperature is comparatively high, if the temperature is reduced it behaves as a semiconductor[85] with an activation energy of conduction $E = 0.149$ eV.

In connection with the discovery of the superconductivity of the salts $(TMTSF)_2X$ ($X = BF_4$, ClO_4, NO_3 or PF_6),[105] the properties of the unsubstituted TSF combined with singly charged anions are of interest. The non-stoichiometric salts $(TSF)X_{0.67}$, where $X = ClO_4$ or BF_4, which are analogues of the salts of unsubstituted TTF,[77,84] have been obtained[82] by oxidising TSF with copper(II) salts. Salts having the 2:1 composition could not be isolated. X-Ray diffraction study of the salt $(TSF)(ClO_4)_{0.67}$[87] showed that the stack of the TSF molecules is divided into triads of molecules in terms of the type of overlap and that this apparently is the immediate cause of the significant decrease of the conductivity of this salt[86] (Table 2).

2. Organic Metals Based on Dibenzotetrathiofulvalene

The introduction of two benzene rings into the TTF molecule increases the extent of its π-electron system and the electron-donating capacity of dibenzotetrathiofulvalene (DBTT) then decreases compared with the unsubstituted TTF.[89] In the neutral state the DBTTF molecules are packed in regular stacks with interplanar distances between the molecules of 3.544 Å.[90]

The interaction of DBTTF with chlorine and bromine leads to the formation of mixtures of products with different stoichiometries[91,92], as for the unsubstituted TTF.[69] Individual single crystal compounds with chlorine were not isolated and compounds having the formula $(DBTTF)Cl_{0.7-1.0}$ were obtained. When DBTTF : Br = 1 : 1.2 in the reaction mixture, the compound $(DBTTF)Br_{1.2}$ is obtained; other compounds with bromine have the composition $(DBTTF)Br_{0.8-1.0}$.[91]

The reaction of DBTTF with iodine has been investigated in nitrobenzene and acetonitrile[91]. For the reactant ratio DBTTF : I = 1 : 0.5 in nitrobenzene, the compound $(DBTTF)_2I_3$ was isolated; further increase of the amount of iodine leads to the compound $(DBTTF)I_3$. In acetonitrile, the salt $(DBTTF)_2I_3$ was isolated for the ratio DBTTF : I = 1 : 2 and in the presence of a still greater excess of iodine (up to the ratio 1 : 10) the salt $(DBTTF)I_3$ was obtained. Compounds having the compositions $(DBTTF)I_{0.5}$ and $(DBTTF)I_{0.8}$ have been obtained in acetonitrile[94].

The compound $(DBTTF)I_3$ has been investigated by X-ray diffraction[93] (Fig. 2). Stacks made up of alternating groups of three DBTTF molecules and two linear I_3^- anions are characteristic of the structure. The linear I_3^- ions are accommodated in the channels between the mixed stacks. The S–S distance in the structure is shortened to 3.50 A; in addition, there are a series of shortened distances between S atoms and I_3^- groups. This structure of the compound $(DBTTF)I_3$ differs from that of the compounds of the unsubstituted TTF with the halogens, in the structure of which the stacks are made up solely of TTF molecules and the halogen atoms are distributed in the channels between them[76].

The conductivities of $(DBTTF)Cl_{0.7-1.0}$ and $(DBTTF)Br_{0.8-1.0}$ were measured using discs and amount to $10^{-2}-10^{-3}\ \Omega^{-1}\ cm^{-1}$. The conduction in the $(DBTFF)I_3$ single crystals investigated [95] is activated and the magnetic susceptibility of this compound varies in accordance with the properties of an infinite antiferromagnetic chain having an exchange integral $J = 100$ K. [95]

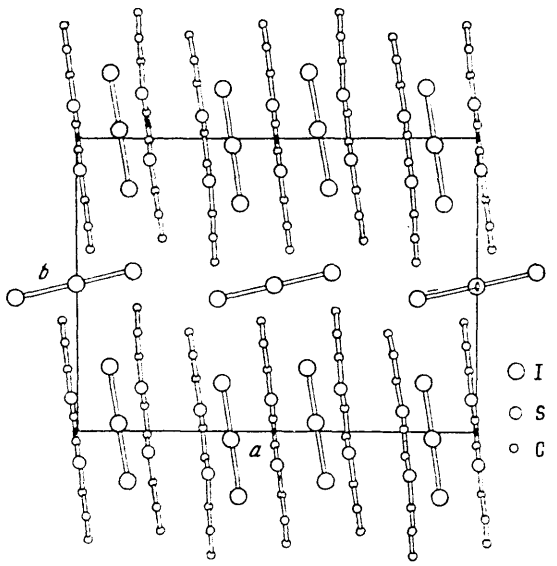

Figure 2. The structure of $(DBTTF)I_3$; [93] the side view of the DBTTF stacks with I_3^- anions accommodated in the channels between the stacks.

Metal halides and their complexes were used for the first time as oxidants for DBTTF. An interesting feature of these reactions is the fact that the oxidant behaves simultaneously as the complex forming anion or the anion can be formed in the course of the reaction[96,97]:

$$DBTTF + MX_4 \rightleftarrows DBTTF^+ + MX_3 + 2X^- \quad ;$$
$$MX_4 + 2X^- \rightleftarrows (MX_6)^{2-}$$
$$M = Sn,\ Te,\ X = Cl,\ Br$$
$$DBTTF + DBTTF^+ + (MX_6)^{2-} \xrightarrow{X=Cl} (DBTTF)_8\,(MCl_6)^{2-} \quad ;$$
$$\xrightarrow{X=Br} (DBTTF)_3\,(MBr_6)^{2-} \quad ;$$
$$M = Pt,\ Re,\ Sn,\ Te.$$

Table 3 presents the characteristics of the radical-ion salts obtained by oxidising DBTTF by various oxidants and the conductivities of the compounds obtained. The series of isostructural DBTTF compounds with doubly charged octahedral anions, having the general formula $(DBTTF)_8(MCl_6)_3^{2-}$, where M = Sn, Pt, Re, or Te, are of greatest interest. A characteristic feature of the structures of these compounds [97,98] is the presence of isolated cationic and anionic stacks arranged along the conducting axis of the crystal. Fig. 3 illustrates the lateral view of the cationic and anionic stacks in the $(DBTTF)_8(SnCl_6)_3$ structure. In the unit cell there are eight cations and three anions per period along the conducting axis of the crystal, the interplanar distance between the DBTTF molecules being identical throughout the stack and equal to 3.49 Å.

X-Ray diffraction study of the $(DBTTF)_8(MCl_6)_3$ complexes, where M = Sn, Pt, or Re, showed[98] that the presence of two sublattices—cationic with the single identical subperiod $c' = 3.49$ Å and anionic with the periods $c'' = 9.30$ Å for $SnCl_6^{2-}$,

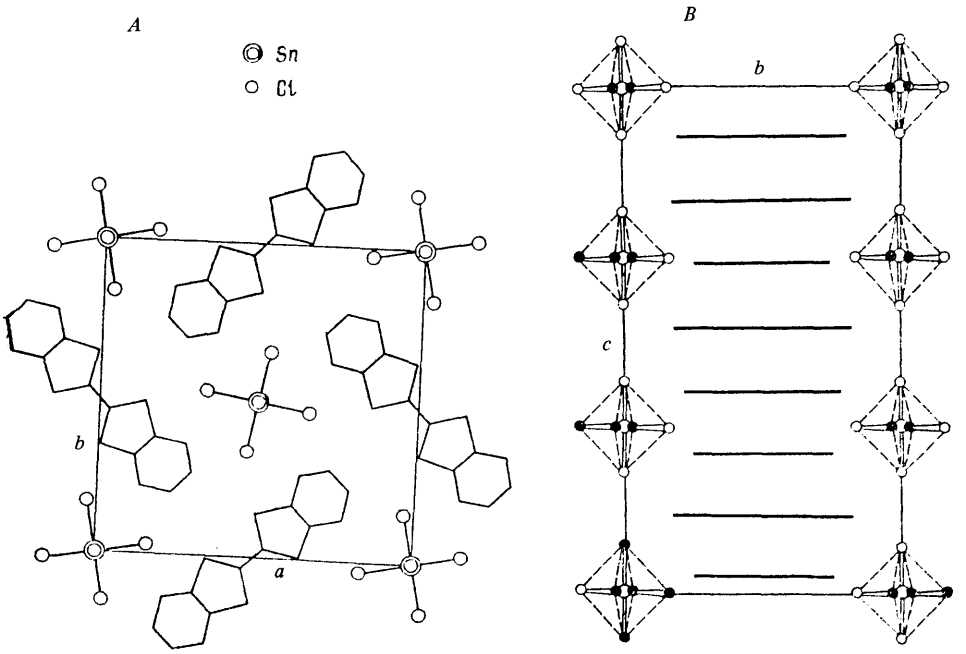

Figure 3. The structure of $(DBTTF)_8(SnCl_6)_3$; [98] *A*) view from above along the DBTTF stacks with the $SnCl_6^{2-}$ anion accommodated in the channels between the DBTTF molecules; *B*) side view of the cationic and anionic DBTTF and $SnCl_6^{2-}$ stacks.

9.52 Å for $PtCl_6^{2-}$, and 9.0 Å for $ReCl_6^{2-}$ —is manifested in the crystals of compounds of DBTTF with the MCl_6^{2-} anions. The ratios of the dimensions of the subperiods $c'':c'$ yield the ratios of the cationic and anionic components, which are 2.67:1, 2.73:1 and 2.59:1, and this also indicates the compositions of the complexes listed in Table 3. The small differences between the cationic components of these complexes, caused by the different dimensions of the octahedral anions which do not interact with one another, do not have a significant influence on the conductivities of the compounds. Conduction takes place via cationic stacks consisting of regularly arranged DBTTF molecules. In the compounds $(DBTTF)_8 \cdot (MCl_6)_3$ there are six radical-cation species and two neutral molecules for three doubly charged anions, so that the charge $(16-6):8=(10/8)e$ is formally localised on each molecule and the conductivity band is five-eighths filled[99].

* Measured for a single crystal.
** THF = tetrahydrofuran.

Measurements of the temperature variation of the conductivities of $(DBTFF)_8(SnCl_6)_3$ and $(DBTTF)_8(PtCl_6)_3$ single crystals showed that σ increases somewhat with decrease of the temperature T (by a factor of approximately 1.5); this is followed by a broad maximum, after which at 180 K the conductivity begins to fall in accordance with an activation law and the salt passes to the dielectric state at 113–117 K.[99]

Measurements of the temperature dependence of the magnetic susceptibilities of the compounds $(DBTTF)_8(MCl_6)_3$, where M = Sn, Pt, Re, or Te, demonstrated a metal-dielectric phase transition at 115 K.[99,100]

The replacement of MCl_6^{2-} by the larger MBr_6^{2-} anions leads to a series of isostructural compounds having the general formula $(DBTTF)_3MBr_6$ (M = Sn, Pt, or Re). It has been shown for $(DBTTF)_3SnBr_6$[98] that the cationic stack is divided into triads with different distances between the DBTTF molecules, amounting to 3.47, 3.44, and 3.44 Å. The conductivities of the $(DBTTF)_3MBr_6$ complexes are lower by an order of magnitude than those of $(DBTTF)_8(MCl_6)_3$; for discs, $\sigma = 10^{-2}\ \Omega^{-1}$ cm^{-1} for all the complexes, while for the single crystals of the compound $(DBTTF)SnBr_6$, we have $\sigma = 40\ \Omega^{-1}$ cm^{-1} at 300 K.

The replacement of one Br^- ion in $PtBr_6^{2-}$ by the dimethyl sulphide group leads to the formation of the singly-charged anion $Br_5PtS(CH_3)_2^-$ and of the charge-transfer radical-cation salt $(DBTTF)[Br_5PtS(CH_3)_2]$, the conductivity of the single crystals of which is $10^{-3}\ \Omega^{-1}$ cm^{-1}.[101]

The selenium analogue of dibenzotetrathiofulvalene, namely dibenzotetraselenofulvalene (DBTSF), has been obtained recently[37,46]. Its electrochemical oxidation in the presence of hexafluorophosphate anions leads[37] to the formation of the non-stoichiometric salts $(DBTSF)(TaF_6)_{0.61}$, $(DBTSF)\cdot(AsF_6)_{0.67}$, and $(DBTSF)(SbF_6)_{0.72}$ with single crystal conductivities of 0.5–20 Ω^{-1} cm^{-1} (Table 3). The properties of tetramethyldibenzotetraselenofulvalene (TMDBTSF), described by Johansen et al.[37], are of special interest in connection with the discovery of the superconductivity of TMTSF derivatives.

3. Organic Metals and Superconductors Based on Tetramethyltetraselenofulvalene

The greatest advance in the field of organic metals during the last three years has been the discovery of their superconductivity#.

The first organic superconductors were obtained in the form of 2:1 single crystal salts by the electrochemical oxidation of tetramethyltetraselenofulvalene in the presence of the corresponding tetra-alkylammonium salt[105,106,107]:

$$2TMTSF + (C_4H_9)_4X \xrightarrow[-e]{} (TMTSF)_2X.$$

The electrochemical method proved to be very suitable for the synthesis of single crystals of conducting compounds, because, during controlled oxidation or reduction by an electric current, the soluble donor or acceptor molecules are converted into less soluble oxidised or reduced complexes. The complexes of unsubstituted TTF,[80] TCQM[108], polycyclic aromatic compounds[54], and metal complexes of dithiolenes[109] have been obtained in this way. If electrochemical oxidation yields products with fairly high conductivities, they crystallise at the anode in the form of thin long needles or plates, since they can themselves function as the electrode, while the non-conducting compounds cover the anode in a thin film and electrocrystallisation stops.

The majority of organic metals are obtained nowadays by the electrochemical crystallisation method described by Mortensen and co-workers[105,110]. The purity of the initial electron-donating compounds, electrolytes, and solvents involved in the electrochemical process must meet very exacting requirements[105]. Special investigations of the influence of the donor purification conditions[110], the specific features of the solvents[111], and the construction of the electrochemical cell[112] on the quality of the crystalline salts formed have been carried out.

Chemical oxidation of TMTSF by copper(II) salts can yield (depending on the concentrations of the initial reactants and their ratio) salts having the compositions $(TMTSF)_2X$ or (TMTSF)X or the dicationic salts $(TMTSF)X_2$[82]:

$$TMTSF + CuX \rightarrow (TMTSF)_nX,$$
$$n = 2;\ 1;\ 0.5;\ X = BF_4,\ ClO_4,\ NO_3\ .$$

However, the resulting $(TMTSF)_2X$ crystals are then of a lower quality than in the electrochemical oxidation. Apart from the 2:1 salts, TMTSF salts of other compositions have

The properties of the superconducting salts $(DMTSF)_2X$ have been discussed in detail in "Proceedings of the International Conference on Low Dimensional Solids", Mol.Cryst. Liq.Cryst., 1982, **79**, Part II, 1–357.

been isolated[107]: $(TMTSF)Br_{0.8}$, $(TMTSF)(Br_3)_{0.8}$, $(TMTSF)_2(SiF_6)$, $(TMTSF)(TeF_5)$, and $(TMTSF)(R\text{-}SO_3)$, where R = *p*-tolyl or phenyl. The properties of compounds having other than 2:1 stoichiometry are those of semiconductors, while the salt $(TMTSF)_2(SiF_6)^{2-}$ is a dielectric[107].

Compounds having the composition $(TMTSF)_2X$, characterised by a wide range of variation of the physical properties from those of semiconductors to superconductors, are of greatest interest.

Table 4 presents the properties of the salts $(TMTSF)_2X$ with various singly-charged inorganic anions obtained hitherto. The anions present in these salts can be divided into the following groups in terms of their symmetry: octahedral (PF_6^-, AsF_6^-, NbF_6^-, SbF_6^-, TaF_6^-, TeF_6^-), tetrahedral symmetrical (BF_4^-, ClO_4^-, BrO_4^-, IO_4^-, ReO_4^-, and TcO_4^-), and tetrahedral asymmetric (FSO_3^- and $CF_3SO_3^-$); in addition there exist the triangular planar NO_3^- anion and the $H_2F_3^-$ anion. It is of interest to follow the differences between the compound $(TMTSF)_2X$ and other tetrathiofulvalene derivatives. All the compounds of the type $(TMTSF)_2X$ are isostructural. The almost planar TMTSF molecules are packed in stacks arranged exactly at right angles to the conducting axis of the crystal [146]. Fig. 4 [113] illustrates the structure of the compound $(TMTSF)_2ClO_4$, which is typical for the entire series of salts $(TMTSF)_2X$. Within the single stack, the molecules are arranged in a zigzag fashion with a shift equal to one quarter of the length of the molecule relative to one another (Fig. 4*a*, side view). Inside the stack, a weak dimerisation is observed: the distances between two neighbouring Se atoms of the TMTSF molecules in the stack are 4.021 and 3.96 Å; the distance between two other Se atoms are somewhat smaller (3.93 and 3.87 Å). A distinctive feature of these structures is the fact that the stacks are arranged in layers (Fig. 4*b*, view from above) with a very short Se-Se distance between the Se atom of neighbouring molecules in the layer, significantly smaller than the sum of the van der Waals radii of the Se atoms, which is 4.00 Å. [114] Such short Se-Se distances are responsible for the two-dimensional nature of this series of compounds (previously such shortened Se-Se distances between neighbouring stacks were found for the compounds TMTSF. .TCQM [115] and $(TST)_2Cl$). [31]

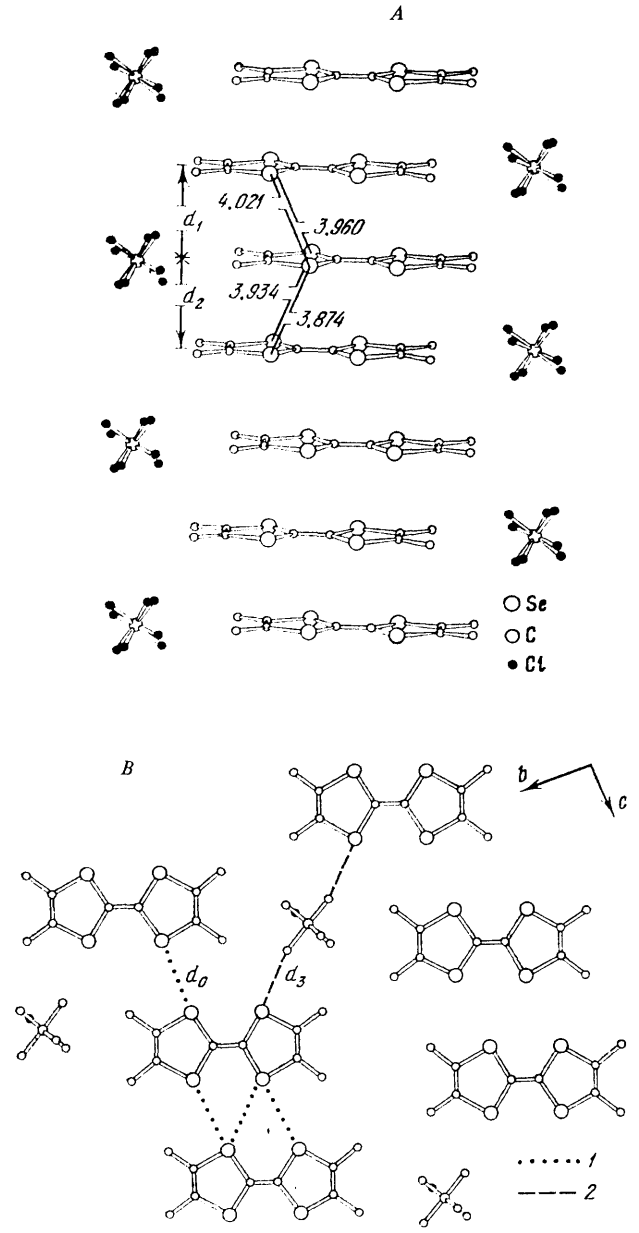

Figure 4. *A*) The structure of $(TMTSF)_2ClO_4$. Notation: d_3 is the minimum Se-O distance (in compounds with the ClO_4^- and BrO_4^- anions) or Se-F distance (for flourine-containing anions; v_0 is the volume of the unit cell; d_0 is the minimum Se-Se distance between TMTSF stacks in the layer; d_1 and d_2 are the interplanar spacings between TMTSF molecules within a single stack.

Note. The numbers in square brackets denote references (Ed. of Translation).

Table 5 lists the Se-Se distances in the stack and between the stacks for a series of salts $(TMTSF)_2X$. All these distances are significantly shorter than the sum of two van der Waals radii of the Se atom. For certain compounds (with PF_6^- and AsF_6^-), a weak dimerisation is observed within the TMTSF stacks ($d_2-d_1=0.03$ Å), but in the main the stacks are virtually not dimerised. With decrease of temperature, all the distances diminish, but the Se-Se distances between the stacks decrease much more than the Se-Se distances within the stacks (Table 5), i.e. the salts $(TMTSF)_2X$ become increasingly two-dimensional as the temperature is reduced[116].

Singly charged anions are arranged in the channels between the layers of TMTSF molecules; their arrangement is clearly seen from Fig. 4*b*. The centrosymmetric anions PF_6^-, AsF_6^-, SbF_6^-, TaF_6^-, and NbF_6^- can occupy only one position in the lattice[4,113,117]. The tetrahedral anions ClO_4^-, BF_4^-, ReO_4^-, BrO_4^-, SO_3F^-, etc., which lack central symmetry, can occupy two statistically non-equivalent positions in the lattice, which can vary with temperature. It has been suggested[117] that at low temperatures the ClO_4^- ions occupy only one position, but X-ray diffraction studies at 125 K [116] have shown that at least up to this temperature there is no ordering in the arrangement of the ClO_4^- ions. It has now been established that the differences between the structures of the anions and the changes occurring in their packing as the temperature is altered actually determine the entire wide variety of the properties of the salts $(TMTSF)_2X$.[4]

All the compounds of the $(TMTSF)_2X$ series have not unduly high electrical conductivities at room temperature, namely $\sigma \cong 400 \pm 100\ \Omega^{-1}\ cm^{-1}$ (Table 4), but, as the temperature is reduced, their conductivity increases very rapidly, reaching values of the order of $10^5\ \Omega^{-1}\ cm^{-1}$ for the majority of the salts before the transition temperature T_t.[107,119]

The salts of the octahedral anions (PF_6^-, AsF_6^-, SbF_6^-, TaF_6^-, and NbF_6^-) undergo the metal–dielectric transition at 12–17 K at normal pressures[107,117] (see Table 4). When an increased pressure is applied, the metal-dielectric transtion in compounds with the hexafluorophosphate anions is fully suppressed and all these compounds become superconducting at 0.9–1.3 K (Table 4).[117] It was shown for the first time in relation to the compound $(TMTSF)_2PF_6^-$ that the metal–dielectric transition is magnetic[120–122] and is associated with the antiferromagnetic ordering of the spins as the temperature is reduced with the formation of a spin density wave. The Peierls transition, which is usual for the organic metals investigated previously and is associated with a structural change in the conducting stack of organic molecules, is not observed for these compounds (the Peierls transition doubles the lattice period along the conducting axis of the crystal, which induces in its turn a periodic increase of the charge denisty along this axis, i.e. a charge density wave is generated[78]).

A different behaviour is characteristic of the salts $(TMTSF)_2X$ containing anions with a reduced symmetry (ClO_4^-, BF_4^-, ReO_4^-, NO_3^-, and FSO_3^-). At the usual pressure the salts $(TMTSF)_2ReO_4$,[123] $(TMTSF)_2FSO_3$,[124–126] and $(TMTSF)_2BF_4$,[105,107] undergo a sharp metal-dielectric phase transition at fairly high temperatures, namely at 180 K,[123] 86 K,[125] and 40 K[107] respectively (Table 4).

The metal-dielectric transition in the salt with the ReO_4^- anion has been attributed to the ordering of the arrangement of the ReO_4^- anions. At a pressure of 9.5 kbar the transition is suppressed and the compound undergoes the superconducting transition at 1.3 K.[123] It has been suggested that the metal–dielectric transition in systems with tetrahedral anions, similar to ReO_4^-, the behaviour of such systems under pressure and the influence of the position of the anion are associated with a special type of the Peierls mechanism which is based on the interaction of the conductivity electron with the ReO_4^- anion[123].

The salt $(TMTSF)_2FSO_3$ [125] differs from all other salts of this series by the fact that the FSO_3^- anion has a permanent dipole moment. The conductivity of the $(TMTSF)_2FSO_3$ single crystals[125] at 300 K is $\sigma = 1600\ \Omega^{-1}\ cm^{-1}$, which is higher than the usual conductivities of the series of $(TMTSF)_2X$ salts approximately by a factor of 4. With decrease of temperature to 86 K, a sharp metal–dielectric transition is observed and can also be noted in measurements of the magnetic susceptibility. It has been suggested[125] that the mechanism responsible for the metal-dielectric transition in this salt is associated with the generation of a charge density wave and not a

spin density wave. The physical properties of the salt are attributed to the influence of the permanent dipole moment of the FSO_3^- anion[125].

A qualtitatively different behaviour is characteristic of the compound $(TMTSF)_2NO_3$.[105,107] With decrease of temperature, the anions of this salt become ordered and the period of the unit cell is doubled along the conducting axis of the crystal.

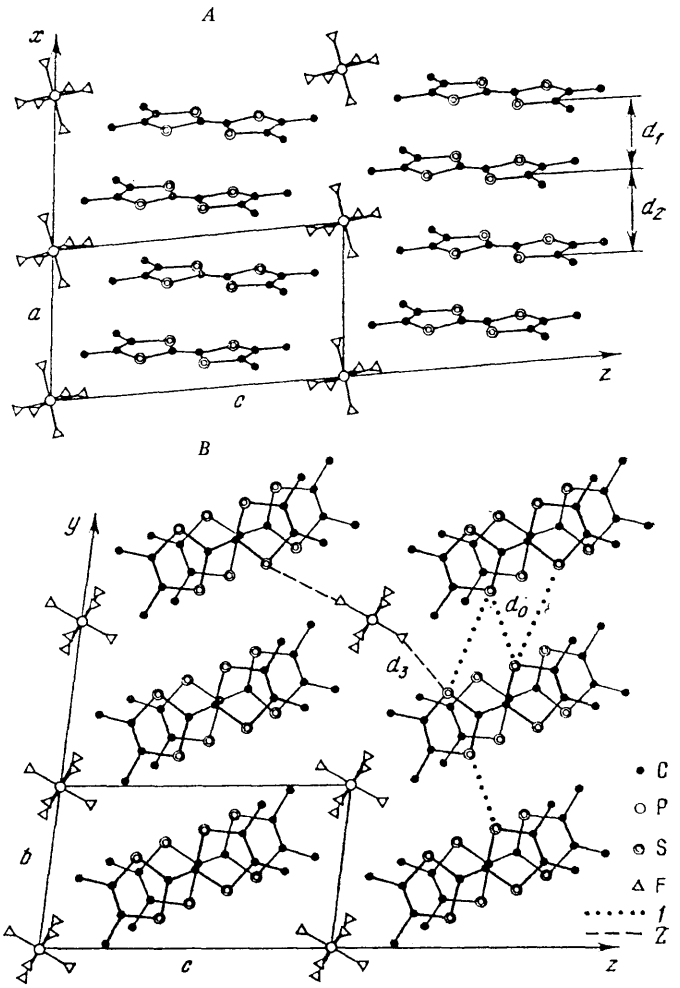

Figure 5. The structure of $(TMTTF)_2PF_6$: *A*) side view of the stacks of TMTTF molecules; the PF_6^- anions are distributed between the TMTTF stacks; *B*) view from above the layers of TMTTF molecules and PF_6^- anions; *1*) S–S distances between stacks of TMTTF molecules in the layer; *2*) S–F distances[135].

The order-disorder transition in the arrangement of the anions induces secondary effects in the electronic system of TMTSF. When pressure is applied, the metal-dielectric transition is suppressed, but the compound does not pass to the superconducting state. This is apparently associated with the fact that the NO_3^- anion is a relatively weak acceptor compared with the other anions investigated[107]. Yet another compound of the $(TMTSF)_2X$ series with the $H_2F_3^-$ anion has been obtained recently[127]. The $H_2F_3^-$ anion has a disordered arrangement and can occupy two possible positions around the centre of symmetry, each with a probability of 50%. This salt is isostructural with the other salts $(TMTSF)_2X$. Although the $(TMTSF)_2H_2F_3^-$ crystal has the smallest volume of the unit cell, the Se–Se distances in it are not the shortest (Table 5). The conductivity of this compound at room temperature is 200 Ω^{-1} cm^{-1}, but as the temperature is reduced, it undergoes the metal–dielectric transition (at 64 K).[127]

The salt $(TMTSF)_2ClO_4$ [105,107,118] is the only compound which does not undergo the metal–dielectric transition as the temperature is reduced and at 1.4 K at normal pressures it passes to the superconducting state. The principal difference between $(TMTSF)_2ClO_4$ and all other salts of this series is believed[106] to consist in the fact that the ClO_4^- ion has the smallest effective anionic radius. As a result of this, the interplanar spacings in the cationic stacks of $(TMTSF)_2ClO_4$ (Table 5) are smaller than in the other salts $(TMTSF)_2X$ under normal conditions and are close to the value which arises, for example, in $(TMTSF)_2PF_6$ under a pressure of 12 kbar.

The study of the resistivity[128] and elecronic heat capacity [129] of this salt as a function of the rate of cooling of the specimens showed a difference in its behaviour on rapid and slow cooling. The difference is associated with the fact that during rapid cooling the high-temperature disorder of the ClO_4^- anion persists and the length of the interchain linkage then diminshes[128,129].

The salts $(TMTSF)_2X$ with other anions, differing from those described in size (IO_4^- [110] and TcO_4^- [131]) and symmetry (TeF_5^- [107] and $CF_3SO_3^-$ [126]) are being investigated.

The main difference between $(TMTSF)_2X$ and all other compounds is the presence of layers of TMTSF molecules in them and shortened Se–Se distances between the stacks of individual TMTSF molecules, i.e. the presence of a definite degree of two-dimensional character. Since the interplanar spacings within the stack, d_1 and d_2 (Table 5), are ~3.6 Å (which is greater than the sum of two van der Waals radii of the carbon atom, equal to 3.4 Å),[114] one may conclude that electrical conduction takes place via short Se–Se contacts[132]. In the compounds $(TMTSF)_2X$, where $X = ClO_4^-$, PF_6^-, and AsF_6^-, the Se atoms are arranged in the stack at distances of 3.992, 4.005, and 3.992 Å respectively, while the corresponding distances between different stacks are 3.866, 3.924, and 3.988 Å (Table 5); thus the distances between the stacks are shorter by 0.05 Å (for AsF_6^-), 0.08 Å for (PF_6^-), and 0.126 Å (for ClO_4^-) than within the stack. It has been shown[116] that the structural changes occurring in the salts $(TMTSF)_2X$ on reduction of temperature are highly anistropic: the average distance between the stacks is shortened to a greater extent [116] (Table 5) (on average by a factor of between 1.6 and 2.1 for different anions) than the distances within the stack.

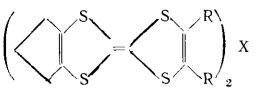
4. Organic Metals Based on Tetramethyltetrathiofulvalene

The observation of the metallic behaviour of the salts $(TMTSF)_2X$ down to low temperatures and of a transition to the superconducting state led investigators to turn to the S-analogues obtained previously[133,134], namely to salts of tetramethyltetrathiofulvalene (TMTTF) with various inorganic anions. Just as the elements S and Se show identical stoichiometries and structures, the structures of the salts $(TMTTF)_2Br$ and $(TMTTF)_2PF_6$ obtained previously[135] are identical with those of the salts $(TMTSF)_2X$; one could therefore expect that the study of the properties of the two series $(TMTSF)_2X$ and $(TMTTF)_2X$ with identical anions would help us to understand the causes of the similarities and differences

observed in the physical properties and to find real experimental parameters correlated with the superconductivity of the compounds. The study of sulphur derivatives has the advantage over the TMTSF salts that the synthesis of the initial compound TMTTF [42] is significantly simpler and does not involve the use of hydrogen selenide or carbon diselenide, which are difficult to obtain and are harmful. TMTTF salts are obtained either chemically[133,134] or electrochemically[136], similarly to the synthesis of TMTSF;[106] both procedures make it possible to obtain salts with the composition $(TMTTF)_2X$.

The oxidation of TMTTF by the halogens I_2, Br_2, and Cl_2 in solution in acetonitrile leads, like that of the unsubstituted TTF, to the formation of a large number of compounds of different compositions, whose conductivities vary within wide limits depending on the degree of charge transfer[133,134]:

Compound	σ, Ω^{-1} cm^{-1}	Compound	σ, Ω^{-1} cm^{-1}
$(TMTTF)_2I$	100	$(TMTTF)_2Br$	200
$(TMTTF)(I_3)_{0.45}$	50	$(TMTTF)Br_{0.8}$	100
$(TMTTF)I_3$	10^{-6}	$(TMTTF)(Br_3)_2$	—
		$(TMTTF)_2Cl$	10



The individual TMTTF chlorides cannot be obtained by the direct oxidation of TMTTF with chlorine, but, using $SOCl_2$ as the oxidant, it is possible to isolate the chloride $(TMTTF)_2Cl$ [137] in the form of long thin needles (together with other reaction products).

By oxidising TMTTF with bivalent copper salts CuX_2 ($X = ClO_4$, BF_4, or NO_3), it is possible to obtain, as in the case of TTF and TMTSF,[82] three types of compounds depending on the reaction conditions (reactant ratio, concentration, and temperature): $(TMTTF)_2X$, (TMTTF)X, and $(TMTTF)X_2$.[82] The anion in CuX_2 must be capable of coordinating to Cu(I) less strongly than CH_3CN and be displaced by the latter from the coordination sphere of Cu(I).[81,82] Otherwise, TMTTF salts with a complex copper-containing anion are formed[138].

When TMTTF is oxidised by the inorganic salts $HgCl_2$,[139] $CuCl_2$,[138] and $MoCl_5$,[140] as for TTF and DBTTF,[96,97] an anion is formed, during the reaction in solution, whereupon crystals appear of both products with partial charge transfer of the type of $(TMTTF)_{1.25}Hg_2Cl_5^-$ with $\sigma = 10\ \Omega^{-1}$ cm^{-1} and $(TMTTF)_2CuCl_2$ with $\sigma = 1\ \Omega^{-1}$ cm^{-1} and compounds having the compositions $(TMTTF)HgCl_2$ and $(TMTTF)CuCl_3$ with $\sigma = 10^{-7}\ \Omega^{-1}$ cm^{-1}, in which complete charge transfer has taken place[138,139].

It is noteworthy that TMTTF complexes with partial charge transfer are, as it were, intermediates in the oxidation of TMTTF by inorganic salts and their isolation depends on the concentrations and ratio of the initial components. Thus, when TMTTF reacts with a 2.5-fold excess of $HgCl_2$ at the concentration $[TMTTF] = 2 \times 10^{-2}$ M, the radical-ion salt $(TMTTF)_{1.3}Hg_2Cl_5$ is formed; when the reactant ratio is smaller, the unreacted orange initial TMTTF is precipitated. Recrystallisation of $(TMTTF)_{1.3}Hg_2Cl_5$ from acetonitrile leads to further oxidation of TMTTF and the formation of the radical-ion salt $(TMTTF)(HgCl_3)$ and calomel. The interaction of TMTTF with $HgCl_2$ in dilute acetonitrile solutions at the concentration $[TMTTF] = 3 \times 10^{-1}$ M and the same reactant ratios does not lead to the product of the partial oxidation of TMTTF, the radical-cation salt $(TMTTF)HgCl_3$ being formed immediately and then crystallising in different modifications [139]. When TMTTF is oxidised by $CuCl_2$, the intermediate compound $(TMTTF)_2CuCl_2$ with partial charge transfer is formed and its formation is followed (possibly as a result of the catalytic oxidation of the $CuCl_2^-$ anion by atmospheric oxygen) by that of the anion $CuCl_3^-$ and of the corresponding radical-cation salt $(TMTTF)CuCl_3$, with complete charge transfer, in two modifications[138].

Preliminary studies of the salts of dimethyl-substituted TTF have shown that dimethyltetrathiofulvalene preferentially forms salts with inorganic anions having 2:1 or 1:1 compositions[110,147]. The conductivity of the latter is 50–300 Ω^{-1}cm^{-1} and there is a metal-dielectric transition at ~200 K. Asymmetric TTF derivatives also give rise to salts having the composition

where R = H or CH_3 and X are various fluorine-containing anions or ClO_4^-,[148,149].

From the standpoint of the study of physical properties, TMTTF salts having the composition $(TMTTF)_2X$ are of greatest interest, as for $(TMTSF)_2X$. The salts $(TMTTF)_2X$ are isostructural with the compound $(TMTSF)_2X$.[141] The degree of charge transfer in these salts, is determined, as for $(TMTSF)_2X$, by the valence state of the anion X^- and, for singly charged anions of the type BF_4^-, NO_3^-, PF_6^-, ClO_4^-, etc. the degree of charge transfer from each TMTTF and TMTSF molecule is 0.5; thus the conductivity band in $(TMTTF)_2X$ and $(TMTSF)_2X$ is three-quarters filled.

However, at normal pressures, the behaviour of the salts $(TMTTF)_2X$ differs from that of their selenium analogues[141]. Structurally the salts $(TMTTF)_2X$ are built up like the salts $(TMTSF)_2X$. The principal structural details can be seen in Fig.5, which represents the structure of the salt $(TMTTF)_2PF_6$.[135] Evidently here we have the same zigzag arrangement of the TMTTF molecules in the stack with a shift equivalent to one quarter of the length of the molecule along the conducting axis of the crystal (Fig.5*a*) and the stacks are arranged in individual layers (Fig.5*b*), while the PF_6^- anions are accommodated between layers of TMTTF molecules. However, the sulphur and selenium compounds differ significantly from one another in the distances between the individual molecular stacks in the layer.

In the salts $(TMTTF)_2X$ the interaction between neighbouring stacks in the layer can take place effectively via sulphur atoms in close proximity. Each TMTFF molecule has two sulphur atoms which are closest to the sulphur atoms of the next molecule. Table 6 presents the distances within the stack of TMTTF molecules (d_1 and d_2) and the S–S distances between neighbouring stacks. Evidently, these distances differ significantly for salts with different anions. The S–S distances within the stacks are not the same and differ slightly, i.e. the packing of the TMTTF molecules in the crystal is somewhat dimeric[136].

Table 6. Distances between TMTTF stacks (d_0) and within the TMTTF stacks (d_1 and d_2) for $(TMTTF)_2X$ salts[141].

Anion	Br^-	I^-	PF_6^-	ClO_4^-	BF_4^-	NO_3^-	SCN^-
d_0, Å	3.73	3.80	3.99	3.99	3.88	3.79	4.01
d_1, Å	3.53	3.54	3.62	3.59	3.56	3.56	3.56
d_2, Å	3.50	3.50	3.52	3.52	3.54	3.50	3.49
d_1-d_2, Å	0.03	0.04	0.10	0.07	0.02	0.06	0.07

All the interplanar spacings within the stack are less than the van der Waals radius of the sulphur atom, which is 3.6 Å. On the other hand, the S–S distances between the stacks are greater than 3.6 Å for all the salts $(TMTTF)_2X$ (Table 6).

Thus, these compounds are more one-dimensional than their selenium analogues. This is in fact responsible for the differences between the physical properties of the salts $(TMTSF)_2X$ and $(TMTTF)_2X$. The salt $(TMTTF)_2Br$, which has the smallest S–S distances and is least dimerised, is characterised by the highest conductivities among the series of compounds $(TMTTF)_2X$ (Table 7).

Table 7. Characteristics of the tetramethyltetrathiofulvalene salts $(TMTTF)_2X$ with different inorganic anions[136,141].

Anion	Cl^-	Br^-	I^-	PF_6^-	ClO_4^-	BF_4^-	NO_3^-	SCN^-
σ^*, Ω^{-1} cm^{-1}	10**	240	100	40	40	50	95	40
T_{max}, K	—	100	215	230	228	210	210	250
$\sigma_{max}/\sigma_{300}$	—	3.8	1.23	1.1	1.10	1.23	1.3	1.06
T_t, K	—	19	—	15	75; 10	41	160	—
T_t(K)/p(kbar)		24/25	10/30	30/30	—	—	—	—

Notation: T_{max} is the temperature at which the maximum conductivity of the specimen is observed; $\sigma_{max}/\sigma_{300}$ K is the ratio of the maximum conductivity to the conductivity at room temperature; T_t is the metal-dielectric transition temperature; T_t/p is the temperature of the phase transition in the specimen at a pressure p.

* At 300 K.

** According to the data of Zhilyaeva et al[137].

The salts $(TMTTF)_2X$ have significantly lower conductivities at room temperatures ($\sigma = 40$–300 Ω^{-1} cm^{-1}) (Table 7) compared with the conductivities of the salts $(TMTSF)_2X$. When the temperature is reduced, the conductivity of $(TMTTF)_2X$ initially increases slightly (Table 7) up to 210–250 K and then begins to fall. An appreciable increase of conductivity (by a factor of 3.8) is observed only for $(TMTTF)_2Br$ and its decrease begins at 100 K.

Different types of behaviour, depending on the structure of the anion, are characteristic of the salts $(TMTTF)_2X$, as for $(TMTSF)_2X$.

The salt with the non-centrosymmetric anion SCN^- undergoes a sharp metal-dielectric transition at 160 K.[141] Some change in conductivity of $(TMTTF)_2ClO_4$ is observed at 75 K; this transition is manifested clearly in measurements of the magnetic susceptibility and heat capacity. The conductivity curves for the salts $(TMTTF)_2BF_4$ and $(TMTTF)_2NO_3$ show no distinct transitions but, in the measurement of the magnetic susceptibility and heat capacity of $(TMTTF)_2BF_4$, a transition is clearly shown at 40 K.[141]

It has been shown[142] that the phase transitions observed for all the salts $(TMTTF)_2X$ with tetrahedral anions are not of the Peierls type and are more probably associated with the ordering of the anionic sublattice, which is manifested in the study of various physical properties of these salts.

Among the salts with centrosymmetric anions, only $(TMTTF)_2Br$ shows a clear phase transition at 19 K, while the transition of $(TMTTF)_2PF_6$, determined from magnetic susceptibility measurements, is at 15 K.

A correlation has been found[141] between the conductivities of the salts $(TMTTF)_2X$ and the S–S distances for salts with different anions: $Br^- > NO_3^- > I^- > BF_4^- > ClO_4^- > PF_6^- > SCN^-$ (Tables 6 and 7).

The physical properties of the salts $(TMTTF)_2X$ change abruptly when pressure is applied. The conductivities of the salts $(TMTTF)_2BF_6$ and $(TMTTF)_2ClO_4$ increase sharply up to 10^5 Ω^{-1} cm^{-1} at pressures up to 30 kbar and the metal–dielectric transition is observed at the very low temperatures of 10 and 30 K respectively (Table 7). The metallic state of $(TMTTF)_2Br$ under pressure is stabilised down to the very lowest temperatures and its conductivity reaches 10^6 Ω^{-1} cm^{-1} before the metal-dielectric transition. The influence of pressure on the properties of $(TMTTF)_2Br$ is extremely complex. At 22 kbar the metallic state is stabilised down to 10 K, after which there is a transition to the dielectric state. The same specimen under a pressure of 25 kbar does not undergo the transition to the dielectric state and may pass to the superconducting state[136,141,142]. However, all these effects change very markedly from specimen to specimen; when the temperature is reduced, some of their crystals at atmospheric pressure exhibit an increase of conductivity by a factor of 400. These characteristics of the behaviour of the salt $(TMTTF)_2Br$ have been studied in detail[142].

The behaviour of the salts $(TMTTF)_2X$ after the application of pressure can be explained by their significantly greater one-dimensional character[141,142] compared with $(TMTSF)_2X$; the salts $(TMTTF)_2X$ therefore exhibit only under pressure the properties characteristic of the salts $(TMTSF)_2X$ at atmospheric pressure.

5. Organic Metals Based on Bis(ethylenedithiolo)tetrathiofulvalene

A report has been published recently on the synthesis of a new class of organic superconductors based on bis(ethylenedithiolo)tetrathiofulvalene (BEDT-TTF).[33] It had been stated earlier[47] that the radical-ion salt BEDT-TTF.TCQM has a very high conductivity ($\sigma = 40$ Ω^{-1} cm^{-1}) for a pressed specimen. The first salt of this electron donor with an inorganic anion was obtained[143] by the electrochemical oxidation of BEDT-TTF in methylene chloride and has the composition $(BEDT\text{-}TTF)_2ClO_4.0.5CH_2Cl_2$. Its conductivity at room temperature is 25–30 Ω^{-1} cm^{-1}; as the temperature is reduced, σ increases, reaching 1000 Ω^{-1} cm^{-1} at 16 K, and then diminishes slightly but remains high at the helium temperatures: $\sigma = 650$ Ω^{-1} cm^{-1} at 1.4 K.[143] The anisotropy of the conductivity of the specimen is $\sigma_\parallel/\sigma_\perp = 0.9$ at room temperature, diminishing somewhat (down to 0.4) at 3 K. This enabled the authors[143] to claim that the compound is dimeric, which has been confirmed by structural studies[144]. The distance between the BEDT-TTF molecules within the stack is fairly large, but the S–S distances between neighbouring stacks are extremely short, amounting to 3.3–3.45 Å (compared with the van der Waals radius of the sulphur atom of 3.6 Å), which is responsible for the highly two-dimensional character of this compound. The superconducting transition has not so far been observed for this compound, but its conductivity remains metallic down to 1.4 K. This is the first observation of the metallic properties of an electron-donating sulphur-containing compound down to such a low temperature[143].

BEDT-TTF salts with various inorganic anions have been obtained by the electrochemical oxidation of BEDT-TTF in tetrahydrofuran (THF);[33] the BEDT-TTF salts with the ReO_4^- anion exhibit the most interesting properties. Compounds of several compositions, namely the thin acicular crystals of $(BEDT\text{-}TTF)(ReO_4)_2.THF$ and the lamellar crystals of the two salts $(BEDT\text{-}TTF)_4(ReO_4)_2$ and $(BEDT\text{-}TTF)_6(ReO_4)_4$, whose composition does not include the solvent, were obtained in the course of electrochemical oxidation. All the salts obtained

have different conductivity properties. Among these compounds, the salt $(BEDT\text{-}TTF)_4(ReO_4)_2$ is a superconductor with the superconducting transition at 2 K and a pressure of 4 kbar. It is of interest that the structure of this salt is very similar to that of $(TMTTF)_2X$ and $(TMTSF)_2X$. The BEDT-TTF molecules are also arranged in a stack in a zigzag fashion along the conducting axis and form layers made up of BEDT-TTF molecules between which the ReO_4^- anions are accommodated. The S–S distance along the stack is significantly longer than between individual stacks in the layer. However, there are differences: (1) the methylene groups CH_2 are displaced from the plane of the main molecules; (2) the ReO_4^- anions are ordered at room temperature, in contrast to the salts $(TMTSF)_2ReO_4$ or $(TMTTF)_2ReO_4$. The conductivity of $(BEDT\text{-}TTF)_4(ReO_4)_2$ at room temperature and at the usual pressure is 200 Ω^{-1} cm^{-1}, while on decrease of temperature the metal-dielectric transition takes place.

Thus yet another class of organic superconductors based on a sulphur-containing electron donor has been discovered[33]. According to preliminary data, the selenium analogue bis-(ethylenediseleno)tetraselenofulvalene (BEDT-TTSF), obtained by the same authors[145], give rise to 1:1 salts as a result of the electrochemical reaction in the presence of the ReO_4^- and ClO_4^- anions, the conductivities of single crystal specimens amounting to 10^{-1}–10^{-2} Ω^{-1} cm^{-1}. The authors noted the very low solubility of BEDS-TSF and the difficulties in electrocrystallisation associated with this factor.

---oOo---

The data described show that the compounds based on tetrathiofulvalene derivatives examined here can give rise to salts with a wide range of properties—from a dielectric to a superconductor. However, the metallic state characteristic of these salts over a certain range of temperature is frequently unstable and the metal–dielectric transition takes place. The main task, namely the preparation of an organic semiconductor or an organic metal stable down to the very lowest temperatures, is therefore still far from being solved.

Theory shows that the metallic state cannot be stabilised in a one-dimensional system. Quasi-one-dimensional systems with a certain amount of two-dimensional or three-dimensional character are necessary. The metallic state in such systems can be unstable in relation to the superconducting transition and the compound can become a superconductor under appropriate conditions.

As shown above, the amount of three-dimensional character in quasi-one-dimensional organic metals can be increased by applying pressure. This can lead in its turn to partial or complete suppression of the low-temperature transition to the dielectric state.

However, the greatest possibilities in this respect arise in synthetic chemistry. The introduction of four (and even two) methyl groups into the TTF molecule makes it possible to obtain qualitatively new compounds having the composition $(TMTTF)_2X$, differing in their structure from the non-stoichiometric compounds $(TTF)X_n$, for which the 2:1 composition cannot be obtained.

Simple replacement of the S atom by the Se atom in the TMTTF molecule makes it possible to increase the degree of interaction between the stacks in the quasi-one-dimensional metal, i.e. to increase the amount of two-dimensional or three-dimensional character of the compound without altering the structure of the compound as a whole. This is apparently the cause of the appearance of superconductivity following the application of pressure to the salts $(TMTSF)_2X$, where $X = PF_6^-$, AsF_6^-, TaF_6^-, SbF_6^-, ReO_4^-, or FSO_3^-, while the compound $(TMTSF)_2ClO_4$ undergoes the superconducting transition at 1.4 K even at atmospheric pressure.

The increase of the number of sulphur atoms in the structure of the cation made possible in its turn the synthesis of the first superconductor based on a sulphur-containing donor: $(BEDT\text{-}TTF)_4(ReO_4)_2$.

By selecting the appropriate anion, it is possible to vary widely the physical properties in a single series of compounds. In conformity with the correlation found[131] between the unit cell parameters and the superconducting properties of the salts $(TMTSF)_2X$, it has been suggested that the salts of TMTSF with the POF_2^- anion or with the mixed anions ClO_4^-–BF_4^-, etc. may have properties closest to those of the superconducting salt $(TMTSF)_2ClO_4$.

Characteristic Features of the Polymerisation of Acetylene and Its Derivatives

A.A.Matnishyan and V.M.Kobryanskii

The requirements which must be met by polymers with a conjugation system, used as organic semiconductors, are analysed. The characteristic features of ionic, radical and stereospecific polymerisation of acetylene and its derivatives are considered and the mechanisms of the destruction of the active centres in the ionic polymerisation as well as the methods of preparation of high-molecular-weight polymers are discussed.
The bibliography includes 52 references.

III. Conclusion 755

I. INTRODUCTION

The polymerisation of acetylene and its derivatives is one of the fundamental methods for the synthesis of polymers with a conjugation system (PCS), which are beginning to be used at the present time as organic semiconductors and metals. Studies on the creation of organic semiconductors based on PCS can be referred to two periods. During the first period (from the beginning of the 1950s until the middle 1970s), hundreds of PCS of different structure were synthesised and extensive experimental data on their properties were accumulated. The polymers obtained had a whole series of interesting physicochemical and electrophysical characteristics. Some of them have found practical applications as thermostable materials and stabilisers in relation to the thermo-oxidative degradation of saturated polymers[1-7]. The work of A.A.Berlin has made an enormous contribution to the development of this field. During this period, the first semiconductor devices and photosensitive materials were created. However, the properties of the PCS did not satisfy the requirements of modern electronics, for which much more ordered polymers with a much higher molecular weight, forming films or crystals, are essential. The materials developed did not therefore find extensive practical applications.

The beginning of the second period of the synthesis of organic semiconductors and metals based on PCS is associated with the work of Wegner, Shirakava, and Heeger.

In 1968–1971 Wegner[8-10] demonstrated for the first time the possibility of creating polyconjugated single crystals based on substituted diacetylenes. The polymerisation was carried out in the solid phase with thermal, thermochemical, and radiation initiation. Later, whole series of single crystals of polydiacetylenes of different structure were synthesised. The study of the electrophysical and optical characteristics of the polymers obtained showed that they can be used as materials for non-linear optics. It was also shown that they are semiconductors with a high mobility of charge carriers. According to the estimates of different workers, the mobility of the carriers is in the range 10^3–10^5 $cm^2 V^{-1} s^{-1}$.

In 1971–1975 Shirakava and co-workers[11-13] were the first to synthesise a free highly ordered polyacetylene film on the surface of the $Al(C_2H_5)_3$–$Ti(OBu)_4$ catalytic system. The authors showed that a film in the *cis*-form is formed at −78 °C. Isomerisation to the more stable *trans*-form takes place either directly during the synthesis or during subsequent heat treatment. The films obtained have a metallic lustre and a conductivity between 10^{-9} Ω^{-1} cm^{-1} (for the *cis*-form) and 10^{-5} Ω^{-1} cm^{-1} (for the *trans*-form).

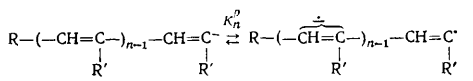
In 1977–78 Heeger and co-workers[14,15] established that the conductivity of polyacetylene films doped with powerful electron donors or acceptors increases by 12 orders of magnitude (from 10^{-9} Ω^{-1} to 10^3 Ω^{-1} cm^{-1}). The conductivity of an oriented polyacetylene film doped with AsF_5 was found to be 2×10^3 Ω^{-1} cm^{-1}.

These studies aroused enormous interest among physicists and chemists working in the field of organic semiconductors. They demonstrated the possibility, in principle, of creating organic metals and semiconductors whose properties are comparable to those of the corresponding inorganic materials. During this period, the number of studies on the synthesis and properties of PCS began to increase sharply. At the present time, many laboratories both in this country and abroad are engaged in research into this field. During recent years, a whole series of PCS which exhibit metallic conductivity on doping with powerful electron donors or acceptors have been synthesised. These are polyacetylene[11-15], polyphenylene[16-18], polypyrrole[19,20], poly(phenylene sulphide)[21,22], and polyheptadiyne[23]. This list is probably incomplete because the search for new polymers is still being continued. The study of the electrophysical characteristics of these polymers showed that, depending on the nature and concentrations of the doping agents, it is possible to obtain *n*- and *p*-type semiconductors or materials with metallic conductivity, which can find practical applications in new semiconductor devices, energy photoconverters, and organic accumulators and in the future also as substitutes for metals.

Analysis of the literature data shows that PCS must satisfy certain requirements in their practical utilisation as organic semiconductors and metals.

1. The polymers must have high molecular weights and must have a continuous conjugation chain.
2. The polymers must form films or crystals which are homogeneous and whose mechanical characteristics and purity satisfy the requirements of modern electronics.
3. In order to obtain specified electrophysical characteristics, it is essential to introduce into the polymers powerful electron donors and acceptors, which must be distributed uniformly throughout the bulk of the materials.
4. A high conductivity can be expected only for PCS in which the chemical structure and superstructure do not prevent intermolecular interactions.

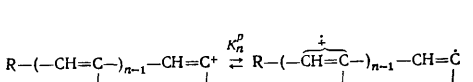
5. The materials synthesised must retain their mechanical and electrophysical characteristics for a long time.



This review analyses the characteristic features of the polymerisation of acetylene and its derivatives and prsents certain experimental results in the synthesis of PCS.

II. POLYMERISATION METHODS

As already stated, studies on the polymerisation of monomers with a triple bond have been prosecuted since the end of the 1950s. In recent years a number of new original and review publications have appeared on the synthesis of PCS.[24–29] Analysis of the experimental results for the synthesis of high-molecular-weight polymers permits the conclusion that the classical methods of ionic and radical polymerisation do not lead to high-molecular-weight PCS; the latter can be obtained only in the presence of certain complex catalysts and variable-valence metal salts.



1. Ionic Polymerisation

We shall consider in greater detail the mechanism of the ionic polymerisation of acetylene derivatives. It follows from the literature data compiled in a review[24] that the anionic and cationic polymerisations of acetylene derivatives lead to the formation of polymers with a degree of polymerisation $n \cong 10$. In a study of the anionic polymerisation of phenylacetylene in the presence of butyl-lithium in hexamethylphosphoramide we showed[30,31] that the low molecular weight of the polyphenylacetylene formed is associated with electron transfer from the active centre to the conjugated chain:

This reaction results in the formation of a radical at the end of the chain and a radical-anion delocalised over the conjugation chain. Subsequently the radical is destroyed via a linear or quadratic mechanism, while the radical-anion is detected by ESR for a long time. The equilibrium constant of this reaction depends on the electron affinity of the radical formed and of the conjugated chain. The electron affinity of the radical is independent of the chain length, because the orbital in which it is located is orthogonal with respect to the orbitals of the conjugated chain. On the other hand, the electron affinity of the conjugated chain increases with chain length[32]. The probability of electron transfer (or the isomerisation of the active centres) should therefore increase with increasing degree of polymerisation.

Analogous features have been observed also in the cationic polymerisation of acetylene derivatives with the sole difference that the electron is transferred from a polyene chain to an active centre with formation of a radical at the end of the chain and a radical-cation delocalised over the conjugation system:

The equilibrium constant of this reaction depends on the difference between the ionisation potentials of the polyene chain and the radical formed. The ionisation potential of the radical is independent of chain length, while that of the conjugation system decreases with increasing chain length[32]. In the cationic polymerisation of acetylene derivatives the probability of electron transfer (the isomerisation of active centres) should therefore also increase with increasing degree of polymerisation.

The equilibrium constants of the electron transfer reactions in the anionic and cationic polymerisation of acetylene and phenylacetylene, calculated from data quoted in a handbook[32], are listed in Table 1. Evidently the anionic and cationic polymerisation of acetylene should be accompanied by the isomerisation of the active centres already in the first 2–3 units. In the polymerisation of phenylacetylene the isomerisation of the active centres should begin after the attainment of a degree of polymerisation $n \cong 5$–10. The increase of the degree of polymerisation on passing from acetylene to phenylacetylene is associated with the fact that the benzene ring stabilises the ion at the end of the chain.

The kinetics of the ionic polymerisation of acetylene derivatives have been analysed[33] taking into account the isomerisation reactions of the active centres and it was shown that the molecular weight distribution of the polymers formed is described by the equation

$$\rho(n) = f(n) \cdot \left(\prod_{i=1}^{n} \frac{1}{1+f(i)} \right), \qquad (1)$$

where $f(n) = (k_t/k_p M) K_n^p$, k_t is the rate constant for the linear termination of radicals, k_p the chain propagation rate constant, M the concentration of the monomer, and K_n^p the equilibrium constant of the electron transfer reaction.

Table 1. The equilibrium constants of the electron transfer reaction.

n	Anionic polymerisation		Cationic polymerisation	
	polyacetylene	polyphenylacetylene	polyacetylene	polyphenylacetylene
2	$7.95 \cdot 10^{-11}$	$7.85 \cdot 10^{-19}$	$2.35 \cdot 10^{2}$	$7.9 \cdot 10^{-13}$
3	$1.58 \cdot 10^{-9}$	$6.41 \cdot 10^{-12}$	$5.26 \cdot 10^{8}$	$3.3 \cdot 10^{-6}$
4	$1.7 \cdot 10^{12}$	$4.16 \cdot 10^{-8}$	$5 \cdot 10^{27}$	$4.55 \cdot 10^{-2}$
5	$4 \cdot 10^{17}$	$5 \cdot 10^{-5}$	—	$2.2 \cdot 10^{1}$
6	—	$9.5 \cdot 10^{-4}$	—	$1.05 \cdot 10^{3}$
7	—	$1.41 \cdot 10^{-2}$	—	$1.59 \cdot 10^{4}$
8	—	$9.7 \cdot 10^{-2}$	—	$1.1 \cdot 10^{5}$
9	—	0.312	—	—
10	—	2.16	—	—

Table 2 lists the number-average ($\bar{\Pi}_n$), weight-average ($\bar{\Pi}_w$), and z-average ($\bar{\Pi}_z$) degrees of polymerisation and the ratios $\bar{\Pi}_w/\bar{\Pi}_n$ and $\bar{\Pi}_z/\bar{\Pi}_w$ calculated by Eqn.(1) for the anionic polymerisation of phenylacetylene. Table 2 shows that, regardless of the ratio of the chain termination and propagation rate constants, low-molecular-weight polymers with a narrow weight distribution are formed. An increase of molecular weight can be achieved by decreasing the termination rate constant or by introducing into the acetylene molecule a substituent which stabilises the ion on the end of the chain.

From the ionic polymerisation scheme discussed above, it follows that the formation of high-molecular-weight polymers is possible only in the absence of the isomerisation reactions of the active centres. One of the possible polymerisation pathways without the isomerisation of the active centres may involve the formation of complexes with a conjugation

system directly in the course of chain propagation. We shall examine the mechanism of such a process in relation to the cationic polymerisation of acetylene derivatives. The reaction system should contain, apart from the monomer and initiator, the molecules of a powerful electron acceptor capable of forming stable donor–acceptor or radical-ion complexes with the polyene chain. In this case the propagation of the conjugation chain will be accompanied by the formation of complexes between the macromolecules and the acceptor molecules in which the electron density is displaced in the direction away from the polyene chain. Such macromolecules are incapable of giving up an electron to the active centre. In the prence of a sufficient number of electron acceptor molecules the cationic polymerisation should therefore proceed without the isomerisation of the active centres. Since strong Lewis acids behave simultaneously as electron acceptors and initiators of cationic polymerisation, when the process described above is carried out with their participation there is no need to employ an initiator and a separate complex-forming agent. The polymerisation is performed in the presence of large amounts of Lewis acids and the rate of initiation is regulated by introducing a specific amount of a cocatalyst. It is only necessary that the formation of complexes between the Lewis acids and the monomer should not prevent the chain propagation reaction.

Table 2. Parameters of the anionic polymerisation of phenylacetylene*.

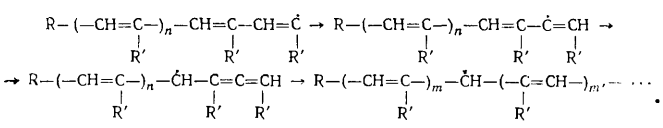
*E_R = electron affinity of the radical formed on electron transfer.

An analogous process can be carried out also in the anionic polymerisation of acetylene derivatives but in this case powerful electron donors must be used as substances functioning simultaneously as an initiator and a complex-forming agent. Such substances can be alkali metals.

Analysis of the model kinetics of ionic polymerisation with complex formation shows that the molecular weight distribution of the polymers formed is described by the equation

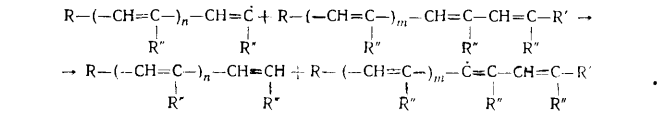
$$\rho(n) = f(n) \cdot \left[\prod_{i=1}^{n} \frac{(1 + K_{n-1}^{K})}{(1 + K_n^{K}) + f(i)} \right], \qquad (2)$$

where K_n^C is the complex formation equilibrium constant. It follows from Eqn.(2) that, when the equilibrium complex formation constant K_n^C is much greater than the equilibrium constant of the electron transfer reaction K_n^D, the polymerisation proceeds without the isomerisation of the active centres.



The possibility of obtaining polyacetylene films doped with AsF_5 directly in the course of the synthesis was first demonstrated in 1980.[34] The process was carried out by mixing gaseous acetylene and AsF_5 at different pressures and temperatures. Using an analogous procedure, we synthesised[35,36] SbF_5-doped films of polyacetylene and polyvinylacetylene with conductivities up to $10^{-2}\ \Omega^{-1}\ cm^{-1}$; the study of the polymerisation of vinylacetylene in the presence of various acceptors showed that the yield of the polymer decreases in the following sequence: $SbF_5 > H_2SO_4 > TiCl_4 > SnCl_4 >$ polyphosphoric acid[35,36].

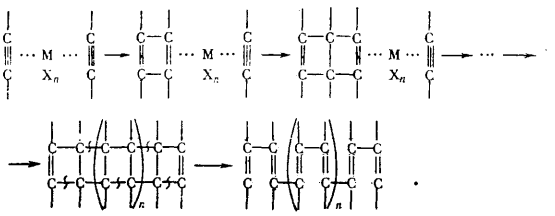
The results show that the ionic polymerisation of acetylene derivatives in the presence of large amounts of a complex-forming agent is likely to be useful for the synthesis of organic semiconductors and metals because the complex formation process virtually constitutes doping of the polymer and makes it possible to obtain in a single stage highly conducting materials in the form of films. Such processes can be readily carried under technological conditions and make it possible to obtain films on various surfaces.



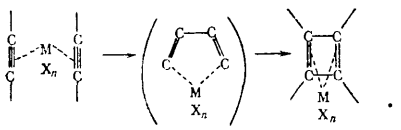
2. Radical Polymerisation

We believe that the radical polymerisation of acetylene derivates suffers from no fundamental limitations to the formation of high-molecular-weight polymers. However, it is known[6] that PCS are effective inhibitors of thermal and thermo-oxidative degradation, i.e. exhibit an enhanced affinity for radicals. In the radical polymerisation of acetylene derivatives there is therefore a possibility of the occurrence of side reactions the most important of which are as follows:-

(a) intramolecular isomerisation of the chain propagating radical:



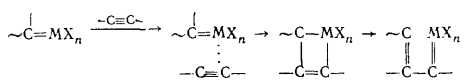
(b) intermolecular interaction of the chain propagating radical with the conjugated macromolecule via an addition or substitution mechanism:



During these reactions, radicals delocalised over the conjugated system are formed and chain propagation ceases. The contribution of these reactions to the polymerisation process depends on the chemical structure of the monomer, the concentration, the temperature and the state of aggegation. The most suitable process for the formation of high-molecular-weight polymers is probably solid-phase polymerisation at low temperatures such as the polymerisation of single crystals of substituted diacetylenes. In solution, high-molecular-weight polymers are formed only when the polymerisation is accompanied by breaks in the conjugation in the system. For example, the polymerisation of vinylacetylene monomers[37,38] proceeds statistically at the double bond in the 1–4 positions. The breaks in the conjugation chain make it possible to obtain polymers with molecular weights of 10^4–10^6.[39,40] Subsequent heat treatment leads to rearrangements and the formation of a conjugated polymer.

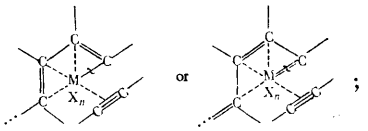
3. Polymerisation of Acetylene and Its Derivatives in the Presence of Complex Catalysts and Variable-Valence Metals

There are few literature data on this problem, but the existing results suggest that, in the presence of these catalytic systems, the possibility of obtaining high-molecular-weight polymers is also associated with the absence of isomerisation reactions of the active centres. The polymerisation of phenylacetylene in the presence of metal carbonyls and various additives has been investigated[41-43]. The authors suggested that the chain propagation proceeds with formation of four-membered rings, which then isomerise to a polyconjugated polymer via the mechanism

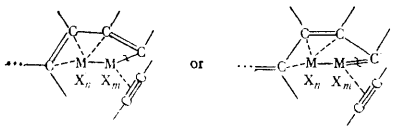


This mechanism is based on data concerning the formation of cyclobutadiene complexes in the presence of metal carbonyls. For example, it has been shown[47] that diphenylacetylene forms a cyclobutadiene complex in the presence of derivatives of iron tricarbonyl:

In the course of the reaction it is sometimes possible to detect intermediates. It is seen from the above scheme that the formation of high-molecular-weight polymers is associated with the formation of non-conjugated ladder macromolecules in the first stage.



An intereresting polymerisation mechanism has been proposed in a large series of studies by Masuda and co-workers[28,29,45-47], who investigated the polymerisation of acetylene derivatives in the presence of various metal chlorides and carbonyls. They showed that the polymerisation of phenylacetylene in the presence of $W(CO)_6$ in CCl_4 under the influence of ultraviolet radiation makes it possible to obtain polymers with a molecular weight $\overline{M}_n \cong 80\,000$–$100\,000$, while 2-chlorophenylacetylene gives rise to polymers with $\overline{M}_w \cong 400\,000$ in the presence of $Mo(CO)_6$ under ultraviolet irradiation. The same workers showed that, by selecting the appropriate solvent, it is possible to obtain a polyphenylacetylene with $\overline{M}_n \cong 100\,000$ also in the presence of metal chlorides and their complexes. It has been suggested that the polymerisation proceeds via a stage involving the formation of a four-membered metal-containing cyclobutene unit:



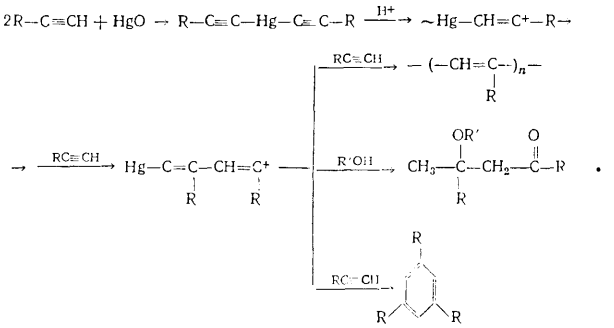
We believe that the formation of high-molecular-weight polymers in the polymerisation of acetylene derivatives in the presence of complex catalyst and variable-valence metals is associated with the tendency of the polyconjugated macromolecules formed to produce donor–acceptor complexes. It has already been stated than an increase in the conjugation chain length entails a decrease of the ionisation potential and an increase of the electron affinity of the macromolecules.

Therefore, regardless of the nature of the active centre and its linkage with the catalyst, the growing macromolecule also tends to form a coordinate bond with the catalyst. The strength of this bond should increase with increasing chain length.

In order to obtain high-molecular-weight polymers, it is necessary that the complex formed should not prevent the chain propagation reaction. Otherwise, cyclobutadiene and benzene derivatives or low-molecular-weight polymers are formed. The reaction complex can be illustrated schematically as follows:-

(3)

(4)



In such a complex the active centre is fixed on the catalyst via an additional coordinate bond with the conjugated system, which prevents its isomerisation and destruction. The available scattered literature data[48,49] concerning the structure of such complexes suggest that the preferential formation of high-molecular-weight polymers is observed when the catalytic centre contains several metal atoms [see Scheme (4)]. On the other hand, if the catalytic centre contains one metal atom, then low-molecular-weight products are formed [see Scheme (3)].

We investigated the polymerisation of acetylene, vinylacetylene, and their derivatives in the presence of palladium salts, mercury(II) oxide in conjunction with Lewis acids, and Ziegler and Latinger catalysts[50].

The catalytic system based on soluble palladium salts with ligands (pyridine and dimethylformamide) ensures a high yield of polymers in the polymerisation of propargyl derivatives, particularly with electron-accepting substituents[51,52]. The polymers obtained from bromo-substituted propargyl derivatives and their copolymers with diethylbenzene and divinylethynylmethanol have a conductivity of 10^{-8}–10^{-4} Ω^{-1} cm^{-1}. The covalently bound bromine atom in these polymers is apparently fairly labile and can be split off directly in the course of synthesis, forming complexes with the conjugation system.

The catalytic system consisting of a mixture of mercury(II) oxide and Lewis acids initiates a process which combines the features of ionic and coordination polymerisation. It proved to be effective in the polymerisation of acetylene and its derivatives. The polymerisation of acetylene in the presence of the homogeneous mercury(II) oxide–boron trifluoride etherate catalytic system has been studied for various component ratios. A soluble complex with an absorption maximum at 390 nm is formed in the first stage. At a concentration of the components of 10^{-4} M, the formation of a complex is observed immediately after the addition of the acetylene solution. The polymer is precipitated as a red-brown deposit which blackens on standing and contains residues of the catalyst. In the polymerisation of gaseous acetylene in the presence of a layer of catalysts deposited on a support, it was possible to grow films several millimetres thick. The polymerisation of vinylacetylene in the presence of the same catalytic system begins at a temperature as low as −70 °C. The yield of the polymer increases with increase of temperature.

Despite their inertness, propargyl derivatives polymerise almost quantitatively and the first stage involves the formation of mercury bisacetylides, which subsequently catalyse the polymerisation[50]. The polymerisation of phenylacetylene also proceeds via a stage in which mercury bisacetylide is formed. The mercury bisacetylide isolated is soluble in the monomer and has a high catalytic activity. It has been suggested that the polymerisation proceeds via a cationic mechanism. The formation of a σ-complex of mercury with the acetylenic bond loosens the latter and facilitates attack by the proton. In a simplified form the process can be represented by the following scheme:

In the presence of alcohol, it was possible to isolated the dimeric cation termination product, namely 3-methoxy-1,3-diphenyl-1-butanone, which confirms the validity of the above scheme.

It has been shown[27] that the $Co(NO_3)_2$–$NaBH_4$ catalytic system makes it possible to obtain a highly ordered polyacetylene, the degree of crystallinity of which is higher than that of the substance obtained by the Shirakava method. Polyacetylene films of any size on various surfaces can be obtained in the presence of this system†.

III. CONCLUSION

The data examined in this review show that a qualitative leap forward has been achieved in recent years as regards the creation of organic semiconductors and metals based on polymers with a conjugated system. Methods have been developed for the preparation of polymers in the form of films whose conductivity increases by 10–16 orders of magnitude after the interaction of powerful electron donors or acceptors. The electrophysical characteristics of polyacetylene, polyphenylene, and certain other polymers already make it possible to devise on their basis accumulators, photoconverters, and semiconductor devices.

Analysis of the mechanisms of the ionic, radical, and stereospecific polymerisation of acetylene derivatives has shown that the destruction of the active centres is associated with a decrease of the ionisation potential and an increase of the electron affinity of the polymer chain. Ionic polymerisation in the presence of a complex-forming agent and polymerisation in the presence of metal complex catalysts are most promising for the preparation of organic semiconductors and metals. The results presented suggest that procedures for the preparation of organic semiconductors whose parameters will enable them to compete with the corresponding inorganic materials will be developed in the next few years.

Transport Processes in Electrically Conducting Dispersely Filled Polymeric Composites

V.G.Shevchenko and A.T.Ponomarenko

The mechanisms of electrical conduction in polymeric composites with electrically conducting fillers are examined on the basis of effective medium, fluctuation tunnelling, and percolation models. The properties of the conducting fillers—metals, graphite, and technical carbon—are analysed. Factors influencing the electrical conductivity of the composites, in particular the methods of preparation of the filler and of the material, are discussed. The prospects for the utilisation of composites of this type are indicated.

I. INTRODUCTION

In connection with the increasing demands imposed by the technology and economic factors, many branches of industry have been faced in recent years with the increasingly acute problem of the manufacture of materials with a set of new properties. This applies particularly to materials which should combine the properties characteristic of semiconductors and metals and also polymeric materials. In principle, these requirements can be satisfied in two ways—either by synthesising polymers with a new chemical structure, for example, polymers with a conjugation system, and doping them or by introducing an electrically conducting filler (powders, metals, graphite, carbon black, etc.) into polymeric dielectrics. Both these procedures are well known from the literature. The creation of materials of this type naturally requires the knowledge of the structure and mechanism of the generation and transport of [current] carriers in the materials. Because of their chemical structure, an extensive literature has been devoted to polymeric materials with semiconducting properties[1,2], while electrically conducting polymeric composites have been studied to a much lesser extent at the present stage of development[3-6]. This review deals mainly with transport processes in electrically conducting polymeric composites.

The range of applications of such materials is fairly broad and the study of the existing and the creation of new electrically conducting materials therefore constitutes an extremely urgent task[7].

II. ELECTRICALLY CONDUCTING FILLERS

Various metals, graphite, and technical carbon (carbon black) can be used as electrically conducting fillers. Fig.1 presents typical relations between the resistivities ρ_v of the compositions and the concentration of the electrically conducting filler. At low concentrations ρ_v is close to the resistivity of the polymer, its value decreasing sharply subsequently and approaching ρ_v for the filler at higher concentrations. Fig.1 shows that organic fillers are usually more effective as electrically conducting additives than metallic powders. We shall consider the properties of various types of fillers.

1. Metallic Fillers

When metals (Cu, Al, Ni, Zn, Au, Ag) are introduced into a polymer, a fairly high conductivity is reached only at their high concentrations[3], because the surfaces of the particles of many of the available metals are in most cases coated by an oxide film, which hinders the transport of carriers between the filler particles. Furthermore, the density of the metal greatly exceeds that of the polymer, which results in a considerable increase of the weight of the composite. All these factors resulted in the use of metals only in certain instances: in compositions with various ceramics (the so-called cermets) in order to obtain high-resistance resistors[8] and also in electrically conducting adhesives used in the electronic industry in order to avoid the welding of components. In the latter case expensive colloidal silver must be used at fairly high concentrations (up to 70 wt.%) in order to obtain the required conductivities and this naturally limits the applications of such adhesives[9].

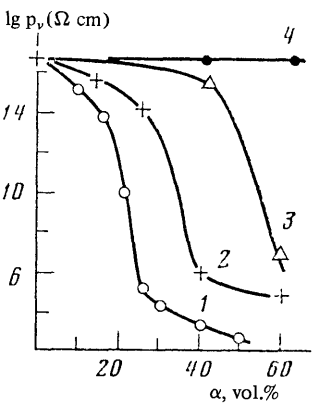

Figure 1. Dependence of the specific bulk-phase resistivity ρ_v of the composition based on low-density polyethylene on the concentration of electrically conducting fillers[3]: *1*) acetylenic carbon black; *2*) ZKA graphite; *3*) PAK-3 aluminium powder; *4*) zinc dust.

The use of special mixing procedures or the application of metallic particles of an unusual shape (in the form of scale, metallic leaf, dendrites, etc.) makes it possible to reduce their concentration necessary for the attainment of specific levels of conductivity[10,11].

The theoretical principles of the preparation of colloidal metals and composites based on them were developed approximately ten years ago[12,13]. Polymeric composites with highly dispersed metallic fillers have been obtained by electrolytic[13] and thermal[13,14] methods.

2. Graphite

It is known[15,16] that the crystal lattice of graphite consists of a set of planes in each of which the carbon atoms form a network of regular hexagons with a side of 0.418 Å.[17] The distance between the planes of the conjugated π-bonds is much greater (3.35 Å) and the planes are therefore weakly bound to one another and graphite can be readily cleaved. The conductivity of graphite in the plane of the layers σ_a is metallic and reaches $10^4\ \Omega^{-1}\ cm^{-1}$ at a concentration of carriers $n \cong 10^{19}\ cm^{-3}$ and their mobility $\mu \cong 10^4\ cm^2\ V^{-1}\ s^{-1}$.[16] The conductivity at right angles to the layers σ_c depends greatly on the perfection of the structure of the single crystal, the presence of impurities, and many other factors. For this reason graphites are classified as semimetals. The anisotropy of the electrical conductivity (σ_a/σ_c) varies within fairly wide limits: from 250 to 10^4. The natural graphite used as the conducting filler has a polycrystalline structure with a high content of amorphous carbon and the conductivity of such graphites is therefore low. Furthermore, the graphite particles are unable to form chain structures and the increase of the conductivity of the composites is therefore achieved by introducing high concentrations of the filler, which impairs the physicomechanical properties of the material[3]. For these reasons, natural graphite was not considered previously as a promising electrically conducting filler. However, data obtained recently concerning new methods of filling[18–20] may modify this view.

It has been observed recently that the introduction into graphite of powerful electron acceptors (SbF_5 and AsF_5), which form the so-called intercalated or layer graphite compounds, increases the conductivity of graphite to values exceeding that of the best conductor—copper. The employment of such compounds as conducting fillers appears to be extremely interesting in some cases[21].

3. Technical Carbon (Carbon Black)

The most widely used electrically conducting filler is carbon black (technical carbon). At the present time more than 90% of technical carbon manufactured and consumed consists of pitch carbon black but special varieties of acetylenic carbon black are most frequently employed as fillers[22]. X-Ray diffraction studies of the carbon black particles have shown that they consist of individual small crystalline cells of the graphite type. The disposition of carbon atoms in the layer is the same as in graphite crystals but the distance between layers is greater. The sites where the end faces of the parallel layers emerge on the surfaces of the particles have an increased energy and hence an increased adsorption capacity. This is in fact the reason for the ability of carbon black particles to form chains and network structures—the property referred to as "degree of structure" of the carbon black[5]. The active sections on its surface can also adsorb extraneous components (for example, oxygen) and the presence of the latter impairs the "degree of structure" of the carbon black. For this reason, the conductivity of the carbon black usually increases with decrease of the concentration of volatile substances[23]. Another factor which determines the conductivity of the carbon black is the specific surface which depends on the size and porosity of the particles.

Thus technical carbon (carbon black) which is effective as an electrically conducting filler must have the following characteristics: a large specific adsorption surface, a high porosity, a small particle size, a low content of volatile admixtures, and a high degree of structure[24]. It will be shown below that the conductivity of the composite is determined not only by the characteristics of the filler but also by the method of mixing of the components.

III. THE MECHANISMS OF ELECTRICAL CONDUCTION IN POLYMERIC COMPOSITES

Electrically conducting composites lack long-range order in the distribution of filler particles and such materials are therefore classified as typical disordered systems. The results obtained for disordered semiconductors and other systems can be used in the study of transport phenomena in the composites under consideration[25].

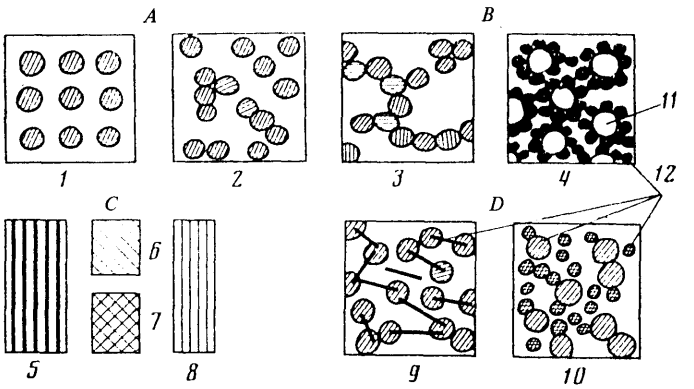

Figure 2. Different types of distribution of fillers in a polymer matrix: *A*) disperse systems [*1*) matrix mixture; *2*) statistical mixture]; *B*) structured disperse systems [*3*) two-component system; *4*) three-component system]; *C*) filler in the form of fibres, fabrics, and strips [*5*) layer structure; *7*) biaxially oriented structure; *6*) and *8*) monoaxially oriented structure]; *D*) mixed filler [*9*) fibre–sphere; *10*) two spheres]; *11*) dielectric; *12*) various forms of conducting fillers.

To a first approximation, it is possible to distinguish matrix systems, statistical mixtures, and structured compositions in terms of the nature of the distribution of the components[4]. In matrix systems one phase is continuous and at any concentration. In statistical mixtures the components are distributed at random and do not form regular structures. Systems whose components form chain, planar, or bulk-phase structures are classified as structured composites. Fig. 2 presents typical structures of composites and the distribution of the filler in the matrix.

In a number of studies theoretical calculations have been made to establish a relation between the properties of the components, on the one hand, and those of the composite, on the other. The early investigations of transport phenomena date back to 1892 when Rayleigh examined the conductivity of a matrix with a cubic packing of conducting spheres[26]. In the same year Maxwell proposed a mathematical analysis of systems containing spheres distributed at random in a continuous matrix[27]. Odelevskii proposed in 1951 a method for the calculation of the generalised conductivity of heterogeneous composites[28]. His relations can be used to calculate the electrical and thermal conductivities, magnetic permeabilities, and dielectric constants of composites. Such generalisation is possible because the equations describing the scalar and vector fields of these quantities are formally identical. The electrical conductivity of a matrix system (polymer matrix) is described by the equation

$$\sigma = \sigma_p\left(1+\frac{\alpha_f}{\frac{1+\alpha_f}{3}+\frac{\sigma_p}{\sigma_f+\sigma_p}}\right)$$

For a statistical mixture, we have

$$\sigma = \frac{(3\alpha_p-1)\sigma_p+(3\alpha_f-1)\sigma_f}{4}+\left[\frac{[(3\alpha_p-1)\sigma_p+(3\alpha_f-1)\sigma_f]^2}{16}+\frac{\sigma_f\sigma_p}{2}\right]^{1/2},$$

where α_p, α_f, σ_p, and σ_f are the concentrations and conductivities of the polymer and filler respectively.

The Lorentz–Lorenz and Lichtenecker formulae are also available for the calculation of the conductivities of mixtures[4,8,29,30].

It is noteworthy that none of the expressions enumerated above employ any specific mechanism of the transport of carriers in the composites but are based on the "effective medium" model. Reliable results are therefore obtained with the aid of the above computational formulae only in cases where σ_p and σ_f do not differ by a factor greater than 10^2. In many composites with a polymer matrix, this condition is not observed: the conductivity of polymers [polyethylene, polystyrene, and poly(vinyl chloride)] is 10^{-12}–10^{-16} Ω^{-1} cm^{-1},[4] while that of carbon black is 10 Ω^{-1} cm^{-1} [22] and that of graphite is up to 10^4 Ω^{-1} cm^{-1}.[16] Thus new approaches are necessary for the description of the properties of electrically conducting polymeric composites.

There is so far no unanimous view concerning the mechanism of electrical conduction in filled polymers. The following views are the most common: (a) charge transfer is based on the direct contact between the particles of the electrically conducting filler distributed in the specimen in the form of chains[31,32]; (b) charge transfer takes place not only on direct contact between the conducting particles, but also as a result of electron tunnelling through the dielectric layers of the polymer[33]. The level of the experimental technique does not so far permit an unambiguous answer to the question whether the sharp increase of conductivity with increase of the concentration of the filler is associated with the direct contact of the filler particles with one another or whether a mutual approach of the conducting particles to within distances necessary for the achievement of the tunnel effect is sufficient.

In order to estimate the dominant type of contact, analysis of the dependence of the current on the potential is frequently employed[4]. To a first approximation, this dependence is described by an equation of the type

$$i = cu^n,$$

where c and n are constants. The direct proportionality between the current and the potential ($n = 1$; Ohm's law) indicates the dominance of carbon black–carbon black contacts. A deviation from Ohm's law shows that the carbon black particles are separated by layers of the polymer.

In the presence of the tunnel effect, the dependence of the current on the potential is described by another expression:

$$i = Au^{n_1}e^{B/u},$$

where A, B, and n_1 are constants. It has been established experimentally that, with increase of the potential, this formula is suitable for the description of certain real systems starting from a critical potential[34]. However, one should note that the resistance may be Ohmic also in the presence of the tunnel effect. The characteristics of contacts of different types have been examined[35,36].

1. The Fluctuation Tunnelling Model

The fluctuation tunnelling model is apparently closest to reality[37]. According to this model, the conductivity of polymers filled with carbon black is determined by two factors. The ability of the carbon black to combine into chain structures (clusters) is responsible for charge transfer between the particles within the cluster directly via contacts. For certain relatively high degrees of filling, the distance between the clusters becomes much smaller than the dimensions of the latter and the conductivity is determined by the tunnelling of electrons between the clusters at the point of the maximum approach of the latter. Tunnelling is promoted by the thermal energy fluctuations (kT), which modulate the energy barrier; the decrease of the height of the energy barrier induced by the fluctuations can be fairly large. Furthermore, the presence of fluctuations leads to the appearance of a temperature dependence of the conductivity.

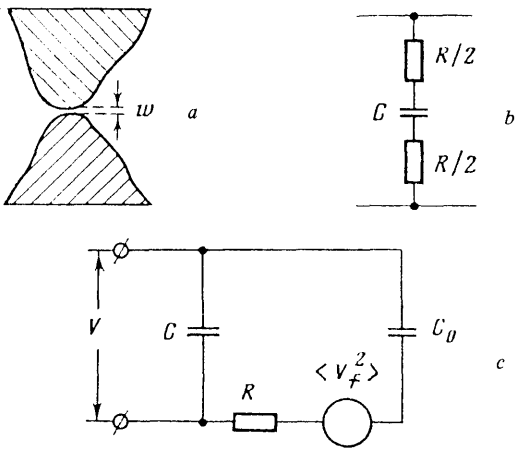

Figure 3. Equivalent circuit of the tunnel transition in the fluctuation tunnelling model[37]: *a*) type of contact; *b*) circuit; *c*) equivalent circuit (C_0 is the total capacitance between two particles).

Such a barrier can be represented approximately by a series-connected resistance R and a capacitance $C = S/4\pi w$ (where S is the area and w the distance between the clusters in the region of their maximum approach) and also by an equivalent circuit (Fig. 3). The fluctuations of the potential are described by the familiar Nyquist formula $\langle V_f \rangle^2 = 4kTRdf$, where df is the frequency range. Averaging with respect to the frequency and taking into account the equivalent circuit

yields the thermal fluctuations of the potential drop across the barrier $\langle V_T \rangle^2 = kT/C$.

Calculations yield the following temperature dependence of the resistivity of the composites:

$$\rho = \rho_0 \exp\left[\frac{T_1}{T + T_0}\right],$$

where T_1 is the temperature corresponding to the energy necessary for the electron jump across the gap between the clusters and T_0 is the temperature below which ρ is independent of temperature.

Experimental results have shown that composites based on poly(vinyl chloride) (PVC), filled with various types of carbon black, have conductivities whose temperature variation is described by the above formula[38]. This indicates the fluctuation mechanism of the conduction in the systems considered (Fig.4).

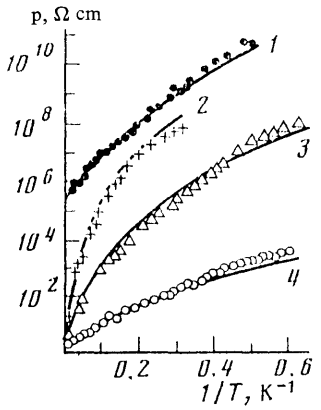

Figure 4. Temperature variation of ρ for carbon black-filled PVC compositions[38]: *1*) Mogul-L carbon black (45 wt.%); *2*) Columbia SA40-220 carbon black (15 wt.%); *3*) Columbia SA40-220 carbon black (20 wt.%); *4*) Ketjenblack EC carbon black (16 wt.%).

A characteristic feature of polymeric composites of this kind is that electrical breakdown occurs for comparatively low electric field strengths $E < 10^2$ V cm^{-1}. The low breakdown potentials are due to the fact that the potential drop occurs mainly in the gap between the conducting clusters and the gaps w are much smaller than the size of the cluster W. The field strength in the gap therefore reaches EW/w, which is sufficient for thermal breakdown[38].

2. The Degree of Linkage in Polymeric Composites

In order to estimate the degree of linkage between the particles of the electrically conducting filler in composites, one can apparently employ the approach developed for the determination of a measure of the degree of linkage of graphite[39]. The ratio of the electrical conductivity of the test specimen σ_m to the electrical conductivity of pore-free volumes σ_0, i.e. $K = \sigma_m/\sigma_0$, is used as a quantitative characteristic of the macrostructure of graphite. The quantity K varies from $K \cong 0$ for graphite powder to $K = 1$ for the single crystal. The conductivity σ_0 is determined from the concentration of the charge carriers n_0 and their mobility μ_0 by means of the formula $\sigma = en_0/\mu_0$. The quantity n_0 is usually close in magnitude to the concentration of carriers in the single crystal ($n_0 = 1.1 \times 10^{19}$ cm^{-3} at 300 K). This quantity can be determined by ESR. The following formula is used to determine μ_0:

$$\mu_0 = \frac{1}{H}\left[\frac{\rho(H) - \rho(0)}{\rho(0)}\right]^{1/4},$$

where H is the magnetic field and $\rho(H)$ the resistivity in the magnetic field.

We may note that K for different graphite specimens is linearly correlated with Young's modulus E, which in certain cases is determined solely by the degree of linkage in the specimen (Fig.5). The application of a similar approach to electrically conducting polymeric composites can yield information about the aggregation of the filler particles and the formation of conducting chain structures.

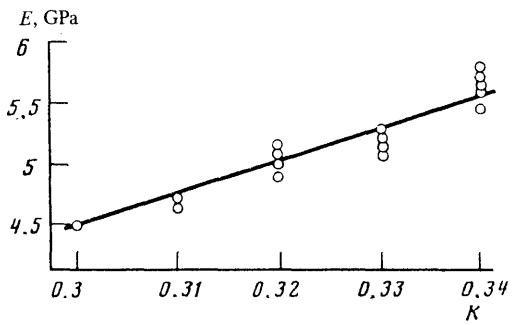

Figure 5. Dependence of Young's modulus E on the degree of linkage $K = \sigma_m/\sigma_0$ for graphite specimens[39].

3. The Percolation Theory

The most general approach to the description of the conductivity of non-ordered structures is apparently one involving the percolation theory[40,41]. Diffusion is usually regarded as the random movement of particles in an ordered medium; on the other hand, percolation is represented as directed movement in a non-ordered system. An example may be provided by the flow of water through porous minerals. Percolation in a regular lattice or in a continuous medium may be considered.

For a lattice made up of regularly distributed sites, where the neighbouring sites are connected by bonds, there is a possibility of, for example, flow of a current, a liquid, etc. between the sites. Disorder is introduced in two ways into such a system: (a) in a random fashion with a probability $1 - c$ by blocking (rupturing) the bonds in the system (the bond problem); (b) in a random fashion with a probability of $1 - c$ by blocking the sites (the site problem).

A macroscopically large (infinite) system is said to be permeable if the flow of a liquid (current, heat, etc.) through it via non-ruptured bonds (in case a) or similarly via bonds passing through non-blocked sites (in case b) is possible. The problem consists in the determination of the minimum value of c ($c = c^*$) down to which the infinite system remains permeable. The flow threshhold constitutes the threshhold of the formation of an infinite cluster of bonds "hooked" onto one another.

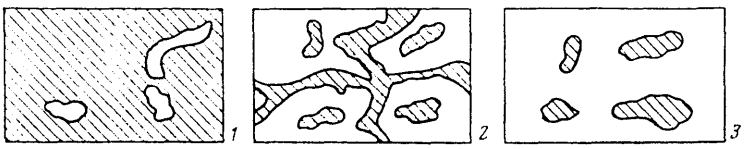

Figure 6. Dependence of the degree of linkage in a composite on the concentration of the conducting filler (shaded region) (c^* = percolation threshhold): 1) $c < c^*$; 2) $c = c^*$; 3) $c > 1 - c^*$.

If the distribution of conductivity in the material defined by $\sigma = 0$ with a probability $1 - c$ and $\sigma = \sigma_0$ with a probability c obtains, then, according to the percolation theory, the conducting parts of the material under conditions where $c < c^*$ are insulated from one another and the overall conductivity is zero. When $c \geq c^*$, a continuous conducting pathway appears through the entire specimen and the conductivity increases further with increase of c. Finally, when $c > 1 - c^*$, the non-conducting parts of the material are insulated from one another. Thus in the vicinity of the percolation threshhold c^*, there is an insulator–conductor transition, as shown in Fig.6.

More accurate results have also been obtained for binary continuous media[42], for which the local conductivity σ is equal to σ_0 with a probability c and to σ_1 with a probability $1 - c$, while $x = \sigma_1/\sigma_0 \ll 1$. The following relations have been obtained:

$$\sigma \sim \sigma_0 (c - c^*)^{\beta} \quad \text{when } c \gg c^*,$$
$$\sigma \sim \sigma_1 (c^* - c)^{-1} \quad \text{when } c \ll c^*,$$
$$\sigma \sim \sigma_0 x^{\delta} \quad \text{when } c \to c^*,$$

and $\delta = \beta/(\alpha + \beta)$. These relations are illustrated schematically in Fig.7.[42] The parameters for different problems of the percolation theory are presented below[42]:

	c^*	β	δ
Three-dimensional bond problem	0.25	1.6	0.67
Two-dimensional bond problem	0.48	1.1	0.51
Three-dimensional problem of percolation in a continuous medium	0.145	1.4	0.65
Three-dimensional model of a continuous (additive) medium	0.33	1	0.5

The model of an electrically conducting composite in which the filler particles are distributed at the sites of a regular three-dimensional lattice (cubic, diamond-like, etc.) has been examined[43]. It was assumed that the particles located at neighbouring sites are in contact. With increase of the filler concentration, the dimensions of the cluster consisting of particles in contact increase until a continuous chain passing from one edge to another is formed (i.e. the percolation threshhold is attained). In contrast to the traditional approaches of the percolation theory[40,41], this problem is solved by analogy with the problem of random motion in a three-dimensional lattice and resembles the model employed by Flory in the analysis of the conformations of polymeric chain molecules[44]. As a result, relations were obtained for different types of lattice between the average length of the continuous chain and the conductivity, on the one hand, and the filler concentration, on the other. The average percolation threshhold obtained[43] for six types of lattice was 0.095, which the author believes to be close to the value of 0.145 obtained by other methods[42].

An interesting example of a system of practical importance in which there is a dielectric–conductor transition of the percolation type is provided by the so-called granulated metals or cermets, which are composites consisting of a non-conducting matrix (SiO_2, Al_2O_3) in which fine grains of a metal (Ni, Pt, Au, etc.) are dispersed[8,45]. Such systems are used to prepare thick-film resistors.

The study of the dependence of the conductivities of such systems on the content of the metal c_M indicates the presence of three regions[45]. When $c_M < 0.4$, the system consists of insulated unconnected particles of the metal distributed in the dielectric matrix. In this case conductivity is due to the thermally activated tunnelling of charge carriers between the metallic particles. The transport of charge carriers takes place via electron "jumps" from one neutral grain to another; this results in the formation of a pair consisting of positively and negatively charged grains, which requires a definite consumption of energy. A characteristic temperature variation of the conductivity of the form $\sigma \propto e^{-A/\sqrt{T}}$ arises as a consequence[45].

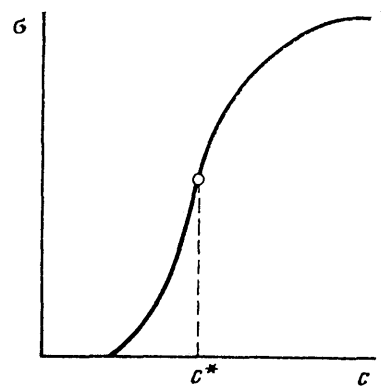

Figure 7. Dependence of the electrical conductivity σ on the concentration c_M of the conducting filler near the percolation threshhold for a two-component random medium.

In the region $0.4 < c_M < 0.5$ the percolation threshhold occurs; conducting chains permeating the entire specimen begin to be formed. When $c_M > 0.5$, the metal forms a continuous phase in which particles of the dielectric are distributed.

The high concentration of the metal corresponding to the percolation threshhold (50% of the filler instead of the theoretical value of 15%) is explained by the fact that, during the preparation of the cermets, layers of oxides preventing the transfer of electrons are formed on the surface of the metallic grains even when the particles are in contact. This shows that phenomena at the interface play an important role in the mechanism of conduction in composites. Indeed, when

$c_M > 0.5$ the resistivity varies in the following manner with the contact force between the particles:

$$\rho_c = 0.8\rho_M\left(\frac{E}{p}\right)^{1/3},$$

where ρ_M is the resistivity of the conducting phase, E the modulus of elasticity, and p the pressure in the system, equal to the ratio of the contact force to the area of contact[8].

Thus, in order to ensure electrical conduction, a simple contact between the particles of the conducting phase is insufficient—conditions ensuring an obstacle-free electron transfer between the particles are necessary.

4. Structured Composites

The so-called structured composites merit separate consideration. An example is provided by systems obtained by pressing mixtures of polyethylene or polypropylene and metal powders[10,11]. In this case the specimen is pressed at a temperature below the melting point of the polymer and the polymer particles do not therefore fuse and are merely deformed, while the metallic particles are distributed on the surface of polymer grains, forming a separate continuous two-dimensional phase. Such a structure is illustrated in Fig.2*B* (see structure 4). The dependence of the resistivity ρ_v on the content of the metal is illustrated schematically in Fig.8. Evidently, up to a concentration c_A, the conductivity varies little—a continuous filler phase is not formed. From the instant of the formation of the continuous phase, the resistivity falls sharply but, at a concentration in excess of c_B, the decrease slows down.

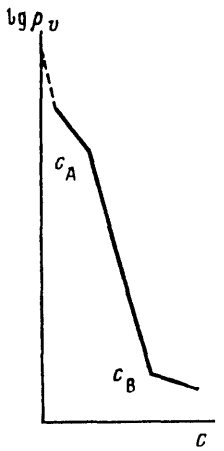

Figure 8. Schematic illustration of the dependence of ρ_v for the polyethylene–nickel composite on the nickel concentration[10].

The degree of filling c_B corresponds to the case where a close-packed layer of metallic particles is formed on the surface of each grain, i.e. N_p polymer spheres with a radius R_p are coated by N_M metallic spheres with a radius R_M:

$$N_p \times 4\pi R_p^2 = N_M\, \pi R_M^2 \Phi\,,$$

where Φ is a coefficient which depends on the type of packing.

When $c > c_A$, the layers of filler particles are built up and the conductivity increases slightly, approaching the conductivity of the filler. The quantity c_B is calculated from the formula

$$c_B = \frac{\frac{4}{3}\pi N_M R_M^3}{\frac{4}{3}\pi N_M R_M^3 + \frac{4}{3}\pi N_p R_p^3} = \frac{1}{1 + \frac{\Phi}{4}\cdot\frac{R_p}{R_M}}\,.$$

When $c_A = \frac{1}{2}(P_c c_B)$, the two-dimensional metallic phase is a monolayer (P_c is the packing coefficient).

The packing coefficients Φ and P_c for different types of lattice are as follows in the case of a structured composite:

	Hexagonal lattice	Cubic lattice	Trigonal lattice
Φ	1.11	1.27	1.375
P_c	1/3	1/2	2/3

It is noteworthy that the transition c_A for structured composites corresponds to much lower degrees of filling than for a statistical mixture. Comparison of the experimental and theoretical results for the dependence of the percolation threshholds c_A on the ratio of the particle radii R_P/R_M for a structured composite is indicated below:

R_P/R_M	30	16	12	10	7.5
c_A (theor.)	2.9	5.1	6.5	7.5	9
c_A (exp.)	6	6	11	13	14

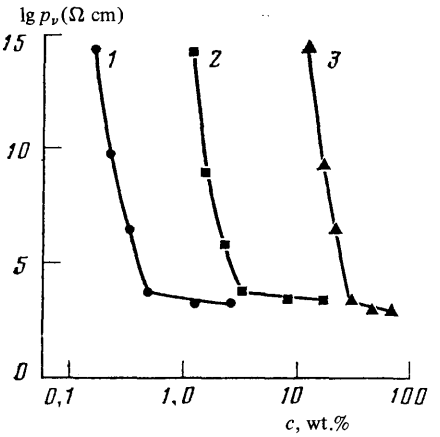

Figure 9. Dependence of ρ_v on the concentration c of the Ketjenblack EC carbon black for different methods of preparation of polymeric composites based on polystyrene[46] (see text).

IV. METHODS FOR THE PREPARATION OF COMPOSITES AND THEIR ELECTRICAL CONDUCTIVITIES

The examples quoted above show that the method of preparation of the composites is important for the attainment of a specific electrical conductivity. Shear forces, which should be maximum in the stage where the composite is prepared and minimum in the stage involving the formation of articles from it, play an important role here. The temperature and mixing time of the components, the order in which they are introduced, the presence of substances altering the viscosity of the mixture, etc. have a significant influence on the conductivities of composites[3,10].

This can be illustrated by several further examples. The dependence of ρ_V for the polystyrene–Ketjenblack EC carbon black composites on the carbon black concentration has been investigated[46] for different methods of preparation of the composite. Three mixing procedures were used: (1) pressing of a mixture of carbon black with the powdered polymer; (2) mixing of the carbon black with a solution of the polymer in toluene in a ball mill followed by the casting of a film with slow evaporation of the solvent, comminution of the film, and pressing; (3) calendering of a mixture of carbon black and the polymer between heated rollers, grinding of the product, and pressing. Fig. 9 shows that the critical concentration of the carbon black c_B for the first method is only 0.5%; evidently this case is close to the model described above with $R_P/R_M \gg 1$. For the third method, c_B increases to 25%. In this procedure it is apparently more difficult to retain the conducting carbon black structure.

Certain carbon black-filled compositions are used to prepare articles by extrusion. Thus the RCA Company (USA) uses the propylene–vinyl chloride copolymer–Ketjenblack EC carbon black composition to manufacture video discs for the recording of television programmes[47]. Fig. 10 illustrates the dependence of ρ_V for such a composition (measured using d.c. and a.c.) on the number of extrusions n. Evidently the optimum conducting structure is formed when $n = 2$; after a larger number of extrusions, the structure breaks down.

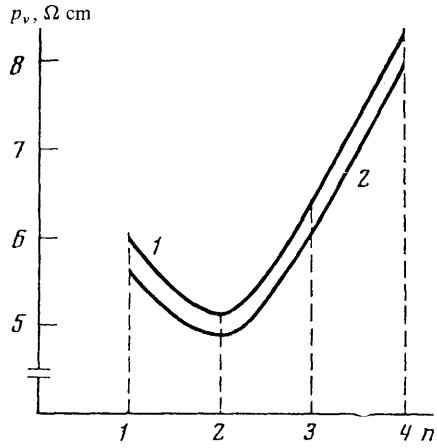

Figure 10. Dependence of ρ_V for the composition comprising the propylene–vinyl chloride copolymer and the Ketjenblack EC carbon black on the number of extrusions[47]: *1*) $f = 0$; *2*) $f = 9.5$ MHz.

Surfactants are used to improve the dispersion of the carbon black in polymers. Binary fillers are also employed. Thus, when 110 parts of kaolin are added to the ED-16 epoxide resin containing 10 parts of graphite per 100 parts of the resin, the ρ_V of the composition diminishes by six orders of magnitude (from 10^9 to 10^3 Ω m). In the absence of kaolin, the same value of ρ_V can be obtained only after the introduction of 50 parts of graphite. The effect of kaolin is explained by the fact that it promotes a rigid fixation of the electrically conducting structures which determine the stability of the electrical properties of the filled material[48,49].

In the preparation of electrically conducting films from pyrolysed polymers on the surfaces of inert fillers (kaolin, talc, etc.), there is a possibility of obtaining compositions based on these fillers and polyethylene and with a low content of the conducting component for which ρ_V is smaller by 5–11 orders of magnitude than the value for the initial polymer. The content of the conducting component (pyrolysed polyacrylonitrile) is then only 1–3%.[50]

A new method for the preparation of filled polymeric materials—the method of polymerisation filling—has been developed recently[18,19,41]. In this procedure the catalyst is deposited on the surface of the filler where polymerisation takes place. The resulting material can then be converted into articles by the usual methods. Polypropylene–graphite compositions have been obtained by this procedure; for comparison, the same compositions were prepared by extrusion[20] and it was found that the films of the polymerisation filled polymers have a much smaller resistivity ρ_V (by 2–8 orders of magnitude) than the extruded films with the same graphite content. A specific instance of the interaction of the filler and polymer apparently occurs here, which leads to the cleavage of the graphite along its planes and its more effective dispersion in the polymer. The details of this process are in the research stage, but many results support this hypothesis.

In conclusion one should mention organic polymers which are as it were "intrinsic" composites. Their electrical, optical, and certain other characteristics indicate the presence of conducting regions in a non-conducting matrix of the same composition. Among such systems, mention may be made of pyrolysed polymers (polyacrylonitrile, polyimides[38]) as well as doped polyacetylene[51,52].

V. APPLICATIONS OF CONDUCTING COMPOSITES

The range of applications of conducting composites is extremely wide. New possibilities for their employment are nowadays discussed in the literature, in particular in meeting the requirements of radioelectronics for the creation of low-noise and high-frequency cables and shields over a wide frequency range, in components of radioelectronic apparatus, in highly efficient solar batteries, and in other fields[7,53,54].

The employment of capacitive transducers for the decoding of information from video discs require the creation of compositions with a high degree of homogeneity in the distribution of the filler in the matrix and with reproducible properties. The Ketjenblack EC composition[47] mentioned above satisfies such requirements.

Among other potential applications of such composites are those in the chemical industry and non-ferrous metallurgy where there is a need to replace the scarce lead and leaded steel employed in the manufacture of electrofilters[55,56]. Composites with a level of conductivity not less than 10^{-6} Ω^{-1} cm^{-1} are widely used as antistatic materials[3].

A tendency has arisen in recent years to employ highly filled composites incorporating carbon fibre fabrics in electrical engineering for the manufacture of collectors and contact rings in electrical machines[57,58]. The comparatively small-scale application of conducting composites in the preparation of tensotransducers, necessary both in the modelling and employment of constructional equipment, is no less important[59].

As already stated, the creation of highly conducting polymeric adhesives constitutes an urgent task, since hitherto they have been made from scarce noble metals (Au, Ag, etc.)[9].

Vigorous studies are being prosecuted nowadays in order to prepare conducting composites with the aid of new methods—polymerisation filling[20,60], electrochemical deposition of metals from salt solutions into a polymer solution[12,57], and high-speed thermal decomposition of solutions of the metal carbonyls, formates, and oxalates in polymers[14]. This factor gives rise to the hope for the creation of new composites with a set of new valuable properties[61,62].

* * *

One of the main difficulties in the study of the electrical conductivities of organic, including polymeric, materials is that they cannot be treated within the framework of classical ideas, for example, within the framework of the band model. A criterion of the applicability of this model is a current carrier mobility $\mu > 1\ cm^2\ V^{-1}\ s^{-1}$. For the majority of the electrically conducting polymers in composites, this condition is [not?] fulfilled: thus $\mu \cong 10^{-4}\ cm^2\ V^{-1}\ s^{-1}$ for carbon black-filled raw rubbers[34]. Another factor which hinders the understanding of the mechanism of electrical conduction in composites (for example, those based on polyolefins) is that the concentration of the intrinsic current carriers in polymers of this class is negligible. Thus the conducting properties of such composites are determined, firstly, by the material of the filler and secondly, by the properties of the filler–polymer interface. Since the electrical conductivity is ensured by carriers injected from the filler, it is necessary to create interphase injecting contacts (ohmic contacts are suitable in some cases).

Thus, in order to understand the mechanism of the electrical conduction in polymeric composites, it is necessary to take into account the influence of a number of factors, which include the properties of the filler and the polymer, the distribution of the filler in the matrix, and the type of contacts between the polymer and the filler particles. None of the models existing at the present time takes into account all these factors and reflect only one of the characteristic aspects of the phenomenon. In view of the increasing use of such composites, it is therefore necessary to carry out combined theoretical and experimental studies on the lines discussed above.

Metallic Clusters in Polymer Matrices

S.P.Gubin and I.D.Kosobudskii

The methods of synthesis, the properties, and the structure of new composite materials based on polymers and on clusters of the transition metals are discussed. The properties of metal-polymer systems of this type are shown to be very different from those of ordinary metal-polymer systems, in which the metal particle size is greater than 100 μm. The effect of the clusters on the structure of the polymers is examined, and examples of the dependence of the electrophysical and magnetic properties of metal-polymers on the concentration of metallic clusters are given. 62 references.

I. INTRODUCTION

Exploratory research on new types of material based on polymers for use in electronics has been intensified in the last few years both within and outside the Soviet Union. The outcome of much of this work has been polyconjugated polymers, such as polyacetyl, polyphenylene, polydiactylene, polypyrrole, etc.[1-3] Being dielectrics with a wide forbidden gap in the energy spectrum of their charge carriers these materials can be doped with electron acceptors (such as halogens, or arsenic or antimony pentafluorides) to give organic semiconductors and organic metals whose electrophysical parameters can be controlled between wide limits.

However, these polymeric materials are still far from being generally available, for a number of reasons, including the lack of large-scale methods of preparation of the initial polyconjugated polymers. We have therefore turned our attention towards the familiar and readily available polymers polyethylene and Teflon. The controlled addition of dopants of different chemical nature (both donors and acceptors) to these materials had be developed. Since the introduction of metal particles of various sizes into this type of polymer matrix had already been demonstrated, we initialy used clusters of the transition metals as dopants.

The expectation that this modification of polyethylene and Teflon could lead to new materials with interesting electrophysical properties was stimulated by a series of papers by Enikolopyan and co-workers[4,5], who showed that the injection mechanism of electrical conduction (which they had observed at high pressures) can be realised at ordinary pressures if the integration of metal and the polymer can be carried out at the "molecular level".

In this review we shall examine the methods of preparing single-phase metal–polymer composites from the inert polymer matrices Teflon and polyethylene (not containing multiple bonds) doped with metal particles of size comparable to the thickness of a single polymer chain. By this approach we have produced a new type of material (which we have termed "cluspols") in which metal clusters are accommodated within the natural cavities of the polymer matrix[6].

II. METHOD OF PREPARING METAL–POLYMERS

Industrial methods of preparing metal–polymer composites usually rely on metal powders (of fairly large particle size), which are added to a melt of the polymer with stirring. However, this method cannot give a uniform distribution of particles in the polymer, and furthermore it tends to degrade the stability characteristics of the composite.

Several alternative methods of preparing metal–polymers have been described: we shall examine some of them in detail.

1) The electrochemical reduction of metals from solutions in the presence of surface-active substances (SAS).[7-11] Polymers containing functional groups can play the role of the SAS. It has been shown[12] that even when the amount of active filler is very small its particles act as centres for the formation of a continuous three-dimensional network through the adsorption and orientation of the polymer molecules under the influence of the field of force of the filler particles. The influence of various factors on the current yield and on the dispersion of the metallic filler has been studied in detail[13-15]. The electro-flotation[16] and the electro-acoustic method[17] are variants of the electrochemical method of synthesis of metal–polymers.

2) The mechanochemical method of synthesis of metal–polymers[18,19] relies on the high adsorption and chemisorption activity of the surface created during the dispersion of a metal. Polymerisation processes during the vibratory milling of salts, metals, and oxides in the presence of vinyl monomers have been studied, and chemical grafting of the metallic particles to the polymer surface was observed during the milling of iron, nickel, titanium, and chromium.

It was reported[20] that the absence of reactive functional groups in the polymer affects the physicochemical properties of the polymer: for example, grinding finely divided iron with polyethylene (even in large excess) does not form a metal–polymer. Furthermore, the main properties of the resulting composite are strongly dependent on the dispersion conditions, and on the shape of the metal particles. Optimising the dispersion time is equally important, since excessively long mechanical treatment of the polymer system may cause mechanical degradation[21]. Thus the mechanical method of synthesis of metal–polymers is applicable mainly to polymers which contain functional groups or multiple bonds, and which can therefore generate chemisorptive interactions between the polymer molecules and the surface of the metal particles[22,23].

3) The displacement method depends on the fact that in the presence of polymers metals can be displaced from salt solutions and form metal–polymers if the electronegativity of the matrix is high enough. This method does not appear to have been widely used: the few papers which refer to it are reviewed in Ref.24.

4) The thermal method of metal–polymer synthesis is the most widespread at the moment[25–28]. It relies on the tendency of the slats of organic acids (formates, oxalates, etc.) and of many metal–organic compounds (MOC) to dissociate into the metal (or metal oxide) and give a volatile compound when heated. Thermoplastic polymers can be used as the organic host material for the decomposition of MOC, giving metal-filled composites as the reaction product.

Unlike the usual mechanical mixtures of polymers and metals, in metal–polymers prepared by the thermal method, the metal particles have a fairly high dispersion, they are evenly distributed through the bulk of the polymer, and the sorption of the macromolecules on their surface is strong and irreversible[29–36].

5) The plasmochemical method. Metal-containing composite materials have been prepared[37] by a high-frequency plasma technique in which the polymerisation process was carried out within the plasma chamber. Two methods of transferring the metal to the gas phase before incorporating it in the growing polymer have been proposed: evaporation of the metal (tin) in an inert gas atmosphere and decomposition in the plasma of a volatile compound of the metal [for example, $Cr(CO)_6$]. The products were analysed by the ESCA method, and it was found that the technique can produce highly dispersed metallic particles in a polymer, covering a wide range of metal–polymer compositions. It was also found that the metal particle size depends on the properties of the polymer: for example, in C_2H_4 the size of Sn particles was 150 Å, in C_6H_4 the size of Cr particles was 500–700 Å, and in C_2F_4 the size of Cr particles was 3000 Å.

Though this method seems very promising for the preparation of metal-containing polymers it does not appear to have been used for this purpose.

6) Cryochemical methods of synthesis of metal-containing polymers[38] are potentially very useful. They rely on the fast diffusion of metal vapours towards a cooled surface covered with a thin layer of polymer. Alternatively, the reaction is carried out in a rotating reactor, and the metal–polymer composite is obtained in the bulb of the rotating apparatus. Francis and co-workers[39,40] prepared metal-containing polymers of the poly(methyl phenyl siloxane) type (DC-150) and studied their u.v. spectra. Various metals (titanium, chromium, molybdenum, vanadium, and tungsten) were used as fillers. It was shown that at low concentrations of the metal in the polymer the metallic clusters are coordinated to the phenyl groups of the polymer to give compounds of the *bis*-arene type. Monatomic, diatomic, and triatomic metal clusters, both single and bimetallic (Cr_xTi_y, etc.) were obtained[40] in a matrix of poly(methyl phenyl siloxane). However, the metal–polymer composites thus obtained were found to be unstable if the temperature was allowed to rise to 25 °C or if the concentration of metal was increased.

Thus, in spite of the many methods of synthesis of metal–polymers already disclosed, new methods are needed for the preparation of materials stable under normal conditions and containing a narrow distribution of particle sizes in the range of 15–50 Å.

1. Effect of Dispersed Fillers on the Properties and Structure of Polymers

Let us examine more closely the structure of the polymer molecules, and calculate the effect of the introduction of relatively coarse metallic filler particles on some of the properties of the polymers.

The structure of polymers is characterised by crystalline regions (blocks, or stacks) randomly distributed within the amorphous mass. Orientational ordering of the crystalline fragments can be obtained by stretching or rolling the polymer[41].

The insertion of even relatively small metal particles (~250 Å) should cause substantial disruption of the polymer structure: in practice, the metal particles in metal–polymers are several orders of magnitude larger, and their influence on the polymer structure is correspondingly more marked.

The presence of metallic fillers of ordinary particle size (1–5 μm) can produce some specific properties in polymer materials (for example, enhanced thermal and electrical conductivity, higher magnetic susceptibility and specific heat, and resistance to ionising radiation). However, usefully large changes in properties are achieved only at high concentrations of the metallic filler[42]. Thus, in nickel–polyethylene composites the required electrical conductivity (5.8×10^3 Ohm^{-1} m^{-1}) could be achieved only at a concentration of metallic particles greater than 50 vol.% (90 wt.%). According to current views, the highest conductivity is observed when a substantial fraction of the sample volume is occupied by connected chains of electrically conducting particles with a cross-section equal to the area of contact of the particles. This type of material has only limited applications in technology because its properties cannot be optimised.

In the electrical conductivity scale of materials the extreme positions are occupied on the one hand by typical insulators such as Teflon and polyethylene, and on the other hand by typical metals such as copper and silver. The conductivity can be increased by 5–14 orders of magnitude in some materials by doping[1]. The doping (a special type of alloying) usually involves placing particles of the doping element in vacancies of the crystal lattice of the host material. The two types of particle should be comparable in size. From this formal analogy we can expect the doping of polyethylene or Teflon with metals to bring their conductivity into the typical semiconductor range.

Thus the problem of controlling the electrophysical properties of Teflon or polyethylene reduces to introducing into these polymer matrices dopants comparable in size to the vacancies (or holes) in the initial polymer.

Let us consider once again the structure of the polymer matrices. Polyethylene and Teflon are typical semi-crystalline polymers, with a crystallinity of 60–85% and 75–80% respectively. The molecules in the polymer chain form a planar zig-zag structure with an angle of 112° between the units. In the case of polyethylene the self-repeating unit consists of two CH_2 groups. The polytetrafluoro-ethylene molecule has a more complex zig-zag structure because of the fairly large size of the fluorine atoms[43].

The crystalline part of the polymer structure usually consists of platelets 10–20 μm wide and ~100 Å thick. The main axes of the chains are found to lie at right angles to the plane of the platelets. The thickness of the platelets is much smaller than the chain length. Thus one molecule of polyethylene (with a mass of 50000 and a length of 4500 Å, say) repeatedly crosses the boundaries between crystalline and amorphous regions. Even the crystalline parts of the polymer contain a large number of holes (or defects): these include stacking faults, irregular arrangement of tapes, plates, etc., and therefore the microcrystallites in polymers are usually treated as formations with a high concentration of defects[44].

The amorphous regions in the polymer structure are even "looser", and contain a larger number of natural "holes": the bond between the chains is weaker than in the crystalline blocks, giving greater mobility to the amorphous segments of the molecules.

2. Method of Synthesis of Composite Materials of the "Cluspol" Type

We shall now consider the methods of forming metallic clusters in the natural holes of polymeric matrices by the fast monomolecular thermal decomposition of solutions of metal compounds in a melt of the polymer.

According to modern views, melts of polymers consist of distinct spherulites which retain (in a slightly distorted form) the original platelets or lamellae as unchanged constituents. In other words, the melt retains the short-range order of the initial polymer structure, but the pre-existing holes become accessible for the insertion of metallic particles[45].

The thermal decomposition of metal compounds has been studied widely, under various conditions. In some cases it was shown to be a good method of preparing highly dispersed and very pure metal particles[46]. An overall scheme of thermal decomposition with formation of volatile ligands and a "hot" metal atom M* is given below. The cluster of metal atoms M_n which begins to grow in the melt is stabilised in the polymer matrix. A specific example [the thermal decomposition of $Fe(CO)_5$] is also given.

$$ML_n \rightarrow M^* + nL$$
$$mM^* \rightarrow [M]_m \text{ (cluster)}$$
$$Fe(CO)_5 \rightarrow Fe + 5CO$$
$$\Delta G_{400K} = -8.98 \text{ kcal mole}^{-1}; \Delta G_{600K} = -36.82 \text{ kcal mole}^{-1};$$
$$\Delta G_{1000K} = -92.50 \text{ kcal mole}^{-1}$$
$$15Fe + 4CO \rightarrow Fe_3O_4 + 4Fe_3C$$
$$Fe_3O_4 + 6CO \rightarrow Fe_3C + 5CO_2$$
$$CO \rightleftarrows 0.5CO_2 + 0.5C$$

It is found that an increase in temperature causes an increase in the extent of decomposition of the carbonyl by the main reaction, and correspondingly lowers the yield of side-products[47].

In some recent work the thermal decomposition of metal carbonyls has been used as a source of pure metals (polymer fillers). Thus the preparation of zero-valent iron by the thermal decomposition of $Fe(CO)_5$ in a solution of "functional" polymers has been described[27,48]. It was shown that polymers containing functional groups act as catalysts for the thermal decomposition of $Fe(CO)_5$ to iron(0) through an intermediate of the butadienyl–$Fe(CO)_3$ type, whereas in polymers without functional groups the thermal decomposition goes through the disproportionation of $Fe(CO)_5$. The average size of the iron particles in the composites was ~70–80 Å.

Ultra-dispersed particles of Fe_2O_3 were obtained[49–51] by thermal decomposition of $Fe(CO)_5$ under oxidising conditions in polymers not containing functional groups (polyethylene, polytetrafluoro-ethylene, polypropylene). The preparative method consists in the adsorption of $Fe(CO)_5$ on the surface and in the bulk of the polymers, followed by thermal oxidation at 105 °C in air. The value of this method in the preparation of stable composites of iron(III) oxide and polymers was convincingly demonstrated. The average size of the Fe_2O_3 particles was 30–80 Å.

For the reasons mentioned above the formation of metallic clusters in a polymer melt was carried out at the highest permissible melt temperature, well in excess of the incipient thermal decomposition temperature of the compound. Additional requirements included the highest possible dilution of the solution of metal-containing compound in the thermal decomposition step and the fastest and fullest possible removal of the volatile ligands from the reaction mixture. The proposed method was tested with several types of polymer and different metal compounds (iron, cobalt, molybdenum, and chromium carbonyls, π-allyl compounds of the platinum metals, and acetates, formates, and other metal compounds)[5]. The metal–polymer materials prepared in this way can easily be shaped by moulding. The products included films of high-pressure polyethylene HPPE + M (where M = Fe, Cr, Ni, Cu) prepared at 125 °C and 150 atm, and sheets and rods of polytetrafluoro-ethylene PTFE-40 + Fe prepared at ~280 °C and 150 atm.

The method has been repeatedly shown to be applicable to a wide range of polymer matrices with different types of compounds and different metals, as well as metallic mixtures, alloys, oxides, sulphides, etc. The resulting powders can be formed into articles of any shape by standard methods. Thus we have developed a method of producing a new type of material for which the technical term "cluspol" has been proposed.

The detailed structural features of these materials, including the distribution of the metal particles, their state of oxidation, interactions with the polymer matrix, etc. were studied by a wide range of physicochemical and analytical methods (DTA, X-ray phase analysis, low-angle X-ray diffraction, i.r. spectroscopy, NMR spectroscopy, and Mössbauer spectroscopy).

On the whole, the most sustained and detailed studies were made on high-pressure polyethylene and Teflon-40 containing iron clusters. Samples containing other metals or other matrices received only occasional study.

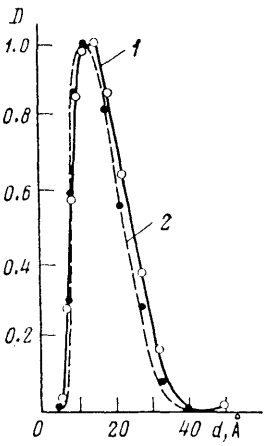

Figure 1. Size distribution of chromium clusters in a Teflon-40 matrix containing 1.0 (*1*) and 5.0 wt.% of Cr (*2*).

III. STRUCTURE AND PHYSICOCHEMICAL PROPERTIES

1. X-Ray and Mössbauer Studies of Metallic Clusters in Polymer Matrices

Metal lines cannot be detected by X-ray phase analysis in "cluspol" materials until the concentration of metal exceeds 10%. Samples containing less than 10% of metal were studied by the low-angle X-ray diffraction method[6]. A typical distribution is shown in Fig.1. Chromium in Teflon-40 gave a particle size distribution curve with a single narrow maximum at $d \cong 12.1$ Å. In the case of iron clusters in a polyethylene matrix the picture is more complex: at low concentrations we again find a narrow distribution with a maximum at 14.8 Å,

but at higher iron concentrations a second, flat maximum appears in the curve at $d \cong 70$ Å (Fig.2). A further increase in the concentration of metal in the material shifts the peak towards larger cluster sizes, but even in this case more than 80% of the clusters have a diameter smaller than 40 Å.[6]

The low-angle X-ray diffraction method can be used to determine the periodicity of the distribution of clusters in the matrix: typical results[6] for iron clusters in polyethylene are shown in Table 1. We note that at high concentrations the average distance between clusters is not more than two or three cluster diameters. The size of the iron clusters was determined by the static magnetic susceptibility method. From the plots (Fig.3*b*) of the specific magnetisation against temeprature for different iron concentrations we note that the downward slope is steeper than for massive iron (which has a Curie temperature of ~1000 K). A size dependence of the Curie temeprature cannot be excluded for very small particles.

Table 1. Periodicity (l) of the distribution of iron clusters in high-pressure polyethylene[6].

[Fe], wt.%	l, Å	[Fe], wt.%	l, Å
1.10	315±30	8.08	110±5
2.64	220±12	29.6	90±5

By measuring magnetisation in small fields the size of the iron clusters in the polymer matrix was determined on the assumption that the separate clusters display supermagnetism[52]. We know that the number of iron atoms (n) in a superparamagnetic particle, its volume (V), and its size (r) can all be determined from the initial slope of the experimental magnetisation curve:

$$n=\mu/2.2\ \mu_B;\ V=nM_B(\mathrm{Fe})/N_A\rho$$

where μ is the magnetic moment of the superparamagnetic particles, $2.2\mu_B$ is the magnetic moment of the Fe atom, and ρ is the density. We note from Fig.3*a* that the initial linear portion is most developed in the sample with an iron concentration of 3 wt.%. For this composition the following results were obtained: $n = 286$, $V = 3401$ Å^3, and $r = 15.1$ Å. The deviation from linearity arises because of the presence (in addition to the main group of supermagnetic particles ~15 Å in size) of a smaller number of larger particles which contribute ~5% to the toal magnetisation. These results are fully consistent with those obtained by low-angle diffraction on the same samples.

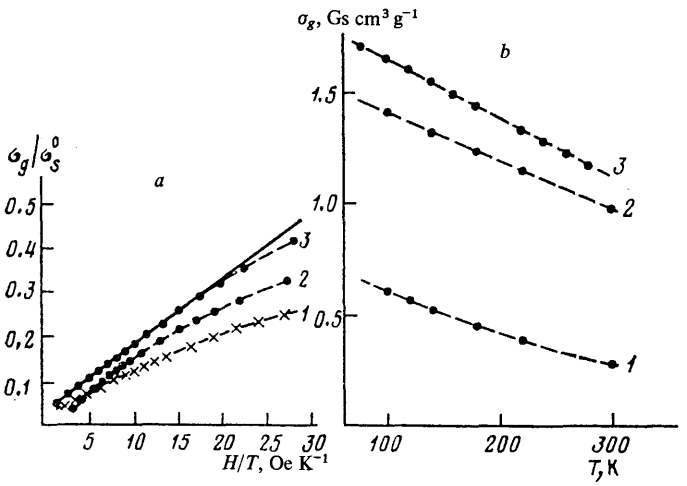

Figure 3. (*a*) Plot of the ratio σ_g/σ_s^0 (where σ_s^0 is the saturation magnetisation at 0 K) against H/T, and (*b*) temperature dependence of the specific magnetisation σ_g, for samples of polyethylene with different iron content: *1*) 1.0, *2*) 2.0, *3*) 3.0 wt.%.

The presence of iron clusters in these materials is confirmed by the Mössbauer spectra of "cluspol" samples. In the typical spectra shown in Fig.4 the main component at 300 K is a doublet with a quadrupole splitting of 0.6–0.9 mm s^{-1} and an isomeric shift of 0.6–0.7 mm s^{-1}. The parameters of the spectrum differ from the values for both α and γ

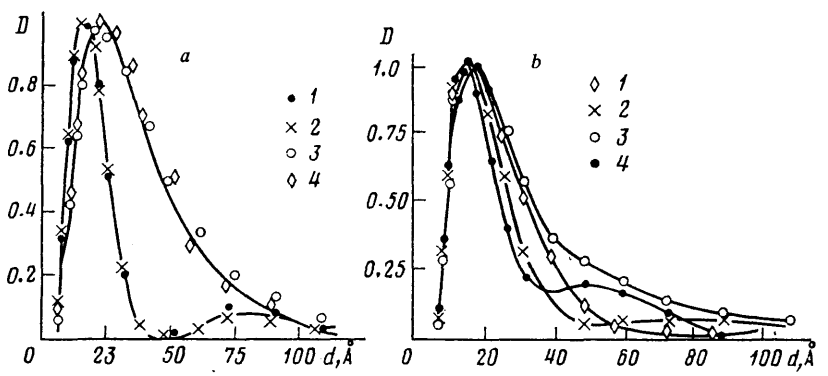

Figure 2. Size distribution of iron clusters in a high-pressure polyethylene matrix (*a*) and in Teflon (*b*); Fe content of the HPPE matrix: *1*) 0.7, *2*) 1.0, *3*) 5.0, *4*) 7.0 wt.%; Fe content of Teflon; *1*) 1.0, *2*) 5.0, *3*) 25.6, *4*) 10.0 wt.%.

iron (whether massive or in thin-film form)[55,54], and they agree with the parameters of the Mössbauer spectra of iron clusters in an argon matrix[55].

Thus the available data convincingly show that the proposed method gives metallic clusters with a narrow size distribution, and that these clusters are stabilised in the polymer matrix.

2. Effect of Metallic Clusters on Polymer Structure: NMR Studies

The nature of the interaction between metallic clusters and the polymer matrix, and the resulting changes in the matrix, were studied by NMR. The NMR spectra of the initial polyethylene samples are symmetrical, and consist of a broad and a narrow component (Fig.5). The narrow component is associated with the amorphous part of the polymer, the broad component with the crystalline part. An increase in the concentration of metallic clusters produces marked changes in the NMR spectra. Initially the intensity and the width of the narrow component are affected, but at higher concentrations the broad component begins to expand rapidly and beyond a certain metal concentration the NMR spectrum can no longer be measured[56].

Both the crystalline and the amorphous regions of the polymer can act as localisation sites for the clusters. The processes by which the metal particles are incorporated into the polymer can be monitored by analysing the NMR spectra.

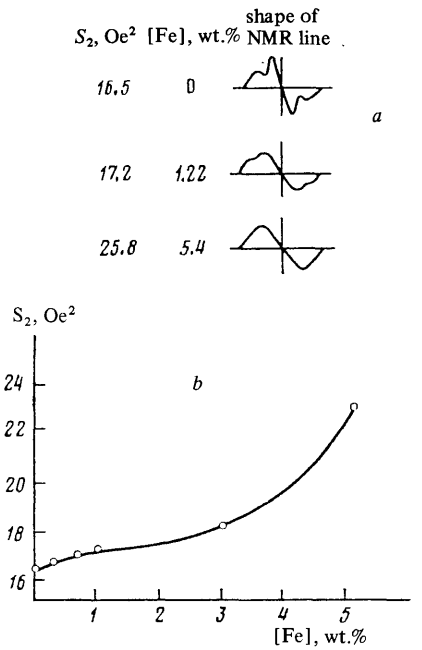

Figure 5. Effect of increasing the iron content on the shape of the NMR line (*a*) and on the value of the second moment S_2 (*b*) for composite polymers based on polyethylene.

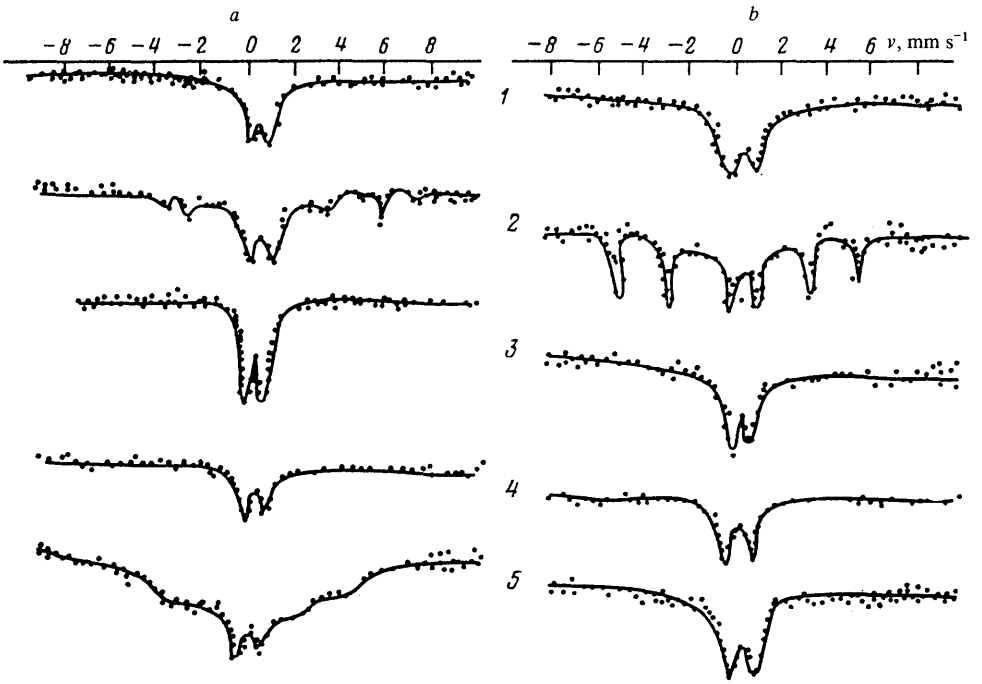

Figure 4. Mössbauer spectra of "cluspol" materials: (*a*) PE + Fe, (*b*) PTFE + Fe. Metal concentration: *1*) 3.0, *2*) 5.0, *3*) 7.0, *4*) 10.0, *5*) 30.0 wt.%.

Thus, as we have already pointed out, the narrow component is the first to be affected in the PE spectrum. Since the NMR spectra give information on the mobility of molecular chains, the decrease in intensity and increase in width of this component indicate changes in the segmental motion of the molecular chains in the amorphous phase, and also in the rotational and diffusive motions of the CH_2 groups about the fixed axes[57]. Thus the NMR results confirm that the formation of metallic particles begins in the amorphous regions, which are "looser" than the crystalline regions.

The introduction of metallic clusters makes the material more monolithic (more "pseudo-crystalline"), and also more thermally stable.

Table 2. Effect of the presence of iron clusters on the melting points of composites.

Sample	[Fe], wt.%	T_f, °C	Sample	[Fe], wt.%	T_f, °C
PP (atact.)*	0	89.0	PP (atact.)	30	155.0
PP (atact.)	3	123.0	PP* (isotact.)	0	158.0
PP (atact.)	5	145.0	PP (isotact.)	5	166.0

*Sample heated and treated in the same way as in the preparation of "cluspols" except for the addition of the MOC.

Direct experimental measurements of the thermal stability of the polymers (Fig.6) show that the addition of small amounts of metal raises T_{dec} by 50–80 K. More interesting results were obtained with atactic polypropylene (PP), which is a waxy substance with a softening temperature of ~90 °C. The addition of even very small amounts of iron to this material causes a sharp rise in the melting point, which can be made to approach the melting point of isotactic polypropylene (Table 2).

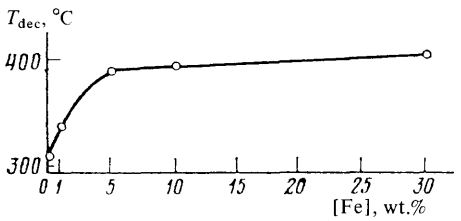

Figure 6. Effect of the addition of iron clusters on the thermal stability T_{dec} of polyethylene.

Since thermal stability is often related to molecular mobility, we should examine the dynamics of the polymer chains. The temperature dependence of the spin–lattice relaxation time (T_1) of the protons has been studied in a sample of LPPE (low-pressure polyethylene) containing ~30 wt.% of iron (particle size ~20 Å). Temperature plots of the spin–lattice relaxation times in the initial PE and in LPPE + 30% Fe are shown in Fig.7. This behaviour of T_1 reflects an average of the molecular mobility characteristics of the two phases (crystalline, and amorphous). The minima at 260 and 280 K for PE and PE + 30% Fe respectively can obviously be ascribed to the segmental motion of the polymer chains, whose thermodynamic characteristics tend to describe the thermal stability of the PE. In the temperature region of the minima in T_1 the correlation frequency (ν_c) of the molecular motion is equal to the spin precession frequency ν_0 (~40 MHz). The depth of the relaxation minimum in this case is a measure of the amplitude of the segmental motion of the polymer chain elements as well as of the change in the relative amount of the phases with different molecular mobility.

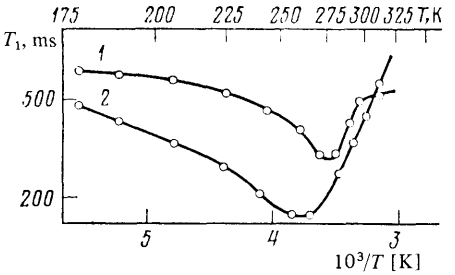

Figure 7. Temperature dependence of the spin–lattice relaxation time in the initial polyethylene and in polyethylene containing 30 wt.% of iron: *1*) initial LPPE, *2*) LPPE + 30%.

Thus the shift of the relaxation minimum in the high-temperature region of PE + 30% Fe, and the increase in T_1, denote the same effect: a strongly hindered segmental motion (as compared with the initial PE), and a correspondingly lower displacement amplitude. Since the amorphous phase has a higher molecular mobility, the motion of the polymer chains is suppressed in this phase at first, and the thermodynamic characteristics change towards those of the crystalline phase. However, conversion of the amorphous phase into a crystalline phase by the addition of finely divided iron seems unlikely. More probably, the very small iron particles are deposited initially in the amorphous, looser regions of the PE sample, where they suppress the molecular motions both by decreasing the free volume and (possibly) by forming chemical bonds with the matrix. This process, which increases the thermal stability, should be accompanied by changes in all the spectral characteristics, including the spin–lattice relaxation time, the specific heat, and the mechanical properties at ordinary temperatures.

Very surprising results were obtained by comparing the melt-flow indices of polyethylene and polyethylene with 20% of iron: the average flow decreased from 6.12 g to 0.049 g, i.e. more than 100-fold.

3. Some Physicochemical Properties of Materials of the "Cluspol" Type

The polymer matrices (polyethylene and Teflon) are relatively inert towards corrosive media. The interaction of powdered "cluspol" materials with hydrochloric and with hydrofluoric acid (diluted with water in a ratio of 1:1) and with bromine at 50 °C for 5 h has been studied[6]. No significant breakdown of the material was noted, but the colour of the powder changed from black to dark grey, and a small amount of metal was transferred to the solution. Thus, at

an iron concentration of 7.39 wt.%, 14% of the iron originally present was extracted into the solution.

The low-angle X-ray diffraction curves for these samples (Fig.8) show that acid treatment of the HPPE + Fe material tends to wash out the clusters with $d \geq 60$ Å. In the NMR spectra of the treated smaples a narrow component appeared with the broad component, though it had been previously established that this NMR component does not occur in polyethylene containing more than 3 wt.% of iron. These results suggest that the localisation sites of the larger ($d > 60$ Å) clusters are in the outer, mainly amorphous regions of the polymer particles. The remaining clusters (15–20 Å in diameter) are formed in the holes of the structure and are strongly held there. In polyethylene the localisation sites of the 15–20 Å clusters are probably crystal defects (in the crystalline regions) and holes (in the amorphous phase).

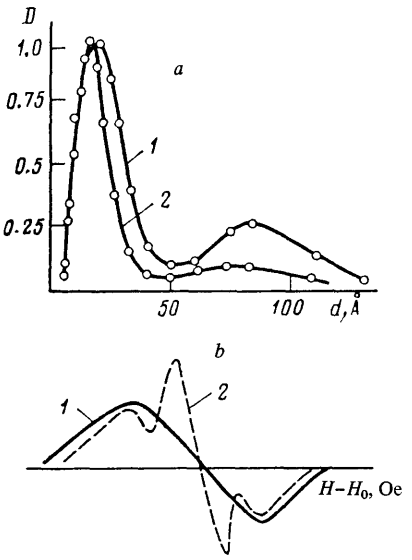

Figure 8. Changes in particle size distribution from low-angle X-ray diffraction results (*a*) and from the shift in the NMR spectra (*b*) produced by acid treatment of "cluspol" samples: *1*) initial sample, *2*) sample treated with HCl.

Thus we have developed a method of preparing "cluspol" materials containing metallic clusters with a narrow size distribution in polymeric matrices of the polyethylene and Teflon type. We have shown that the method is applicable to a wide range of metals and to different matrices. From a combination of physicochemical and structural studies we conclude that the metal clusters are located in natural holes of the polymer matrix, where they interact strongly with the matrix. The properties of the material and its physicochemical characteristics (magnetic, electrical, etc.) do not point to the presence of a metallic phase. The strong cluster–polymer interaction produces quasi-crystalline properties in the polymer matrix. Thus the materials of the "cluspol" type can be treated as single-phased metal–polymers in certain ranges of metal concentration.

Studies of the properties of these materials have only recently started: two types of characteristic (electrophysical, and magnetic properties) have been examined.

4. Electrophysical Properties of "Cluspol" Materials

The polymer matrices used for the preparation of "cluspol" materials are typical dielectrics. The addition of metallic particles to dielectrics in order to obtain electrically conducting polymer composites has long been a standard procedure in industry (in particular, electronics and radio), to give electrically conducting coatings, adhesives, etc.[58,59] The metal content of these composites is usually several tens of per cent by weight, and the particle size of the metal varies from a fraction of a micrometer to tens of micrometers.

Table 3. Electrical resistivity of "cluspol" composites.

No.	Sample	[Fe], wt.%	*R*, Ohm m
1	Teflon-40	20	10^{13}–10^{14}
2	Teflon-40	30	14
3	HPPE	20	$2.4 \cdot 10^2$

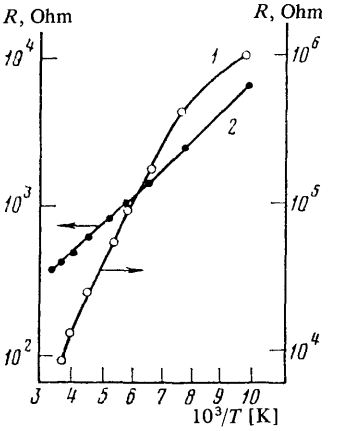

Figure 9. Resistance of "cluspol" samples against reciprocal temperature: *1*) PTFE + 30 Fe, *2*) HPPE + 20% Fe.

In "cluspol" materials the metallic clusters are accommodated in natural holes of the polymer matrix, at average distances from each other of 90–220 Å (depending on the metal concentration). This configuration of the clusters excludes the possibility of direct contact between metal particles and the formation of electrically conducting channels. Our electrophysical measurements on samples of "cluspol" materials (see Table 3) show that the addition of iron clusters to the polymer matrix can lower its electrical resistivity from 10^{15}–10^{16} Ohm m (a typical value for polymers such as HPPE and PTFE) to as little as 14 Ohm m (a typical semiconductor value).

These results also show that the resistance is very sensitive to the sample preparation conditions. For example, sample No.2 was prepared by pressing the powder into a cylinder at 120 atm and 280 °C, and used to study the variation of resistance with reciprocal temperature. We note from the results (Fig.9) that the electrical conductance increases with temperature in the experimental temperature range. The

plot is very similar to comparable plots for typical semiconductors.

Thus the electrophysical properties of polymers can be controlled between wide limits by introducing metallic clusters into natural holes of the polymer. However, more detailed and comprehensive studies of these effects are needed.

5. Magnetic Properties of "Cluspol" Materials

The static magnetic properties were measured for concentrations between 0.1 and 30 wt.% of iron at temperatures between 1.6 and 300 K with fields of up to 10 kOe (Fig.10). A characteristic temperature (T_m) corresponding to a maximum in the plot of magnetisation against temperature was observed in all samples cooled from 300 K to 4.2 K in the absence of a magnetic field. This maximum disappears if the sample is cooled in a field[60,61].

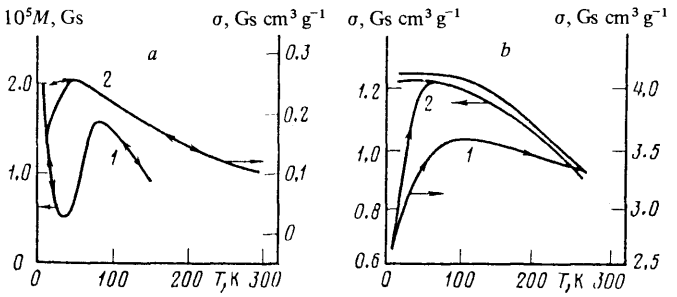

Figure 10. Temperature dependence of the magnetisation of samples containing different amounts of metal: (*a*) *1*) PTFE + 1% Fe, H = 10.2 kOe; *2*) PTFE + 5% Fe, H = 10.2 kOe; (*b*) *1*) PTFE + 30% Fe, H = 1.9 kOe, *2*) HPPE + 30% Fe, H = 1.3 kOe.

The magnetic properties are determined by the ensemble of superparamagnetic particles of the given metal, whose crystal structure differs from that of the massive metal. For the PE + Fe samples we have shown[56] that the change in structure is caused by the influence of the polymeric macromolecules; analogous effects are reported in Ref.62. The change in crystal structure of the particles produces sharp changes in magnetic properties. In iron and cobalt the effective anisotropy constant of the crystal field is increased[61]. Below the temperature T_m, determined by the locking temperature T_{lock}, the magnetic moments of the iron and cobalt particles are "frozen" in the anisotropic crystal field. The presence of T_{lock} makes the magnetic properties of the sample a function of the cooling conditions (as in the case of the spin glasses). In the PE + Cr samples the magnetic moments of the particles remain unfrozen down to 1.6 K (possibly because of their very small size). The iron metal–polymers contain, in addition to particles with $d \geqslant 100$ Å, much smaller particles which remain supermagnetic down to 1.6 K.

Thus our results show that the exchange and other collective interactions between particles of metallic clusters are retained in "cluspol" materials.

IV. POSSIBLE APPLICATIONS OF "CLUSPOL" MATERIALS

At the present stage of development insufficient data are available for the fields of application of the new material to be identified. It appears likely, however, that these materials will be exploited as thermally stable materials, as magnetic materials with properties similar to those of amorphous magnets and spin glasses, and as a new class of semiconducting polymers offering a wide range of parameters.

The Technology, Structure, and Properties of Organosilicon Dielectrics-polyorganosilasesquioxanes

A.M.Ton'shin, B.A.Kamaritskii, and V.N.Spektor

The available information about the technology of the preparation of polyorganosilasesquioxanes, their structure, and properties is described systematically, surveyed, and compared with that on inorganic oxide dielectrics. The possibilities and advantages of their application as dielectric materials in semiconductor electronics are examined; analysis of the experimental literature data has led to the conclusion that the method of preparation has a decisive influence on the mechanism of the formation of oligomer molecules their conversion into polymers, and their interaction with various supports.
The bibliography includes 281 references.

I. INTRODUCTION

The development of the leading branches of the national economy such as power engineering, electronics, computer technology, electrical engineering, radioengineering, instrument making, etc. is linked directly to the accelerated incorporation in industry of new physical principles and expansion of the applications of those already known. This is possible solely on the basis of materials with characteristics conforming to the maximum extent to their functional purpose[1].

One of the most widely used materials in modern electronic engineering is single crystal silicon[2,3], on the basis of which a whole range of semiconductor devices has been created. The importance of silicon as a general purpose semiconducting material will not diminish in the future. Following the expansion of the assortment of special purpose semiconductors such as compounds of the type $A^{III}B^{V}$, $A^{I}B^{V}$, $A_2^{II}B^{IV}$, $A^{II}B^{V}$, $A^{II}B^{VI}$, oxides, chalcogenides, ternary and more complex inorganic compounds[2,3], and organic semiconductors[1,4], silicon will be employed still more vigorously and economically in electronic structures where its useful properties are most fully realised.

II. DIELECTRIC MATERIALS IN ELECTRONIC INSTRUMENT MAKING

The necessity to employ dielectric materials in the manufacture of semiconductor instruments[3,5] and integrated circuits is generally known. In metal–dielectric-semiconductor metallic structures (MDS structures) or, as a special case, metal–oxide–semiconductor structures (MOS structures), the dielectrics are active structural elements. Furthermore, oxide dielectrics are used in the technology of semiconductor instrument making as masks in thermal diffusion or ion beam doping processes[6-8]. Amorphous silicon dioxide, formed either by the thermal oxidation of the surface of a single crystal[9,10] or by the decomposition of organosilicon compounds, for example, pyrolysis, hydrolysis, or treatment in a glow discharge plasma[11-13], is widely used in silicon devices. The influence of the conditions of preparation on the quality of amorphous silicon dioxide films has been examined[14-17] and the dependence of the electrical strengths of the films obtained by different methods (thermal oxidation in dry oxygen, high-frequency and reactive deposition) on the method of preparation has been established[15]. As in prolonged annealing in an atmosphere of nitrogen at temperatures in the range 250–500 °C,[14] an increase of the defectiveness of the film is due to the development of pores all the way through the film and the formation of microcrystallites in the amorphous dielectric. The processes involved in the preparation of silicon and titanium oxides without carbonaceous impurities (the limiting impurities for a dielectric on the surface of silicon in view of the possible carbidisation) by the hydrolysis of the corresponding tetraethoxy-derivatives have been subjected to thermodynamic analysis[16] and the process conditions have been determined.

The influence of the properties of amorphous silicon dioxide on the parameters of silicon MOS structures has been examined in detail in a number of studies[10,18-35]. Analysis of the results[19-21,32,33,35] has led to the concept of the structure of the silicon single crystal–amorphous SiO_2 system illustrated in Fig.1, from which one can see the complex structure of the transition layer incorporating both the material of the single crystal, as a result of the dissolution of oxygen in the surface regions and the formation of additional surface and interphase[35] states of different kinds, and to an even greater extent the material of the amorphous dielectric particularly near the interface. The amorphous SiO_2 on the surface of a silicon single crystal is distinguished by a pronounced layer inhomogeneity and undergoes a series of phase transitions depending on the distance from the interface.

Region I (Fig.1) of amorphous SiO_2 (distance up to 10 Å), incorporated in the transition layer, is characterised by the non-stoichiometry of the oxide[19,21,22,33] and the presence of incomplete hydrated and distorted silicon–oxygen tetrahedra[19]. It is followed by region II (between 10 and 30 Å), consisting of amorphous material with a pseudo-coesite structure, which is due to the operation of compressive forces (the compensating stretching forces act on the silicon single crystal). The relaxation of the internal stresses[22,31] in the $Si–SiO_2$ system, which occurs mainly in this region, leads to local breaks in the continuity of the layer. It is significant[31] that, regardless of the oxidation conditions, the grown oxide may be metastable and the structural mechanical stresses in it do not relax fully. Region III is a zone of the phase transition[20] from the non-equilibrium pseudo-coesite structure to the pseudotridymite structure of the bulk-phase oxide characteristic of amorphous SiO_2 (region IV). This phase transition is characterised by an intensification of the $p_\pi d_\pi$ interaction and therefore extends up to 30 Å.

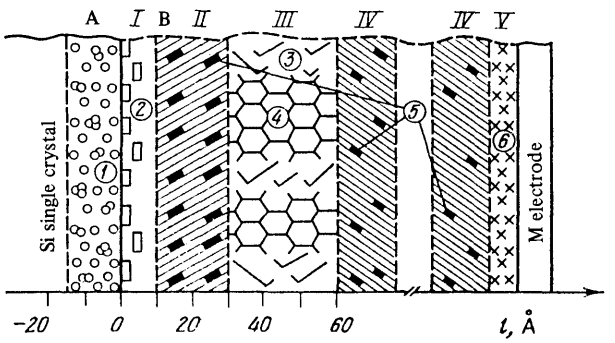

Figure 1. Schematic illustration of the MOS structure on silicon with thermal oxide[19–21,32,33,35]: region A—stretching stresses relaxation zone in a silicon single crystal saturated with interstitial oxygen atoms and clusters (1); region I—transition region corresponding to the non-stoichiometric oxide SiO_x (with $x < 2$) containing inclusions of polycrystalline SiO_2 (2), concentrated predominantly in the immediate vicinity of the interface; region II—existence of the oxide in the short-range and long-range order pseudocoesite modifications with inclusions of nuclear crystals of the oxide (5); region B = region I + region II—compressive stresses relaxation zone in the amorphous oxide; region III—region of the pseudocoesite—pseudotridymite phase transition with dislocation boundaries (3) and hexagonal channels (4); region IV—characteristic region of the bulk of the oxide existing in the short-range and long-range order pseudotridymite modifications with inclusion of 10–50 Å nuclear crystallites of the oxide (5); region V—region of the oxide near the electrode with an incorporated limited space charge and atoms of the electrode metal (6) (the monomolecular and multimolecular layers of the metal oxide exist on the surface of the sputtered metallic polycrystalline electrode at the metal–amorphous SiO_2 interface).

The concept of the fragmented spatial atomic network in the bulk of amorphous silicon dioxide, formed by a mosaic of self-limited ordered clusters–rings formed by 4, 6, and 8 silicon–oxygen tetrahedra, is being developed[20]. The internal boundaries of regions II and IV constitute a system of hexagonal channels and the coesite–tridymite phase transformation region III leads to the formation of extensive defects–assemblies of dislocations. It is difficult to agree with one of the conclusions of the authors of the above studies[20], namely that the multilayer structure of the thermal SiO_2 film is the main cause of the high degree of perfection of the SiO_2/Si system. This conclusion must be compared with the results of other investigations of the structure of the layer of amorphous SiO_2 on single crystal silicon[19,21] from which follows the necessity to take into account the heterogeneity of the material of the oxide film within the layer, in particular, the formation of nuclear crystallites within the bulk of the film with dimensions amounting to tens of angstroms and of polycrystalline inclusions and local discontinuities near the interface[21].

Thus there is a metastable compensation of various defects in the $SiO_2–Si$ system, which is the reason for the marked dependence of the quality and characteristics of the resulting electronic structures[29,34] on the conditions of their formation. In MOS structures it is necessary to take into account also the characteristics of region V—the zone of the dielectric near the electrode, the properties of the dielectric–metal contacts, and the nature of the metal[26]. The phenomena involving the heterogeneity of amorphous silicon dioxide examined above determine the charge instabilities and fluctuations[10,25,27] and their dependence on external factors: the influence of optical radiation[28], γ-radiation[23,24], the presence of impurities[24], and ion transport[30]. In connection with the foregoing, the claim[18] that the properties of vitreous substances are most clearly related to their structure in terms of "average order" is valid.

The influence of the transition layer between the semiconductor single crystal and the amorphous oxide dielectric, which to a large extent determined the concentration of the interphase and surface states of the single crystal, is manifested more distinctly when one used, instead of silicon dioxide, other oxides in the MOS structures, for example, titanium dioxide. In contrast to silicon dioxide, the titanium dioxide layer cannot be grown thermally on the surface of a silicon single crystal and the usual method of its deposition consists in decomposing organotitanium compounds[8,16,36]. The temperature dependence of the degree of crystallinity of titanium dioxide films on single crystal silicon under sputtering and annealing conditions has been published[36] and a schematic description of the structure of the system has been presented: a TiO_2 film on single crystal silicon at different deposition and annealing temperatures. It was observed that, at any TiO_2 deposition temperature, a multicomponent heterogeneous system is formed in which there is a more or less extensive transition layer, the degree of crystallinity of the film increasing sharply with increase of temperature. At a deposition temperature in excess of 550 °C, three phases coexist in the material of the oxide: amorphous phase, anatase, and rutile, while at the optimum decomposition temperature for organotitanium compounds (725–925 °C [16]), almost completely crystalline titanium dioxide (rutile with anatase inclusions) is produced. Furthermore, under all deposition conditions, a more or less extensive polycrystalline transition layer is present in the single crystal–oxide system.

The increase of the instability of the amorphous state in connection with the formation of polycrystalline structures is possible in many technological processes for the preparation of thin oxide films. For example, in the preparation of two- and multi-layer oxide films of the $SiO_2–Al_2O_3$ type[37], there is a possibility of the formation of polycrystalline silicates, while

the interaction of complex oxides in the formation of protective oxide films obtained by anodising the surfaces of semiconductor crystals of the $A^{III}B^{V}$ and $A^{II}B^{VI}$ type can also lead to the formation of polycrystalline compounds. The most general process for these semiconductors involving the deposition of dielectric coatings is therefore the decomposition of organoelemental, usually organosilicon, compounds or silicon halides and hydrides. Depending on the process conditions and the composition of the gaseous or vapour phase, SiO_2 or silicon oxide nitride (SiON) is formed on the surface of the semiconductor single crystal. A transition layer containing the products of the chemical reactions of the material of the film and the single crystal is formed at the interface. The formation of an interface between GaAs and InP semiconductor single crystals and the amorphous dielectrics SiO_2 and SiON deposited chemically on them from the vapour phase has been described[38]. The properties of the interface and the structure of the insulating layers depend greatly on the process temperature and the chemical nature of the semiconductor single crystal. The general inhomogeneity of the dielectric coating has been noted.

The use of organisolicon polymers in electronic engineering holds out most promise and this is in fact the subject of the present review. On must note that such prospects are based on serious experience gained in the industrial manufacture and applications of organosilicon resins and varnishes[42–46] in electronics and semiconductor instrument making.

III. THE SYNTHESIS AND TECHNOLOGY OF THE PREPARATION OF OLIGO-ORGANOSILASESQUIOXANES

The founder of the chemistry and technology of organosilicon compounds is academician K.A.Andrianov, who began his researches in this field in the 1930's and has consistently developed various fundamental and applied fields of organosilicon chemistry, in particular the chemistry and technology of organosilicon polymers.

This review is devoted to the technology, structure, and properties of oligo- and poly-organosilasesquioxanes (OOSSO and POSSO), i.e. organosilicon compounds with a functionality up to three and above. Subsequently the term "functionality (F)" will be understood as the average functionality of the initial mixture of organochlorosilanes (OCS), corresponding to the number of chlorine atoms bound to the silicon atom and involved in the hydrolytic condensation reaction. Compounds with $F = 2.0$ and, in particular, siloxane rubbers have been described in detail in a monograph by Voronkov and co-workers, which lists 5000 references[50], while the industrial technology and certain applications of polyorganosiloxanes have been described in monographs[51,52] and in another publication[53].

The expression "functionality of the oligomer (polymer)" implies that the compound has been obtained by the hydrolysis of a mixture of OCS having the same functionality.

We shall consider mainly studies which have not been covered by earlier surveys[50–52].

1. Preparation of Oligo-organosilasesquioxanes

The preparation of soluble and fusible OOSSO leads to new possibilities in the technology of electronic instrument making. OOSSO hardened directly on a support have come to be used in specific semiconductor instruments and integrated circuits, where they serve as materials of passivating films, active dielectric layers, protective coatings[54–56], and thermal diffusion masks[57] instead of silicon dioxide, obtained traditionally by oxidising the surface of single crystal silicon or by decomposing organosilanes.

In the periodic synthesis of OOSSO [58,59] there is a great probability of the formation of an infusible and insoluble skeletal polymer—gel, while in the hydrolysis of OCS with large substituents there is less likelihood of such a process[60].

The preparation of general purpose dielectrics requires oligomers without a microgel and with a low carbon content (with small substituents), which are synthesised by the appropriate organisation of the technological process.

The residence time of the OCS in the periodic type of reactor is determined by the sum of the time taken to prepare the reactant charge, the reaction time, and the time taken to remove the product. The residence times in the reactor for the first and last portions of the OCS therefore differ greatly, which leads to a considerable scatter of the molecular weights of the resulting OOSSO and the formation of large amounts of gel. The contact time between OCS and the reaction mass in a continuous operation vat reactor with stirring can also differ greatly for the first portions of the reactant according to Levenspiel[61] and Reikhsfel'd et al.[62] Only two-thirds of the OCS introduced is passed straight through the reactor and its contact time is equal to the time taken to traverse the volume of the reactor; 1–3% of the reactant remains in the reactor in constant circulation. With this organisation of the technological process, it is difficult to avoid gel formation and a considerable scatter of the molecular weights of the resulting oligomer. It has been shown[57] that the use of such an oligomer as the electronic resistor for thermal diffusion masks on a semiconductor support does not lead to optimum results.

Other ways of obtaining oligomers without a microgel and with a narrow molecular weight distribution (MWD) in a periodic reactor are possible. Higher alkyltrichlorosilanes with a number of carbon atoms n_C in the substituent between 6 and 10 have been hydrolysed in concentrated hydrochloric acid at the normal pressure[63]. This results in the formation of comparatively low-molecular-weight substances with a high content of hydroxy-groups and having the general formula $[RSiO(OH)]_n$, where R = C_6H_{13}, C_7H_{15}, C_8H_{17}, or C_9H_{19} and $n = 6$ or 8; they are readily soluble in benzene, toluene, and ether and on heating are converted into liquid alkylsilasesquioxanes having the general formula $[RSiO_{1.5}]_{6;8}$. Their hydrolysis in the absence of a solvent results in the formation of stable emulsions in this instance. It has been suggested that the hydrolysis of higher OCS be carried out under a pressure of 15–80 atm with 0.165–0.465 mole of water per Si–Cl bond[64]. The hydrolytic reaction proceeds via an intermediate[65]. A method has been proposed[66] for the preparation of the oligomer by the hydrolysis of tetraethoxysilane in ethanol. All these methods, which are of undoubted preparative interest, suffer from many disadvantages from the standpoint of the preparation of high-quality dielectric films and coatings for semiconducting materials because the oligomers obtained have a high ineradicable impurity content.

One of the few instances where the periodic organisation of the technological process does not entail a reduction of quality and involves merely a decrease of the yield of the desired product is the synthesis of octaorganocyclo-octasilasesquioxanes[67], for example, octavinylcyclo-octasilasesquioxane[68] or ethylvinylcyclooctasilasesquioxane[69]. A characteristic feature of these compounds are that they can be isolated from the mixture of reaction products by sublimation in the form of pure substances, undergoing a comparatively far-reaching purification under these conditions.

2. The Preparation of OOSSO with Small Aliphatic and Aromatic Substituents

A general purpose dielectric for electronic engineering must meet fairly rigorous requirements—all its dielectric characteristics (ε, $\tan\delta$, ρ_V, E_{br}, the space charge Q_V, and the surface charge Q_S) must be at least not inferior to those of the pyrolytic silicon dioxide and at the same time must ensure either the possibility of the realisation of new physical principles in electronic instrument making or must have sufficient technological advantages which would justify the expenditure on its development and employment. With the periodic organisation of the process or in a discontinuous action vat reactor, it is impossible to obtain products satisfying the above requirements.

One of the most important methods of terminating the growing chain in three-dimensional polycondensation involves the cyclisation reaction[70]. The cyclisation processes in the hydrolytic condensation of OCS are most influenced by the hydrolysis conditions.

On the basis of the foregoing considerations and a number of investigations[60,70-80], one can formulate the principal requirements to be met by the continuous process involving the hydrolytic condensation and cocondensation of OCS, particularly when the functionality of the mixtures to be hydrolysed is $F \geq 3.0$: (1) no mixing of the reaction products with the initial OCS; (2) a minimal residence time of the reaction products in an acid medium; (3) effective removal of heat from the entire volume of the reactant; (4) the universality of the hydrolytic condensation of various OCS and their mixtures with $4.0 > F \geq 2.0$; (5) simple scaling.

For the given conditions, the above requirements are satisfied to the greatest extent by the technological formulation of the processes put forward and justified by Andrianov et al.[70]

In view of the high lability and instability of silanols (the intermediates in the hydrolysis of OCS), the study of the condensation process is difficult. However, this process can be described qualitatively from the standpoint of the kinetics of homogeneous chemical reactions[81,82].

Since the hydrochloric acid formed in hydrolytic condensation catalyses further condensation reactions of the Si–OH groups, an important task in the organisation of the continuous operation process is the regulation of its overall rate. This is achieved by familiar procedures[83]: by introducing an acceptor into the reaction mixture which binds chemically the hydrogen chloride, by analogy with the continuous procedure for the synthesis of tetrabutoxytitanium[36,83]; with the aid of high dilution (with a high yield of cyclic products)[84]; using monomers with large organic substituents at the silicon atom[63,85]; by the preliminary partial alkoxylation (acylation) of the organotrichlorosilanes, as in the industrial preparation of the KO-928 varnish.

In the course of the subsequent hydrolytic condensation, the partly esterified products[80] behave like bifunctional OCS, since the rate of hydrolysis of the Si–Cl bond is much higher than that of the Si–OR or Si–O–COR bond[86].

The hydrolytic condensation of OCS or OCS systems with a high functionality and a small substituent at the silicon atom, in particular the methyl substituent, is accompanied by the formation of methylsilanols, which are extremely labile and sensitive to changes in the pH of the medium[87].

A straight glass condenser with an internal diameter of 20 mm and 700 mm high can serve as a laboratory model of the reactor for the continuous hydrolysis of lower OCS.[70] Under industrial conditions, for example, in the manufacture of the KO-812 varnish, a tubular reactor with the same diameter and height of the tube is used, which is necessary to maintain the hydrodynamic and heat and mass exchange conditions. Laboratory apparatus for the preparation of a solution of oligo-organosilasesquioxane without a microgel is illustrated in Fig. 2. Solutions of oligomers with functionalities in the range $2.0 \leq F < 4.0$ can be prepared on such apparatus[70], which has been demonstrated in relation to a series of industrial recipes for organosilicon resins and varnishes, for example K-5, K-9, K-81, and KM-9. In the lower part of the reactor there is an atomiser through which a solution of chlorosilane is introduced into the water entering the reactor. The volume flow rate of the components is 2.8 ml s^{-1}, which corresponds to an average flow rate of the reaction mixture in the tube of 30 mm s^{-1}. For a specified kinematic viscosity ν, these conditions determine a Reynolds number $Re \cong 300$. For these values of Re and in the absence of perturbations at the inlet, the flow in circular tubes is laminar, which makes it possible to neglect diffusion as a slower concentration equalising process. For the same reason, the temperature and the flow rate are constant throughout the cross-section.

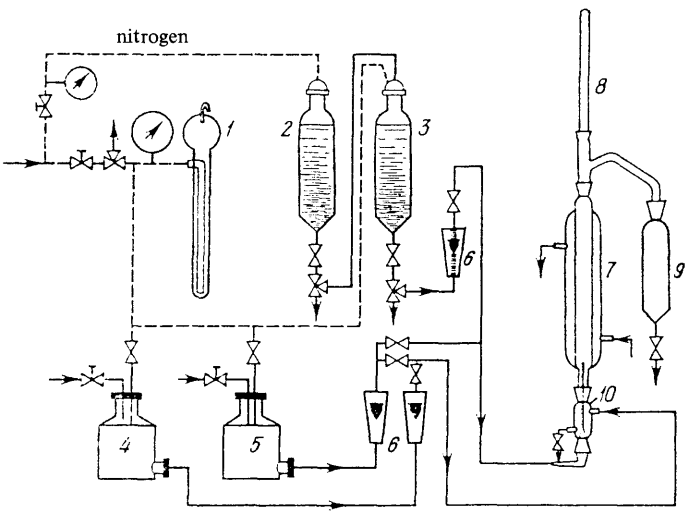

Figure 2. Schematic illustration of the laboratory apparatus for the continuous hydrolysis of organochlorosilanes[73,88]: 1) manostat; 2) reservoir for the preparation of OCS solutions; 3) OCS supply reservoir; 4) water supply reservoir; 5) acetone supply reservoir; 6) flow meters; 7) reactor; 8) thermometer; 9) receiver; 10) partitioning device.

Near the inlet for the OCS solution into the reactor, vigorous turbulent mixing takes place due to the chemical hydrolysis of the OCS, with local evolution of much heat and hydrogen chloride, and also a velocity gradient. The eddy relaxation time τ_V is equal to the ratio of the cross-section of the characteristic volume ($S_p \cong 1$ cm^2) to the viscosity ($\nu \cong 0.01$ cm^2 s^{-1}) and amounts to $\tau_V \cong 100$ s. Comparison of the reaction time $t_r \cong 20$ s and τ_V shows that turbulent mixing of the substance within the limits of the isolated volume takes place throughout the reaction time.

Thus the reaction zone is divided into two sections—the vicinity of the site of injection of the reactants and the rest of the reactor; the hydrolytic condensation reaction of trichloromethylsilane (TCMS) can be regarded as occurring

in two stages: the three-step irreversible hydrolysis of TCMS and the condensation of methylsilanetriol. Since the reaction in the first step proceeds during a very short charactertisic time ($\tau_2 \ll 10^{-2}$ s), one may claim that the entire TCMS hydrolyses during a period shorter than 1 s, which corresponds to the region of the reactor near the nozzle of the atomiser (size ~35 mm), from which the solution of the monomeric methylsilanetriol at a concentration equal to that of the initial TCMS (c_0) enters the reactor.

Methylsilanetriol dimers are formed in the reactor:

$$2H_3CSi(OH)_3 \xrightarrow{k_1} H_3CSi(OH)_2-O-Si(OH)_2CH_3 \quad , \qquad (1)$$

and methylsilanetriol adds to the oligomer:

$$H_3CSi(OH)_2-O-[-Si(CH_3)(OH)-O-]_n-Si(OH)_2CH_3 + \\ + H_3CSi(OH)_3 \xrightarrow{k} H_3CSi(OH)_2-O-[-Si(CH_3)(OH)-O-]_{n+1}-Si(OH)_2CH_3 . \qquad (2)$$

The methylsilanetriol condensation processes are bimolecular, so that the rate of formation of dimers via reaction (1) is defined as $k_1c_1^2$ and the rate of addition of methylsilanetriol via reaction (2) to the oligomer is kc_1c (here c_1 and c are the current concentrations of methylsilanetriol and the oligomer respectively).

The onset of the condensation of silanetriol via reactions (1) and (2) is characterised by the conditions $c \to 0$ and $c_1 \cong c_0$, so that $kc_1c \ll k_1c_1^2$. Hence it follows that the rate of addition must become appreciable only in the final stages of the condensation, but in this case it is also low because by that time virtually no unreacted methylsilanetriol remains in the reaction medium.

In contrast to the studies by Roberts[57] and Pruvost et al.[72], in the investigations of Andrianov and co-workers[70,71,82] reaction conditions ensuring the complete suppression of the gel formation process were rigorously maintained. The formation of the microgel begins when the average length of the siloxane chain ($\bar{L}$) corresponds to ten or more monomer units [$n \geq 8$ in the equation of reaction (2)]. The increase of $\bar{L}$ for all the molecules, for example by a factor of two (due to the condensation of pairs of molecules), is associated with a decrease by a factor of two of the concentration c. Consequently synthesis without the formation of a gel requires that $c \cong 0.1c_1$ during the time $t_r \cong 20$ s. The rate constant $k_1 \cong 1 \times 10^4$ and $K = 1 \times 10^3$ ml mol^{-1} s^{-1}, which depend both on the composition of the reaction medium (the nature and proportions of the solvents, the initial concentration of TCMS, etc.) and on the reaction conditions (temperature, contact time, etc.), satisfy such conditions.

Similar requirements to be met by the process conditions hold also for other OCS with a high functionality—trichlorovinylsilane and trichlorophenylsilane, as well as the products of their cohydrolysis with one another or with TCMS, dichlorodimethylsilane, silicon tetrachloride, and polysilicic acids[71,78,89–112]. The influence of the conditions of the synthesis on the relative contributions of the homofunctional and heterofunctional pathways in the hydrolytic condensation and hence on the composition of the reaction products has been noted in studies of hydrolysis of TCMS [70,71,77,83,113,114] and of the hydrolysis of trichlorovinyl- and trichlorophenylsilanes, the cohydrolysis of various OCS having small substituents, and the cohydrolysis of OCS with silicon tetrachloride and polysilicic acids[78,79,83,87–90,98–106,112]. The generality of the competitive mechanism of the linear chain propagation and cyclic compound formation reactions can be demonstrated in relation to the trimethylsilylation of the inorganic compound $Ag_{10}Si_4O_{13}$, which leads to the cyclisation of the linear chain anion $Si_4O_{13}^{10-}$,[115] by analogy with the hydrolysis of trichlorophenylsilane[99], which leads to the formation of the xonotlitic ribbon [or double chain (Ed. of Translation)] oligomers.

As was to be expected from Eqns.(1) and (2), on decrease of the water:TCMS ratio, the content of the oligomer in the organic phase increases and the losses of the water-soluble products in the aqueous phase diminish. However, when the reaction is carried out when there is a deficiency of water, the scatter of the molecular weights of the products may increase. The methods for the investigation of the hydrodynamic process parameters are applicable to the analysis of the products of the hydrolytic condensation of OCS.[100,101,116]

The kinetics of the hydrolytic condensation of OCS as a whole have been considered[77,81,82,113]; in order to obtain quantitative information about the kinetics of reaction (2), it is apparently useful to employ the kinetic method for the calculation of the MWD of the chains between the branching nodes in non-equilibrium polycondensation reactions[117].

In order to obtain materials with the required characteristics, it is important to know the influence of the conditions and various factors on the formation and structure of the oligomers directly in the technological process[88,90], since the structure ultimately determines, for example, the defectiveness and the film-forming properties of the coatings. It has been stated[79,98,102] that, in the cohydrolysis of trichlorophenyl- and trichlorovinyl-silanes, the resulting mixture does not contain the products of the separate hydrolysis reactions and the fractions of the oligomers and polymers retain the initial ratio of the phenyl and vinyl substituents (3:1).[79]

The hydrolytic condensation of TCMS yields a product which is a complex mixture of polycyclic derivatives with various structures. The synthesis of oligomethylsilasesquioxane in a total displacement flow-type reactor with the parallel injection of reactants in a complex acetone–toluene solvent[118] using the thermostatic attachment has been described[88]. The influence of the synthesis temperature on the physicochemical and electrophysical characteristics of the resulting materials has been investigated. The experimental data indicate an increase of the degree of reaction with increase of temperature (Fig.3).

3. Optimisation of the Continuous Hydrolytic OCS Condensation Process

The hydrolytic reactions of OCS permit the variation of the ratio of the solvents and water within fairly wide limits[70,72,77,78,90,104–106,113]. A significant alteration of the process conditions can change the composition (see, for example, Andrianov et al.[114]) or the structure[89,105] of the hydrolytic condensation products.

The necessity to obtain materials with specified properties brought to the fore the problem of optimisation, whose solution makes it possible to automate the continuous hydrolytic OCS condensation process.

For example OCS systems with $F \geq 3.0$ and a small organic substituent are extremely unstable and tend to form gels. The ratio and the order of introduction of the reaction components, for example, TCMS, acetone, toluene, and water, are important in the hydrolytic condensation of such systems[71,77,83,88].

A definite component ratio for which the process could be carried out without gel formation when acetone is introduced simultaneously with the solution of TCMS in toluene has been found experimentally[70,72]. This ratio has been adopted[118] as a basis in devising an optimisation design. The aim of the optimisation was to reduce the consumption of solvents whilst ensuring the formation of a product free from a gel. In order to minimise the consumption of solvents, a consecutive simplex optimisation method was used, because it is

effective in the solution of problems with several responses and limitations.

Optimisation yielded a point with a minimum consumption of solvents (2.81 litres of solvents per litre of TCMS, which is smaller by a factor of 2.6 compared with the periodic process—by a factor of 2.3 with respect to acetone and by a factor of 3.8 with respect to toluene[118]). Tests[71,88] for the stability of a technological regime without gel formation made it possible to recommend the following amounts of the solvent components per litre of TCMS in the process to be carried out under practical conditions: 2.3 litres of acetone, 0.7 litre of toluene, and 2.3 litres of water (temperature 40° ± 5 °C).

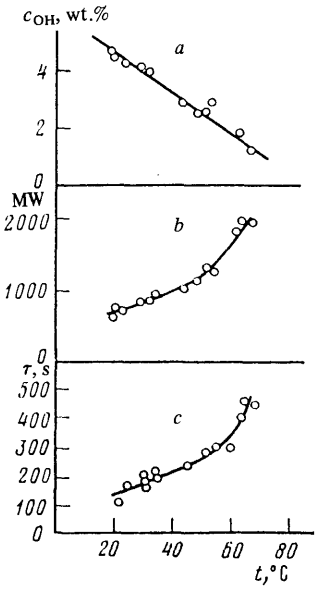

Figure 3. Dependence of the properties of oligomers on the temperature of the synthesis t:[88] *a*) content of hydroxy-groups c_{OH}; *b*) average molecular weight $\overline{MW}$; *c*) gel formation time τ at 200 °C.

The concentration of the required products in the extract and the refined material (in the case of the hydrolytic OCS condensation in the organic and aqueous stages respectively) and the degree of extraction of the reaction products are extremely important technological characteristics of the combined processes involving both chemical interaction and extraction.

The characteristics of the influence of the parameters of the continuous synthesis of OOSSO in a flow type reactor on the concentration of oligomers in the organic and aqueous phases, the content of the hydroxy-groups in the oligomer, the gel formation time, and other characteristics of the hydrolytic condensation products have been investigated[71,77,83,88,113,118].

In conformity with the adopted aim, the concentration of the oligomer in the organic phase, determined from the content of the dry residue, was adopted as the response function and the process temperature, the specific consumptions of acetone, toluene, and water, and the overall volume rate of injection of the components into the reactor were adopted as the factors to be investigated[88,118]. The regression and variance analyses of the resulting equation and its coefficients demonstrated the significance of all the factors investigated except the rate of injection of the reactants (within the limits investigated). The specific consumption of acetone has the greatest influence on the content of oligomers in the organic phase[71,118]; as it increases, the concentration of oligomers falls. The increase of the specific consumptions of acetone and water[71,77,113] leads to a proportional diminution, and an increase of the synthesis temperature[88,118], to an increase of the concentration of the oligomers in the organic phase in the range 19–24%. The concentration of oligomers in the organic phase, calculated from the regression equation for the process carried out under the conditions of the minimum consumption of the solvents, agrees with the experimental value within the limits of the error.

The degree of extraction of the reaction products determines to a large extent whether or not the process is economical. An increase of the synthesis temperature entails a corresponding increase of the yield of the polycyclic products sparingly soluble in the aqueous phase[49,92,114] and hence a diminution of their losses. An increase of the consumption of acetone leads to an increase of the solubility of OOSSO in the aqueous acetone phase and to an increase of the losses. An increase of the consumption of water (a decrease of the concentration of HCl) produces a decrease of the rate of condensation and an increase of the fraction of primary hydrolysis products (organosilanetriols), which are readily soluble in water[49,113] and are carried away with the latter. The complex dependence of the degree of extraction of the products on the consumption of toluene is explained by the fact that the extraction of oligomers from the reaction mixture consists mainly in the extraction from the water–acetone fraction into the toluene–acetone fraction. The initial increase of the degree of extraction with increasing consumption of toluene is therefore associated with the decrease of the solubility of the oligomers in the water–acetone fraction depleted in acetone. A further increase of the consumption of toluene, in which the solubility of the oligomers is low[49], leads to a decrease of the solubility of the oligomers in the organic phase and an increase of the losses of the required product owing to its transfer to the aqueous phase.

The method for the optimisation of the technological process involving the hydrolysis of TCMS can be applied in the study of the hydrolytic condensation of other OCS and the cocondensation of their mixture. Continuous hydrolytic condensation processes with the vinyl-, chloromethyl-, and phenyl-substituted trichlorosilanes have been optimised with the aid of the consecutive simplex method[118] and the data obtained by different workers for the hydrolytic condensation of OCS and their mixtures have been compared[49–51,70,71,77,79,83,87,88,90,92,95,104,113,114].

The possibility of continuous processes involving the hydrolytic cocondensation of TCMS with trichlorosilane, silicon tetrachloride, and polysilicic acid has been examined[89,93–95]. It has been established[70], that the formation of fully soluble products is ensured by carrying out the processes in acetone with subsequent extraction of the reaction products.

4. The Shell Model of the Hydrolytic OCS Condensation Process

The hydrolysable systems in a total displacement reactor have been analysed on the basis of the ideas of the kinetics of homogeneous chemical reactions[81,82] in the presence of

acetone, ensuring homogenisation, in the reaction mixture[121]. However, almost all hydrolytic OCS condensation processes realised in industry proceed as a rule under heterogeneous conditions, which requires allowance for diffusion processes in the study of the polycondensation kinetics. As early as 1959, Sokolov was the first to draw attention to this[119] and proposed a model for the hydrolytic condensation of OCS in a heterogeneous system.

In order to attain a free energy minimum, it is believed[120] that the shell of dispersed-phase species can be divided into several layers. The outer hydrophilic layer consists of solvated molecules of oligo-organosiloxanes. The intermediate layer imparts rigidity to the shell of the globule and consists of oligomers with a wide range of molecular weights. This layer grows as a result of the inflow of the OCS hydrolysis products from the inner cavity within the globule. The inner organophilic layer consists of solvated OCS molecules. Hydrolytic processes, which begin within the inner cavity of the globule, are completed in this layer and the condensation processes, completed in the intermediate layer, begin in it.

The probable mechanism of the heterophase hydrolytic polycondensation was examined above. After the formation of the globules, the rate of reaction is determined by the conditions governing the diffusion of the reactants through the interface[120]. As diffusion processes take place, the intraglobular osmotic pressure increases until the rupture of the shell of the globule accompanied by the ejection into the water–acetone matrix of the contents of the inner cavity of the globule and the formation of a new interface. With decreasing concentration of the monomer, the size of the new globule may not then differ appreciably from the initial size, but the rate of reaction within the globules falls. During the passage of the globule through the reactor, the process involving the rupture of its shell may be frequently repeated.

The above model makes it possible to describe the quantitative picture of the process and to explain the difference in the behaviour of the particles of the solid phase of silica gel or hydrated quartz, tending to coalesce[122,123], and the globules described above, whose surface also contains silanol groups, ensuring the possibility of the polycondensation reaction with formation of siloxane linkages. However, the outer hydrophilic surface of the globules constitutes a barrier which prevents the spontaneous coalescence of the particles coming into contact or colliding. The time of contact between the particles, which in the case under consideration is shorter than 25 s while in the studies quoted above[122,123] it amounted to 10–1000 s, has a definite influence on the aggregative stability of the systems. Nevertheless in the case which we have considered there is also a possibility of the coalescence of the globules when certain process parameters are altered (see, for example, Andrianov et al.[89]), which leads to the formation of an insoluble structured polymer and in some cases also to an uncontrollable reaction—the avalanche-like formation of a gel, which completely blocks the reactor.

The hydrolytic condensation process results in the formation of a solution from which the oligomer can be isolated in the solid state. When the process proceeds with formation of multishell globules, the structure of the oligomers as well as the structure of the polymers obtained from them should depend on the process parameters and the oligomer isolation conditions. An X-ray diffraction study of these relations has been carried out.

The results obtained, presented in Fig. 4*a*, demonstrate the influence of the temperature and the composition of the reaction mass on the changes in the supermolecular structures of the oligomers formed. The degree of crystallinity of all the oligomers is slight (it does not exceed 5%). This precludes a quantitative interpretation of the results—only a qualitative treatment is possible. On the basis of the model of the particle and the process mechanism, the insignificant degree of crystallinity of the oligomethylsilasesquioxanes obtained in acetone can be explained by the decisive influence of the rate of diffusion of the reactants through the outer shell of the globule, which favours the formation of low-molecular-weight crystallisable cyclic oligomers of the type of tetrahydroxytetramethylcyclotetrasiloxane (T_4).

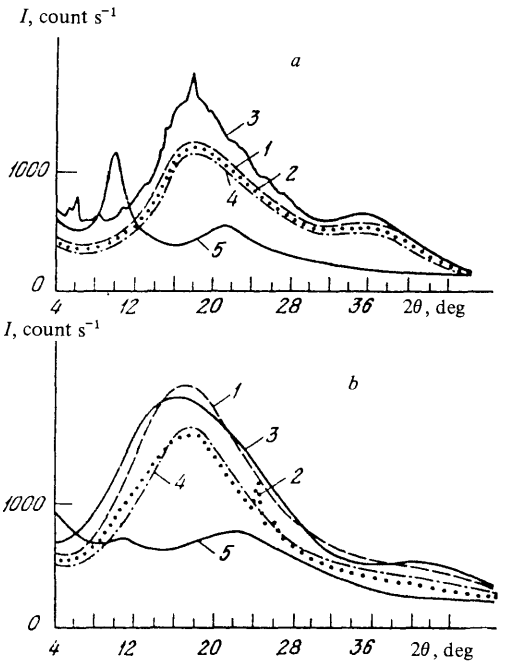

Figure 4. Diffractometer traces for oligo-organosilasesquioxanes (*a*) and polyorganosilasesquioxanes (*b*) (the numbers of the specimens corresponds to those quoted in the Table)[120].

The rate of the subsequent cocondensation of T_4 is reduced as a consequence of the solvation of the hydroxy-groups by acetone. It is significant that the structure of the layer depends on temperature because the constants of the solvation processes and the hydrogen bond formation processes, responsible for the formation of the outer layer, are temperature dependent. When a complex solvent (acetone + toluene) is used, the oligomers formed are amorphous with respect to X-rays.

The data presented in Fig. 4*b* show that the polymers obtained by the condensation of the oligomer containing ~5% of the crystalline phase are fully amorphous, while those obtained by the condensation of the completely amorphous oligomers are apparently crystalline, but the degree of crystallinity does not exceed 5% in this case either.

An additional argument in support of the shell model is the result of the analysis of the width of the first amorphous halo on the diffractometer traces, which is associated with the interchain scattering of X-rays[124,125]. Fig. 4*a* shows the first amorphous halo is extensive (up to $2\theta = 15–18°$), which

indicates an appreciable scatter of the interchain distances, approaching in certain cases 100 Å. Such distances are impossible even for a helical arrangement of the cyclic three-dimensional macromolecules. This indicates the presence of supermolecular formations organised in a more complex manner. The Table lists the half-widths of the amorphous halos calculated from the experimental data (Fig. 4) for the test specimens and, for comparison, the specimen obtained in the presence of a large excess of acetone and water relative to the calculated optimum amount[118]. The Table shows that, while the position of the maximum of the first amorphous halo is relatively constant for all the specimens, its half-width is appreciably altered for the test specimens and is almost an order of magnitude greater than for the control specimen[120].

Dependence of the half-width of the first amorphous halo ($\Delta\theta$) on diffractometer traces for oligomethylsilasesquioxanes on the conditions of synthesis[120].

No. of specimen	T, K	Solvent	$\Delta\theta_1$, deg
1	276	acetone	0.113
2	283	acetone + toluene	0.104
3	280	acetone	0.126
4	278	acetone	0.096
5	313	acetone + toluene*	0.027

*The dilution conditions differ from the optimum conditions calculated by Andrianov et al.[118]

5. Optimisation of the Continuous Process Involving the Synthesis of OOSSO on the Basis of Their Molecular Weight Distribution

In many instances, for example, during the preparation of blended composites, in which it is necessary to ensure an effective distribution of the binder on the filler surface, a wide molecular weight distribution (MWD) is a positive characteristic of the oligomer obtained. Low-molecular-weight reactive cyclic compounds of the type of T_4 or the dimer hexaorganotetrahydroxybicyclotetrasiloxane (T_6) can ensure an even more complete adaptation of the binder as a result of the building up of the oligomeric molecules via a mechanism similar to that of the reactions of siloxanediols with diorganodichlorosilanes[126] or of organocyclosiloxanes with organosilicon diols[127].

However, the attempts to obtain thin dielectric layers and films of polyorganosilasesquioxanes (POSSO) by the polycondensation of the corresponding oligomers lead to negative results in the case of materials with a wide MWD, namely numerous cavities and cracks appear in the film[128], in contrast to the coating obtained on the basis of an oligomer with a narrow MWD.[120]

In order to obtain defect-free structures, one can use one of three methods: the deposition of the polymer or polymerisation on the surface to be protected[11,129–132]; gas and liquid transport chemical reactions and molecular growth ensuring the formation of extremely perfect amorphous oxide films[133–139] (these methods are relatively unsuitable for the formation of polymeric coatings); finally, the preparation of oligomers with a very narrow molecular weight distribution[75, 140] followed by their hardening on the support[109–111].

It follows from the studies devoted to periodic and continuous hydrolytic OCS condensation processes, which dealt with the reaction kinetics[75,81–83,87,88,92–95,104,113,114,141,142] and the MWD of the products formed[49,50,71,75,78,79,88,104,106,120,140], that the formation of products with a narrow MWD can be achieved by altering the conditions in the second stage of the reaction to ensure the predominance of the cyclisation reactions by optimising the process with respect to the MWD of cyclolinear products. The oligomeric intermediates obtained have specific applications depending on the technology of their subsequent converison into the polymer[108–111,140]. The possibility of using cyclic products[71] virtually free of hydroxy-groups as film-forming materials has been demonstrated in studies on the volatility of octaorganocyclo-octasilasesquioxanes (T_8) [69,143] and their polycondensation under the influence of radiation[57,111,140] or catalysts[144–148]. However, despite the comparatively satisfactory characteristics of the films and coatings formed, organocyclosiloxanes with $F \geq 3.0$, in contrast to cyclic compounds with $F = 2.0$,[50] have nowadays found only limited applications[58] in view of the complexity of the technological formulation of the deposition and polycondensation processes, although in the future one may expect their extensive employment in electronics and instrument making as development of apparatus becomes cheaper.

The method of preparation of polymeric dielectric layers from soluble cyclolinear OOSSO, containing 2–4 mole % of hydroxy-groups and with a molecular weight scatter less than 25% is significantly simpler[89,140]. It involves the deposition of solutions of the oligomers on a support by dipping, pouring, pulverisation, or centrifugation with subsequent drying and polymerisation of the material of the film by any of the known methods[52,120,140].

The polymerisation of such oligomers involves preferentially the functional groups and leads to highly cross-linked POSSO [89,140] (as in the study of Katz and Zewi[149]) to which one can apply the statistical model of the structure of a network polymer developed by Topolkaraev et al.[150] for the description of the interrelation between the chemical structure of the initial monomers or oligomers, the kinetics of the condensation reaction, and the technology of the preparation of the network monomer.

In order to obtain oligomers with such characteristics, Kamaritskii[71] used a procedure for the optimisation of the hydrolytic condensation of OCS and in particular TCMS on the basis of the MWD parameters, used as the response, analogously to the procedure described earlier. It has been shown[140] that, when the process is carried out in the vicinity of the new optimum and with a rigorous temperature control in a total displacement flow reactor, it is possible to obtain OMSSO with an average molecular weight $\bar{M} \cong 700$ (with a scatter $\Delta M/\bar{M} \leq 25\%$) and with a hydroxy-group content $c_{OH} = 2$–4 mole %. The products obtained[140] can be described by the revised molecular formula $[H_3CSiO_{1.5}]_{8\pm1.5} \cdot [H_3CSiO(OH)_{1.5\pm0.5}$. The processes involving the subsequent conversion of the OMSSO into the polymer depend decisively on $\Delta M/\bar{M}$ and c_{OH}. The above optimisation has been refined[75] on the basis of the consumption of the raw material components and their ratio taking into account the kinetics of the hydrolytic condensation reaction and, in another study[88], also on the basis of the temperature regime in the process.

6. The Synthesis of Higher-Purity OOSSO; The Possibilities of the Secondary Purification of Oligomers

The dielectrics used in electronic instrument making must meet high requirements as regards homogeneity and purity[151, 152]. The task of improving the materials involves the

improvement of these characteristics or the reduction of the harmful influence of the inhomogeneities or impurities. An example of the reduction of the breakdown characteristics and of the deepening of the breakdown channel, caused by various inhomogeneities in the materials of the dielectrics, has been presented[153].

Polyorganosilasesquioxanes are compounds which are related, on the one hand, to silicates with large cations, forming ribbon structures of the montmorillonite, xonotlite, and kaolinite type[99] (in this sense they fit within the framework of Belov's general classification of silicates[154,155]), and, on the other hand, to silicon dioxide. The properties of silicates and silicon dioxide have so far been investigated in greater detail than those of POSSO, so that the influence of impurities in POSSO can be estimated from their effect on the properties of silicate-based materials which have been studied in detail.

In the industrial manufacture of the KO-812 varnish as well as other organosilicon varnishes[51] and also in the usual laboratory practice, the stabilisation of oligomers in solution is achieved by washing the hydrolytic reaction mixture with a concentrated solution of a salt followed by treatment with KIL clay. The most frequently encountered impurity in POSSO therefore consists of alkali metal ions which are the limiting impurities for silicon and germanium devices and integrated circuits. The Poole–Frenkel' effect has been considered[156] in weak (up to 4×10^5 V cm^{-1}) fields in amorphous silicon dioxide ($E_{br}^{POSSO} \cong 5 \times 10^6$ V cm^{-1}). For films without the limiting impurities, a relation has been obtained between the current density and the applied potential, which has the form usual for the Poole–Frenkel' effect:

$$I = A \cdot \exp\{-(E_{act} - \beta F)^{1/2}/kT\},$$

where the activation energy $E_{act} = 0.2$–1.0 eV, $T = 295$–362 K, and the current density in the oligomers obtained directly by the reaction becomes proportional to n_{Na^+} when the content of sodium ions is only $n_{Na^+} = 10^{17}$–10^{20} cm^{-3}, which is significantly lower than the overall concentration of alkali metal ions (ΣC_M). In oligomers purified to the maximum extent, $n_{Na^+} = 5 \times 10^{13}$–$1 \times 10^{19}$ cm^{-3} and ion transport therefore is unavoidable in MDS structures to which a potential has been applied.

In silica structures there are two types of organisation of the $[SiO_2]_\infty^0$ and $[Si_6O_{17}]^{10-}$ cells—in the form of an infinite three-dimensional network and ribbons of the xonotlite type[157]. The silicates $Ag_{10}[Si_4O_{13}]$ [115] and $[Cu(NH_2CH_2CH_2.NH_2)_2]_4Si_8O_{20}.38H_2O$, incorporating the $Si_8O_{20}^{8-}$ structural element[158] (Fig.5), are similar or analogous to the silicon–oxygen skeleton of the T_8 – $R_8[SiO_{1.5}]_8$ cyclosilasesquioxane (Fig.6).[159] This indicates the similarity of the structural elements of amorphous silica, POSSO, and silicates with large cations and, whereas the possibility of a ribbon–ring transition has been demonstrated[115] for the $[Si_4O_{13}]^{10-}$ anion, in other investigations[49,53] the possibility of the reverse ring–ribbon transition, leading to the formation of a large number of terminal $\equiv$Si–O linkages, at which the alkali metal ions are fixed, has been indicated. The increase of the relative number of non-bridging oxygen atoms[160] and ionogenic terminal groups associated with this factor makes possible both ion and charge transport. These results are important for the estimation of the dependence of the dielectric characteristics of POSSO on the degree of their purification, which follows, for example, from the study of Saratov et al.[161]

The influence of the degree of purification of silicon dioxide on the heats of desorption of the dehydroxylation and de-ethoxylation products has been demonstrated[162,163] and in another investigation[164] the dependence of the activity of silica fillers on the chemical composition has been established, which, as will be shown below, has a significant influence on the character of the reaction at the interface[108].

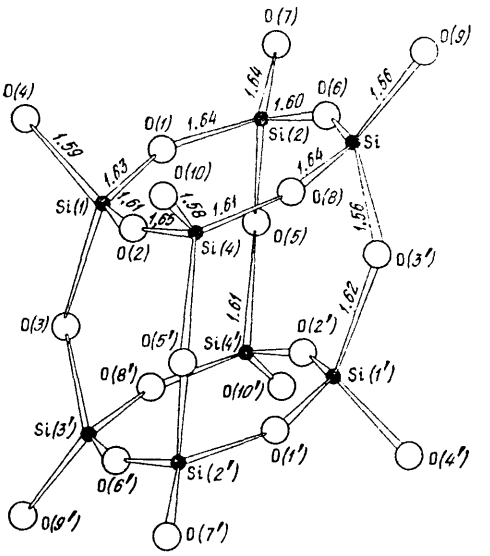

Figure 5. The structure of the skeletal anion $[(SiO_{1.5})_8O_8]^{8-}$.[158]

The sensitivity with respect to active impurities of POSSO with $F \geq 3.0$, having a structure closest to that of SiO_2, and skeletal and ribbon silicates has been investigated[165] by pulsed polarisation and EPR. It has been shown that even very small amounts ($< 2 \times 10^{-2}$ wt.%) of organic free radicals have an appreciable influence on the electret charge and on the character of the EPR spectrum. The statement that there is a possibility of a low-temperature mechanochemical formation of free-radical states in polyorganosiloxanes is of particular interest in this connection[166]. The relaxation of stresses in the large helix of cyclolinear POSSO [121,140] can occur as a result of the rupture of a certain number of $\equiv$Si–O–Si$\equiv$ linkages[89] with formation of ionic[160] and free-radical states[166], which determine the intrinsic impurity content of the POSSO and to a large extent their electret capacity[165]. Inioc states are as a rule to a greater or smaller extent compensated either by external impurities or as a result of the interaction with traces of water:

$$\equiv Si^{\oplus} \quad \equiv Si{-}O^{\ominus} + \begin{matrix} O{-}H \\ | \\ H \end{matrix} \rightleftharpoons 2(\equiv Si{-}OH)\,.$$

Yet another cause of the formation of inhomogeneities in the structure of oligo- and poly-organosiloxanes may be hydrolytic OCS condensation side reactions due to the presence of impurities in the initial monomers. Admixtures of trichlorosilane can initiate gel formation under the conditions of the hydrolytic condensation of trichloromethyl- or trichlorophenyl-silane, whereas traces of chlorotrimethylsilane induce the effective termination of chain propagation, which is the reason for the necessity for the careful control of the quality of the monomers. A chromato-atomic absorption method for the determination of the above impurities in silicon tetrachloride has been proposed[167].

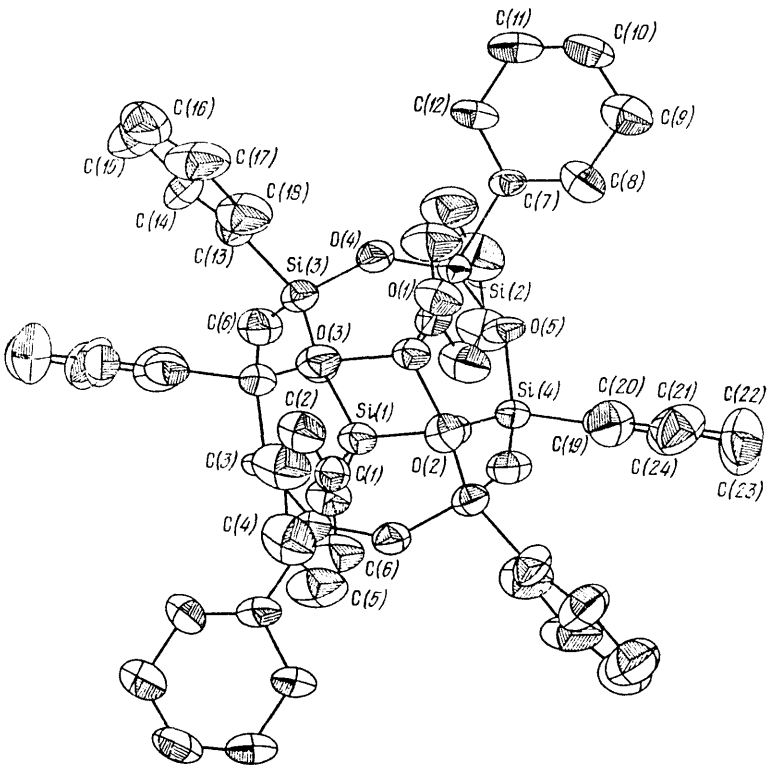

Figure 6. The structure of octaphenylcyclo-octasilasesquioxane $[RSiO_{1.5}]_8$ [projection along the Si(1)—midpoint of the Si(1′)Si(2′)Si(3′)Si(4′) face line]. Only the independent atoms have been numbered; Si(1′) denotes the atom linked to the Si(1) centre of symmetry[159].

Thus, in order to obtain a sufficiently pure product, meeting the requirements of electronic instrument making, it is essential that the reagents, including the solvents and water, be prepared carefully and also that suitable materials be selected for the technological equipment. Additional purification of the oligomer can be achieved by its reprecipitation from an appropriate solvent. However, it is difficult to hope for sufficiently complete elimination of alkali metal ions from the oligomer, since the ions apparently block some of the hydroxy-groups via ion-exchange reactions of the type

$$\equiv Si{-}OH + Na^{\oplus} \rightleftarrows \equiv Si{-}ONa + H^{\oplus}.$$

The above problem must therefore be solved also by other methods, for example, by limiting the mobility of ions by binding them in complexes with the matrix elements. It is known that for silicon dioxide this aim is attained by doping it with Al^{3+}, which results in the formation of capture centres. The energy characteristics of such centres, namely E_M = 0.50 ± 0.05 eV and H_H = 0.65 ± 0.09 eV, and their content (~1 × 10^{18} cm^{-3}) have been determined[168]. These data can serve as an approximate guide in selecting the lower limit of the content of the analogous centres in polyorganoaluminosilasesquioxanes, where the aluminium heteroatom has been introduced chemically into the siloxane chain[169].

7. Modification of OOSSO

Careful examination of the technology of the preparation and purification of OOSSO to make possible their use as dielectric materials in semiconductor electronics[108–111] led to the discovery of the special role of the phenomena on the surface of the support and in the immediate vicinity of the interface[108,170] of the solid phases, of the special significance of the presence and concentration of hydroxy-groups, traces of water, and limiting impurities, of the structure of the amorphous phase (in particular the ratio of the short-range and long-range disorders), and of the stresses arising both in the bulk of the amorphous films and at the interface with the support and in the support itself. Studies of amorphous and crystalline silicon dioxide proved productive for the elucidation of these problems. Studies of very thin films[171,172], both natural (grown by oxidising the surface of silicon) and deposited in a high-frequency discharge plasma, have in general not altered but merely refined the details of the picture of the boundary region illustrated in Fig. 1. One can actually state that silicon dioxide films with an increased content of carbonaceous impurities[173] and hydroxy-groups[17,174] or films formed under the decisive influence of water vapour[17,175] have come to be more vigorously

investigated during the last decade. This trend is associated with the fact that the presence of a limited amount of impurities, which do not greatly diminish the dielectric characteristics of the amorphous oxide, makes it possible to compensate for the disadvantages of SiO_2 discussed above. In this connection, investigations of the state of the OH groups in quartz[176] and silica[177], of the collective states for different modifications of SiO_2,[178-181] and of the structural defects in amorphous SiO_2 films on the surface of single crystal silicon[182] have developed greatly.

An important addition to all that has been said before about the SiO_2–Si reference system involves allowance for the stresses arising in multilayer structures. For example, a study has been made[183] of the influence of heat teatment on the stresses in amorphous silicon dioxide films deposited on a support by electron beam evaporation and a fairly old study[184] provided a general method for the estimation of internal stresses arising in multilayer structures. However, the study of the influence of the doping process on the relaxation processes in silicon dioxide layers is of greatest interest from the standpoint of the usefulness of the modification of siloxanes[185].

Silicon dioxide meets the principal requirements of electronics and electronic instrument making and is technologically convenient but is diffucult to modify. A material capable of competing with amorphous silicon dioxide should have effective dielectric properties, should be no less technologically convenient, and should be readily modified. These requirements are satisfied by structures based on POSSO.

(a) Modification of OOSSO by the introduction of a heteroatom directly into the siloxane chain. The modification of OOSSO by the introduction of Al, Ti, and Pb atoms into the siloxane chain in order to obtain polyorganoelementosiloxanes with improved dielectric characteristics different from those of POSSO has been described[111,128,169]. Aluminium heteroatoms were introduced in order to reduce the mobility of the alkali metal ions (mainly sodium ions), titanium atoms were introduced to increase the dielectric constant of the material, and lead atoms were introduced to reduce its permeability to accelerated ions[111]. The most important condition governing the modification was the retention of the non-crystallisability of the material over the entire range of its operating conditions (this was first observed for unmodified POSSO [89]).

There exist a series of methods for the introduction of the aluminium heteroatom into the siloxane chain. The preparation of oligomeric alumino-organosiloxanes by the reaction of aluminium compounds (for example, aluminium isopropoxide) with α,ω-dihydroxyorganosiloxanes having the general formula HO[RR'SiO]OH, where R = methyl and R' = methyl or vinyl, formed via a reaction, involving the opening of the ring in the corresponding organocyclosiloxanes with an alcoholic solution of alkali[128] followed by the neutralisation of the products with acetic acid, is technologically the most convenient. Depending on the reactant ratio and the nature of the siloxane diols employed, different oligo-organoaluminosiloxanes have been synthesised: oligodimethylaluminosiloxanes with the silicon : aluminium ratios g = 4, 8, and 12; oligomethylphenylaluminosiloxanes with g = 1.8, 2,4, 3.6, 4.25, and 13.2; oligomethylvinylaluminosiloxane with g = 12. The reaction scheme, for example, in the case of an equimolar reactant ratio, is

$$Al(OC_3H_7)_3 + HO-[-SiRR'-O-]_n-H \rightarrow -\overset{\displaystyle OC_3H_7}{\underset{|}{Al}}-[-OSiRR'-]_n-O- \ .$$

Linear oligomers are formed, which is confirmed by the presence of an infrared band with $\bar{\nu}$ = 1130 cm^{-1}, caused by the vibrations of the C–O bond in the isopropyl group. With increase of the relative amount of siloxanediol, i.e. in the presence of an excess of Si–OH groups, this band disappears, which is associated with the formation of network oligomers. It is significant that oligomers without hydroxy-groups are formed in this case, which follows from the absence of the characteristic infrared absorption bands in the range 3200–3600 cm^{-1}.

Consequently in the aluminium isopropoxide–siloxanediol system there is a possibility not only of heterofunctional cocondensation but also homofunctional cocondensation of siloxanediols, catalysed by aluminium compounds, takes place. The oligomers formed are readily soluble in organic solvents.

Films of oligo-organoaluminosiloxanes (OOASO) have been obtained[128] from toluene solutions on glass, silicon, and steel supports. The polymerisation was carried out by heat treatment and was accompanied by the loss of fusibility and solubility of the films. The rigidity of polyorganoaluminosiloxane films increases with decrease of the ratio g.

Satisfactory coatings are obtained on the basis of MM-12, MV-12, and MF-13.2 varnishes.

A stronger intermolecular interaction in polyorganoaluminosiloxanes compared with POSSO has been established[128] and has been confirmed by infrared spectroscopic data. It is associated with the presence of the aluminium atom in the siloxane chain. The dielectric parameters of polyorganoaluminosiloxanes satisfy the requirement that their functionality be high while retaining the non-crystallisability characteristic of OOSSO. In addition, polyorganoaluminosiloxanes are characterised by the reduced mobility of alkali metal ions compared with POSSO and SiO_2, which makes it possible to reduce appreciably the time drift of the parameters of silicon semiconductor devices.

The method of preparation of modified OOSSO by the synthesis of spiro-compounds, whose range is apparently largely limited to compounds of Group IV elements, for example, titanium-containing compounds, is promising[186].

In principle, there is a possibility of other procedures for the synthesis of oligo-organoelementosiloxanes: the synthesis of reactive monomers incorporating a heteroatom[109-111,187,188] and the interaction of OCS with the oxides and hydroxides of elements under special conditions (for example, a study has been made[189] of the interaction of TCMS with titanium dioxide in a fluidised bed). However, such processes are less selective than the specific synthesis of oligomers with a heteroatom in the siloxane chain and can lead to oligomers incorporating a heteroatom both directly in the siloxane chain and in the surrounding groups.

(b) Modification of OOSSO by the introduction of a heteroatom into the groups surrounding the siloxane chain. Numerous studies surveyed in monographs[48-50,52,92,190] and others[83,96,191,192] were devoted to the influence of the groups surrounding the siloxane chain on the properties of polyorganosiloxanes (POSO). The vast majority of such investigations involve the replacement of the alkyl group by an aryl or alkoxy-group. Such modifications of the surrounding groups are undesirable, since they involve an increase in the relative content of carbon which constitutes a limiting impurity in the dielectric–single crystal silicon (germanium) structures, which one attempts to avoid as far as possible in the formation of metal oxide films and coatings[16].

More homogeneous materials with a better distribution of modifying heteroatoms can be obtained by opening three-dimensional cyclic structures of the type of T_8, T_{10}, or T_{12} with formation of compounds having a ladder (double stranded)

structure[53] with the simultaneous introduction of organometallic compounds, tetrabutoxytitanium[36,83], tetraethoxysilane, etc.[165,193], which add to the non-bridging oxygen atoms. The influence of the metal on the siloxane chain via an oxygen atom is localised in mono- and oligo-elementosiloxanes in the vicinity of the M–O–Si group[161]. The oligomers formed in this way retain their capacity for polymerisation and the corresponding polymers, while possessing the specified dielectric characteristics, retain their non-crystallisability characteristic of POSSO.

(c) Modification of POSO by chemical doping. The method of chemical doping makes it possible to alter sharply the characteristics of polymers using comparatively small amounts of dopants and additives, imparting to such polymers and the materials based on them special properties necessary for specific applications[194,195]. It is know that in the thermal and thermo-oxidative stabilities of polydiorganosiloxanes increase appreciably after the introduction of a series of heteroatoms into the main chain[50,196]. A similar effect can be achieved also by the introduction into the polymer matrix of certain low-molecular-weight siloxanes[197] or elementocyclosilazanes (for example, those containing the titanophosphinate group), whose effect apparently consists in the formation of rare interchain cross-links. Even when their concentration is very low, such cross-links alter the properties of the polymer, which can no longer be regarded as linear; its thermal stability, mechanical properties[198], and electrical strength are changed.

When the POSSO has already been formed, this mechanism cannot operate and chemical doping is carried out in the stage involving the formation of an oligomer film by introducing small amounts of organometallic or organic compounds which react with the oligomers and are incorporated in the polymer matrix in the course of hardening[165,193]. This method makes it possible to control within certain limits the electrophysical and particularly the electret characteristics of the materials. In this case, apart from the formation of additional cross-links between the elements of the helix or between the cyclolinear chains of the polymer, the additives can be incorporated into the groups surrounding the main chain. The relative contributions of these processes are determined both by the conditions governing the introduction of the additives and by the conditions in the hardening of the polymer.

As in the doping of semiconductors[3], the POSSO chemical doping processes involve a fundamental difficulty associated with the limited capacity of the matrix, i.e. the fact that it can incorporate in its structure not more than a strictly specified amount of the dopant. Beyond these limits, phenomena, which as a rule vitiate all the advantages achieved by the modification of the initial matrix, take place. It is difficult to say what constitutes the starting point of the impairment of the material: the appearance of presegregations of a new phase or the breakdown of the sections of the matrix adjoining directly the regions of the support with an electric field gradient (surface defects, charged impurities, outcrops of dislocations on the single crystal surface)—it is difficult to separate these two processes in time. This is followed by the appearance of discontinuities in the matrix with segregation of the impurity along the boundaries of the macroblocks, analogous to those described by Spektor[199], and finally crystalline or amorphous inclusions of the independent phase of the dopant or the products of its reaction independent of the matrix are formed. Under the conditions of doping at concentrations far outside the limits of the chemical capacity of the matrix, all these effects operate simultaneously[193].

The modification procedures enumerated above, in particular chemical doping, depend greatly on the conditions governing the conversion of the OOSSO into the corresponding polymers and also on the chemical nature of the oligomers and modifying agents employed.

IV. OLIGOMER POLYCONDENSATION PROCESSES

In view of their instability (tendency towards structure formation in both the solid state and in solution)†, oligoorganosilasesquioxanes are of no practical value.

In order to convert these intermediates into the finished materials, it is necessary to convert the oligomers into the corresponding high-molecular-weight products. The general characteristics of the polycondensation of OOSSO have been examined in a number of studies[49,50,52,53,78,89,90,92,119,129,275]. In the heat treatment of oligomers, one can arbitrarily distinguish two stages of the process. The first stage develops in the oligomer melt at temperatures in the range 70–120 °C [depending on the molecular weight (M_{OOSSO}) and on the MWD of the oligomer]. The second stage takes place in the solid phase after hardening. Competing reactions are polycondensation involving hydroxy-groups and ring opening. In fact the temperature ranges of these reactions overlap to only a slight extent—the first reaction is almost completed after the attainment of 200 °C, while the second reaction is only beginning at these temperatures. However, both reactions influence the formation of the structure of the POSSO matrix. Taking into account the data on the structure of amorphous silica[157], it is necessary to postulate the presence of residual hydroxy-groups in POSSO up to temperatures exceeding significantly that of the thermal or thermo-oxidative elimination of hydrocarbon groups[120]. The presence of residual hydroxy-groups in the POSSO matrix plays an important role in the interaction of POSSO with the supports[108]. Low-molecular-weight compounds of the type of T_8 and other three-dimensional cyclic compounds undergo thermal polymerisation with difficulty. Catalytic reactions with ring opening[53] of the type of the polymerisation of cyclic oligomers with $F = 2.0$ [145,147,201] or cross-linking under the influence of high-energy radiations[57,110,111], are more characteristic of these compounds.

The process which is more likely to take place in the solid phase under the influence of high temperatures[202] involves the elimination of organic groups, which leads to the formation of a material whose properties are similar to those of silicon dioxide[120]. However, the purity of this material, obtained under the usual conditions in bulk, is greatly inferior to that of silicon dioxide obtained by fusing quartz, by the oxidation of the surface of silicon, and even by the decomposition of tetraethoxysilane or other organosilicon monomers. This is associated with the fact that the thermal degradation of polyorganosiloxane, like that of polyorganoelementosiloxanes[203], entails the segregation of a new phase in the form of a cluster or colloidal carbon or of graphite inclusions accompanied by the darkening of the material. High-energy radiations (ultraviolet radiation, X-rays, and neutron, electron, and proton beams) have an effect similar to high temperatures as regards the degradation of the polymers.

---

†An exception to this rule is provided by cyclic three-dimensional compounds, for example, octaorganocyclo-octasilasesquioxanes, which form an independent subclass of silasesquioxanes[200], but these also have poor mechanical properties.

The influence of ultraviolet radiation in the region of 265 and 420 nm and of proton beams with an energy of 500 keV on POSSO has been investigated[204,205] as a function of the organic group and it was shown in particular, that the replacement of 27–50 mole % of the methyl groups in PMSSO by phenyl groups increases appreciably the radiation stability of the polymers. The resistance of the organic groups, particularly phenyl groups, to the action of temperature and irradiation can be significantly increased by introducing into the organosiloxane matrix transition metals or other complex-forming fillers[206–209].

The preparation from POSSO of a material whose composition is identical to that of silicon dioxide, which is essential for applications in electronics, becomes possible in the thermo-oxidative annealing of thin (up to 1 μm) PMSSO films with $F \geq 3.0$.[120] In this case the process *in vacuo* can be described by the overall equation

$$\{H_3CSiO_{1.5}\}_n + 3n/2\,O_2 \rightarrow \{SiO_2\}_n + nCO + 3n/2\,H_2O\ .$$

Volatile reaction products leave the film without causing breaks in its continuity. The process leads to the formation of new siloxane linkages, giving rise to interchain cross-links.

In studying the temperature dependence of the polycondensation mechanism, one must take into account the fact that, as shown, in particular, in the study of Andrianov et al.[108], the heterolytic mechanism of the cleavage of siloxane linkages predominates at moderate temperatures (up to ~400 °C):

$$\equiv Si{-}O{-}Si\equiv \rightleftarrows Si^{\oplus} + \equiv Si{-}O^{\ominus}\ ,$$

while at higher temperatures (above 400 °C), the homolytic mechanism predominates:

$$\equiv Si{-}O{-}Si\equiv \rightleftarrows \equiv\dot{S}i + \equiv Si{-}O^{\cdot}\ .$$

The low-temperature hardening of siloxanes is accelerated by ionic catalysts[144,146,210]. The coexistence of various polycondensation mechanisms can be illustrated by the results of its determination of the rates of hardening of thin oligomer films on various supports (Fig.7).

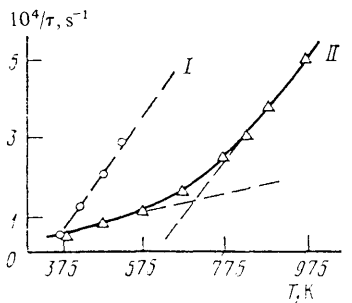

Figure 7. Dependence of the rate of hardening of oligomethylsilasesquioxane on different supports: I) on a metal; II) on single crystal silicon.

The knowledge of only the general characteristics of the polycondensation of OOSSO is insufficient for the development of processes leading to the formation of dielectric films and coatings directly on the surfaces of any semiconductors.

For a better understanding of the problems arising in the development of such materials, we shall list the main requirements which they must meet:

(1) Dielectric properties not inferior to those of amorphous silicon dioxide ($\varepsilon \cong 3.0$; $\tan\delta \cong 1 \times 10^{-2}$; the number $n_{por} < 5\ cm^{-2}$; $E_{br} > 1 \times 10^6\ \Omega\ cm^{-1}$; $\rho_V > 1 \times 10^{14}\ \Omega\ cm$; $Q_V \cong 5 \times 10^{11}$ e.s.u. of charge per cm^2; $\mu_M^{POSSO} \cong \mu_M^{SiO_2}$).

(2) The maximum attainable layer and surface homogeneity in the absence of any inclusions of another phase.

(3) Minimal stresses both in the bulk of the dielectric film and at the interface with the semiconductor.

(4) Maintenance of the concentration of the surface states of the protected semiconductors at the initial level and if possible its reduction.

(5) Resistance to the action of corrosive media (NH_3, PH_3, AsH_3, etc.), moisture, and solvents.

(6) Resistance to the action of accelerated ions.

(7) Capacity for being modified within fairly wide limits at least as regards ε and Q_V ($2.0 < \varepsilon < 15$; $1 \times 10^{10} < Q_V < 1 \times 10^{14}$) with retention of other dielectric characteristics at a fairly high level.

(8) Capacity for being etched with standard solvents at rates v_{etch} comparable to $v_{etch}^{SiO_2}$ and capacity for being modified as regards v_{etch}.

Naturally no one material can meet all these requirements simultaneously. It is necessary to create a series of materials of one class obtained by isotypical technological processes.

Dielectric materials likely to be useful in electronics and instrument making have been developed in a series of studies[36,55–57,70–75,83,86,88,89,99,107–112,118,120,128,140,160,165,169,170,193,194,211,212,275] in conformity with these requirements on the basis of comprehensive investigations of the relation between preparation and conversion conditions and the molecular and phase structure of the products with control of the physicomechnical and electrophysical characteristics.

Homogeneous oligomers free from particles of a heterophase (gel) are obtained in a total displacement flow reactor with parallel injection of the components. A broad MWD complicates the technology of the hardening of the oligomers. Fusion within wide temperature limits results in the existence of the oligomer in the form of a two-phase system throughout some time from the beginning of the process. Reactions in the liquid phase are faster than in the solid phase, so that polymerisation in the melt is completed, while part of the oligomer has still not fused and, by the time when the residual oligomer has melted and begun to polymerise, the head fraction has already solidified. Furthermore, the polymerisation conditions near the upper limits of the fusion temperature range differ from the initial conditions, which creates an additional inhomogeneity and stresses in the films. It has been noted[78,90] that larger oligomeric seeds create a more defective structure.

Under the conditions of a wide MWD, the growth of large helices is hindered, the alternation of helical and xonotlitic structures becomes possible[99] and the presence of such comparatively small ribbon inclusions can reduce the electrical strength of the material. Thus, in order to obtain high-quality dielectric films based on POSSO, it is preferable to have an oligomer with the narrowest possible MWD (in the limit, individual oligomeric molecules) and this dictates the necessity to optimise the synthesis of the OOSSO with respect to the MWD.

In order to obtain the composites and press-materials based on OOSSO, some of the solvent is left in the oligomer as a binder before the final polymerisation stage. This ensures more effective mixing and moulding of articles and also reduces the adhesion of the composites to the press-moulds.

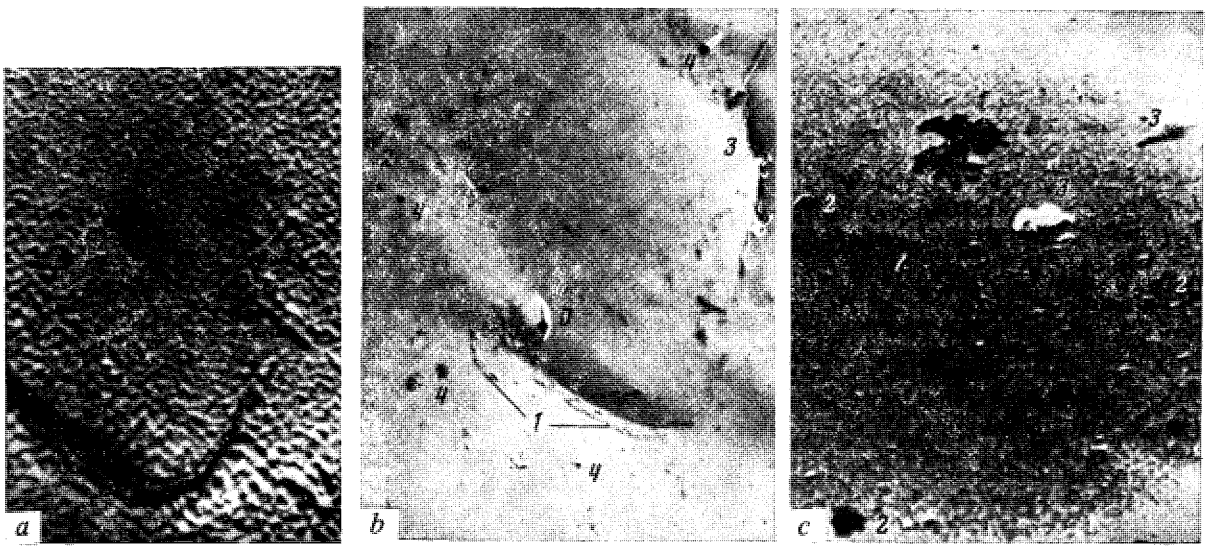

Figure 8. Comparison of the structures of regions of polymethylsilasesquioxane and amorphous silicon dioxide films (×420) which have undergone electrical breakdown[120,140]: *a*) ideal surface of PMSSO film with different thicknesses; *b*) breakdown of the ideal PMSSO film (the Al electrode is deposited on top) on single crystal silicon (10 breakdown steps in one region with restoration of electrical stability after 9 cycles); *O*—centre of breakdown crater; 1) surface fusion of the material of the electrode along the breakdown trajectory; 2) breaks in the Al electrode with surface fusion associated with surface electrical breakdowns; 3) massive breaks in the Al electrode associated with electrical breakdown by reverse currents; 4) satellite punctures in the Al electrode; *c*) electrical breakdown of a film of amorphous silicon dixoide (the Al electrode is deposited on top) on single crystal silicon (single electrical breakdown): 1) breakdown crater; 2) satellite breaks on the periphery; 3) ejected surface-fused material of the electrode.

When thin films are formed over a large area, this method is unsuitable because numerous defects (for example, large and small open and closed bubbles) are formed on the surface of the film in this instance; they are produced when the solvent and the water formed in the polycondensation process are removed. Although such shallow defects do not influence the integral dielectric properties of the moulded POSSO films, they can prove to be weak sections in local electrical breakdown. Hardening is therefore carried out under controlled conditions[120,128,140] ensuring the removal of the solvent and condensation of water through the surface of the film.

The dielectric layers formed in this way and based on polymethylsilasesquioxane, polyphenylsilasesquioxane, and other POSSO [89,108–112,120,140] are distinguished by homogeneity throughout their bulk and an even surface (Fig.8*a*) with average dimensions of the rugosities (of the type of spherical growth formations) smaller than for thermo-oxidative silicon dioxide[213] and with smaller ejections of the dielectric material on repeated electrical breakdown than in the case of a single electrical breakdown of an SiO_2 film (8*b* and 8*c*).

Unfortunately direct control of the OOSSO polycondensation processes on the protected surfaces is difficult to achieve by traditional methods in view of the small thickness of the films formed. However, bearing in mind the initiating effects of the point defects in a silicon single crystal[108], one can employ the results of the study of these processes on specimens of the free oligomer.

The weight loss effects and thermal phenomena in the polycondensation of a number of oligomers have been investigated[214].

V. PROBLEMS OF THE INTERACTION OF OLIGO- AND POLYORGANOSILASESQUIOXANES WITH A SOLID HETEROPHASE

The first applications of POSSO with high functionality were associated with their thermal stability and hydrophobic properties. Parameters of the materials such as their resistance to high temperatures and ionising radiations[202–205,209] and corrosive media[215–217], mechanical characteristics[198] and low cost achieved by a wide variety of procedures for the preparation of binders[71–73,107,218–222] and composites based on them[223–229] were also of decisive importance at this stage. In this first stage of research, compositions with interesting electrophysical[55,152,190] and electronic[229] characteristics were already obtained. Studies involving the investigation of the mechanisms of the interaction of reactive monomers[133,189, 192,230–233] and oligomers[133,233–236] with the solid phase of the filler (textile fibres, silicates and cements, silica gel, and aerosils), taking into account the functionality of the groups on their surfaces[236,237], may be regarded as the next stage. Finally, the general postulates concerning the interaction at the interface between two solid phases, one of which is an organosilicon dielectric, were formulated[108,170] on the systemtic basis of ideas concerning the transition layer in semiconductor–dielectric and metal–dielectric systems[7,8,13,35,36, 238–240] and the structure of the surface layers of amorphous element–oxygen solid phases[160,180,241], as well as experimental data obtained for the organosilicon dielectric–silicon and organosilicon dielectric–metal systems[54,56,109–111,120,128,129,140, 151,165,169,193,212].

1. Blended Compositions Based on Organosilicon Binders

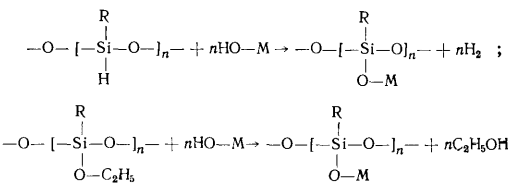
Problems concerning the formation of compositions filled with glass fibre and their characteristics have been described comprehensively in the literature[47–53,92,190], so that in the present section we shall therefore consider only individual examples of blended compositions based on organosilicon binders (OSB) [71,107] which are of interest either as regards their applications or from the standpoint of the general characteristics discovered.

The possibility of employing organosiloxanes in the electrotechnical industry for the formation of insulating layers and enamels having an improved heat resistance, and reduced flammability and with a low evolution of toxic volatile substances was first examined by Schwarz[129]. A number of studies have been devoted to problems of the thermal stability of composites based on filled polyorganosiloxanes[206–209,223,224]. It has been noted that the thermal stability of polyphenylsilasesquioxanes filled with metals increases as a function of the filler metal in the sequence Pb < Fe < Ni < Bi < Cd < Cu < Co. The activity of the metal is determined not only by its chemical nature but also by its degree of dispersion, which has been confirmed in relation to the composite of OSB and iron carbonyl powder[226].

A report[223] describes the creation of a series of thermostable and corrosion-resistant dielectric compositions based on oligomers obtained by the hydrolytic condensation of OCS (TCMS, trichlorophenylsilane, and dichlorodimethylsilane) in the presence of iron(III) chloride and zinc or aluminium dust or titanium dioxide as fillers and the possibility of modifying varnish compositions by means of organic solvents and by adding a polyester (in the case of hot hardening: 2 h at 180–200 °C) or an alkyl resin (in cold hardening; 2 h at room temperature) was examined. Another report[224] is devoted to a comparative study of the characteristics of enamels made from these composites placed on steel supports. For satisfactory dielectric parameters, the best thermal stability is shown by the polymethylphenylsiloxane enamel with zinc dust and the greatest chemical stability and resistance to the atmosphere is shown by an enamel with the rutile titanium dioxide phase modified with 20 wt.% of polyester.

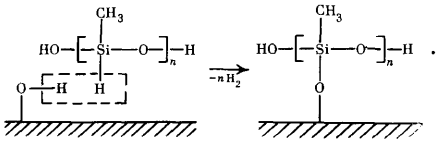
The definite structural similarity between POSSO, particularly those obtained under specific conditions[99], and silicates with large cations[154,155] was already mentioned previously. The study of the interaction and structrual transformations in POSSO composites with iron-containing chrysotile-asbestos[227] and OSB with fluorophlogopite[228] is of definite interest in this connection. The first composition is of special interest, since the supermolecular organisation of chrysotileasbestos, having the formula $Mg_6[Si_4O_{11}].(OH)_6.H_2O$, belongs to an extremely rare type of tubular crystals and agrees well with the helical organisation of POSSO.[140] Furthermore, it can be seen from the formula that this mineral contains a large amount of active hydroxy-groups and, in view of its intrinsic low (mainly ionic) electrical conductivity and capacity for cocondensation via the hydroxy-groups with OOSSO, this ensures a high thermal stability and effective dielectric characteristics of the composite[227].

The most striking result in the application of blended OSB composites with a filler in electronic instrument making has been achieved in the study of photocapacitive characteristics of inhomogeneous structures consisting of dispersions of photoconducting microcrystalline cadmium sulphide particles in an organosilicon varnish[229]. The possibility of developing photovaractor elements for the frequency range 10^3–10^6 Hz for illumination intensities of 10^{-2}–10^3 lm with a maximum overlap coefficient of ~5 has been demonstrated experimentally.



2. Cocondensation of Mono-, Oligo-, and Poly-Organosiloxanes with Functional Groups on the Surface of a Solid Phase

The interface formation processes in the reaction of mono-, oligo-, and poly-organosiloxanes with amorphous or polycrystalline oxide phases are fairly complex. In this case the structure of the phase of the support "dictates" the structure of the junction boundary, as shown in a study[241] in which the author emphasises the decisive role of the short-range order of the formation of the surface layer in the molecular deposition of oxides layer by layer using the principle of the isoenergetic state of oxygen, characterised in any solid stable oxides by the approximately constant overall bond energy $E_{E-O} \cong 240$ kcal g-atom^{-1}. A calculation (tested experimentally) has been carried out by the extended Hückel–Hoffman method specifically for the [SiO_4] tetrahedron in SiO_2 and led to the following results: charge on the oxygen atom $N_O = -0.93$; population (total order) of the Si–O bond $P_{Si-O} = 0.539$; bond energy $E_{Si-O} = 104.3$ kcal mol^{-1}; π-bonding ~16%; coordination number $k = 2$; overall electron population of the oxygen bond in the silicon dioxide lattice $kP_{Si-O} = 1.078$, i.e. $kP_{E-O} \cong 1$ as in other stable oxides. These conclusions are in good agreement with the results of a study[180] where data for the splitting of the optical frequencies in the spectra of amorphous bodies led the authors to the conclusion that the influence of the orientation of the silicon–oxygen tetrahedra makes a small contribution and that account must be taken of the long-range effect by introducing a term related to the Coulombic forces determined by the presence of effective charges on the silicon and oxygen atoms. The state of the hydroxy-groups on the surface of the oxide has been investigated in detail[241] and the cause of the difference between the states of the hydroxy-groups on the surfaces of aerosils and quartz glass with [SiO_4] octahedra, on the one hand, and silica gels and silicic acid hydrogel with [SiO_6] hexahedra, on the other, was discussed. In this case the difference is caused by the binding of the OH group to the nearest silicon atom, whose state also depends on the coordination. The conclusion[241] that there are different states of the OH groups on the SiO_2 surface has been confirmed by the preparation of aerosils with isolated amino-groups on the surfaces[237].

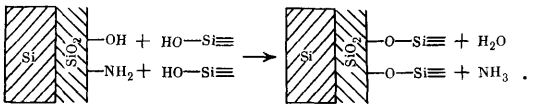


These studies, carried out on simple objects, permit at least a qualitative understanding of the processes occurring on the surfaces of materials related to polyorganosiloxanes[134, 233,235,236].

It has been shown that the interaction of polydimethylsiloxane rubbers with aerosils proceeds via the silanol groups[236], which is confirmed by the different behaviour of rubbers with free and blocked terminal silanol groups. However, physical interaction forces nevertheless play a decisive role in the above system, which is manifested by a decrease of the content of the polymer bound to aerosil at temperatures in excess of 200–240 °C. On the other hand, when the surface of highly dispersed silicon dioxide was modified by low-molecular-weight silazanes and siloxanes, the formation of a chemical bond between the surface of silicon dioxide and the compound employed was established[134]. It has been shown[34] that the different interactions of the organosilicon monomer and oligomers[233] with Portland cement having the composition (wt.%) 22.06 SiO_2, 3.98 Fe_2O_3; 3.89 Al_2O_3, 63.9 CaO, 2.68 SO_3, 1.65 MgO, 1.42 H_2O, and 0.27 Na_2O and its fully hydrated (to the extent of 99.9%) modification is determined mainly by the relative contributions of two processes: chemical reaction involving the active groups (Si–H, Si–OH, and Si–OR) and adsorption. The products of the chemical reactions were identified chromatographically[233]. For example, the presence of molecular hydrogen and ethanol in the products is attributed to the occurrence

of the following processes:

The detection of molecular-hydrogen is particularly important, confirming the mechanism proposed by Reikhsfel'd et al.[234]:



According to this mechanism, the terminal hydroxy-groups of the oligomer are retained and can participate in the subsequent polycondensation or cocondensation with epoxide resins. Although the result of the analysis of the reaction products for molecular hydrogen is not quoted in the above study[234], the proposed mechanism has been confirmed by other data[233].

3. The Mechanism of the Interaction of Oligo- and Polyorganosiloxane with the Surface of Single Crystal Silicon and the Possibility of the Polymerisation Filling of Polyorganosilasesquioxanes

It was noted above that among polyorganosiloxanes, the best dielectric characteristics, not inferior to the characteristics of amorphous silicon dioxide, are those of polyorganosilasesquioxanes with $F \geq 3.0$ and small substituents, as a rule methyl substituents. PMSSO have therefore found applications in semiconductor devices and integrated circuits as passivating films, active dielectric layers, protective coatings, and masks in doping processes[56,108,110,111]. The advantages achieved by employing POSSO are associated not only with the simplification of the technology of the formation of the layers and films directly on the surface of the semiconductor single crystal and with their non-crystallisability[89, 110,111] but also with the possibility of the passivation of the surface of a single crystal when the latter interacts with POSSO as a result of the decrease of the concentration of the surface states (of the type of surface impurities and point defects). The phenomenon is caused by the occurrence of a complex set of chemical reactions on the surface of the single crystal.

We may recall that in the single crystal silicon–amorphous silicon dioxide system there is a transition layer at the interface, which is completed by a thin layer of the natural oxide growing on the surface of the silicon single crystal at room temperature in air. The thickness of this layer varies in the range 15–30 Å as a function of the material of the single crystal and external conditions. The nature of the interphase states is determined by the supersaturation of the surface layer of the single crystal with oxygen, the presence of stresses due to the incompatibility between the surface layer subjected to stretching stresses and the pseudocoesite layer subjected to compressive stresses, as well as the presence of microcrystallite inclusions and discontinuities in the intermediate $SiO_x (x < 2)$ layer. Furthermore, the concentration of the interphase states increases appreciably due to the presence on the single crystal surface of interstitial silicon atoms—adatoms, vacancies, and their clusters[108] and also as a consequence of the presence of hydroxy-groups and other functional groups (for example, NH_2) and impurities sorbed on the silicon dioxide surface. The influence of the interphase state on the electronics of the semiconductor–dielectric structures has been described in detail in the literature[151]. The self-limited ordered clusters examined in Section II [20] have structures very similar to those of POSSO and the stresses arising in the transition region may partly relax as a result of the cleavage of the Si–O bond via a free-radical mechanism[166].

On the basis of the data described above, we shall consider the mechanism of the interaction of PMSSO with the natural oxide film. The interaction with the oligomer melt begins from the oxide surface via the functional groups[169] in accordance with the scheme

The removal of volatile reaction products from the surface layer does not present difficulties under these conditions. The next stage, initiated by free-radical states present in the pseudocoesite layer, consists in the incorporation of the substance of this layer in the polymer matrix, which is accompanied by an increase of the overall functionality of the material. Bearing in mind the ratio of the amounts of the interacting OMSSO and the amorphous silicon dioxide, which can be readily found from the relative thicknesses of the layer—on average a ~20 Å SiO_2 layer (including the ~10 Å SiO_x layer with $x < 2$) and a $\sim 5 \times 10^4$ Å OMSSO layer—it is easy to understand why the overall increase of functionality is small.

The next, concluding stage is associated with the polycondensation of the oligomer at 180–200 °C and the formation of an infusible and insoluble skeletal polymer on the surface of the support. The processes involving the incorporation of a silicon dioxide layer in the overall polymer structure are completed in this temperature range and there is a sharp decrease of the concentration of hydroxy-groups. The inter-relation of the oligomer–polymer–synthetic silicon dioxide (from the polymer)–fused quartz structures and the character of the reactions can be seen from a comparison of their infrared spectra illustrated in Fig.9. The presence of a small but finite number of hydroxy-groups in the polymer formed ensures the possibility of the generation at temperatures below 200 °C of ionic states in the relaxed POSSO matrix and of the competition between heterolytic and homolytic silanol bond dissociation processes at temperatures of 200–400 °C; above 400 °C, the latter process becomes dominant[108]. These processes are described by the equations of the formation reactions of ionic states:

$$\equiv Si{-}O{-}H \rightarrow \equiv Si{-}O^{\ominus} + H^{\oplus} ,$$
$$\equiv Si{-}O{-}H \rightarrow \equiv Si^{\oplus} + HO^{\ominus} ,$$

and free-radical states:

$$\equiv Si{-}O{-}H \rightarrow \equiv Si{-}O^{\cdot} + H^{\cdot} ,$$
$$\equiv Si{-}O{-}H \rightarrow \equiv \dot{Si} + HO^{\cdot} .$$

The terms "ionic state" and "free-radical state" imply that the charge or the unpaired electron on the silicon or on what have become non-bridging oxygen atoms are bound and localised in a certain element of the matrix[108] and their movement involves the mechanism of the exchange interaction with the nearest neighbours[160,170]. The non-chain products of the cleavage of the silanol bonds, namely HO°, H°, $HO^{\cdot}$, and

H$^{\cdot}$, are not localised, possess a definite mobility in the siloxane matrix, and are capable of interacting with POSSO via a mechanism involving ring opening[108,170]:

$$\equiv Si-O-Si\equiv + HO^{\ominus} \rightarrow \equiv Si-O^{\ominus} + \equiv Si-OH \ ,$$
$$\equiv Si-O-Si\equiv + H\dot{O} \rightarrow \equiv Si-\dot{O} + \equiv Si-OH \ ,$$
$$\equiv Si-O-Si\equiv + H^{\oplus} \rightarrow \equiv Si^{\oplus} + \equiv Si-OH \ ,$$
$$\equiv Si-O-Si\equiv + H^{\cdot} \rightarrow \equiv \dot{S}i + \equiv Si-OH \ .$$

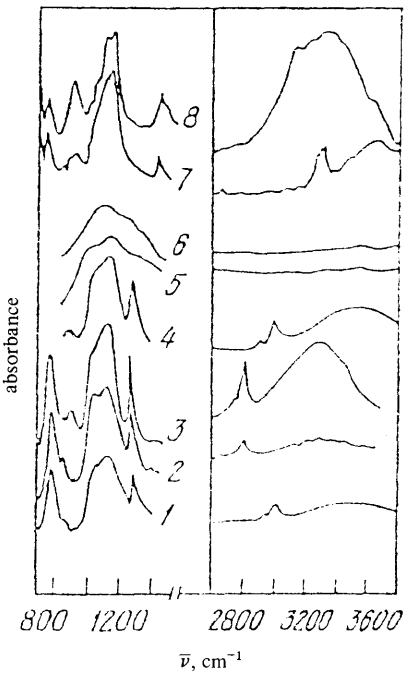


Figure 9. Comparative infrared spectroscopy of polyorganosilasesquioxanes, synthetic silicon dioxide, and fused quartz[89,110,111,120,275]: 1)–3) OMSSO, $F = 3.25$, $F = 3.14$, and $F = 3.0$ respectively; 4) PMSSO, $F = 3.0$ (prepolymer); 5) PMSSO annealed in air at 700 °C for 1 h; 6) fused quartz; 7) octaphenylcyclo-octasilasesquioxane; 8) tetrahydroxy-tetraphenylcyclotetrasiloxane.

Bearing in mind that the macroscopic mobility of fragments of the three-dimensional siloxane chain in which the ionic or free-radical states are localised is zero at a concentration of hydroxide ions or hydroxy-radicals $c_{HO^{\ominus}} \leq a$ or $c_{HO^{\cdot}} \leq b$ (whereupon the probability of their recombination is low), one may assert that, up to a certain consideration limit, the processes involving the generation of ionic or free-radical states in the matrix predominate over their recombination processes.

The structural defects on the surface of a dislocation-free silicon single crystal are point defects of the type of interstitial atoms, vacancies or their clusters. We shall examine only individual defects, which does not alter the overall picture. In the case of a simplified model of a section of the single crystal silicon surface with two point defects—a vacancy and an interstitial atom—it has been estimated that the long-range influence of these defects in the POSSO matrix extends over more than 54 Å [108] on the basis of the data of Panteleev and Opulich[242], which in the case of polyphenylsilasesquioxane, with the interchain distance $d = 12.8$ Å,[89] covers, in the direction at right angles to the interface, more than four molecular layers and, for PMSSO with $d = 8.4$ Å, more than six molecular layers.

The silanol bonds may be cleaved under the influence of the gradient of the electromagnetic field of the point defects consisting of an interstitial atom or a vacancy (similarly to the situation discussed in the study of Vorotyntsev and Kornyshev[240]). The gradients of the electromagnetic field of point defects constitute at the same time the driving force of the migration of the ionic and free-radical states in the organosiloxane matrix. Bearing in mind the paramagnetism of the vast majority of the single crystal silicon surface states considered, their interaction with the ionic states emerging at the interface has been shown[108] to take place as a result of charge transfer:

$$\equiv Si-O^{\ominus} + \{R^{\pm}\} \rightarrow \equiv Si-O^{\cdot} + \{R^{\pm}\cdot\bar{e}\} \ ,$$
$$\equiv Si^{\oplus} + \{R^{\pm}\cdot\bar{e}\} \rightarrow \equiv \dot{S}i + \{R^{\pm}\} \ ,$$

where $\{R^{\pm}\}$ represents a semiconductor in the form of an infinite donor–acceptor reservoir relative to a single ion.

The charge transfer results in the formation of localised free-radical states capable of interacting, following a sufficiently close approach to the interface, with the unpaired electrons localised at the defects. Very few charged surface states interact directly with the ionic states emerging at the interface.

As free-radical states of the type $\equiv Si-O^{\cdot}$ approach an interstitial silicon atom on the single crystal surface, there is a possibility of its multistage interaction with three uncompensated bonds, which can be described by the following overall expression:

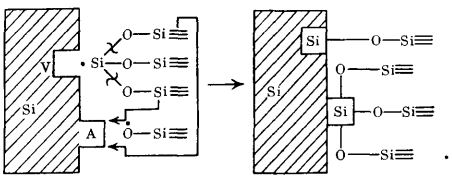
$$3\,(\equiv Si-O^{\cdot}) + A\{M\} \rightarrow \begin{matrix} \equiv Si-O \\ \equiv Si-O \\ \equiv Si-O \end{matrix} \!\!> Si-\{M\} \ , \qquad (3)$$

where A{M} is an interstitial atom (Si) on the surface of the single crystal {M}, which will be henceforth referred to as an adatom.

The interaction of a free-radical state of the type $\equiv \dot{S}i$ with a point defect of the type of a vacancy V{M} can be described analogously:

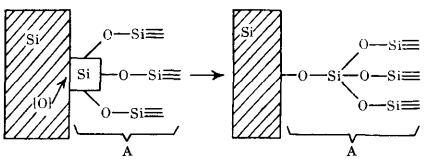
$$\begin{matrix} \equiv Si-O \\ \equiv Si-O \\ \equiv Si-O \end{matrix} \!\!> \dot{S}i + V\{M\} \rightarrow \equiv Si-O-\{M\} + 2\,(\equiv Si-\dot{O}) \ .$$

Bearing in mind that the number of vacancies in the atomic plane of a dislocation-free single crystal is approximately equal to the number of adatoms[108,243] and that the number of free-radical states of the type $\equiv \dot{S}i$ generated in the organosiloxane matrix is approximately equal to the number of states of the type $\equiv Si-O^{\cdot}$, the overall annihilation process in the interaction of free-radical states of the amorphous organosiloxane matrix and surface states of the type of the point defects of the silicon single crystal can be described by the equation[108]



$$\equiv \dot{S}i + V\{M\}A + \dot{O}-Si\equiv \rightarrow \equiv Si-O-\{M\}-Si\equiv \qquad (4)$$

However, since the Si–Si bond formed as a result of reactions (3) and (4) in the systems considered (especially under the conditions of the saturation of the surface layers of the silicon single crystal with oxygen) is energetically unfavourable, it either dissociates or is oxidised further to form a siloxane linkage.



The mechanisms examined together with the processes involving the dislodging of the impurities sorbed on the surface of the natural oxide[54,169] and their sorption by the

amorphous phase of the dielectric can explain the decrease of the concentration of the surface states of single crystal silicon when it is protected by a POSSO film[108-111].

On the basis of the data of Andrianov et al.[108], the following mechanism for the interaction of a single silicon crystal with POSSO has been put forward[110,111]:

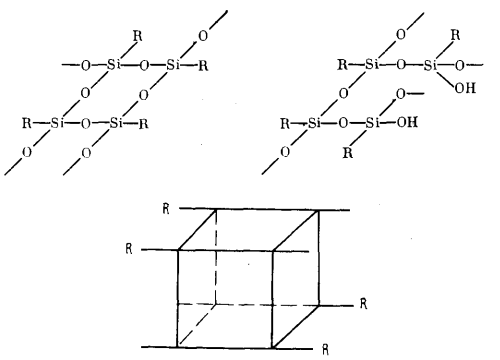
Taking into account data[239] for the atomic state of oxygen in the surface layer of a silicon single crystal, this mechanism can be refined:

with an increase of the functionality of the local cluster A from 3.0 to 3.25.

The results of a study of the photothermostimulated exoelectron emission over a wide temeprature range[120] may serve as confirmation of the mechanisms of the observed decrease of the concentration of interphase states. The experimental data obtained for systems comprising a POSSO film both on normal silicon and silicon of the *n*- and *p*-types lead to the important conclusion that there are two stages in the interaction. The first stage begins at the melting point of the oligomer and terminates with its complete conversion into the polymer. It is characterised by the fixation of the surface structures and the formation of an interface and in essence constitutes a pseudoepitaxial process in which an interfacial layer is formed on an ideal single crystal surface which continues on further increase of the ideality of the surface. This is manifested by a relative independence of the intensity of the exoelectron emission of temperature on the luminescence curves. The interaction between the film and the support decreases the regularity of the POSSO structure compared with the initial material as a consequence of the interaction with the layer of the natural oxide and the dissolution of the impurities sorbed by the natural oxide on the surface of the single crystal in the OOSSO melt with their subsequent sorption in the bulk of the infusible polymer[169,170] via the mechanisms presented above.

The temperature of the onset of the second stage of the interaction of the finished polymer with the support depends greatly on the defectiveness of the surface and the character of the impurities in the bulk of the silicon. For normal silicon, this temperature is in the range 377–393 °C and diminishes with increase of the concentration of the surface point defects. The structure of the spectrum of the photothermostimulated exoemission is in this case fairly simple and is characterised by a single broad luminescence band. Two emission maxima are observed for *n*-type silicon in the range 347–377 °C with a separation $\Delta T = 18$ °C and for *p*-type silicon there are two maxima in the range 393–423 °C with a separation $\Delta T = 7$ °C. This result can be explained by the different effects of the donor and acceptor impurities on the charge state of the surface point defects and the surface as a whole and is due to the different efficiencies of the annihilation of ionic and free-radical states of the type $\equiv Si^{O}$ and $\equiv \dot{S}i-O^{O}$, on the one hand, and $\equiv Si$ and $\equiv Si-O$, on the other.

The mechanism of the interaction of oligo- and poly-organosilasesquioxanes with single crystal silicon described[100,111,140,169,170] is useful in the development of a technology for polymerisation-filled composites, with dielectric characteristics modifiable within wide limits, on the basis of POSSO and transition metal oxides such as titanium dioxide or tin dioxide. In this case the filler particles can be regarded as single crystals. The activation of the filler surface makes it possible to increase the concentration of the active functional groups and to obtain a polymerisation-filled POSSO composite with 70 wt.% of tin dioxide as the filler bound to the polymer matrix via Si–O–Sn linkages.



VI. THE STRUCTURE OF CYCLIC ORGANOSILASESQUIOXANES, OLIGO-ORGANOSILASESQUIOXANES, and POLY-ORGANOSILASESQUIOXANES

The discovery of the relation between the molecular structure and macroscopic characteristics of polymeric dielectrics[89,149,152] has stimulated studies on the molecular structure of POSSO and modified materials based on them. However, their electrical strength[244] and other electrophysical parameters depend greatly also on the character of the disorder of the condensed phase, which is analysed either in terms of the radial distribution function for monatomic materials (its application to a diatomic material[245] can lead to inaccuracies) or in terms of the atomic pair function[246]. The degree and character of the possible ordering in disordered tetrahedral structures, which are of definite interest for comparison with siloxane matrices, have been examined in two investigations[18,247].

Polyorganosiloxanes are tetra-atomic systems and accurate quantitative X-ray diffraction methods for the analysis of amorphous solids are inapplicable to their investigation. However, a number of studies have been carried out in order to obtain X-ray diffraction data to determine the most general characteristics such as the average interchain distances[82,116,124,248-250].

1. The Molecular Structure of Oligo- and Poly-organosilasequioxanes. The Statistical Copolymer Model

In order to reach a conclusion about the supermolecular organisation of a condensed non-ordered phase when limited structural data are available, it is necessary to have data on the molecular structure. The molecular structures of oligo- and poly-organosilasesquioxanes have been investigated[89] by infrared spectroscopy and NMR for a series of specimens with different functionalities obtained under different rigorously controlled conditions. The reaction products consisted of a complex mixture of oligomers whose MWD was determined by the process conditions. In addition, a study was made of the products of the thermal polycondensation of the oligomers obtained, of the high-temperature annealing of the polymers in air at 700 °C, and, for comparison, of amorphous silicon dioxide. The results of the infrared spectroscopic investigation of the specimens (Fig.9)[89,109-111,120] show that the structure of the molecules of oligo- and poly-organosiloxanes can include both planar and large three-dimensional cyclic units predominantly of the T_8 type.

The molecules of oligomers can incorporate all three types of cyclic units. The absorption band in the range 915–930 cm^{-1}, whose intensity decreases with decrease of the content of hydroxy-groups and can be assigned, according to Andrianov et al.[89], to the deformation vibrations of the OH group in a planar ring, in agreement with other data[251], is of definite interest.

Low-resolution NMR spectra[89] also indicate the absence of both intermolecular and intramolecular hydrogen bonds from the test specimens. The predominantly dispersion character of the intermolecular interaction is indicated, apart from the low mechanical characteristics, also by X-ray diffractometer data. All the oligo- and poly-organosiloxane specimens investigated are amorphous to X-rays regardless of the method of their preparation and the heat treatment conditions[89,110,111,120]. The maximum of the first amorphous halo occurs at 8.4 Å for oligomethylsilasesquioxanes regardless of their functionality $F = 3.0–3.25$; for oligophenylsilasesquioxanes, the maximum is at 12.8 Å, which agrees well with the value ~13 Å quoted in other studies[104,250], etc.

The data enumerated permit certain conclusions about the molecular structure of oligo- and poly-organosilasesquioxanes[89,109–111,120,140]. The structure can be described statistically by an average model incorporating structures of the T_8 type, in completely closed T_8 rings, closed and open rings of the type T_6 and T_4, and also statistically distributed OH groups. Here it is necessary to take into account the possibility of the involvement of fragments of smaller rings in the formation of the structures of larger rings. This model corresponds to the arrangement of the macromolecule in the form of a large helix[140] in which there are breaks in the rings ensuring the relaxation of structural stresses and segmentation at intervals corresponding to approximately one turn of the helix, which is consistent with the measured dimensions of the Kuhn segment[116]. If the analogy between OOSSO and POSSO, on the one hand, and silicates with large cations, on the other, is extended, one can postulate that the polyphenylsilasesquioxanes obtained under the conditions of the studies of Janin and Guyot[99] and Andrianov et al.[78] should resemble the xonotlite ribbon-like structures having unsatisfactory dielectric properties, while the OOSSO obtained under the conditions of the studies of Kamaritskii et al.[88] and Andrianov et al.[89] resemble more closely chrysotile asbestos or, what is even more likely, potassium cerium silicate with a three-dimensional anionic skeleton, namely $K_2CeSi_6O_{15}$,[252,253] whose structure constitutes a new example of an anionic purely silicon–oxygen skeleton made up of xonotlite ribbons which extend along the y axis and undergo a significant deformation due to the puckering of the rings and their mutual rotation in the xy plane. Direct condensation of the strips at the $z = 0$ and $z = 1/2$ levels leads to an open network of centrosymmetric eight-membered (xonotlite) rings and six-membered (lovozerite) rings perpendicular to them. When the rings are joined together, helices made up of tetrahedra around parallel z axes 2_1 arise. The formula of the skeletal anion does not have the standard form $[SiO_2]_{\infty\infty\infty}$ and is in fact $[Si_2O_5]_{\infty\infty\infty}$ owing to the presence of a single free O atom in each tetrahedron. In the formula of this silicate with eight-membered rings there are only six Si atoms, because the initial pair of atoms in the second ring constitutes the final pair of the first ring.

On the basis of the results of a number of investigations[78,79,88,89,104,110–113,120,128,140], we proposed a statistical copolymer model for OOSSO and POSSO, for both cyclic three-dimensional cage-like organosilasesquioxanes and for the compounds with the ladder structure. In the study of ladder POSSO, it was observed[78] that, on formation of ladder macromolecules with a double stranded cyclolinear structure, one of the essential stages involves the rearrangement of the cyclic three-dimensional ("cage-like") fragments. It has been pointed out that polyphenylsilasesquioxanes have a high degree of order only in individual polycyclic sections distributed statistically along the chain. Furthermore, it has been stated directly[104] that the elementary units of the macromolecular chain are polydisperse as regards dimensions. The fact that in the hydrolytic cocondensation of trichlorophenylsilane and trichlorovinylsilane in their mixture there are no products of their separate hydrolysis, mentioned above, is also striking[79].

2. The Study of the Phase Structure of Cyclo-, Oligo-, and Poly-organosiloxanes. The Interrelation of the Structural Forms

As stated above, the non-crystallisability of POSSO, noted in a number of studies[56,88,89,109–112,120,140,165], limits the applicability of diffraction methods also in the study of their structures[89]. The non-crystallisability of POSSO is determined to some extent by the skeletal structure of their molecules, because the possibility of a three-dimensional rearrangement of molecular fragments, requiring the dissociation of at least two of the three siloxane linkages, is virtually ruled out. The crystallisation of the synthetic material obtained by the thermal oxidation of POSSO, which inherits the molecular structure of the latter and whose composition $\{SiO_2\}_n$ is identical with that of silicon dioxide, requires the dissociation of $3n$ Si–O bonds[111].

A genetic approach to the morphological changes in siloxanes has been proposed[112], starting with the simplest rings [tetraphenyltetrahydroxycyclotetrasiloxane (T_4), its dimer hexaphenyltetrahydroxybicyclotetrasiloxane $(T_4)_2$, and octaphenylcyclo-octasilasesquioxane[159] (T_8)] and proceeding via the corresponding oligomers and pre-polymers to give infusible and insoluble polyphenylsilasesquioxanes. The compounds T_4 and T_8 are crystalline substances and X-ray diffraction data have been obtained for them by a standard diffractometric method using Cu K_α radiation and have been checked by an especially developed photomethod[254].

According to Andrianov et al.[89], neither oxidation-reduction nor disproportionation processes take place during the hydrolytic condensation of OCS. In the products of the hydrolytic condensation of OCS each silicon atom is linked to three oxygen atoms and to one organic group. Furthermore, it was shown in the same study[89] that the large molecules have a cyclic three-dimensional structure and consist mainly of alternating large (T_8) and small (T_4) rings. It follows from this that the problem of the description of the structure of oligo- and polyorganosilasesquioxanes can be reduced to a quantitative analysis of the contents of the above structural fragments.

A method based on the Selyakov–Scherrer spreading of the polycrystalline reflections of the T_4 and T_8 rings and on a graphical comparison of the curves thus obtained with the experimental curves for oligomers and polymers with different degrees of condensation has been proposed[112]. This procedure is carried out taking into account the influence of termination, in terms of the scattering angles allowed for, on the amorphous halo patterns[255]. The characteristics of the variation of the structural forms between two probable structural elements can be readily traced from the change in the positions of the first amorphous haloes of the oligomeric and polymeric materials; on the basis of these data, a nomogram has been constructed[112] for the quantitative analysis of the contents of the T_4 and T_8 structural fragments in macromolecules. This approach can be used also in the study of other polymers[256].

The presence of cyclic structures in amorphous polyorganosiloxanes makes it possible to discuss the results for crystalline cyclic organosilicon compounds[159,257–262]. X-Ray diffraction studies on the large rings of organosilasesquioxanes have been carried out[159–200,263–265]. In order to establish a relation between the non-equivalence of the silicon atoms and the distortion of the silicon–oxygen skeletons in ethyl- and vinyl-octacyclo-octasilasesquioxanes and to refine the structure of T_8, they were investigated by high-resolution NMR in the solid state[266]. The study of the infrared spectra[267], mass spectra[268], and volatility[269] made it possible to revise their molecular structures and to permit the development of a technology for their application. A study[143] involving the measurement of the vapour pressures of a series of OOSSO is also of interest in this sense.

VII. THE ADHESION CHARACTERISTICS OF LAYERS AND COATINGS BASED ON POLYORGANOSILASESQUIOXANES

The physicomechnical properties of POSSO have been examined in a number of studies[194,198,211,212,270]. One of the most important properties of a coating must be its effective adhesion to the support. It is known that adhesion depends on a multiplicity of factors and is determined by the properties of both the adhering substance and the substrate. A study has been made[212] of the dependence of the adhesion strength of a layer of POSSO on various supports on the chemical structure and the technology of the preparation of the film and of the adhesion properties of coatings based on polymethyl-, polyvinyl-, polymethylvinyl-, polymethylphenyl-, and polydichlorophenylmethyl-silasesquioxanes, obtained from solutions of the corresponding oligomers at different concentrations in the range 10–25 wt.% in solution in the 1:1 acetone–toluene mixture, which made it possible to obtain films of different thickness (ranging from 1.0 to 6.0 μm). A polished steel support proved to be most suitable for tests on adhesion strength. At the same time measurements were made of the dielectric characteristics of the material. At a concentration of the oligomer solution below 10 wt.%, there was almost no adhesion between the plates, which can apparently be explained by the impossibility of the formation of a monolithic film between them.

The adhesion strength of various POSSO in relation to a steel support increases, other conditions being equal, with increase of the oligomer concentration, reaching a limiting value at an OOSSO concentration of 20 wt.% and then remaining almost unchanged. The degree of adhesion depends strongly on the nature of the organic substituents at the silicon atoms and also on the conditions in the heat treatment of the specimens.

The adhesion strength of POSSO is definitely influenced by their functionality. The increase of the overall rigidity of the polymer film with increase of the functionality from 2.9 to 3.0 impairs the adhesion strength. This effect can be associated with the increase of the contribution of the relaxation phenomena with increase in elasticity and also with the change in the number of effective contacts at the adherent–substrate boundary.

There is a correlation between the adhesion strength and the angle of wetting of various supports by solutions of the corresponding OOSSO. It has been established[212] that oligophenylsilasesquioxanes are characterised by increasing wetting angles on various supports and that an increase of concentration entails an increase of the wetting angle. These features are common to a series of surfaces: steel, chromium-plated steel, single crystal silicon, glass, and gold-plated sital. Furthermore, it is known that the wettability of a surface improves (the wetting angle diminishes) with improvement of the quality of the preparation of the surface—a polished surface is wetted more effectively than a non-polished surface.

In the study of adhesion properties in a support–POSSO system account must be taken of a series of factors. The surfaces of the majority of supports are coated by a more or less thin layer of oxide and in these cases the properties of the surface hydroxy-groups are determined to a decisive extent by the nature and structure of these oxides[241]. The presence of reactive hydroxy-groups in OOSSO improves the adhesion of the dielectric coating to the supports. In this case, if the hydroxy-groups on the surface of the support are reactive with respect to the silanol bonds of the oligomer, condensation and grafting of the molecules to the surface take place. On the other hand, if the surface layer consists of adsorption water, there is a possibility of interaction with the rings, leading to the rupture of the surface layer of the oxide and then to direct interaction of the organosiloxane with the support, as happens in the aluminium–amorphous SiO_2 system[271].

The modification of POSSO both at the molecular level (for example, by introducing the aluminium heteroatom directly into the siloxane chain[128]) and in the bulk phase level exerts a major influence on the adhesion properties of such systems. However, one must then bear in mind that the bulk-phase modification usually leads to an appreciable impairment of the overall dielectric characteristics of the materials.

VIII. ELECTROPHYSICAL PROPERTIES OF POLYORGANOSILASESQUIOXANES AND MODIFIED MATERIALS BASED ON POLYORGANOSILOXANES

All the preceding discussion of both the synthesis and the technology of the preparation of oligo- and poly-organosilasesquioxanes and modified materials based on polyorganosiloxanes as well as their structure and physicomechanical characteristics was based on a single postulate, namely that the ultimate result must be the creation of materials with specified electrophysical, namely dielectric, properties: at the same time their compatibility with both traditional semiconductors[108–111] and with special purpose semiconductors, particularly organic semiconductors[1] as well as adequate advantages in the technology of electronic instrument making must be ensured. We shall consider the two most important methods for the investigation of the electrophysical properties of dielectrics—dielectric spectroscopy and polarisability of polyorganosilasesquioxanes and related materials,

the discussion being preceded by certain new ideas concerning the mechanism of the transport of current carriers in disordered dielectrics[272].

1. The Tunnel Electrical Conductivity of Disordered Dielectrics

In amorphous materials the lack of structural order induces the localisation of electronic states and determines the character of the conductivity of disordered polymeric dielectrics[272]. Electron transfer via localised states is described by methods of the permeation theory[273], which can be explained by a simplified model. The quantum nature of the jump conductivity permits the hypothesis of electron tunnelling between localised states. An attempt has been made[272] to develop a tunnel model of the electrical conductivity of disordered systems and to test it experimentally on amorphous polymeric dielectrics.

The analogous character of the calculated and experimental relations between the conductivity and the concentration of localisation centres confirms the validity of the model involving electron transfer via localised centres in polymeric disordered dielectrics[274].

The tunnel model proposed[272,274] leads to an expression for the electrical conductivity which agrees with the results of the permeation theory[273]. This model makes it possible to explain the deviations of the experimental results from calculations based on the permeation theory. It can be used to describe the electrical conductivity of disordered polymeric dielectrics.

2. Dielectric Spectroscopy of Polyorganosilasesquioxanes and Modified Materials based on Polyorganosiloxane

The quality of a dielectric material should be assessed and the scope and regions of its applications should be determined not so much in terms of each of the parameters enumerated at the beginning of the present study as, firstly, in terms of the sum of the dielectric properties (naturally subject to the condition that none of the parameters determining the usefulness of the material is below the lower limit), secondly, in terms of the possibility of altering within the required limits one or several parameters in accordance with the functional purpose of the material without a significant impairment of the sum of its dielectric properties, and, thirdly, in terms of the stability of both functionally significant parameters and the sum of the dielectric properties in relation to external influences[110,111], usually the influence of temperature or moisture content or their combined influence. The influences of radiation, gaseous atmospheres[56], acids, salts, bases[128], etc. must be regarded as other external influences of practical importance but encountered more rarely.

The dielectric parameters of PMSSO differ little from the characteristics of amorphous SiO_2. However, it has been shown[88] that, when the hydrolytic condensation of TCMS is carried out under otherwise optimal conditions, the values of tan δ and ε at different frequencies depend on the temperature of the synthesis. The knowledge of these relations makes it possible to obtain materials with specified characteristics and the modification is carried out using the differences in the course of the polycondensations of oligomers at different temperatures[275]. The dielectric properties can be altered by this procedure only within certain limits.

Significantly greater changes in the parameters of the substance can be achieved by chemical doping (or by the introduction of a heteroatom) directly into the siloxane chain[120,211], or by employing a molecular fragment whose chemical nature is different from that of the organosiloxane matrix[194], or by the structural modification of polyorganosiloxanes. Better results can be achieved by the last method than by chemical doping, but, within fairly narrow limits of the modifier concentrations, all the relations governing the properties of the material (both electrophysical and physicochemical) pass through a sharp maximum with increase of the concentration of the dopant owing to the appearance of the heterophase of the modifier or its reaction products. Although the introduction of a heteroatom into the siloxane chain causes a smaller change in the dielectric characteristics, it leads to the precipitation of the heterophase and ensures a high resistance to external influences, since the modification is carried out at the molecular level.

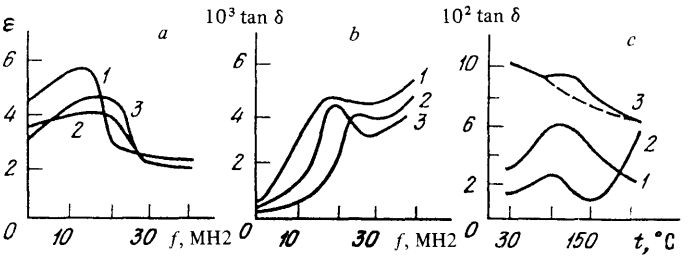


Figure 10. Dielectric spectroscopy of polyorganoaluminosiloxanes: *a*) frequency dependence of the dielectric constant ε; *b*) frequency dependence of the tangent of the dielectric loss angle tan δ; *a* and *b*: 1) MM-12; 2) MV-12; 3) MF-13.2; *c*) temperature dependence of tan δ for MM-12 at different frequencies (Hz): 1) 5×10^4; 2) 2×10^6; 3) 4×10^6.[128]

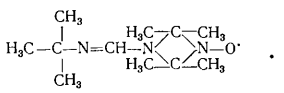
The dielectric parameters (ε and tan δ) of films based on polyorganoaluminosiloxanes have been investigated[128] over a wide range of frequencies and temperatures (Fig.10). Calculation of the relaxation time from the frequency of the maximum of the dielectric losses (Fig.10*b*) yields $(6-8) \times 10^{-9}$ s, which is characteristic of dipoles or dipolar complexes with a high molecular weight. The temperature variation of tan δ (Fig.10*c*) has a characteristic dielectric losses maximum at a temperature which is higher the higher the frequency, while ε initially increases with temperature, which can be accounted for by the increase of the mobility of the fragments of the polymer molecules resulting in a facilitation of the orientation of the dipoles. On further increase of temperature, the intensification of thermal vibrations reduces the degree of order and ε falls after it has passed through a maximum. Films based on polyorganoaluminosiloxanes have fairly low values of tan δ over a wide temperature range up to 350–400 °C, which makes it possible to classify them as high-temperature dielectrics. At low frequencies the values of ε and tan δ diminish with increase of the aluminium content in the siloxane chain, which is apparently associated with the increase of the rigidity of the polymer structure, while at high frequencies, where polyaluminosiloxanes can be regarded as non-polar dielectrics, ε and tan δ are almost independent of the aluminium content in the polymer. The electrical strength of such films increases slightly with increasing aluminium content in the siloxane matrix.

3. The Polarisability of Modified Polyorganosiloxanes. The Electret Effect

The polarisability of dielectrics is one of their fundamental characteristics which makes it possible to discover the kinetic relations governing the accumulation and dissipation of the charge. All the effects occurring on active dielectrics—the charge bond, the electret effect, and others—are determined, when other dielectric properties are satisfactory, by their polarisability.



The results of studies of the processes involving the accumulation and dissipation of charges in electrets for various methods of imparting an electric charge (thermo-, electro-, and tribo-electrets) and studies of the influence of a large number of external stabilising and destabilising factors (acoustic, thermal, electromagnetic, and combined influences) have been described[123]. It was established that, when electrets, including PMSSO, are subjected to an acoustic influence, the spectrum of the relaxation times of the charges changes and the relaxation times τ diminish to a greater extent the more prolonged the influence. It has been noted that electrets with a higher level of charge (>100 V) are less stable when subjected to an acoustic influence of long duration. Comparison of different influences leads to the following relation between the relaxation times:

$$\tau(\text{control}) \gg \tau(\text{acoustic}) \gtrsim \tau(\text{electromagnetic}) > \tau(\text{combined}).$$

In a polarised dielectric medium the phase velocity V_ϕ of ultrasound increases with increase of the space density of the electric charge Q_V. For example, in poly(methyl methacrylate) a change in Q_V by 1×10^2 C m^{-3} alters V_α by 10%.[193]

The characteristic features of the electret effect are investigated by studying the spectrum of the electric states of localised charge carriers in polarised dielectrics. Specific modification of the capture centres by the introduction of donor–acceptor additives[165,211] into the polymer matrix alters the spectrum of the charge relaxation times of the electret and the differentiation of additional TSD current peaks makes it possible to relate models of the capture centres to the structure of the polymer at the molecular level[276].

Thus the kinetic characteristics of electrets based on PMSSO and modified materials obtained by the chemical polycondensation of OMSSO and an oligomer in the presence of an electron-donating additive in the form of a long-lived free radical R have been studied[165]:

The concentration of this radical is 0–10 wt.%. A discrete measurement of the electret potential difference $U_k(t)$ was carried out. In order to compare the characteristics of electrets with different initial potential differences $U_k(0)$, the time variation of the dimensionless quantity $k = U_k(t)/(U_k(0)$ was analysed. The OMSSO polycondensation phenomena and the structural changes in the specimens on polycondensation were investigated by gravimetric, X-ray diffraction, and EPR methods. In the course of the increase of the polarisation potential U_n from 0.5 to 4.0 kV, a change in the sign of $U_k(0)$ as a consequence of the reverse discharge effect was observed. The study of the structural changes in the oligomer following the introduction of R demonstrated an increase of the average interatomic distances r and Δr and a redistribution of the contributions of the scattered intensity owing to the increase of the contribution of scattering by atoms and the decrease of the contribution of scattering by chains. The magnitude of the effect is proportional to the concentration of the radicals R. During polarisation, the influence of the injected radicals R passes through a minimum[165] because they are involved in at least two competing reactions—chain termination and the grafting of the radical to the groups around the siloxane chain. The latter reaction determines the polarisation of the polymer and the generation of a stable electret state.

IX. CONCLUSION

The wide range of applications of highly functional organosilicon polymers[42,46,49–54,56,57,75,98,107–111,120,128,151,152,165,190,193,208,215,217,234,277] can be supplemented by applications in which their dielectric properties play an important but not a decisive role and the entire set of the useful properties of materials based on them is employed[194,278,279]. Clearly such polymers have a whole series of other useful qualities, among which one may mention thermal, plasma, and tracking stability, but evidently their joint survey within the framework of a single article is impossible.

The methods developed for the conversion of soluble and fusible oligomers[49,56,57,75,88,104,108–111,120,128,140,165,169,170,211,212,275] lead to the formation of polymers with the required properties only when oligomers with rigorously defined properties are used as the starting materials and with a rigorous maintenance of specific conditions in the polycondensation process. The presence in the oligomer of even filterable gel particles results in a sharp impairment of the dielectric characteristics of materials based on POSSO. Highly functional oligomers are metastable and, depending on the degree of purification and the storage conditions, their properties deteriorate more or less rapidly and they give rise to products with a wider range of MWD, up to the formation of gel particles.

One of the most important stages in the technological chain leading to the preparation of the materials is therefore the first stage in which soluble and fusible oligomers with a specific set of physicochemical characteristics (average molecular weight, MWD, the number of hydroxy-groups, the content of limiting impurities, etc.) are formed[89,92,93]. The formation of such oligomers requires an appropriate organisation of the technological process. The chemical nature of the hardening processes and of the interaction with the supports is also determined by the technological conditions. Thus the formation of materials based on metastable substances is determined at the technological level.

The dependence of the dielectric properties of materials on the molecular and phase structure of the polymer, on the one hand, and the distinct dependence of its structure on the synthesis conditions, on the other[70,88], show that the quality of the polymeric materials is in many respects determined by the methods, technological procedures, and the conditions in the preparation of oligomers as well as the monitoring of the intermediate products, since the parameters of the future material and the quality of the articles made from it are in fact determined at this level.

The Electret Effect in Polymers. Advances in the Preparation and Application of Electrets

G.A. Lushcheikin

Recent advances in the development of the theory of electret effects in polymers (except photo- and bio-electrets) are discussed: they include the phenomenological theory, the nature of the residual polarisation and of the injected charge, and the nature of the piezo- and pyro-effects in polymer electrets. Successful applications of electret-thermal analysis to the study of molecular mobility in polymers are discussed. The principal directions of the practical exploitation of polymer electrets are outlined. The goals of further studies and of technological developments are defined. 99 references.

I. INTRODUCTION

The term electret effect describes the ability of dielectrics to develop electric charges and retain them for long times. Polymer electrets can be prepared by various methods: by cooling the polymer in an electric field (thermo-electrets), by polymerisation or cross-linking in an electric field (chemo-electrets), by the application of a strong electric field (electro-electrets), by charging in a corona discharge (corona electrets), by exposure to radiation (e.g. to an electron beam, radiation electrets), and by evaporating a solution of the polymer in an electric field (cryo-electrets). Electrets have been obtained also by mechanical deformation (mechano-electrets), by frictional electrification (tribo-electrets), and by exposing a polymer to a magnetic field (magneto-electrets).[1]

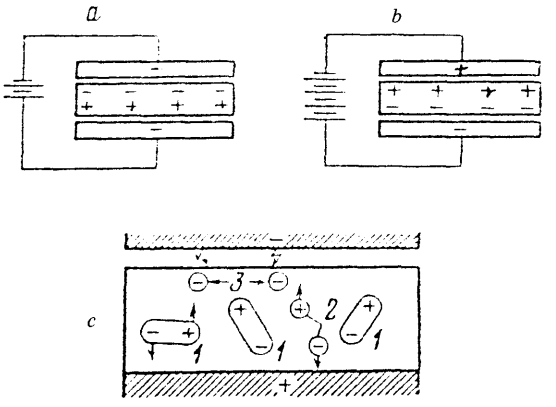

Figure 1. Configuration of charge and electrodes in an electret: (*a*) hetero-charged electret, (*b*) homo-charged electret, (*c*) charges in the electret (*1*, oriented dipole, and dipoles undergoing orientation; *2*, displaced ions; *3*, injected charge carriers).

Electrets can be classified according to the type of charge into those whose charge is due to the orientation of dipoles and the displacement of ions "frozen" in the electric field, and which therefore retain a residual polarisation P or "hetero-charge", and the electrets whose charge is due to carriers injected from outside ("homo-charge", or real free charge σ_p, see Fig.1). In a real electret the surface charge density σ_{eff} is equal to the sum of these two types of charge (of opposite sign):

$$\sigma_{eff}=\sigma_p-P\,.$$

If residual polarisation is initially absent ($P = 0$), some polarisation will appear during storage under the influence of the internal field of the electret. The changes in surface charge density are determined by the time dependence of σ_p and P.

II. FORMATION AND STABILITY OF ELECTRET CHARGES

1. Phenomenological Theory

The phenomenological theory of electrets gives a general description of the electret effect. By formulating various hypotheses on the role of the charges σ_p and P different expressions can be obtained for the time dependence $\sigma_{eff}(t)$. A detailed phenomenological theory was developed by Gubkin[2], who also discussed alternative phenomenological theories.

According to modern views, electrets contain a residual, frozen polarisation P and a real charge σ_p. It is usually assumed that the polarisation decays by an exponential law with a relaxation time τ_p, and that the real charge also decreases exponentially and is determined by the Maxwell relaxation time τ_M:

$$\begin{gathered}P(t)=P_0\exp(-t/\tau_p)\\ \sigma_p(t)=\sigma_p(0)\exp(-t/\tau_M)\\ \tau_M=\varepsilon_0\varepsilon\rho\,.\end{gathered}\qquad(1)$$

In these expressions P_0 and $\sigma_p(0)$ are the initial values of P and σ_p, ρ is the (volume) electrical resistivity, ε is the dielectric constant, and ε_0 is the permittivity of free space 8.854×10^{-12} F m^{-1}. If electrodes are placed near the electret, and a gap l is left between the electret surface and the electrodes, the parameter ε in Eqn.(1) is replaced by the coefficient K, defined as

$$K=\varepsilon+L/l$$

where L is the thickness of the electret[2]. The result is an expression in the form of

$$\frac{d\sigma_{eff}(t)}{dt} + \frac{\sigma_{eff}(t)}{\varepsilon_0 K\rho} + \frac{dP(t)}{dt} = 0 .$$

In the theory developed by Perlman[3] no allowance is made for the formation of residual polarisation during the preparation of the electret: a "ready-made" electro-electret is assumed, and only the changes in polarisation due to ageing are discussed. Other workers used slightly different initial assumptions[4,5], but they all obtained expressions of the type of

$$\sigma_{eff}(t) = \sum_i \sigma_i(0) \exp(-t/\tau_i)$$

where in most cases $i = 1, 2, 3$.

Let us consider the case of the thermo-electret. The expression for the polarisation induced by the internal field of the electret during ageing is

$$P = \varepsilon_0 \int_0^t E(t') \frac{d\chi(t-t')}{dt'} dt$$

where E is the intensity of the internal field of the electret, χ is the dielectric susceptibility, consisting of the susceptibility corresponding to polarisation, $\chi_\infty = (\varepsilon - 1)$, established instantaneously and constant in time, and the time-dependent susceptibility $\chi_p(t)$, associated with the polarisation slowly induced under the influence of the internal field:

$$P = P_{max}(1 - e^{-t/\tau_p})$$

where $P_{max} = P_0 = \varepsilon_0 \Delta\varepsilon E$ (and $\Delta\varepsilon$ is the increment of the dielectric constant, see below). The general time dependence $\sigma_{eff}(t)$ in this case becomes

$$\sigma_{eff}(t) = \sigma_p(0) e^{-t/\tau_M} - P_0 e^{-t/\tau_p} - \frac{1}{\varepsilon\varepsilon_0} \int_0^t \sigma_{eff}(t) \frac{d[\chi(t-t')]}{dt'} dt .$$

By solving this equation (using the Laplace transform) we obtain the following expression for an open-circuited electret

$$\sigma_{eff}(t) = \frac{\sigma_p(0)[(1/\tau_p) - (1/\tau_M)]}{[(1/\tau) - (1/\tau_M)]} e^{-t/\tau_M} + \left[\frac{\sigma_p(0)(\Delta\varepsilon/\varepsilon\tau_p)}{(1/\tau) - (1/\tau_M)} - P_0\right] e^{-t/\tau} \quad (2)$$

where $\tau = \tau_p \varepsilon/(\varepsilon + \Delta\varepsilon)$. Putting $\varepsilon = \varepsilon_\infty$ and $\Delta\varepsilon + \varepsilon_\infty = \varepsilon_{st}$ we obtain $\tau = \tau_p \varepsilon_\infty / \varepsilon_{st}$, i.e. an expression for the decay time constant of the charge, where τ_p is the rise time constant of the charge in the same condenser[6].

In real electrets τ_p is often much smaller than τ_M: in this case Eqn.(2) simplifies to

$$\sigma_{eff}(t) = \frac{\varepsilon\sigma_p(0)}{\varepsilon + \Delta\varepsilon} e^{-t/\tau_M} + \left[\sigma_p(0)\frac{\Delta\varepsilon}{\varepsilon + \Delta\varepsilon} - P_0\right] e^{-t/\tau} . \quad (3)$$

or

$$\sigma_{eff}(t) = \frac{\varepsilon_\infty}{\varepsilon_{st}} \sigma_p(0) e^{-t/\tau_M} + \left[\frac{\varepsilon_{ст} - \varepsilon_\infty}{\varepsilon_{st}} \sigma_p(0) - P_0\right] e^{-t/\tau} . \quad (4)$$

In the presence of a gap between the electrode and the electret we replace ε by K in Eqns.(3) and (4).

In practice the real charge is often found to have two components: a rapidly decaying (σ'_p) and a slowly decaying (σ_p) component. Assuming that the decay time constant of σ'_p is so small that slow polarisation cannot develop in the field of this charge we obtain

$$\sigma_{eff}(t) = \sigma'_p(0) e^{-t/\tau'_M} + \frac{\varepsilon_\infty}{\varepsilon_{st}} \sigma_p(0) e^{-t/\tau_M} + \left[\frac{\varepsilon_{st} - \varepsilon_\infty}{\varepsilon_{st}} \sigma_p(0) - P_0\right] e^{-t/\tau} . \quad (5)$$

Each term in Eqn.(5) has a clear physical significance. The first describes the capture of injected carriers by shallow traps near the surface of the dielectric. The σ'_p component of the charge plays an important role in static electrification and in charging in a corona discharge[7]: this charge can easily be removed by wrapping the electret in a metal foil or by applying an earthed electrode to it.

The second term depends on the capture of injected carriers by deep traps, whose energy is relatively high (see below). Thus the charge component σ_p can relax (at least partially) through compensation by the charge carriers of the polymer itself, and therefore the activation energy for the relaxation of this charge component at temperatures above the glass transition point is equal to the temperature coefficient of the conductivity of the polymer[8].

The third term in (5) is determined by polarisation. A thermo-electret prepared from a polar polymer will have a residual polarisation P_0. Since in many cases $\tau < \tau_M$ the presence of P_0 shortens the time needed to stabilise the electret. From the plots (Fig.2) of the $\sigma_{eff}(t)$ dependence for an electret charged in a corona discharge and for a thermo-electret we note that the latter stabilises relatively quickly whereas the former needs a long time to reach a quasi-constant value of σ_{eff}. [Stability is defined as a state in which σ_{eff} remains within a prescribed range (±15%, say) of its nominal value throughout the useful life of the electret (10 years, say).] Stabilisation can be accelerated by corona charging at elevated temperatures or by heating the already charged electret. In this case τ decreases, and a quasi-constant value of σ_{eff} is established more rapidly. For a polymer with a small value of the difference $\varepsilon_{st} - \varepsilon_\infty$ (i.e. a non-polar polymer), or a polymer with $\tau \geq \tau_M$ (a polar polymer with a very high glass transition temperature, such as a polycarbonate with a norbornane ring[9]) the stabilisation time is reduced to the very short time needed for the decay of the σ'_p component. We note that a good example of a non-polar polymer suitable for the preparation of stable electrets is a film of polytetrafluoroethylene or of the copolymer of tetrafluoroethylene and hexafluoropropene.

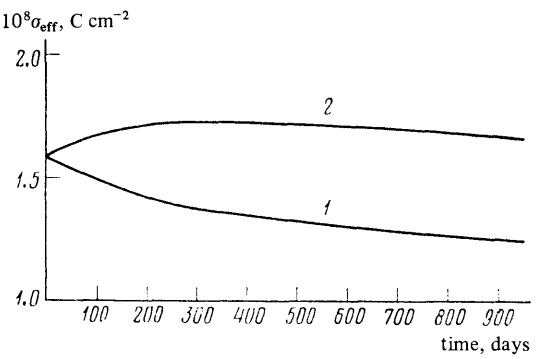

Figure 2. Time dependence of the surface charge σ_{eff} of electrets made from a polar polymer (polycarbonate): *1*) corona electret, *2*) thermo-electret ($\rho_{res} = 1.3 \times 10^{21}$ Ohm cm, $\varepsilon = 3$, $\Delta\varepsilon = 0.44$, $\tau = 8 \times 10^6$ s).

The constancy of P is determined by the molecular mobility, whereas the stability of the charge σ_p is determined by the electrical conductivity (which is also largely dependent, however, on the molecular mobility).

Polarisation can arise also in the crystalline regions of polar polymers. Thus, a rearrangement of the crystalline structure can be induced in poly(vinylidene fluoride) and polyamide-11 by strong electric fields [over 10^8 V m^{-1} in the case

of poly(vinylidene fluoride)]. Rotation of the $-CH_2-CF_2-$ chain in the direction of the field is energetically favourable, and results in a change of the crystal structure from the low-polarity α form to the more polar, spontaneously polarisable β form, in which P_0 can be as high as 0.1 C m^{-2}.[10]

2. Residual Polarisation

Let us consider the development of residual polarisation[11]. We shall heat the dielectric to the polarisation temperature T_p, which is higher than the transition temperature (for example, the glass transition temperature T_g, see Fig. 3). At temperature T_p the dielectric constant rises as a result of the increased segmental mobility which allows the dipoles to become oriented in the field. When the electric field E_p is applied the polarisation of the sample is described by the equation

$$P(T_p) = \varepsilon_0[\varepsilon(T_p) - 1] \cdot E_p \ .$$

If the dielectric is now cooled in the field to the temperature T_K, where $T_K < T_g$, and the external field is removed, the polarisation of the sample decreases by the amount

$$P(T_K) = \varepsilon_0[\varepsilon(T_K) - 1]E_p \ .$$

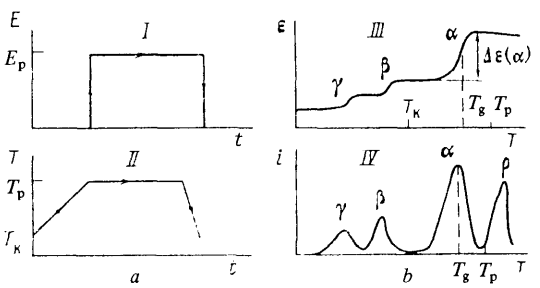

Figure 3. Preparation of a thermo-electret. (*a*) time dependences: *I*) field strength E_p, *II*) temperature *T*; (*b*) temperature dependences: *III*) dielectric constant, *IV*) TSD current during heating of the thermo-electret.

Since $\varepsilon(T_p)$ is greater than $\varepsilon(T_K)$, $P(T_p)$ is greater than $P(T_K)$, and the difference between these quantities is equal to the residual polarisation:

$$P_0 = P(T_p) - P(T_K) = \varepsilon_0[\varepsilon(T_p) - \varepsilon(T_K)]E_p \qquad (6)$$

or

$$P_0 = \varepsilon_0 \Delta\varepsilon E_p \ .$$

Here $\Delta\varepsilon$ is the temperature increment of the dielectric constant, approximately equal to the frequency increment of the dielectric constant at the transition temperature T_g: $\Delta\varepsilon \cong \varepsilon_{st} - \varepsilon_\infty$ (where ε_{st} is the static dielectric constant, and ε_∞ is the dielectric constant for a field of infinite frequency). Thus we have

$$P_0 = \varepsilon_0(\varepsilon_{st} - \varepsilon_\infty)E_p \ . \qquad (7)$$

The equality of P_0 [calculated by formula (6)] and of the heterocharge was established experimentally for polycarbonate and poly(methyl methacrylate) thermo-electrets polarised at $E_p < 10^6$ V m^{-1}, for which the injection of charge carriers is small. The values of $P(T_p)$ and $P(T_K)$ can be determined experimentally by integrating the charging currents at T_p and the discharge currents at T_K (after subtracting the conduction currents):

$$P(T_p) = \int_0^\infty i_p(T_p)\,dt; \quad P(T_K) = \int_0^\infty i_p(T_K)\,dt$$

where i_p is the current density.

However, the relationship (7) is not obeyed if we use the frequency increment of the dielectric constant obtained from the frequency dependence of ε′ and ε″ at temperatures higher than T_g.

It has been reported[12] that in polar polymers such as poly(vinyl chloride) the dielectric constant in the glass transition region increases as the measurement frequency is decreased to 0.1, 0.01, and 0.001 Hz, and the effect was ascribed to the increase in the effective dipole moment μ_{eff} caused by the increase in length of the segment (the mobile portion of the chain). Since $\Delta\varepsilon$ is proportional to $N\mu_{eff}^2$,

$$\Delta\varepsilon \simeq \text{const} \cdot N\mu_{eff}^2/T$$

an increase in the length of the segment (by a factor of 2, say) lowers the concentration *N* of dipoles by the same factor, but it raises μ_{eff}^2 by a factor of 4 (the parameter μ_{eff} contains contributions from all the groups present in the segment: $\mu_{eff} \cong n\mu_0$). The steep increase of ε near T_g is treated[12] as a typical ferroelectric effect, and T_g is identified with the Curie temperature of poly(vinyl chloride).

Thus Eqn. (7) is valid only if the measurement of ε is carried out under the conditions used in the preparation of the electret (frequency range, polarisation and depolarisation time, field strength). The dielectric losses ε″ and the dielectric constant ε′ can be calculated from the charging and discharging currents by using the Fourier transform

$$\varepsilon'' = \frac{1}{C_0 V}\int_0^\infty i_p \sin\omega t \cdot dt$$

$$\varepsilon' = \frac{1}{C_0 V}\int_0^\infty i_p \cos\omega t \cdot dt \ .$$

For ε″ we have the simplified formula[13]

$$\varepsilon'' = i_a/2\pi f_{equiv} C_0 V \ .$$

The equivalent frequency of the measurements is given by the expression

$$f_{equiv} = 0{,}1/t_p \ . \qquad (8)$$

Since the polarisation time t_p is tens of minutes, $f_{equiv} \cong 10^{-2}-10^{-4}$ Hz. Since electrets are stored for many months or years, the parameters ε and $\Delta\varepsilon$ which appear in expressions (2)–(5) should be determined at $f_{equiv} \cong 10^{-6}-10^{-9}$ Hz.

3. Charge Injection

The application of a strong electric field to a polymer causes injection of charge carriers into the polymer. The stability of this charge (σ_p) is formally determined by the electrical conductivity $\gamma = 1/\rho$. There are two different theories of the nature of electrical conduction in polymers. According to the first the electrical conductivity of polymers is ionic and depends on the concentration of impurities[14]. According to the second it is of the electron–hole type[15]. Ionic conduction is predominant at temperatures above T_g, when the segmental mobility is high, and also in plasticised polymers, for example of the poly(vinyl chloride) type.

Electronic charge transfer processes are predominant at high field strengths (above 10^6 V m^{-1}) in polymers at temperatures below T_g, in polymers with conjugated bonds (semiconducting polymers), and in polymer dielectrics with a relatively large number of conjugated bonds (for example, poly-imides[16]). However, even at low temperatures (below T_g) the contact charging of a dielectric without an applied external field on a clean surface in a vacuum takes place by electron transfer[17], whereas in air the charging is determined by the migration of ions in the adsorption layers on the surface[18].

The injected charge σ_p is produced by the injection of electrons and holes from the electrodes[19] (electro- and thermo-electrets), the injection of electrons, holes, and (or) ions from the air (corona electrets, electro- and thermo-electrets with a poor electrode–electret contact), the injection of electrons, holes, and ions from a liquid (in the case of charging from liquid electrodes), and by electron injection when the sample is irradiated with a beam of electrons. During charging in a corona discharge the main process consists in sorption of ionised air molecules on the polymer surface followed by electron transfer (from the molecule to the surface) and desorption of the molecules. At normal field strengths the charge carriers penetrate to a small depth into the polymer dielectric (1–1.5 μm), forming a charged layer ("cloud") which slowly diffuses into the dielectric[20]. The surface layer of dielectric with its high concentration of injected carriers has an abnormally high electrical conductivity. Depending on the "short-circuiting" conditions of the electret (i.e. on the disposition of the electrodes) the charge carriers will diffuse under the influence of the field of the electret either into the bulk of the sample or towards the nearest surface. When the electret is stored some of the carriers in shallow traps are captured by the deep traps. The depth of these traps determines the stability of the charge σ_p. The retrapping of the charge carriers can be accelerated by heating the electret.

The nature of the deep traps, which determines the value and the stability of σ_p, is discussed in Ref. 21. The injected charge carriers interact with the polymer molecules. For example, the interaction of electrons with a fluorinated polyolefin chain (polytetrafluoro-ethylene, tetrafluoro-ethylene–hexafluoro-propene copolymer) produces stable ions because of the high electron affinity of the fluorine molecule. The electrons can also interact with the carbonyl group to give charged groups of the $CH_2–CO^-–CH_2–$ type[22].

Impurity ions and phase separation boundaries can also act as traps. Electrons near an amorphous–crystalline interface of the polymer are slowed down, and their field induces the reorientation of neighbouring dipoles and polar groups. If the adjacent units of the molecular chain have sufficient mobility, the conformation of the chain can change. For example, in poly(ethylene terephthalate), studied by frustrated total internal reflection i.r. spectroscopy, charging in a corona discharge produces a change in the conformation of the chains in the surface layer: the *trans* conformation is partially converted into the *gauche* conformation according to the observed changes in the i.r. spectral absorption bands at 502, 633, 897, 973, and 1172 cm^{-1}. When the electret is discharged the original conformation is partially restored[23].

Studies of the thermally stimulated depolarisation currents of electrets containing injected charges have shown that the TSD maxima for the discharge of injected homo-charge (ρ maxima) occur at the same temperatures as the maxima of the molecular mobility at the crystallite boundaries (α_c relaxation). We should stress that this type of molecular mobility can seldom be detected by the traditional methods of dielectric spectroscopy because the contributing dipoles are weak and few in number: the position of the ρ maximum on the temperature scale corresponds to the maximum of the dynamic mechanical losses at a frequency of ~10^{-4} Hz.[24] Increasing the aggregate surface area of the crystallites per unit volume of the polymer (for example, by decreasing the crystallite size while keeping the overall crystallinity constant) raises the α_c maximum, i.e. it increases the trapped charge (for example, in polychlorotrifluoroethylene).[25]

The TSD current maximum corresponding to relaxation of the injected charge is called the ρ maximum because the activation energy for the relaxation of this component of the charge is equal to the temperature coefficient of the electrical resistivity ρ. Evidently, charge relaxation is due to the mobility of the polymer ions or of the injected ions: the motion of these ions can compensate the trapped space charge.

4. Surface Density of Charges

The time for which the surface density of charge σ_{eff} persists is determined by the stability of σ_p and P. Ultimately, the determining factor is the low electrical conductivity of the electret, which is produced in polymer dielectrics by a low concentration of intrinsic, free charge carriers and also (under the normal conditions of use of the electret) by a low internal field, especially if the electret is "shorted", i.e. in the presence of closely spaced electrodes. Under these conditions the electrical conductivity of the sample falls to 10^{-23} Ohm^{-1} m^{-1} or less[26].

The maximum value of the charge σ_{eff} is limited by the dielectric strength of air[1]. It increases as the thickness of the electret decreases:

$$\sigma_{eff}^{max} = 100\,\varepsilon_0[200 + (3\varepsilon/L)^{1/2}]^2 .$$

In this expression ε is the dielectric constant of the electret. On the other hand the maximum surface potential V_{max} decreases as the thickness decreases: $V = \sigma_{eff}L/\varepsilon\varepsilon_0$. For samples 2 mm thick the maximum value of σ_{eff} is ~5×10^{-5} C m^{-2}, and for films 10 μm thick it is ~2×10^{-4} C m^{-2}.[1]

III. THE ELECTRET EFFECT IN POLYMERS

1. Electret-thermal Analysis of Polymers

The study of the kinetic relaxation characteristics of electret charges can be greater accelerated by a programmed heating of the electret with measurement of the thermally stimulated depolarisation (TSD) current.

The relaxation parameters are calculated from the TSD currents[11] by formulae which assume that 1) the electret contains only one type of dipole, 2) all the dipoles have the same relaxation time τ, and 3) the temperature dependence of the relaxation time is exponential,

$$\tau = A \exp(W/RT)$$

where R is the gas constant, A is the pre-exponential factor, and W is the activation energy (temperature coefficient) of the charge relaxation. With these assumptions we obtain the following formula for the TSD current of an electret heated at a linear rate b:[27–29]

$$i(T) = -\frac{P_0}{A}\exp\left[-\frac{W}{RT} - \frac{1}{bA}\int_{T_0}^{T}\exp\left(-\frac{W}{RT}\right)dT\right] \qquad (9)$$

where T_0 is the initial temperature. The relaxation time of the charge (τ_{max}) at the temperature of the TSD current maximum is given by the expression

$$\tau_{max} = RT^2_{max}/Wb\,. \qquad (10)$$

In the initial portion of the plot of TSD current against temperature we can use the expression

$$\lg i = \text{const} - 0{,}4343\ W/RT\,. \qquad (11)$$

By using Eqns.(9)–(11) we can calculate the macroscopic characteristics W, T_{max}, and A. However, these quantities cannot be related to the characteristics of the dielectric relaxation of the polymer obtained from measurements over a range of frequency and temperature. This is most probably because the above assumptions are never strictly applicable. Polymers often contain several types of dipole (polar groups), or if they contain dipoles of one type only their mobility can arise in two ways: either cooperatively, in a relatively long section (segment) of the macromolecule, or by being in a short side-chain (possibly in conjunction with other groups of the chain). The former alternative gives dielectric losses of the dipole segment type, the latter of the dipole group type. The second assumption (that all the dipoles have the same relaxation time) is also invalid. Polymers always show some range of dipole relaxation times, characterised by a distribution function. If the form of this function is known (for example, a Cole–Cole or a Fuoss–Kirkwood distribution) the expressions which relate the complex dielectric constant ε^* to the relaxation time become simpler, and the relationships of the components ε' and ε'' with each other and with the relaxation time are also simplified. The third assumption is exactly satisfied for dipole group relaxation and approximately satisfied for dipole segment relaxation.

These considerations suggest that the relaxation characteristics of the electret charges obtained from the TSD currents may be correlated with the characteristics normally used in dielectric spectroscopy. The charging current of a condenser in which the dielectric relaxation is described by the Cole–Cole theory is given by the formula[13]

$$i_p = \frac{Q}{\tau}\frac{1}{\Gamma(1-\alpha)}\left(\frac{t}{\tau}\right)^{1-\alpha} \text{(for } t \ll \tau)\,.$$

It follows from this expression that for a change in the temperature of the experiment (which results in a change of τ) we can write

$$i_p = \text{const}\cdot t^{-(1-\alpha)}\exp[-(1-\alpha)E/RT]\,.$$

Thus the experimental temperature coefficient W is related to the apparent activation energy of the dipole relaxation E by the expression

$$W = (1-\alpha)E \qquad (12)$$

where $(1 - \alpha)$ is a parameter which characterises the distribution of relaxation times according to the Cole–Cole theory, and is approximately equal to the distribution parameter λ of the Fuoss–Kirkwood theory[13]. By allowing for Eqn.(12) we can use formulae (9)–(11) to determine the dielectric relaxation parameters in the low frequency region if we also note that determining the relaxation characteristics from the TSD currents is equivalent to determining the dielectric losses at the frequency f_{equiv} by Eqn.(8) with $t_p = \tau_{max}$ [where τ_{max} is given by Eqn.(10)].

A more satisfactory description of the experimental results can be obtained by assuming that the parameters E and λ are independent of temperature[11]. In this case the TSD current is given by the expression

$$i(T) = -\frac{P_0 E\lambda b}{\pi RT^2}\,\text{sech}\left[\frac{E\lambda}{R}\left(\frac{1}{T}-\frac{1}{T_{max}}\right)\right] \qquad (13)$$

where T_{max} is the reference temperature, which for large values of E/RT becomes equal to the temperature of the TSD current peak.

The dielectric losses at the frequency f_{equiv} can be calculated if the TSD current is known:

$$\varepsilon''(T) = \pi RT^2 i(T)/2\varepsilon_0 E E_p b\,. \qquad (14)$$

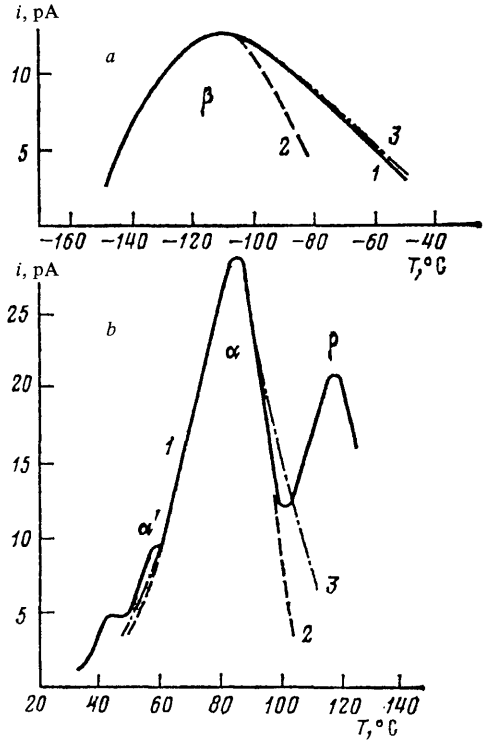

Figure 4. Temperature dependence of the TSD current of a poly(ethylene terephthalate) film thermo-electret (ETA thermogram): (*a*) low-temperature region (β relaxation); (*b*) high-temperature region (α relaxation); *1*) experimental, *2*) calculated by formula (9), *3*) calculated by formula (13).

The expressions obtained by making these assumptions [(13) and (14)] are fairly simple, but they satisfactorily describe the TSD current in the dipole group relaxation region and also, to some extent, in the dipole segment relaxation region (at temperatures below the glass transition, see Fig.4).[11] The increasing discrepancy between calculation and experiment above the glass transition temperature is not surprising, since we know that in this region the temperature dependence of the relaxation time is no longer a simple exponential but is described by the Williams–Lundell–Fermi equation[30].

By first preparing the electret and then measuring its TSD current (i.e. by carrying out an electret-thermal analysis of the polymer) we obtain not only the characteristics of the electret but also the dielectric relaxation and the molecular mobility characteristics of the polymer. A parallel study of the dielectric relaxation and of the relaxation of

mechanical stresses in the polymer establishes the interrelation between electret and dielectric characteristics and allows the electret-thermal analysis (ETA) thermograms to be interpreted.

Our measurements were carried out with poly(ethylene terephthalate),[31] polycarbonates[32–34], poly(methyl methacrylate) and methacrylate copolymers[35,36] poly(butene terephthalate),[37] poly(vinyl chloride),[38,39] polyamides and poly-imides (see p.193 of Ref.1, and also Refs.40–42), poly(vinyl fluoride) and poly(vinylidene fluoride),[43], polychlorotrifluoroethylene[25], phenol–formaldehyde resins[44], and polyalkane-imide[45].

Like the temperature plots of the dielectric losses, the ETA thermograms include at least two maxima: one in the region of the glass transition temperature, corresponding to dipole segment relaxation, and the other at lower temperatures, corresponding to dipole group relaxation (Fig.4).[32] The TSD current maxima are found at temperatures corresponding to the measurements of dielectric losses at 10^{-3}–10^{-4} Hz frequency. These frequencies are the equivalent frequencies calculated by formula (8). Measurements over a wide range of temperature and frequency (from 10^{6} to 10^{-4} Hz) show that the dielectric constant increment and the shape of the relaxation time distribution function both change with temperature. As the measurement frequency is lowered these relaxation characteristics approach the values given by the ETA. At temperatures above T_g we find a maximum in the TSD current (called the ρ maximum, see above).

In amorphous poly(ethylene terephthalate) (PETP) [31] the ETA thermogram gave one maximum near 60 °C, corresponding to the glass transition in the polymer. An increase in the degree of crystallinity of the sample produces a maximum at 82 °C which characterises the glass transition in the more ordered regions of the amorphous phase (possibly near the boundaries of the crystallites). In oriented crystalline PETP we find only a small maximum near 60 °C, but a large sharp maximum near 82 °C. Thus the relaxation time of the electret hetero-charge τ increases with the crystallinity of the sample, but even in oriented, crystalline PETP τ is small, and the surface charge gradually decays.

Polycarbonate based on *bis*-phenol A is amorphous and has a large residual polarisation[32,46]. The peak temperature on the ETA thermogram for the relaxation of the residual polarisation (α) is quite high (~150 °C), but we also find an additional maximum near 120 °C (α') which results in an immediate decay of charge after polarisation, followed by a long period of charge stability. Crystallisation lowers the secondary maximum α', thus shortening the charge stability time. A small increase in charge stability can be obtained by increasing the molecular weight of the polymer and by stretching the polymer samples to increase their orientation.

Chemical modification of the polymer (by adding triazine groups) increases the stability of the hetero-charges as well as the extent of charging by increasing the polarity of the polymer molccule[34]. The magnitude of the hetero-charge increases with both the polarity and the number of the triazine groups. The addition of norbornane groups[33,34] causes a marked increase in the glass transition temperature of the polycarbonate, thus shortening the stabilisation time of the electrets and offering a useful method of preparing electrets with a large and stable charge[47].

Poly-imides have high glass transition temperatures, and the lifetime of the hetero-charges is large in these materials, but their electrical conductivity (which is electronic) is fairly high at high temperatures[48,49]. Therefore large hetero-charges cannot be obtained in poly-imides. The lifetime of the injected charge is determined by the parameter τ_M, which under ordinary conditions (room temperature and pressure) is only 10^{6}–10^{7} s (which can be contrasted with up to 10^{9} s in polycarbonates.

In polyamides we find[50] that near the glass transition temperature the dielectric constant increment decreases very rapidly with temperature. For this reason the maximum on the ETA thermogram corresponding to randomisation of segment orientations is not usually observed. The strong peak found in the ETA thermogram is due to ionic relaxation of the Maxwell–Wagner type at the interface between the amorphous phase and the crystallites. This maximum appears in the temperature plots of dielectric measurements at frequencies below 1 Hz, and its height increases as the frequency is lowered. On the temperature scale the maximum occurs slightly above the glass transition point (α relaxation temperature). A high degree of crystallinity favours low electrical conductivity, and therefore in some of these materials (for example, polyamide-6,6) the homo-charge is very long-lived[51].

Plasticising treatment of poly(vinyl chloride) lowers the temperature of the TSD current maximum in the region of the glass transition by the same amount as it lowers the glass transition temperature[38]. The addition of plasticisers also lowers the peaks in the region of dipole group losses. A detailed analysis of the results showed that the loss of hetero-charge calculated from the area of the peak in the dipole group loss area is proportional to the increase in the elastic modulus in the temperature range from the maximum of the dipole group loss peak to the maximum of the dipole segment loss peak, i.e. it is proportional to the "deplasticising" effect.

In crystalline polyalkane-imides the dipole segment relaxation maximum decreases because the temperature increment of the dielectric constant falls to such an extent as to be undetectable unless a special technique is used to resolve the TSD current peaks[45]. In this polymer (as in polychlorotrifluoroethylene) a TSD current maximum is found at temperatures above the glass transition: it is associated with the relaxation of dipoles in the crystalline regions (α_c relaxation).

In polychlorotrifluoro-ethylene[25] several maxima are found in the glass transition region. The shape of the ETA thermogram is a function of the technology used in the preparation of the sample, and in particular of the pressure and cooling regime. The position of the maxima in the α_c relaxation region can be used to monitor the changes in polymer structure caused by different preparative regimes. Though PCTFE is a polar polymer, stable electrets (whether hetero-charged or homo-charged) cannot be prepared from it because the glass transition temperature is low and the activation energy of the α_c relaxation is low.

Vulcanised compositions of acrylonitrile and butadiene copolymers contain large (CN) polar groups. The electret hetero-charge resulting from the orientation of these groups is considerable, but the glass transition temperature lies below room temperature and therefore the hetero-charge is stable only at low temperatures. The Maxwell relaxation time is short (though it increases as the concentration of nitrile groups decreases), and therefore the homocharge is also unstable. Evidently, electrets based on vulcanised polar rubbers can be obtained only by carrying out the vulcanisation in an electric field ("chemo-electrets").[52] On the other hand, stable corona electrets can be prepared from vulcanisates of non-polar elastomers (for example, polydimethylsiloxane).[53]

In amorphous polymers such as polycarbonates and poly-imides which show a tendency towards structure formation we find (as in PETF) TSD current maxima at temperatures slightly below the glass transition temperature. Experiments

at frequencies between 10^{-1} and 10^{-4} Hz showed that the height of the maximum on the temperature plot (α') increases as the measurement frequency decreases. The height of the maximum increases with heat treatment (annealing), thermal ageing, and exposure to active media[58], which increase the hardness and brittleness of the material and lower its electrical conductivity. In every case the height of the maximum changes in the same sense as the stated parameters. After heat treatment leading to the breakdown of supermolecular formations and to the restoration of the initial properties of the polymer the height of the second maxima (α') of the TSD current also falls.

In partially crystalline polymers (PETF) the α' maximum at ~60 °C decreases as the crystallinity increases. This maximum may be associated with the motion of segments in the disordered regions of the amorphous phase, as opposed to the segments at the boundaries between the amorphous phase and the crystalline regions[31]. The latter have a limited choice of conformations, and their mobility is similarly limited: as a result, the temperature of the TSD current maximum caused by the randomisation of their orientations increases with the crystallinity of the sample.

The height of the maxima at temperatures below 0 °C (dipole group relaxation) is usually less than the value calculated from the increment of the dielectric constant at higher temperatures. This effect is part of the general increase in relaxation rates at higher temperatures.

The temperatures of the TSD current maxima due to dipole relaxation are always consistent with extrapolations of the temperatures of the dielectric loss maxima measured at 10^1 to 10^6 Hz, or with direct measurements at 10^{-3}–10^{-4} Hz frequencies (Fig. 5).

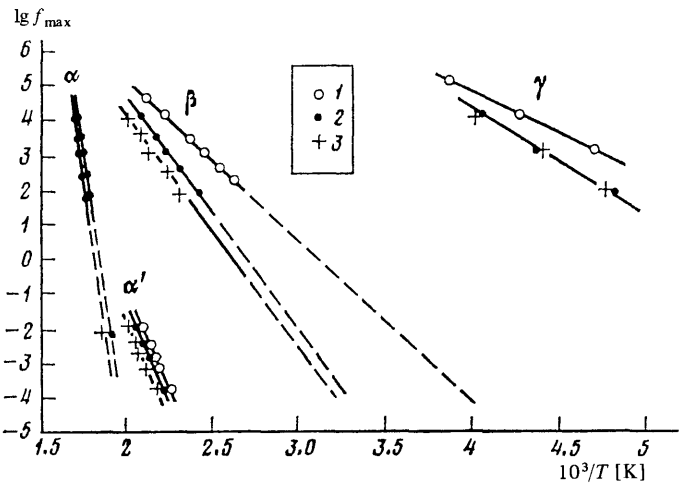

Figure 5. Logarithm of the frequency of the dielectric loss maximum against reciprocal absolute temperature for polyimides (*1* polypyromellitimide, *2* DFO, *3* BZF). The experimental points for $f_{equiv} \approx 10^{-4}$ Hz are obtained from ETA data.

In almost all the ETA thermograms we find, at temperatures higher than the polarisation temperature, a maximum in the TSD current due to the relaxation of bulk charges caused by ionic mobility (the ρ maximum). This maximum is observed, for example, at 120 °C in PETF and at 180 °C in polycarbonate. In some polymers (for example, poly-imides) this maximum is not observed: it is replaced by a monotonic increase in the TSD current due to pyro-electric effects. The height of the ρ maximum depends on the field strength, the polarisation time, and the electrode material.

As formula (14) shows, the measurement of dielectric relaxation by electret-thermal analysis can be used to determine the dielectric loss tangent: in a polymer with $E = 500$ kJ mole^{-1} and $\varepsilon = 3$ (with $E_p = 100$ kV cm^{-1}, $T = 293$ K, $b = 1$ K min^{-1}, and a detector sensitivity of 10^{-14}–10^{-15} A) the result was 10^{-6} (an improvement by two orders of magnitude on the sensitivity of conventional methods of measuring dielectric losses at audio frequencies. Furthermore, the ETA method has an enhanced resolving power due to the lower frequencies at which the measurements are made.

Notes: T_{max} for the dielectric measurements is the temperature of the ε″ maximum at 1 kHz; the W values shown in brackets were calculated by Eqn. (11), the others by Eqn. (10); PBTF is poly(butene terephthalate), PI is polyimide.

Some results obtained by ETA and by dielectric measurements respectively are compared in Table 1. They relate to a rigid (without air-gap) contact between the electrode and the electret. This type of data can be useful in studies of dipole and molecular mobility in polymers, but under real electret application conditions a gap is almost invariably present (usually, between one charged surface and its counter-electrode). If the TSD currents are measured under these conditions slightly different characteristics are obtained[23]. In particular, the TSD current associated with the ρ maximum often flows in the inverse direction as a result of the decay of the injected charge carriers. In contact-less measurements the quantity determined is often the potential difference V rather than the TSD current. The temperature dependence of V for the electret is an operational characteristic of the electret; the TSD current (measured with an air gap) is proportional to the differential of $V(T)$ with respect to time: $i(T) \propto dV(T)/dt$.[23]

In electrets formed by corona charging or by irradiation with an electron beam (rather than by thermal polarisation) measurements of thermal depolarisation give the parameters

of the traps in which the injected carriers are captured[54,55]. It should be noted, however, that these traps are often emptied by the "unfreezing" of the mobility of the corresponding structure elements, and therefore most of the TSD current peaks occur at the same temperatures as the TSD current peaks of thermo-electrets. Furthermore, the presence of injected charges in the electret gives rise to an electric field in which dipoles can become oriented if the temperature of the sample is raised, and therefore the measured TSD currents are in fact polarisation rather than depolarisation currents. According to formula (4) if $P_0 = 0$ the polarisation in the field of injected charges is proportional to $(\varepsilon_{st} - \varepsilon_\infty)/\varepsilon_{st}$. Experiments of this type on PETP have shown[23] that two maxima appear in the thermogram of corona electrets (the α and the ρ maximum), and that the ratio of their areas is equal to the ratio $\Delta\varepsilon/\varepsilon_{st} = 0.10-0.12$.

Some workers[19,55] do not specially distinguish the current maxima due to polarisation of the electret in the field of the injected charge, and they formally ascribe them to the emission of charge carriers from the traps (which is clearly incorrect). The error of this interpretation was pointed out by McGhie and coworkers[43] (among others) after a detailed study of injection and polarisation currents in poly(vinyl fluoride).

Recent work has shown[24] that the ρ maximum often occurs not at the temperature for which $\tau_M = \tau_{max}$ but at the temperature corresponding to the "unfreezing" of the mobility of the charge carriers at the crystallite boundaries (the α_c relaxation). In polychlorotrifluoro-ethylene, as in poly(vinylidene fluoride), this temperature is ~130 °C. The α_c relaxation is poorly revealed by dielectric measurements at audio frequencies, but it is clearly seen in dynamic mechanical measurements[56]. This was confirmed by our own measurements on poly(ethylene terephthalate), polycarbonate, and poly(vinylidene fluoride).

The dependence of the charges on the field intensity E_p shows a direct proportionality between P and E_p for the α maximum, as expected for dipole polarisation, whereas for the ρ maximum the plot of lg σ_{eff} against $E_p^{1/2}$ is linear, which is typical of injected charge.

We may assume that injected electrons are trapped mainly at the interface between the amorphous and the crystalline phase, where they cause orientation of the surrounding dipoles with a corresponding change in the structure of the polymer. Thus the depth of the trap is determined by the sum of the energies needed to produce the conformational changes in all the surrounding portions of macromolecules resulting from the charge carrier injection. When the electret is heated to the temperature of the α_c relaxation the traps are emptied by the "unfreezing" of the mobility of the charge carriers at the crystallite boundaries.

2. Changes in Polymer Structure Caused by Interaction with an Electric Field

The polarisation of polar polymers causes some changes in the properties and structure of the polymers. Thus, changes in mechanical properties have been reported[57]. The induced elasticity limit $\sigma_{i.e.}$ (fluidity limit) of polycarbonate increases by ~20% in thermo-electrets as compared to the unpolarised polymer. The increase in $\sigma_{i.e.}$ with polarisation time and with field strength, and the decrease in $\sigma_{i.e.}$ during storage, are consistent with the increase or decrease in residual polarisation P_0 (determined by integrating the TSD current). The following relationship is observed:

$$\sigma_{i.e.} = \sigma_0 + CP_0$$

where σ_0 is the induced elasticity limit of the initial polymer, and C is a material constant [$C = 8.82 \times 10^{10}$ N C^{-1} for polycarbonate, $C = 1.09 \times 10^{10}$ N C^{-1} for poly(ethylene terephthalate),[57] and $C = 1.24 \times 10^7$ N C^{-1} for poly(vinyl fluoride)]. The coefficient C has the dimensions of an electrostriction coefficient: it defines the effectiveness of the interaction between the residual polarisation and the mechanical properties of the polymer. The small value of C for poly(vinyl fluoride) reflects the low stability of P_0 at room temperature (at which the measurements of $\sigma_{i.e.}$ were made).

In polycarbonate electrets the velocity of sound is lower and the density is slightly higher than in the initial polymer. These changes can be ascribed to the formation of ordered, denser regions separated by less ordered and less dense regions. Similar changes in structure take place during lengthy heat treatment of the polymers at temperatures close to T_g;[58] these changes are accelerated if the ordering process is assisted by an electric field. The thermophysical properties of the polymer are affected at the same time. A sharp increase in the height of the specific heat maximum (as compared with the unpolarised material) is observed by differential scanning calorimetry on the thermograms of electrets near T_g. For example, in poly(vinyl chloride) the enthalpy ΔH increases 1.5-fold. This thermal effect is due to the breakdown of the residual polarisation[50].

***Pentaplast, or Pentone.

Mechanical deformation of polar polymers produces mechano-electrets[1,59-63] in which the size of the charge increases with the degree of deformation. Mechano-electrets have well developed piezo-electric properties[62], stronger than those of thermo-electrets made from the same polymers[63]. The orientation of the macromolecules during deformation induces a preferred orientation of the dipoles (with their polar groups normal to the deformation plane). The increases in the induced elasticity limit and in the mechanical strength of the polymer samples resulting from polarisation[57] are the inverse effects of the formation of mechano-electrets.

In crystalline polymers [poly(vinylidene fluoride), polyamide-11] changes in structure of the crystallites can be produced by a polarising field. In poly(vinylidene fluoride) the crystalline α form is converted into the β form[64] by the rotation of the dipoles (CF_2 groups) round the axis of the macromolecule chain. A theoretical analysis[65] has shown that this rearrangement is assisted by the simultaneous rotation of all the CF_2 groups in the chain, which gives the lowest total free energy. The dependence of the polarisation P on the field strength E_p for a slowly changing field (10^{-1}–10^{-4} Hz) has a typical relaxation form with a hysteresis loop (as in ferroelectric materials). Similar electret properties have been reported for poly-3,3-*bis*-chloromethyloxyethane (Pentaplast),[66] polyamide-11,[67] and the copolymers of vinylidene fluoride and trifluoro-ethylene[68,69].

Unfortunately, studies of hysteresis phenomena have not been made on other polymers. In view of the relaxation form of the molecular mobility we may assume that ferroelectric phenomena are present to a greater or lesser extent in all polar polymers.

Changes in structure of polyacrylonitrile after polarisation have been studied by i.r. spectroscopy and X-ray structural analysis[61]. This work has revealed ordering effects in the segments and an increase in the density of ordered regions. Similar effects were observed when the sample was annealed without an electric field, but in a lesser degree. The authors point out[61] the similarity between the changes in structure of polyacrylonitrile and those of polycarbonate[57].

IV. PIEZO- AND PYRO-ELECTRIC PROPERTIES OF ELECTRETS

1. Piezo-electricity in Polymer Electrets

The piezo-effect in electrets[70–81] is due to the change in the surface charge density caused by deformation of the polymer[70]:

$$d_{33} = \frac{dP}{dF} - 2\eta \frac{\sigma_{eff}}{E_{el}} \qquad (15)$$

where F is the load, η is Poisson's ratio, E_{el} is the elastic modulus, and d_{33} is the piezo-modulus of the planar polymer electret under compression (the polarisation axis is assumed to coincide with the deformation axis "3").

Experiments on ceramic electrets have shown that the second term of Eqn.(15) is too small to account for the observed piezo-effect. However, in polymer electrets the elastic modulus is small, and in rubber "chemo-electrets" the piezo-effect is fully accounted for by the second component[52,71].

Later work with a large number of polymers (see p.145 of Ref.1) showed that the piezo-effect tends to increase with the polarity of the polymer, whereas its stability increases with the rigidity of the macromolecular chain. A theoretical analysis[10] demonstrated that if the dielectric constant is unaffected by the deformation (i.e. if the electrostriction coefficient is small) the piezo-modulus under expansion d_{31} reflects exclusively the changes in geometric shape of the sample, and is given by

$$d_{31} = -(1-\eta) P_0/E_{el}$$

whereas under compression

$$d_{33} = -2\eta P_0/E_{el} . \qquad (16)$$

These relationships are useful for predicting the practical value of electret devices based on the piezo-electric properties of polymers. Knowing E_{el} and the P_0 value given by integration of the TSD current or calculated by formula (7) we can find the piezo-modulus. Calculated and experimental values of the piezo-modulus d_{31} are compared in Table 2.

Broadhurst and Davies[72] allowed for the Onsager internal field. Assuming that the formation of residual polarisation orients the dipoles along the field at an average angle θ to the direction of the polarising field, they obtained the expression for P_0

$$P_0 = (\varepsilon_\infty + 2) N \mu_0 \langle \cos\theta \rangle / 3 \qquad (17)$$

which gave the formula for $d = dP_0/dF$

$$d = -P_0 \frac{\varepsilon_\infty}{3} \alpha \qquad (18)$$

where α is the volume compressibility. Since under compression $\alpha = (1/V)(dV/dE) = 2\eta/E_{el}$, and since $\varepsilon_\infty \cong 3$ for poly(vinyl chloride), for which formula (18) has been shown to be valid[73], we arrive at an expression identical to Eqn.(16).[10]

Eqns.(16) and (17) are convenient for electrets with a residual polarisation consisting of oriented and "frozen" dipoles. It is found experimentally[74] that non-polar polymers with an injected homo-charge σ_p also show a piezo-effect, especially under flexural deformation, though the piezo-modulus is small.

In poly(vinylidene fluoride) the piezo-effect is so large as to require special discussion. Poly(vinylidene fluoride) (PVDF) is a polar polymer characterised [like poly(vinyl fluoride)] by a low glass transition temperature (below room temperature). Therefore under normal conditions the polymer in the amorphous phase is in a highly elastic state, and thermo-electrets made from this material are unstable. Injected charge carriers (homo-charges) are captured in traps at the boundary between the amorphous and the crystalline phase, from which they can be freed only by the "unfreezing" of the mobility of the macromolecules on the crystallite surfaces (α_c relaxation). This effect is confirmed by dynamic mechanical measurements[24], and is analogous to the corresponding process in polytetrafluoro-ethylene (a typical electret material).

We can assume that charge carriers trapped near the surface can survive for a long time ($\geq 10^{10}$ s), and generate a strong internal field in which the dipoles are oriented[10]. The application of a mechanical load to a dielectric with oriented dipoles produces a piezo-effect whose magnitude depends on the injected charge σ_p (measured by integrating the TSD current in the region of the α_c relaxation), on the depth of injection l, on the sample thickness L, and on the polarisability (defined as $\Delta\varepsilon = \varepsilon_{st} - \varepsilon_\infty$). The piezo-modulus under expansion is

$$d_{31} = \frac{(1-\eta)}{E_{el}} \frac{\Delta\varepsilon(\alpha)}{\varepsilon_{st}} \sigma_p \frac{l}{L+l} .$$

Inserting $l = 1$ μm with $L = 20$ μm and $\varepsilon_{st} = n_\lambda^2 + \Delta\varepsilon(\alpha) = 2.2 + 6.2 = 8.4$ for a non-oriented film of PVDF in its less polar, crystalline σ form, with $\sigma_p = 0.057$ C m^{-2} and $E_{el} = 1.1 \times 10^9$ Pa, we obtain $d_{31} = 1$ pC N^{-1}. After orientation the parameter $\Delta\varepsilon(\alpha)$ increases to 8–11, and σ_p increases to 1.48 C m^{-2} for polarising fields up to 450 kV cm^{-1}. In this case d_{31} increases to 22–30 pC N^{-1}, which corresponds to the highest experimentally observed values of d_{31}.

This theoretical model by allowing for the role of injected charges brings all the polymer electrets into a coherent group. It can be used to calculate the change in structure of PVDF in an electric field in terms of changes in ε only. Similar views have been expressed by other workers[67,76,77].

However, wide acceptance has been gained by the view[78–80] that the piezo-effect in PVDF and in the copolymers of vinylidene fluoride is due mainly to spontaneous polarisation

in the crystallites of the β form, which is formed from the crystalline α form by the orienting effect of stretching the sample or under the influence of very strong electric fields ($\sim 10^8$ V m^{-1}).

Other workers[74,81] have allowed for the crystallites of the polar, spontaneously polarised β form dispersed in the amorphous matrix as well as for the change in dielectric constant produced by the deformation. This approach gave the following expression for the piezo-modulus d in PVDF:

$$d = \frac{P_0}{E_{el}}\left[\frac{\varepsilon_{cr}}{2\varepsilon+\varepsilon_{cr}}\left(\frac{\varkappa}{\varepsilon}-\frac{\varkappa_{cr}}{\varepsilon_{cr}}h\right)+2\eta\right]+v\left(\frac{3\varepsilon}{2\varepsilon+\varepsilon_{cr}}\right)h \qquad (19)$$

where the subscript "cr" refers to the polymer in the crystalline form, v is the volume fraction of the crystalline phase, $h = 5E_{el}/[3E_{el} + 2E_{el}(cr)]$, and $\varkappa$ is the electro-striction coefficient, equal to $E(\partial\varepsilon/\partial F)$. The calculation shows that the component d [due to the change in shape of the sample and related to the Poisson ratio by Eqn.(19)] accounts for ~78% of the piezo-effect[81]. However, the parameter P_0 is identified[81] with the spontaneous polarisation of the electret in the crystalline β form rather than with the polarisation in the field of the injected charge.

Thus the piezo-effect in polymer electrets may be due to the change in surface density of the homo-charge caused by deformation ($d\sigma_p/dF$), the change in density of the residual polarisation P_0 (dP_0/dF), or the "true" piezo-effect in the spontaneously polarised particles (in PVDF these particles consist of polarised crystallites of the β phase).

These spontaneously polarised particles need not even (in general) be particles of the polymer: they could be introduced as a powdered inorganic ferro-electric. In this case the piezo-electric properties of the resulting composite materials can be extremely high. By combining a suitable content of ferro-electric powder with a polymer having adequate polarity and intrinsic piezo-electric properties materials with very favourable characteristics have been obtained[82-85]. The production of polymeric or composite piezo-elements is incomparably simpler than the preparation of ceramic devices, and the piezo-sensitivity per stage of the former ($g_{33} = d_{33}/.\varepsilon\varepsilon_0$) is 10–100 times greater than in the ceramic ferro-electric devices because of the lower ε values in polymers.

2. Pyro-electricity in Polymer Electrets

Pyro-electricity appears as a result of changes in polarisation P or in the density of injected charges produced by changes in temperature.

The pyro-coefficient p, which characterises the change in charge density of the dielectric produced by a change in temperature of one degree, is directly proportional to P_0 and to the volume thermal expansion coefficient α:[73]

$$p = -\frac{\varepsilon_\infty}{3}\alpha P_0 .$$

The pyro-effect associated with σ_p is usually small. In the case of polymers containing a ferro-electric component [poly(vinylidene fluoride)] the pyro-effect is described by a formula derived from a mixture of a ferro-electric and a non-polar substance[81]:

$$p = P_0\left[\frac{\varepsilon_{cr}}{2\varepsilon+\varepsilon_{cr}}\left(\frac{\lambda}{\varepsilon}-\frac{\lambda_{cr}}{\varepsilon_{cr}}\right)-\beta\right]+v\left(\frac{3\varepsilon}{2\varepsilon+\varepsilon_{cr}}\right)P \qquad (20)$$

where $\lambda = \partial\varepsilon/\partial T$ is the temperature coefficient of the dielectric constant, and β is the linear thermal expansion coefficient. It was found experimentally that the component of p due to the volume change [and associated with the coefficient β in Eqn.(20)] makes a 50% contribution to the pyro-effect in PVDF.

Composite materials based on polymers with added ferro-electrics offer large values of the pyro-coefficient p. Some recent results are summarised in Table 3.

V. APPLICATIONS OF POLYMER ELECTRETS

Electrets can find applications: 1) as dielectrics, with an added external electric field, 2) as dielectrics, with an internal polarisation, 3) as piezo-electric materials, and 4) as pyro-electric materials.

Table 3. Pyro-electric properties of polymer electrets.

Polymer	E_p, kV cm^{-1}	T_p, °C	$10^5 p$, C m^{-2}K^{-1}	Refs.
PVC	320	90	0.11	[73]
PAN	215	109	0.054	[73]
PAN	—	—	3.9	[96]
PVDF, not oriented, α-form	300	100	2.4	[76]
PVDF, uniaxially oriented, β-form	2200	20	2—20	[76]
PVDF, biaxially oriented, β-form	2200	20	2,7—8.0	[76]

As dielectrics (with an external electric field) electrets are widely used in filters, for controlling electron beams (and in particular for focussing electron beams), and in electro-mechanical transducers (microphones, pick-ups, etc.). The most widely used of these devices is the electret condenser microphone, currently manufactured on a scale of millions per annum. The use of electrets has greatly simplified microphone design, allowing a reduction in size to ~5 mm coupled with improved properties (for example, the linearity region of industrially produced electret microphones extends from 50 to 16000 Hz).[2,86-88] Special electret microphones for studying ultrasound and infrasound have also been described[89]. Electret fibre filters[90], developed outside the Soviet Union under the name "filtret",[91] are now widely used: they are cheap, much more efficient than previous fibre filters, and they offer excellent protection against airborne industrial or radioactive dust.

The incidence of thrombosis has been reduced by using artificial blood vessels and artificial heart components with electret properties[92].

In their second function electrets can be used as a very special type of electric cell. A temperature rise (for example, in a fire alarm device) may give a TSD current sufficient to activate a radio transmitter (see p. 204 of Ref.1).

As piezo-electric materials[93] polymer electrets have been used in stereo headphones, acoustic pick-ups[94], and igniters, and also in fans. Over 40 different applications of piezo-electric poly(vinylidene fluoride) polymer film have already been patented[76]. Applications in hydro-acoustics, in switching systems for fibre optics, in the generation of focussed ultrasonic signals, and in the prevention of fouling of ships' hulls by marine plants and molluscs[95] are especially interesting.

Likely future pyro-electric applications of polymer electrets (for example, based on acrylonitrile) include the direct conversion of solar into electrical energy[96], night viewing with infrared radiation [poly(vinylidene fluoride)], and various forms of pyro-electric detector and other devices[76,93].

* * *

In conclusion we note that the prospects of more widespread applications of polymer electrets are good. New uses are being discovered every year, in very different branches of technology. We should also stress that only a small number of polymer electret materials has been exploited in practice so far. For the production of external electric fields the following materials have been used most widely: polytetrafluoro-ethylene, the tetrafluoro-ethylene–hexafluoropropene copolymer, polycarbonate, and poly(methyl methacrylate), whereas polypropene, poly(chlorotrifluoroethylene), and poly(methyl siloxane) are beginning to find practical applications. Materials used in practical piezoelectric devices include poly(vinylidene fluoride), poly(vinyl chloride), and composite polymer materials containing a ferro-electric ceramic filler (lead titanate zirconate).

We can expect practical applications of polymer electrets in pyro-electric devices, and the development of an increasingly wide range of polymers for use in electric field generators and in piezo-electric devices (polyamides, polysulphones, and vinylidene fluoride copolymers[97]). Further developments in the modification of the physico-mechanical properties of polymers by the application of electric or magnetic fields can also be expected.

The study of the influence of an external electric field on the structure of polymer electrets is still in its initial stages[98,99].

Molecular Photocatalytic Systems for Solar Energy Conversion: Catalysts for the Evolution of Hydrogen and Oxygen from Water †

K.I.Zamaraev and V.N.Parmon

This review is devoted to recent advances in the development and study of homogeneous and heterogeneous catalysts for the reduction of water to molecular hydrogen and its oxidation to molecular oxygen. The production of micro-heterogeneous systems for photocatalytic charge separation is also discussed. 114 references.

I. INTRODUCTION

Mankind's total annual energy consumption now stands at the enormous value of ~10^{17} kcal, and is still rising rapidly, doubling every 15–20 years[1–3]. However, our reserves of mineral fuels which provide the main input to the energy balance (~80% of the primary energy resources, including ~60% of petroleum and gas) are strictly limited: the total energy equivalent of the explored reserves of these fuels is estimated to be[3–5] 10^{19}–10^{20} kcal. Thus the search for alternative sources of energy is a very important problem.

It is thought that for the immediate future the energy requirements of the world community will be satisfied by an increase in the mining and conversion of coal (including its conversion into artificial liquid fuel), and in the use of nuclear sources of electrical energy and heat. The raw materials required by these two branches of energetics are assured for at least one century. In both cases the level of scientific and technological development already reached is high enough to make early practical exploitation a real possibility. However, we should not forget that a substantial increase in the use of coal and of nuclear fuel will present a number of as yet unsolved problems arising from possibly detrimental effects on the environment. For example, the combustion and treatment of coal will require the development of cheap purification plant to prevent the accumulation of sulphur oxides, carcinogens, and other harmful substances in the atmosphere. There is even a danger that at the expected rate of increase of energy

† Paper presented to the Second Conference on the Physics and Chemistry of Free radicals in memory of Academician V.V.Voevodskii, Novosibirsk, June 1982.

consumption the anthropogenic heat evolution from the use of fossil and nuclear fuels may reach several per cent of the total heat balance of the Earth by the middle of the next century, with unpredictable effects on the Earth's climate[6]. Equally unpredictable are the consequences of enriching the atmosphere in carbon dioxide (unavoidably produced by the combustion of organic substances).

For the more distance future we must look to two sources of energy available almost without limit: thermo-nuclear energy and solar energy[1]. Neither of these sources can yet be widely exploited because the level of scientific and technological development is inadequate at present in both cases. However, there is every reason to expect very rapid progress. Basic research on a controlled thermo-nuclear reaction is in progress. Although this reaction has not yet been realised experimentally, the potential advantages of thermo-nuclear synthesis as a source of energy have been widely discussed for many years. On the other hand the possibilities offered by solar energy are less clearly characterised, though it is known that the energy content of the Sun's rays which reach the Earth is far in excess of even the highest estimates of mankind's increasing requirements[1-3,7,8]. The only problem is to learn how to use this energy effectively.

There can be no doubt that in the near future the traditional sources of energy will continue to play a major role in the overall energy balance of mankind. Nevertheless, even the International Energy Conference (an organisation traditionally opposed to the use of solar energy) admits the possibility of a significant increase in the direct exploitation of solar energy: in particular, it is expected that by the year 2020 up to 10–15% of the world's energy requirements will be provided by solar energy converters[2].

One of the most promising methods of utilising solar energy is its direct conversion into chemical fuel energy[1,9-11]. Storing the Sun's energy in the form of chemical fuels would overcome the most serious obstacle to the widespread use of solar energy (its dependence on seasonal, meteorological, and other natural conditions) as well as making the energy available in a more concentrated and generally usable form (a high-level chemical energy source).

In principle any chemical process in which free energy is accumulated can be used for the conversion of solar energy. The most attractive, at present, are the reactions which produce high-energy fuels (hydrogen, hydrocarbons, alcohols and carbohydrates, hydrazine, ammonia, etc.) from water and atmospheric gases, which offer a readily available and almost inexhaustible raw material (see, for example, the recent reviews in Refs.12 and 13). The advantages of these reactions include the high energy content of the resulting fuel (the combustible–oxidiser (oxygen) pair of chemical substances), and also the possibility in principle of achieving a relatively high efficiency (up to ~30%) in the conversion of solar energy[14-16]. We should stress that the production of all these fuels takes place *in vivo* in plants and micro-organisms (either by photosynthesis, followed by fermentation of the products to hydrogen, methane, alcohols, etc., or by atmospheric nitrogen fixation).

However, these reactions do not proceed spontaneously in sunlight outside the living organism. They require the development of *photocatalytic* systems, consisting of *photocatalysts* (for the photochemical step) and *ordinary catalysts* (for the subsequent dark reaction steps giving the energy-rich chemical substances).

Photocatalysts are substances which can induce (by the absorption of light quanta) chemical reactions between the components of a reaction by undergoing repeated chemical interactions to form an intermediate and regenerating themselves after each interaction. (The term "photocatalyst" is often replaced, in published papers, by the term "photosensitiser", on the assumption that the two are synonymous. It would be more correct to reserve the term "photosensitiser" for substances which induce reactions by energy transfer to the reactants rather than by forming chemical intermediates with them.)

The most interesting of the fuel-producing processes listed above is the production of hydrogen by the decomposition of water. Hydrogen is one of the preferred (and ecologically clean) chemical fuels for energy production in the future. It is also a valuable raw material for the chemical industry, used in large quantities for the catalytic reduction of carbon dioxide and molecular nitrogen to give all the fuels listed above. Lastly, existing information on the chemical reaction mechanisms suggests that the photocatalytic decomposition of water should be the most easily realisable of all the reactions for storing solar energy as fuels.

Some definite advances in the development of photocatalytic systems for the decomposition of water into hydrogen and oxygen have already been reported. The systems can arbitrarily be classified into two groups: semiconductor systems and molecular systems.

Semiconductor systems rely on massive or on finely divided semiconductors as photocatalysts (mainly oxides, phosphides, arsenides and chalcogenides of the transition metals). By using these substances solar energy has been converted into chemical fuel energy with reasonable efficiencies (up to 1–2%) (see the pioneering paper by Fujishima and Honda[17], and also the most recent reviews[18-21] and their references). The efficiency of semiconductor photocatalytic systems for the decomposition of water will probably be further increased by research now in progess. A detailed analysis of the present situation in the field of semiconductor photocatalysis will be found in the same reviews[18-21].

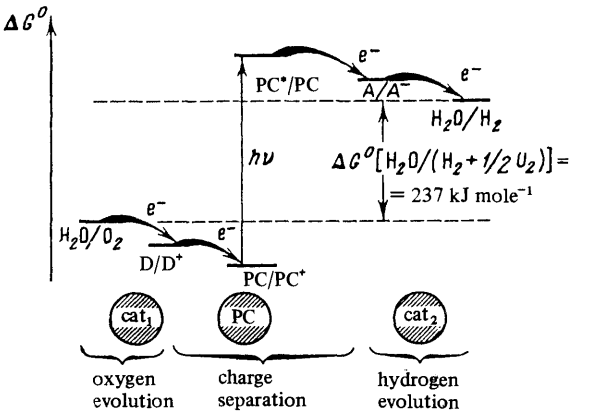

Figure 1. Energy diagram for the decomposition of water in a molecular photo-catalytic system; ΔG° is the change in free energy for the process, the curved arrows show the electron transfer paths.

Molecular photocatalytic systems attempt to reproduce (or model) the natural photosynthesis schemes. Work on these systems began later than on the semiconductor systems,

and has not yet produced really significant advances. However, since we know that the efficiency of the conversion of solar energy by the molecular systems used in natural photosynthesis is quite high (up to 6–10% for the relatively complex reaction between CO_2 and H_2O [22,23]) there is every reason to expect the early development of efficient artifical converters for the much simpler water decomposition reaction.

Recent progress in the development of molecular photocatalytic systems for the decomposition of water have been discussed in a number of reviews[21,24–29], including one by the present writers[12]. Among the papers published since our review[12] the most noteworthy are Refs.30 and 31 (see also Refs.21 and 25), which claim the development of the first artificial molecular system capable of yielding the full cycle of decomposition of water into hydrogen and oxygen under the influence of visible light (albeit with a modest efficiency).

The water decomposition schemes most often considered include three steps (see Fig.1): charge separation, i.e. the production (under the influence of light and in the presence of the photocatalyst PC) of relatively strong chemical oxidisers (D^+) and reducers (A^-)

$$D + A \xrightarrow[PC]{h\nu} D^+ + A^- \qquad (1)$$

followed by catalytic processes for the evolution from water of oxygen by the oxidisers D^+

$$4D^+ + 2H_2O \xrightarrow{cat_1} 4D + 4H^+ + O_2\uparrow \qquad (2)$$

and of hydrogen by the reducers A^-

$$2A^- + 2H^+ \xrightarrow{cat_2} 2A + H_2\uparrow . \qquad (3)$$

Light is not needed for the last two steps. The overall process is described by the equation

$$2H_2O \xrightarrow[cat_1,\ cat_2]{h\nu,\ PC,\ D,\ A} 2H_2 + O_2 .$$

Thus efficient catalysts of three types must be developed in order to realise the decomposition of water into hydrogen and oxygen by sunlight in the presence of a molecular photocatalytic system: catalysts for charge separation in visible light, catalysts for oyxgen evolution from water by one-electron oxidisers, and catalysts for hydrogen evolution from water by one-electron reducers. For example, in the proposed[30,31] molecular photocatalytic system the compounds PC, A, cat_1, and cat_2 are, respectively, the *tris*-bipyridyl complex of ruthenium(II) [$Ru(bipy)_3^{2+}$], the organic bication *N,N'*-dimethyl-4,4'-dipyridine ("methylviologen", MV^{2+}), colloidal ruthenium dioxide, and colloidal platinum. The photocatalyst PC also acts as the intermediate donor D.

In this review we shall discuss the main results of recent work carried out in our laboratory since the publication of our last review[12] on the development and characterisation of catalysts for all three steps in the decomposition of water by molecular photocatalytic systems: we shall begin with the hydrogen evolution step, which is the most developed at present.

II. EVOLUTION OF HYDROGEN FROM WATER

The one-electron reducers A^- formed in the charge separation step [reaction (1)] can evolve hydrogen from water by reaction (3) only in the presence of special catalysts. Even the earliest workers[32–38] had suggested several possible catalysts for this process: supported[39–41] or colloidal precious metals (references given below), and biological enzymes (hydrogenase and nitrogenase[28,34,39,42–48]). To compare the relative merits of these catalysts in practical photocatalytic systems we need detailed quantitative information on their catalytic activity and stability, and also on the dependence of these properties on the formation conditions of the catalyst. Studies of this type are now being made in a number of laboratories on colloidal metal catalysts (see, for example, Refs.21 and 41–56, and their lists of references).

In the following sections we shall discuss two types of catalyst for the evolution of hydrogen from water: 1) highly dispersed precious metals, stabilised in polymer globules and grandules which are permeable to the reducing agent and to water molecules, and 2) heteropolyanions (compounds containing several transition metal ions which can be fully and reversibly reduced by accepting two or more electrons). Thus the heteropolyanions can be treated as structural and functional models of the hydrogenase and nitrogenase enzymes, whose active centres also contain several transition metal ions and are reduced reversibly by several electrons.

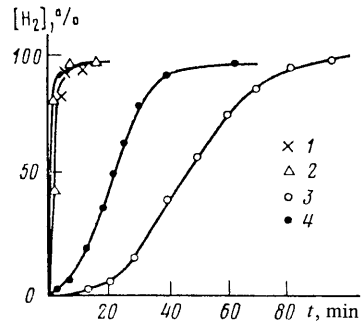

Figure 2. Kinetics of hydrogen evolution (in per cent of the stoichiometric yield) from a 1.5×10^{-2} M solution of VSO_4 in water in the presence of various catalysts: *1*) [Rh·en]Cl_3, *2*) and *3*) Rh–PEI of composition Rh : N ≅ 1 : 2 and 1 : 4 respectively, *4*) $[Rh(en)_2Cl_2](ClO_4)$. Volume of solutions 20 cm^3, amount of rhodium in solution ~10^{-5} g-atom, pH of solutions adjusted to pH : 0 by H_2SO_4, temperature 298 K.[57]

1. The Rhodium–Ethylenediamine and Rhodium–Polyethyleneimine Systems

We have shown[57] that the coordinationally unsaturated complexes of rhodium(III) with ethylenediamine (en) and with its polymeric analogues (polyethyleneimines) are active catalysts for the evoluation of hydrogen from water by one-electron reducers such as V^{2+}(aq), Cr^{2+}(aq), and the cation radical methylviologen (MV^+), by the reaction

$$2A^- + 2H^+ \xrightarrow{cat_2} 2A + H_2\uparrow$$

or

$$2A^- + 2H_2O \xrightarrow{cat_2} 2A + H_2\uparrow + 2OH^- \qquad (3a)$$

The most interesting in practice are the heterogeneous catalysts based on polymers: branching polyethyleneimine (PEI) of molecular weight ~20 000 and the commercial ion exchanger AN-221 (granulated, partially cross-linked polyethyleneimine).

Studies by ESR, X-ray photo-electron spectroscopy (XPS), and optical spectroscopy in the visible and u.v. regions have shown[58] that in the initial forms of the catalyst based on monomeric ethylenediamine almost the whole of the rhodium is present as the rhodium(III) complex, whereas in catalysts based on polyethyleneimine up to 5% of the rhodium (depending on the preparative conditions) can be present as a rhodium(II) compound, the remainder being in the form of a rhodium(III) compound. It was shown that whereas with monomeric ligands the initial complexes can have the composition Rh : N = 1 : 6, 1 : 4, and 1 : 2 (the latter complexes being obtained only in mixtures with Rh : N = 1 : 4 complexes), in the case of polymeric deprotonated ligands initial complexes of composition Rh : N = 1 : 4 and 1 : 2 are formed. By varying the metal–ligand ratio in the synthesis we can obtain heterogenised metal–polymer complexes predominantly of the Rh : N = 1 : 2 or 1 : 4 composition.

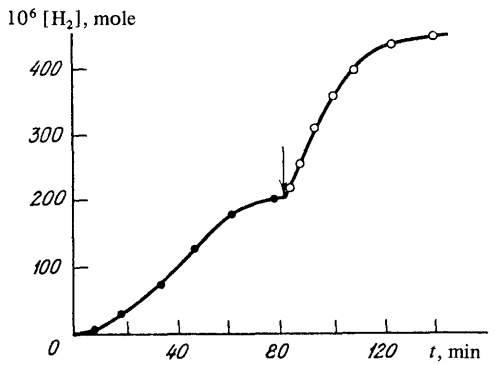

Figure 3. Kinetics of the evolution of hydrogen from a 1.5×10^{-2} M solution of VSO_4 in water in the presence of the polymer catalyst Rh–PEI of composition Rh : N ≅ 1 : 4; other conditions as in Fig. 2, the arrow denotes the addition of the second portion of VSO_4.

The addition of complexes of rhodium with ethylenediamine or polyethyleneimine to solutions of reducing agents such as V^{2+}(aq) (redox potential $E_0 = -0.25$ V relative to the NHE) and Cr^{2+}(aq) ($E_0 = -0.4$ V) causes evolution of molecular hydrogen. Typical H_2 evolution kinetic curves are shown in Fig. 2. They are S-shaped, with an initial induction period during which the reaction gradually accelerates. The induction period probably corresponds to the formation of the active forms of the catalyst (possibly highly dispersed particles of metallic rhodium, see below). The slowing down of the reaction at long times indicates depletion of the reducing agent. Thus, at the plateau of Fig. 2 the amount of hydrogen evolved is almost exactly 100% of stoichiometric for reaction (3) or (3a). At the same time by adding reducing agent at its original concentration when the reaction has come to an end we can produce a renewed evolution of hydrogen in which the slope of the kinetic curve is either the same as that of the initial curve or greater (see Fig. 3). As Fig. 2 shows, both with the monomeric and with the polymeric ligand the activated catalysts prepared from complexes of composition Rh : N = 1 : 2 have a much higher activity than those prepared from complexes of composition Rh : N = 1 : 4. In the presence of monomeric coordinationally unsaturated complexes of composition Rh : N = 1 : 6 no hydrogen is evolved by the reaction with V^{2+}(aq) or Cr^{2+}(aq).

According to X-ray structural analysis and XPS results[58] the activation of the monomer complexes of composition Rh : N = 1 : 2 causes complete reduction to finely divided metallic rhodium. The formation of a phase of metallic rhodium of very small particle size was observed also in all the activated polymer catalysts. Electron microscopic studies of the particles of metallic rhodium in polymer catalysts revealed a complex size distribution, depending on the catalyst preparation conditions. However, in every case we can detect a large number of small (10–30 Å) particles partially coalescing into larger and irregular formations. Evidently, the metallic rhodium is responsible for the catalytic activity of all the catalysts based on ethylenediamine and polyethyleneimine.

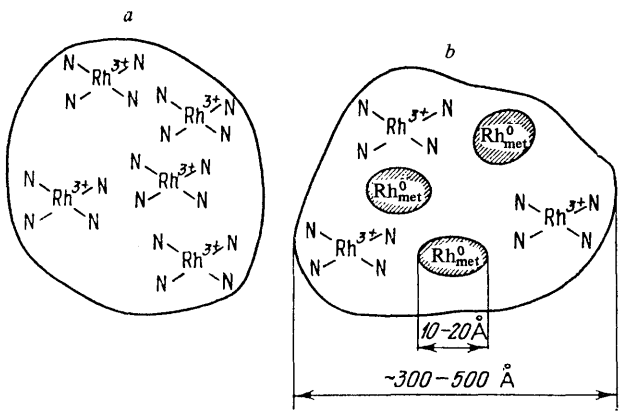

Figure 4. Structure of the Rh–PEI catalyst of composition Rh : N ≅ 1 : 4 (*a*) before and (*b*) after activation.

However, in the activated polyethyleneimine catalysts of composition Rh : N = 1 : 4 not all the rhodium ions are reduced to the metal. The reflection spectra of these catalysts in the u.v. and visible regions indicate the presence of large amounts of unchanged initial complexes of composition Rh : N = 1 : 4.[58] The XPS spectra also suggest that most of the rhodium on the sample surface is in the form of Rh^{3+} ions rather than of metal. A schematic model of the activated catalysts consistent with the results of various physicochemical methods of analysis is shown in Fig. 4. We note that the size of the finely divided metal particles in the polymer globule is strongly dependent on the catalyst activation conditions. Thus, an increase in the pH of the solution in which activation takes place causes a marked decrease in particle size.

The maximum rate (α) of hydrogen evolution (i.e. the rate in the region of maximum slope of the S-shaped kinetic curves) referred to 1 g-atom of added rhodium[59] was taken as the quantitative characteristic of the catalytic activity. Values of α for catalysts prepared by different methods are compared in Table 1. In the case of the most active catalysts

(Nos.7, 8, 11, 12) the tabulated value is not the parameter α but its lower limit. This is because reaction (3) had almost gone to completion when the first gas sample was taken for chromatographic analysis, and its rate could not be measured to better than a lower estimate.

Table 1. Catalytic activity (α, mole H_2 mole^{-1} Rh h^{-1}) of complexes of rhodium with polyamines towards the evolution of hydrogen from 1.5×10^{-2} M solutions of VSO_4 in water at 298 K (pH adjusted with H_2SO_4). [59]

No.	Initial form of catalyst	pH	$[V^{2+}]/[Rh^{3+}]$	α
1	$[Rh(en)_3](ClO_4)_3$ (Rh : N = 1 : 6)	0	30	<0.01

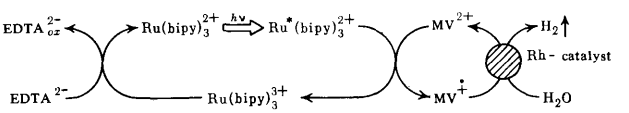
14	ditto	2	120	640*

*Catalytic granules ground to a powder of particle size less than 0.1 mm; initial size of the granules 2 mm.

It is clear from Table 1 that the catalysts prepared from complexes (with monomeric ligands) of composition Rh : N = 1 : 2 have an activity several orders higher than the complexes of composition Rh : N = 1 : 4 with the same ligands. The lower activity of the catalysts prepared from the latter complexes can be ascribed to the less complete conversion of the ionic forms of rhodium into highly dispersed metal particles. Thus the activation of the monomer complex of composition Rh : N = 1 : 2 is accompanied by a visible precipitation of metallic rhodium in the solution, whereas during the activation of the complexes of composition Rh : N = 1 : 4 the precipitation of metallic rhodium is undetectable.

The dependence of the catalytic activity α on the concentration of H^+ ions was studied [59] for monomer complexes of composition Rh : N = 1 : 4. We see from Table 2 that the parameter α for these catalysts increases monotonically with the concentration of H^+ in the solution where reaction (3) is taking place after activation of the catalyst. However, this increase in α is much slower than expected from the law of mass action for a reaction in which the H^+ ion appears in the rate-limiting step. Further work is needed to explain the observed dependence of α on $[H^+]$.

As in the case of the monomer complex, changing from a polymer complex with a ratio Rh : N = 1 : 4 to a polymer with Rh : N = 1 : 2 causes a large increase in catalytic activity. Again, as in the case of the monomer catalyst of composition Rh : N = 1 : 2, and for the same reason, we could only obtain a lower estimate of α for the polymers with Rh : N ≅ 1 : 2.



In the catalyst Rh—AN-221, consisting of granules of the AN-221 anion exchanger containing ~7% of rhodium (Rh : N = 1 : 3.4), we studied [59] the dependence of the rate of hydrogen evolution on the size of the granules and on the concentration of the catalyst and of the two reactants (H^+ and V^{2+}(aq) ions). At high enough rates of stirring of the solution, the rate of evolution of hydrogen was found to increase in proportion to the amount of catalyst (i.e. α was independent of the amount of catalyst). Thus the rate of hydrogen evolution is limited under these conditions by processes involving the catalyst, and not by mass transfer in solution or at the interface between the solution and the gas phase. However, we found a substantial increase in rate for a decrease in the particle size of the catalyst (for example, α = 8.7 for granules 2 mm in diameter and α = 640 for the same catalyst ground to a granule size of less than 0.1 mm, see Nos.13 and 14 in Table 1). This suggests rate limitation by mass transfer processes within the polymer granule rather than by the catalytic reaction.

A study [59] of the dependence of α on the concentration of V^{2+}(aq) showed an increase of α with $[V^{2+}(aq)]$ at low concentrations of V^{2+}(aq) (<5×10^{-3} M), but at higher concentrations (5×10^{-3}–2×10^{-2} M) α was independent of $[V^{2+}(aq)]$. It follows that at low concentrations of V^{2+}(aq) the process is limited by reactions involving these ions. On the other hand at high concentrations of V^{2+}(aq) the rate of this step is so high that the reaction is no longer rate-limiting. Thus the diffusion within the polymer particle of some other participant in the reaction (reactant, or product) becomes rate-limiting at these concentrations.

The dependence of α on the concentration of H^+ ions was studied only at low concentrations of V^{2+}(aq) in solutions of constant ionic strength (μ = 2 M) generated by additions of sodium sulphate: in this case the changes in α are described by the equation $\alpha \propto [H^+]^{0.2}$. The data were obtained by measuring α at different pH values for the same sample of catalyst previously activated at pH 2 and 298 K in a solution containing 10^{-2} M VSO_4 and a ratio of $[V^{2+}(aq)]/[Rh^{3+}] = 20$. Thus in this case the dependence of α on $[H^+]$ is weaker than expected from the law of mass action if the rate-limiting step involves H^+. As in the case of the monomer catalyst, further work is needed to explain the observed dependence of α on $[H^+]$ for this catalyst. However, we note that in this case the dependence could reflect the influence of H^+ ions on the structure of the polymer granule, which contains easily protonised nitrogen atoms.

It follows that at high concentrations of V^{2+}(aq) the rate of the catalytic process with rhodium catalysts in anion exchange resins is determined (most probably) by diffusion of the products of reaction (3) within the polymer granules, i.e. by the diffusion of V^{3+} cations up or of hydrogen molecules.

As expected, all these rhodium catalysts remain active when used in the classical photocatalytic system for hydrogen evolution from water with the *tris*-bipyridyl complex of ruthenium(II) (photocatalyst), methylviologen MV^{2+} (intermediate electron-transfer acceptor), and anions of ethylenediaminetetra-acetic acid $EDTA^{2-}$ (irreversibly consumed electron donor):

Throughout this review we shall use the symbol $EDTA^{2-}_{ox}$ to denote the products of irreversible oxidation of $EDTA^{2-}$.

Polymer rhodium catalysts (like other catalysts containing finely divided metals when activated) cause fairly rapid deactivation of this photocatalytic system, probably by hydrogenating the charge transfer agent MV^{2+}.

It is interesting to compare the activity of these catalysts in the evolution of hydrogen from aqueous solutions with the activity of the hydrogenase enzymes in the same reaction.

Published values of α for hydrogenase lie between 10^4 and 10^7 mole H_2 mole^{-1} of enzyme h^{-1},[48] i.e. they are much greater than the α values for catalysts based on rhodium polymer complexes. The difference becomes much smaller if we compare the α′ activities, i.e. the activities referred to unit mass of rhodium and of the enzyme (rather than to 1 mole of rhodium and of the enzyme). Thus for the more active catalysts based on an anion exchanger α′ can be as high as ~0.5 mole H_2 g^{-1} of catalyst h^{-1}, as compared with 0.2–200 mole H_2 g^{-1} of enzyme h^{-1} for hydrogenase[48].

While inferior to the best hydrogenases in catalytic activity per unit weight, the catalysts based on rhodium polymer complexes are superior in stability, especially in acid media (where hydrogenases are deactivated almost instantaneously). Furthermore, unlike hydrogenase, the activated catalysts based on anion exchangers and on PEI can be stored in air for long periods without significant loss of activity. We also note that the activity of rhodium polymer catalysts can be improved by eliminating (or decreasing) the diffusional limitations of the reaction.

Catalytic activity towards the evolution of hydrogen from water under the influence of one-electron reducing agents was observed also for the complexes of PEI with ruthenium[57], palladium, and platinum[60]. Thus catalysts for the evolution of hydrogen from water can be obtained by immobilising ions of other metals (not only rhodium) on PEI and reducing them to the metal. An important practical advantage of this type of catalyst for the future is their stability in aqueous solutions over a very wide range of pH, and their availability in the form of granules or films with controlled geometric characteristics.

2. Systems with Heteropoly Compounds

The heteropoly compounds have been identified as a potentially useful class for use in systems for evolution of hydrogen from water: as was pointed out above, they can be treated as models of the active centres in hydrogenases and nitrogenase. We know, for example, that highly reduced forms of heteropolyacids (HPA) of the 12-series have negative (or near-zero) electrochemical reduction potentials relative to the NHE, i.e. they satisfy the thermodynamic requirements for hydrogen evolution from acidic aqueous solutions. Thus the reduction potential E_0 for the acid $H_3[PMo_{12}O_{40}]$ (HPA-I) reduced by six electrons and for the acid $H_4[SiMo_{12}O_{40}]$ (HPA-II) reduced by four electrons is close to +0.1 V, whereas for the heteropolyacids reduced by two electrons $H_3[PW_{12}O_{40}]$ (HPA-III) and $H_4[SiW_{12}O_{40}]$ (HPA-IV) the E_0 values are close to 0 and −0.2 V respectively[61–63]. We have observed[64,65] spontaneous and relatively fast hydrogen evolution from acid solutions by these reduced forms of the heteropolyacids, without any auxiliary catalysts.

The reaction has been studied most fully for solutions of HPA-IV (silicotungstic acid),[64,66] whose structure is shown in Fig.5. It was found that HPA-IV reduced by two electrons on zinc amalgam (HPA.H_2) can evolve hydrogen rapidly from aqueous solutions in a yield of almost 100% of stoichiometric for the reaction

$$\mathrm{HPA\cdot H_2} \xrightarrow{k_{eff}} \mathrm{HPA\cdot H^{+1}/_2H_2\uparrow} \ . \qquad (4)$$

The kinetics of this process satisfy the scheme

$$\mathrm{HPA.H_2} \xrightarrow{k_1} \mathrm{HPA + H_2\ (slow\ H_2\ evolution)} \ , \qquad (4a)$$

$$\mathrm{HPA.H_2 + HPA \rightarrow 2HPA.H\ (fast\ disproportionation)} \ , \qquad (4b)$$

which corresponds to a first-order equation for the change in concentration of the reactants in the overall reaction. In this scheme HPA and HPA.H are, respectively, the initial (oxidised) form of the acid and the form reduced by two electrons (HPA-IV). The rate constant k_1, measured in three independent experiments from the disappearance of HPA.H_2 (monitored by an optical method) and from the accumulation of H_2 (monitored chromatographically) or of HPA.H (monitored by ESR), was found to be $k_1 = (3.5 \pm 2) \times 10^{-4}$ s^{-1}. (The k_1 value given here is a slight improvement over the previously reported value[64] $k_1 = k_{eff}/2 = (6 \pm 4) \times 10^{-4}$ s^{-1}.)

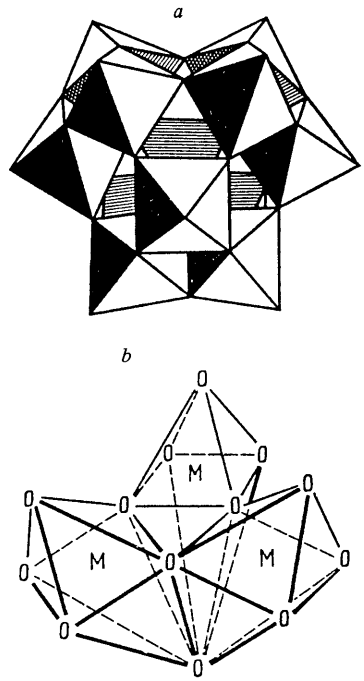


Figure 5. (*a*) Typical structure of heteropoly anions of the 12-series. The metal cations M are within the corner- and edge-sharing octahedra formed by the oxygen anions, the hetero-atom lies at the centre of the heteropoly anion; (*b*) configuration of the ions in a "triad" of adjacent octahedra.

The k_1 values obtained from the disappearance of HPA.H_2 and from the accumulation of H_2 are shown, as an example, in Fig.6. The fast disproportionation step (4b) is further confirmed by the lower yield of H_2 caused by the addition of the oxidised form to the solution, while the constant k_1 for the H_2 evolution process is unchanged.

It was found[66] that the hydrogen evolution rate constant k_1 is almost independent of pH in the range pH 1–4. This means that the protonation of the HPA forms reduced by one or two electrons cannot be rate-limiting, and we may assume that the step which controls the rate of evolution is the reduction of the strongly bound ("isolated") protons, previously observed[67] by NMR in the crystal hydrates of the reduced forms of some HPA, or the reduction of water molecules solvating the HPA.H_2 species. The mechanism of this reaction has not yet been fully investigated, but a number of significant features can already be pointed out. Thus we have found[66] a marked isotope effect, giving an almost two-fold decrease in reaction rate between ordinary water and

heavy water. The isotope effect confirms that the rate-limiting step of reaction (4) involves protons or water molecules. We also found that the reaction has a low activation energy $E^{\neq} = 6 \pm 3$ kcal mole^{-1} but a high and negative entropy of activation $\Delta S^{\neq} \cong -50$ e.u. The large value of $|\Delta S^{\neq}|$ can be explained, for example, by the complexity of the elementary act (reduction of internal protons with transfer of two electrons from the HPA.H_2 skeleton to two bound protons already in close proximity and ready to form an H_2 molecule). We also note that this reaction is markedly accelerated by visible (including red) light, which assists the transfer of electrons from the HPA.H_2 skeleton to protons or water molecules attached to the skeleton by exciting the inter-valency charge transfer levels of the reduced forms of HPA.[62,68]

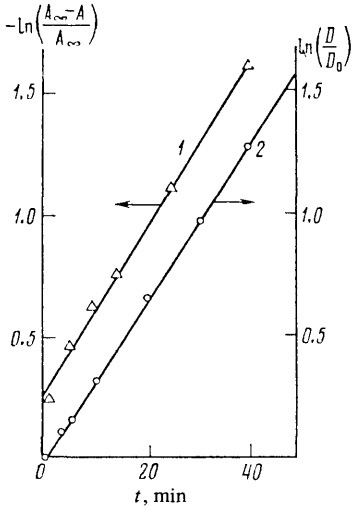

Figure 6. Kinetics of the hydrogen evolution (*1*) and of the disappearance of HPA.H_2 (*2*) in aqueous solutions of reduced 12-silicotungstic heteropolyacid (HPA-IV) at pH 2 and room temperature under anaerobic conditions: A is the height of the hydrogen peak in the chromatogram, A_∞ defines the total hydrogen evolution (initial concentration of heteropolyacid 2.2×10^{-3} M); D is the optical density of the solution at $\lambda = 650$ nm for an optical path 1 cm long, D_0 refers to the initial instant (initial concentration of heteropolyacid 5×10^{-4} M).

Hydrogen evolution has been observed also from aqueous-alcoholic solutions (0.1–10 M in alcohol) of phosphomolybdic acid reduced by six electrons (HPA-I), silicomolybdic acid reduced by four electrons (HPA-II), and phosphotungstic acid reduced by two electrons (HPA-III).[65] The rate constants ($k_1 \cong 10^{-4}$–10^{-3} s^{-1}) for all these HPA were close to the value $k_1 = (3.5 \pm 2) \times 10^{-4}$ s^{-1} given above for HPA-IV in aqueous solution. Hence we can assume that the evolution reaction has the same rate-limiting step for any highly reduced form of these heteropolyacids.

The ability of the reduced forms of HPA to evolve hydrogen from aqueous solutions, coupled with the well known tendency of HPA to be reduced by various types of reducing agents, suggest that HPA may act as homogeneous catalysts for the evolution of hydrogen from water by various reducing agents.

In fact, HPA-I and HPA-II catalyse the evolution of hydrogen from acidic aqueous solutions of several two-electron reducers, including relatively weak ones such as tin(II) ($E_0 = 0.15$ V relative to the NHE) or the sulphite ion SO_3^{2-} ($E_0 \cong 0.07$ V). We note that in the presence of these reducing agents the formation of highly reduced forms of HPA-I and HPA-II was not observed, and the rate of evolution of H_2 was much lower than the rate of evolution from highly reduced forms of HPA under otherwise similar conditions. Hence we may assume that the observed slow evolution of hydrogen (over tens of hours) is due either to the very weakly reduced forms of HPA-I and HPA-II themselves (for example, by the reaction HPA.H + HPA.H → 2HPA + H_2, which can go from left to right at low H_2 pressures) or to the disproportionation of these forms to give more highly reduced heteropolyacids, which can evolve hydrogen (as we shall show below) with fairly high rate constants.

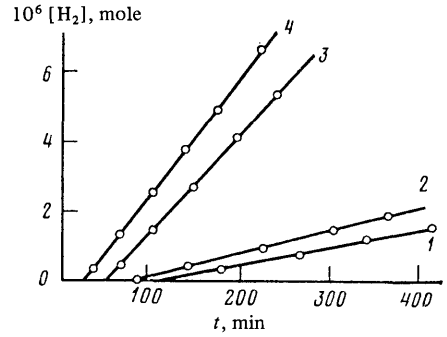

Figure 7. Kinetics of hydrogen evolution from 8 cm^3 of an 8.7 M solution of ethanol in water containing 0.25 M H_2SO_4 and: *1*) 1.3×10^{-4} M HPA-I, *2*) 10^{-4} M HPA-II, *3*) 5×10^{-4} M HPA-III, *4*) 4×10^{-4} M HPV-IV, irradiated with filtered u.v. light ($\lambda < 400$ nm) from a DRSh-1000 lamp.[65]

Heteropolyacids can also act as photocatalysts and bring about (under the influence of light) endoergic ($\Delta G > 0$) reactions in which hydrogen is evolved from water as a result of the irreversible removal of donors. Thus we have observed[65] hydrogen evolution by irradiation of oxidised forms of heteropolyacids in aqueous-ethanolic (0.1–10 M in alcohol) solutions at pH 1–4 with near u.v. light. Typical kinetic curves for this process are shown in Fig.7. We note that hydrogen evolution begins after a period of induction, and then proceeds at a constant rate. The rate of evolution stays constant even after lengthy irradiation, when the number of moles of H_2 evolved is much greater than the number of moles of HPA present in the irradiated solution.

Thus the hydrogen evolution process is truly catalytic. From the absorption spectra in the visible and u.v. regions and from fast redox titrations with $KMnO_4$ solutions we find that under the influence of light of wave length $\lambda \leq 400$ nm, HPA-I is reduced by two, four, and six electrons successively during the induction period, HPA-II by two and four electrons, and HPA-III and HPA-IV by one and two electrons. The quantum yield of the formation of reduced forms of HPA in the initial portions of the kinetic curves of Fig.7 (at $\lambda = 333$ nm) is several per cent for HPA-I and HPA-II and ~20% for HPA-III and HPA-IV.[65,69] Hence the induction

period of the H_2 evolution kinetic curves seems to be related to the accumulation of forms of HPA which are reduced sufficiently to evolve hydrogen spontaneously from acid aqueous-ethanolic solutions. These reduced forms of HPA are produced by the oxidation of ethanol. The detection[65] of acetaldehyde (in a proportion of 1 : 1 with the evolved hydrogen) after the photocatalytic reaction is consistent with this conclusion.

A decrease by a large factor in the intensity of u.v. light causes a substantial increase in the period of induction, though the rate of evolution of H_2 on the linear part of the curve is only marginally affected. The generation of hydrogen continues even after the light is switched off: we observe only a gradual slowing down as the reduced form of the HPA is used up[65].

For aqueous-ethanolic solutions of silicotungstic acid (HPA-IV) a rate constant of $k_1 \cong 5 \times 10^{-4}$ s^{-1} was calculated for the evolution of hydrogen on the stationary part of the accumulation curve (Fig.7). The constant was defined as the ratio of the rate of evolution of H_2 to the steady-state concentration of the two-electron reduced form HPA.H_2 of this heteropolyacid (see above).

These facts suggest the following overall scheme (for HPA-III and HPA-IV, say) to describe the photocatalytic evolution of H_2 from aqueous-ethanolic solutions of the oxidised forms of heteropolyacids:

$$C_2H_5OH + HPA \xrightarrow{h\nu} CH_3CHO + HPA \cdot H_2 \qquad (5a)$$

$$HPA \cdot H_2 \longrightarrow HPA + H_2\uparrow \cdot \qquad (5b)$$

The rate-limiting step is reaction (5b), which takes place spontaneously even in the absence of light but (as was pointed out above) can be accelerated by irradiation with visible light of wavelength corresponding to the intervalency charge transfer absorption band. Unlike reaction (5b), reaction (5a) proceeds only under irradiation. It is almost certainly a complex reaction, i.e. a reaction consisting of several steps[69]. Further work is needed to clarify the relative roles of two-electron processes

$$C_2H_5OH + HPA \xrightarrow{h\nu} CH_3CHO + HPA \cdot H_2$$

and of one-electron processes

$$C_2H_5OH + HPA \xrightarrow{h\nu} CH_3\dot{C}HOH + HPA{\cdot}H$$

$$C_2H_5OH + HPA{\cdot}H \xrightarrow{h\nu} CH_3\dot{C}HOH + HPA \cdot H_2$$

$$CH_3\dot{C}HOH + HPA \rightarrow CH_3CHO + HPA{\cdot}H$$

$$CH_3\dot{C}HOH + HPA{\cdot}H \rightarrow CH_3CHO + HPA{\cdot}H_2,\ HPA + HPA{\cdot}H_2 \rightleftarrows 2HPA{\cdot}H$$

in reaction (5a).

Thus in this photochemical process the heteropolyacids take part in cyclic reactions including steps in which the HPA are reduced by two or more electrons, followed by hydrogen evolution by the reduced forms of HPA and by regeneration of the initial (oxidised) forms. Under these conditions the HPA performs two functions at the same time: that of a photo-catalyst and that of a catalyst for the "dark" H_2 evolution reaction. The photo-catalytic hydrogen evolution

$$C_2H_5OH \xrightarrow[PC]{h\nu} CH_3CHO + H_2\uparrow$$

in this system is an endoergic process, leading to a small (~0.2 eV) acquisition of energy from the light at each act of evolution of molecular H_2.

III. EVOLUTION OF OXYGEN FROM WATER

This step is much more difficult than the hydrogen evolution to carry out in practice, because reaction (2) requires the transfer of four electrons, and furthermore conditions leading to the formation of the product molecule (oxygen) in the triplet rather than the singlet state must be provided. A systematic search for catalysts for reaction (2) has only recently been started. We have examined[70–73] a series of homogeneous metal complex catalysts for reaction (2), using the compounds $Ru(bipy)_3^{3+}$, $Fe(bipy)_3^{3+}$, and $Fe(phen)_3^{3+}$ as the oxidiser D^+. Some of these catalysts allow oxygen evolution from water not only in alkaline or neutral solutions but also in weakly acid solutions (down to pH 5). The series of homogeneous catalysts for the oxygen evolution step was also reported from another laboratory almost simultaneously[74–77]. Many heterogeneous catalysts for this step have also been discovered[21,52,75–87]: for example, the oxides of ruthenium, platinum, iridium, cobalt, and manganese.

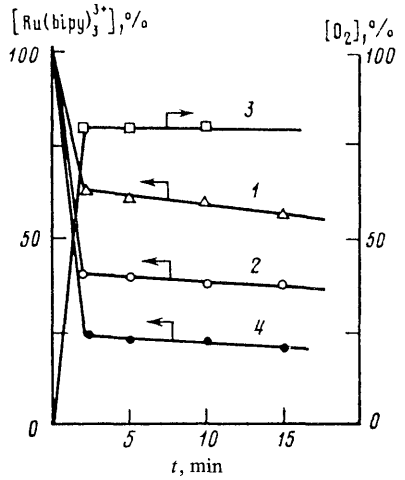

Figure 8. Kinetics of the reduction of the oxidiser and of the formation of oxygen during fast adjustment to a more alkaline pH of 8×10^{-4} M solutions of $Ru(bipy)_3^{3+}$ in 0.01 *N* HCl: *1*) and *4*) adjusted to a final pH of 3.5 and 6 respectively in the absence of the catalyst, *2*) and *3*) adjusted to a final pH of 3.5 in the presence of the catalyst (5×10^{-5} M $CoCl_2$), temperature 298 K. The stoichiometry of the oxygen evolution was calculated with respect to the reduced fraction of the oxidiser[73].

1. Systems with Homogeneous Catalysts Based on Transition Metal Complexes

We have studied two classes of compounds which act as homogeneous catalysts for reaction (2): 1) the partially hydrolysable (or aquated) complexes of various transition metals with nitrogen- or oxygen-containing ligands[70,71,73] (see also Ref. 76), and 2) water-soluble phthalocyanines and porphyrins of various metals[72]. Catalysts of the first type are the more effective, the highest activity (up to one molecule of O_2 per metal atom in the catalyst per minute at 20 °C) being found in the iron, cobalt, and copper complexes, but they are less stable than the catalysts of the second type.

It has been reported[75–77,79,84] that compounds of the first type have a high catalytic activity not only for the "dark" evolution of oxygen from water but also in model photo-catalytic systems, in which the evolution of oxygen from water is coupled with the irreversible reduction of an electron acceptor.

The study of the mechanisms by which the homogeneous catalysts contribute to reaction (2) is still in progress, but some important features of their mode of action have already been established. We should stress first of all the experimental difficulties encountered in the study of reaction (2). When complexes with bipy or phen are used as the oxidiser D^+ the reaction is very sensitive to effects of the wall of the vessel. For example, in glass reactors oxygen is sometimes evolved by reaction (2) even in the absence of special catalysts, the amount of oxygen evolved depending on the composition of the glass and on the presence of rough areas or micro-cracks on its surface. The requirement of wall inertness is most fully met by polyethylene vessels.

Another difficulty in the study of the mechanism of action of these catalysts in reaction (2) is the lack of sufficiently fast methods of recording the kinetics of oxygen evolution. The characteristic times of the fast step in reaction (2) in the presence of the catalyst and after pH adjustment to the required alkalinity are usually a few seconds (see below, and Fig.8). However, the time constant of the fastest instrumental methods of detecting oxygen directly in solution (by using a Clark electrode) is 20–30 s. Therefore the most informative data on the kinetics of oxygen evolution (i.e. directly from the activity of the catalyst) are not available to us at the moment. The effectivness of the catalyst can only be characterised by the ratio of the amount of oxygen evolved to the amount expected from stoichiometry considerations. This ratio (β), expressed in per cent, will be termed the effectiveness of the catalyst.

It is found that 100% effectivness is only very rarely achieved in a catalyst: a much lower β value is usually obtained. This is probably due to the partial loss of oxidiser (D^+) by fast oxidation side-reactions involving the ligands (which enter into the composition of both the oxidisers and the catalysts). We note that side reactions in the absence of the catalyst can cause substantial reduction of D^+ in less than 10 s (~40% in acid solutions and ~90–95% in alkaline solutions, see below and Fig.8): no oxygen is evolved in this case. Thus the role of the catalyst in reaction (2) is to guide the reduction of D^+ towards the evolution of oxygen rather than towards the oxidation of the ligands.

In the presence of catalysts, after adding alkali to obtain the required pH to the acid (pH 1–2) solutions containing the initial reagents (oxidiser and catalyst) as in the experiments[70–72] on the initiation of the oxygen evolution, only a part of the oxidiser is consumed in the fast (a few seconds) oxygen evolution and ligand oxidation processes (see Fig.8). The unused oxidiser D^+ is reduced more slowly, in times of the order of tens of minutes. With some (but not all) catalysts this slow reduction of the oxidiser is accompanied by evolution of oxygen from the water by reaction (2).

The loss of oxidiser in the fast step of the process is strongly dependent on the pH of the solution. Thus if alkali is added to give pH 3 approximately one-half of the oxidiser is usually reduced rapidly; at pH 9 this loss amounts to 80–90%.

It is interesting to find that the effectiveness β measured at pH 3 for most of the homogeneous catalysts under the most favourable conditions and referred to the amount of oxidiser reduced in the fast reactions does not vary over a wide range (see Table 2). We should also note the complex behaviour of some of these homogeneous catalysts in solutions with different pH. Thus, whereas at pH 3 all the cobalt complexes have approximately the same effectiveness as catalysts when $Ru(bipy)_3^{3+}$ is used as the oxidiser (see Table 2), in solutions of pH 9–10 they can be arranged in the following series of increasing effectiveness:

$$\underset{\beta,\ \%}{\text{Catalyst}}\ \underset{10}{Co(NH_3)_6^{3+}} < \underset{39}{Co(NH_3)_5Cl^{2+}} < \underset{42}{Co(NH_3)_5(H_2O)^{3+}} < \underset{60}{Co^{2+}(aq)} < \underset{66}{Co(NH_3)_4(H_2O)_2^{3+}} < \underset{70}{Co(bipy)_{3-x}(H_2O)_x^{3+}}$$

This series probably reflects the role of the coordination of water molecules or hydroxyl ions to the catalyst molecules in the evolution of oxygen molecules under these conditions.

Table 2. Consumption of oxidiser (Q) in the fast step of the water oxidation process and effectiveness β of various homogeneous catalysts in an 8×10^{-4} M solution of $Ru(bipy)_3^{3+}$ after pH adjustment to pH 3.0–3.2 at 298 K (c is the concentration of catalyst) [73].

$10^4 c$, M	Q, %	β, %	$10^4 c$, M	Q, %	β, %
0	40	0	$[Co(NH_3)_5(H_2O)]Cl_3$		
$CoCl_2$			0.9	30	45
0.5	60	85	8.3	55	85
2.2	55	75	30.0	55	85
4.3	30	65	$[Co(NH_3)_4(H_2O)_2]Cl_3$		
6.4	20	27	2.0	50	70
Cis- and *trans*-$[Co(en)_2Cl_2]Cl$, *trans*-$[Co(en)_2Cl(H_2O)]Cl_2$			20.0	40	70

2.2	60	75	0.07	55	70
8.3	60	75	0.22	60	60
20.0	45	70	0.64	65	40
$[Co(NH_3)_5Cl]Cl_2$			$[(bipy)_2FeOFe(bipy)_2]Cl_4$		
5.0	50	80	0.25	60	85
10.0	50	80	1.0	60	85
			10.0	50	90

Note. The precision of the determination of Q and β is ±5%.

The complexity of the homogeneous catalysis process combining the above catalysts with *tris*-bipyridyl and *tris*-phenanthroline complexes as oxidisers is confirmed by the strong dependence of β on the experimental conditions, in particular the pH and the storage time of the solutions before the reaction, and also on the procedure used in mixing the reagents (for example, whether the catalyst is added to the acid solution of oxidiser before adding alkali, or whether the catalyst is added in an already alkaline solution to an acid solution of the oxidiser). Evidently these results can be explained by postulating hydrolysis processes in the activation of the catalyst: of course, both the rate and the direction of these processes can be expected to depend on the pH of the medium.

The role of hydrolysis in the conversion of the initial complexes into catalytically active compounds has been demonstrated for systems containing the complexes $Fe_m(bipy)_n \cdot (OH)_p^{(3m-p)+}$ or $Fe_m(phen)_n(OH)_p^{(3m-p)+}$ at pH > 4 as catalysts[70]. It was shown that the bipyridyl and phenanthroline complexes of iron(III) containing OH^- ions as ligands are much more effective catalysts than the same complexes without the OH^- ligands. By comparing the data on the

effectiveness of these complexes with the data on their hydrolysis mechanism we conclude that in some of our systems the catalytically active intermediates are binuclear di-μ-hydroxo $\left(M\begin{smallmatrix}OH\\OH\end{smallmatrix}M\right)$ or di-μ-oxo $\left(M\begin{smallmatrix}O\\O\end{smallmatrix}M\right)$ structures (where M is a metal).

Evidently, the oxygen evolution reaction begins with a series of four consecutive one-electron reactions in which the catalyst is oxidised by D^+ particles, and each metal ion in the binuclear catalyst can give up two electrons to the oxidisers. The subsequent reactions (oxygen evolution and regeneration of the active forms of the catalyst) proceed without the formation of free (non-coordinated) forms of intermediates in the oxidation of water such as ·OH radicals and also, at least for some of the present catalysts, H_2O_2 molecules and $H\dot{O}_2$ radicals[70]. For example, the catalytic action of partially hydrolysed bipyridyl complexes of iron(III) can be interpreted by the following alternative schemes:

$$M\begin{smallmatrix}OH\\OH\end{smallmatrix}M + 2D^+ \rightarrow M\begin{smallmatrix}O\\O\end{smallmatrix}M + 2H^+ + 2D$$

$$M\begin{smallmatrix}O\\O\end{smallmatrix}M + 2D^+ \xrightarrow{2H_2O} M\begin{smallmatrix}OH\\OH\end{smallmatrix}M + 2H^+ + 2D + O_2\uparrow \qquad (6)$$

or

$$M\begin{smallmatrix}OH\\OH\end{smallmatrix}M + 2D^+ \xrightarrow{2H_2O} M_2(H_2O)_2 \text{ (or } 2M(H_2O)) + 2H^+ + 2D + O_2\uparrow \qquad (7)$$

$$M_2(H_2O)_2 \text{ (or } 2M(H_2O)) + 2D^+ \rightarrow M\begin{smallmatrix}OH\\OH\end{smallmatrix}M + 2H^+ + 2D$$

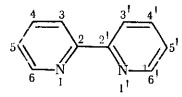
For the catalysts in which M = Fe(III) or Co(III) the evolution of molecular oxygen from an oxidised $M\begin{smallmatrix}OH\\OH\end{smallmatrix}M$ centre can take place through the formation and dissociation of a binuclear μ-peroxo complex

$$M - O_2^{2-} - M \rightleftarrows 2M^- + O_2\uparrow$$

or a mononuclear peroxo complex

$$M - O_2^- \rightleftarrows M - O_2 \rightleftarrows M^- + O_2\uparrow$$

as intermediates. These reversible oxygenation reactions of cobalt(II) and iron(II) complexes in alkaline solutions are well known (see, for example, Refs.88–91).



Among the catalysts of the second type the most effective (β ≅ 70%) are the tetrasulphophthalocyanine and tetrasulphophenylporphin of cobalt(II).[72] If $Ru(bipy)_3^{3+}$ is used as the oxidiser D^+ the effectiveness of the tetrasulphophthalocyanines of various metals at pH 9 can be arranged in the following sequence:

Metals	Co(II)	> Fe(II)	> Zn II	> Cu(II)	> Ni(II)	> Mn(II)	> Cr(II)
β, %	65	47	25	21	18	14	5

Metal-free phthalocyanines do not show a significant catalytic activity. The mechanism of the action of these catalysts is still unclear. We can note, nevertheless, that the catalytic activity of metal phthalocyanines is not produced by dissociation with formation of aquo-complexes of the metal ions. Thus, at ~10^{-5} M concentration the aquo-ions of Cr(III), Mn(II), Bi(II), and Al(III) have no catalytic activity towards the oxidation of water by oxidisers of the $Ru(bipy)_3^{3+}$ type, whereas the phthalocyanines of the same metals at the same concentration have a marked catalytic activity[72]. We should also stress that in very acid solutions (in which the reaction (2) is suppressed) some of these metal phthalocyanines undergo a fast and quantitative two-electron oxidation accompanied by one-electron reduction of the oxidiser $Ru(bipy)_3^{3+}$. It is at least possible that in more alkaline solutions these doubly oxidised forms of metal phthalocyanines take part (as intermediates) in the oxygen evolution reaction.

An interesting feature of these catalysts, providing additional evidence of the complexity of the catalytic reaction (2), is the presence at pH > 4 of clear maxima in the plots of the effectiveness of the catalyst against concentration. For example, at pH 9 the optimum concentration for catalysts of the first group is ~10^{-4} M, and for catalysts of the second group ~10^{-5} M. The existence of optimum concentrations of the homogeneous catalysts is noted also for the evolution of oxygen at pH 3 (see Table 2), but in this case the dependence of β on the concentration of the catalyst is usually monotonic, without extrema.

The possibility that the role of the oxidisers D^+ in reaction (2) goes beyond the transfer of an electron from the catalyst to the oxidiser cannot be excluded. Indeed, the addition of anions (chloride, perchlorate, sulphate, carbonate, acetate, borate, etc.) as sodium salts partially suppresses both the evolution of oxygen in reaction (2) and the secondary reduction of D^+ by the oxidation of the ligands (even in the absence of catalysts). However, the catalyst effectiveness β calculated from the amount of oxidiser D^+ which is reduced does not vary significantly under these conditions. We are therefore forced to the conclusion that reaction (2) and the secondary reaction share a number of steps which are affected by the interaction between the particular oxidised (D^+) used in these experiments and the anions, but are unaffected by the catalyst. Thus, in the proton magnetic resonance spectra of the complex $Ru(bipy)_3^{3+}$ a strong chemical shift of the signals from the 6 and 6′ protons of bipyridyl

is observed after addition of various anions (see Fig.9), due no doubt to the out-of-sphere coordination of the anions to the bipyridyl ligand. This anion coordination may also suppress some other interaction of the oxidiser with water molecules (or their ionic forms) playing an as yet unrecognised role in both reaction (2) and the secondary process. Work on these effects is in progress.

At the same time the inner-sphere coordination of water to the cation of the oxidiser by replacing even one of the coordinating nitrogen atoms of the ligands does not appear to be an intermediate step of reaction (2). Thus we have shown[73] that the mixed complexes of ruthenium(III) $[Ru(bipy)_2(Py)_2]^{3+}$ (where Py is pyridine), in which the replacement of the ligands probably occurs at different rates and with different equilibrium constants than for the *tris*-bipyridyl complex, can evolve oxygen from water with the same effectiveness as $Ru(bipy)_3^{3+}$ when used as the oxidiser D^+ in the presence of homogeneous catalysts[73]. However, in the complexes $[Ru(bipy)_2.(Py)(H_2O)]^{3+}$, which contain water in the first coordination sphere, this property is not found because their oxidation potential is too low. We note that the even more highly hydrolysed form of this complex $[RuO(bipy)_2]^{2+}$, though itself unable to oxidise water, is nevertheless an effective homogeneous catalyst for the oxidation of water when $Ru(bipy)_3^{3+}$ is used as the oxidiser D^+ [73] (see also Refs. 92 and 93).

We may hope that work now in progress on the mechanism of the homogeneous catalysis of reaction (2) by using $Ru(bipy)_3^{3+}$ as the oxidiser will lead to the development of effective and stable catalysts for the oxygen evolution step, able to operate in a closed water decomposition cycle using the $Ru(bipy)_3^{2+}$ comples as the photocatalyst for step (1).

2. Systems with Heterogeneous Catalysts Based on the Hydroxides and Mixed Oxides of the Transition Metals

The search for and study of potential heterogeneous (as well as homogeneous) catalysts for reaction (2) is an important current problem. As was mentioned above, these catalysts are being studied in a number of laboratories, the materials in most cases being simple oxides. We have examined[94] the possibility of using another class of compounds as heterogeneous catalysts of reaction (2): base metal hydroxides and spinels, which are mixed oxides of general formula $M^{II}M^{III}_2O_4$ (where M^{II} and M^{III} are bivalent and a tervalent metal respectively). Spinels of various compositions are widely used as oxidation catalysts and as anodes for the electrochemical evolution of oxygen[95].

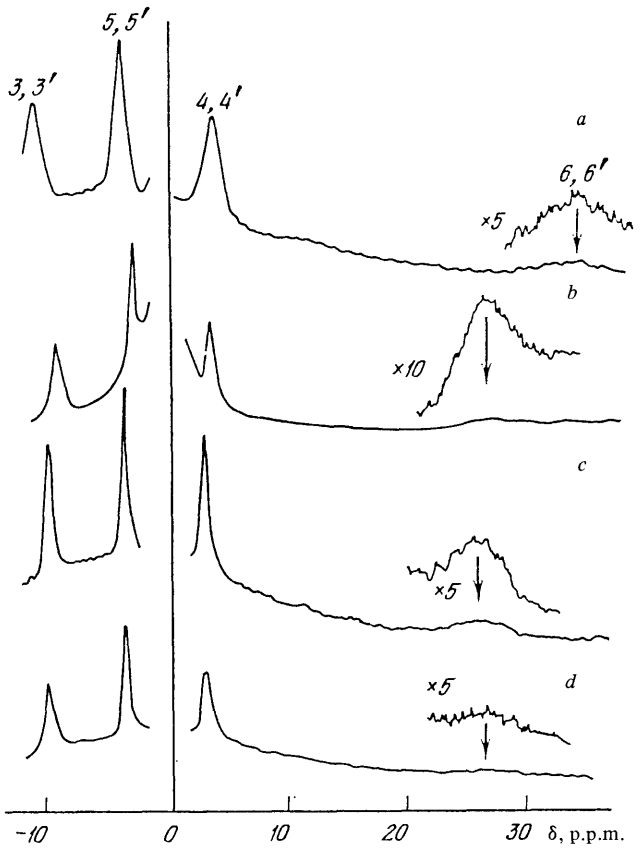


Figure 9. NMR spectra ("Bruker CXP-300" Fourier spectrometer, frequency 300 MHz) of a 10^{-3} M solution of $Ru(bipy)^{3+}_3$ in D_2O containing also: (*a*) 0.01 M DCl, (*b*) 1 M DCl, (*c*) 1 M NaCl, (*d*) 1 M Na_2SO_4; temperature 293 K, 200 spectral scans. The chemical shifts are measured relative to the signals of the water protons. The peaks are numbered according to the position of the protons in 2,2′-bipyridyl.

Measurements of the effectiveness β of heterogeneous catalysts (hydroxides and spinels) used in conjunction with *tris*-bipyridyl complexes of ruthenium(III) and iron(III) as the oxidiser D^+ are summarised in Table 3. As in the study of the homogeneous catalysts, the amount of oxygen evolved was determined after adding a 0.1 *N* solution of NaOH to weakly acid (pH ~ 2, spinels) or to neutral solutions (hydroxides) of the oxidiser containing the catalyst. The weight of catalyst added was 20 mg for 10 ml of solution; no oxygen was evolved unless the solution was made alkaline.

We should stress that spinels prepared by standard methods may contain various impurities such as the salts used in their preparation or oxides or hydroxides foreign to the spinel. Most of these impurities are removed by steeping the spinel in a weakly acid solution, but this treatment transfers to the solution metal ions which can act (as stated above) as homogeneous catalysts for reaction (2) even at very low concentrations (10^{-4}–10^{-5} M). Therefore all the spinel samples were finely ground before the determination of β and washed repeatedly with 0.1 *N* hydrochloric acid until free from metal ions, thus ensuring the absence of effects from homogeneous side-reaction on the measurements.

Table 3. Effectiveness β of heterogeneous catalysts in 8×10^{-4} M solutions of $Ru(bipy)^{3+}_3$ and $Fe(bipy)^{3+}_3$ at 298 K.

Catalyst	β %	Catalyst	β %
Oxidiser $Fe(bipy)_3^{3+}$		Oxidiser $Ru(bipy)_3^{3+}$	
$NiCo_2O_4 \cdot Co_2O_4$	70	$CoFe_2O_4$	60
$CuCr_2O_4 \cdot CoCr_2O_4$	50	$CoFe_2O_4$*	60
$CoFe_2O_4$	40	$CoFe_2O_4$**	17
$FeCr_2O_4$	40	$Co^{II}Co_2^{III}O_4$	35
$Co^{II}Co_2^{III}O_4$	37	$Cr_2(OH)_3$	60
$CoCr_2O_4$	35	$Cu(OH)_2$	45
		$Fe(OH)_3$	40
		$Co(OH)_3$	25
		$Ni(OH)_3$	20
		$Al(OH)_3$	0

*pH 5–6; **pH 3–4, otherwise pH 10–11.

Note. The precision of the measurement of β is ±5%. The catalyst was ground to a powder of particle size less than 0.05 mm and was taken in amounts of 20 mg per 10 cm^3 of solution.

The catalytic activity of the iron(III) and cobalt(III) hydroxides in reaction (2) is mentioned also in Ref.76.

The heterogeneous catalysts studied in our laboratory are similar to the homogeneous catalysts in effectiveness (see Tables 2 and 3), but their stability is much higher. In addition to the substances listed in Table 3, zinc and copper ferrites and iron and copper cobaltites have been found to be catalytically active in reaction (2).

It would be premature to attempt a discussion of the mechanism of the oxidation of water by reaction (2) in the presence of spinels. In particular, the effect of the spinel structure and of the nature of the bivalent and tervalent metal cations is still unclear. It is obvious, however, that surface compounds containing water or its fragments must play an important part in reaction (2). In contact with water the spinel surface may become rapdily hydroxylated, so that the catalytically active centres are not the spinels themselves but compounds not very different from the hydroxides of the corresponding metals. In this case we would expect the formation on the catalyst surface of bridging compounds similar to the complexes proposed for reactions (6) and (7).

IV. PHOTOCHEMICAL CHARGE SEPARATION

The lack of effective methods of realising reaction (2) in practice is the most serious obstacle to the development of molecular photocatalytic systems for the decomposition of water in a closed cycle (i.e. a cycle in which no substance is consumed irreversibly except water). The main problem is to suppress the reverse recombination reaction $D^+ + A^- \rightarrow D + A$, which is a simple exothermic process and therefore usually much faster than the complex catalytic reactions (2) and (3).

Several possible ways of suppressing the reverse reaction are being studied in our laboratory at present. Two of these will be discussed below: one based on the use of lipid vesicles, the other on micro-emulsions.

1. Charge Separation in Solutions of Lipid Vesicles

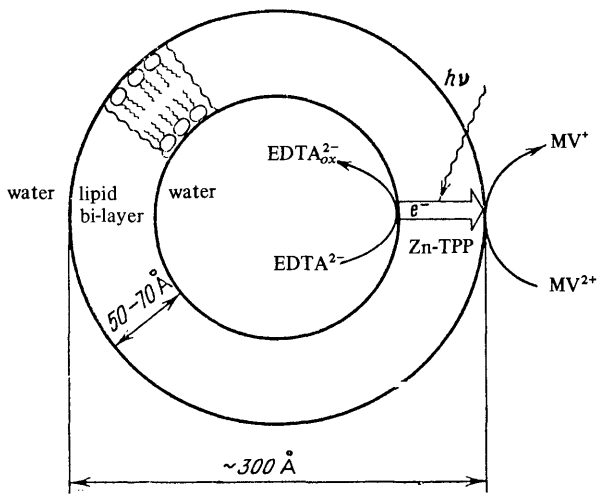

Figure 10. Scheme of the photo-transfer of an electron through the membranes of lipid vesicles containing Zn-TPP as photocatalyst.

The vesicles, whose structure is shown schematically in Fig.10, consist of a shell formed by a two-layer lipid membrane. The vesicles described below were prepared by using either the natural lipid lecithin or the synthetic lipid dipalmitoylphosphatidylcholine (DPPC). The inner cavity of the vesicles was filled with an aqueous solution of electron donors (the sodium salt of ethylenediaminetetra-acetic acid, Na-EDTA, or nicotinamide dinucleotide, NADN), whereas the outer volume contained an electron acceptor (methylviologen, MV^{2+}). It has been convincingly shown[81,96–99] that irradiation of solutions of vesicles containing photo-catalysts in the membrane can produce electron transfer across the membrane, leading to the formation of D^+ and A^- species which are prevented from recombining by being on opposite sides of the membrane. The photocatalysts used in these experiments had long hydrophobic groups: chlorophyll[97,100], or surface-active derivatives of zinc porphyrin[98] or of the *tris*-bipyridyl ruthenium complex[81,96,99]. The photo-catalyst used in our work was much simpler, and did not contain long hydrophobic groups: zinc tetraphenylporphin (Zn-TPP).[101–104]

Irradiation of a solution of vesicles with light of wavelength corresponding to the Soret band of Zn-TPP ($\lambda \cong 425$ nm) or to its long-wave absorption bands ($\lambda > 500$ nm) causes photo-transfer of electrons from the donor particles within the vesicle to acceptor particles outside it (see Fig.11), the metallo porphyrin contributing repeatedly to the cycle in which MV^{2+} is reduced by the electron donors and thus behaving as a true photocatalyst[101]. The quantum yield of the reduction of MV^{2+} in the natural lecithin system irradiation with focussed filtered light from a DKSSh-1000 lamp in the region of the Soret band or of the long-wave absorption bands was 0.01 to 0.1%, the highest observed quantum yield (for light in the long-wavelength absorption band region) being 0.15 ± 0.04%.[104]

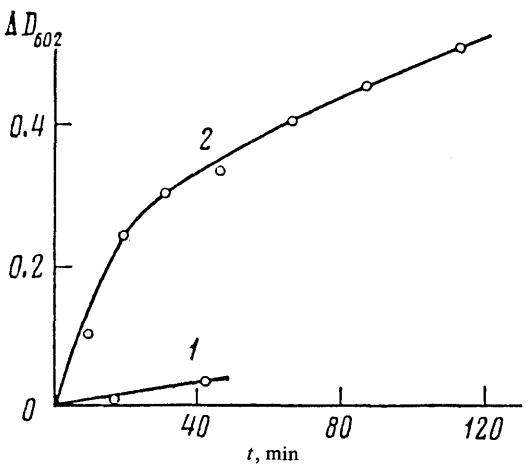

Figure 11. Change in optical density at $\lambda = 602$ nm due to the accumulation of MV^+ during irradiation by light with $\lambda > 500$ nm (from a DRSh-1000 lamp) of a solution of egg lecithin vesicles containing Zn-TPP: curve *1* was obtained in the absence of electron donors, curve *2* in the presence of 0.2 M Na_2-EDTA inside the vesicles[101]. The concentration of lecithin, Zn-TPP, and MV^{2+} are (respectively) 2.4×10^{-3} g cm^{-3}, 6×10^{-5} M, and 2×10^{-2} M; temperature 298 K. When a synthetic lipid was used the accumulation of MV^+ in the absence of Na_2-EDTA was negligible.

The observation of electron photo-transfer across a membrane by light of wavelength corresponding to the long-wave absorption bands, i.e. under the influence of quanta able to excit only the first singlet level of Zn-TPP, is evidence of the important part played by the lower excited states of Zn-TPP in the electron photo-transfer process.

In the flash photolysis of a solution of vesicles containing only Zn-TPP but no electron donors or acceptors the transient optical spectrum shows an absorption assigned to the triplet electronically excited state of porphyrin ($Zn\text{-}TPP^T$) and to the porphyrin cation radical ($Zn\text{-}TPP^+$). The very fast deactivation of the triplet states is probably caused by the annihilation reaction

$$2Zn\text{-}TPP^T \longrightarrow 2Zn\text{-}TPP + \Delta E \qquad (8)$$

The rate of this process is much higher in the vesicle solution than in a homogeneous solution containing the same total amount of porphyrin because of the high local concentration of porphyrin in the lipid bi-layer (up to 2.5×10^{-2} M, i.e. well in excess of the average concentration). The cation radical Zn-TPP^{+} may also be produced by the annihilation of triplet states:

$$2\text{Zn-TPP}^{T} \rightarrow \text{Zn-TPP}^{+} + \text{Zn-TPP}^{-} \quad (9)$$

Unfortunately we were unable to detect the anion radical Zn-TPP^{-} directly because of the strong absorption of the triplet states in the region of the characteristic absorption lines of Zn-TPP^{-}.

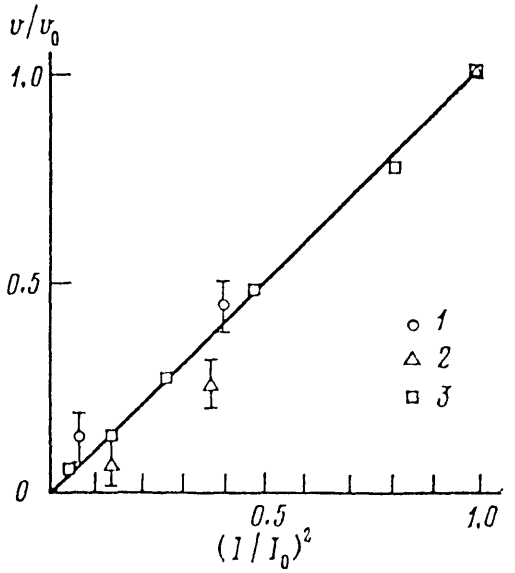

Figure 12. Initial rate (v) of accumulation of MV^{+} in a solution of lipid vesicles against the intensity (I) of exciting light for irradiation in the region of the Soret band (*1*, *3*) and of the long-wave absorption bands (*2*) of zinc porphin: *1*) and *2*) refer to vesicles of natural lecithin, under the conditions stated in Fig.11, *3*) refers to vesicles of synthetic DPPC, with concentrations of DPPC and MV^{2+} of 5×10^{-3} g cm^{-3} and 0.1 M respectively, [Zn-TPP] : : [DPPC] = 1 : 50, other conditions as in Fig.11;[101,102] v_0 is the initial rate of accumulation of MV^{+} for a light intensity I_0.

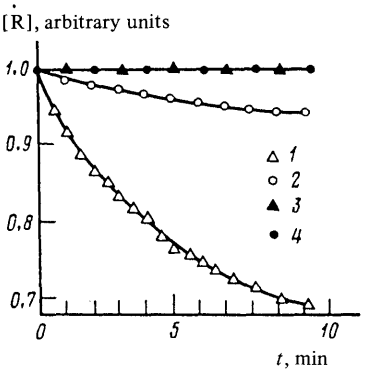
When MV^{2+} is present outside the vesicles a strong and long-lived absorption due to the cation radicals MV^{+} and Zn-TPP^{+} is observed immediately after the flash. The disappearance (by recombination) of these products of the flash photolysis takes place in parallel, and is described by a second-order equation with rate constant $k = (1.9 \pm 0.2) \times 10^{8}$ litre mole^{-1} s^{-1}. In this way the concentrations of MV^{+} and Zn-TPP^{+} immediately after a flash $\leq 10^{-5}$ s long are about one-quarter of the concentration of Zn-TPP in the sample, i.e. they are much higher than the concentration of Zn-TPP^{+} observed immediately after the same flash but in the absence of MV^{2+}. The large amount of MV^{+} formed and its disappearance by a second-order reaction (i.e. by interaction with extraneous cation radicals rather than with the cation radicals of the matrix Zn-TPP^{+}) suggest that both the formation of MV^{+} and its migration from the reaction cage after the electron photo-transfer act have a high probability.

The presence of EDTA^{2-} as the sodium salt inside the vesicle has no effect on the flash photolysis of vesicles containing Zn-TPP, both in the presence and in the absence of MV^{2+} in the outer solution.

The one-quantum[81,96,97] and the two-quantum[98] mechanisms for the activation of photo-transfer through the membranes of lipid vesicles have been discussed in published papers. For both the natural and the synthetic lipid (at 287–333 K) we have observed[103] a square-law dependence of the initial rate of accumulation of MV^{+} on the intensity of the exciting light (Fig.12), which suggests a two-quantum mechanism for the photo-transfer involving Zn-TPP over the whole range of temperature. This dependence is observed with light of wavelength in the region of both the Soret band and the long-wave absorption bands of Zn-TPP, and therefore it is not related to the nature of the primary singlet-excited state. This suggests that the photo-transfer process involves the triplet-excited Zn-TPP molecules. It is interesting to note that when EDTA^{2-} is present on the same side (the outside) as MV^{2+}, i.e. when the membrane is used merely as a carrier of the water-insoluble photocatalyst Zn-TPP, the initial rate of accumulation of MV^{+} is linearly dependent on the light intensity, denoting a one-quantum mechanism for the photo-transfer of an electron from EDTA^{2-} to MV^{2+}.



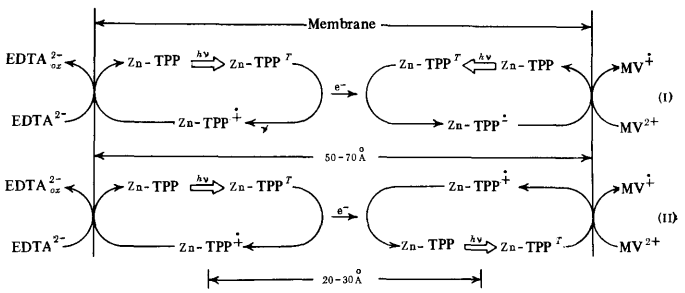


Figure 13. Kinetics of the photo-reduction of Doksil spin probes (Ṙ) trapped in vesicles of synthetic DPPC with (*1*, *2*) and without (*3*, *4*) zinc porphin in the bi-layer. Concentrations of the lipid and of Na_2-EDTA 10 mg cm^{-2} and 0.2 M respectively, [Zn-TPP] : [DPPC] = 1 : 50, [spin probe] : [lipid] = 1 : 200, 298 K. Spin probes: *1*) and *3*) 5-DOKSIL, *2*) and *4*) 16-DOKSIL.[102]

In order to determine the mechanism of electron photo-transfer through the membrane we need to establish the location of the electronically excited porphyrin molecules within the lipid bi-layer, since in principle they could be evenly distributed throughout the thickness, localised near the centre, or localised near the surface. We tried to answer this question by studying the irreversible photo-reduction of amphiphilic Doksil spin probes (a stearic acid derivative) localised in the vesicle membrane, interacting with electronically excited Zn-TPP molecules[102]. We found that under comparable conditions the rate of photo-reduction of the spin probes having an ṄO fragment near the surface of the

bi-layer (i.e. those with a paramagnetic substituent on the fifth carbon atom from the carboxyl group, "5-Doksil") is much greater than the rate of reduction of the probes with the $\dot{N}$–O fragment deep within the bi-layer (with their paramagnetic substituent on the 16th carbon atom, "16-Doksil") (see Fig. 13). Since the rate of photo-reduction of the $\dot{N}$–O fragments must increase with decreasing distance to the electronically excited Zn-TPP molecule we may conclude that the latter is preferentially localised near the surface of the bi-layer.

From these results we may suggest two alternative schemes for the phototransfer of an electron through the membrane which are consistent with both the steady-state and the flash photolysis data:

(where the symbol $EDTA^{2-}_{ox}$ refers, as before, to the products of the irreversible oxidation of $EDTA^{2-}$). According to scheme (I) the process responsible for the electron transfer through the membrane are the annhiliation of two Zn-TPP^T molecules with formation of Zn-TPP$^+$ and Zn-TPP$^-$ and the subsequent reactions of these ion radicals with $EDTA^{2-}$ and MV^{2+}. According to scheme (II) the electron transfer through the membrane is due to the reaction between Zn-TPP^T and MV^{2+}, followed by the transfer of an electron to the Zn-TPP$^+$ formed near the outer surface of the vesicle from another Zn-TPP^T particle near the inner surface, and lastly by the interaction of the resulting Zn-TPP$^+$ and $EDTA^{2-}$ particles. In both cases a square-law dependence of the initial rate of accumulation of MV^+ on the light intensity can be expected.

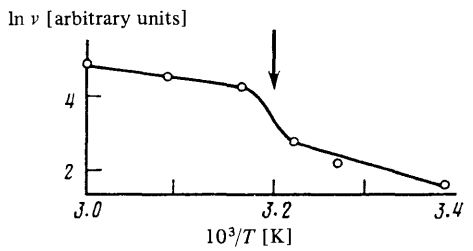

Figure 14. Temperature dependence of the initial rate (ν) of accumulation of MV^+ in a solution of synthetic DPPC vesicles. Concentrations of lipid, Zn-TPP, and MV^{2+} 1.5×10^{-3} g cm^{-3}, 3.7×10^{-5} M, and 2×10^{-2} M respectively; concentration of Na_2-EDTA in the cavity of the vesicles 0.2 M. Irradiation with light in the region of the long-wave absorption bands of Zn-TPP. The arrow denotes the temperature of the phase transition of the lipid (~315 K).[103]

The published values[105] of the redox potentials of the species involved in these schemes suggest that both variants are thermodynamically possible.

As was shown above, the presence of MV^{2+} outside the vesicles causes a large increase in the initial concentration of Zn-TPP$^+$ during flash photolysis. This means that the transfer of an electron from Zn-TPP^T to MV^{2+} (on the outer surface of the vesicle) is a more effective channel for the disappearance of Zn-TPP^T than reaction (9) under the present conditions. Therefore we consider scheme (II) to be the more realistic. The diffusion of a charged photolysis intermediate (Zn-TPP$^+$) in the non-polar lipid membrane is probably slow. Under these conditions electron transfer through the membrane can occur, for example, by a tunnelling exchange between Zn-TPP and Zn-TPP$^+$. It is interesting to note that when the temperature is lowered through the melting point of the lipid the rate of photo-transfer of electrons through the membrane drops sharply but does not fall to zero (Fig. 14).[103] A similar effect (electron transfer at a significant rate below the freezing point of the system) had been observed earlier for the recombination of light-separated charges in the photo-system I of plants (see, for example, Ref. 106, and also Ref. 107 and its list of references).

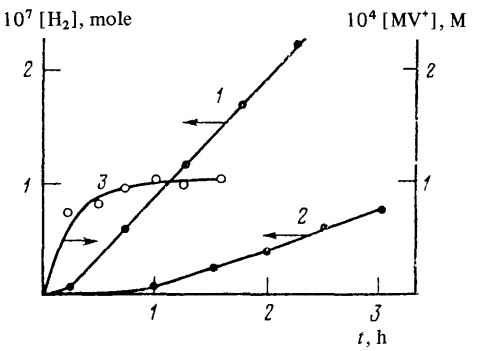

Figure 15. Kinetics of the accumulation of hydrogen over 1 cm^3 of a solution of egg licithin lipid vesicles containing Zn-TPP in the lipid bi-layer, a 0.2 M solution of Na_2-EDTA in the vesicle cavities, and in the outer volume MV^{2+} and a hydrogen evolution catalyst (*1*, *Tiocapsa roseopersicina* hydrogenase; *2*, activated Rh–AN-221 heterogeneous catalyst). Irradiation with light of $\lambda > 510$ nm from a DKSSH-1000 lamp; concentration of lipid, Zn-TPP, and MV^{2+} 6.7 mg cm^{-3}, 1.7×10^{-4} M, and 4.3×10^{-3} M respectively; temperature 303 K. Curve *3* shows the development of a steady-state concentration of MV^+ in the presence of hydrogenase (measured in parallel with the kinetic curve *1*). A pH of 7.2 was maintained both within and outside the vesicles by an ammonium buffer[104].

The continuing square-law dependence of the rate of photo-transfer of electrons through the membrane on the light intensity below the phase transition temperature of the lipid suggests that the mechanisms are similar at temperatures above and below the phase transition. The stepwise change in rate at the transition point is probably due to the unfreezing of the lateral diffusion modes of the reactants caused by the melting of the lipid. We note that a similar (stepwise) change in rate with temperature is found by flash photolysis in this system even for long-range interactions such as the triplet–triplet deactivation of excited porphyrin molecules [reaction (8)].[103]

The similarity between the mechanism of charge photo-separation by scheme (II) and the mechanism of charge photo-separation now generally accepted ("Z-scheme") for photosynthesis in plants is unmistakable. The vesicles containing metallo-porphyrins can therefore be treated as analogues of biological charge photo-separation systems, and a substantial increase in quantum yield may therefore be expected (by analogy with those systems) by suitable choice of photocatalyst, electron donor and acceptor, and lipid.

The photo-reduction of MV^{2+} by the electron donors $EDTA^{2-}$ or NADN is endothermic, and therefore (with NADN, for example) each act of photo-transfer is accompanied by the storage of 0.12 eV of energy. For irradiation with light of wavelength in the region of the long-wave absorption bands of Zn-TPP this corresponding to a storage of ~3% of the combined energy of the two light quanta needed for the photo-transfer of an electron.

Thus by inserting a fairly simple photocatalyst (zinc tetraphenylporphin) into the lipid membrane we can induce electron photo-transfer through the membrane by visible light (admittedly, so far, in low quantum yield). The reduced form of the electron acceptor used in our experiments, MV^{+}, can evolve molecular hydrogen from water even at neutral pH values in the presence of suitable catalysts. We were able to observe this process (at pH ~ 7) by adding to the solution outside the vesicles the hydrogenase enzyme *Thiocapsa roseopersicina* at ~10^{-6} M concentration, or the heterogeneous catalyst Rh–AN-221 (described above) in an activated form[104]. The effective quantum yield of the photo-catalytic hydrogen evolution measured in the stationary region (Fig.15) was $(1.0 \pm 0.3) \times 10^{-2}$% in the first case and $(0.3 \pm 0.1) \times 10^{-2}$% in the second. By comparing these values with the measured quantum yield of MV^{+} $(4.0 \pm 1.0) \times 10^{-2}$% on the initial portion of the kinetic curve for its formation, and under similar conditions, we conclude that the efficiency of the "dark" catalytic processes developed for these systems is already relatively high. The reason for the lower quantum yield of hydrogen (as compared with the yield of MV^{+}) is still not clear, though we should see that because of the stoichiometry of reaction (3) the quantum yield of hydrogen cannot be greater than one-half the quantum yield of MV^{+}: one possible cause is the screening effect on the photo-catalyst by the added hydrogen evolution catalysts.

Although the oxidation potential of the oxidised forms of these donors is insufficient to evolve oxygen from water, we note that the oxidation potential E_0 of one of the intermediates ($Zn\text{-}TPP^{+}$, $E_0 = +1.0$ V with respect to the NHE [105]) is high enough if a pH $\geq$ 5 is maintained inside the vesicle. This justifies the hope that the full water decomposition cycle may be realised in the near future in a system based on Zn-TPP and related metallo-porphyrins by optimising the choice of electron donors.

Knowing the mechanism of electron photo-transfer through a bi-layer membrane containing Zn-TPP should assist the solution of important problems such as maximising the quantum yield of the electron photo-transfer and improving the spectral sensitivity of the process, since (at $\lambda > 450$ nm, for example) the useful spectral range is limited by the relatively narrow absorption bands of Zn-TPP (total width 50–100 nm).

Thus, if scheme (II) is correct the rate of electron photo-transfer through the membrane should increase with the rate of regeneration of Zn-TPP molecules from the cation radical $Zn\text{-}TPP^{+}$ formed by the photo-transfer, and with the rate of excitation of Zn-TPP molecules on the inner surface of the membrane by energy transfer through some "antenna", analogous to the chlorophyll molecules in the chloroplasts of plants. We achieved this by using the complex $Ry(bipy)_3^{2+}$ at a concentration of ~0.07 M in the inner cavity of the lecithin vesicles[108] as a sensitising additive, able in principle to bring about both the transfer of an electron from the inner cavity to the $Zn\text{-}TPP^{+}$ and the transfer of energy to Zn-TPP. At this concentration of $Ru(bipy)_3^{2+}$ the absorption spectrum of the vesicle solution contains (in addition to strong Zn-TPP absorption bands) a fairly strong absorption band at $\lambda \cong 460$ nm due to the added sensitiser.

Irradiation of this combined system (containing both Zn-TPP and $Ru(bipy)_3^{2+}$) with light of $\lambda > 415$ nm, which excites both these photosensitive complexes, results in much faster electron photo-transfer through the membrane. Under these conditions we observed the highest ever quantum yield (~0.6%) for the photo-transfer through a membrane to MV^{2+} of an electron in vesicles containing a photocatalyst inside a lipid bi-layer. The quantum yield was calculated as the ratio of the initial rate of electron photo-transfer to the total number of quanta absorbed by the system (i.e. allowing for the absorption of both $Ru(bipy)_3^{2+}$ and Zn-TPP).

The details of the mechanism by which $Ru(bipy)_3^{2+}$ sensitises this system are being studied at the moment. We shall only note that if this sensitising effect is associated with the formation of the strong oxidiser $Ru(bipy)_3^{3+}$ (for which $E_0 = +1.3$ V relative to the NHE) in the inner cavity of the vesicle, for example by a reaction such as

$$Zn\text{-}TPP^{+} + {}^{*}Ru(bipy)_3^{2+} \rightarrow Zn\text{-}TPP + Ru(bipy)_3^{3+})$$

it should be possible (by an appropriate choice of homogeneous catalyst, e.g. a cobalt or iron complex, see Section III) to evolve oxygen from water in the cavity of the vesicle and thus complete the cycle of the photocatalytic decomposition of water.

Indeed, we have found[108] that the processes in this system are affected by the presence of cobalt chloride (an active oxygen evolution homogeneous catalyst) in the inner cavity of vesicles sensitised by the ruthenium complex. Thus, if the Na_2-EDTA solution in the cavity is replaced by a $(1–5) \times 10^{-4}$ M solution of $CoCl_2$ in a borate buffer (pH 9) to allow oxygen evolution a small quantity of MV^{+} is formed during irradiation of the system: if other conditions are kept constant the initial rate of accumulation is always greater in the presence of $CoCl_2$ than in its absence (when, as stated above, the accumulation of MV^{+} is due to the irreversible oxidation of impurities in egg lecithin).

We may suggest that in the presence of $CoCl_2$ the strong oxidiser $Ru(bipy)_3^{3+}$ produced by the irradiation contributes to the catalytic oxidation of water, which under these conditions may be faster than the oxidation of the impurities. However, a final judgement on the possibility of oxidation of water in the inner cavities of vesicles sensitised by $Ru(bipy)_3^{2+}$ must await direct experimental evidence on the presence (or absence) of evolved oxygen.

We note that after the addition of $Ru(bipy)_3^{2+}$ to the vesicle cavity the scheme proposed for this system becomes even more similar to the "Z-scheme" of natural photosynthesis: on the outer surface of the membrane we find the analogue of "photo-system I", and on the inner surface the analogue of "photo-system II".

Some of our latest results[109] show that $Ru(bipy)_3^{2+}$ within the inner cavity of vesicles can act as a photocatalyst and induce electron transfer even if the membrane is "photo-passive" (i.e. if the lipid bi-layer does not contain a photocatalyst). This photo-transfer takes place in the prescence of photo-inactive compounds (electron carriers) able to penetrate into the lipid bi-layer or to pass through it carrying an electron from the electronically excited state of $Ru(bipy)_3^{2+}$.

Thus when $Ru(bipy)_3^{2+}$ ions in the cavity of lecithin vesicles are excited by light together with the irreversible electron donor $EDTA^{2-}$, and if the lipid membrane contains the water-insoluble electron carriers cetylviologen dibromide

(N,N'-dicetyl-4,4'-dipyridine, CV^{2+}) or decylviologen (N,N'-didecyl-4,4'-dipyridine) we observe photocatalytic transfer of an electron from $EDTA^{2-}$ in the inner cavity to the reversible electron acceptor $Fe(CN)_6^{3-}$ in the outer volume of the vesicle, which cannot pass through the lipid membrane. The quantum yield of the electron photo-transfer to $Fe(CN)_6^{3-}$ is strongly dependent on the concentration of the electron carrier in the membrane, reaching (2.3 ± 0.5)% in the case of CV^{2+} for a molar ratio of CV^{2+} : lipid = 1 : 100, and (15 ± 5)% for a molar ratio of CV^{2+} : lipid = 1 : 20 (temperature 293 K, excitation of the $Ru(bipy)_3^{2+}$ by monochromatic light of wavelength 488 nm at a radiation density of 1.0 W cm^{-2}. local concentrations of $Ru(bipy)_3^{2+}$, $EDTA^{2-}$, and $Fe(CN)_6^{3-}$ 1.6×10^{-3}, 0.2, and 10^{-3} M respectively).

Photocatalytic electron transfer through these membranes was observed also after replacing the $Fe(CN)_6^{3-}$ outside the vesicle by two-electron acceptors such as the water-soluble dyes of the phenothiazine series (Methylene Blue, thionine); the quantum yield of the electron transfer through the lipid bi-layer under these conditions was again of the order of several per cent.

We should stress that the quantum yields for electron transfer quoted above are much higher than the usual values for the "photo-active" membrances (containing a photo-catalyst within the membrane) discussed in this review. Therefore the long-term prospects of photocatalytic systems based on photo-passive membranes are also good.

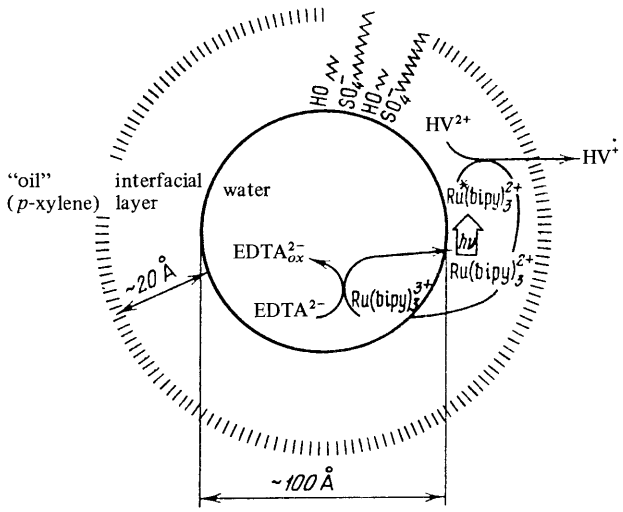

Figure 16. Scheme of the photo-transfer of an electron between phases in an anionic ME-I micro-emulsion of the "water in oil" type containing heptylviologen (N,N'-diheptyl-4,4'-dipyridine) HV^{2+}, $Ru(bipy)_3^{2+}$, and $EDTA^{2-}$.

2. Charge Separation in Micro-emulsions

The recombination of the products of reaction (1) can be suppressed also by using micro-emulsions of the "water in oil" type. We have studied the following micro-emulsion compositions (in wt.%): p-xylene (60.8%), n-pentanol (22.0%), sodium dodecyl sulphate (3.6%), and water (13.6%) (micro-emulsion ME-I [110,111]), and also toluene (71.3%), n-pentanol (7.4%), decylammonium propionate (9.1%), and water (12.2%) (micro-emulsion ME-II [111]). Both are transparent, slightly opalescent solutions containing water drops ~100 Å in diameter in p-xylene [112] or toluene. These droplets are surrounded by a layer on n-pentanol molecules and partially dissociated molecules of sodium dodecyl sulphate (SDS) in the emulsion ME-I, or of decylammonium propionate (DAP) in ME-II, which create an interface ~20 Å thick. The structure of ME-I is shown in Fig. 16.

The photocatalysts added to the micro-emulsion were the complex $Ru(bipy)_3^{2+}$ or its surface-active analogue $Ru(C_{17}\text{-bipy})(bipy)_2^{2+}$, which differs from $Ru(bipy)_3^{2+}$ in having one bipyridyl ligand replaced by a bipyridyl derivative (4-methyl-4'-heptadecyl-2,2'-bipyridyl) with a long hydrophobic cetyl chain in the fourth position[113]. By comparing data on the rate of fluorescence quenching of the ruthenium(II) complexes in homogeneous aqueous solutions and in micro-emulsions by substances readily soluble in water but poorly soluble in p-xylene or toluene (see Table 4) we conclude that the ruthenium photocatalysts are found mainly at the interface. Thus the large decrease in the quenching rate constant produced by changing from homogeneous solutions to micro-emulsions shows that the photocatalysts are not localised in the aqueous phase. On the other hand they cannot be localised in the organic phase, because if they were they could not interact with the quenchers (which are in the water phase) with the observed rate constants of $k_q \geq 10^7$ litre $mole^{-1}$ s^{-1}.

Table 4. Rate constants k_q for the luminescence quenching of ruthenium(II) complexes in homogeneous solutions and in micro-emulsions at 297 K .

Complex	A	10^3[A], M	10^{-8} k_q, litre $mole^{-1}$ s^{-1}
	medium: water		
$Ru(bipy)_3^{2+}$	MV^{2+}	5	4.7
$Ru(bipy)_3^{2+}$	HV^{2+}	5	8.0
	medium: ethanol + toluene (1 : 1)		
$Ru(bipy)_3^{2+}$	CV^{2+}	1	6.1
	medium: ME-I		
$Ru(bipy)_3^{2+}$	MV^{2+}	4—25	0.8
$Ru(bipy)_3^{2+}$	HV^{2+}	4—25	0.5
$Ru(bipy)_3^{2+}$	CV^{2+}	3	2.5
$Ru(C_{17}\text{-bipy})(bipy)_2^{2+}$	MV^{2+}	4—25	0.5
$Ru(C_{17}\text{-bipy})(bipy)_2^{2+}$	HV^{2+}	4—25	0.9
$Ru(C_{17}\text{-bipy})(bipy)_2^{2+}$	CV^{2+}	3	4.6
	medium: ME-II		
$Ru(bipy)_3^{2+}$	CV^{2+}	1	8.0
$Ru(C_{17}\text{-bipy})(bipy)_2^{2+}$	CV^{2+}	1	8.8

Notes. A is the quencher. For the micro-emulsions the local concentrations of the water-soluble MV^{2+} and HV^{2+} are given on the assumption that these species are present only in the water phase. In the case of the water-insoluble CV^{2+} the concentration is calculated in terms of the whole volume. The effective bimolecular quenching rate constants were obtained by dividing the quenching rate by the concentrations as defined above.

Irradiation with visible light ($\lambda > 450$ nm) of the micro-emulsion ME-I containing, in addition to the photocatalyst [$Ru(bipy)_3^{2+}$, 6×10^{-5} M], an electron acceptor (heptylviologen, HV^{2+}, 3×10^{-4} M) and an electron donor (Na_2-EDTA, 6×10^{-3} M) localised mainly in the water phase, causes accumulation of the cation radicals HV^{+} with a quantum yield of

~1%.[110] In the absence of Na_2-EDTA or of the ruthenium complex no HV^{+} is formed. Photolysis of a homogeneous aqueous solution containing $Ru(bipy)_3^{2+}$, HV^{2+}, and Na_2-EDTA produces a violet precipitate of water-insoluble HV^{+} which can be extracted easily and quantitatively by a mixture of *p*-xylene and n-pentanol in the same ratio as in the micro-emulsion. This shows that the HV^{+} cation radical formed by photolysis of the ME-I micro-emulsion must also reside mainly in the organic phase. The electron donors ($EDTA^{2-}$ anions) cannot be accommodated in the interface (saturated with SDS anions) or in the non-polar organic phase, and therefore they can only be in the aqueous phase of the micro-emulsion. Since we are able to achieve almost complete reduction of HV^{2+} to HV^{+} it appears that the $Ru(bipy)_3^{2+}$ present at the interface in an amount five times smaller than the heptylviologen acts as a true photocatalyst for the transfer of an electron from the donor $EDTA^{2-}$ (localised in the water phase) to the acceptor HV^{2+} (whose reduced form is extracted into the organic phase).

Flash photolysis of a homogeneous aqueous solution containing only $Ru(bipy)_3^{2+}$ and HV^{2+} produces the cation radical HV^{+}, whose concentration then decreases as a result of recombination with the oxidiser $Ru(bipy)_3^{3+}$ formed together with the HV^{+}. The disappearance of HV^{+} obeys the law of second-order kinetics with a rate constant $k = (1.5 \pm 0.1) \times 10^9$ litre^{-1} s^{-1} up to an extent of reaction of 99%. In contrast, the decrease in optical density of HV^{+} after flash photolysis of an ME-I micro-emulsion containing only $Ru(bipy)_3^{2+}$ and HV^{2+} is kinetically more complex (see curve *1* of Fig.17). At short times we observe a bimolecular disappearance of HV^{+} with a rate constant $k = (1.2 \pm 0.1) \times 10^9$ litre mole^{-1} s^{-1}, but after ~1 ms the disappearance of HV^{+} slows down and the bimolecular law is not obeyed.

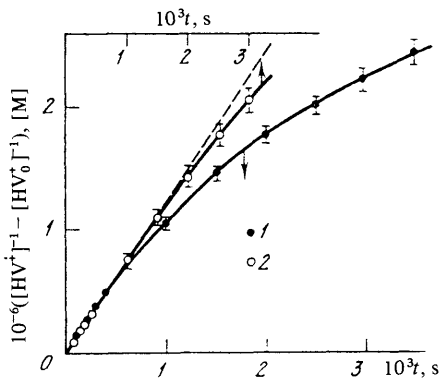

Figure 17. Kinetic curves for the recombination of HV^{+} with $Ru(bipy)_3^{3+}$ (*1*) and of HV^{+} with $Ru(C_{17}\text{-bipy})(bipy)_2^{3+}$ (*2*) after flash photolysis of an ME-I micro-emulsion containing 3.1×10^{-3} M HV^{2+} and 2.5×10^{-4} M ruthenium complexes; temperature 298 K. The broken line denotes second-order kinetics with the rate constants calculated from the initial portions of the experimental kinetic curves[110].

This type of recombination kinetics can be explained as follows (a more detailed analysis can be found in Ref.110). During the photolytic flash one of the primary products of electron photo-transfer at the interface (the species HV^{+}) can distribute itself between the interface and the organic phase in accordance with its solubility, whereas the second product [$Ru(bipy)_3^{3+}$] diffuses slowly into the aqueous phase where it can oxidise $EDTA^{2-}$ if this species is present. The initial portion of the kinetic curve, described by the bimolecular law, corresponds to recombination of the HV^{+} with the $Ru(bipy)_3^{3+}$ which has not yet migrated into the water phase. The slowing down of the recombination observed at long times shows that some of the oxidiser $Ru(bipy)_3^{3+}$ has migrated away from the sphere of action and is no longer available to recombine with the HV^{+} in the interfacial layer.

This explanation of the shape of curve *1* in Fig.17 suggests that the replacement of $Ru(bipy)_3^{2+}$ by the more lyophilic complex $Ru(C_{17}\text{-bipy})(bipy)_2^{2+}$ should result in less marked deviations of the recombination kinetics from the bimolecular law, since the transfer of the oxidised form of the photocatalyst from the interface to the aqueous phase would then be hindered. As curve *2* of Fig.17 shows, this prediction is borne out in practice.

Table 5. Recombination rate constants k and relative probabilities P/P_0 of the oxidiser and the reducer formed by electron photo-transfer from a donor to an acceptor emerging from the original pair in homogeneous aqueous solutions and in micro-emulsions at 298 K.[111]

Donor	Acceptor	$10^8\,k(\pm1)$, $M^{-1}\,s^{-1}$	P/P_0
	medium: water		
$Ru(bipy)_3^{2+}$	MV^{2+}	17	1.00
$Ru(bipy)_3^{2+}$	HV^{2+}	15	0.95
	medium: ME-I		
$Ru(bipy)_3^{2+}$	MV^{2+}	25	0.24
$Ru(bipy)_3^{2+}$	HV^{2+}	12	0.67
$Ru(bipy)_3^{2+}$	CV^{2+}	12	0.15
$Ru(C_{17}\text{-bipy})(bipy)_2^{2+}$	HV^{2+}	7.8	0.35
ditto	CV^{2+}	8.0	0.15
	medium: ME-II		
$Ru(bipy)_3^{2+}$	CV^{2+}	2.7	2.8
$Ru(C_{17}\text{-bipy})(bipy)_2^{2+}$	CV^{2+}	6.7	0.7

Notes. In the case of water solutions the k values are given for a low ionic strength ($\mu < 0.05$ M); P_0 is the probability of the electron photo-transfer products emerging from the original pair in the $Ru(bipy)_3^{2+}$–MV^{2+} system in aqueous solution; the precision of the measurements of P/P_0 is ±10%.

Thus, owing to the fast extraction of HV^{+} into the organic phase coupled with a much slower migration of $Ru(bipy)_3^{3+}$ into the water phase, some of the primary products of the electron photo-transfer process are in different phases, and as a result their recombination is suppressed. These results justify the hope that effective segregation of the products of primary electron photo-transfer into different phases may be achieved in the near future by varying the electric charge of the interfacial layer of the micro-emulsion and the hydrophilic and oleophilic properties of the primary electron donor and acceptor (by introducing appropriate substituents).

Thus, by varying these properties we should be able to control the two most important parameters of the system, responsible in the final analysis for effectiveness of the extraction of the primary charge separation products: the effective rate constant k for the recombination of the primary oxidiser and reducer in the interfacial layer of the micro-emulsion and the probability P of the oxidiser and the

reducer breaking away from their initially paired configuration. We note that a marked deviation of the parameter P from unity is the most usual explanation of small quantum yields in bimolecular oxidation–reduction reactions involving excited states. Our values[111] of k and P for the micro-emulsions ME-I (with a negatively charged interfacial layer) and ME-II (positively charged layer) are listed in Table 5 for different pairs of electron donor and electron acceptor having different lyophilicities. The rate constant k was measured from the initial slope of the kinetic curve for the recombination of the primary oxidiser and reducer, recorded by the flash photolysis method. The probability P was determined by comparing the initial concentrations of the reduced forms of the viologens, observed immediately after a photolytic light flash of duration less than 10^{-5} s, with the concentration of MV^{+} observed under similar conditions in a homogeneous aqueous solution containing $Ru(bipy)_3^{2+}$: the absolute value of the probability P for the $Ru(bipy)_3^{2+}$–MV^{2+} system in water was found[114] to be 25%.

It is clear from Table 5 that, as expected, the best results (i.e. a more than six-fold decrease in k and an almost three-fold increase in P to $P = 2.8 \times 25\% = 70\%$ as compared with a homogeneous aqueous solution) are obtained in micro-emulsions with a positively charged interface if the electron donor has a low lyophilicity [$Ru(bipy)_3^{2+}$] and the electron acceptor has the highest possible lyophilicity (cetylviologen, CV^{2+}). A positive charge on the interface of the micro-emulsion prevents the charge separation products of the same (i.e. positive) sign from recombining at the phase boundary.

We note that in a really effective photo-catalytic system the recombination of the D^{+} and A^{-} particles created by reaction (1) should be slow enough to allow reactions (2) and (3) to proceed, with evolution of hydrogen and oxygen. We should stress that the reduced forms of HV^{+} and CV^{+} (like the reduced form MV^{+}) can evolve hydrogen from water in the presence of the catalysts discussed in Section II; the prospects of the evolution of oxygen from water by $Ru(bipy)_3^{3+}$ and its analogues are discussed in Section III.

---o0o---

This general assessment of the present state of photocatalytic converters of solar energy into chemical energy by exploiting the water decomposition reaction shows that the development of effective charge separation systems continues to be the major problem facing the creation of practical molecular photocatalytic systems for decomposing water into hydrogen and oxygen. We may hope that as soon as these systems are discovered the efficient decomposition of water by sunlight under laboratory conditions will be a practical possibility.

The Thermodynamics of the Formation of Outer-sphere Complexes in Solution

V.E.Mironov and A.K. Pyartman

Data on the thermodynamics of the formation of outer-sphere complexes of coordination compounds of cobalt(III), rhodium(III), iridium(III), platinum(IV), chromium(III), iron(II), ruthenium(II), (III), and osmium(II) have been reviewed. Various regular features of outer-sphere complex formation by inert hydrophilic and hydrophobic cationic complexes with d^6, d^5, and d^3 electron configurations of the central metal ion in aqueous and aqueous-organic solutions have been established. The bibliography contains 144 references.

I. INTRODUCTION

The formation of outer-sphere complexes[1] is a widespread phenomenon, since most inner-sphere complexes form outer-sphere associates, depending on the composition of the surrounding medium. Detailed studies of outer-sphere complexes (OSC) carried out in recent years have revealed the characteristic features of their formation and new possibilities for their practical application, and this has led to an increased interest in the comprehensive study of OSC.[2]

In the last 15 years, several reviews of the stability and structural characteristics of OSC in solution have been published[2-8]. Reference has been made[1] to a monograph on this topic[9], but this has not yet appeared.

Outer-sphere complexes can be divided into two groups. The first group consists of compounds formed by inert, and the second group of compounds formed by labile (in Taube's terminology) [10] inner-sphere complexes. The OSC of both groups are characterised by high rates of formation and dissociation of the outer coordination sphere[11], that is this sphere is always labile. A large proportion of studies have been carried out for OSC formed by inert coordination compounds. In a number of cases, as a consequence of differences in the rate of formation or in the stability of the inner and outer spheres, it is also possible to carry out qualitative and semi-quantitative studies of the thermodynamics of the formation of OSC by labile inner-sphere complexes[11-18].

Most present-day and earlier studies of OSC have been carried out at a single temperature[19,20]. Only in a few studies have the measurements been made at several temperatures, and the enthalpy and entropy changes for the formation of the OSC calculated from the temperature dependence of the equilibrium constants. The enthalpy changes on OSC formation are small ($<\pm 20-40$ kJ mole^{-1}), and the temperature-coefficient method gives appreciable errors in the determination of small thermal effects[21,22]. Accurate values of the enthalpy and entropy changes can be obtained only by direct thermochemical measurements using highly sensitive calorimeters. Up to the present, all such measurements (except of the heats of two reactions[23]) have been carried out only in the laboratory of the authors of the present review. The aim of the present work is to summarise and discuss critically the data obtained on the thermodynamics of the formation of OSC and to examine other studies of similar content.

Data on the thermodynamics of the formation of OSC by inert cationic complexes of cobalt(III), rhodium(III), iridium(III), platinum(IV), chromium(III), iron(II), ruthenium(II), (III), and osmium(II) are reviewed. Almost all the data relate to aqueous solutions. Some information on outer-sphere interactions in aqueous-organic solvents is also given.

An unsymmetrical standard state[24,25] (that is different for the solvent and the solutes) is used in the study of solutions of electrolytes in general and of OSC in particular. A hypothetical molal (molar) solution with the properties of an infinitely dilute solution is taken as standard for OSC (and for their components). The state of the pure liquid at a definite temperature and pressure is taken as the standard state for the solvent.

The recalculation of the values of the stability constants of the OSC and the enthalpy changes for their formation (from solutions with definite ionic strengths of constant magnitude to the standard state indicated above) is carried out[26] using Vasil'ev's equations[27,28].

The problem of selecting inert salts to keep the ionic strengths constant is solved in various ways. The experience of a large number of studies has shown[26,29] that the perchlorate anion is the most "inert" with respect to hydrophilic cationic complexes, and the fluoride anion the most inert with respect to hydrophobic cationic complexes. This situation (with allowance for the solubility of the background salts) explains why lithium or sodium perchlorates are most frequently used as inert salts in the study of OSC formed by aquoammine, ethylenediamine, and similar hydrophilic complexes. Sodium or potassium fluorides are chosen as inert salts in the study of the OSC of tris(2,2'-bipyridyl), tris(1,10-phenanthroline), and other hydrophobic compounds.

It is of interest to compare the association constants of a number of inert cationic complexes with the perchlorate ion, which is most widely used as inert anion.

The data in Table 1 show that for most cationic complexes with a charge of 1–4, the values of the logarithms of the stability constants of the perchlorate associates are ≥ 1. Increase in the size of the cationic complexes, for example in the series hexammine-, tris(ethylenediamine)-, and tris-(propylenediamine)cobalt(III), leads to a slight decrease in the stability constants (Table 1). A similar change is observed on going from tris(ethylenediamine)cobalt(III) to

tris(ethylenediamine)rhodium(III) or from *trans*-dichlorobis-(ethylenediamine)rhodium(III) to *trans*-dichlorobis(ethylenediamine)iridium(III). On the other hand, for the hydrophobic tris(2,2'-bipyridyl) and tris(1,10-phenanthroline) compounds, the change from iron(II) to ruthenium(II) and osmium(II) leads to an increase in the stability of the perchlorate associates.

Table 1. Logarithms of the association constants of transition metal complexes with the perchlorate ion at 298 K.

Methods: El = electrical conductivity measurement, S = solubility measurement, Sp = spectrophotometrically, K = study of the reaction kinetics, E = extraction.

Doubly-charged hydrophobic complexes[29,53–55] form more stable perchlorate associates than triply- and quadruply-charged hydrophilic cations (Table 1). The non-electrolyte *trans*-dicyanobis(1,10-phenanthroline)iron(II) tends to associate with the perchlorate ion. It should be particularly emphasised that a change in the charge of the coordination compound is not a decisive factor in the formation of perchlorate associates[54]. Many singly-charged cations have the same association constants with perchlorate ion as tris(ethylenediamine)cobalt(III). Judging from the values of the stability constants of the perchlorate associates of tris(ethylenediamine)- and haxamminecobalt(III), increase in the ionic strength of the solution leads to a decrease in the stability of the perchlorate associates (Table 1). The applicability of this regular feature is usually confirmed by published data[29,40,51,53,55], although in some cases there are exceptions [the perchlorate associates of tris(1,10-phenanthroline)-ruthenium(II) and iron(II)].

The ionic strength of the solution has practically no influence on the stability of the associates of coordination compounds with molecules[56,57] and neutral complexes with anions[54]. It should be noted that the values of the stability constants obtained at ionic strengths I which differ in magnitude and in the salts used to establish them can be extrapolated to $I = 0$ using Vasil'ev's equation[27]. This equation uses a distance of maximum approach of the ions equal to 4.9 Å. Change in this quantity over the range 3–6 Å, however, usually has little influence[26,58] on the values of the stability constants at $I = 0$.

Beginning from values of $I \leq 0.2$–0.3, the stability constants can be recalculated to $I = 0$ using Davies' equation[1], but in a number of cases[59–61] it does not lead to the same values as those obtained using Vasil'ev's equation.

Structural changes in the solvent and solvation processes in the second sphere have a significant influence on the formation of OSC in aqueous-organic solutions[62–65]. If the formation of OSC in aqueous solution is represented as the replacement of water molecules in the second sphere by an outer-sphere ligand

$$[MA_N](H_2O)_x(aq) + L(aq) \rightleftarrows [MA_N](H_2O)_yL(aq) + (x-y)H_2O \quad (1)$$

(M is the metal ion, A the inner-sphere ligands, and N their number), then the equilibrium constant of reaction (1) is related to the stability constant of the OSC by the relationship[64]:

$$\beta_e = \beta_1[H_2O]^{x-y} = \beta_1[H_2O]^z \quad (2)$$

Table 2. Logarithms of the stability constants lg β_1 of the outer-sphere complexes $[MA_N]SO_4$ and the equilibrium constants of reaction (1) lg β_e in aqueous methanol solutions at 298 K.[62,63]

MA_N	Methanol, mass %					
	0	10	20	30	40	50
$[Co(NH_3)_6]^{3+}$	3.48 6.97	3.54 6.94	3.68 6.98	3.79 6.97	3.91 6.95	4.08 6.96
$[Co(NH_3)_5Cl]^{2+}$	2.70 6.19	2.79 6.19	2.87 6.17	3.03 6.21	3.16 6.20	3.20 6.18
$[Fe(bipy)_3]^{2+}$	1.45 4.94	1.60 5.00	1.65 4.95	1.75 4.93	1.91 4.95	2.10 4.98

Note. The value of lg β_1 is given in the upper row, and the value of lg β_e in the lower row. The standard deviations for the values of lg β_1 are ±(0.03–0.05).

If equilibrium (1) does not break down in aqueous-organic solutions, and resolvation processes do not take place in the second sphere, it follows from the law of mass action that the role of the organic component often reduces to the role of a diluent of the water, and the correction $[H_2O]^z$ leads to a constant lg β_e in aqueous-organic solutions; z is an integer[64]. For sulphate OSC of hydrophilic and hydrophobic cationic complexes, the introduction of methanol, ethanol,

propanol, acetone, dioxan, and other solvents up to a concentration of 40–50 mass % does not change the values of $\lg \beta_e$ for $z = 2$. For the halide OSC of tris(ethylenediamine)cobalt(III),[65] the introduction of acetone up to 20 mass % does not change the values of $\lg \beta_e$.

Table 2 gives the stability constants in aqueous glycol solutions, where the correction $[H_2O]^z$ does not lead to constant values of $\lg \beta_e$. This case requires verification, since in the system being considered, the introduction of 20 mass % ethylene glycol lowers the value of the stability constant, and at higher ethylene glycol concentrations it increases. To date, this form of dependence of the values of the stability constants on the concentration of the organic component has been noted[66] only for this system. Moreoever, this effect is not observed for sulphate OSC of nitropentamminecobalt(III) in aqueous ethylene glycol solutions (Table 3). Additional verification of this idea for OSC with highly-charged anions, and also extension of the range of solvents and cationic complexes with different charge, containing inner-sphere ligands of different character, are required.

In some systems[67], the replacement of even 80% of water by methanol does not lead to a change in the constant β_e. This indicates the predominant role of the dilution factor.

Table 3. Logarithms of the stability constants[66,67] $\lg \beta_1$ and the equilibrium constants for reaction (1) $\lg \beta_e$ [62,63] for monosulphate OSC of tris(1,10-phenanthroline)iron(II) in aqueous methanol and aqueous ethylene glycol solutions at 298 K.

II. METHODS FOR DETERMINING THE CHANGES IN THERMODYNAMIC FUNCTIONS FOR THE FORMATION OF OUTER SPHERE COMPLEXES IN SOLUTION

The ultimate aim of the study of equilibria in solutions is the determination of the stoichiometry of the forms produced, and the calculation of stability constants and the changes in the thermodynamic functions (enthalpy, entropy, etc.) on complex formation[68]. From these viewpoints it is necessary, in the study of OSC, to establish the stoichiometry of the forms produced by the coordinatively-saturated complex $[MA_N]$ (N is the limiting coordination number) and the outer-sphere ligand L (anion or molecule). This problem is solved by the analysis and mathematical treatment of relationships of the type: solution property–solution composition. For the quantitative solution of this problem it is necessary to establish, in explicit, implicit, or parametric form, the functional relationship between the measured physicochemical property of the solution as a whole and its analytical composition. This functional relationship is established using three fundamental physicochemical concepts, given mathematically[68] by: 1) the material balance equations, 2) the equations of the law of mass action, and 3) equations relating a measured property of the solution as a whole, the partial contributions to this property from the individual chemical forms, and the equilibrium concentrations of these forms.

When an OSC with stoichiometry $[MA_N]L_m$ is formed in solution, the corresponding material balance equations have the form:

$$C_M = \{[MA_N]\} + \sum_m \{[MA_N]L_m\} \quad (3)$$

$$C_L = \{L\} + \sum_m m\{[MA_N]L_m\} \quad (4)$$

where c_M and c_L are the total (analytical) concentrations of the coordination compound $[MA_N]$ and the outer-sphere ligand L.

For the formation of OSC according to Eqn.(1), the corresponding equations of the law of mass action will be

$$\beta_1 = \{[MA_N]L\}/\{[MA_N]\} \cdot \{L\} \quad (5)$$

where β_1 is the concentration stability constant, which depends on temperature, pressure, the chemical character of $[MA_N]$ and L, and the nature of the forming medium. The concentration constant becomes constant if the conditions of a constant ionic medium with respect to the participants of the process being studied are observed [reaction (1)].[68]

The third group of equations is determined by the physicochemical method of study used.

The heats of formation of OSC in solution have been determined using a double differential microcalorimeter with a sensitivity of $(5.52 \pm 0.12) \times 10^{-3}$ J and a cell volume of 10 cm^3. The measurements were made by thermometric titration[59]. The complex compounds were synthesised by the usual methods, and analysed for the metal, hydrogen, carbon, nitrogen, and halogen. The difference between the observed and calculated concentration of the components determined did not exceed 0.5 abs.%. The purity of the synthesised and recrystallised specimens was verified from the published absorption spectra. The salt solutions used in the experiments were prepared from the "analytically pure" or "chemically pure" grade reagents, purified by recrystallising two or three times from water.

The heats of mixing of solutions containing $[MA_N]$ and the background electrolyte $[M'\Phi]$ at I = const with solutions of salts of the outer-sphere ligand M'L were measured. The heats of mixing of $M'\Phi$ with M'L were measured separately in additional experiments.

The heat of complex formation (Q) is related to the enthalpy change (ΔH_m^0) for the formation of the species $[MA_N]L_m$ by the expression

$$Q = V \sum_m \Delta H_m^0 \{[MA_N]L_m\} \quad (6)$$

where V is the volume of the solution, and $\{[MA_N]L_m\}$ represents the equilibrium concentrations of the forms $[MA_N]L_m$.

Eqns.(3)–(5) lead to the equation

$$\frac{Q}{V \cdot c_M} = \sum_m \frac{\Delta H_m^0 \beta_m \{L\}^m}{\left(1 + \sum_m \beta_m \{L\}^m\right)} \quad (7)$$

In most of the systems studied, the stoichiometry of the OSC formed and the values of the stability constants obtained from the results of independent methods of study (for example potentiometry, spectrophotometry, solubility, etc.) have

been used. The values of the stability constants were used to calculate the corresponding enthalpy changes for the formation of OSC from Eqn.(7). In a number of cases, the calculation of ΔH_1^0 and β_1 for single-ligand OSC have been carried out directly from thermochemical data[68].

The values of the free energy changes were calculated from the relationship[68]:

$$\Delta G_i^0 = -RT \ln \beta_i \ . \qquad (8)$$

The corresponding entropy changes for the formation of the OSC were calculated from the equation[68]:

$$\Delta G_i^0 = \Delta H_i^0 - T\Delta S_i^0 . \qquad (9)$$

The values of the changes in the thermodynamic functions are given with their uncertainties in the form of the standard deviations (see Tables 4–12). The results were treated by the least-squares method with allowance for the difference in the accuracy of the experimental data by introducing appropriate statistical weights[68], reflecting the estimates of the dispersions of the results on the measurement of the values of the heat.

III. OUTER-SPHERE COMPLEXES OF COBALT(III)

The outer-sphere complexes of cobalt(III) and the thermodynamics of their formation have been studied in most detail. A review of the study of OSC of cobalt(III) was published in 1970.[5] At that time, however, thermochemical measurements had been carried out for the formation of only the OSC of tris(ethylenediamine)cobalt(III). The studies were carried out in 3.0 M solutions of sodium or lithium perchlorate. The standard state indicated was used[67–77] in thermochemical studies of OSC up to 1975, when the first thermochemical studies[78–80] in dilute solutions with extrapolation of the thermodynamic data to aqueous solutions with zero ionic strength were published. Since 1975, thermochemical studies of the thermodynamics of formation have been carried out in solutions with ionic strengths of 0.1, 0.2, 0.3, 0.4, 0.5, and sometimes 0.75 and 1.0 [26,45,78–94] for the compounds of hexammine-,[79] tris(ethylenediamine)-,[79,81,83] tris(propylenediamine)-,[79] tris(2,2′-bipyridyl)-,[93] tris(1,10-phenanthroline)-,[94] chloro-,[80,87] bromo-,[80,85] nitro-,[80,85] sulphato-,[80,85], acetato-,[82,85] pentamminecarbonato-,[76] oxalato-,[92] malato-,[92] succinato-,[92] phthalato-,[92] tetrammine-, bis(acetylacetonato)-(ethylediamine)-,[88] and acetylacetonato, bis(ethylenediamine)-cobalt(III) [45] with sulphate, thiosulphate, sulphite, selenite, tellurite, and carbonate ions.

The thermochemical method has been used to study halide, thiocyanate, nitrate, carboxylate, and other OSC of cobalt(III). These measurements were made[93–102] in solutions with an ionic strength $I = 3$, maintained by adding sodium or lithium perchlorate.

The enthalpy changes for the formation of the OSC of cobalt(III) have usually been calculated[78–102] using the stability constants of the OSC, determined from potentiometric, solubility, spectrophotometric, and other data.

To illustrate ideas developed below, a small fraction of the data on the thermodynamics of the formation of OSC of cobalt(III) is given in Tables 4–8. Table 4 shows that in aqueous solutions with zero ionic strength, tris(ethylenediamine)-cobalt(III) forms mono- and bis(ligand) OSC with positive values of the entropy change. The enthalpy changes in these processes are small, and lie in the range ±2 kJ mole^{-1}. The differences between the stabilities of the OSC of tris-(ethylenediamine)cobalt(III) with different doubly-charged ligands are slight (Table 4); only the carbonate ion forms comparatively less stable OSC. A regular decrease in the stability constants and the positive values of the entropy changes is observed with increase in the serial number of the added ligand. The entropy changes are ~57–58 J mole^{-1} K^{-1} for the formation of mono-ligand OSC, and ~34 J mole^{-1} K^{-1} for the formation of bis(ligand) OSC.

Table 4. Values of the changes in the consecutive thermodynamic functions for the formation of OSC of tris(ethylenediamine)cobalt(III) at 298 K in aqueous solutions with zero ionic strength[79,103,104].

The data in Table 5 show that the stability of the sulphate OSC tends to decrease in the cationic complex order: hexammine- > tris(ethylenediamine)- > tris(propylenediamine)-cobalt(III); there is a slight decrease in the contribution of the entropy component to the free energy change. The

decrease in these quantities is small, however, and lies at the error limit in the determination of the thermodynamic parameters.

Table 6. Values of the changes in the thermodynamic functions for the formation of the monosulphate OSC $[Co(en)_x \cdot (acac)_{3-x}]$ at 298 K and different ionic strengths, maintained using sodium perchlorate and sulphate[88].

{0	{13.3}	{29.7}	{54}

Note. The standard deviations of the determinations are ±(0.4–0.6) kJ mole^{-1} for ΔG_1^0; ±(0.8–0.6) kJ mole^{-1} for ΔH_1^0; and ±(3–20) J mole^{-1} K^{-1} for ΔS_1^0.

The values are given for a combination of potentiometric and thermochemical methods; the values in round brackets correspond to purely thermochemical data, and those in braces were obtained by the electrical conductivity method at 293–318 K.

For hydrophilic cationic complexes, the change from the hexammine- [tris(diamine)-] to acidopentammine- and then acidotetramminecobalt(III) leads to a marked decrease in the stability of the OSC with doubly-charged ligands. This decrease in the stability of OSC with decrease in the charge of the central group is accompanied by a regular increase in the positive contribution of the enthalpy component, and is clearly observed for monoligand OSC (Table 5).

The differences in the stability of OSC formed by different acidopentammines of cobalt(III) lie just beyond the error limits in the determination of the changes in the thermodynamic functions (see Table 5). Similar conclusions can be reached about the stability of the OSC of acidotetramminecobalt(III) compounds (Table 5). Sulphatopentamminecobalt(III) forms outer-sphere complexes with stabilities close to those of acidotetrammines of cobalt(III), due to the fact that these complexes have the same charge of +1. The date in Table 5 indicate that the entropy changes are 63 ± 8 J mole^{-1} K^{-1} for the formation of the monoligand OSC of cobalt(III) ammines, and 29 ± 8 J mole^{-1} K^{-1} for the formation of the bis(ligand) OSC.

Table 8. Values of the enthalpy and entropy changes for the formation of associates of amines with coordination compounds of cobalt(III) in aqueous lithium perchlorate or chloride solutions at 298 K.[105]

Note. The standard deviations of the determinations are ±(0.8–2.0) kJ mole^{-1} for ΔH_1^0, and ±(3–8) J mole^{-1} K^{-1} for ΔS_1^0.

Similar entropy changes are characteristic of the addition of various other doubly-charged anions[78–87,91,92]. The results of Refs. 32, 34, and 105–112 were obtained from the temperature dependence of the stability constants of only single-ligand OSC, and most of them confirm the conclusion that the entropy change has the practically constant value given above. Analysis of the data in Ref. 111 shows that the enthalpy change for the formation of monohydrogen phosphate OSC of tris(ethyldiamine)cobalt(III) is close to zero, and calculation of the entropy changes gives a value of 63 J mole^{-1} K^{-1}. A study of the association of tris(biguanidine)cobalt(III) with the sulphate ion at 298 K and 308 K[112] showed that the entropy changes for the formation of monoligand OSC are 59 J mole^{-1} K^{-1}. With the assumption that temperature does not influence the stability constant of the mono-oxalato-complex of hexamminecobalt(III),[32,34] we obtain entropy changes of 63 J mole^{-1} K^{-1}. Chloropentamminecobalt(III), even with the quadruply-charged pyrophosphate ion, forms OSC whose entropy changes at 293 K and an ionic strength of 0.1 are 70 J mole^{-1} K^{-1}.[23]

In a number of cases, the formation of OSC in which the number of added ligands is three has been detected[78–102]. The small values of the changes in the thermodynamic functions, however, together with the large errors in their determination and the possibility of a contribution from changes in the activity coefficients, make an unambiguous quantitative discussion of the regular features of the formation of these OSC impossible[113,114].

It is of interest to compare the data of the present authors[80] on the thermodynamics of the formation of OSC of cobalt(III) with published data[114,115] obtained for monoligand complexes from kinetic and sometimes spectrophotometric studies.

The dependence of the acid hydrolysis constant on the sulphate ion concentration for chloropentamminecobalt(III) at an ionic strength of 0.3 and temperatures of 313–328 K [115] made

it possible to determine the association constant, equal to 32.5, and $\Delta G_1^0 = -9.2$ kJ mole^{-1}, $\Delta H_1^0 = -17.2$ kJ mole^{-1}, and $\Delta S_1^0 = -26$ J mole^{-1} K^{-1}. The direct determination of these parameters from potentiometric and thermochemical data[80] gave values of the above functions equal to 14, -8.2 kJ mole^{-1}, 6.3 kJ mole^{-1}, and 48.5 J mole^{-1} K^{-1} respectively. Comparison of the direct and indirect data on the enthalpy and entropy changes for the formation of the sulphate associate of chloropentamminecobalt(III) shows differences even in the signs of these functions.

Doubt must be cast on the values obtained from the kinetic data[115], and also on the published thermodynamic characteristics[116] of the malate and phthalate OSC of chloropentamminecobalt(III). Contrary to the data of Ref.116, these monoligand OSC should be formed with positive enthalpy and entropy changes. The enthalpy and entropy changes at 313 K in 0.3 M sodium perchlorate solutions, however, are respectively -25 kJ mole^{-1} and -53 J mole^{-1} K^{-1} for the malate OSC, and -27 kJ mole^{-1} and -58 J mole^{-1} K^{-1} for the phthalate OSC of chloropentamminecobalt(III).[116] The values of the enthalpy and entropy changes for the formation of phthalate OSC of aquopentamminecobalt(III) in solutions with an ionic strength of 0.3 at 323 K, equal to 24 kJ mole^{-1} and 100 kJ mole^{-1}, obtained[117] from the temperature dependence of the association constants, appear more correct. The latter were determined from the dependence of the rate constants of inner-sphere ligand replacement on the concentration of the outer-sphere ligand.

Since the dependence of the rate constants of hydrolysis, inner-sphere ligand replacement, etc. on the concentration of the outer-sphere ligand is non-linear, the determination of the stability constants of the resulting OSC from kinetic data is difficult, and associated with appreciable errors[118]. In most cases, the influence of temperature on the stability constants of the OSC is weak[119,120], and it is not possible to determine the enthalpy and entropy components of the free energy change.

The successive replacement of ethylenediamine by acetylacetone in the inner sphere of cobalt(III) leads (Tables 5 and 6) to a decreased stability of the monosulphate OSC. The positive contribution of the entropy component tends to get smaller with increase in the number of acetylacetone molecules in the inner sphere of cobalt(III). Published ideas on the reasons for this decrease are contradictory[45]. The decrease in the stability of the hydrate layer[47] and the increase in the donor–acceptor interaction with the π-system of the acetylacetone molecules with an increase in their number in the inner sphere represent[121] equally weighty arguments explaining the decrease in the contribution of ΔS_1^0 to ΔG_1^0.

The formation of monosulphate OSC by the hydrophobic tris(2,2′-bipyridyl)cobalt(III) and tris(1,10-phenanthroline)-cobalt(III), unlike the formation of OSC by hydrophilic cations (Tables 4 and 5), takes place with negative values of the enthalpy and entropy changes (Table 7). The absence of acidic protons, the hydrophobic character of the inner-sphere ligands, and the formation of π-bonds between M and phen (bipy) suggest that the solvation of these cations is determined by the dipole moment of the solvent and van der Waals interaction[93,94].

The reaction of tris(2,2′-bipyridyl)- and tris(1,10-phenanthroline)cobalt(III) with a solvent is determined by the strong hydrophobic character of 1,10-phenanthroline and 2,2′-bipyridyl.[122] The large size of the cationic complexes and the shielding of the central metal ion by the inner-sphere ligands, which form $\pi(M \rightarrow Am)$ bonds, where Am = bipy or phen, weaken the electrostriction interaction of the cationic complex with the solvent molecules. With ion-dipole and van der Waals interactions of the solvent with coordination compounds, hydrophobic hydration may take place[123]. In this case, large ionic complexes such as tris(1,10-phenanthroline)-cobalt(III) do not have a primary hydrate layer, and the influence of their secondary hydration is revealed chiefly in the effect on the structure of water layers adjoining the ions, which increases the degree of ordering. It must be assumed that the formation of associates in this case is accompanied by the combination of the cavities in which the ions are situated, or by the replacement of solvent molecules by the outer-sphere ligand in the secondary hydrate layer. Processes of this kind should not lead to the extensive desolvation processes in the case of highly charged hydrated ions which are observed in the outer-sphere association of sulphate ions with tris(1,10-phenanthroline)cobalt(III), where in contrast to the outer-sphere association of hydrophilic amine compounds of cobalt(III) their formation is accompanied by appreciable negative enthalpy and entropy changes (Tables 4–7).

The data in Tables 4–7 and Refs.14 and 79–94 show unambiguously that the nature of the interaction of coordination compounds with a solvent plays a predominant role in the formation of outer-sphere complexes. Ahrland's criterion[124] for the thermodynamic determination of the type of complex (inner- or outer-sphere) in labile systems is not general; its applicability is restricted to hydrophilic systems, and it cannot be used in hydrophobic systems[93,94].

Thermochemical studies of the reaction of cationic cobalt(III) complexes with amines in the outer sphere are complicated[62] by the high values of the heats of mixing of the solutions of the background electrolytes with amines. For this reason, the thermodynamics of the formation of OSC with amines has been studied[105] only from the temperature dependence of the stability constants of the OSC. The values of the enthalpy and entropy changes obtained in this way are naturally approximate. The quantitative data obtained (Table 8) indicate, however, that the addition of ammonia, ethylenediamine, and pyridine to hexamminecobalt(III) and also to tris(ethylenediamine)- and acetatopentamminecobalt(III) is accompanied by negative enthalpy and entropy changes. The addition of ethylenediamine and pyridine is accompanied by negative enthalpy and entropy changes of greater absolute magnitude than the addition of ammonia (Table 8). The ratio of the thermodynamic functions indicated above is due to the greater complexity of the structures of ethylenediamine and pyridine compared with ammonia.

Published data[26,76,79,81–83,92–94] make it possible to analyse the nature of the influence of the ionic strength of the solution on the formation of OSC. In all the systems examined, except the OSC of tris(2,2′-bipyridyl)- and tris(1,10-phenanthroline)cobalt(III), the ionic strength was maintained using sodium perchlorate. Increase in the concentration of this salt (that is in the ionic strength of the solution) decreases the values of the stability constants of the OSC. This decrease takes place as far as saturated sodium perchlorate solutions, and is due to the association of the cationic complexes with the perchlorate ion. The quantitative characteristics of the first stage of this association were examined in the previous section of the present review.

The contributions of the enthalpy and entropy components of the free energy changes vary in different ways with increase in the ionic strength of the solution for cationic complexes with different charges. In most cases, a decrease in the stability of the OSC of the tris(diamine)-compounds of cobalt(III) accompanies a decrease in the entropy component of the free energy changes at $I = 0$–0.5. The change from $I = 0.5$ to $I = 3.0$ leads to a further decrease in the stability of the OSC with an increase in the endothermicity of OSC formation[26,79,81–83].

For the doubly-charged cationic complexes, for example acidopentamminecobalt(III), and also for the singly-charged sulphatopentammine- and carboxylatotetramminecobalt(III), a decrease in the stability of the OSC is observed with increase in the ionic strength of the solution and the simultaneous increase in the positive enthalpy changes for the formation of the OSC.[26,76,92].

For the mixed coordination compounds $[M(en)_x(acac)_{3-x}]$, increase in the ionic strength of the solution leads to an increase in the positive enthalpy changes and to smaller positive values of the entropy change (Table 6). Increase in the ionic strength of the solution, maintained using sodium fluoride, leads to a decrease in the stability of the OSC of tris(2,2'-bipyridyl)cobalt(III), and also tris(1,10-phenanthroline)cobalt(III), and the absolute values of the negative enthalpy and entropy for the formation of the OSC increase[26, 93,94]. The influence of the ionic strength of the solution on the thermodynamic functions for the formation of the OSC is due to the association of the cationic complexes with the ions of the background electrolyte, and also to the dehydrating influence of the added electrolyte.

Table 9. Changes in the thermodynamic functions for the formation of monoligand OSC of the tris(ethylenediamine) compounds of chromium(III), rhodium(III), iridium(III), ruthenium(III), and platinum(IV) in solutions with $I = 0$ at 298 K.[29,45,78,84,91,125–128]

IV. OUTER-SPHERE COMPLEXES OF RHODIUM(III), IRIDIUM(III), PLATINUM(IV), AND CHROMIUM(III)

The study of the thermodynamics of the formation of OSC by rhodium(III), iridium(III), platinum(IV), and chromium(III) cations using the thermochemical method and extrapolation of the thermodynamic functions to aqueous solutions with zero ionic strength has been much less extensive than that for the corresponding cobalt(III) compounds. The formation of OSC by the tris(ethylenediamine) compounds of all these metals has been studied[45,78,84,92,125–127]; in addition, the formation of OSC with the chloropentammines has been studied for rhodium(III) [90,128] and platinum(IV),[45,86,89] with the tris(propylenediamine) compound for chromium(III),[91] and for the *trans*-dichlorobis(ethylenediamine) compounds for rhodium(III), iridium(III), and platinum(IV).[45] As with the cobalt(III) complexes, the outer-sphere ligands used were the sulphate, thiosulphate, sulphite, selenite, tellurite, and carbonate ions. The reaction of hydroxopentammineplatinum(IV) with chloride and bromide ions has been studied[45,89]. The OSC complexes of hexammine- and tris(1,10-phenanthroline)chromium(III) with sulphate ions have been studied[129,130] at different temperatures by the electrical conductivity method. Some of the data on the thermodynamics of the formation of the OSC of rhodium(III), iridium(III), platinum(IV), and chromium(III) are given in Tables 9–11.

Table 11. Changes in the thermodynamic functions for the formation of monosulphate OSC by *trans*-$[M(en)_2Cl_2]^{2+}$ ions in solutions with zero ionic strength at 298 K.[45]

M	$-\Delta G_1^0$, kJ mole^{-1}	ΔH_1^0, kJ mole^{-1}	ΔS_1^0, J mole^{-1}K^{-1}
Co(III)(Co(en)$_2$(SCN)Cl$^+$)	13.0	6.3	63
Rh(III)	12.1	5.4	59
Ir(III)	10.9	3.8	46
Pt(IV)	15.1	5.0	67

Note. See footnote to Table 9.

The data in Tables 9 and 11 show that in aqueous solutions with zero ionic strength at 298 K, all the monoligand OSC with doubly-charged ligands studied are formed with small (less than ±8.4 kJ mole^{-1}) changes in the enthalpy, and positive values of the entropy changes, equal to 63 ± 8 J mole^{-1} K^{-1}. The values of the entropy changes for practically all the OSC of hydrophilic cationic complexes lie in this range. There are only a few systems in which the

entropy changes lie outside this range. They include the sulphate OSC of *trans*-dichlorobis(ethylenediamine)iridium-(III), where $\Delta S_1^0 = 46$ J mole^{-1} K^{-1},[45] and also the sulphate and sulphite OSC of tris(ethylenediamine)platinum(IV), where $\Delta S_1^0 = 76$ J mole^{-1} K^{-1} and 84 J mole^{-1} K^{-1} respectively[76,84]. It is not yet possible to say unambiguously whether these deviations are due to experimental error or to specific features of the formation of the OSC.

In most cases, in contrast to the OSC of amine compounds of cobalt(III), only the formation of monoligand associates by amine compounds of rhodium(III), iridium(III), platinum-(IV), and chromium(III) has been studied. Qualitative and semi-quantitative indications of the formation of multiligand complexes have been reported[29,78,84]. Attempts to determine the thermodynamic characteristics of the formation of even the bis(ligand) OSC of, for example, chromium(III),[78,84] rhodium(III),[78,84] or platinum(IV),[31] however, gave extremely rough or approximate values of the thermodynamic functions. It can only be assumed that the bis(ligand) associates are formed with approximately the same changes in the thermodynamic functions as the OSC of cobalt(III).

The stability of the monoligand OSC of tris(diamine) compounds of rhodium(III), iridium(III), chromium(III), and platinum(IV) decrease in the following order of doubly-charged anions: thiosulphate > sulphite > selenite > tellurite > sulphate ions (Tables 9–11). This is less characteristic of the OSC of amine compounds of cobalt(III). A deviation from the above order is observed for OSC of chloropentamminerhodium(III), where the sulphate associates are more stable than the thiosulphate.

The chloride and bromide associates of tris(ethylenediamine)-, and also chloro- and hydroxopentammineplatinum-(IV), are formed (Table 10) with positive values of the enthalpy and entropy changes. The enthalpy and entropy changes for the formation of the bromide OSC of platinum(IV) are positive and of larger magnitude than those for the formation of the chloride OSC (Table 10). Usually, in the series of "fluoride–iodide" OSC, the absolute magnitude of the entropy changes decrease[71,94], even taking negative values for bromide and iodide OSC,[51,99] and high positive values of the enthalpy and entropy changes are observed only for fluoride OSC.[94] This variation of the enthalpy and entropy changes in the halide ion series is due to hydration factors. The anomalous ratios of the enthalpy and entropy changes for the chloride and bromide OSC of amine compounds of platinum(IV)[45] require verification.

The formation of sulphate OSC of hexamminechromium(III) takes place at values of the enthalpy changes close to zero, and the entropy changes are 63 J mole^{-1} K^{-1}.[127] At the same time, tris(1,10-phenanthroline) chromium(III) adds on sulphate ion with negative values of the enthalpy and entropy changes[126], confirming the thermodynamic data for the corresponding OSC of hydrophilic and hydrophobic cobalt(III) cations (Tables 5 and 7).

On going from the tris(diamine) compounds to the acidopentammines, and then to the *trans*-dichloro- or chloro-(thiocyanato)- (Tables 9–11) -bis(ethylenediamine) compounds of cobalt(III), rhodium(III), and iridium(III), the stability of the OSC decreases in this order for cationic complexes, because of the decrease in the charge on the cationic complexes. The stability of the OSC increases significantly on going from the triply-charged cations of cobalt(III), rhodium(III), and iridium(III) to the quadruply-charged cations of platinum(IV) (Tables 9 and 11).

Interesting relationships are observed in the analysis of data on the stability of the OSC of chloropentammines of cobalt(III) and rhodium(III) (Table 9). The thiosulphate, selenite, and tellurite OSC of chloropentamminecobalt(III) are more stable than the corresponding rhodium(III) compounds. The thiosulphate, selenite, and tellurite ions can transfer charge to the antibonding orbitals of chloropentamminecobalt(III). As a consequence of the greater splitting of the *d* orbitals in the rhodium(III) complexes, the outer-sphere charge transfer in these compounds is less than that in the corresponding cobalt(III) compounds[90,94,130]. For the association of sulphate ions, the charge transfer is slight, because the stabilities of the OSC of the chloropentammines of cobalt(III) and rhodium(III) with the sulphate ion are practically identical.

For most hydrophilic cationic complexes of cobalt(III), rhodium(III), chromium(III), platinum(IV), and iridium(III),[79,81,83,84,123–130] increase in the ionic strength of the solution, maintained by sodium perchlorate, leads to a decrease in the stability of OSC with different ligands L; with increase in I, the positive contribution of the entropy changes decreases. For the sulphate and tellurite OSC of tris(ethylenediamine)-iridium(III), the positive values of the enthalpy changes increase with increase in the ionic strength of the solution.

It should be noted that the dependence of the enthalpy and entropy changes on the ionic strength of the solution is not unique even for the OSC of cationic complexes with similar properties, for example chloropentamminecobalt(III) and chloropentamminerhodium(III).[130] Further studies are necessary to determine the reasons for such marked differences in the changes in the thermodynamic functions.

Table 12. Changes in the thermodynamic functions for the formation of monoligand chloride and sulphate OSC of tris-(2,2′-bipyridyl) compounds of iron(II) and ruthenium(II) at 298 K in aqueous solutions with constant ionic strengths, maintained using sodium fluoride[31,55].

Note. The standard deviations of the determinations are ±(0.3–0.5) kJ mole^{-1} for ΔG_1^0; ±(0.4–0.8) kJ mole^{-1} for ΔH_1^0; and ±(2–4) J mole^{-1} K^{-1} for ΔS_1^0. The data for the osmium(II) OSC are given in brackets.

V. OUTER-SPHERE COMPLEXES OF IRON(II), RUTHENIUM-(II), (III); AND OSMIUM(II)

At present, there are only isolated accurate data[34,131,132] on the thermodynamics of the formation of OSC by cationic complexes of iron(II) and ruthenium(II), (III), and information on the composition and stability constants of OSC of

osmium(II). The OSC of amine compounds of ruthenium(III) have been most fully studied by the thermochemical method[29]. Halide, perchlorate, sulphate, thiosulphate, sulphite, and selenite ions were used as outer-sphere ligands. Some of the data on the thermodynamics of the formation of these OSC are given in Tables 9 and 12.

The data in Table 12 and published data[29,53–55,57] indicate that the stability of the OSC of the tris(2,2′-bipyridyl) and tris(1,10-phenanthroline) compounds of iron(II), ruthenium(II), and osmium(II), in the great majority of cases, increases on going from Fe^{II} to Os^{II}; from the tris(2,2′-bipyridyl) to the tris(1,10-phenanthroline) complexes; and with change in the outer-sphere ligands in the order: chloride < bromide < iodide < perchlorate ions.

There is a linear correlation between lg β_1 and the heats of hydration of the outer-sphere ligands[29,31,33]

$$\lg\beta_1 = A + B\,\Delta H^0_{hydr}(L)$$

where A and B are constants for each cationic complex. For the OSC of iron(II), ruthenium(II), and osmium(II) studied, A lies in the range 3.4–8.5, and B in the range 0.018 to 0.062. A linear relationship is also observed between the value of lg β_1 and the reciprocal of the crystal-chemical radius (Goldschmidt) of the outer-sphere anion after allowing an empirical correction of 0.028 nm. The existence of these corrections indicates that in the association of hydrophobic cationic complexes, an important role is played by both electrostatic and hydration factors.

The stability of the above OSC decreases regularly with increase in the serial number of the added ligand. The published data[133,134] indicating deviations from this regular trend require verification. The increase in the stability of the chloride OSC in the order iron(II) < ruthenium(II) < osmium(II) is related to the decrease in the positive contribution of the enthalpy changes.

Studies by the present authors[55,131] have shown that the stability of the OSC depends to a much greater extent on the nature of the central metal ion when the inner sphere contains ligands forming π-bonds than when inner-sphere ligands forming only σ-bonds are present. In some systems (even when the inner sphere contains π-bonds), the differences in the stability of the OSC when, for example, ruthenium(II) is replaced by osmium(II) are small and disappear. This is indicated by the values of the free energy changes for the monochloride complexes of the tris(2,2′-bipyridyl) compounds of ruthenium(II) and osmium(II) in aqueous solutions with zero ionic strength, given in Table 12.

In general, the stability of monoligand OSC of tris(2,2′-bipyridyl) and tris(1,10-phenanthroline) complexes decreases in the following metal ion order: $Os^{II} > Ru^{II} > Co^{III} > Fe^{II}$. The tendency to form π-acceptor bonds increases from Fe^{II} to Os^{II}, that is in the order $3d^6 > 4d^6 > 5d^6$ ions. The hydrophobic properties of the cationic complexes increase in the order indicated, since the influence of the charge on the metal ion on the water molecules becomes weaker as it is shielded by ligands forming π-acceptor bonds. The position of Co^{III} in this series is explained by the decrease in the strength of the hydrophobic properties of the cationic complexes $[CoAm_3]^{3+}$, where Am = phen or bipy, compared with $[MAm_3]^{2+}$, where M = Ru^{II} or Os^{II}, and contradicts simple electrostatic ideas.

The greater stability of the OSC of tris(1,10-phenanthroline) complexes compared with tris(2,2′-bipyridyl) compounds is due to the more hydrophobic properties of 1,10-phenanthroline and the coplanar structure of the inner-sphere molecules of 2,2′-bipyridyl, which increases the size of the complexes $[M(bipy)_3]^{z+}$ compared with $[M(phen)_3]^{z+}$. This effect is not so marked for Co^{II} and Fe^{II}, but is appreciable for Ru^{II} and Os^{II}.

The order of the outer-sphere anions with respect to decreased stability of the OSC of hydrophobic cations is determined by the fact that a decrease in the heat of hydration and an increase in the size of the anions lead to an increase in their tendency to associate with hydrophobic cations. It must be assumed, however, that in these interactions, use is made of the structural cavities of the 2,2′-bipyridyl and 1,10-phenanthroline molecules coordinated to the cations, that is "hydrophobic packets". A number of experimental data[133,134], and also the fact that the maximum number of added ligands in the outer sphere is three[135,136], confirm this. For some tris(2,2′-bipyridyl) and tris(1,10-phenanthroline) complex systems, however, there are indications that a fourth ligand is attached. The question of the existence of these OSC remains open.

Sulphate OSC of tris(2,2′-bipyridyl)ruthenium(II) (Table 12), like the corresponding compounds of other hydrophobic cations, are formed with negative values of the enthalpy and entropy changes. In contrast to the case of the sulphate OSC of tris(2,2′-bipyridyl)cobalt(III), however, a sharp increase in the absolute magnitude of the negative values of the entropy changes is not observed with increase in the ionic strength of the solution.

Sulphate, thiosulphate, sulphite, and selenite OSC have been studied for a number of compounds of ruthenium(III). Tris(ethylenediamine)ruthenium(III) forms more stable OSC than chloropentammineruthenium(III), and this is explained by the charges of the cationic complexes (Table 9). As in the case of other coordination compounds of transition metals, the change from tris(ethylenediamine) OSC to chloropentammine OSC leads to an increase in the positive values of the enthalpy changes (Table 9). At zero ionic strength, OSC of chloropentammineruthenium(III) are formed, with higher values of the entropy changes (up to 84 J $mole^{-1}$ K^{-1}) compared with the OSC of tris(ethylenediamine)- and, probably, nitrosylpentammineruthenium(III) [137] ($\Delta S^0_1 \cong 54$–57 J $mole^{-1}$ K^{-1}), in contrast to the relationship observed for other metals. This is apparently due to the greater dehydration of the cationic complexes on the formation of the OSC of chloropentammineruthenium(III), compared with tris(ethylenediamine)ruthenium(III).

The stability of the OSC of tris(ethylenediamine)ruthenium(III) decreases[29] in the order of outer-sphere ligands: thiosulphate > sulphate > sulphite > selenite > sulphate ions, and that for chloropentammineruthenium(III) in the order: thiosulphate > sulphate > selenite > sulphite ions, but the decrease is small [the free energy changes for tris(ethylenediamine)ruthenium(III) and chloropentammineruthenium(III) in solutions with zero ionic strength are 0.5 kJ $mole^{-1}$ and 1.6 kJ $mole^{-1}$ respectively]. In aqueous solutions with zero ionic strength, the stability of the OSC of ruthenium(III) decreases in the following order of cationic complexes[31]:

$$[Ru(NH_3)_5(NO)]^{3+} > [Ru(en)_3]^{3+} > [Ru(NH_3)_5Cl]^{2+}.$$

The strong π-acceptor properties of the nitrosyl group and the possible resulting change in the actual state of ruthenium from Ru^{III} to Ru^{IV} [138] are responsible for the high stability of the OSC of $[Ru(NH_3)_5(NO)]^{3+}$ compared with those of $[Ru(en)_3]^{3+}$; the replacement of the nitrosyl group in the inner sphere of the cationic complex by chloride ion decreases the stability of the resulting OSC, since the charge on the cationic complex is lowered.

Unlike the OSC of the tris(ethylenediamine) compounds of cobalt(III), rhodium(III),[26,92,125] and chromium(III),[78] for the OSC of tris(ethylenediamine)ruthenium(III),[31] increased ionic strength of the solution leads to an increase in the positive values of the enthalpy changes and to a decrease in the contribution of the entropy component of the free energy.

VI. SOME GENERAL REGULAR FEATURES OF THE THERMODYNAMICS OF THE FORMATION OF OUTER-SPHERE COMPLEXES

Analysis of the data in Tables 4, 5, and 9–12, and the fairly accurate published data[106–109], show that entropy changes of $\Delta S_1^0 = 63 \pm 8$ J mole^{-1} K^{-1} and $\Delta S_2^0 = 29 \pm 8$ J mole^{-1} K^{-1} accompany the addition of the first and second doubly-charged anions to the great majority of hydrophilic coordinately-saturated inert and labile cationic complexes with charges from +1 to +4 in aqueous solutions with zero ionic strength at temperatures close to 298 K. The removal of one solvent molecule from the inner sphere of a cation into an aqueous solution leads to an entropy change of 30.54 J mole^{-1} K^{-1}.[139,140] This value is close to the entropy of fusion of ice[141] and to the entropies of water molecules coordinated, for example, to praseodymium(III) or ytterbium(III).[142] If it is assumed that the difference in the partial molar entropies of the associate and the ligand of the cationic complex is close to zero, it may be concluded that the addition of the first doubly-charged anions in the inner sphere is accompanied by the liberation of two water molecules.

The liberation of two water molecules on the addition, in the inner sphere, of the first doubly-charged anions to both hydrophilic and hydrophobic cationic complexes is indicated by data on the formation constants of OSC in aqueous-organic solutions (Tables 2 and 3). The entropy changes for the formation of OSC by hydrophobic cations (Table 7) do not indicate unambiguously the removal of two water molecules, since they are negative.

It has been suggested that sulphate ions are dehydrated when they add on to cations[106,107]. On the other hand, the difference in the entropy changes in the first and second stages of outer-sphere association provide a basis for assuming that water molecules are liberated as a consequence of dehydration of the cationic complex[26,98,124].

Increase in the ionic strength of the solution should decrease the magnitude of the entropy changes for the formation of OSC, if these changes are related to the dehydration of the anion–ligand, since the water hydrating this anion reaily combines with other ions. This is not observed in all systems, however[26,92,125]. At the same time, for hydrophobic cationic complexes it is necessary to assume that ions can associate by the combination of cavities or the entry of two ions into one cage created by the solvent[123]. In this process, the liberation of water molecules may take place from distant spheres of the hydrated cationic complex or from the anion–ligand.

The great majority of research workers consider that the formation of the first acido-OSC, like that of ordinary ion pairs, can be described[45,106,107] by the electrostatic theories of Bjerrum and Fuoss[143,144]. The processes of OSC formation should take place with a decrease in enthalpy and an increase in entropy[23], since according to these theories it is possible to write

$$\Delta H_1^0, \text{kJ mole}^{-1} = 0.891 \cdot b$$

$$\Delta S_1^0, \text{J mole}^{-1}\text{K}^{-1} = 58.16 \cdot \lg a^0 + 11.3 \cdot b - 49.8$$

where a^0 is the distance of closest approach of the associating ions, $b = z_C z_A e^2/\varepsilon k T a^0$, where z_C and z_A are the charges on the complex and the outer-sphere ligand, e the charge on the electron, ε the dielectric constant of the solvent, and k the Boltzmann constant.

Thus for charges of the associating ions equal to 1, 2, and 3, and $a^0 = 0.357$ nm, the enthalpy changes should be equal to[23] 1.7, 7.1, and 15.9 kJ mole^{-1}, and the entropy changes 5, 73, and 177 J mole^{-1} K^{-1} respectively. Increase in a^0 to 0.714 nm changes these values[23] to 0.8, 3.3, and 8.0 kJ mole^{-1}, and 11.3, 45.2, and 101.7 J mole^{-1} K^{-1}. The data in Tables 5, 10, and 11 show that the model based on the theories of Bjerrum and Fuoss effectively describes the changes in the thermodynamic functions for the formation of OSC by doubly-charged hydrophilic complexes with doubly-charged anions for $a^0 = 0.3$–0.5 nm. The associates of triply-charged hydrophilic cations with doubly-charged anions correspond only approximately to this model. The experimental data indicate, however, that the positive values of the enthalpy changes increase with decrease in the charge on the cationic complex (according to the theory, the positive values of the enthalpy should decrease[23]), and the positive values of the entropy change remain practically unchanged or increase slightly (according to the theory, the positive values of the entropy changes should decrease[23]). The changes in the thermodynamic functions for the formation of OSC by hydrophobic cations with doubly-charged anions (see Table 7) do not agree at all with the theories of Bjerrum and Fuoss[106,107] or with Ahrland's concept[106,107].

On the basis of the fact that the entropy changes for the formation of OSC by hydrophilic cationic complexes with doubly-charged anions are practically constant, and the regular decrease in the stability of the OSC with decrease in the charge of the complex and increase in the positive values of the enthalpy changes, some authors have predicted the values of the thermodynamic functions for the formation of OSC in systems which have not yet been studied[26,45]. For several systems, it has been found that the predicted values are close to those determined experimentally.

The formation of OSC by coordination compounds of cobalt(III), rhodium(III), chromium(III), and platinum(IV) is concentrated electrolyte solutions at 298 K is accompanied by free energy changes in the range ±(2–4) kJ mole^{-1}; the enthalpy and entropy changes lie in the range ±40 kJ mole^{-1} and ±(80–120) J mole^{-1} K^{-1}.[49,57,69–77,92–102] According to Ref. 26, there is a compensation effect between the values of the enthalpy and entropy changes under these conditions.

The lack of data on the thermodynamics of the OSC of inert coordination compounds of the transition metals at present makes a wider generalisation impossible (particularly for multiligand OSC). An increase in the volume of information and an increase in the accuracy and reliability of the experimental data are necessary.

Electron Paramagnetic Resonance of Free Radicals in the Two-millimetre Wavelength Range

O.Ya.Grinberg, A.A.Dubinskii, and Ya.S.Lebedev

Experimental data obtained in recent years on the electron paramagnetic resonance (EPR) of free radicals in the two-millimetre wavelength range are surveyed. It is shown that measurement of the spectra in this range makes it possible to increase greatly the amount of information derivable by the EPR method and its absolute sensitivity. The results of measurements of the magnetic resonance parameters of nitroxy-radicals, nitroxy-biradicals, and peroxy-radicals as well as data on the molecular mobilities of the above radicals in various matrices are presented.
The bibliography includes 62 references.

I. INTRODUCTION

The vigorous development of experimental methods whereby the amount of information derivable by the EPR method is increased and which open up completely new fields in which the method can be applied has taken place at the present time. The new fields include magnetic resonance laser spectroscopy in the submillimetre and near infrared ranges, used to investigate free radicals in the gas phase[1-3], the spin echo electron spectroscopy[4,5], used mainly to investigate the paramagnetic centres in solids, various combined methods employing the spin polarisation effects in which the EPR signal is recorded optically or from the change in the yield of the chemical reaction[6-10], saturation transfer spectroscopy[11], EPR in inhomogeneous fields (EPR tomography)[12], and a number of other new methods.

However, the majority of the methods indicated are applicable only to the solution of specific problems and to the investigation of specific objects. We shall consider the development of a new universal EPR technique associated with a sharp increase of the frequency of the measurements. For species with spin paramagnetism, an increase of the frequency of the measurements is associated simultaneously with the necessity to increase the magnetic field strength. Therefore, in contrast to experiments in the gas phase where the rotational or vibrational Zeeman transitions are used, in the case of spin-only resonance progress has been made virtually only in the two-millimetre wavelength range. However, in this range studies on the EPR of free radicals, biradicals, and certain paramagnetic complexes carried out in recent years at the Institute of Chemical Physics of the USSR Academy of Sciences have already yielded what we believe to be extremely interesting and very promising results. The state of this field is considered in the present review.

II. EPR IN THE MILLIMETRE RANGE: GENERAL PRINCIPLES AND POSSIBILITIES OF MEASUREMENT

The switch to stronger magnetic fields and the corresponding increase of the frequency of the measurements should in principle improve the fundamental characteristics of the magnetic resonance spectrometers: sensitivity and resolving power. Thus the sensitivity of EPR spectrometers is proportional to ω^{α}, where α assumes values ranging from 1/2 to 9/2 depending on the conditions of the measurement. It follows from the condition for magnetic resonance $\omega = \gamma H$ that, for centres of different types differing in the gyromagnetic ratio γ, the resonance fields at a fixed frequency of the measurement ω differ more the higher this frequency.

It can be shown on the basis of the most general physical considerations that the optimum, from the standpoint of the amount of information which can be derived, frequency of the observation of the magnetic resonance corresponds to kT/h in order of magnitude and occurs in the range $10^{12}-10^{13}$ Hz at the usual temperatures, i.e. constitutes the "physically optimal" submillimetre wavelength range.

Practice gained in NMR research has shown that a switch to the measurement of magnetic resonance in strong fields with a corresponding increase of the resonance frequency makes it possible to realise the possibilities underlying this procedure for the improvement of the sensitivity and spectral resolution. Whereas 20 years ago the 10-40 MHz wavelength range was usually employed, at the present time NMR is recorded in the wavelength range 300-400 MHz. On the other hand, in EPR the three-centimetre or X-range has been dominant during three decades. The explanation is that the experimental basis of the EPR spectroscopy, which was for a number of reasons developed from the very beginning in the 3-cm range, proved to be extremely successful and satisfied for many years the requirements of experimenters as regards sensitivity and resolution and also made it possible to combine readily EPR with various sources of the generation of paramagnetic species and with other research techniques. Another cause is probably that, in contrast to NMR, the usefulness of using high transitions in EPR is not quite so evident. Indeed, the basis of the increase of the spectral resolution with increasing magnetic field strength in NMR is the great variety and specificity of the chemical shifts for nuclei of different functional groups. The analogue of the chemical shift in EPR, which determines the displacement of the resonance lines with increasing field strength, is the g-factor.

For free radicals, which are the main objects of EPR studies in chemical physics, biology, and medicine, the values of g are near those of the g-factor of the free electron ($g_e = 2.0023$) and in most cases are not characteristic as the chemical shift in NMR. Bearing

in mind that experimenters have a large source of information in the field of EPR, namely the hyperfine and fine structures, one can imagine that interest in EPR studies in strong fields was insufficient to overcome the technical difficulties arising in this connection, which significantly held back the development of millimetre EPR spectroscopy. In particular, in the millimetre range not all the elements of the microwave technique are equivalent to those employed at the 3-cm range. Furthermore, here it is not always possible to use the best constructional solutions found for 3-cm EPR spectrometers. It was therefore expected that the sensitivity of a spectrometer of the millimetre range would not exceed or would even be inferior to the sensitivity of spectrometers for the 3-cm range.

Thus, general considerations alone are insufficient to provide an answer to the question of the likely usefulness of the development of high-frequency EPR; a special and broadly based series of experiments is necessary.

Fairly numerous studies in wavelength ranges below 3 cm are now available : in the K-range (12 mm) and the Q-range (8mm). An improvement of the absolute sensitivity of 2×10^{10} spins G^{-1} in the 3-cm range to 5×10^{9} spins G^{-1} in the Q-range was indeed achieved. However, in view of the increase of the working volume of the specimen, due to the decrease of the size of the measuring cell, the concentration sensitivity of such spectrometers was not improved.

We shall now turn to the problem of spectral resolution. At the present time one of the significant difficulties in the interpretation of the spectra consists in the identity of the g-factors for different radicals, which leads to the superposition of their spectra. This hinders greatly the interpretation of the spectra and the derivation of information from them; in particular, it precludes the use of the values of g as a source of information about the structure of the radicals. An analogous situation arises also in the absence of superimposed signals in the analysis of weakly anisotropic spectra in frozen solutions and powders[13].

The values of g for typical organic radicals differ from one another by $(1-10) \times 10^{-4}$. In the study of the signals in the three-centimetre range usually employed this leads to a line shift with respect to the field of 1–10 G and the overall extent of the spectra (taking into account the hyperfine structure) is 10–100 G. Comparison of the above values shows that, for an effective resolution of the spectral components of different free radicals, it is necessary to increase the working frequency by more than an order of magnitude compared with the centimetre EPR range, i.e. it is necessary to switch to the millimetre range for the measurement of EPR. According to estimates, a switch to the 12- and 8-mm ranges is in most cases insufficient for the effective resolution of the spectral lines.

In measurements at a wavelength $\lambda < 3$ mm the resolution should be sufficient in most cases, provided that the width of the individual line at least does not increase in this frequency range. Theoretical models predict a wide variety of line width–frequency relations, involving both a sharp increase and a sharp decrease, so that only systematic measurements can solve the problem of the likely usefulness of the millimetre range in high-resolution EPR.

The creation of spectrometers for the 1–3 mm range, suitable for the solution of physicochemical problems, requires the elucidation of a set of questions: (1) the question of sources, transmitting elements, and detectors for the millimetre and submillimetre radiations; (2) the question of the magnetic system of the spectrometer ensuring sufficiently intense fields, which must be varied and scanned over a wide range with retention of the high stability and homogeneity of the field; (3) the question of temperature control and the replacement in the course of the experiment of specimens of different types, including liquid and vitreous specimens.

Sources of the most traditional type in EPR spectroscopy consist of klystron oscillators. A series of their instruments and devices using wavelength ranges down to 2 mm have now been made based on the klystron. Thus the second harmonic of the klystron oscillator for the 4-mm range is used in the specrometer described in a monograph[14]. A specially developed klystron for the 2-millimetre range has been employed[15]. Backward-ware oscillators (carcinotrons[16]) have found extensive applications in spectrometers for the millimetre range; with their aid, it is possible to proceed to still shorter wavelengths[17].

With the aid of laser sources, it is possible to move into the infrared range and beyond. However, one must not forget that in the spectroscopy of free radicals an increase of the frequency of the spectrometer requires a proportional increase in the polarising magnetic field. Thus a field of ~1 MG is required for $\lambda = 0.1$ mm. Field strengths of 1 MG in an EPR spectrometer have been achieved[18] under pulsed conditions within a multisection solenoid of special design and pulsing lasers with the working wavelengths $\lambda = 337$ μm (based on HCN vapour) and $\lambda = 119$ μm (based on H_2O vapour) have been used as sources of radiation. Unfortunately, a spectrometer constructed on this principle cannot apparently be used for extensive studies of free radicals in view of its low concentration sensitivity due both to the obligatory broad recording band (for an amplitude of 1 MG of a pulsing field with a duration of 200 μs, the time taken to traverse a signal with a width of 10 G is 2 ns) and to the large on-off time ratio of the pulses. Furthermore, it is impossible to avoid the occurrence of large distortions in the shape of the spectrum which are difficult to analyse. Nevertheless, in cases where these factors do not play a significant role, such a spectrometer does indeed make it possible to obtain interesting information, which is not accessible by other methods[19].

The most promising magnetic systems are based on a superconducting solenoid. Superconducting 50–100 kG systems, in which the magnetic fields are generated in fairly large volumes, are nowadays commercially available and are fairly widely used in NMR. It is noteworthy that, since fairly large changes in the magnetic field strength are necessary in the course of the experiment during EPR measurements, the magnet of the EPR spectrometer must operate under the given power supply conditions and the cryomagnetic systems of NMR spectrometers operating under frozen field conditions are unsuitable for direct use in an EPR spectrometer. Appropriate modification of the magnetic system and its power supply do not apparently present fundamental difficulties.

The availability of the principal elements of EPR microwave spectrometers—magnetic systems, oscillators, and detectors (high-temperature crystalline and low-temperature n-InSB detectors)—made it possible to create a whole series of specialised EPR devices for the millimetre range[16,20–24]. It is noteworthy that the apparatus employed in the above studies had a limited scope with respect to two parameters which are of central importance in physicochemical research, namely sensitivity and the possibility of extensive variation of the temperature of the measurement.

The greatest possibilities for an increase of sensitivity involve the optimisation of the measuring cell of the spectrometer. In measurements using the simplest "through" circuits without a resonator, the sensitivity is minimal and amounts to 10^{13}–10^{14} spins G^{-1}.[24] The situation improves when extra large resonators[15] or Fabry–Perrault resonator interferometers[25] are used. However, these resonators

cannot be regarded as the best: in order to avoid unduly large losses of energy, it is necessary to employ specimens of special shape (which to not distort the distribution of the microwave field) and small size, i.e. to ensure low filling coefficients. We believe that the best solution involves the employment of low-mode volume resonators analogous to those employed in the X-range. Thus an absolute sensitivity of 4×10^7 spins G^{-1} and a concentration sensitivity of 2×10^{11} spins cm^{-3} G^{-1} have been obtained for a resonator of type H_{011} in the 2-mm range[26].

In spectrometers with a superconducting solenoid the specimen is placed within the solenoid and hence within a helium cryostat. The conditions in the EPR measurements are then necessarily limited to temperatures in the vicinity of 4 K; access to this specimen for its replacement and various manipulations is also hindered. In order to ensure the possibility of regulating the temperature of the specimen within a wide range, it is essential that the cryostat be provided with a thermally insulated working chamber for the measuring cell (as, for example, in the study of Galkin et al. [15]).

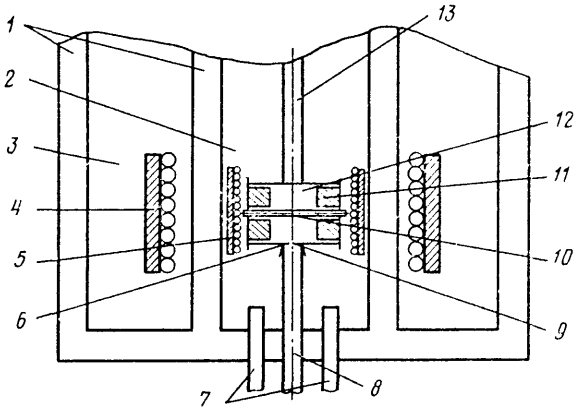

Figure 1. Schematic illustration of the positioning of the resonator in the working chamber of the cryostat of the EPR spectrometer for the two-millimetre range: *1*) thermally insulated vacuum jackets; *2*) working chamber; *3*) liquid helium; *4*) superconducting solenoid; *5*) magnetic modulation coils; *6*) disconnectable junction between the resonator and the UHF supply waveguide; *7*) inlet and outlet for the heat exchanger in the thermal stabilisation system; *8*) UHF supply waveguide; *9*) aperture for the adjustable linkage; *10*) bulb for the specimen 0.7 mm in diameter; *11*) adjustable piston for the adjustment of the volume of the resonator; *12*) cylindrical H_{011} resonator; *13*) fixing rod for the resonator and the regulating mechanims[26].

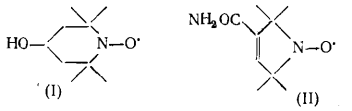
The above discussion shows that an EPR spectrometer for the 2-mm range with a polarising field up to 70 kG, with provision for the regulation of the temperature of the measurement within a wide range and with a sensitivity sufficient for the investigation of the majority of objects traditional in EPR spectroscopy, is at present entirely realistic. The concentration sensitivity attained in the 2-mm range is comparable to the sensitivity of standard spectrometers for the 3-cm range and the absolute sensitivity is greatly superior to the latter. This created conditions for the formulation of experiments designed to elucidate the prospects for the employment of EPR in the millimetre range in the study of free radicals.

A cryostat with a temperature controlled working chamber, in which was placed a type H_{011} resonator with a special tuning system and the junctions between the resonator and the waveguide, ensuring a rapid replacement of the specimens in the course of measurements, was incorporated in the EPR spectrometer for the two-millimetre range[15] which is used nowadays in the Institute of Chemical Physics of the USSR Academy of Sciences (Fig.1). So far as we are aware, this is at present the only experimental apparatus permitting the measurement of electron spin resonance spectra in the two-millimetre wavelength range for liquid, vitrified, and powdered specimens over a wide temperature range (100–350 K) and with a fairly high concentration sensitivity (2×10^{11} spins G^{-1} cm^{-2}). As already mentioned, the absolute sensitivity is 4×10^7 spins G^{-1} at room temperature and is maximum for EPR (a higher sensitivity can be achieved only in "on-equilibrium" experiments with optical or "chemical" recording of the signal[7,8] but such experiments are possible only for special objects). Liquid, frozen, and friable specimens were placed in a capillary ~0.7 mm in diameter (0.2 mm) for aqueous solutions), which was located on the resonator axis: solid single crystal specimens can be attached on the bottom of the resonator or on a special rod. The majority of the results described above were obtained on this apparatus. The system illustrated in Fig.1 is unsuitable for the study of specimens in the form of suspensions, native tissues, etc., which are difficult to insert into a thin capillary. Resonators of the Fabry–Perrault type can probably be usefully employed for specimens of this kind.

III. DETERMINATION OF THE MAGNETIC RESONANCE PARAMETERS AND THE STRUCTURE OF FREE RADICALS AND BIRADICALS



The g- factor of the paramagnetic centre (or the set of g-tensors) is one of the fundamental magnetic-resonance parameters[27]. The first systematic study undertaken in order to employ the g-factors to obtain physicochemical information about free radicals is apparently that of Stone[28]. He developed a general theory relating to g-factor to the molecular and electronic structure of the radical, devised a semi-empirical method for the calculation of g-factors, and compared the calculated and experimental data. Subsequently a whole series of similar studies were carried out in which the influence of solvents on the g-factor was considered apart from structural aspects and various modifications of Stone's theory were developed. Aromatic radicals[29], semiquinones[30], phenoxy-radicals[31], nitrofuran radical-anions[32], nitroxy-radicals[33], peroxy-radicals[34], and other radicals were investigated in succession. The possibility of the experimental observation and fairly accurate measurement of the changes in the g-factors within a "homologous" series of compounds or solvents was of decisive importance in these investigations.

Several studies devoted the the analysis of the accuracy of the experimental determination of the g-factor have been described[35,36]. The procedure involving the relative measurement of the g-factor on the basis of the shift of the given line relative to the reference signal is most widely used and is most convenient. In measurements of this type there is no need for the simultaneous accurate determination of the absolute frequency and field strength and it is sufficient to measure the resonance field of the reference line and the distance from the latter to the measured line with a much lower accuracy. The precision of such measurements is,

however, lower the greater the width of the individual components of the spectrum. Thus only solutions of radicals having EPR spectra with fairly narrow lines, whose width does not exceed 0.1–0.3 G, are susceptible to studies in the 3-cm range. The switch to the millimetre EPR range makes it possible, in principle, to increase greatly the accuracy of the measurements of the components of the g-tensor and thus to extend greatly the class of objects susceptible to investigation.

However, one should bear in mind that an improvement of resolution would be observed when addtional line broadening does not occur following an increase of the resonance frequency. As already mentioned, only experiment can lead to the discovery of systems in which a real improvement of the resolution of the spectra in measurements in the millimetre EPR range is possible.

Measurements in the millimetre range of the EPR spectra of free radicals with $g = 2$ in solution at room temperature were achieved for the first time in 1976.[37] Fig. 2 presents the spectra of a solution (10^{-3}M) of a mixture of stable radicals (I) and (II) in dioxan[37]:

Spectrum a, obtained on a standard spectrometer for the three-centrimetre range, demonstrates a virtually complete supersposition of the components of the individual spectra. Fig. 2b illustrates the complete resolution of the components of the individual spectra in measurements on a spectrometer for the two-millimetre range. The difference between the g-factors for radicals (I) and (II) is $\Delta g = 2.40 \times 10^{-4}$. The accuracy of the relative measurements is to within a factor reaching 10^{-5}, which makes it possible to employ the g-factor as an effective characteristic of individual paramagnetic compounds. Fig. 2b also shows that the width of the individual lines of the spectrum hardly changes on passing from the three-centimetre to the millimetre range.

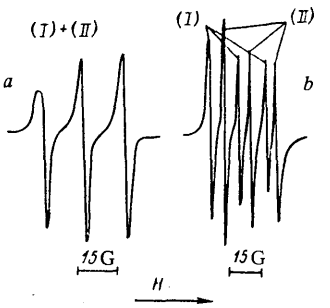


Figure 2. EPR spectra of solutions of a mixture of radicals (I) and (II) (1:1), 10^{-3}M) in dioxane. Measurements at 300 K on spectrometers for the 3-cm (a) and 2-mm (b) ranges[37].

In certain systems, usually in solids, such a transition leads to an additional broadening of the lines, but an improvement of the resolution is nevertheless still attained. An example of this type is provided by the peroxy-radicals $RO_2^{\cdot}$ investigated by Grinberg et al.[38], The simplest radicals of this series, namely $HO_2^{\cdot}$, were obtained in the photolysis of a 30% frozen H_2O_2/H_2O solution at 77 K. In contrast to the 3-cm range, in the 2-mm range the resonance lines corresponding to the radicals in which the principal axes of the g-tensor are directed along the external magnetic field canonical components) are fully resolved (Fig. 3a), which made it possible to determine the main values of the g-tensor ($g_1 = 2.00382$, $g_2 = 2.00821$, and $g_3 = 2.03362$). After heating the specimen to 140 K, some of the $HO_2^{\cdot}$ radicals recombined, which led to a narrowing and shift of the lines: $\delta g_1 = -1.05 \times 10^{-3}$ and $\delta g_2 = 1.33 \times 10^{-3}$. These changes in the EPR spectrum indicate, on the one hand, the structural inhomogeneity of the specimen as a possible cause of the additional line broadening in the two-millimetre spectra; on the other hand, they indicate a correlation between the stability of the radicals and their environment. Differences between the magnetic parameters of the middle (R_mO_2) and terminal (R_tO_2) peroxy-radicals in polytetrafluoroethylene have also been observed[38] (Fig. 3b). The principal values of the g-tensor were obtained: $g_1^m = 2.00232$; $g_2^m = 2.00743$; $g_3^m = 2.03813$; $g_1^t = 2.00278$; $g_2^t = 2.00770$; $g_3^t = 2.03963$.

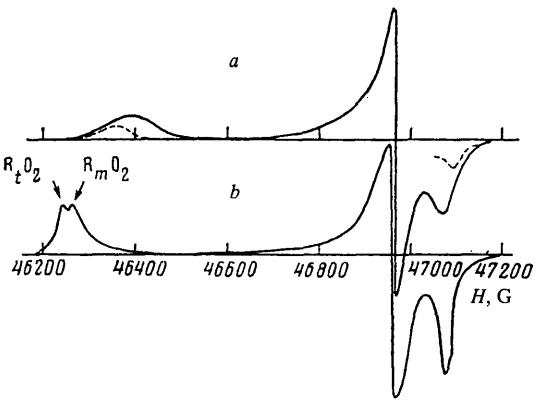

Figure 3. EPR spectra of peroxy-radicals in the 2-mm range: a) in H_2O_2/H_2O at 77 K; dashed line—after annealing at temperatures up to 140 K; b) in polytetrafluoroethylene[38].

Fig. 4a presents yet another example which demonstrates the complete separation of the spectra of the peroxy-, alkyl, and allyl radicals in polytetrafluoroethylene as a result of the effective resolution by the spectrometer in the two-millimetre range. The spectrum for the same specimen recorded in the 3-cm range, illustrated in Fig. 4b, is an unresolved blend of overlapping spectra unsuitable for analysis. The examples presented show clearly that the switch to the millimetre EPR range for free radicals in condensed media does indeed entail an improvement of the resolution with respect to the g-factor, which permits the separate recording of the group of lines of different radicals. On the other hand, the advantages of high-resolution spectroscopy can be used for the analysis of complex spectra of radicals of the same type when canonical groups of lines are resolved with increase of the resonance field strength. Figs. 5 and 6 present as examples the spectral solutions of the familiar compound $VOSO_4$ in H_2O and of the stable diphenylpicrylhydrazyl radical (DPPH) in toluene. Fig. 5 shows how appreciable is the simplification of the overall form of the spectrum of the vanadyl group in

the two-millimtre range compared with the spectrum in the three-centimetre range as a result of the separation of the components with perpendicular and parallel orientations to give isolated groups. On the other hand, the DPPH spectrum (Fig.6) shows the appearance of additional components but their positions make it possible to extract new information, inaccessible in measurements in the 3-cm range, about the components of the A and g tensors of the radical in a frozen toluene solution: $A = 20.9$ G and $g_{\parallel} = 2.00254$. It is noteworthy that a qualitative demonstration of the possibility of the resolution of the anisotropic doublet in the spectrum of DPPH powder was achieved as early as 1964.[16]

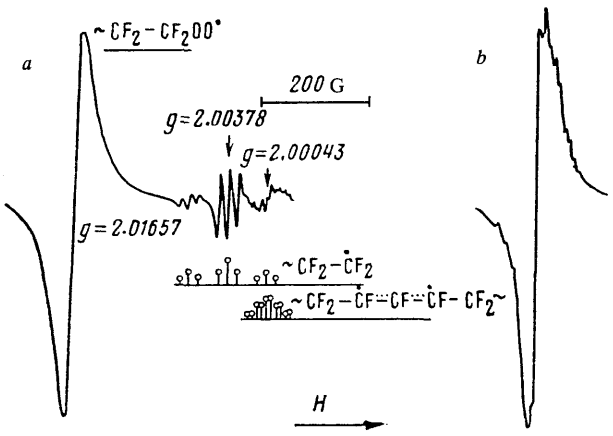

Figure 4. *a*) Separation of the EPR signals of the allyl, alkyl, and peroxy-radicals in polytetrafluoroethylene in the 2-mm range; *b*) spectrum of the same specimen in the 3-mm range[38].

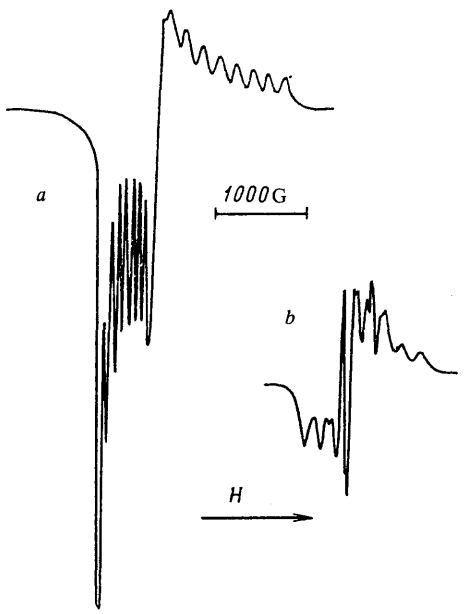

Figure 5. EPR spectra of VO^{2+} ions in sulphate glass in the 2-mm (*a*) and 3-cm (*b*) ranges[26].

The possibility of determining the principal values of the g- and A-tensors, which appears in the two-millimetre range, is particularly valuable in the case of nitroxy-radicals, which are widely used in chemical, biological, and medical research as spin probes and labels[39]. In order to obtain such information in the 3-cm range, the EPR spectra of single crystals, containing radicals as regular inclusions, were investigated. The preparation of such single crystals is difficult. Furthermore, the application of the method of spin labels and probes requires the introduction of radicals into different and as a rule non-single crystal matrices. Since the medium can influence the magnetic parameters[40], the employment of data obtained for single crystals is not always correct and inaccurate calculations of these data must be regarded solely as the zeroth approximation for undetermined variable parameters[39]. The magnetic resonance parameters measured directly in real polyoriented objects are therefore particularly valuable.

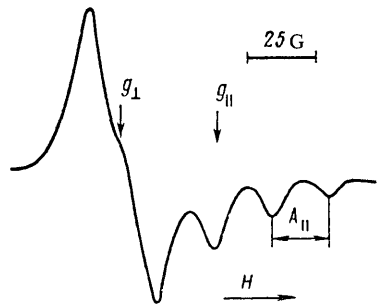

Figure 6. EPR spectrum of a frozen solution of DPPH in toluene in the 2-mm range[26].

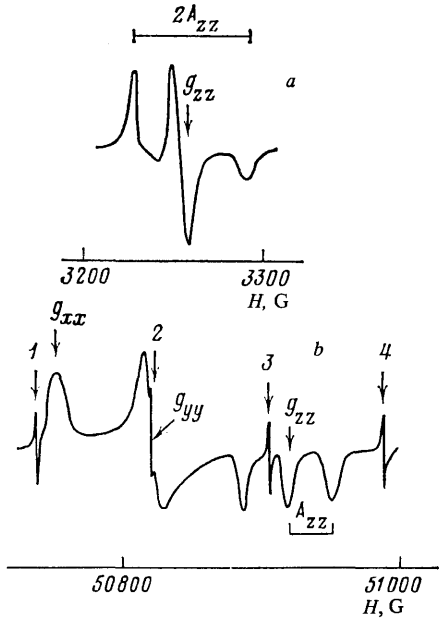

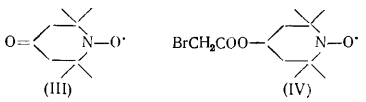

Figure 7. EPR spectra of a radical (III) solution in polystyrene at 77 K in the 3-cm (*a*) and 2-mm (*b*) ranges. The arrows indicate the components of the 1–4 spectrum of the Mn^{2+} lateral standard in MgO.

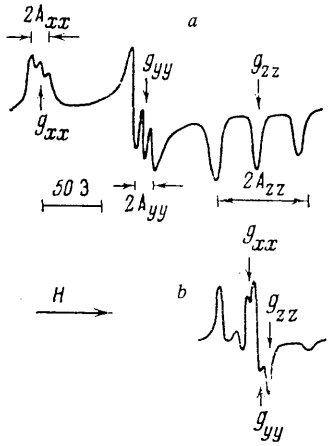
Fig.7 presents the spectra of a solid solution (10^{-3}M) of the stable radical (III) in polystyrene at 77 K.[37] Components corresponding to the three principal values of the anisotropic g-factor are distinctly seen in the spectrum obtained in the 2-mm range. One of the values of the anisotropic A-tensor can also be readily measured. Determination of the remaining principle values of the A-tensors (A_{xx} and A_{yy}) from the spectra of nitroxy-radicals of the type illustrated in Fig.7 is evidently difficult (z represents the direction at right angles to the plane of the radical fragment and x the direction along the N–O bond).

(III) (IV)



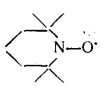


Figure 8. EPR spectra of a solution of deuterated radical (IV) in toluene at 140 K: *a*) 2-mm range; *b*) 3-cm range.

In order to improve the resolution of the UHF lines in the 2-mm EPR spectra, the familiar procedure of isotope substitution of H by D or of ^{14}N or ^{15}N has been used[41]. Fig.8*a* illustrates the spectrum of radical (IV) and the characteristic points from which the complete set of magnetic resonance parameters were determined directly. For comparison, Fig.8*b* presents the spectrum of the same radical in the three-centimetre range. It is noteworthy that for deuterium-substituted radicals there is a possibility, in principle, of determining the parameters also from the spectra in the 3-cm range[49]. However, this entails necessarily a complex analysis involving a theoretical calculation of the spectrum, which lowers the accuracy of the determination of the parameters and leads to a sharp increase of the time consumed. All the magnetic-resonance parameters of radical (V) with the ^{15}N isotope can be determined directly from the spectrum in Fig.9, as for the spectrum in Fig.8*a*.

(V)

The magnetic parameters of nitroxy-radicals of different types (about 70 individual structures) have been determined[43] from the EPR spectra in the 2-mm range. The principal values of the g-tensor of the nitroxy-radicals determined in the above study are presented in Fig.10 in terms of plots of g_{xx} against g_{yy} and g_{zz}. The figure shows that g_{xx} is most sensitive to the structure of the radical. It is noteworthy that the points corresponding to different radicals in the "space of g-factors" do not coincide in most cases, which permits the conclusion that the EPR resolution attained in the 2-mm range makes the g-tensor of nitroxy-radicals a characteristic parameter which extends the availabel range of analytical procedures. Analysis of Fig.10 shows that the values of g for nitroxy-radicals with identical structures of the radical ring are grouped in a definite region corresponding mainly to radicals of the given series. The values of g_{xx} for nitroxy-radicals of the piperidine series are in the range from 2.00975 to 2.01005, those for radicals of the 4-piperidine series are between 2.00955 and 2.00970, those for radicals of the 3-imidazoline series with the nitrone group are between 2.00917 and 2.00930, and those for radicals of the series without the nitrone group are in the range from 2.00905 to 2.00915, i.e. they decrease in the series of radical structures enumerated.

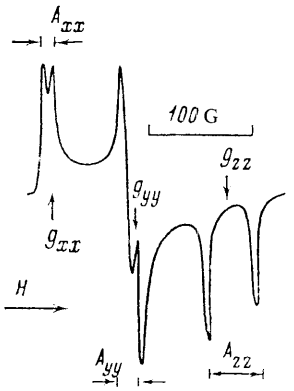

Figure 9. EPR spectrum of a solutlion of radical (V) with nitrogen substituted by ^{15}N in toluene at 140 K in the 2-mm range.

This behaviour, established in relation to a large number of radicals, is useful both in the assignment of the radicals to a particular class (i.e. in identification on the basis of EPR spectra) and in estimating the magnetic parameters of the radical on the basis of the type of its structure. These data are particularly important for the theoretical analysis of the structure of the radicals and its influence on the spectroscopic parameters. Thus in the series enumerated, there is a successive intensification of the interactions of π orbitals localised in the peripheral part of the radical with the π^* orbital of the N–O bond (the interatomic distance diminishes and the overlap of the orbitals improves), which alters the energy of the singly populated π^* orbital:

$$\delta E_{\pi^*} \simeq \Sigma \frac{V^2_{\pi^*\alpha}}{\Delta E_{\pi^*\alpha}} \qquad (1)$$

where α is the index of the peripheral orbital, $V^2_{\pi^*\alpha}$ the square of the matrix element approximately proportional to the overlap integral of the π^* and α orbitals, and $\Delta E_{\pi^*\alpha}$ the

difference between the energies of these orbitals. Overlap with the bonding peripheral π orbitals is more effective than with the antibonding orbitals, because in the latter there is partial compensation of the contributions by individual atomic orbitals. Terms with positive ΔE therefore predominate in the sum defined by Eqn.(1), which leads to an overall increase of the level of the singly populated π^* orbital of the NO group. The approximation[44]

$$\Delta g_{xx} = \lambda \rho_O^{\pi} / \Delta E_{n\pi^*}$$

is used for Δgxx. Here λ is the spin-orbital coupling constant for the oxygen atom, ρ_O^{π} the spin density at the oxygen atom, and $\Delta E_{n\pi^*}$ the energy of the $n-\pi^*$ transition.

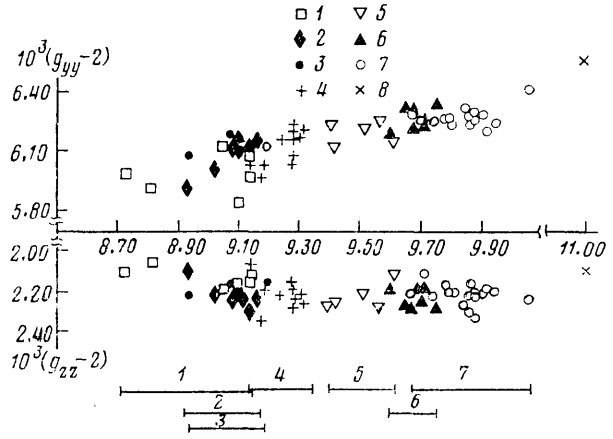

Figure 10. Principal values of the g-tensors for nitroxy-radicals having different structures; radicals derived from: *1*) imidazolidines; *2*) imidazolines; *3*) pyrrolidines; *4*) imidazolines with the N → O group; *5*) imidazolidines with phenyl substituents in the 4,4′-positions; *6*) 4-piperidines; *7*) piperidines; *8*) nitronylnitroxy-radical. The ranges incorporating the values of g_{xx} for radicals with the same ring structure are indicated below.

The positive shift δE_{π}^* leads to a decrease of gxx, which agrees with the relation discovered. Apart from the "direct" influence of peripheral orbitals described above, there are also other factors acting on gxx. It has been noted[43] that an increase of gxx is accompanied by an increase of the N-O bond length, a decrease of the angle between the N-O bond and the -C-N-C- plane, and the decrease of the CNC angle in the radical fragment. The examples presented show that high-resolution EPR (millimetre range) makes it possible to increase the accuracy of the measurement of the g-tensor components and to observe experimentally the fine changes in these quantities under the influence of various factors. The measured principal values of the A- and g- tensors can apparently be used to identify the radicals, in the study of the interaction of the radicals with the molecules of the medium, and in comparing spectroscopic data with the results of quantum-chemical calculations for radicals of different structures.

In certain cases it is possible to obtain from spectra in the two-millimetre range information about the structure of the centres investigated. The spectrum (Fig.11) of the middle peroxy-radical in polytetrafluoroethylene (PTFE), characterised by an axially-symmetrical g-tensor owing to the movement of the radical fragment around the polymer axis, has been recorded[44] at 300 K.

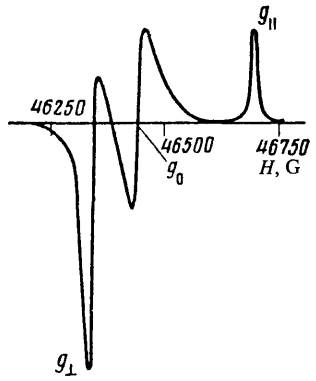

Figure 11. Spectrum of peroxy-radicals in polytetrafluoroethylene at 300 K; $g_{\parallel}$ and $g_{\perp}$ are components of the g-factor of the middle radical R_mO_2; g_0 is the component of the g-factor of the residual terminal R_tO_2 radical.

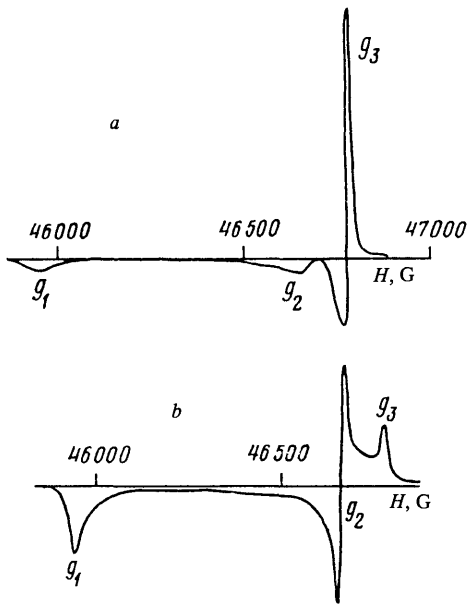

Figure 12. EPR spectrum at 100 K in the 2-mm range of the middle radical in polytetrafluoroethylene specimens oriented by stretching: *a*) extension axis parallel to the field; *b*) axis perpendicular to the field[44].

For radicals the axis of rotation of which is parallel to the external magnetic field, the presence or absence of rotation is in no way manifested in the EPR spectra. In the absence of rotation, the spectrum of these species are characterised by its g-factor

$$g = (g_1^2 l_1^2 + g_2^2 l_2^2 + g_3^2 l_3^2)^{1/2}, \qquad (2)$$

where l_i are the directional cosines of the axis of rotation relative to the principal axes of the g-tensor. For rapid rotation, the spectrum of these species in semioriented specimens corresponds to the components with $g = g_{\parallel}$. The above equation together with the relation

$$l_1^2 + l_2^2 + l_3^2 = 1 \qquad (3)$$

defines the curve on the surface of a single sphere—the geometrical locus of the possible positions of the end of the vector of the directional axis of rotation. Additional data about the position of the axis of rotation have been obtained from the spectra of partially oriented polytetrafluoroethylene specimens. Fig.12 shows that, when the axis of extension of the specimen is oriented along the magnetic field, the intensity of the g_2 component falls sharply. Consequently the molecular axis corresponding to this component is located near the plane perpendicular to the axis of extension. Having assumed that the axis of rotation coincides with the longitudinal axis of the molecule, which is oriented along the axis of extension during the stretching process, one can find that $l_2 \cong 0$. This estimate and Eqns.(2) and (3) made it possible to establish, after substituting the values of g_i, that the polymer axis in the XY plane makes an angle $\theta = 72°$ with the direction of the O–O bond. The location of the CO_2 fragment in the polytetrafluoroethylene molecule and the orientation of the principal axis of the g-tensor relative to the molecular axis are shown in Fig.13.

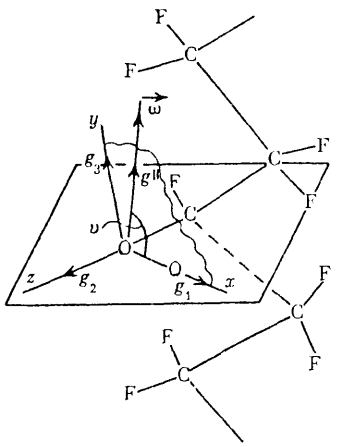

Figure 13. Disposition of the CO_2 fragment and of the principal axes of the g-tensor for the middle peroxy-radical relative to the polytetrafluoroethylene molecule[44].

The application of two-millimetre EPR holds out promise for extensive possibilities in the study of the structures of biradicals. Fig.14 illustrates the EPR spectra of a toluene solution of the *trans*-bis(2,2,5,5-tetramethyl-3-oxo-3-imidazolin-1-oxy-4-yl)ethylene biradical in the 3-cm and 2-mm ranges. Preliminary inspection showed already that the spectrum in the two-millimetre range is simpler and more convenient for analysis. The components in the spectrum in Fig.14 can be assigned by comparison with the spectrum of the monoradical (Fig.7). The spectrum of the biradical has a greater multiplicity of lines in the hyperfine structure (HFS) compared with the spectrum of the monoradical: the electrons of the biradical interact with the magnetic nuclei of both fragments. Furthermore, a doublet dipole–dipole line splitting appears. The spectrum illustrated in Fig.14*a* results precisely from the splitting of the canonical components in the spectrum of the monoradical (Fig.7) into dipole doublets when account is taken of the increase of the HFS multiplicity manifested in the z components.

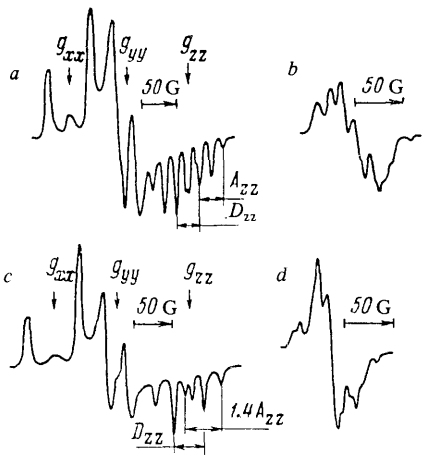

Figure 14. EPR spectra of nitroxy-biradicals (structure shown in Fig.15) in a 10^{-3} M solution in toluene at 140 K: *a*) and *b*) with ^{14}N atoms; *c*) and *d*) with ^{15}N atoms; *a*) and *c*) in the 2-mm range; *b*) and *d*) in the 3-cm range[45].

The positions of the components in the spectrum of the biradical are determined by the set of parameters characterising its structure and magnetic interactions, in particular the principal values of the fine structure D-tensor and the relative orientations of the axes of the g- and D-tensors. It has been established[45] that the axes of the g-tensors of both nitroxy-fragments of the biradical have the same directions and that the symmetry axis of the D-tensor is in the xy plane of the g-tensor and makes an angle of 14° with the x axis of the g-tensor.

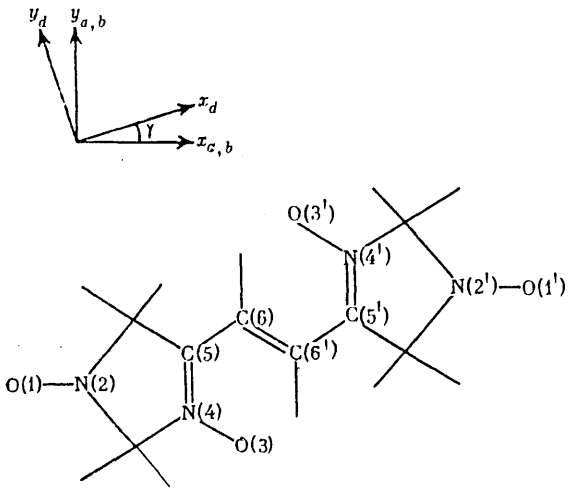
The geometrical structure of the biradical was established on the basis of the data obtained: the molecule has a planar structure and the *cis*, *trans*, *cis*-conformation relative to the C(5)–C(6), C(6)–C(6′), and C(6′)–C(5′) axes (Fig.15). Quantitative estimates of the delocalisation of the spin density from the NO radical fragment to the π-system of the C(3)–C(4)...C(4′)–C(3′) biradical have shown that the spin densities in the atomic orbitals of these nuclei are ~1%.

The examples considered demonstrate that, in the measurement of the spectra of free radicals in the 2-mm range in condensed media, an additional broadening of the individual lines is not as a rule observed. An increase of the resonance frequency entails a real increase of the resolution of the EPR spectra of free radicals which makes it possible to record separately the spectra of different radicals in the mixture, increases the accuracy of the measurement of the g-factors, and simplifies or simply makes possible the analysis of the spectra of the paramagnetic centres. From our point of view, the results presented justify the treatment of the spectroscopy in the millimetre range as high-resolution EPR spectroscopy with respect to the g-factor, which can yield valuable

physicochemical information about the structure of the paramagnetic species and their interaction with the medium.

IV. THE STUDY OF MOLECULAR MOVEMENTS

Studies of the molecular mobility in condensed media occupy a notable place in modern researches by EPR. Such investigations are based on the sensitivity of the form of the EPR spectra to the relaxation processes caused by the movements of the paramagnetic centres and their environment. The method of spin labels and probes, developed largely for the investigation of molecular mobility in biological objects[39] and polymeric matrices[46], has become particularly widespread. However, one already has to reckon with the limitations to this method associated, in particular, with the inadequate resolution in the spectra of typical labels (stable nitroxy-radicals are usually employed as labels and probes[39]). In this situation it is natural to use procedures which improve the spectral resolution, the most effective of which involves the measurement of the EPR spectra in strong fields.



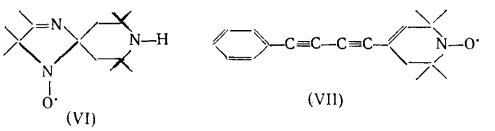


Figure 15. The structure of the *trans*-bis(2,2,5,5-tetramethyl-3-oxo-3-imidazolin-1-oxy-4-yl)ethylene biradical. Above —the relative dispositions of the axes of the $D(x_d, y_d)$ and $g(x_{a,b}, y_{a,b})$-tensors[45].

As early as 1976, interesting possibilities for the employment of EPR spectra in the two-millimetre range in the study of molecular mobility were noted[37]: in the fully resolved z components of the spectra of probe nitroxy-radicals, it is easy to observe the broadening (Fig.16) in which the frequencies of molecular movements in the range 10^7–10^8 s^{-1} can be determined directly (in the centimetre range a complex calculation of the line form is usually needed for this purpose. We shall consider the studies whose results demonstrate new, compared with the centimetre range, qualitative and quantitative possibilities for the employment of the millimetre EPR range. Studies of the anisotropy of the rotational lines are particularly instructive in this respect.

The procedure for the analysis of the anisotropy of the rotation developed for the EPR spectra in the three-centimetre range are more suitable for the region of rapid movements[47]. The knowledge of much more accurate values of all the magnetic parameters of the probe radical proved important under these conditions. In the previous Section it was shown that a realistic possibility for the determination of such data arises only in EPR measurements in the millimetre range. Thus progress in the determination of the magnetic parameters of nitroxy-radicals with the aid of millimetre EPR can serve as a basis for extensive studies of the anisotropy of rapid rotations in the centimetre range.

In the region of slow movements the manifestation of the anisotropy of the rotation leads to non-specific changes in the spectra in the 3-cm range[48] whose employment for the determination of the anistropy is difficult. On the other hand, in the millimetre EPR there is an entirely realistic possibility for the investigation of the anisotropy of the rotation precisely in the region of slow movements and important conclusions about the nature of the rotation (the presence of anisotropy, the direction of the preferential rotation axis) can be obtained directly from experimental data without resorting to a complex analysis of the spectra.

Radicals with different shapes, namely elongated[(VI) and (VII)] and nearly spherical [(V)], have been selected[49] for the study of the anistropy of the rotation of nitroxy-radicals in viscous matrices (liquid paraffin, vitrified toluene, etc.):

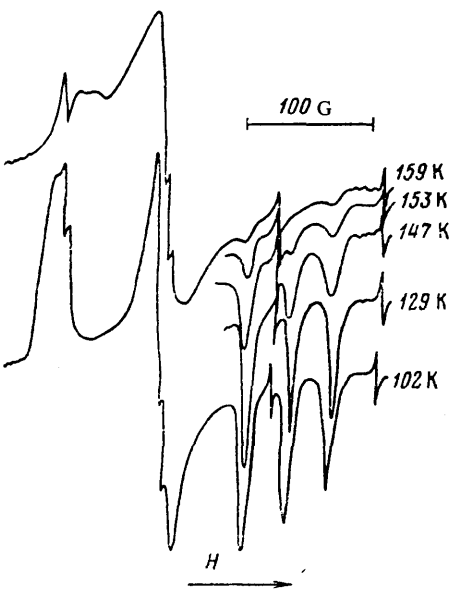

Figure 16. EPR spectra of radical (V) in a solution of polystyrene in toluene (15%) at different temperatures in the 2-mm range.

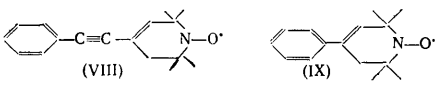
Furthermore, the long axes of radicals (VI) and (VII) are oriented in different ways relative to the principal axes of the g-tensor of the radical fragment. The direction of the long axis of radical (VII) is close to that of the x axis of the g-tensor, while radical (VI) direction of this axis is close to



that of the y axis. Fig.17 shows how the EPR spectra of the chosen radicals vary when the rotational mobility of the probes is "unfrozen" with the increase of temperature. The spectra were recorded in the two-millimeter range at 100–350 K. Fig.17 shows that the relaxation changes, manifested primarily in the broadening and displacement of the components of the spectrum, begin at lower temperatures for radical (VI) and are characterised by a greater depth for the x and z components than for the y component.

The effect described has a simple qualitative explanation. For species with anisotropic magnetic parameters, different resonance frequencies correspond to different orientations in an extermal magnetic field. Rotation of the species leads to exchange between states with different resonance frequencies, which induces relaxation changes in the spectrum. However, each rotation is not involved in such exchange with identical efficiency. In particular, the rotation of the molecule about the axis directed along the magnetic field does not alter the angle between the field and the axes of the g- and A-tensors, i.e. does not affect the resonance frequency. For the "ellipsoidal" radicals distributed isotropically in the specimen, the axis of rotation in some of the centres is oriented along the field and no relaxation changes are manifested in the EPR signals corresponding to these centres. In the case of radicals (VI) the species oriented with the y axis of the g-tensor along the field satisfy this condition. These species in fact give rise to the y component of the EPR spectra, which does not therefore exhibit relaxation changes whatever the changes in the other parts of the spectrum—the x and z components. Only on further increase of temperature, when movements giving rise to a reorientation of the direction of the long axis of the radical are fairly effective, does the y component begin to participate in the frequency exchange.

The anisotropy of rotation is manifested to an even greater extent in the spectra of radical (VII) which has a somewhat more extended shape. Here rotation takes place preferentially about the x axis of the g-tensor and it can be seen from Fig.17 that the x component of the spectrum is incorporated in the relaxation process significantly later than the y and z components. The longitudinal ($\nu_\parallel$) and tranverse ($\nu_\perp$) frequencies of the rotational correlation then differ so much that complete averaging of the spectral y and z components as far as the "exchange-narrowed" triplet is attained and the spectrum assumes the form characteristic of the axial symmetry of the A- and g-tensors. As in the case of radical (VI), further heating leads to the broadening of the parallel x component and the perpendicular components and to their displacement towards the centre of gravity of the spectrum.

In the spectra of radical (V) relaxation changes are observed simultaneously and to an equal extent for all three canonical components. In this case there is apparently no separate axis of preferred rotations, in agreement with the approximately spherical shape of the radical.

The influence of the matrix on the degree of anisotropy of the rotation of the probe was investigated in greater detail in a study[50] where the spectra were analysed within the framework of the model involving changes in the orientation of the molecule in jumps by uncorrelated angles[51]. It was shown[50] that in the region of "slow" movements the effect reduces to a broadening of the canonical components of the spectrum equivalent to the convolution of the initial line form with a Lorentzian line whose width is different for different components in anisotropic rotation. Thus, in rotation about the x axis of the g-tensor of the radical fragment along which radicals (VII), (VIII), and (IX) are extended, i.e.

the y and z components are convoluted with a Lorentzian line having a width

$$\delta_L = 1/\gamma\tau_\parallel + 1/\gamma\tau_\perp$$

and the x component is convoluted with a line having a width

$$\delta_L = 2/\gamma\tau_\perp ,$$

where $\tau_\parallel$ and $\tau_\perp$ are the correlation times of the axially symmetrical movement about the long and short axes of the probe respectively and γ is the gyromagnetic ratio.

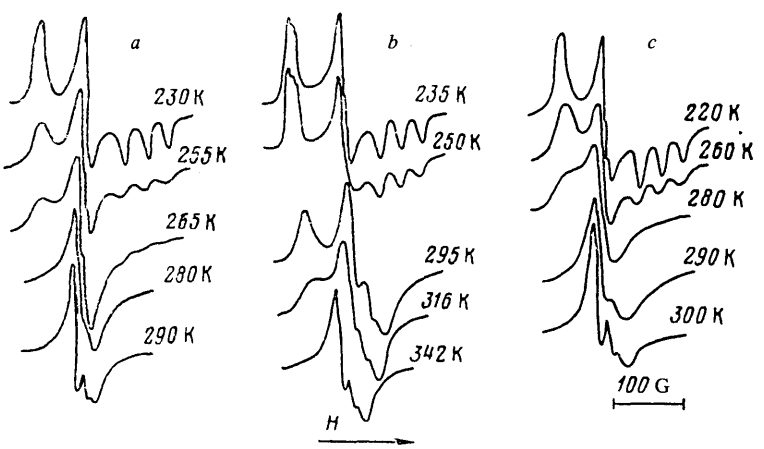


Figure 17. EPR spectra of solutions of the nitroxy-radicals (VI) (*a*), (VII) (*b*), and (V) (*c*) in liquid paraffin at different temperatures in the 2-mm range[49].

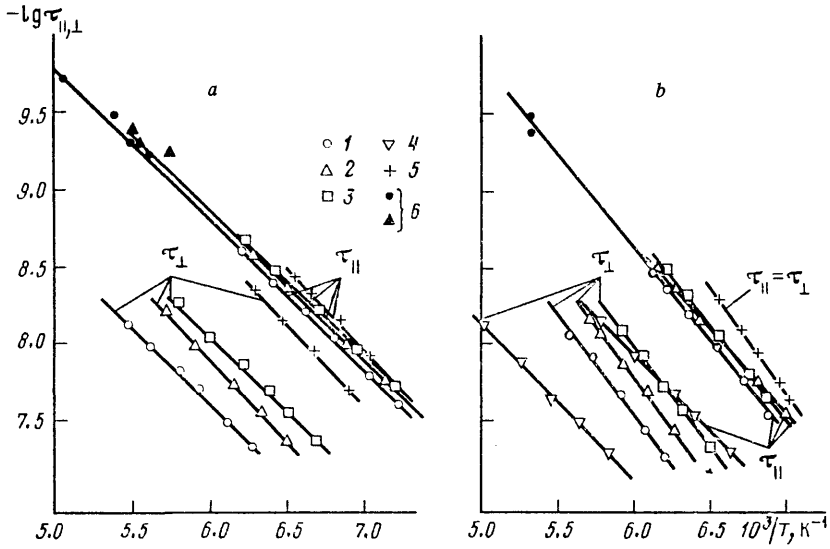

Figure 18. Arrhenius relations for the rotational correlation times of the radicals: *a*) in methanol; *b*) in toluene; *1*) radical (VII); *2*) radical (VIII); *3*) radical (IX); *4*) radical (X); *5*) radical (I); *6*) measurements based on the exchange-narrowed triplet[50].

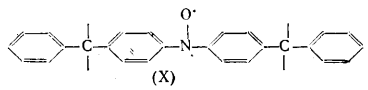
If the rotation of the probe was sufficiently anisotropic and a resolved triplet was formed as a result of the averaging of the *y* and *z* components of the spectrum, the correlation times $\tau_\parallel$ and $\tau_\perp$ were determined from the formulae

$$\delta_L^\parallel = 2/\gamma\tau_\perp$$



$$\delta_L^\perp = 2/\gamma\tau_\perp + \gamma(\Delta H_m)^2\tau_\parallel/8$$

for the parallel and perpendicular components respectively, where

$$\Delta H_m = g_0 H_0(1/g_{zz} - 1/g_{yy}) + m(A_{zz} - A_{yy});$$

$m = -1$, 0, +1 is the projection of the nuclear spin of nitrogen onto the magnetic field. Alcohols, (methyl, propyl, isodecyl, and isopentyl), toluene, liquid paraffin, and *p*-methoxybenzylidene-*p'*-butylaniline (MBBA) were chosen as the solvents.

Fig.18 presents the Arrhenius temperature variations of $\tau_\parallel$ and $\gamma_\perp$ for solutions of the radicals in toluene and methanol (in other solvents the relations were analogous). Over the entire range of measurements, the relations are linear. Fig.18 shows that a decrease of the length of the radical leads to a considerable (by a factor up to three) shortening of the time $\tau_\perp$. The time $\tau_\parallel$ for the same series of radicals diminishes by only 20%. For the radical

(X)

whose transverse dimension is greater than that of the radicals (VII)–(IX) and (V) and is close to the longitudinal dimension of radical (VIII), the variation of $\tau_\parallel$(X) is also close to that of $\tau_\perp$(VIII).

Thus the relations between the correlation times $\tau_\parallel$ and $\tau_\perp$ for different radicals in the same solvent are determined mainly by the dimensions of the radicals and $\tau_\parallel$ is influenced by the transverse dimension of the radical, while $\tau_\perp$ is influenced by its length.

The anisotropy parameters ($N = \tau_\perp/\tau_\parallel$) were measured for all the radicals at the temperature corresponding to the same $\tau_\parallel = 2\times10^{-9}$ s. The choice of this temperature was dictated by the fact that in its vicinity it is possible to determine simultaneously $\tau_\parallel$ and $\tau_\perp$ from the rotational broadening of the spectra. It was found that the anisotropy parameters *N* are either independent of temperature or decrease somewhat as the temperature is raised. However, the $N(T)$ relation could not be elucidated accurately, because the correlation times could be measured only over an inadequately wide temperature range. It was found that the anisotropy parameters depend greatly on the solvent and on the shape of the radicals. For example, in the series of alcohols *N* diminishes with increasing molecular weight of the alcohol: for radical (VIII), $N = 11.7$ in methanol and $N = 7$ in decyl alcohol. The lowest anisotropy parameters have been obtained for MBBA ($N = 5.7$) at temperatures below the region of its liquid-crystal state. A correlation with the parameters for different radicals in different solvents has been observed: firstly, the more extended molecule the greater the anistropy of its rotation in the given solvent and, secondly, if the anisotropy parameter of any one radical is greater in one solvent than in another, then an analogous relation is observed also for other radicals. The dependence of *N* on the properties of the radical and the solvent has been represented[50] by the empirical formula

$$N = KN_0, \qquad (4)$$

where N_0 is a parameter characterising the radical and depending solely on its geometrical dimensions; *K* is a parameter characterising the solvent for extended radicals; for spherical radicals, $N = 1$. Fig.19 illustrates the linear correlation between *N* and *K* in accordance with Eqn.(4). In order to account for the experimental data obtained, certain models of motion were examined[50] and it was shown that the model involving the "flickering of the free volume" yields the best agreement with experiment.

Another example of the study of the anisotropy of rotations in the millimetre range has been published by Grinberg et al.[44] They investigated the middle and terminal peroxy-radicals in polytetrafluoroethylene. In previous studies it had been found from three-centimetre[52] and eight-millimetre[53] data that the middle radical rotates as a rigid rotator in the vicinity of 300 K and that the axis of rotation is approximately perpendicular to the O–O bond. In the two-millimetre EPR range, not only all three principal values of the g-tensor but also the effective values of $g_\parallel$ and $g_\perp$ can be measured accurately by virtue of the full resolution of the components (Figs.3 and 11). The values of $g_\parallel$ and $g_\perp$ characterise the spectrum of the middle radical on partial averaging of the initial anisotropy to give cylindrical symmetry as a result of the rapid rotations about the axis of the rotator. The possibility of the accurate measurement of these parameters enabled the authors[44] to establish finally the disposition of the axis of rotation of the middle radical (the axis of the polymer chain) relative to the principal axes of the g-tensor. It was also found that, for the terminal peroxy-radicals the PTFE in the region of rapid movements (above 290 K), there is likewise no complete averaging of the spectra to give an isotropic singlet. It is noteworthy that these spectra (Fig.20) do not reduce either to the doublet characteristic of monoaxial rotation with the components $g_\parallel$ and $g_\perp$ (of the type shown in Fig.11), but consist of a set of such doublets with different parameters and statistical weighting factors. Thus it was possible to observe not only a definite "constraint" of the movement of the terminal groups at the polymer chain, leading to the anistropy of the rotation of the terminal RO_2 groups, but also the presence of a set of different structures of this fragment.

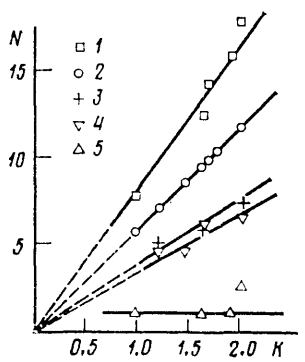


Figure 19. Dependence of the anisotropy parameter for different radicals on the solvent; radical: *1*) (VII); *2*) (VIII); *3*) (X); *4*) (IX); *5*) (I).[50]

A certain distribution of properties is in general characteristic of condensed media. In particular, molecular mobility can be inhomogeneous, i.e. characterised by a distribution with respect to rotational correlation times. The influence of kinetic inhomogeneity on chemical processes is well known[54,55] and procedures for its description have been adequately developed. There exist data concerning the manifestation of multiple frequencies of molecular rotations and the relaxation changes in the EPR spectra, but analysis is extremely difficult. The point is that even in the simple case of motion with a single correlation time, the changes in the spectrum are extremely complex, so that, for example, the determination of τ_c does not reduce (except in the region of rapid rotations) to the measurement of simple spectral parameters and it is in fact necessary to carry out a full synthesis of the spectrum and to compare it with experiment.

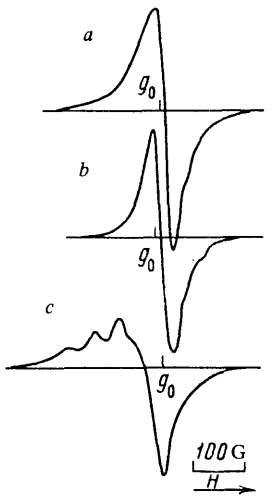

Figure 20. EPR spectra of terminal peroxy-radicals in the isotropic (*a*) and oriented by stretching (*b*,*c*) polytetrafluoroethylene specimens. The extension axis is parallel to the field at 300 K (*c*) or is perpendicular to the field (*b*); g_0—signal of the reference standard[44].

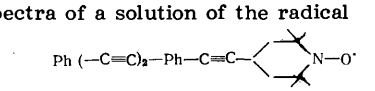
If one considers in addition the influence on the spectrum of the anisotropy of the rotation of the dynamic model of motion (diffusion, jump, or free rotation[56]), then the problem of the determination of the parameters of the distribution with respect to the correlation times of the molecular movement of the radicals from the EPR spectra in the three-centimetre range becomes virtually insoluble. Progress can be made in this field only in special cases of the so called "isolated", i.e. well resolved from the remainder of the spectrum, components. If the movement of the paramagnetic centre induces the frequency exchange of this component with the spectrum, the changes reduce simply to a broadening linear in terms of the exchange frequency and to its shift to an extent for which its overlap with other parts of the spectrum begins. An example of such components can be provided by the forbidden $\Delta M_S = 2$ transitions in radical dimers, on the basis of the spectra of which it proved possible[57,58] to establish the presence of distributions with respect to the correlation times and to determine the parameters of the distribution. Another example may be the canonical components in the spectra characterised by the anisotropy of the magnetic parameters. Since the effectiveness of the employment of these components in order to characterise the movement depends on the degree of their resolution, the best results can be obtained in the millimetre EPR range.

Such analysis of the relaxation changes of the x component of the spectrum (Fig.3) of the middle peroxy-radical in polytetrafluoroethylene as a function of temperature has been carried out[44]. The decrease of the amplitude of the x component is far in advance of its broadening, i.e. the integral

intensity diminishes, which is inconsistent with the hypothesis that relaxation processes influence spectra of this type. According to calculations[59], the changes in the canonical components of the anisotropic spectra reduce, as already mentioned, to their broadening and displacements and, so long as the component is observed as an isolated component, i.e. the overlap with the neighbouring components has not begun, its integral intensity remains unaltered. The decrease of the integral intensity of the x component observed in the case under consideration can be induced by the scatter of the values of τ_C in the specimen, so that the component for some of the radicals characterised by short τ_C is greatly broadened and is not recorded.



The analysis of the decrease of the intensity of the x component with increase of temperature[44] established the distribution with respect to the activation energies for the movement of the radical and led to the determination of the parameters of this distribution. It must be specially emphasised that, whereas the data obtained previously for the inhomogeneity of the molecular mobility referred to movements involving different types of rotation, in the given instance one is dealing with rotations of a rigorously defined type—about the axis of the polymer chain.

The anisotropy of the rotational mobility is frequently accompanied by the orientational order of the molecules in the specimen. The character of the rotation of the probe molecule is determined by the structure of its immediate environment—the structure of the "cell" in which it is placed. The cell follows to some extent the shape of the probe and is elongated for an elongated species. The probe is oriented preferentially along the long axis of the chain. If the specimen as a whole is disordered, the cells are distributed isotropically. However, the specimen can be also non-isotropic—for example, it can consist of extended polymers, liquid crystals in external fields deposited on the support of the system, etc. In such cases the angular distribution of the probes is also non-isotropic, which is manifested in their EPR spectra.

The possiblity of the analysis of the angular distribution of the radicals on the basis of EPR spectra depends on the anisotropy of their magnetic-resonance parameters, i.e. on the extent to which the resonance fields for different orientations of the radical relative to the direction of the magnetic field of the spectrometer are different. The data presented in the preceding Sections show that only in the millimetre EPR range it is possible to achieve the optimum conditions for the investigation of the anisotropy of the distribution of the nitroxy-radicals widely used as probes and labels as well as peroxy-radicals for which the ~O–O· fragment can be regarded as a paramagnetic label on the "body" of the molecule.

We considered above, in relation to the study of Grinberg et al.[44], how the orientation of PTFE molecules by the stretching of the polymer is manifested in the EPR spectra of peroxy-radicals in the 2-mm range (Figs.12 and 20). It must be emphasised that an increase of the spectral resolution did in fact permit in the given instance a detailed description of the structure of the radical centre (Fig.12) and the differentiation of the individual structures of chemically equivalent radicals.

The study of the orientational order of nitroxy-radicals in the millimetre EPR range is very promising[60]. Fig.2 presents the spectra of a solution of the radical

in MBBA at different temperatures of the measurement. The compound MBBA is characterised by the presence of a nematic phase in the range 290–318 K. The spectrum (Fig.21*a*) of the isotropic liquid phase (above 318 K) has a structure characteristic of the axial symmetry of the g- and A-tensors and corresponds to probes rapidly rotating around the long x axis of the radical ($g \cong g_{xx}$) and the directions of the x axes are distributed isotropically (analogously to Fig.17*b*). On passing to the nematic phase (Fig.21*b*), the spectrum is localised in the vicinity of the resonance field corresponding to the orientation of the radical with the x axis along the direction of the field. Thus the orientation of the domains of the nematic MBBA in the magnetic field leads to a pronounced (almost complete) orientation of the "cells" containing the probe. This structure of the matrix can be "frozen" by the rapid cooling of MBBA to below 250 K. Fig.21*c* presents the spectrum of the frozen specimen, which is close to the spectrum in Fig.21*b*.

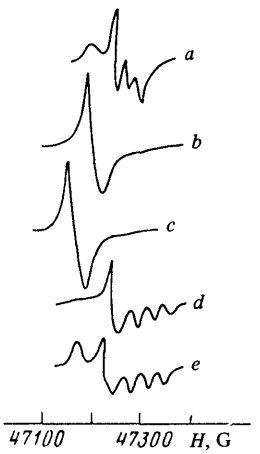


Figure 21. EPR spectra of a solution of nitroxy-radicals in MBBA in the 2-mm range. Temperature of the measurement (K): *a*) 320; *b*) 290; *c*)–*e*) 200; *c*) specimen of the nematic phase frozen at 200 K in the field of the spectrometer; *d*) specimen *c* frozen outside the field of the spectrometer; *e*) frozen specimen of the isotropic MBBA phase.

Ordering in the nematic MBBA phase can be induced also under the influence of the walls of the bulb. If the specimen (quartz capillary with an internal diameter of 0.5 mm) is kept at 300 K, is rapidly frozen outside the field, and the EPR is recorded without raising the temperature, then the corresponding spectrum (Fig.21*d*) does not contain the x components, which corresponds to a distribution of the radicals with the x axis preferentially perpendicular to the field [the axis of the bulb in the spectrometer (Fig.1) is perpendicular to the axis of the solenoid]. Freezing of an isotropic phase specimen leads to the spectrum illustrated in Fig.21*e*, which corresponds to a random distribution of the radicals. The loss of orientational order is also observed in frozen specimens subjected to preliminary orientation under the influence of the field of the spectrometer or the walls of the bulb. Under these conditions, in the initial spectrum of the type illustrated in Fig.21*c* the y and z components appear and increase in intensity, the intensity of the x component falls, and in the limit the spectrum tends to the form shown in Fig.21*e*. Such randomisation apparently corresponds to a transition from the vitrified structure of the liquid crystal to the polycrystalline form and is extremely slow (tens of minutes at 250 K).

The example considered demonstrates the possibilities of the millimetre EPR range in the study of the angular distribution of radicals and the factors leading to the establishment and loss of orientational order in the substance.

Whereas in the case of slow molecular movements, the millimetre EPR makes it possible to obtain different qualitative characteristics of the movements of radicals, in the case of rapid movements such EPR permits a considerable expansion of the range of the measured correlation times. In the region of small values of τ_c the components of the spectrum occupy positions defined by the isotropic (averaged as a result of rotation) values of the magnetic parameters and the widths contain a contribution "incompletely averaged" by the movement. Thus in the simplest case of the frequency exchange between the components of a doublet with a 1:1 intensity ratio separated by a frequency interval $\Delta\omega$, the residual broadening is[61]

$$\delta H \simeq (\Delta\omega)^2\tau_c/\gamma \ .$$

The expresson for δH relating to spectra with anisotropic parameters can be more complex (see Chapter III in Berlinger's book[39]), but here too the residual broadening is greater the greater the initial extent of the spectrum in the limit corresponding to slow molecular movements. The range of the averaged frequencies then increases with increase of the polarising field owing to the contribution determined by the anisotropy of the g-factor ($\Delta\omega \cong \gamma\Delta g H_0$), so that complete averaging in the spectra in the millimetre range requires higher frequencies of the movement than in the 3-cm range.

The limits within which τ_c is accessible to measurement which are attainable in the 3-cm and 2-mm ranges have been compared[62]. It was shown that, on the side of rapid movements, the boundary of the measured correlation times shifts from 6×10^{-11} to 4×10^{-12} s on passing from the three-centimetre range to the two-millimetre range. The above values change somewhat when the matrix is replaced or when the structure of the probe is altered as a result of a change in the limiting (not averaged by rotation) line width, but the overall effect of the transition to the 2-mm range (amounting to more than an order of magnitude) is preserved.

V. CONCLUSION

The results presented above, obtained with the aid of EPR in the two-millimetre range, demonstrate, in the present authors' view, the possibility of obtaining qualitatively new information in fields such as the metrology of free radicals, the study of molecular mobility, the study of the electronic and geometrical structures of radicals and biradicals, the study of matrix effects, etc. It is important to note that the qualitative leap forward is due to the appearance of the possibility of measuring electron spin resonance in strong fields over a wide temperature range and in objects of different types, characteristic of both chemistry and biology. All the advances enumerated above are associated with the increase of the resolving power of the method. The relative increase of frequency on passing from the 8-mm range, adopted for a long time, to the 2-mm range does not exceed the increase of the frequency on passing from the 3-cm to the 8-mm range, but experiment confirmed the estimates presented at the beginning of this review, according to which conditions leading to a high resolution of the spectra of typical organic free radicals occur precisely in the wavelength range shorter than 3 mm. This makes it possible to regard the EPR spectroscopy in the two-millimetre range as a method for the investigation of free radicals which has a high resolving power with respect to the g-factors. Apart from the applications already tested, one may specify a series of further applications whose likely usefulness follows from the parmeters attained in the EPR in the millimetre range.

The high absolute sensitivity ($\sim5\times10^7$ spin G^{-1}) can be used for the investigation of micro-objects. With this sensitivity, it is easy to show by calculation that the signal due to 10^{-13} g of the stable DPPH radicals can be recorded. If a spin-labelled object with a concentration of the usual spin labels of 10^{-5} mole cm^{-3} is used, then a specimen with a linear dimension of 2–3 μm can be used to measure the spectrum, i.e. in principle there is a possibility of investigating individual living cells, etc. For ferromagnetic particles with a narrow ferromagnetic resonance line, the lower limit of the size of the specimen may be only 10^{-15} cm^3.

The high absolute sensitivity combined with a high resolution with respect to the g-factor, which makes it possible to detect the perturbations induced by weak intra-electronic and interelectronic interactions, makes it possible, in principle, to use the EPR millimetre range for microchemical analysis using stable radicals as specific reagents. The high absolute sensitivity and also the high sensitivity to the angular orientation of the paramagnetic centre in the presence of the anisotropy of the g-factor make EPR in strong fields a promising procedure for tomography (zeugmatography) of small objects with a higher spatial resolution than in NMR or EPR in the centimetre range. Estimates have shown that in favourable situations (high concentrations, narrow lines) the spatial resolution can reach 0.1–1 μm.

The suppression of forbidden transitions and the weakening of the interaction between the individual resonances make EPR in intense fields a convenient method for the investigation of the relaxation effects, transmission effects, and the transfer of saturation.

Thus by no means all the possibilities inherent in the EPR spectroscopy of the two-millimetre range have been so far realised. All this gives rise to the hope that greater sophistication of the experimental technique associated with the transition to the range of millimetre wavelengths will be justified by the increase of the amount of information derivable from the measurements and the expansion of the applications of the EPR method.

Electron Spin Echo Study of the Steric Characteristics of the Formation and Reactions of Radicals in a Solid Phase

Yu.D.Tsvetkov

The general characteristics of electron spin echo (ESE) spectrometers are considered. A Soviet spectrometer and certain foreign instruments used in physicochemical research are described. The fundamental postulates and results of the theory of magnetic dipole-dipole interactions are briefly formulated in relation to the analysis of the results obtained by the ESE method.
Studies by the ESE method of the steric characteristics of chemical reactions in solids are surveyed. Investigations of the structures of radical tracks in irradiated organic and inorganic systems are considered and it is shown that data concerning the pair distribution function with respect to distances in ion—radical pairs can be obtained by the relaxation probe method and the method of double electron—electron resonance in ESE spectroscopy. The principal results of the investigation of the pair distribution in the formation of radicals under the influence of ultraviolet light and γ-rays as well as the changes in the pair distribution in the course of diffusion and reactions of free radicals and atoms in frozen glasses are discussed.
The bibliography includes 64 references.

I. INTRODUCTION

The development of UHF techniques in recent years makes pulsed EPR methods increasingly available for various physicochemical applications. Among these procedures, the electron spin echo (ESE) method—a special pulse variant of EPR, analogous in its experimental formulation to pulsed echo methods in NMR spectroscopy[1,2]—has developed extensively. In this method, under $\omega_0 = \gamma H_0$ resonance conditions (γ is the gyromagnetic ratio for the electron and H_0 the external magnetic field), the spin system is acted upon by a series of UHF pulses and the spontaneous emission from the system—the spin echo signal—is investigated (Fig.1). In the two-pulse variant of the excitation, the primary echo is produced, while in the three-pulse variant a stimulated echo is produced. The first 90° UHF pulse gives rise to a coherent state of the spin system, which is correlated as regards initial phase. The break up of this state into individual "isochromatic components" in the $xy \perp \mathbf{H}_0$ plane of the coordinate system, rotating at a frequency ω_0 about the z axis, is caused by phase relaxation (transverse) processes (with a time T_2) and the restoration of the magnetisation to the equilibrium value M_0 along the $z \parallel \mathbf{H}_0$ axis is due to the spin-lattice relaxation (longitudinal) with a characteristic time T_1. A 180° pulse applied at a time interval τ reverses the movement of the isochromatic component, which gives rise to the echo signal at time 2τ. The signal amplitude $V(2\tau)$ diminishes as the time interval τ between the UHF pulses is altered.

The spin echo for paramagnetic species was first observed by Blume[3,4] (USA) in a study of solutions of sodium in liquid ammonia. The ESE theory has been at present developed in fair detail[5-7]. For physicochemical applications, the following characteristics of the ESE method must be noted.

1. Compared with the stationary EPR method, which constitutes a frequency domain spectroscopy, ESE is a time domain spectroscopy in which the times of the evolution of the spin system (T_1, T_2) are recorded directly.

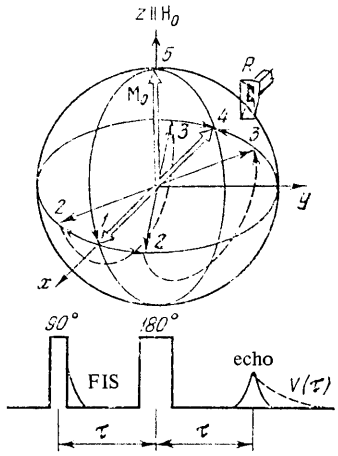

Figure 1. The vector model of the generation of a spin echo signal; a 90° pulse rotates the magnetisation vector $\mathbf{M}_0$ in the xy plane (*1*); decomposition of $\mathbf{M}_0$ into isochromatic components at a rate T_2^{-1} (*2*) inducing a free induction signal (FIS) in the receiver (*R*); rotation of the isochromatic components by an 180° pulse (*3*); restoration of $\mathbf{M}_0$ along the x direction (*4*)—the generation of the echo signal; restoration of $\mathbf{M}_0$ along the z direction as a result of the spin–lattice relaxation at a rate T_1^{-1}; τ—time between pulses; $V(\tau)$—decay of the echo signal as τ is altered.

2. The possibility of obtaining the ESE signal (the break up of the overall magnetisation vector $\mathbf{M}_0$ into isochromatic components and its subsequent restoration) arises via a mechanism involving the static inhomogeneous broadening of the EPR line, while the kinetics of the decrease of the LSE

signal $V(2\tau)$ with increase of the time interval between the UHF pulses, i.e. the form of the relation, contain information about the different time-dependent stochastic processes in the spin system. These processes also arise as a consequence of magnetic interactions such as magnetic dipolar (electron–electron and electron–nucleus) or exchange interactions. Thus ESE makes it possible to investigate magnetic interactions under conditions uncomplicated by the inhomogeneous static line broadening of the kind which occurs in the stationary EPR.

3. The magnetic interactions in the spin system lead in addition to the modulation of the relaxation decay of the ESE signal. The Fourier transformation of the modulated decrease yields the frequencies and amplitudes of the magnetic interactions. A unique feature of ESE is the possibility of analysing relatively weak hyperfine and quadrupole interactions in polyoriented systems, which creates a basis for structural applications of the method.

4. As a pulsed variant of EPR spectroscopy, ESE can be conveniently combined with various physical and specially pulsed influences on the test system. There exist kinetic variants of ESE in which paramagnetic species are generated by light[8], a laser pulse[9], or a fast electron pulse[10]. Methods in which the system is acted upon by electric field pulses have been developed[11].

In the present review we shall consider only one of the fields of the physicochemical applications of the ESE method—studies of the steric characteristics of the formation and reactions of free radicals, atoms, and ions in solids. These investigations are based on measurements for magnetic dipole–dipole interactions. They were begun at the Institute of Chemical Kinetics and Combustion of the Siberian Division of the USSR Academy of Sciences in 1965 on the initiative of Acad.V.V.Voevodskii. Reviews of the early results may be found in other publications[6,7,12].

II. ELECTRON SPIN ECHO SPECTROMETERS

Approximately 30 ESE spectrometers are actually working or are in the adjustment stage in various laboratories throughout the world. In foreign laboratories the spectrometers are as a rule assembled from separate units purchased from various firms. In contrast to the first models[6,13,14], the instruments constructed nowadays are coherent ESE spectrometers, which implies that, for a fixed phase of the exciting UHF pulses, the phase of the detected ESE signal is also known. A coherent spectrometer is more sensitive than an incoherent one and has a linear characteristic—the change in the amplitude of the detected signal is proportional to the amplitude of the signal applied to the input of the detector. In addition, there is a possibility of direct measurements of the polarisation of the ESE signal, which arises in various chemical reactions, i.e. the phenomenon of the electronic polarisation of the spins[15].

The ESE signal arises when the spin system is acted upon by a series of UHF pulses which rotate the vector $\mathbf{M}_0$ through a definite angle θ. In the two-pulse variant of the excitation, the amplitude of the echo signal is determined by the angles θ_1 and θ_2:

$$V = V(2\tau)\sin\theta_1 \sin^2\frac{\theta_2}{2}$$

$$\theta_{1,2} = \gamma H_1 \tau_{p_{1,2}}$$

where H_1 is the amplitude of the UHF pulse and τ_p its duration. The duration of the pulses in experiments designed to investigate the phase or spin–lattice relaxation must be much shorter than T_1 and T_2. The times T_1, $T_2 \cong 10^{-7}$ s are nowadays of practical interest, so that we must have $\tau_p \cong 2 \times 10^{-8}$ s, which yields $H_1 \cong 5$ G for $\theta = 90°$. Such a strength of the UHF magnetic field is ensured by a source with a pulse power $P_p \cong 1$ kW.[6] Naturally one can employ also less powerful sources for the excitation of the ESE signal. However, one must then bear in mind that, for small H_1, the signal amplitude diminishes in proportion to H_1^3. Furthermore, for a whole series of experiments, including studies of the dipolar interactions and modulation phenomena, one must excite at least a major portion of the EPR spectrum if not the entire spectrum with a width ΔH, i.e. it is necessary that the condition $H_1 \cong \Delta H$ should hold. In general purpose ESE spectrometers the power of the pulses from the exciting source is therefore as a rule ~1 kW.

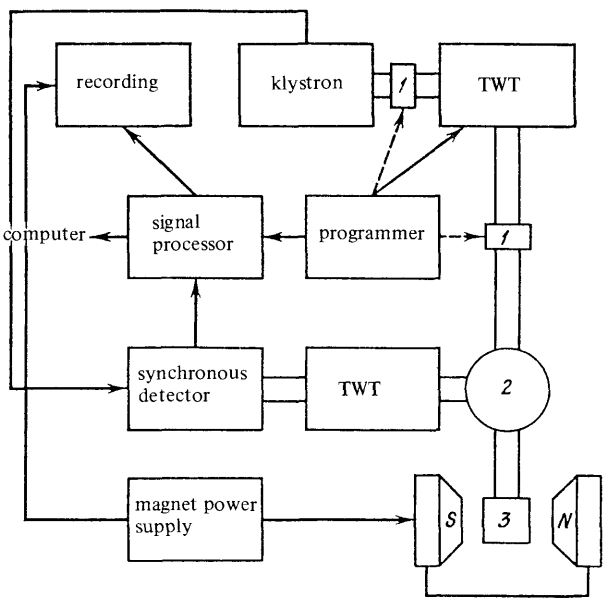

Figure 2. Generalised block schematic of an ESE spectrometer: 1) UHF switch; 2) circulator; 3) cavity; TWT—travelling wave tubes.

A block schematic of a spectrometer for the 3-cm wavelength range is illustrated in a general form in Fig. 2. One or several travelling wave tubes (TWT), which function as amplifiers of the power of the triggering klystron, are usually employed as a source of the UHF pulses; the UHF part of the spectrometer contains standard elements for EPR spectroscopy: attenuators, circulators, phase inverters, and switches. In contrast to EPR spectroscopy, the cavity need not have a high Q factor (see below). Apart from the additional frequency tuning, provision is usually made for reducing the Q factor by introducing an absorbing element such as a carbon or ferrite plate at the antinode of the electric field. Before it reaches the synchronous (balanced) detector, the signal is additionally amplified with the aid of special low-noise and low-inertia TWT. Beyond the detector, the signal in the form of a pulse enters the interpretation unit, which incorporates elements transforming the signal into a digital form, a signal accumulation system, and a system for its treatment in order to suppress noise. In a digital

or analogue form, the signal is applied to the recording device—a pen recorder, a perforated tape, another digital indicator, or a computer.

The most important element of the ESE spectrometer is a programmable pulse sequence generator. By controlling the TWT or UHF switches, it ensures the formation of a train of UHF pulses, determines their duration τ_p, the intervals between the pulses, and the time scan of these intervals as well as the frequency of the repetition of a series of pulses, and controls the signal treatment unit of the recording unit. Finally, each spectrometer contains a scanning unit and a unit for the calibration of the permanent magnetic field H_0.

According to theoretical estimates[6], the sensitivity of the ideal coherent ESE spectrometer is in the range 10^{10}–10^{11} spins in the specimen for a phase relaxation time $T_2 = 3 \times 10^{-7}$ s, a spin–lattice relaxation time $T_1 = 3 \times 10^{-6}$–10^{-4} s, and a signal recording time of 1 s, which corresponds to the sensitivity of modern stationary EPR spectrometers. An increase of sensitivity can be achieved by increasing the recording time as a result of the increased number of accumulations. We may note that, so far as we are aware, measurements of the sensitivity of ESE spectrometers, necessary for comparison with calculated values, are not available in the literature.

For any time domain spectroscopy, the most significant parameter of the ESE spectrometer is its resolving power with respect to time. This parameter should be understood as the minimum relaxation time, for example, the phase relaxation time T_2 recorded by the spectrometer ($T_{2,\min}$). For an ideal spectrometer, on excitation with a train of 90–180° pulses with durations τ_p and $2\tau_p$, we have

$$T_{2,\min}^{id} \geqslant 3\tau_p$$

In the case of a real spectrometer there is in addition a significant contribution by the so-called "ringing" of the cavity. When a resonator is acted upon by pulses, a reflected signal is generated, whose rear front is represented by an exponential function decaying with a time constant $t_0 = Q/2\omega_0$. This signal overloads the UHF amplifier with respect to time[6]:

$$\tau_r = t_0 \ln P_p/pP_n$$

where P_p is the power of the UHF pulse, $P_n = kT\omega_0/2Q$ the power of the noise, and p the amplification factor. Thus the minimum time T_2 which can be recorded by the spectrometer increases by an amount τ_r:

$$T_{2,\min} \geqslant 3\tau_p + \tau_r .$$

For $P_p = 1$ kW, $Q = 500$ $T = 300$, and $p = 100$, this additional so-called "ringing" time or "dead" time of the spectrometer is approximately 120 ns. Taking into account the fact that commuting UHF devices nowadays have a fast response time of ~10–20 ns, the real resolving power of the spectrometer is 200–300 ns. More accurate estimates[5,6] yielded similar values. The simplest method for reducing $T_{2,\min}$, by decreasing Q to low values, is evidently inapplicable because the sensitivity of the spectrometer is proportional to $Q^{1/2}$.[5,6]

The coherent spectrometer of the Institute of Chemical Kinetics and Combustion of the Siberian Division of the USSR Academy of Sciences has been described in full detail in recent literature[16,17]. One of the characteristic features of this apparatus is the possibility of generating UHF pulses with a power up to 5 kW for a minimum duration of 20 ns, which is ensured by a magnetron operating with synthronisation of its frequency and phase by the UHF oscillations of an amplification cascade based on TWT; when only TWT are used, the power of the pulse is 1 kW. Another feature is the modulation of the UHF phase to suppress the signal due to the "ringing" of the cavity and to increase the time resolution. The ESE signal is excited at a specific frequency of the repetition of the "pulse (90°)–pulse (180°)–echo" cycles. If the phase of the first pulse is reversed in each even cycle, then the phase of the echo signal in the even cycles is also rotated by 180° compared with the phase of the signal in odd cycles. The "ringing" signal, which is independent of the phase of the pulses, is the same for even and odd cycles. By subtracting the signals from the even and odd cycles in the signal processor unit, it is possible to suppress the "ringing" signal. The resolving power of such a spectrometer is approximately 2×10^{-7} s.

The programmable pulse sequence generator (programmer) of the spectrometer generates a series of four pulses, one of which is used for external synchronisation and one is a strobe pulse. The duration of the pulses and the intervals between them are regulated in 1 ns steps. These intervals are varied automatically at specified steps and at a specified rate. The programmer also generates a pulse which rotates by 90° the UHF pulse and ensures the time scan of the pen recorder in the spectrometer.

The stability and convenience of the operation of the spectrometer are also ensured by a special device for the stabilisation of the field and its scan by means of an NMR transducer, which makes it possible to determine the field strength to within 3×10^{-4}% and to alter it at a specified rate in the specified range with continuous digital indication of the value of H_0.

A modified variant of the ESE spectrometer described previously[8], was examined briefly in another communication[19]. This spectrometer is used in the Bell Telephone Laboratories (USA). A TWT with a power up to 1 kW, controlled by a modulator, which is in its turn triggered by the programmable pulse sequence generator, is employed as the source of 20 ns UHF pulses. In the recording circuit there is a coherent receiver of the homodyne type with a videoamplifier, a strobe integrator, and a pen recorder. A novel cavity of the gap type, with a high filling factor and a small size, which is convenient for use at 4.2 K, is incorporated in the spectrometer. In the two-pulse variant, τ is varied over the range 0.14–2.4 μs during the recording of the decay of the ESE signal. A waveguide delay line, which makes it possible to diminish by ~30% the dead time of the spectrometer, has been described[20].

Trifunac et al.[21] described an ESE spectrometer for kinetic studies in pulse radiolysis (Argonne National Laboratory, USA). The source of the UHF pulses is a TWT with a power of 10 W, which amplifies the UHF pulses of the klystron generated with the aid of a fast-response (10 ns) switch. The 90° pulse then has a duration of 30–100 ns, and generates a field $H_1 \cong 1$ G in a cavity of the reflecting type. The circuit employs two further fast-response switches to protect the detecting section of the spectrometer from overload pulses. A low noise TWT or a unipolar amplifier based on field effect transitors can be used in the detector. A characteristic feature of the spectrometer is its employment together with a 3 MeV Van de Graaff accelerator, which makes it possible to irradiate the specimens by intense electron pulses lasting 5–100 ns with a current of ~2 A in the pulse. In a specimen having a volume of 10^{-4} litre, such pulses give rise to a radical concentration of ~10^{-3} M in aqueous media. In kinetic experiments the time interval between the electron pulse and the first 90° UHF pulse was varied. Remote control was used for the part of the apparatus located in the zone unprotected from the radiation, this incorporated the UHF system and control units as well as the permanent H_0 magnetic field unit.

It is known that problems associated with the signals from the bulbs or cuvettes containing the test specimen arise in radiation experiments using, for example, the stationary EPR method. A novel procedure for the reduction or even elimination of this signal has been proposed[21]. If the ESE spectrometer operates under signal detection conditions with inclusion of a radiation pulse (A) and without a pulse (B), then the phase of the B signal before accumulation can be inverted so that $A - B$ difference signals containing only the transient component of the EPR spectrum appear in the accumulator. An example of such an experiment has been presented[21] with the exclusion of the long-lived signal in quartz and the isolation of the spectral lines of the short-lived radical $\dot{C}H_2CO_2$-generated when a solution of potassium acetate is irradiated.

Among other spectrometers described in the literature and used at the present time in vigorous research, we shall mention the second instrument of the Argonne Laboratory[22], the analogous spectrometer at Cornell University (USA)[23], and the spectrometer at the University of Houston (USA)[24]. The ESE spectrometer at the Leyden University in Holland[25] is used to investigate triplet states, while in the University of Delft ESE spectrometers for both the 3 cm [26] and 8 cm [27] ranges are used to study modulation phenomena. The complete list of the spectrometers, some of their technical characteristics, and the main fields of the research carried out on them have been published[28].

III. MAGNETIC DIPOLE–DIPOLE INTERACTIONS IN ESE SPECTROSCOPY

The study of the spatial distribution of paramagnetic centres in solids is based on the theory of magnetic dipole–dipole interactions developed in relation to the ESE method. A review of the present state of the theory can be found in the literature[6,7,29,30]. We shall deal only with the results which are most significant for applications.

The surrounding spins k generate at the site of a given spin p a local field ΔH_p which depends on the relative positions of the spins in the lattice and on the changes in the orientation of the surrounding spins as a function of time. The shift of the resonance frequency of two spins $c/S = 1/2$ corresponding to this field is defined thus:

$$\Delta\omega_{pk}(t) = \gamma^2\hbar r_{pk}^{-3}(1 - 3\cos^2\theta_{pk})\, m_k(t) = A(r_{pk})\cdot m_k(t)\,,$$

where m_k is the projection of the spin k onto the direction of the external field H_0 and $\theta_{pk}$the angle between the vector $\mathbf{r}_{pk}$ and the field $\mathbf{H}_0$. For an assembly of spins k, the shifts are added together:

$$\Delta\omega_p(t) = \sum_k \Delta\omega_{pk}(t)\,.$$

The contribution of this interaction to the time-dependent decrease of the spin echo signal amplitude is defined by the relation

$$V(t) = V_0 \left\langle \exp\left[i \int_0^t S(t)\,\Delta\omega_p(t)\,dt \right] \right\rangle_t \Big\rangle_p\,,$$

where $S(t) = 1$ in the time interval $(0, \tau)$ and $S(t) = -1$ in the time interval $(\tau, 2\tau)$ in the two-pulse ESE variant. Averaging with respect to t is carried out over all the realisations of the time-dependent changes in $m_k(t)$ and the averaging with respect to p takes into account the spatial distribution of the spins k relative to the spins p. If there are only two spins p and k separated by a distance r_{pk}, then the contribution due to the dipole–dipole interaction for the spin k to the decrease of the ESE signal of the spin p must also be averaged with respect to time:

$$V_p(t) = \left\langle \exp\left[iA(r_{pk}) \int_0^t S(t)\, m_k(t)\, dt \right] \right\rangle_t\,.$$

The shift of the resonance frequencies of the spins changes as a function of time as a consequence of random spin flips. Such random changes in the resonance frequencies of the spins are called spectral diffusion. Two mechanisms of random spin flips are usually considered: the spin–lattice relaxation process in which the mutual orientation of the spins is altered (flip-flops). In the latter case the spin excitation migrates in space (there is spin diffusion). If the spin–lattice relaxation makes a definite contribution to the random changes in the resonance frequencies, such spin systems are referred to as type T_1 samples. If the spectral diffusion is induced by random spin flips in the course of spin diffusion, such systems are referred to as type T_2 samples.

Another mechanism of phase relaxation due to the dipole–dipole interaction is associated with a specific pulsed influence on the system of spins in the ESE method: a 180° pulse alters the orientation of the local ΔH_p field generated by the spins k, i.e. executes an "instantaneous" shift of the resonant frequency of the spins. This gives rise to relaxation via the so-called instantaneous diffusion mechanism. Even if the spectral diffusion is fully "frozen", the dipole–dipole interaction between the spins results in a decrease of the ESE signals via the instantaneous diffusion mechanism. If during the time of observation the spins k manage to alter their orientation in a random manner (as a result of spin–lattice relaxation or spin diffusion), they contribute to the decrease of the ESE signal via both instantaneous and spectral diffusion mechanisms. The contribution of the instantaneous diffusion mechanisms depends very greatly on the amplitude H_1 and the duration τ_p of the UHF pulses on the relation between the amplitude of the UHF field H_1 and the overall width and form of the EPR spectral line $[g(\omega)]$.

The random spin flips are described within the framework of various model time distributions. Either an identical average flip rate w is then assumed for all the spins or a distribution of the spins with respect to the flip rate is introduced, for example of the form

$$\varphi(W)\,dW = \left(\frac{3W_{\max}}{2\pi}\right)^{1/2} W^{-3/2} \exp\left(-\frac{3W_{\max}}{2W}\right) dW\,, \qquad (1)$$

where $W_{\max}$ is the most probable flip rate. Using such time distributions, the decrease of the ESE signal has been calculated for the model case of a uniform distribution of spins in space[29].

The paramagnetic centres can be distributed in the lattice of a solid either uniformly or non-uniformly. In the former case they can be stabilised with identical probabilities at any lattice site. For example, a distribution of this type has been observed in frozen vitreous dilute solutions of stable radicals or complexes of paramagnetic ions. The spatial distribution of the paramagnetic centres can be described with the aid of a pair distribution function for the particles $m(r)$, which characterises the probability of finding a paramagnetic centre at a distance r from a specified paramagnetic centre.

If the paramagnetic species are distributed in the specimen in pairs and the distribution with respect to distance within the pairs is specified by the function $n(r)$, then the decrease of the ESE signal is described by the expression

$$V(2\tau) = \int V_p(2\tau, r)\, n(r)\, d^3\mathbf{r}\,.$$

For a uniform distribution of species in the specimens with an average concentration c_{av}, we obtain[29]

$$V(2\tau) = \exp\left\{-c_{cp}\int d^3\mathbf{r}\,[1 - V_p(2\tau, r)]\right\}.$$

The problem of the description of the kinetics of the decay of the ESE signal due to magnetic dipole–dipole interactions of the species is solved in this way in the general case. As a rule, the solution for a wide range of times τ can be obtained only numerically. Hitherto, a wide range of model problems have been analysed in which the spatial distribution of the paramagnetic centres was varied and different types of random processes were employed to describe spectral diffusion[29,31].

The results for systems with a uniform distribution of paramagnetic species are of greatest practical value. For such systems, there is a possibility of a comparison with experiment. They serve as reference standards in the case of a non-uniform distribution of species. Calculation of the rate of decay of the ESE signal owing to the dipole–dipole interactions for a uniform distribution has been carried out for a single spin-flip rate W and for a distribution with respect to rates of type (1). In the latter case, the kinetic expression for example, assumes the form

$$V(2\tau) = \exp\left\{10^{-18}c_{cp}\left[Q_B(\tau, W_{max}) + \left\langle \sin^2\frac{\theta}{2}\right\rangle_{g(\omega)} Q_A(\tau, W_{max})\right]\right\},$$

where $\langle\ldots\rangle_{g(\omega)}$ denotes averaging with respect to the distribution $g(\omega)$ of the frequencies in the EPR spectrum. The exponent, proportional to Q_B, reflects the contribution of spectral diffusion to the decay of the ESE signal and that proportional to Q_A reflects the contribution of the instantaneous diffusion mechanism. The quantities Q_A and Q_B have been calculated numerically as a function of τ and W_{max} and have been published[29,30].

The experimental decay of the ESE signal in the two-pulse method is associated not only with the dipole–dipole interactions between the electron spins but also with the influence of the nuclei of the matrix and of the spin–lattice relaxation on the phase relaxation of the spins. These mechanisms make a signficant contribution to the decay of the ESE signal amplitude and in practice limit the time interval in which the study is carried out from the "ringing" time of the cavity (~0.3 μs) to τ = 2–3 μs. In this interval, the functions Q_A and Q_B can be represented by linear functions in τ for the rates W_{max} in the $0–10^4$ and $10^3–10^5$ s^{-1} ranges. This makes it possible to represent the decay of ESE signal in a general form for systems with a uniform distribution[6,7,30]:

$$V(2\tau) = V(0)\exp(-2b\tau),$$
$$b = b_0 + \left[\alpha_C + \alpha_M\left\langle \sin^2\frac{\theta}{2}\right\rangle_{g(\omega)}\right]c_{av}, \qquad (2)$$
$$b_0 = m\tau^n + T_{2l}^{-1}, \quad \alpha_M c_{av} = \Delta.$$

where $m\tau^n$ is the term corresponding to the electron–nuclear interaction, n = 1–2 and T_{2l}^{-1} is the rate of phase relaxation due to the spin–lattice interaction. In the limiting case where the coefficient $\alpha_M = 8.2 \times 10^{-13}$ cm^3 s^{-1} the quantity Δ corresponds to the static dipole line width.

Relations of type (2) have been observed in the study of the phase relaxation of a whole series of systems with a uniform distribution of paramagnetic species[6,7]. By studying the dependence of the rate of phase relaxation on the average concentration and θ for a known EPR spectrum, whose form is determine by the type of $g(\omega)$, it is possible to obtain α_C and α_M. As an example, Fig. 3 presents data for the concentration dependence of the rate of phase relaxation for vitreous solutions of VO^{2+} ions in sulphuric acid and for solutions of the stable diphenylpicrylhydrazyl radical in methanol (77 K) and Fig. 4 illustrates the dependence of the rate of phase relaxation on the quantity $\langle\sin^2\theta/2\rangle$ for the $\dot{C}H_2OH$ radicals in methanol γ-irradiated at 77 K. We may note that for absorbed γ-radiation doses in excess of 2000 Gr, these radicals are stabilised uniformly in the matrix[32].

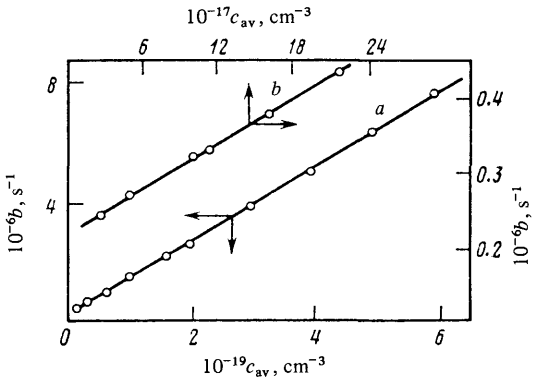

Figure 3. Dependence of the rate of phase relaxation on the concentration of VO^{2+} ions in frozen aqueous sulphuric acid solutions (*a*) and for frozen solutions of diphenylpicrylhydrazyl in methanol (*b*); temperature 77 K.[6,7]

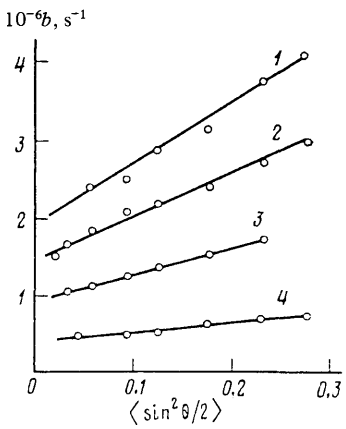

Figure 4. Dependence of the rate of phase relaxation for CH_2OH radicals in methanol (77 K) on the spectrum excitation conditions ($\theta = \gamma H_1 \tau_p$) at different radical concentrations (cm^{-3}): 1) 3×10^{19}; 2) 2.2×10^{19}; 3) 1.3×10^{19}; 4) 0.4×10^{19}. The external magnetic field H_0 is fixed and corresponds to the central line of the triplet in the EPR spectrum of the CH_2OH radical[6,7].

Thus, together with the results of the study of the dependence of the ESE signal amplitude on τ, the investigator obtains a fairly complete set of experimental data characterising the physical mechanism of the phase relaxation in the spin system. The factor important for applications is that the study of phase relaxation leads in its turn also to procedures for the investigation of spatial distribution of paramagnetic centres in solids.

In conformity with the foregoing, the spatial distribution of species determines the rate of decay of the ESE signal in the two-pulse method. As for any inversion problem, it is not possible to obtain directly from the rate $V(2\tau)$ information about the relative spatial distribution of species in the test system, which can be characterised, for example, by the pair distribution function $n(r)$ [$n(r)$ is the probability of finding species at a distance r from one another]. There exist two procedures which facilitate this problem. The first involves the calculation of $V(2\tau)$ for different $n(r)$. A series of interesting results have been obtained recently in this way, but these require a direct experimental test[31]. The second procedure involves modelling the function $n(r)$ investigated by a known function for a uniform distribution of species in a limited isolated volume, which corresponds to the introduction of the concept of a local concentration c_{loc}. If it is assumed that the species are for some reason localised uniformly in a volume $v_{loc} < v_0$, where v_0 is the volume of the specimen, then the decay of the ESE signal can be formulated thus:

$$V(2\tau) = \exp\{-c_{loc} \int d^3r[1 - V_p(2\tau, r)]\}$$

and one can assume subsequently that, in terms of this approximation for systems with a non-uniform distribution of species, relations of type (2) hold, where the quantity $c_{loc} = c_{av}v_0/v_{loc}$ is used as the concentration. Such model concepts concerning the spatial inhomogeneity or the presence of c_{loc} are widely used in the study of radical tracks in irradiated solids.

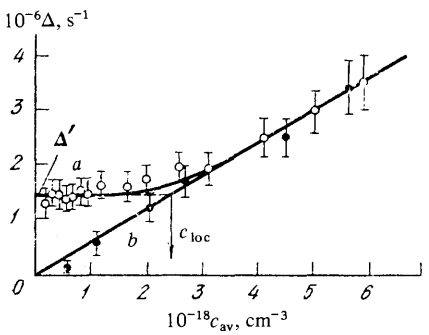

Figure 5. Dependence of the dipole line width Δ on the average concentration of the O^- radical-ions stabilised after the β-irradiation (*a*) and γ-irradiation (*b*) of 9 M aqueous NaOH solutions at 77 K.[33] The local concentration can be obtained from the value of Δ' or from the region of the inflection in the $\Delta(c_{av})$ curve, where $c_{av} = c_{loc}$.

We shall consider briefly only the most significant results obtained recently.

Track effects are manifested most strikingly in the study of the dependence of the relaxation time on the adsorbed dose D or on the average radical concentration in the course of irradiation ($c_{av} = G_R D$, G_R is the radiation yield of the radicals). A typical result for the O^- radical-ions, formed together with the captured electron on β-irradiation of an aqueous 9 M NaOH solution at 77 K, is illustrated by curve *a* in Fig.5.[33] In this system the kinetics of the phase relaxation for the O^- radical-ion are described by Eqns.(2), where $n = 2$, and the main contribution to the rate of phase relaxation comes from the instantaneous diffusion mechanism. The rate of phase relaxation p and the dipole width Δ hardly change at low radical concentrations (before the overlap of the tracks). Subsequently, when the absorbed dose and the overall concentration increase, the dipole interaction between the radicals in different tracks becomes significant. These parameters (*b* and Δ) begin to vary linearly as a function of the average concentration, as for a uniform distribution of radicals or for γ-irradiated specimens (Fig.5, curve *b*), where the track effect can be manifested only for very small absorbed radiation doses.

Track effects had not been observed either in the study (in the course of γ- and β-radiolysis) of the concentration dependence of the rate of relaxation for another particle stabilised in this system, namely the captured electron.

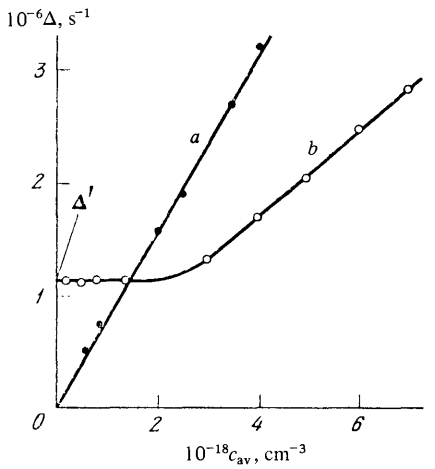

Figure 6. Dependence of the dipole line width on the concentration of paramagnetic species observed on β-irradiation of 1 M solutions of Cd^{2+} ions in methanol at 77 K:[34] *a*) Cd^+ radical-cations; *b*) $\dot{C}H_2OH$ radicals.

IV. RADICAL TRACKS

When the specimen is irradiated, th ionising particle generates positively charged ions and electrons along its path in the solid. As a result of a series of chemical reactions, these primary radiolysis products can be transformed into free radicals or atoms forming a spatially localised track. The appearance of such tracks, particularly for particles with a high ionisation intensity (α- and β-particles, products of nuclear reactions), has been observed and investigated by ESE in studies which have already been reviewed[6,7,12].

Fig.6 presents the results of studies of methanol with added Cd^{2+} ions (0.1–1.0 M), which function as acceptors of the captured electrons. Data for track effects had been obtained earlier for the $\dot{C}H_2OH$ radicals in methanol frozen at 77 K and for its acid solutions[6]. A system with an acceptor proved to be more informative: it was possible to investigate the phase relaxation of both methanol radicals and the Cd^+ radical-cations, because their EPR spectra overlap only partially. A detailed study of the phase relaxation for these species has been carried out[34]. Analysis of the instantaneous diffusion

mechanism yielded the dependence of the dipole line width Δ on the absorbed dose or on the concentration during irradiation (Fig.6).

The local concentrations of the radicals in the track can be determined from the dipole broadening Δ' in the region of track effects or from the concentration of radicals corresponding to the transition region where $c_{av} = c_{loc}$:

$$c_{loc} = \Delta'/\alpha_p \ .$$

The value of α_p can be determined in experiments for the same systems with a uniform distribution of radicals (γ-irradiation). Assuming further that the radical track is an infinitely long cylinder in which the species are distributed unformly, it is possible to determine the radius of such a track:

$$R_{tr} = \left(\frac{G_R \cdot \overline{LET}}{100\pi c_{loc}}\right)^{1/2}$$

where LET is the average linear energy transfer for the given type of radiation.

For a limited volume of any shape, the contribution of the dipole–dipole interaction to the decay of the ESE signal differs from the contribution for an infinitely large specimen even if the species are distributed uniformly within a limited volume. The corrections R_{tr} due to this effect have been calculated[35]. The quantity G_R is determined independently by the stationary EPR method from the average concentrations of radicals for different irradiation doses (radical accumulation curve). Naturally, when the linear dependence on the rate of relaxation or Δ on the concentration is observed over the entire experimental range of doses, then there is a possibility only of estimates of the upper limit to the values of R_{tr}.

The study of phase relaxation makes it possible to determine the local concentration of paramagnetic species in the solid up to 10^{17}–10^{18} cm^{-3}. In certain cases, for example, for hydrogen atoms[36], it is possible to measure concentrations up to 10^{16} cm^{-3} if the method of consecutive series is used, in which the kinetics of the recovery of the ESE signal are investigated as a function of the repetition frequency of a series of UHF pulses. The kinetics of the restoration of the ESE signal are in this case determined by the spin–lattice relaxation and the spin diffusion; the latter depends also on the intensity of the dipole–dipole interaction between the paramagnetic species, which leads to possibilities for estimating c_{loc}.

The kinetics of the spin–lattice relaxation as a function of the concentration of the paramagnetic species in α- and β-irradiated 8 M solutions of sulphuric acid have been investigated[36] at 77 K. The same local concentrations of hydrogen atoms (10^{18} cm^{-3}) were found for the α-tracks as in the study of the phase relaxation in the given system[37]. In contrast to the earlier investigation[37], for β-irradiation it was possible to obtain a more accurate estimate of the local concentrations: $[\dot{H}]_{loc} = 1^{+1.0}_{-0.5} \times 10^{16}$ cm^{-3}.

Thus data have now been obtained about the radical tracks in alkaline, acid, and alcoholic glasses. The mechanism of the radiolysis in these systems has been investigated fairly thoroughly and includes mainly ionic and radical stages leading to the stabilisation of radicals of two types at low temperatures—formed as a result of the reactions of secondary electrons [$\dot{R}(-)$] and those formed by the reactions of positive ions [$\dot{R}(+)$].

In alkaline glasses the precursor of the captured electron e_t is a secondary electron e^- and the precursor of the O^- radical-ion is the H_2O^+ ion[38]:

$$H_2O \rightsquigarrow H_2O^+ + e^- ,$$
$$e^- \rightarrow e_t^- ,$$
$$H_2O^+ + H_2O \rightarrow H_2O + H_2O^+ ,$$
$$H_2O^+ + OH^- \rightarrow H_2O + \dot{O}H ,$$
$$\dot{O}H \rightarrow H^+ + O^- \ .$$

In acid glasses the main radical formation processes can be represented schematically as follows[39]:

$$SO_4^{2-}, (H_2O) \rightsquigarrow SO_4^-, (H_2O^+) + e^- ,$$
$$e^- \rightarrow e_t^- ,$$
$$e_t^- + H^+ \rightarrow \dot{H} ,$$
$$H_2O^+ + SO_4^{2-} \rightarrow H_2O + SO_4^- .$$

In this case the precursor of the $\dot{H}$ atom is a secondary electron and the precursor of the SO_4^- radical-anions is the ionised state of water or SO_4^{2-}. For methanol solutions with Cd^{2+}, the precursors of radical species can also be readily identified, because the main processes are described by the following scheme:

$$CH_3OH \rightsquigarrow CH_3OH^+ + e^- ,$$
$$e^- \rightarrow e_t^- ,$$
$$e_t^- + Cd^{2+} \rightarrow Cd^+ ,$$
$$CH_3OH^+ + CH_3OH \rightarrow CH_3OH_2^+ + \dot{C}H_2OH \ .$$

In the system indicated, it is possible to use the ESE method to investigate the spatial distribution of radicals of two types: $\dot{R}(+)$ and $\dot{R}(-)$. Data for γ-irradiation are compiled in the Table, which reveals the following features: (1) the tracks for the radicals $\dot{R}(+)$, whose precursors are positive ions, have radii of 30–50 Å and are characterised by a local radical concentration of 10^{18}–10^{19} cm^{-3}; (2) if the precursor of the radical is a secondary electron, then the size of the radical track increases to values exceeding 100 Å or more and the local concentration corresponding to doses greater than 5×10^3 Gr is equal to the average concentration; (3) the radiation yields $G_{\dot{R}(+)}$ and $G_{\dot{R}(-)}$ in the systems investigated are almost equal.

The radiation yields of the radicals, their local concentrations, and dimensions of the tracks for certain β-irradiated polar solutions frozen at 77 K.[33–37]

Solution	$\dot{R}(+)$	$\dot{R}(-)$	G_R (for 100 eV)	$10^{-16} c_{loc}$, cm^{-3}	R_{tr}, Å
8 M H_2SO_4	SO_4^-	—	1.5	600	30
8 M H_2SO_4	—	$\dot{H}$	1.5	1	400
9 M NaOH	O^-	—	2.6	400	50
9 M NaOH	—	e_t^-	2.7	20	160
1 M Cd^{2+} in CH_3OH	$\dot{C}H_2OH$	—	2.5	1000	25
1 M Cd^{2+} in CH_3OH	—	Cd^+	2.5	30	130

These data can be accounted for by a detailed analysis of the elementary stages involving the formation, transport, and stabilisation of the radical radiolysis products in the

systems investigated. The radius of the radical track of the $\dot{R}(+)$ species is determined both by the size of the ionisation region and by the positive charge migration reactions. The spatial distribution of the species $\dot{R}(-)$ is determined by the path traversed by secondary electrons before their thermalisation and capture by a trap or an acceptor and by the reverse recombination reaction. A detailed discussion of these problems is outside the scope of this review; it can be found in other publications[34,40-42]. We shall only mention that the results obtained by the ESE method can be regarded as direct confirmation of the model ideas concerning the spatial distribution of radicals in the track of a charged particle, which were put forward as early as the 1950s by Lea[43], Gray[44], and Frolich and Platzman[45].

Studies have also been made on methanol with a Cd^{2+} acceptor on irradiation with species having higher values of LET than for β-particles[40]. Two interesting results were obtained. Firstly, a wide range of absorbed doses was observed in which the rate of phase relaxation is independent of the dose, namely up to concentrations $[\dot{C}H_2OH] \simeq 1.5 \times 10^{19}$ cm^{-3}, which indicates higher values of c_{loc} for these systems. Secondly, it was found that only 10–20% of the $\dot{C}H_2OH$ radicals are involved in the generation of the ESE signal, while the remaining species have phase relaxation times $T_2 < T_{2,min}$ (in the experiments considered $T_{2,min} =$ 400 ns) and do not contribute to the amplitude of the ESE signal. Evidently the local concentration of radicals with short T_2 is greater than 10^{19} cm^{-3}. It has been suggested that they are stabilised in the central part of the track.

An important confirmation that such radical stabilisation is inhomogeneous with respect to the radius of the track has been provided by experiments on photoannealing in such systems. Under the influence of ultraviolet light, the Cd^+ radical-cations interact with methanol, which results in the formation of $\dot{C}H_2OH$ radicals which have a random, uniform spatial distribution in the matrix as a consequence of a series of photochemical reactions and diffusion. Fig.7 illustrates the variation of the amplitude of the ESE signal for the $\dot{C}H_2OH$ radicals during photoannealing. Partial recombination leads to some decrease of the radical concentration determined by the stationary EPR method. On the other hand, the intensity of the ESE signal increases by a factor of six. The diffusion of radicals from the dense part of the track increases their phase relaxation time, which leads in its turn to an increase of the intensity of the ESE signal.

The experiments described show that the radical track has a complex three-dimensional structure and the hypothesis that they consist of cylinders with a uniform distribution of paramagnetic species can be adopted for the interpretation of experimental data only as a first approximation.

In the general case the local concentration constitutes an average characteristic of the spatial distribution of the species. The interpretation of its changes in the course of chemical reactions has not gone beyond qualitative conclusions, which nevertheless proved extremely useful for the understanding of the mechanisms of reactions in solid matrices. It has been shown recently that more detailed information about the relative spatial distribution of species can be obtained by the relaxation probe method and double electron–electron resonance in ESE spectroscopy.

V. THE RELAXATION PROBE. INVESTIGATION OF THE DISTRIBUTION WITH RESPECT TO DISTANCES IN RADICAL–ION PAIRS

Under the influence of light and radiation, paramagnetic species are frequently formed and stabilised as pairs in solids. Different pairs arise both from decomposition of the excited state M* and from ionisation. For example, if the electron is stabilised in the solid phase, the photoionisation of the Ion M^{n+} can give rise to the pairs $M^{(n+1)+}...e_t^-$. The form of the distribution function for such pairs with respect to distance is determined by the lengths of the paths traversed by the electrons, the rates of the reverse electron–ion recombination reaction and the reactions involving electrons and generating atoms or radicals, the diffusion of the latter to their stabilisation sites, and other experimental conditions, i.e. in the general case by the same factors as the geometry of the radical tracks.

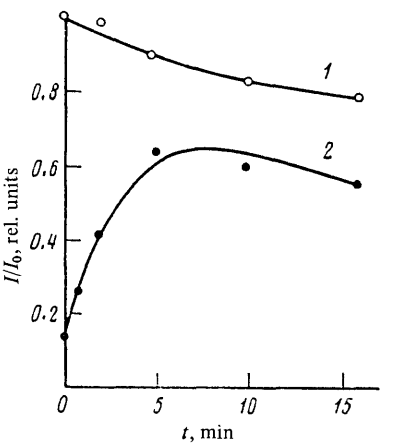

Figure 7. Variation of the relative amplitude I/I_0 of EPR (curve 1) and ESE (curve 2) signals for the $\dot{C}H_2OH$ radicals during photoannealing at 77 K. Specimen—methanol irradiated with α-particles and the ^{7}Li recoil nuclei generated in the reaction $^{10}B(n, \alpha)^7Li$;[40] t = annealing time.

It has been shown in a series of studies[46-51] that the ESE method makes it possible to determine $n(r)$ or to study the properties of this distribution in the case where one of the components of the pair is a species, usually a paramagnetic ion, with a short spin–lattice relaxation time: $T_1 \ll \tau \simeq 10^{-6}$ s.

The main idea of the experiment can be illustrated in the following manner. Radical pairs can be roughly divided into two types. In the pairs of the first type the radicals are close to the ion, within a "black sphere". Owing to the magnetic dipole–dipole interaction with the ion, these radicals have short phase relaxation time T_2^S and make a very small contribution to the intensity of the ESE signal. The main contribution comes from the radicals at large distances from the ion, outside the "black sphere", and having a long relaxation time T_2^l (Fig.8a). The volume of the "black sphere" is defined by the relation

$$V_B = {}^4/_3\pi R^3 \simeq {}^4/_3\pi \left[\frac{2}{3}\gamma^4\hbar^2 S(S+1)\tau_0 T_1\right]^{1/4} \qquad (3)$$

where τ_0 is the time interval between the first and second pulses, which is fixed and is chosen to be the smallest possible, and S is the spin of the ion. Since the relaxation time of the ion T_1 depends on temperature, the radius of the "black sphere" is also a function of temperature and τ_0. The ESE signal intensity depends on the form of the pair distribution function $n(r)$. This dependence is illustrated in Fig.8c which shows how the ESE signal intensity varies with

temperature or with the distance from the ion to the radical in two cases—for the uniform $[n^1(r)]$ and non-uniform $[n_2(r)]$ distributions of the pairs with respect to the distances r. In these experiments the paramagnetic ion behaves as the "probe" of the pair distribution: by altering the temperature and following the signal intensity for the known temperature variation of T_1, it is possible to determine $n(r)$.

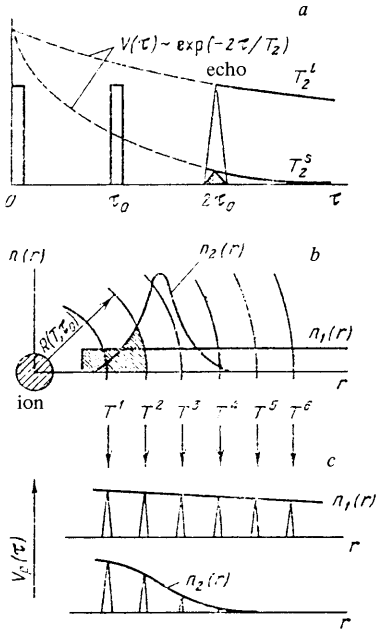

Figure 8. Scheme illustrating the method for the determination of the distribution function with respect to distances in ion–radical pairs from ESE data: *a*) two types of ESE signals arising for a fixed τ from radicals close to the ion (low values of $T_2 = T_2^S$) and remote from the ion (high values of $T_2 = T_2^l$); *b*) schematic representation of the pair distribution function for uniform $[n_1(r)]$ and non-uniform $[n_2(r)]$ distributions; R = radius of the "black sphere" which is different for different temperatures T^i; *c*) dependence of the ESE signal intensity on temperature or distance for two types of $n(r)$.

A theory and methods for the interpretation of the experimental results, which permit the determination of $n(r)$ by the relaxation probe method, have been developed[47,48]. According to the analysis carried out, the function $n(r)$ is given approximately by the relation

$$n(r) = -\frac{d}{dV_B}\left[\frac{V_p(2\tau)}{V_p(0)}\right], \qquad (4)$$

where $V_p(2\tau)$ is the intensity of the ESE signal of the radical in pairs with the ion at a given temperature and for time intervals $\tau = \tau_0$ between the UHF pulses. The quantity V_B, which has the dimensions of volume, is determined experimentally for the same values of the parameters from the relation

$$V_B = -\frac{1}{c_{av}} \ln\left[\frac{V(2\tau)}{V(0)}\right],$$

where $V(2\tau)$ is the spin echo signal intensity for a uniform distribution of the same ions and radicals relative to one another and c_{av} is the average concentration of ions. The distance r is calculated from Eqn.(3).

Thus the experiment reduces to the measurement of the relative intensity of the ESE signal for a fixed τ_0 and different temperatures (1), the measurement of the same quantity for the same system with a uniform distribution of spins (2), and the study of the temperature dependence of T_1 for the ion and V_B(3). The function $n(r)$ is determined by differentiating the experimental curve in accordance with Eqn.(4). The relative accuracy of this method of determination of $n(r)$ is estimated as being to within 30% and the resolving power with respect to r is ~1 Å.[46–48] The relaxation probe method has found applications in studies of the steric characteristics of the formation, diffusion, and reactions of the radicals formed on photolysis and radiolysis of matrices.

1. Distribution of Radicals in Photolysis and Radiolysis

The most detailed information about the function $n(r)$ can be obtained for ions with a fairly short relaxation time $T_1 \ll 10^6$ s. Such ions include Fe^{2+}. A detailed study has therefore been made[47,48] of the pair distribution of the species arising on photolysis of the Fe^{3+} ion in vitreous alcohol matrices via the overall reaction

$$Fe^{3+} + R_2CH(OH) \xrightarrow{h\nu} Fe^{2+} + R_2\dot{C}OH + H^+,$$

where R = H for methanol and R = CH_3 for isopropyl alcohol.

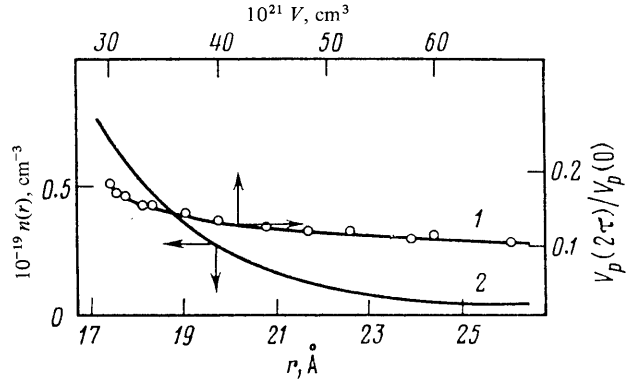

Figure 9. Dependence of the relative ESE signal amplitude $V_p(2\tau)/V_p(0)$ on the volume V_B (curve *1*) and the corresponding pair distribution function (curve *2*) for the Fe^{2+}... $\dot{C}H_2OH$ pairs in methanol irradiated with ultraviolet light[47].

Specimens of two types were investigated—with a spatial distribution of species in pairs (photolysis on irradiation with light at $\lambda > 330$ nm) and with a uniform distribution of radicals. The latter were obtained by photolysis with the unfiltered light of a DRSh-500 lamp, which led to the decomposition of the alcohol radicals into lighter species (for example, CH_3 and HCO in the case of methanol), their diffusion, and their secondary reactions with the matrix. Data were obtained for the dependence of the relative ESE signal amplitude $V_p(2\tau)/V_p(0)$ on temperature and the volume V_B of the "black sphere" (Fig.9, curve *1*). Eqn.(4) makes it

possible to determine the distribution function with respect to radical–ion distances in these experiments (Fig.9, curve 2). For methanol, the function $n(r)$ was found in the range of values of r from 17 to 26 Å; in this range it decreases exponentially with a characteristic descent parameter of 3 Å. Analogous results were obtained also for solutions of Fe^{3+} in isopropyl alcohol.

The analytical form of the functions $n(r)$ in the experiments described cannot be determined for Fe^{2+} ions in the range $r < 17$ Å. The resolving power of the method in the region of short distances (r_{min}) is determined by the possible experimental values of τ_0 and T_1. For $\tau_0 = 0.3 \times 10^{-6}$ s and $T_1 = 10^{-11}$–10^{-10} s, Eqn.(3) yields r_{min} 10–15 Å for ferrous ions. The upper limit, corresponding to $T_1 \cong \tau_0$, is then $r_{max} \cong 70$–100 Å. For the most interesting range $r < 17$ Å, there is, however, a possibility of another approach to the experimental estimation of the form of the function $n(r)$.

If the spin–lattice relaxation time of the ion T_1 is known, it is possible to estimate the relative number of radicals in the region of rapid relaxation (for $r < r_{min}$) by studying the changes in the ESE signal intensity on transition from a non-uniform spatial situation involving pairs to a uniform situation. This can be readily achieved by annealing the specimen at temperatures such that the radical–ion pairs begin to move apart without a significant contribution of recombination. Only an increase of the ESE signal intensity with increase of temperature is observed in such experiments. The constancy of the overall concentration of radicals N_0 is monitored simultaneously by the stationary EPR method. By varying T_1 or τ_0, i.e. the radius of the "black sphere", one obtains a histogram of the spatial distribution—the quantity $\Delta N(r)/N_0$. According to these experiments[47,48], 80% of the total number of Fe^{2+}... $R_2C(OH)$ pairs are located in the range $r < 17$ Å in methanol and isopropyl alcohol (Fig.10*a*).

Analysis of the mechanism of the formation of radicals in frozen solutions in alcohols containing Fe^{3+} ions[52,53] showed that, when light is absorbed by the ion introduced into the alcohol in the form of a halogen complex, phototransfer of an electron from a matrix molecule to the complex takes place. Such phototransfer is apparently most likely for the alcohol molecules closest to the complex. The data obtained by the ESE method (Fog.10*a*) concerning the mutual spatial distribution of ions and radicals are therefore consistent with the hypothesis of the phototransfer of an electron from the matrix. However, since the characteristic average distance in the ion–radical pairs is ~12 Å, one must assume that the radicals are not stabilised at the site of their formation in the first coordination sphere of the complex but execute several jumps up to the stabilisation site. This also gives rise to a set of distances characterising the function $n(r)$, which describes the "tail" of the distribution (Fig.9).

The pair distribution of the species formed on photolysis of M^{n+} ions (where $M^{n+} = Fe^{2+}$ or Cr^{2+}) in glasses of an aqueous solution of sulphuric acid has been investigated by the ESE method[46,49]:

$$M^{n+}(H_2O) \xrightarrow{h\nu} M^{(n+1)+} + \dot{H} .$$

The relaxation time T_1 for these ions is ~10^{-7} s and does not differ significantly from the limiting value $\tau_0 \cong 10^{-6}$ s. It is therefore not possible to determine the detailed form of the function $n(r)$. It has been found by the method involving the isothermal annealing of the specimen that ~80% of the atoms are located at distances from the ion up to 50 Å.

A change in the line shape of the H and D atoms has been observed[49] in the stationary EPR spectrum during annealing. This effect has also been attributed to the characteristic pair distribution of species in the system investigated. Its analysis makes it possible to refine significantly the distribution of the pairs: approximately 30% of the total number of pairs should have distances from 0 to 17 Å. The histogram which follows from the ESE and EPR data on the system indicated is illustrated in Fig.10*b*.

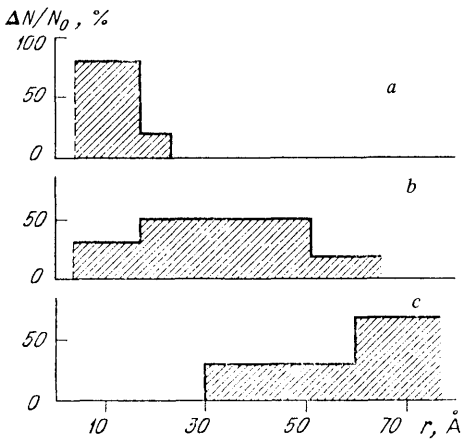

Figure 10. Histograms of the distribution with respect to the distances r in the radical–ion pairs formed on photolysis (*a* and *b*) and radiolysis (*c*) of polar frozen solutions (according to the data in Refs.46–49): *a* Fe^{3+} + RHOH $\xrightarrow{h\nu}$ Fe^{2+}... ROH (R = CH_2, $(CH_3)_2C$); *b* M^{2+} + H_2SO_4 $\xrightarrow{h\nu}$ M^{3+}...H (M = Fe, Cr); *c* $D_2SO_4 \xrightarrow{\gamma} \dot{D}$... SO_4^-.

Two alternative mechanisms for this photochemical reaction have been discussed[54]. According to one of them, the primary reaction step is electron transfer to the water molecule closest to the ion. After this, the H_2O^- species either decomposes into H and OH^- or reacts with H_3O^+ to form H. In the second mechanism, a mobile electron is formed under the influence of light, diffuses through the matrix, and reacts with the acceptor. Recently published experimental data[54,55] support the first mechanism.

If the mobile electron is not formed in the primary step (i.e. the first mechanism is valid), the experimental spatial distribution of H atoms relative to the Fe^{2+} and Cr^{2+} ions implies that the atoms are not stabilised at the site of their formation and diffuse until they are captured by a trap. The distribution function for the pairs with respect to distances has the following form for a model of this kind[56]:

$$n(r) = [4\pi r_0^2 r]^{-1} \cdot \exp[-r/r_0] .$$

It was found that the function describes equally well data obtained by the ESE method and EPR with $r_0 = 15$ Å.

The distribution $n(r)$ for the pairs SO_4^-... H(D), formed on γ-radiolysis of an aqueous solution of sulphuric acid, has been investigated[50]. In this case the mechanism of the formation of the pairs is associated with the ionisation of SO_4^{2-} and H_2O (D_2O) and the capture of a secondary electron by the $H^+(D^+)$ ion. In the determination of $n(r)$ in an analytical form, the same difficulties arise as for the ions Fe^{3+} and Cr^{3+}, since $T_1 = 10^{-6}$ s for SO_4^-. Analysis of the kinetics of the decrease of the ESE signal for the $\dot{D}$... SO_4^- pairs showed that the fraction of pairs with distances from 0 to 60 Å is ~30%. On the basis of considerations concerning the

possible lengths of the paths traversed by a secondary electron, the function describing the distribution of secondary electrons with respect to distances[41], as well as data for the experimental yield of pairs, it has been concluded[50] that a region $0 < r < 30$ Å with zero values of $n(r)$ exists as a result of primary recombination in the spatial distribution of pairs. The histogram for this case is illustrated in Fig.10c.

Thus the series of experiments carried out by the ESE method made it possible to obtain for the first time direct information about the spatial pair distribution of the paramagnetic species formed on ultraviolet and γ-irradiation of a series of polar substances.

2. Diffusion of Radicals

As a result of diffusion, the paramagnetic centres gradually emerge from the "black sphere" near the ion and their phase relaxation times increase, which leads to an increase of the ESE signal intensity for a fixed τ_0. Ultimately, the ESE signal intensity reaches a constant value at long times which corresponds to a uniform distribution of radicals in the system.

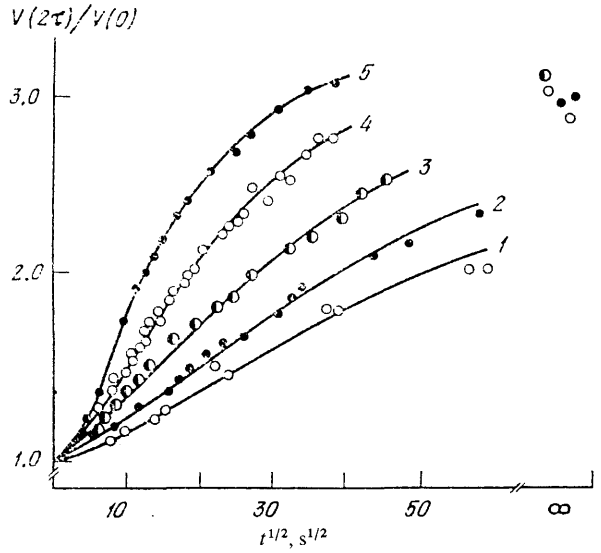

Figure 11. Increase of the ESE signal intensity during the annealing at different temperatures of specimens with $Fe^{3+}...H$ pairs arising on photolysis of Fe^{2+} solutions in 7 M H_2SO_4;[46] temperature (K): 1) 90.1; 2) 91.3; 3) 93; 4) 95; 5) 97.

The dependence of the ESE signal intensity on the annealing time at different temperatures has been investigated[46] for the $Fe^{3+}...\dot{H}$ pairs formed on photolysis of Fe^{2+} ions in frozen solutions of sulphuric acid (Fig.11). The degree of enhancement of the echo signal amplitude on diffusion is determined by the product of the diffusion coefficient of hydrogen atoms and the characteristic annealing time, for example the time of attainment of half the limiting intensity of the ESE signal ($t_{1/2}$) at a given temperature. When the Arrhenius temperature dependence obtains, we have

$$t_{1/2} = D_0^{-1} \exp(E/RT) .$$

$E = 5.5 \pm 0.5$ kcal mol^{-1} and $D_0 = 7 \times 10^{-4}$ cm^2 s^{-1} were found for H atoms from measurements of $t_{1/2}$ at different temperatures in the range 90–100 K.

More detailed information about the mechanism of diffusion in a solid can be obtained by studying the changes in the pair distribution function at different times during diffusion. Such studies have been carried out for radicals in alcohol glasses containing the $Fe^{2+}...R_2\dot{C}OH$ pairs for methanol and isopropyl alcohol[47]. With increased annealing time, the $n(r)$ distribution density tends to zero, as is to be expected from the diffusion equation. This has in fact been observed, for the $Fe^{2+}...\dot{H}$ pairs[46]. In studies of the diffusion of radical–ion pairs in alcohols, it was, however, found that the spatial scale of the diffusion is limited. Starting from a certain instant at a constant annealing temperature, the form of the pair distribution function virtually ceases to depend on the annealing time. This is illustrated by the results of the experimental determination of the pair distribution function with respect to distances at different times, presented in Fig.12*a* for radicals in methanol. For example, at an annealing temperature of 96.5 K, the principal changes in the function $n(r)$ take place during the first two minutes of annealing, which follows from a comparison of curves *0* and *1*. A further increase of annealing time at 96.5 K by an order of magnitude does not entail significant changes in $n(r)$ (curve *2*). An analogous pattern can be observed also in the group of curves characterising the variation of $n(r)$ during annealing at 100 K (curves *3*–*5*). Only an increase of temperature to 112 K results in $n(r)$ close to zero.

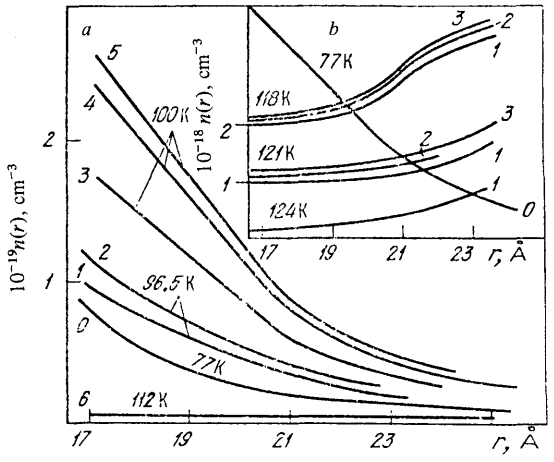

Figure 12. Variation in the course of thermal annealing of the pair distribution function for radical–ion pairs: *a*) $Fe^{2+}...\dot{C}H_2OH$ pairs in methanol; 0) initial $n(r)$ at 77 K; 1) and 2) annealing at 96.5 K for 2 and 20 min respectively; 3)–5) annealing at 100 K for 4, 9, and 19 min respectively; annealing at 112 K for 1 min; *b*) $Fe^{2+}...(CH_3)_2\dot{C}OH$ pairs in isopropyl alcohol; 0) initial $n(r)$. In each group of annealing curves at 118, 121, and 124 K the annealing times are 1, 2, and 6 min for curves *1*, *2*, and *3* respectively.

An analogous picture has been observed for radicals in isopropyl alcohol (Fig.12*b*). The difference from methanol consists only in the fact that, in addition to diffusion, raising the temperature results in a reaction between the radicals

and the ion in which a radical-ion complex is formed. Ultimately the distribution function $n(r)$, established as a result of diffusion and the reaction, does not have a descending form as in the case of methanol but actually increases with increase of r. In the vicinity of the ion a minimum in the distribution density is observed. We may note that the formation of a hydrogen atom–ion complex had been observed earlier for other systems—for iron[57] and copper[58] ions.

The observed characteristics of the diffusion of radicals have been interpreted[47] taking into account the fact that in glasses there are distributions with respect to intermolecular distances, mobilities, and other parameters between different sites. As a consequence of the distribution with respect to diffusion parameters, the radical probably diffuses only as far as the cell which it finds difficult to leave at the given temperature and is trapped there. The higher the temperature the longer the path which it traverses in the search for a suitable trap and the initial pair distribution becomes more diffuse. We may note that analogous characteristics are known for the kinetics of the recombination of radicals in solids: the kinetic curves frequently tend to a limit or have a "stepped" form with a rapid variation of the concentration in the region of short chemical reaction times and a slow change in the region of long chemical reaction times (see, for example, Blyumenfel'd et al.[59]).

3. Changes in the Pair Distribution During Chemical Reactions of Radicals

By studying the pair distribution function in the course of chemical reactions in the matrix by the relaxation probe method, it is possible to infer the scale of the migration of the valence in various elementary steps. Such studies have been carried out for radicals formed on photolysis of Fe^{3+} solutions in isopropyl alcohol[51]. In this system, there is a possibility of various chemical reactions induced by light or by heating the specimen.

Irradiation with light at $\lambda > 330$ nm leads to the formation of pairs consisting of the alcohol radicals $(CH_3)_2\dot{C}OH$ and Fe^{2+} ions. The pair distribution function $n(r)$ in the above reaction has been studied in detail for the range of distances 17–23 Å (as for methanol); the results are presented in Fig.13 (curves *a*). On illumination with light at $\lambda > 300$ nm, the radicals $(CH_3)_2\dot{C}OH$ are transformed into isopropyl radicals $(CH_3)_2\dot{C}H$ by the reaction

$$(CH_3)_2\dot{C}OH + (CH_3)_2CH(OH) \xrightarrow{h\nu} (CH_3)_2\dot{C}H + H_2O + (CH_3)_2CO \quad (5)$$

The concentration of the radicals and the changes in their structure are monitored simultaneously using stationary EPR spectra. After the complete conversion of the alcohol radicals into alkyl radicals, a study was made of the function $n(r)$ for these radicals (Fig.13*b*).

A further three types of reaction can be carried out for the same system on heating or illumination of the specimen and the pair distribution function can be investigated after these transformations. When a specimen containing propyl radicals is heated at 106 K, the substitution reaction

$$(CH_3)_2\dot{C}H + (CH_3)_2CH(OH) \xrightarrow{106\,K} (CH_3)_2\dot{C}OH + (CH_3)_2CH_2 \quad (6)$$

regenerates the alcohol radicals whose pair distribution function is illustrated in Fig.13 (curves *c*). The isopropyl radicals obtained via reaction (5) isomerise under the influence of light at $\lambda > 250$ nm:

$$(CH_3)_2\dot{C}H \xrightarrow{h\nu} CH_3CH_2\dot{C}H_2 \quad (7)$$

In reaction (7) the function $n(r)$ hardly changes and remains close to curve *b* in Fig.13. On the other hand, the propyl alcohol generated by reaction (7) interacts with the matrix at 106 K, regenerating the alcohol radicals:

$$CH_3CH_2\dot{C}H_2 + (CH_3)_2CH(OH) \xrightarrow{106\,K} CH_3CH_2CH_3 + (CH_3)_2\dot{C}OH \quad (8)$$

For the latter, the distribution function proved to be constant and corresponds to a uniform distribution of species.

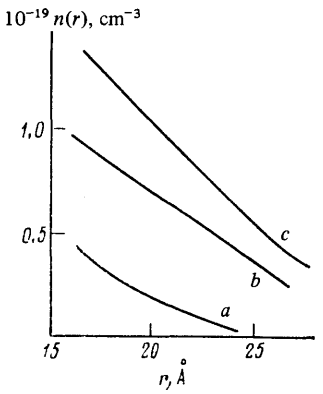

Figure 13. Variation of the form of the pair distribution function $n(r)$ due to chemical reactions in frozen Fe^{3+} solutions in isopropyl alcohol[51]: *a*) initial function $n(r)$ for the $Fe^{2+}...(CH_3)_2\dot{C}OH$ pairs; *b*) the $n(r)$ distribution function for the $Fe^{2+}...(CH_3)_2\dot{C}H$ pairs formed via reaction (5) (see text); this function does not change in reaction (7); *c*) the $n(r)$ function for the $Fe^{2+}...(CH_3)_2\dot{C}OH$ pairs formed in reaction (6).

The spatial migration of the valence for the corresponding reaction can be inferred from the distances between points with identical values of $n(r)$ on the curves in Fig.13. The lattice parameter of isopropyl alcohol is ~4.6 Å. The results presented show that reaction (6) takes place within a "cage" (the valence migrates over a distance of 3–4 Å); in reaction (5) the isopropyl radical is not stabilised at the site of its formation but executes 1–2 jumps before it is captured by a suitable trap (the displacement is by ~8 Å). The propyl radical diffuses over appreciably longer distances (≳20–30 Å) in the course of reaction (8) in the matrix. Within the limits of the accuracy of the measurements, the isomerisation reaction (7) leads to the migration of the valence over distances ≲1 Å.

VI. THE DOUBLE ELECTRON–ELECTRON RESONANCE METHOD IN ESE SPECTROSCOPY AND ITS APPLICATIONS

The spin probe method is applicable for fairly short T_1 of one member of the pair of spins. If the spins *A* and *B* in the pair have similar and fairly long relaxation times T_1, then phase relaxation can be used in the analysis of their spatial distribution, as in the study of radical tracks. However, this is possible only when the difference between the Zeeman frequencies $\omega_A - \omega_B < \gamma H_1$, i.e. under the conditions of the excitation of the complete EPR spectrum.

A method has been proposed[60] for the investigation of the pair distribution of species with similar or even equal T_1 and different ω_A and ω_B. The method is based on the observation of the variation of the ESE signal amplitude for the spins A when the UHF pumping pulse is switched on at a frequency ω_B (Fig.14). Such an influence on the spins B alters the local field at the site of the location of the spin A, by an amount whose magnitude is determined by the dipole–dipole interaction between A and B. Additional dephasing of the precession of the spins A arises, which reduces in its turn the echo signal amplitude A_A due to A compared with its value V_A^0 in the absence of the pulsed pumping of the spins B; thus the UHF pulse at a frequency ω_B stimulates the instantaneous diffusion process. An analogous formulation of the experiment can be found also in NMR spectroscopy[61].

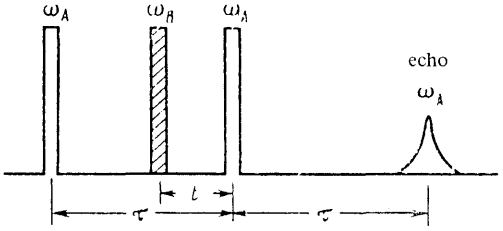

Figure 14. The sequence of the effects of the UHF pulses and the pumping pulse generating the ESE signal in the pulsed double electron–electron resonance method.

A theory of the method has been developed[60] and it has been shown that the experimental ratio V_A/V_A^0, measured for different concentrations of the pairs and extrapolated to zero concentrations of spins (in order to eliminate the decay of the signal owing to the dipole interaction between the pairs), is related to the pair distribution function $n(r)$ by the integral equation

$$[V_A/V_A^0]_{c\to 0} = 1 - p\left[1 - \int_0^\infty 2\pi r^2 n(r) K(u)\, dr\right] \qquad (9)$$

where $p = \langle \sin^2 \theta_B/2 \rangle_{g(\omega B)}$ is the fraction of the spins B excited by a pulse at a frequency ω_B and the averaging is carried out with respect to the EPR spectrum of the species B; $K(u)$ is a function determined by the dipole interactions of the spins of A and B:

$$K(u) = \frac{1}{2}\int_0^\pi \cos[u(1 - 3\cos^2\theta)] \sin\theta d\theta ,$$

where $u = \gamma^2 h r^{-3} t$, θ is the angle between H_0 and the vector $\mathbf{r}$ connecting A and B and t is the time interval between the pulse at a frequency ω_B and a second pulse at a frequency ω_A.

As an example, a study has been made[60] of pairs consisting of hydrogen atoms and the parent hydroquinone radicals formed on photolysis at 77 K of vitreous solutions of hydroquinone in 8 M sulphuric acid solutions. A bimodal cavity of the type already described[62], was used in the ESE spectrometer for such experiments. The specimen was placed at the antinode of the magnetic field for both modes, one of which tuned to the frequency ω_A (hydrogen atoms) and the other to ω_B (hydroquinone radicals). The variation of V_A/V_A^0 was investigated for different times t and radical concentrations c_B. Identical results were obtained for the Ḣ and Ḋ atoms.

In the analysis of the experimental data, an approximate calculation of the values of $n(r)$ by Eqn.(9), in which the core $K(u)$ was replaced by a stepped function, was carried out. In this case, graphical differentiation of the experimental curve represented by the expression

$$V(t) = 1 - [1 - (V_A/V_A^0)_{c_B\to 0}]\frac{1}{p}$$

with respect to the parameter $r = (0.83\gamma^2 ht)^{1/3}$ yields the required distribution function in the form $2\pi r^2 n(r)$. The graph of this function, having a maximum at $r \cong 45$ Å, is presented in Fig.15. Its integration shows that 63% of the pairs are contained in the range 0–85 Å. The remaining pairs have $r > 85$–100 Å and the character of their distribution cannot be determined, since they make a small contribution to the $V(t)$ relation.

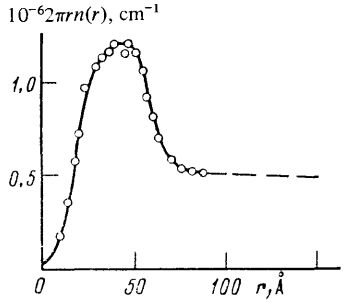

Figure 15. The distribution function with respect to distances for the Ḣ atom–hydroquinone radical pairs formed on photolysis of hydroquinone solutions in 8 M sulphuric acid frozen at 77 K.[60]

According to Shelimov et al.[63] and Bazhin[64], the paramagnetic species in the above system are formed as a result of the photoionisation of hydroquinone (ArH):

$$ArH + H_2O(H_3O^+) \xrightarrow{h\nu} (ArH^+) + \dot{H} + OH^-(H_2O) .$$

The observed distribution of pairs with respect to distances can therefore be due to two processes: the migration of electrons until their capture by a hydronium ion and the diffusion of hydrogen atoms until their stabilisation in traps. Estimates have shown that the energy of the secondary electron arising on photoionisation of hydroquinone in this system does not exceed 1 eV. For electron energies in the range 1–2 eV, the distances traversed in water are 25 Å.[41] On the other hand, according to the results described above[49], the average diffusion distance to the trap is 30 Å. The maximum of the distribution function for the pairs (ArH^+)...H at $r \cong 45$ Å corresponds to the overall contribution of both processes. Further studies are necessary to elucidate the role of different transport processes in the establishment of an inhomogeneous pair distribution in reactions whose primary stage is photoionisation.

By virtue of its greater universality compared with the relaxation probe method, it is to be expected that the double electron–electron resonance pulse method will find extensive application in the future in studies of the spatial distribution of species.

The results discussed above show that ESE constitutes a direct and informative method for the investigation of the spatial distribution of paramagnetic species in the solid

phase. With the aid of ESE, there is a possibility of both a qualitative approach, yielding information about the possible local radical concentrations, and of studies of characteristics such as the pair distribution function of paramagnetic species and the changes in the latter during diffusion and chemical reactions in a solid.

The physicochemical applications of the ESE method, one of which was examined in the present review, are based on the physical theory of the method, which has been fairly adequately developed at the present time, and a continually improving experimental base. It is to be expected that in the future ESE will occupy among the applications of microwave spectroscopic methods in chemistry a place no less important than that of the stationary EPR spectroscopy.

Unsaturated Adamantane Derivatives

E.I.Bagrii and A.T.Saginaev

The literature data on the methods of synthesis and the physical and chemical properties of adamantane derivatives containing C = C double bonds are described systematically and surveyed. Dehydroadamantanes, unsaturated adamantane derivatives with an exocyclic double bond and a double bond remote from the nucleus, as well as their functional derivatives are considered. Much attention is devoted to the reactivity of unsaturated adamantane derivatives.
The bibliography includes 165 references.

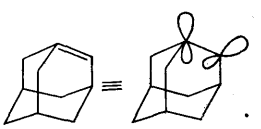
I. INTRODUCTION

The chemistry of organic polyhedranes and in the first place adamantane has developed vigorously in recent years†. Owing to their unusual properties, compounds of this class play an important role in both theoretical and experimental organic chemistry. The biological activity of organic polyhedranes has assumed considerable importance. Many medicinal drugs (rimantadine, amantidine) are at present manufactured on their basis. The high thermal stability of adamantane derivatives and their pronounced hydrophobic properties are used in the manufacture of technical products (polymeric materials, lubricating oils) with improved operational properties.

A series of reviews[1-7] and a monograph[8] have been published in recent years on the chemistry of adamantane and other polyhedranes. However, they devote little space to the chemistry of unsaturated adamantane derivatives. At the same time these compounds are of special interest primarily in view of their high reactivity; they can be used as the starting materials for the synthesis of various functional derivatives of adamantane and also as monomers. The aim of the present review is to give a systematic account and to survey the available data on the methods of synthesis and the chemical properties of adamantane derivatives containing C=C double bonds. The review includes the literature data up to 1980 inclusive and some data published in 1981–1982.

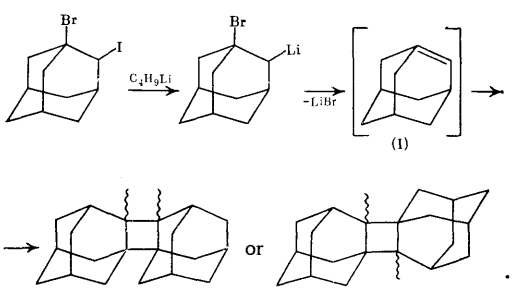
II. DEHYDROADAMANTANES

Three isomers of dehydroadamantane $C_{10}H_{14}$ are possible: 1,2-dehydroadamantane (I), 1,3-dehydroadamantane (II), and 2,4-dehydroadamantane (III):



(I) (II) (III)

1,2-Dehydroadamantane belongs to the class of the so-called anti-Bredt olefins[9]. The isomers (II) and (III) can be classified as unsaturated derivatives only as a matter of convention. However, it is useful to consider them in view of the fact that, in terms of their chemical properties (primarily their high reactivity), they are extremely close to adamantane derivatives containing a multiple bond.

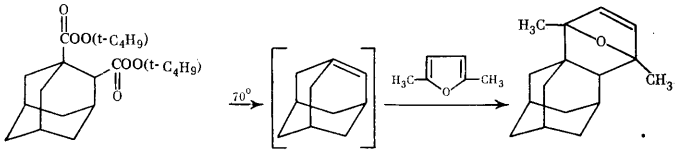


1,3-Dehydroadamantane is a strained system with two inverted carbon atoms. The 2,4-dehydroadamantane molecule is less strained and in terms of its properties is close to other alicyclic hydrocarbons containing a three-membered ring.

The possibility of the existence of 1,2-dehydroadamantane, or tricyclo[3.3.1.$1^{3,7}$]dec-1-ene, or adamantene constitutes an interesting problem in the chemistry of adamantane. Calculations have shown that adamantene is a highly strained olefin, since the overlap of the p orbitals of the C(1) and C(2) atoms, located in different planes, is difficult (a major deformation of the rigid skeleton is required). Under the usual conditions, this compound is unstable. At the same time there is much indirect evidence for its existence, 1,2-dehydroadamantane being formed as an intermediate in many reactions usually employed for the synthesis of strained olefins:

(I)

Thus bisdehalogenation of 1-bromo-2-iodoadamantane with n-butyl- or s-butyl-lithium yielded a hydrocarbon $C_{20}H_{28}$:[10]

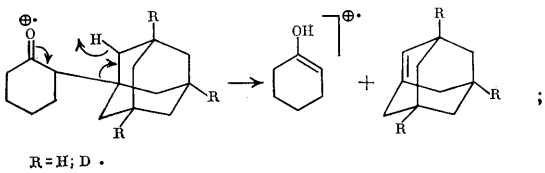


Analogous dimers have been obtained in 98% yield on treatment of 1,2-di-iodoadamantane with n-butyl-lithium in pentane at 0 °C;[11] at -80 °C in pentane in the presence of a large excess of butadiene a butadiene–adamantane adduct was isolated in addition to the dimer (85%).[12,13] When a

† During this year, 50 years have elapsed since the discovery of adamantane; it was first detected by Landa and Macháček in the petroleum of the Hodonin deposit (Czechoslovakia).

mixture of 1,2-di-iodoadamantane and lithium diphenyl phosphate is heated in tetrahydrofuran (VHF) and then oxidised with hydrogen peroxide, an adamantane dimer is also formed[14].

Adamantene is likewise produced as an intermediate in the decomposition of the di-t-butyl ester of the adamantane-1,2-dicarboxylic peracid in 2,5-dimethylfuran[15]. An adamantane–dimethylfuran adduct was then obtained by the Diels–Alder reaction:



Debromination of 1,2-dibromoadamantane by treatment with $(CH_3Si)_2Hg$ in boiling benzene also leads to the formation of adamantene as an intermediate, which dimerises in the absence of acceptors and, when the reaction is carried out in the presence of 2,5-dimethylfuran, gives rise to the corresponding Diels–Alder adduct[16].

The formation of adamantene has been confirmed by spectroscopic methods. According to infrared and EPR spectroscopic data, the main product of the interaction of 1,2-dibromo- and 1,2-di-iodo-adamantane with sodium and potassium vapours stabilised in an argon matrix at 10 K is adamantene; the 1-adamantyl radical is also formed in small amounts[17]. After heating the matrix to approximately 20 °C, [2 + 2] dimers and small amounts of 1,1'-biadamantyl were detected in the reaction mixture by gas chromatography–mass spectrometry. Judging from the infrared spectroscopic data, the character of the C=C bond in adamantene is closer to that of an unstrained C=C bond than to a biradical. However, this double bond has a partial radical character, which is evident from the formation of a dimer, of which ordinary olefins are incapable[17].

The attempt to obtain adamantene by the photoelimination reaction from 1-adamantylacetone was unsuccessful[18]. At the same time the formation of adamantene from adamantyl esters (1- and 2-adamantyl phenylacetates) via the photoelimination reaction in methanol has been observed; in both cases the subsequent ionic addition of the residue of the solvent molecule to adamantene leads to the same product; 1-methoxyadamantane[19].

The formation of the adamantene ion (*m/e* 134) from 2-adamantyl trifluoroacetate has been demonstrated by the kinetic field ionisation method[20].

The ionisation of 2-(1-adamantyl)cyclohexanone on electron impact in a high vacuum (10^{-6} mmHg) leads to the formation of the 1-hydroxycyclohexenylium radical-cation and the neutral compound (I):[21]

R=H; D.

The closest cyclic homologue of adamantene is 3-homoadamantene (IV), whose strain energy is much lower in view of the greater size of the ring containing the C=C double bond (Table 1)[22]. The theoretical existence of 3-homoadamantene was predicted in a number of studies[23–25]. It was obtained in a pure form (condensed on a NaCl plate at −196 °C) by the pyrolysis of 1-adamantyldiazomethane *in vacuo* (10^{-3} mmHg, 375 °C). When compound (IV) is heated to room temperature, the 3-homoadamantene dimer is formed according to infrared spectroscopic data[26]; it has also been described in other communications[27,28]. Its pyrolysis at 500° to 520 °C leads to 3-vinylnoradamantane (V), 4-methylene-protoadamantane (VI), and 4-homoadamantane (VII):[27]

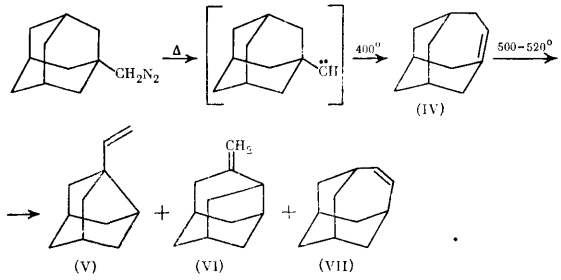


Table 1. The stability of certain olefins with a C=C bond at the base of the bridge[22].

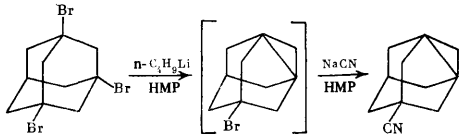


Olefin	$\Delta H°$, kcal mol^{-1}	$E°$, kcal mol^{-1}	$\Delta E°$, kcal mol^{-1}
Bicyclo[2,2,2]oct-1-ene	+42.72	50.6	40.4
Adamantene	+32.26	43.0	39.5
3-Homoadamantene	+18.92	35.3	20.2
Bicyclo[3,3,2]dec-1-ene	+6.18	25.2	4.7
Bicyclo[4,4,1]undec-1-ene	−8.95	15.7	−1.5

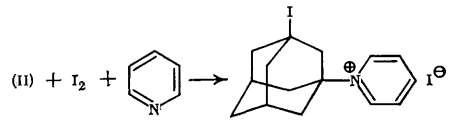
Note. $\Delta H°$ is the heat of formation, $E°$ the strain energy, and $\Delta E°$ the difference between the strain energies of the alkene and the corresponding alkane.

1,3- and 2,4-Dehydroadamantanes, which are entirely stable compounds, are obtained by the reactions usually employed for the synthesis of cyclopropane hydrocarbons (1,3-elimination, insertion of a carbene, etc.).

1,3-Dehydroadamantane was first synthesised by treating 1,3-dibromoadamantane with the Na–K alloy in boiling heptane; its structure was confirmed by chemical reactions involving the opening of the three-membered rings[29] A 9 : 1 mixture of 1,3-dehydroadamantane and adamantane has been obtained analogously in 77% yield from 1,3-dibromoadamantane in ether containing traces of t-butyl alcohol and (or) hexamethylphosphoramide (HMP).[30] Under these conditions, 1,3-dibromo-5,7-dimethyladamantane gives rise to a 1 : 1 mixture of 1,3-dehydro-5,7-dimethyladamantane and 1,3-dimethyladamantane in 78% yield[30].

When lithium is used, the cyclisation of 1,3-dibromoadamantane takes place in THF at room temperature. However, the presence of a catalyst, namely alkylarylchlorosilane, is required in this instance; the yield of compound (II) is 80%.[31] Treatment of 1,3,5-tribromoadamantane with n-butyl-lithium at −35 °C in ether containing HMP (in proportions of 25 : 1) leads to 5-bromo-1,3-dehydroadamantane, which is converted into the stable 5-cyano-1,3-dehydroadamantane following the addition of NaCN:[32]

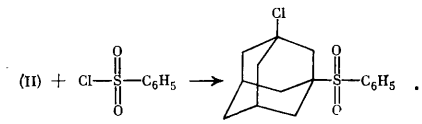
The formation of compound (II) is also observed in the polarographic reduction of 1,3-dibromoadamantane[33].



Like other alicyclic hydrocarbons containing a strained three-membered ring, 1,3-dehydroadamantane and its derivatives are very reactive. The C(1)–C(3) bond in compound (II) is greatly weakened; its length is 1.64 Å while the lengths of other C–C bonds in adamantane are 1.53 Å [Majerski et al.[5] (p.37)]. Because of this, the reactions of 1,3-dehydroadamantane proceed selectively with the opening of the three-membered ring and the formation of 1-mono- or 1,3-di-substituted derivatives of adamantane; the fragmentation of the adamantane ring also takes place sometimes.

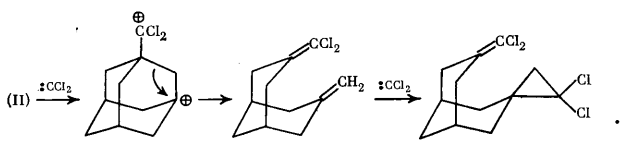
The oxidation of compound (II) with air at 20 °C in heptane leads to a peroxide, which decomposes explosively at 160 °C.[29] In air and in solution in pentane at room temperature, compound (II) is converted into a mixture of copolymers with oxygen, whose main component is the explosive polyperoxyadamantane $(OC_{10}H_{14}O)_n$.[29,30]

On heating (130–160 °C) in a sealed tube, compound (II) is converted into a white polymer (1,3-polyadamantane) having the composition $(C_{10}H_{14})_n$, which is insoluble in organic solvents and is stable in an atmosphere of nitrogen at 400 °C. An analogous polydimethyladamantane is formed from 1,3-dehydro-5,7-dimethyladamantane at 90–145 °C. In the absence of oxygen, compound (II) is thermally stable, its half-life at 195 °C in solution in n-octane amounting to approximately 4 h.[29,30]



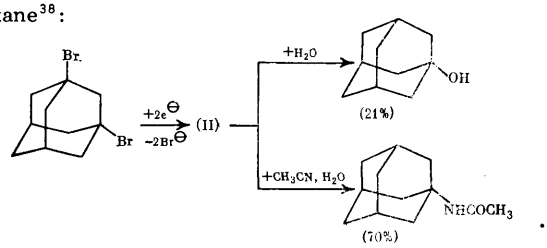
Catalytic hydrogenation of compound (II) leads to adamantane in 82% yield and the interaction of compound (II) with bromine or iodine gives rise to 1,3-dibromo- and 1,3-di-iodo-adamantane respectively[29].

Treatment of compound (II) with iodine in the presence of pyridine produces *N*-(3-iodo-1-adamantyl)pyridinium iodide[34]:



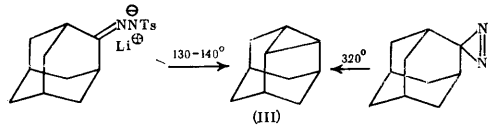
This reaction is one of the first examples of coupled intermolecular halogenoamination.

1,3-Dehydroadamantane combines with benzenesulphonyl halides even in the absence of a catalyst[35]:

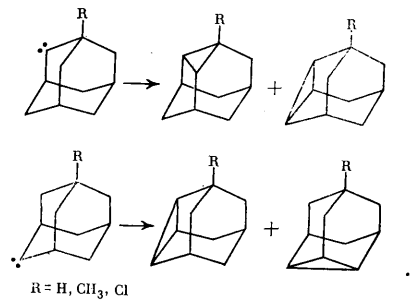


Under the conditions of the catalytic generation of dichlorocarbene, 1,3-dehydroadamantane combines with two equivalents of the carbene to form 7-dichloromethylenebicyclo[3.3.1]nonane-3-spiro-1-(2',2'-dichloro)cyclopropane[36]:

The reaction of compound (II) with aryliodosocarboxylates having the general formula $ArI(OCOR)_2$, where R = alkyl or aryl, has been investigated[37]. The main products of this reaction in inert solvents at room temperature are iodobenzene and 1,3-diacyloxyadamantenes.

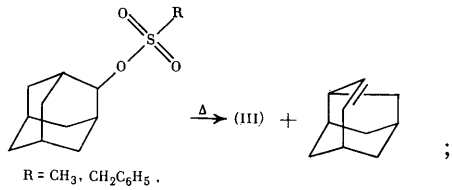


1,3-Dehydroadamantane is formed in the electrochemical reduction of 1,3-dibromoadamantane in acetonitrile at a mercury electrode. It reacts with acetonitrile and the water contained in it to form 1-adamantanol and 1-acetamidoadamantane[38]:



The addition of acetic acid to compound (II) leads to 1-adamantyl acetate[39].

The reaction of compound (II) with maleic anhydride, acrylonitrile, and dimethyl acetylenedicarboxylate results in the formation of oligomeric products[40]. The reactions are carried out at room temperature and in the absence of polymerisation initiators; the homopolymerisation of each monomer takes place under more severe conditions.



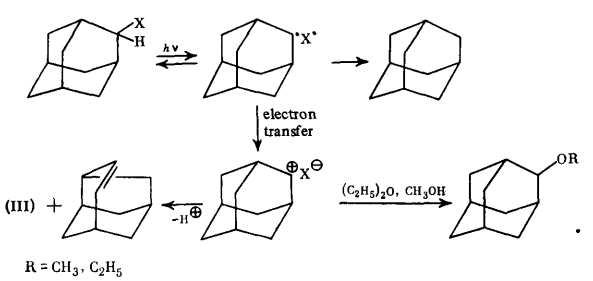
2,4-Dehydroadamantane or tetracyclo[4.3.1.$0^{2,4}$.$0^{3,8}$]decane is an extremely stable compound (m.p. 202.5–203.5 °C). In a pure form, compound (III) has been obtained by the pyrolysis of the dry lithium salt of 2-adamantanone *p*-tosylhydrazone at 130–140 °C (yield 65%)[41] and adamantane-2-spiro-3'-diazirine at 320 °C (yield 96%):[42]

Derivatives of 2,4-dehydroadamantane containing bridgehead substituents have been obtained recently by the hydrolysis of the corresponding alkali metal salts of tosylhydrazones#. It was established that the proportions of the products of the intramolecular insertion of the intermediate carbenes in the C–H bond depend on the substituent and its position relative to the carbene centre:

The pyrolysis of adamantane-2-sulphonate at 520 °C leads to compound (III) and protoadamantene (in 57 and 38% yields respectively):[43]

S.Hiršl-Starčevič and Z.Majerski, J.Org.Chem., 1982, **47**, 2520.

Irradiation of solutions of 2-iodo- and 2-bromo-adamantanes with ultraviolet light leads to a mixture of adamantane, compound (III), protoadamantene and respectively (depending on the solvent employed) 2-ethoxy- or 2-methoxy-adamantane[44]. The last two compounds are obtained as a result of the nucleophilic attack by solvent molecules on the intermediate 2-adamantyl cation; the deprotonation of the cation leads to a mixture of compound (III) and protoadamantene:



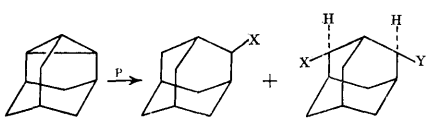


Table 2. 2-Substituted adamantanes formed on interaction of 2,4-dihydroadamantane with electrophiles[45].

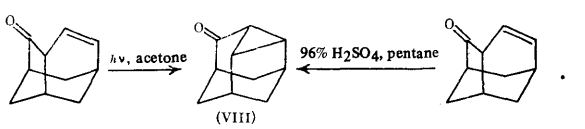
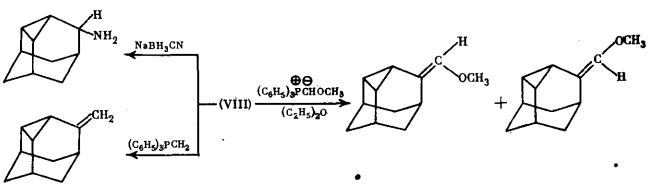


Reagents P	Substituent X	Yield, %
HI	I	24
CH_3COOH, H_2SO_4	$OCOCH_3$	94
CH_3OH, BF_3	OCH_3	80
C_6H_6, $AlCl_3$, BF_3	C_6H_5	70
$C_6H_5CH_3$, $AlCl_3$, BF_3	$C_6H_4CH_3$	50
$C_6H_5OCH_3$, $AlCl_3$, BF_3	$C_6H_4OCH_3$	86

The availability of 2,4-dehydroadamantane provides a unique possibility for the synthesis from it of 2-mono- and 2,4-di-substituted adamantane derivatives, which are otherwise difficult to obtain, as a result of the opening of the three-membered ring by electrophiles (Tables 2 and 3).[45,46] The reactions of compound (III) with such reagents (P) proceed in accordance with the following general mechanism:



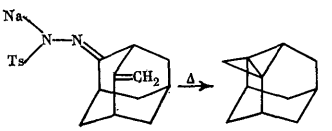
The oligomerisation of compound (III) under the influence of $AlCl_3$ leads to a dimer and a trimer; higher oligomers have not been detected in the reaction products[47]. It has been suggested that the oligomerisation proceeds via an ionic chain mechanism with the intermediate formation of the 1-adamantyl cation.

The 2,4-dehydroadamantane derivative (VIII) has been obtained by the photoisomerisation[48,49] of 2-protoadamantenone or its isomerisation in the presence of an acid catalyst[50]:

Compound (VIII) has been synthesised in several stages from norbornadiene with an overall yield of 2%.[51] It is readily converted into compound (III) by the Wolff–Kishner reaction in 75% yield[52].

The presence of the active carbonyl group permits the synthesis of other 2-substituted 8,9-dehydroadamantanes from compound (VIII):[48]

2,4-Methano-2,4-dehydroadamantane, which is the closest cyclic homologue of 2,4-dehydroadamantane, has been obtained by the pyrolysis of the dry sodium salt of 4-methylene-2-adamantanone tosylhydrazone[53], is relatively stable at room temperature, and reacts rapidly with oxygen, methanol, and bromine to form a complex mixture of products. The structure of this propellane has been demonstrated by ^{13}C NMR.[54]



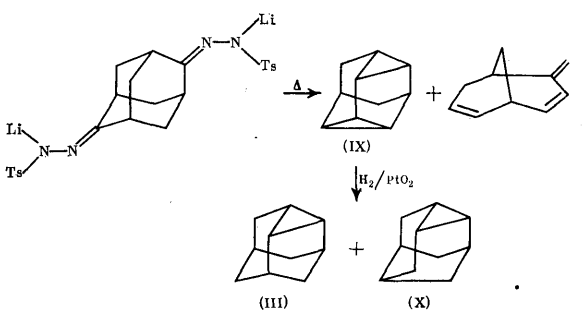


Table 3. 2,4-Disubstituted adamantanes formed on interaction of 2,4-dehydroadamantane with electrophiles[45].

Reagents P	Substituents		Yield, %
	X	Y

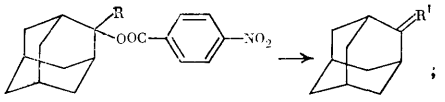
2,4,6,9-Tetradehydroadamantane (IX) or pentacyclo-[4.4.0.$0^{2,10}$.$0^{3,5}$.$0^{4,8}$]decane is of considerable interest. It is a stable compound, melting at 152–154 °C and capable of withstanding heating to 250 °C for 10 min without change of structure. It has been obtained by the thermolysis of the dilithium salt of 2,6-adamantanedione bistosylhydrazone[55,56]:

Catalytic hydrogenation of compound (IX) over a platinum catalyst at room temperature and atmospheric pressure in the presence of THF and acetic acid results in the cleavage of only one cyclopropane ring with formation of a mixture of two $C_{10}H_{14}$ hydrocarbons: 2,4-dehydroadamantane and, mainly, dehydroprotoadamantane (X) or tetracyclo[4.4.0. .$0^{2,10}$.$0^{4,8}$]decane. Compound (IX) does not isomerise under the influence of temperature and a catalyst (80 °C, $AgBF_4$).[56]

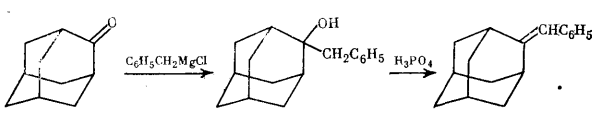
III. ADAMANTANE DERIVATIVES CONTAINING AN EXOCYCLIC C=C DOUBLE BOND

By virtue of the characteristic features of the adamantane structure, an exocyclic π-bond is possible only in a bridging position in the nucleus:



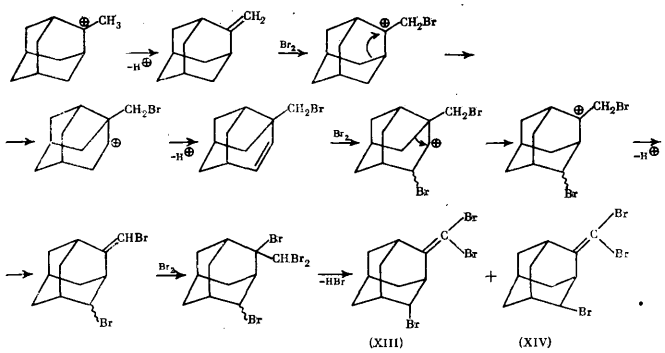
(XI) (XII)

Compounds of type (XI) are as a rule obtained by the traditional method—the dehydration of the corresponding tertiary alcohols produced by the condensation of adamantanone and lithium alkyls or Grignard reagents. In particular, 2-methyleneadamantane[57,58], 2-ethylideneadamantane[60,61], 2-propylideneadamantane[60], 2-isobutylideneadamantane[60], and 2-butylideneadamantane[60,62] have been obtained in this way.



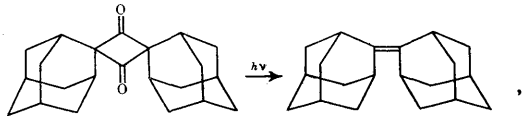
Certain derivatives of unsaturated compounds of type (XI) such as 2-hydroxy-6-methyleneadamantane[65], 6-ethylidene-2-methyladamantane or 6-propylideneadamantane[68], and 8-methylene- and 8-isopropylidene-2,6-dioxa-adamantanes[69] are also obtained by the dehydration of the corresponding alcohols. Iodine is the best dehydrating agent[63], since acid catalysts can lead to the formation of side products, as happens, in particular, on heating 2-methyl-2-adamantanol with phosphoric acid[58,64]. When 2-methyl- and 2-isopropyl-2-adamantanols are treated with acetic anhydride, methyleneadamantane and a mixture of isopropylideneadamantane with isopropenyladamantane are obtained respectively[65]. Refluxing of 2-isopropyl-2-adamantanol and 2-isopentyl-2-adamantanol in xylene in the presence of I_2 resulted in the formation of isopropylideneadamantane and isopentylideneadamantane respectively[63].

Another way of obtaining these olefins involves the solvolysis of 2-alkyl-2-adamantyl *p*-nitrobenzoates[59]:



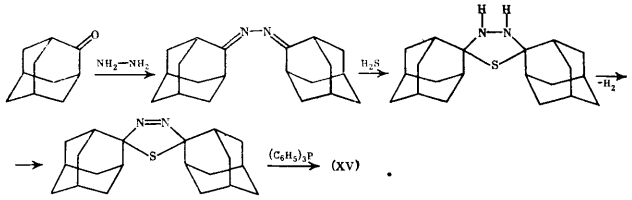
R = CH_3, C_2H_5, $CH_2C(CH_3)_3$, iso-C_3H_7;
R' = CH_2, $CHCH_3$, $CHC(CH_3)_3C(CH_3)_2$.

There are data concerning the synthesis of di-t-butylmethyleneadamantane by the thermolysis of the corresponding adamantane-2-spiro-thiadiazoline[66]. Benzylideneadamantane has been obtained in 90% yield by the dehydration of 2-benzyl-2-adamantanol in the presence of a tenfold excess of 85% orthophosphoric acid at 120 °C:[67]



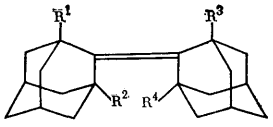
Bromo-derivatives of 2-methyleneadamantane (XIII) and (XIV) have been obtained as a result of the unusual course of the bromination of 2-methyladamantane[70]:

(XIII) (XIV)



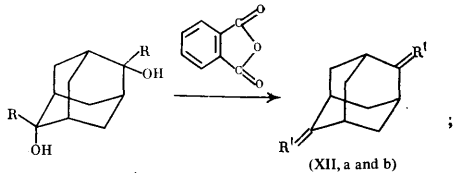
ω-Bromomethyleneadamantane has been synthesised by brominating methyleneadamantane with *N*-bromosuccinimide in the presence of Br_2O_2 or by the Wittig reaction from 2-adamantanone and $(C_6H_5)_3P{=}CHBr$.[71]

Adamantylideneadamantane (XV) is of significant interest; it is formed by the photochemical decarbonylation of the 2-adamantylketen dimer[72],



(XV)

and the debromination of *gem*-2-dibromoadamantane with the aid of the zinc–copper couple[73]. Compound (XV) has also been synthesised in accordance with the following scheme[74]:

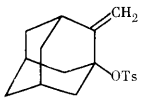


Many methyl derivatives of adamantylideneadamantane (XV, a–e) have been synthesised too[75,76]:

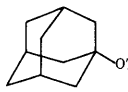
(XVa-e)

(a) R^1, R^2, R^3, R^4 = H;
(b) R^1, R^4 = H, R^2, R^3 = CH_3;
(c) R^1, R^3 = H, R^2, R^4 = CH_3;
(d) R^1, R^2 = H, R^3, R^4 = CH_3;
(e) R^1, R^2, R^3, R^4 = CH_3.

The bisunsaturated derivatives of adamantane of type (XII) have been obtained by the dehydration of the corresponding diols[77]:



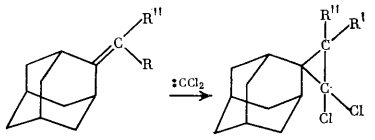
(XII, a and b)



(a) R = CH_3, R' = CH_2 (45%);
(b) R = C_2H_5, R' = C_2H_4 (90%).

In terms of their chemical properties, unsaturated derivatives of adamantane of types (XI) and (XII) are close to other alicyclic hydrocarbons containing an isolated exocyclic C=C double bond. The catalytic hydrogenation of hydrocarbons of types (XI) and (XII) leads to 2-alkyl- and 2,6-dialkyl-adamantanes[77]: on reaction with methylene iodide in the presence of the zinc-copper couple or with diazomethane in the presence of copper bromide, methylene- and ethylidene-adamantanes give rise to the corresponding cyclopropane derivatives[78]: methyleneadamantane combines with dichloro- and dibromo-carbenes to form 2,2-dichloro- and 2,2-dibromo-(2-adamantyl)spiro-1'-cyclopropanes[79].

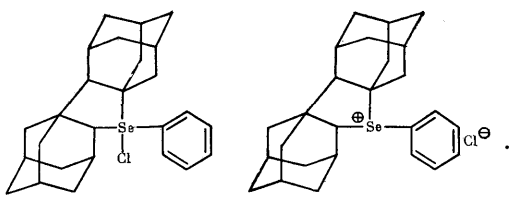
At the same time the presence of the bulky adamantyl group gives rise to major steric hindrance, which reduces the reactivity of the C=C bond and the rigidity of the structure prevents the appearance of the possible conjugation effects. Thus, as a consequence of the hindrance to the conjugation between the cationic centre and the adjoining double bond in 2-methylene-1-adamantanyl tosylate, the rate of solvolysis of the tosylate (XVI) is lower than that of the unsubstituted tosylate (XVII) by a factor of 10^4, although the opposite relation might have been expected[80]:



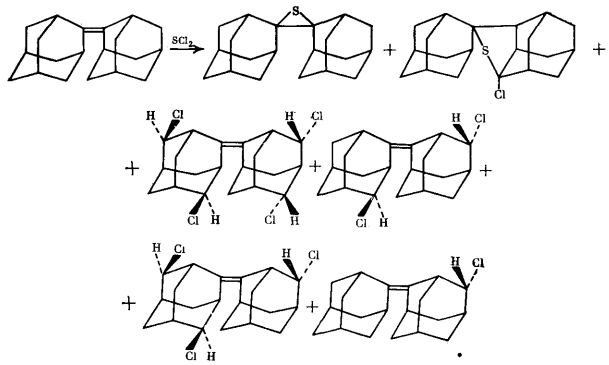
(XVI)

(XVII)

The reactivity of the double bonds of the olefins (XI) in the reactions with dichlorocarbene depends significantly on the size and character of the substituent[81]:



(XI)



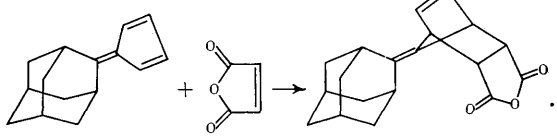
R' = R'' = H; R' = CH_3, R'' = H; R' = C_2H_5, R'' = H; R' = $(CH_3)_2CH$, R'' = H; R' = $(CH_3)_2CHCH_2$, R'' = H; R' = C_6H_5, R'' = H; R' = R'' = CH_3; R' = R'' = C_6H_5. The groups R' and R'' increase (primary alkyl groups) or decrease (isopropyl and phenyl groups) the reactivity of the double bond in conformity with the manifestation of the inductive and steric effects by the latter. The hydrocarbon (XI, R' = R'' = C_6H_5) does not react with dichlorocarbene.

Steric effects are shown particularly strikingly for adamantylideneadamantane. When compound (XV) was halogenated, its stable complexes with chlorine and bromine were isolated[82,83]. On the basis of ^{13}C NMR investigations, the structure of two-electron three-centre π-complexes was attributed to them[84].

The unique behaviour of the double bond of compound (XV) permits the synthesis of thermally stable complexes[85]:

The reaction of SCl_2 with the highly hindered double bond in compound (XV) proceeds in an unusual manner and, depending on the reaction conditions, results in the formation of compounds containing S-heterocycles and also chloro-substituted adamantylideneadamantanes[86,87]:

The reaction of compound (XV) with $MoOCl_4$ or $SbCl_5$ in the presence of Lewis acids leads respectively to adamantylideneadamantanechloronium heptachlorodioxodimolybdate and hexachloroantimonate[88]:



$$2MoOCl_4 + A{=}A \rightarrow [A(Cl)A]^{\oplus}\,[Mo_2O_2Cl_7]^{\ominus},$$

$$2\,SbCl_5 + A{=}A \rightarrow [A(Cl)A]^{\oplus}\,[SbCl_6]^{\ominus} + SbCl_3,$$

where A = 2-adamantylidene.

As a result of the considerable hindrance of the double bond, the addition of dichlorocarbene to compound (XV) takes place twenty times more slowly than to the hydrocarbon (XI, R' = R'' = H).

2-Cyclopentadienylideneadamantane (XVIII), which can be readily obtained from 2-adamantanone and cyclopentadiene, has interesting synthetic possibilities[89]. Its hydrogenation leads to 2-cyclopentenyl- and 2-cyclopentyl-adamantanes[89,90]. The hydrocarbon (XVIII) enters actively into condensation reactions with dienophiles, for example[91]:

(XVIII)

IV. ADAMANTANE DERIVATIVES WITH A C=C DOUBLE BOND IN A SIDE CHAIN

The adamantane derivatives belonging to this group include compounds containing an unsaturated substituent at both bridgehead and bridging positions, as well as compounds having two (identical or different) substituents in the 1- and 3-positions. Traditional methods are usually employed successfully for their synthesis, although some exceptions are known. Thus, despite the wide-scale variation of the reaction conditions in the dehydration of 1-(1-hydroxyethyl)-adamantane, 1-vinyladamantane (XIX) could not be obtained[92]. The attempt to synthesise compound (XIX) by the pyrolysis of a quaternary ammonium base, namely 2-(1-adamantyl)-ethyltrimethylammonium hydroxide, was also unsuccessful[93].

1-Vinyladamantane was first synthesised by the dehydration of 1-ethyladamantane in the presence of a catalyst containing aluminium and chromium, molybdenum, and tungsten hydroxides[94]. A patent was later published[95] in which several methods for the dehydration of 1-(1-hydroxyethyl)-adamantane are described. Compound (XIX) has been obtained in the highest yields (85–95%) by the pyrolysis of the borate and acetate derived from the initial alcohol. The yield of compound (XIX) in the dehydration of the unsubstituted alcohol over alumina at 350–400 °C did not exceed 30%.

The thermal cleavage of 2-(1-adamantyl)ethyl *S*-methyl xanthate leads to compound (XIX) in 77% yield[93] §:

$$AdCH_2CH_2OC(=S)SCH_3 \xrightarrow{270^\circ} AdCH{=}CH_2 + S{=}C(OH)SCH_3$$
(XIX)

Compound (XIX) has been synthesised in 80% yield by the dehydration of the borate of 1-(2-hydroxyethyl)adamantane at 300 °C.[96] 1-(Vinyl)adamantane is the product of the debromination (with Zn in dimethylformamide) of 1-adamantyl-1,2-dibromoethane[97,98].

The interaction of adamantane with acetylene under the influence of ^{60}Co γ-radiation also leads to compound (XIX) in 8% yield[99]. This method cannot evidently have any preparative value, although it is of interest as the first example of the formation of 1-vinyladamantane via a radical chain mechanism.

A procedure has been proposed recently for the synthesis of 1-vinyladamantane homologues by the reaction of 1-propenyladamantanes with ethylene in the presence of an alumina–rhenium heptoxide catalyst (10–20% Re_2O_7 and 80 to 90% Al_2O_3) at 20 °C and atmospheric pressure[100].

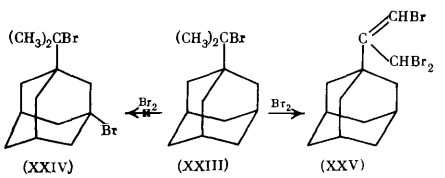
Propenyladamantanes are formed when adamantane and its homologues react with propene over industrial alumina and zeolite-containing catalysts[101]. If the starting material is 1-adamantanol, trifluoroacetic acid can also be used as the catalyst[102,103].

Regardless of the method of preparation of 1-propenyladamantane (XX), its formation is accompanied by that of its isomer—1-allyladamantane (XXI). In the dehydrohalogenation of 1-(2-bromopropyl)adamantane, the contents of compounds (XX) and (XXI) in the reaction mixture are 80 and 7.4 respectively[104]:

$$AdCH_2CHBrCH_3 \rightarrow \underset{(XX)}{AdCH{=}CHCH_3} + \underset{(XXI)}{AdCH_2CH{=}CH_2}$$

The products of the pyrolysis of 1-(1-adamantyl)-2-propyl acetate contain 70% of compound (XX) and 30% of compound (XXI).[105] Compound (XX) is probably thermodynamically more stable.

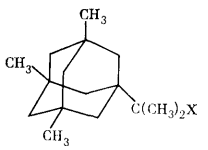
1-Allyladamantane has been synthesised by the debromination of 3-(1-adamantyl)-1,2-dibromopropane with zinc in boiling ethanol in 89% yield[104], and also by the reaction of 1-chloroadamantane with $CH_2{=}CHCH_2SI(CH_3)_3$ with participation of Lewis acids ($TiCl_4$).[106,107]



1-Isopropenyladamantane (XXII) has been synthesised by the dehydration of a tertiary alcohol—2-(1-adamantyl-2-propanol—by acetic anhydride[108] or iodine[109]:

$$AdC(CH_3)_2OH \rightarrow \underset{(XXII)}{AdC(CH_3){=}CH_2}$$

When an attempt was made to synthesise t-butyladamantane from 2-(1-adamantyl)-2-propanol, the main product was also compound (XXII):[110]

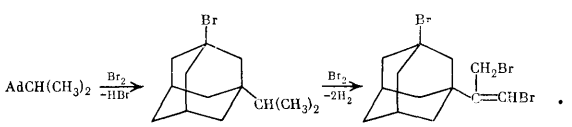


$$AdC(CH_3)_2OH \xrightarrow{SOBr_2} AdC(CH_3)_2Br \xrightarrow{CH_3MgI} AdC(CH_3)_3$$
$$\rightarrow \underset{(XXII)}{AdC(CH_3){=}CH_2} \leftarrow$$

Unsaturated derivatives of the type considered are likewise formed in halogenation reactions. Thus, instead of the expected bromo-derivative (XXIV), the unsaturated tribromo-derivative (XXV) is obtained on bromination of 2-(1-adamantyl)-2-bromopropane (XXIII):[111]

(XXIV) (XXIII) (XXV)

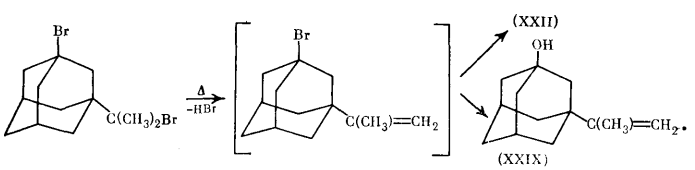
Bromination of compounds (XXVI) and (XXVII) proceeds analogously, i.e. with formation of unsaturated products[111]:



(a) X = Br (XXVI)
(b) X = H (XXVII)

In conformity with the proposed reaction mechanism, the C=C bond is formed on deprotonation of the intermediate carbonium ions[111], as in the bromination of 2-methyladamantane considered above[70]:

$$AdC(CH_3)_2Br \xrightarrow[-Br_3^\ominus]{+Br_2} AdC^\oplus(CH_3)_2 \xrightarrow{-H^\oplus} AdC(CH_3){=}CH_2 \xrightarrow{+Br_2}$$
$$\rightarrow AdC(CH_3)BrCH_2Br \xrightarrow[-2H^\oplus,\,-Br_3^\ominus]{+Br_2} \underset{CHBr_2}{AdC^\oplus CH_2Br} \xrightarrow{-H^\oplus} \underset{CHBr_2}{AdC{=}CHBr}$$

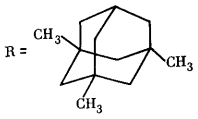


An analogous mechanism operates in all probability in the alkenylation of adamantane by propene[101].

1-Isopropyladamantane is usually brominated exclusively in the nucleus, forming 1-bromo-3-isopropyladamantane. However, on increasing the reaction time under the conditions adopted [95–100 °C, $AdCH(CH_3)_2 : Br_2 = 1 : 22$], further bromination takes place with formation of compound (XXVIII):[112]

(XXVIII)

Thermal dehydrobromination of 2-bromo-2-(3-bromo-1-adamantyl)propane results in the formation of a monobromide, which is converted into the olefin (XXII) and the unsaturated alcohol (XXIX)[113] (p.75):



(XXIX)

Fluoro-substituted alkenyladamantanes, which are of great practical interest, are obtained by the dehydrofluorination reaction. Thus dehydrofluorination of 1-hexafluoropropyladamantane in the presence of $C_2H_5OH/NaOH$ leads to 1-pentafluoropropenyladamantane in 75% yield[114]. Spectroscopic data demonstrate the presence of a double bond in the vinyl position.

§ Here and henceforth Ad = 1-adamantyl.

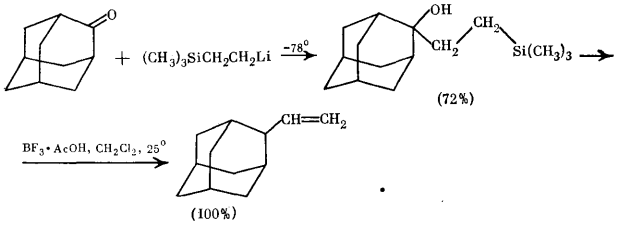
1-Isopropenyl-3,5,7-trimethyladamantane (XXX) has been synthesised[113] by the dehydration of the corresponding alcohol, which was obtained from methyl 3,5,7-trimethyladamantane-1-carboxylate (XXXI):

$$\underset{\text{(XXXI)}}{RC(O)OCH_3} \xrightarrow{CH_3MgI} RC(CH_3)_2OH \xrightarrow{-H_2O} \underset{\text{(XXX)}}{RC(CH_3)=CH_2};$$

1-Isopropenyl-2-methyladamantane is a product of the dehydration of 2-(2-methyl-1-adamantyl)-2-propanol by acetic anhydride[115].

1-(1-Adamantyl)-2-methyl-2-propanol has been used to synthesise the butenyladamantanes (XXXIII) and (XXXIV).[116] The dehydration takes place both on heating the alcohol with acetic anhydride[115] or anhydrous oxalic acid[105] and on treatment of the alcohol with hydrogen bromide in glacial acetic acid[105,116]. Evidently, the conversion of the alcohol takes place in two stages—via the intermediate formation of the tertiary carbonium ion (XXXII), which is stabilised as a result of the electron-donating effect of the adamantane nucleus:

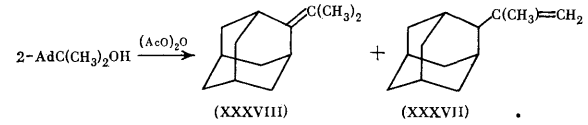
$$AdCH_2C(CH_3)_2OH \xrightarrow{HBr,CH_3COOH} \underset{\text{(XXXII)}}{AdCH_2\overset{\oplus}{C}(CH_3)_2} \begin{cases} \xrightarrow{-H^{\oplus}} \underset{\text{(XXXIII)}}{AdCH_2C(CH_3)=CH_2} + \underset{\text{(XXXIV)}}{AdCH=C(CH_3)_2} \\ \longrightarrow \overset{\oplus}{Ad} + CH_2=C(CH_3)_2 \end{cases}.$$



Further reactions of the ion (XXXII) take place with formation of the more stable 1-adamantyl cation as an electrophilic fragment or with elimination of the proton and the formation of unsaturated compounds.

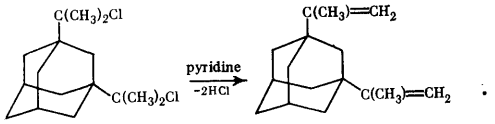
1-(1-Adamantyl)-2-chloro-2-phenylethylene (XXXV) has been synthesised from 1-chloroadamantane[106,107]:

$$AdCl + C_6H_5C{\equiv}CSi(CH_3)_3 \xrightarrow{TiCl_4} \underset{\text{(XXXV)}}{AdCH=CClC_6H_5}.$$



To confirm the structure of compound (XXXV), $C_6H_5CH=$CHAd (XXXVI) was synthesised by the Wittig reaction from adamantane-1-carboxyaldehyde and $C_6H_5CH=P(C_6H_5)_3$. The reduction of compound (XXXV) by zinc in boiling alcohol leads to *cis*-(XXXVI).

Adamantanes with an unsaturated side chain in the 2-position have been hardly investigated. 2-Vinyladamantane can be obtained in a high yield by the direct conversion of adamantanone under the influence of β-[(trimethylsilyl)ethyl]-lithium¶:



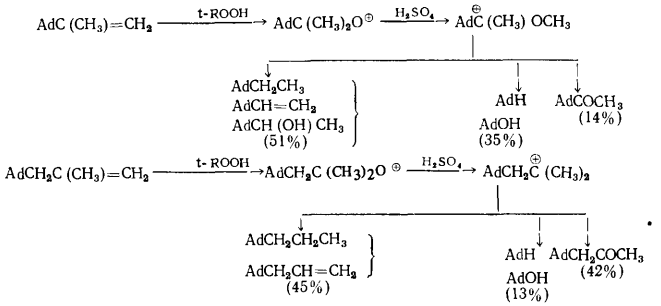
¶ S.R.Wilson and A.Shedrinsky, J.Org.Chem., 1982, **47**, 1983.

The formation of 2-isopropenyladamantane (XXXVII) in a 1 : 4 mixture with 2-isopropylideneadamantane (XXXVIII) on dehydration of 2-(2-adamantyl)-2-propanol has been noted[65]:

Adamantanes containing two unsaturated substituents in the molecule have been obtained by analogous methods. Thus 1,3-di-isopropenyladamantane has been synthesised by the dehydrochlorination of a dichloro-derivative[117]:

1-Allyl-3-vinyladamantane and 1,3-diallyladamantane have been obtained by the dehydrobromination of the corresponding bromo-derivatives[104].

Unsaturated hydrocarbons of the adamantane series, containing the double bond in the α-position in the side chain, are as a rule liquids with boiling points above 200 °C, which are fairly stable on heating. A study of the mass spectra of these compounds has shown that their molecular ions (M^+) are much more stable than the M^+ derived from the corresponding alkyladamantanes (the M^+ intensities for 1-ethyl- and 1-vinyl-adamantanes are 4 and 92% respectively)[118,119]. The intensity of the ions with *m/e* 135 (or their homologues), corresponding to the elimination of alkenyl groups, is low. These data indicate the greater stability of the C_{ad}–C_{alk} bond in alkenyl adamantanes than in alkyladamantanes. This may be the result of the interaction of the C=C bond with the excess electron density within the adamantane nucleus (1,3-conjugation); such conjugation can arise as a result of the overlap within the skeleton of the rear portions of the orbitals of the four bridgehead carbon atoms (a cage effect is postulated—see, for example, Fort[8] (p.161). However, such interaction, if it does in fact occur, is energetically insignificant, since its appreciable influence on the chemical properties of the compounds has not been observed. Thus 1-vinyladamantane and 1-allyladamantane have the same reactivities in relation to iodine[120]. The hydrogenation of these olefins gave high yields (80–95%) of the corresponding alkyladamantanes[93,105,116]. 1-Vinyladamantane usually combines with HBr according to the Markovnikov rule[93]. However, under certain conditions the main product of the addition of HBr to 1-vinyladamantane is 1-(1-adamantyl)-2-bromoethane and not 1-(1-adamantyl)-1-bromoethane (XXXIX):[121]



$$\underset{\delta^{\ominus}}{AdCH}=\underset{\delta^{\oplus}}{CH_2} \xrightarrow{H^{\oplus}(HBr)} AdCH_2\overset{\oplus}{C}H_2 \rightarrow AdCH(\overset{\oplus}{C})CH_3 \xrightarrow{Br^{\ominus}} \underset{\text{(XXXIX) (27\%)}}{AdCHBrCH_3}$$
$$\xrightarrow{Br^{\ominus}} \underset{\text{(73\%)}}{AdCH_2CH_2Br}.$$

The addition of bromine to 1-vinyladamantane yields 1-(1-adamantyl)-1,2-dibromoethane, the dehydrobromination of which leads to a mixture of unsaturated compounds[121]:

$$AdCH=CH_2 + Br_2 \rightarrow AdCHBrCH_2Br \xrightarrow[5h,\ reflux]{C_2H_5OH+KOH}$$
$$\rightarrow \underset{(59\%)}{AdCBr=CH_2} + \underset{(34\%)}{\textit{trans}\text{-}AdCH=CHBr} + \underset{(7\%)}{AdC{\equiv}CH}.$$

The epoxidation of 1-vinyladamantane has been achieved with the aid of t-butyl hydroperoxide in the presence of $Mo(CO)_6$; 1-epoxyadamantane has been polymerised with the opening of the epoxide ring[122].

The introduction of the adamantane nucleus into tertiary hydroperoxides should influence significantly their rearrangement in an acid medium, because a high tendency towards the formation of a cation is a distinctive feature of adamantane derivatives. Thus the hydroperoxides obtained from 1-isopropenyl- and 1-isobutenyl-adamantanes in 70% H_2SO_4 in the presence of cyclohexane give rise to a complex mixture of products[123]:

The interaction of 1-isopropenyl- and 2-isopropenyl-adamantanes[124] or 3-bromo-1-isopropenyladamantane[125] with methylene iodide in the presence of the zinc–copper couple or with diazomethane in the presence of copper bromide results in the formation of the corresponding cyclopropane derivatives, whose hydrogenolysis leads to alkyladamantanes.

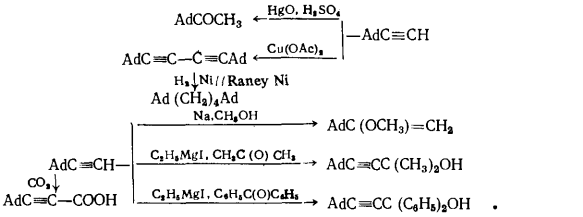
Unsaturated adamantane derivatives are active in the 1,3-dipolar cycloaddition of nitrile *N*-oxides[120]. The reactivities of the unsaturated compounds investigated vary in the sequence

$$AdCH{=}CH_2 \cong AdCH_2CH{=}CH_2 > AdC(CH_3){=}CH_2 > AdC{\equiv}CH\ .$$

The decrease of reactivity in this sequence can be accounted for partly by the influence of steric factors.

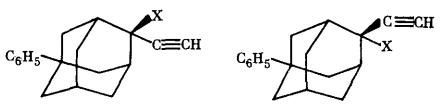
Unsaturated hydrocarbons of the adamantane series can be polymerised. Thus the polymer of 1-allyladamantane has been obtained in 12.5% yield in the presence of a Ziegler–Natta catalyst. The copolymerisation of 1-allyladamantane with vinylcyclohexane led to a copolymer in 10% yield[104]. The kinetics of the copolymerisation of 3,5-dimethyl-1-vinyladamantane with vinyl acetate have been investigated[126].

The cationic polymerisation of 1-vinyladamantane takes place in anhydrous solvents under the influence of AlX_3 (X = Cl or Br);[127,128] the temperature of the onset of the decomposition of poly-1-vinyladamantane is 300 °C.[96] The use of other catalysts of the type of Lewis acids (boron trifluoride etherate, triethyloxonium fluoroborate) does not lead to the formation of a polymer.



$$AdCH{=}CH_2 \xrightarrow{AlCl_3} AdCH_2CH_2{-}[{-}CH(Ad)CH_2{-}]_n{-}CH(Ad)CH_2Cl\ .$$

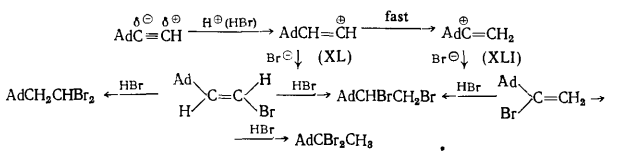
It has been established for the unsaturated adamantane derivatives



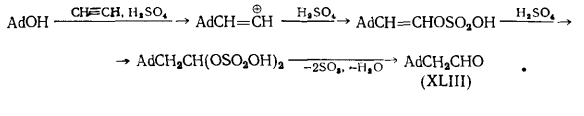
$$CH_2{=}C(CH_3)C(O)O(R)AdX;\quad CH_2{=}CH{-}O(O)C(R)AdX;$$
$$X{=}H,\ Br,\ C(O)OCH_3;\qquad R{=}(CH_2)_n,\ n = 0-2\ ,$$

that the introduction of the adamantyl group into monomers not only does not inhibit their polymerisation but in some cases leads to an increase of their capacity for polymerisation. In the series of methacrylic derivatives of adamantanes and the vinyl esters of adamantanecarboxylic acid, the type of variation of the polymerisation constants shows that, with increase of the distance between the adamantane nucleus and the double bond, the capacity of the monomers for polymerisation diminishes[129–131]. Thermal stability, resistance to hydrolysis, and enhanced surface hardness are distinctive properties of the polymers based on these adamantane derivatives.

1-Ethynyladamantane has been synthesised by the reaction of AdBr with vinyl bromide in the presence of $AlBr_3$ and subsequent dehydrohalogenation of the 1-(1-adamantyl)-1,2-dibromoethane formed by KOH in diethylene glycol[132]. 1-Ethynyladamantane undergoes many reactions characteristic of acetylenic hydrocarbons[132]:

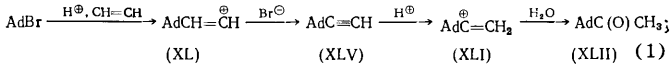


Derivatives of 2-ethynyladamantane have also been synthesised[133]:



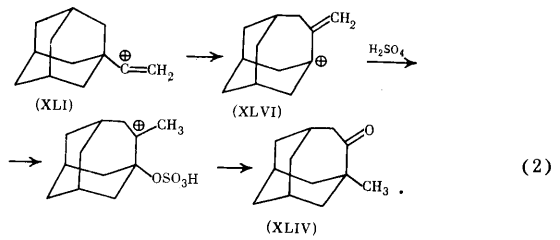
X = Cl; X = OH.

It has been suggested that the reactions of AdBr and AdOH with acetylene in concentrated sulphuric acid[135–138] and of 1-ethynyladamantane with 90% sulphuric acid[139] and with HBr in glacial acetic acid[134] proceed via the intermediate formation of adamantylvinyl cations (XL), which readily isomerise to the more stable cations (XLI). The reaction pathways of the cations (XL) and (XLI), which depends on the source from which (XL) is obtained (AdX + HC≡CH or AdC≡CH), the nature of the leaving group X (Br or OH) in AdX, and the degree of substitution in the adamantane nucleus, determine the composition of the reaction products. Thus 1-ethynyladamantane combines with HBr in glacial acetic acid to form a mixture of all the possible products[134]:



In concentrated sulphuric acid the reaction of acetylene with AdBr leads to 1-adamantyl methyl ketone (XLII) (yield 75%),[135] while the reaction with AdOH results in the formation of a mixture of three products: 1-adamantylacetaldehyde (XLIII) (yield 72%), compound (XLII), and 3-methyl-4-homoadamantanone (XLIV).[136,137] In 90% sulphuric acid 1-ethynyladamantane gives rise to a mixture of the ketones (XLII) and (XLIV).[139]

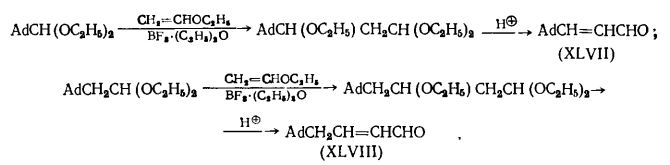
The study of the reaction of AdOH with acetylene in sulphuric and deuterosulphuric acids showed that compound (XLIII) is formed via the mechanism[138]



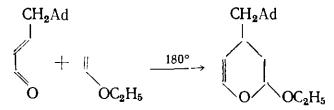
The mechanism of the formation of the ketones (XLII) and (XLIV) has still not been rigorously demonstrated. 1-Adamantyl methyl ketone is probably formed by reaction (1),[137]

while 3-methyl-4-homoadamantanone results from the rearrangement of the adamantanylvinyl cation to the more stable cation (XLVI) [reaction (2)]:[136]

(1)

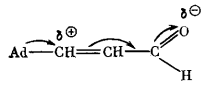


(2)



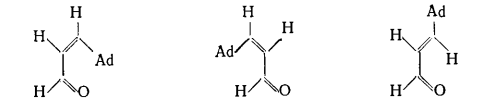
When 1-bromoadamantane was allowed to react with acetylene in solution in methylene chloride in the presence of $AlBr_3$, 1-(1-adamantyl)-2-bromo(chloro)ethylene was formed, which has also been attributed to the intermediate formation of the cation (XLI). It may be that there is also a radical interaction in this instance. 1-Adamantanol does not enter into this reaction[140].

Together with the unsaturated adamantane derivatives discussed above, adamantane-containing unsaturated aldehydes, ketones, acids, and esters have now been also invstigated fairly completely[120].



β-(1-Adamantyl)acrolein (XLVII) and γ-(1-adamantyl)-crotonaldehyde (XLVIII) have been obtained from the corresponding diethyl acetals in yields of 84 and 87% respectively[141,142]:

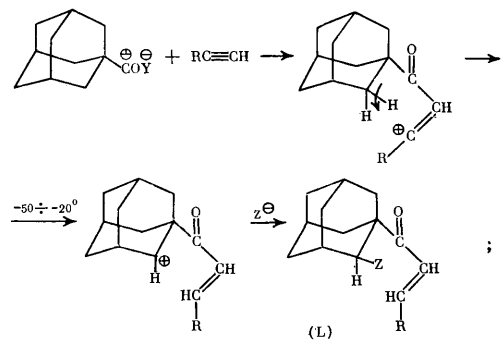
γ-(1-Adamantyl)crotonaldehyde undergoes the Diels–Alder reaction with ethyl vinyl ether to form a substituted 3,4-dihydro-1,2-pyran (XLIX) in 75% yield. On the other hand, the corresponding pyran could not be obtained from compound (XLVII).[141,143]



The different behaviour of the aldehydes (XLVII) and (XLVIII) in the reactions with ethyl vinyl ether is probably a consequence of the different degrees of influence of the Ad and $AdCH_2$ residues on the charge separation in the reaction centre of the aldehyde molecule[141]. In compound (XLVII) the electron-donating effect of the adamantyl residue diminishes the positive charge on the α-carbon atom of the aldehyde, as a result of which the molecule is insufficiently polarised for interaction with ethyl vinyl ether:

The methylene group in compound (XLVIII), which is located between the adamantyl group and the β-carbon atom, weakens the effect of the adamantyl residue and the molecule is polarised to a much greater extent.

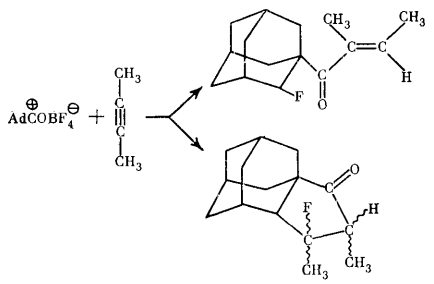
Another factor which has a significant influence on the ability of the unsaturated aldehydes to undergo the Diels–Alder reaction with vinyl ethers is the configuration of the heterodiene. Heterodienes with the cisoid *trans*-conformation (C) are capable of undergoing this reaction:



It has been established by infrared spectroscopy[141] that compound (XLVII) exists predominantly in the *cis*-conformation (A), while its homologue (XLVIII) has mainly the conformation (B). The (A) → (B) transition is apparently impossible for compound (XLVII) because of steric hindrance, while the (B) → (C) transition is entirely feasible for compound (XLVIII).[120,141]

The behaviour of 1-adamantyl vinyl ketone[144] in this reaction has also been investigated[141,143].

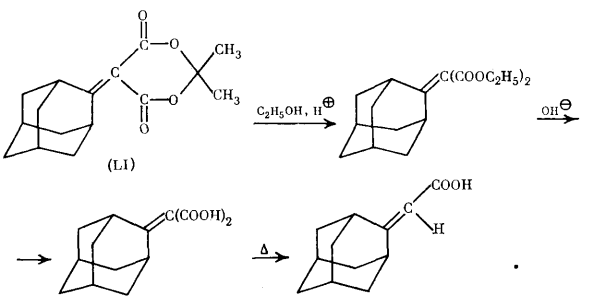
Under the influence of acid catalysts (formic acid, toluene-*p*-sulphonic acid, hydrochloric acid, and phosphorus pentoxide), 2-ethynyl-2-hydroxyladamantane is smoothly converted into adamantylideneacetaldehyde[145], which readily undergoes various reactions characteristic of aldehydes (the Knoevenagel and Wittig reactions), forming adamantane derivatives which are otherwise difficult to obtain.



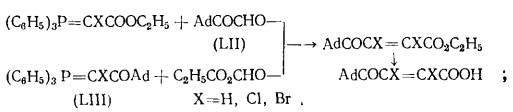
Many adamantane derivatives containing a double bond and a functional group in the side chain have been obtained from the products of the interaction of 1-adamantyl methyl ketone with bromoacetic ester in THF; their reactions have been investigated in two studies[144,146].

The acylation of terminal acetylenes RC≡CH by 1-adamantanoyl tetrafluoroborate or hexafluoroantimonate leads to α,β-unsaturated ketones (L):[147]

The reaction of $CH_3C{\equiv}CH$ and 1-adamantanoyl hexafluoroantimonate in a CH_2Cl_2–$C_2H_4Cl_2$ mixture results in the formaformation mainly of 2-Cl-(*trans*-$CH_3CH{=}CHCO$)Ad.[147,148] 2-Phenyl-1-adamantyl 1-propenyl ketone or 1′-propenyl 2-tolyl-1-adamantyl ketone (L, Z = C_6H_5 or $CH_3C_6H_4$, R = CH_3) and 1-adamantyl 2-phenylpropenyl ketone or 1-adamantyl 2-tolylpropenyl ketone are formed under these conditions in benzene and toluene. The interaction of 1-adamantanoyl tetrafluoroborate and $CH_3C{\equiv}CCH_3$ leads to a mixture of



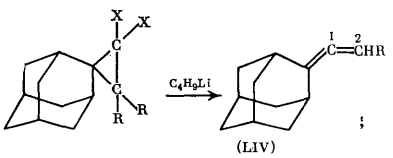
2-fluoro-1-(*cis*-$CH_3CH{=}CHCH_3CO$)Ad and 5-fluoro-5,6-dimethyltetracyclo[6.3.1.1^{3,10}.0^{4,8}]-7-tridecanone:



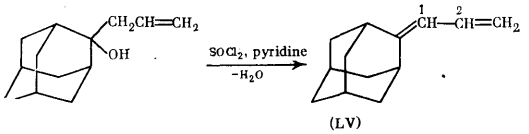
Among unsaturated acids of the adamantane series, adamantylideneacetic[149,150], adamantylidenemalonic[151–153], adamantylidenecyanoacetic[151], β-(1-adamantyl)acrylic[154,155], and α-(2-adamantylacrylic acids[155] are known.

The condensation of 2-adamantanone with malonic acid derivatives (cyanoacetic acid and its methyl ester) makes it possible to obtain derivatives of adamantylidenemalonic acid[151].

The adamantylidene derivative of Meldrum's acid (LI) has been obtained by the reaction of 2-adamantanone with Meldrum's acid in pyridine; 2-adamantylidenemalonic ester has been obtained by the transesterification of compound (LI) in the presence of acid[152]. Hydrolysis of the ester yields adamantylidenemalonic acid, which is converted into adamantylideneacetic acid on decarboxylation:

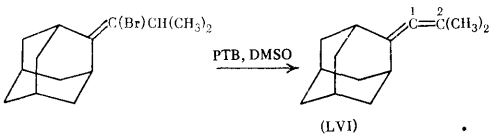


β-(1-Adamantanoyl)acrylic acid and its halogeno-derivatives have been investigated; their esters have been synthesised by the Wittig reaction from 1-adamantylglyoxal (LII) and ethoxycarbonylmethylenetriphenylphosphorane or from ethyl glyoxalate and 1-adamantanoylmethylenetriphenylphosphorane (LIII):[156–159]

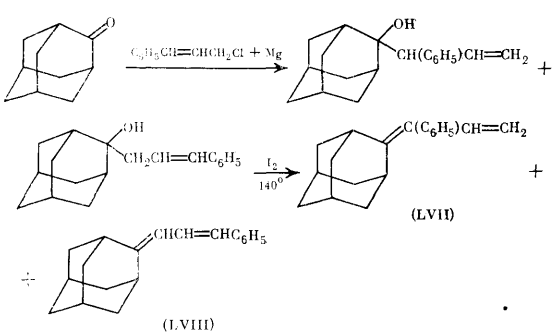


The bromination of β-(1-adamantyl)-β-hydroxybutyric and a series of its derivatives with liquid bromine results in the formation of 2-(1-adamantyl)-1-bromo-2-bromomethylpropiolactone[160].

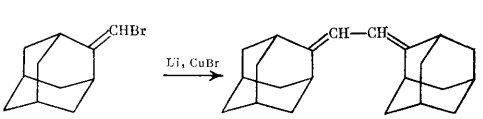
Functional derivatives of adamantane can be used for the synthesis of compounds containing several double bonds in the side chain. Vinylideneadamantane (LIVa) has been obtained by treating 2,2-dibromo- or 2,2-dichloro-(2-adamantyl)-spiro-1-cyclopropane with butyl-lithium:



(a) R = H, (b) R = CH_3, (c) R = C_6H_5; X = Cl, Br .



1-Propenylideneadamantane (LIVb) and 2-phenylethynylideneadamantane (LIVc) have been synthesised analogously[63]: the dehydration of 2-allyl-2-adamantanol leads to allylideneadamantane (LV):[161]



1-(2-Adamantylidene)-2-methyl-1-propene (LVI) has been obtained using potassium t-butoxide (PTB) in dimethyl sulphoxide as the dehydrobrominating agent[63]:

The products of the reaction of 2-adamantanone with 3-chloro-1-phenyl-1-propene and magnesium give rise to a mixture of adamantylidene-2-propenes (LVII) and (LVIII) after dehydration[63]:

1,2-Diadamantylidene-ethane has been obtained by treating bromomethyleneadamantane with lithium in the presence of CuBr:[63]

Certain characteristic features of the variation of the reactivity of the double bond as a function of the size of the substituent, the degree of substitution, and the distance between the double bonds and the nucleus have been discovered in the reaction of dihalogenocarbenes with allenes of the adamantane series[63]. The reactivities of the C(1)=C(2) double bond of vinylideneadamantane (2-Ad=$\overset{1}{C}=\overset{2}{C}H_2$), which is closest to the nucleus, is 12 times lower than in vinylidenecyclohexane and 1.8 times lower than in 1,1-dimethylallene. The cause of this consists in its steric shielding by the adamantane nucleus. The reactivity of the

C(1)=C(2) bond of 1-propenylideneadamantane, which is closest to the nucleus, is smaller almost by a factor of 2 compared with compound (LIVa), while the reactivity of the corresponding bond in methylpropenylideneadamantane (LVI) is zero. Evidently such decrease of reactivity can be accounted for by the steric interaction between the carbene and the methyl group at the C(2) atom in the transition state. In vinylideneadamantane the approach of the carbene to the plane of the C(1)=C(2) bond is equally probable from either side, while in 1-propenylideneadamantane one of the pathways followed in the approach is eclipsed by the methyl group and in compound (LVI) the methyl substituents shield the C(1)=C(2) bond from either side.

The reactivity of the terminal C(2)=C(3) bond in allylideneadamantane (LV) is lower amost by a factor of 6 than in buta-1,3-diene and is higher by a factor of 20 than the reactivity of the double bond in methyleneadamantane (XI, R=R′=H). The reactivity of the 2-Ad=C(1) bond of the diene (LV) is lower by a factor of 36 than the reactivity of the C(2)=C(3) bond. The main cause of the different reactivities of the double bonds in allylideneadamantane is apparently, as in the case of vinylideneadamantane, the steric influence of the adamantane nucleus shielding the 2-Ad=C(1) bond adjoining it. On the other hand, the reduction of the reactivity of the 2-Ad=C(1) bond in allylideneadamantane by a factor of 1.8 compared with methyleneadamantane shows that the steric factor does not operate alone in the case of the diene (LV). As a result of the polarisation of the molecule, the electron-donating effect of the adamantane substituent is transmitted to the terminal double bond and activates it, while the 2-Ad=C(1) bond closest to the nucleus is relatively deactivated. Thus the adamantane nucleus has a strong steric influence on the C=C bond adjoining it, shielding it and hindering the approach of a carbene to it.

1-Adamantyl-substituted allenes, namely 1-(1-adamantyl)-3-chloroallene [162] and 1,3-di(1-adamantylallene [163] have been described:

$$AdCHOHC{\equiv}CH \xrightarrow{SOCl_2} AdCH{=}C{=}CHCl\ ;$$

$$AdC{\equiv}CLi + AdCHO \rightarrow AdC{\equiv}CCHOHAd \xrightarrow{LiAlH_4} AdCH{=}C{=}CHAd\ .$$

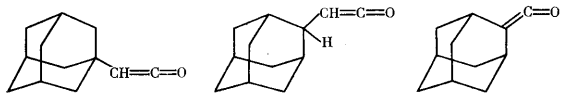
The allenes as a rule polymerise on heating, but under certain conditions dimeric products with a cyclobutane structure can be isolated from 1-(1-adamantyl)-3-chloroallene[162]. The attempt to obtain dimers on heating 1,3-di(1-adamantyl)allene was unsuccessful; the reaction mass contained only polymeric products[163].

Allene derivatives of adamantane (LIX) have been obtained by the reaction of alkenynes with AdBr in the presence of metallic lithium[164]:

$$RC{\equiv}CC(R'){=}CH_2 \xrightarrow{Li,\ THF} Li^{\oplus},$$

$$\overset{\ominus}{R}C{=}C{=}C(R')\dot{C}H_2 \xrightarrow{(AdBr)^{\ominus},\ Li} Li^{\oplus},$$

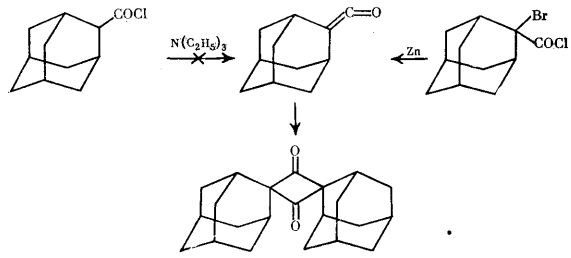
$$\overset{\ominus}{R}C{=}C{=}C(R')CH_2Ad \xrightarrow{H_2O} RCH{=}C{=}C(R')CH_2Ad\ ;$$



$$R{=}C_2H_5,\ R'{=}H;\ R{=}C(CH_3)_3,\ R'{=}H;\ R{=}R'{=}CH_3\ .$$

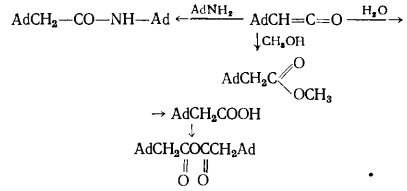
1-Adamantylallene has been synthesised by treating 1-chloroadamantane with trimethylpropargylsilane[106,107]:

$$AdCl + CH{=}CCH_2Si(CH_3)_3 \rightarrow AdCH{=}C{=}CH_2\ .$$

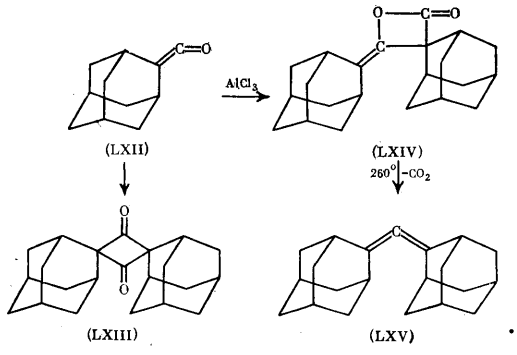


Chloroallene can be obtained with retention of configuration by treating the pure isomer of 2-ethynyl-2,5-dihydroxyadamantane with thionylchloride[133].

Ketens of the adamantane series have also been investigated:



(LX) (LXI) (LXII)



Although the yield of $N(C_2H_5)_3.HCl$ was 90% on treating the chlorides of the corresponding acids with triethylamine, the ketens (LX) and (LXI) could not be obtained in a pure form; only the di-, tri-, and tetrameric products were isolated[72]. The keten (LXII) is formed only when the chloride of 2-bromoadamantane-2-carboxylic acid is treated with zinc in boiling ether, whereupon it is converted immediately into a dimer[72]:

The chemical properties of 1-(1-adamantyl)keten (LX) could be investigated by employing dilute ethereal solutions[72]:

It was shown above that, whereas the keten (LXII) dimerises to the corresponding cyclobutane-1,3-dione under the usual conditions, after the addition of $AlCl_3$ to a boiling dilute ethereal solution of the keten dimerisation to the lactone (LXIV) takes place; on pyrolysis, the compound loses CO_2 and is converted into the allene (LXV):[165]

(LXII) (LXIV) (LXIII) (LXV)

---o0o---

Thus, apart from the features which it has in common with the chemistry of unsaturated derivatives of other alicyclic hydrocarbons, the chemistry of unsaturated adamantane derivatives is characterised by a series of features determined primarily by the presence of the bulky adamantane

nucleus. As a result of the rigidity of the adamantane structure, dehydroadamantanes are highly strained reactive hydrocarbons, which make it possible to obtain from them a wide variety of mono- and di-substituted adamantane derivatives in one stage.

The reactivity of the compounds containing an exocyclic double bond is appreciably lower as a result of steric shielding; at the same time these compounds are of interest in view of the possibility of obtaining stable complexes. In derivatives with a C=C bond in the α,β-position in a side chain, the bond is subjected to appreciable shielding and an electron-donating influence by the adamantyl group. These compounds are also extremely reactive, undergo homopolymerisation and particularly copolymerisation reactions, and can be used to prepare polymeric materials with valuable properties as well as various functional derivatives of adamantane which are of interest from the standpoint of their biological activity.

Kinetics and Mechanism of the Oxidation of Polymers in a Stressed State

N.Ya.Rapoport and G.E.Zaikov

The characteristics of the kinetics and mechanism of the chain oxidation of stressed polymers are considered as a result of structural and conformational changes occurring in polymer matrices under the influence of mechanical stresses. Attention has been concentrated on the kinetics of the autoxidation of polyolefins subjected to the influence of stretching stresses and the kinetics of the ozonisation and autoxidation of stressed raw and cured rubbers. The results of studies on the kinetics of individual stages of the chain process, namely initiation, propagation, degenerate branching, and termination of kinetic chains in stressed polyolefins, are surveyed; the effects of orientational stretching in the kinetics of the oxidation of polyolefins are considered. The relation between the kinetics of oxidation, durability, and the mechanism of the decomposition of oriented specimens subjected to an external mechanical load is discussed. The method of defectoscopy of polymers subjected to the simultaneous influence of mechanical stresses and an oxidising medium, based on the local character of the oxidation of stressed polymers, is considered.
The bibliography includes 128 references.

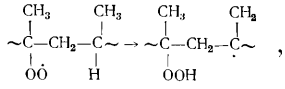
III. Kinetics and mechanism of the oxidation of stressed polymers 902

I. INTRODUCTION



The use of polymeric materials as a rule involves the operation of mechanical stresses applied either from the outside or internal stresses arising during the conversion of the polymer into a finished article and also in the course of the ageing of the polymer. Chemical reactions leading to the ageing of polymers therefore usually take place in stressed polymer matrices. A characteristic feature of chemical reactions in solid polymers is a relation between the reaction kinetics and the structural-physical parameters of the matrix, which differ significantly for the unstressed and stressed specimens. The task of predicting the durability of polymeric articles and the search for the optimal ways of stabilising polymers require the knowledge of and allowance for the influence of mechanical stresses on the kinetics and mechanism of ageing processes. Since the publication of the first study in which the accelerating influence of mechanical stresses on the rate of oxidation of vulcanised rubbers was demonstrated (the authors called this phenomenon mechanical activation[1,2]), more than 30 years have elapsed and extensive and varied experimental data concerning the influence of mechanical stresses on the kinetics of the oxidation of polymers of different classes by molecular oxygen and ozone have accumulated. In the present review an attempt is made to analyse and survey these data.

The structural microheterogeneity of solid polymers, even those in the amorphous state (see, for example, Jech[3] and Arzhakov et al.[4] as well as Lebedev's review[5]) has important kinetic consequences.

1. The microheterogeneity of the distribution of the reactants in the matrix leads to the possibility that their local concentrations differ significantly from the average values and the experimental rate constants calculated in relation to the average concentrations differ appreciably from the true values. The microheterogeneity in the distribution of the reactants can also be one of the causes of the manifestation of polychromatic kinetics characteristic of reactions in solid matrices: the reactions take place at a higher rate in regions with higher local concentrations and, as these regions become exhausted, those with lower local concentrations are "manifested". Formally, this will be described as a distribution with respect to the reaction rate constants. The microheterogeneity of the distribution of reactants is shown most distinctly in amorphous-crystalline polymers. For example, a stable nitroxy-radical is localised exclusively in the amorphous phase of polypropylene (PP)[6]. Antioxidants are also localised in the amorphous regions and the solubility of antioxidants in isotropic PP depends on its supermolecular structure: 80% of antioxidants are dissolved within spherulites and in the interfibril and defective intrafibril regions, while 20% are localised at the interspherulite interfaces[7]. Allowance for the heterogeneity of the distribution of antioxidant molecules in the polymer matrix is extremely important for the practical stabilisation of polymers.

2. The most important structural-physical parameter of a solid polymer for kinetics is the distribution with respect to the frequencies and amplitudes of molecular movements, which also leads to a distribution with respect to the reaction rate constants. This problem has been analysed in detail in a review[8]. The relation between the kinetics and molecular mobility is determined, firstly, by the dependence of the rate of diffusional encounters between the reactant molecules on the molecular mobility of the polymer, and, secondly, by the influence of the molecular dynamics directly on the chemical reactions step (see, for example, Girva and co-workers[6,9,10]). The possible physical mechanisms of the influence of molecular mobility on the reactivity have been discussed[8].

3. Finally the relation between the reaction kinetics and the set of polymer conformations, specific to reactions in polymer matrices, is due to the fact that many reactions in polymers take place intramolecularly. An example may be provided by the radical substitution reaction

(I)

which is a reaction involving the propagation of kinetic chains in the chain oxidation of polyolefins, leading to the migration of a free valence in the specimen. The ratio of the rate constants for the intramolecular and intermolecular reactions (I) in 2,4-dimethylpentane, a low-molecular-weight

analogue of polypropylene, at 100 °C is approximately two orders of magnitude[11]. An important structural requirement for the intramolecular transfer of a hydrogen atom from a carbon atom to a peroxy-radical is the formation of six-membered (or larger) rings in the transition state. In general, the abstraction of a hydrogen atom by a free radical requires that the bond ruptured should be located on the axis of the unpaired electron at a distance of 1.5–2 Å from the latter, i.e. that the pre-start state of the reactant should be located on the reaction coordinate[8]. Evidently the probability of the appearance of such a pre-start state and the probability of the formation of a transition complex having the optimum structure depend on the local conformation of the reaction centre. In polymers structural relaxation takes place slowly and the local mobility of a section of the macromolecule depends on its local conformation[12], so that one can expect a dependence of the kinetics of intramolecular reactions on the set of conformations of the polymer. Examples of such a relation will be considered below.

The conformations of macromolecules can influence, albeit to a smaller extent, also the rates of intermolecular reactions; for example, the rate constant for the abstraction of a hydrogen atom by the t-butoxy-radical in atactic PP at 45 °C is lower by a factor of two than in 2,2,4-trimethylpentane[13], which is associated with the steric hindrance to the reaction in the polymer; such hindrance should depend on the conformations of the macromolecules.

Under the influence of mechanical stresses, all the structural-physical parameters of the matrix significant for the kinetics of chemical reactions change in polymers. We shall consider mainly the effect of stretching stresses, which has been studied in greatest detail.

In the first place we shall note that two types of elasticity—predominantly entropic and predominantly energetic—are characteristic of polymers as a medium consisting of long and flexible chain molecules. The appearance in the polymer of entropic stresses is associated with the deviation of the conformations of the macromolecules from the statistically most probable conformations†. Energetic stresses are determined by the distortion of the valence angles and by the change in the lengths of the chemical bonds.

The calculated moduli of elasticity for various types of deformation of macromolecules have been published[14]. For the "pure" extension of a C=C bond, the modulus of elasticity is 740 GPa, for the extension of a "zig-zag" chain it is 180–340 GPa, and for the bending of a C=C bond and the hindered rotation of helices the moduli are 80 and 4–7 GPa respectively. The moduli of elasticity corresponding to the entropic and energetic stresses differ by two orders of magnitude. The deformation of polymers under the influence of external stretching stresses therefore initially takes place as a result of conformational rearrangements, which lead to the appearance of internal entropic stresses, and only after their completion does the distortion of valence angles and bonds, leading to the weakening of chemical bonds in the macromolecular skeleton, begin.

As will be shown below, entropic stresses become fixed ("frozen") in the amorphous phase of oriented amorphous-crystalline polymers if the latter are not subjected to a special heat treatment inducing the relaxation of the stress (annealing). Energetic stresses in amorphous-crystalline polymers arise after the application of an additional external load to oriented specimens, particularly in the region of plastic deformations.

† As a consequence of the presence of barriers to internal rotation, a purely entropic elasticity does not exist in polymers just as an ideal gas does not exist. We are only concerned with the question which component of elastic forces—entropic or energetic—is dominant.

II. THE INFLUENCE OF MECHANICAL STRETCHING STRESSES ON THE STRUCTURAL-PHYSICAL PARAMETERS OF POLYMER MATRICES

1. The Change in the Supermolecular Structure of Polymers under the Influence of a Stretching Load

Under the influence of stretching stresses, high and reversible (in the case of rubbers) deformations develop in amorphous highly elastic polymers (raw and cured rubbers) and the macromolecules are subjected to an orientation, which relaxes after the removal of the load (the preferred directions in the disposition of the macromolecular axes relative to the stretching axis appear). An enforced elasticity is manifested in vitreous amorphous polymers and an orientation arises which persists after the removal of the load at temperatures not exceeding the glass point. In isotropic amorphous-crystalline polymers the stretching stresses lead to profound structural rearrangements; the spherulitic structure is transformed into a fibrillar structure.

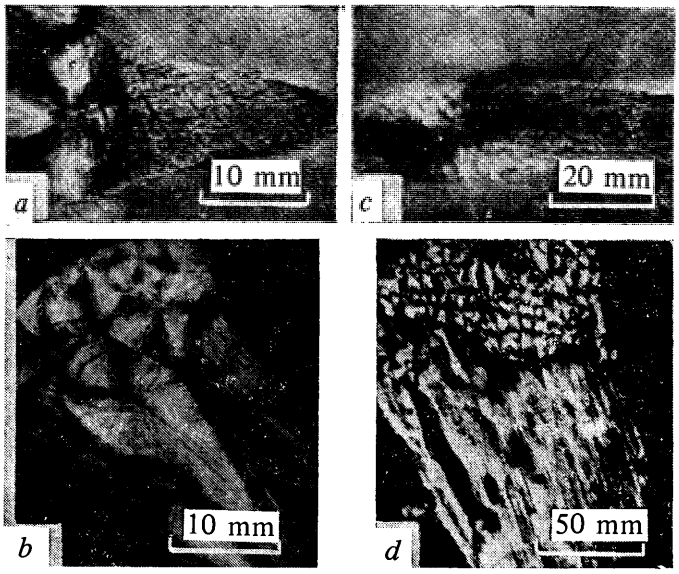


Figure 1. Stages in the deformation of a spherulite and the structure of the neck in isotactic PS[15].

The photomicrographs in Fig. 1 illustrate different stages in the deformation of a single spherulite in isotactic polystyrene (PS)[15]. The deformation of the spherulite takes place abruptly with formation of a "microneck" and a distinct interface persists between the deformed and undeformed parts of the spherulite. After the conversion of the entire spherulite into the "microneck", uniform deformation of the resulting oriented structure takes place and the formation of the microfibrillar structure is completed. In contrast to the

spherulitic structure, the microfibrillar structure is characterised by a distinct anisotropy of its properties. The microfibrils distributed along the direction of the extension contain alternating regions with crystalline and amorphous orders whose dimensions depend on the stretching (and annealing) conditions. The linkages between individual crystallites within the fibrils are formed by "crossing" macromolecules and also by a network of engagements between macromolecules, each of which returns to its "own" crystallite. In the transverse direction the individual microfibrils are linked by cohesive forces and crossing chains whose number is significantly lower than in the intrafibril regions. The transverse strength of monoaxially oriented polymer specimens is therefore much lower than their longitudinal strength.

As a result of the structural rearrangements induced by mechanical stresses, the proportions of the low-molecular-weight compounds in polymers and their solubilities change and there is a significant alteration of the molecular-dynamic properties of the matrices and the set of their conformations.

2. The Change in the Solubilities of Low-Molecular-Weight Compounds in Stressed Polymers

For elastomers, this question has been discussed in greatest detail[16] for rubbers stressed in a complex manner. Under the conditions of static compression, mechanical stresses lead to an anomalous transport of low-molecular-weight substances (plasticisers and inhibitors). The situation is different when elastomers are acted upon by stretching stresses: for deformations which do not induce the crystallisation of raw rubber (less than 200%), the permeability and diffusion characteristics hardly change[17,18]; for greater deformations, the crystallisation of raw rubber results in a significant decrease of the sorption and diffusion coefficients of low-molecular-weight compounds[17].

For vitreous amorphous and amorphous-crystalline polymers, the dependence of the permeability parameters on the stretching stress is complex[19–23]. In the region of stresses corresponding to the elastic deformations of the polymer, the degree of sorption of low-molecular-weight substances increases with increase of the stress owing to the increased fraction of the free volume in the specimen (in the majority of amorphous-crystalline polymers the Poisson coefficient is less than 0.5). In the region of stresses corresponding to plastic deformations, the sorption of low-molecular-weight compounds decreases appreciably with increase of deformation as a consequence of the decreasing density of the amorphous component[21]. The authors[21] based their interpretation of the experimental results on the model of impermeable microfibrils distributed in the bulk of the interfibrillar amorphous component. Despite the approximate nature of this model, in most cases its application is justified by the fact that the solubilities of low-molecular-weight compounds in amorphous-crystalline polymers are proportional to the fraction of the amorphous phase[24,25].

The study of the influence of mechanical stresses on the permeability parameters for oxygen is naturally of greatest interest for the elucidation of the kinetics of oxidation processes. There are few such data in the literature. It has been shown[25] that the solubility of oxygen in PP is proportional to the fraction of the amorphous phase and depends on the supermolecular structure of the polymer. However, one should note that the concept of the impermeability of the crystalline phase of amorphous-crystalline polymers to oxygen is not entirely correct. For example, in the radiation-induced initiation of radicals in the crystalline phase of PP in an oxygen atmosphere, all the alkyl radicals are converted into peroxy-radicals, i.e. oxygen diffuses into the crystalline phase of the PP (and into the even looser crystalline phase of poly-4-methylpent-1-ene). This is not observed in polyethylene (PE): the dense crystalline regions of this polymer are impermeable to oxygen[24] (for further details, see the relevant review[26]—pp.22–30). The solubilities of oxygen in unannealed (subjected to an entropic stress) and annealed (unstressed) oriented films of isotactic PP have been compared[27]. The solubility in the unstressed oriented films proved to be higher by a factor of 1.5–2.5 than in the annealed films. However, the influence of mechanical stresses on the sorption characteristics of the polymer is significantly weaker than their influence on the molecular-dynamic and diffusion parameters.

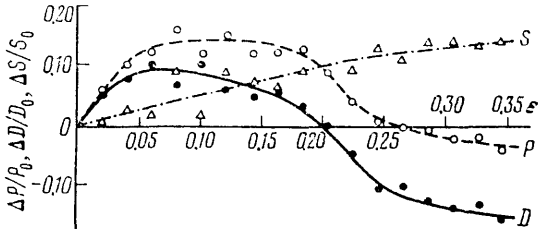

Figure 2. The relative changes in the sorption (S), diffusion (D), and permeability (P) coefficients for CO_2 in PE films as a function of the degree of deformation ε of an isotropic film[21].

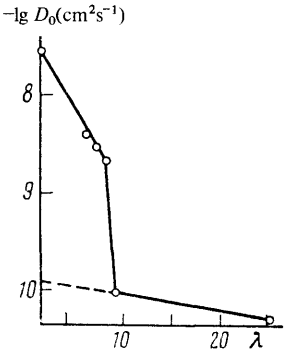

Figure 3. Variation of the diffusion coefficient of CH_2Cl_2 in PE with the degree of orientational extension λ.[21]

3. The Changes in the Molecular Dynamics and Diffusion Parameters in Oriented and Stressed Polymers.

The deformation of elastomers (in the absence of crystallisation) does not change appreciably their diffusion characteristics[17], while the diffusion characteristics of amorphous-crystalline polymers can change by several orders of magnitude on deformation. In the region of small reversible elastic deformations of PE (Fig.2), the diffusion coefficients of gases increase somewhat (like the increase in the degree of

sorption, this is also evidently associated with the increase in free volume), but, after the appearance of the plastic component of the deformation, the diffusion coefficient falls sharply (Figs.2 and 3)[21]; for example, threefold orientation stretching of PE leads to a decrease of the diffusion coefficient of gases by a factor of 40–50. The most marked diminution of the diffusion coefficient takes place over a narrow range of degrees of stretching apparently corresponding to the termination of the formation of a microfibrillar structure[21]. An analogous dependence on the degree of stretching has been observed for the diffusion coefficients of nitrogen and methane in oriented PP (Fig.4)[28].

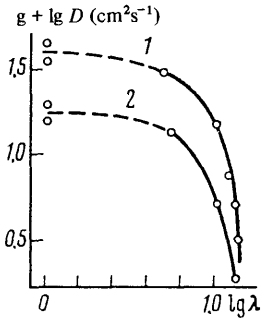

Figure 4. Variation of the diffusion coefficients of nitrogen (curve *1*) and methane (curve *2*) in PP with the degree of extension λ.[28]

One should note that the influence of the deformation of the polymer on the diffusion coefficients of low-molecular-weight substances is greater the greater the size of the diffusant molecule[20].

The change in the polymer permeability parameters on orientational extension is associated with the presence of unstressed extended fragments of the micromolecules in the amorphous phase. The more complete was the preceding relaxation of the amorphous phase, the smaller were the changes in the sorption and diffusion coefficients for the same degree of extension; an increase of the extension temperature or annealing of the oriented polymer above the extension temperature therefore diminish appreciably the changes in the permeability parameters[21].

The changes in the translational diffusion coefficient of low-molecular-weight substances in stressed oriented polymers, apart from the molecular-dynamic polymers, have purely geometrical causes: during their migration, the species must move round impermeable or relatively impermeable crystallites (or microfibrils), which leads to an increase in the length of the diffusional transport path. The contribution of the purely geometrical causes to the change in the translational diffusion coefficients on deformation of the polymer can be isolated by the paramagnetic probe method. The influence of the degree of extension of PP on the rotational and translational mobility of a stable nitroxy-radical, namely the 2,2,6,6-tetramethylpiperidin-1-oxy-radical, has been investigated[29].

Data for the dependence of the translational and rotational diffusion coefficients of this radical in PP on the degree of extension at 80° and 130 °C are presented in Table 1. Evidently at 80 °C, where $\lambda = 7$, the translational diffusion coefficient in the specimen decreases by a factor of 8 compared with the isotropic polymer, while the rotational diffusion coefficient diminishes less than by a factor of 2. These data refer to specimens in which the probe radical has been introduced before extension; on the other hand, if the radical is introduced into specimens which have already been oriented, then, up to $\lambda = 7$, the rotational frequencies do not change at all relative to the isotropic polymer, since the radical enters the "softest" and accessible regions of the specimen. Nevertheless the translational diffusion coefficient of the radical falls compared with its value in the isotropic polymer, which is evidently due solely to geometrical obstacles, which increase as the polymer is oriented. The data obtained made it possible to estimate the coefficient γ, which takes into account the increase, due to the geometrical obstacles arising in the orientational extension, of the path traversed by the radical: $\gamma = 1.4$ and 2.1 for specimens with $\lambda = 4.5$ and 7 respectively. Consequently, for specimens with $\lambda = 7$, all the changes in the translational diffusion coefficient greater than by a factor of two are due to the decrease of the segmental mobility of the macromolecules.

Table 1. Dependence of the translational (D_t) and rotational (D_r) diffusion coefficients of the probe radical on the degree of extension of PP at 80° and 130 °C.[29]

λ	$10^9 D_t$, $cm^2 s^{-1}$	$10^{-8} D_r$, s^{-1}	$10^7 D_t$, $cm^2 s^{-1}$	$10^{-9} D_r$, s^{-1}
	80° C		130° C	
0	5.4	7.9	2.9	7.2
4.5	1.9	6.6	1.7	4.7
7.0	0.7	4.6	1.9	2.8
10.0	—	4.3	—	2.0

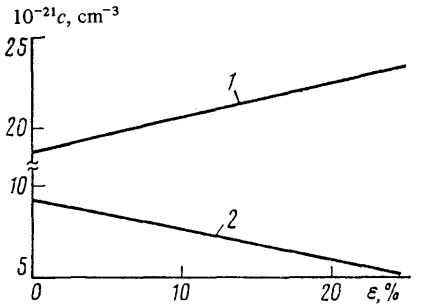

Figure 5. Variation of the concentrations of the *trans*-conformation (line *1*) and the *gauche*-conformation (line *2*) in oriented PE ($\lambda = 10$) under the conditions of additional deformation along the stretching axis[38].

We may note that at room temperature the rotation of the radical in PP is significantly hindered and is relatively insensitive to the stress[29]. The low sensitivity of the rotational mobility of the radical to the external load applied to PP at room temperature is apparently associated with the same factor[30,31]: the maximum changes in the rotational correlation time of the probe in the range of stresses from 0 to 250 MPa do not exceed 9%. Furthermore, NMR spectroscopy has revealed significant changes in the segmental mobility of the molecules of oriented PP subjected to an external load[32].

4. The Change in the Set of Conformations of Micromolecules under the Influence of a Stretching Load.

The change in the molecular dynamics of polymers, to which a load has been applied and which are subjected to orientation, takes place as a result of a change in the set of conformations: the depletion of the specimen in the mobile coiled conformations and its enrichment in the relatively immobile extended conformations (i.e. a decrease of the entropy of the system)[33-39]. Fig.5 illustrates the changes in the concentrations of the *gauche*- and *trans*-isomers when a load is applied to oriented PE (according to the data of Pakhomov et al.[38]). The dependence of the contents of various conformers in the polymer chain on the degree of its extension has been studied theoretically[39]. It was shown that in the initial stage of the extension the chain is stretched mainly as a result of the reorientation of its elements: the coiled G-isomers are distributed more uniformly along the chain, preferentially in the vicinity of extended T-isomers as neighbours, and the fraction of G-isomers begins to fall appreciably only for fairly high degrees of extension (Table 2). The relative positions of the coiled isomers are characterised by the concentrations of triads containing one *trans*-isomer and two coiled isomers (Fig.5). The most stable triads, containing the G-isomers in the extended chain, are the TGT and GTG′ triads, which is natural, since precisely these triads cause the smallest shortening of the chain for the given number of G-isomers (they are incorporated in a "kink" in the PE chain). It has been shown experimentally[38] that, in the region of elastic deformations of PE, the extension of amorphous layers from 40 to 60 Å leads to a more than 30% decrease of the number of TGT and GTG′ triads; on further extension, the specimen breaks. It is natural to suppose that the synchronous disappearance of the above triads is associated with the straightening out of the "kink", i.e. with a simultaneous conversion of two G-isomers into T-isomers; this is also indicated by the activation energy for the deformation (~ 8 kcal mol^{-1}), exceeding by a factor greater than two the height of the barrier to internal rotation in the PE chain.

Table 2.

$\varkappa$	α_{TG}	α_{GG}	α_{G}
0	0.94	0.68	0.80
1	0.90	0.70	0.81
2	0.86	0.72	0.82

Note. α are the degrees of extension of the chain for which the concentrations of the isomers and diads containing the G isomers decrease by a factor of two compared with the unstretched chain ($\alpha = 0$) and $\varkappa = E/kT$ is the thermodynamic rigidity of the chain[39].

It has been shown[39] that the decrease of the concentration of the TGT and GTG′ triads begins for fairly high degrees of extension of the chain (~ 0.9). The fact that the number of these conformers diminishes by more than a third in prerupture PE deformations means that the fraction of chains stretched to this extent is more than one third of the total number of crossing chains; the long range of the degrees of deformation (~ 50%) in which the concentration of these triads diminishes enabled the authors[39] to postulate that in some of the chains there is additional stretching of the fully extended *trans*-chains as a result of the deformation of the valence angles.

It must be emphasised that the above investigators[39] based their calculation on the PE chain model in which the conformation extended to the maximum extent consists of a flat zig-zag. As a consequence of the interaction of the methyl groups, the flat zig-zag does not occur in PP and the conformation extended to the maximum of extent consists of a sequence of TGT triads corresponding to the α-helix in PP crystals.

It follows from the above that the statistical weight of the mobile coiled conformations diminishes following the extension of polymer chains. The corresponding calculations have been carried out for the PE chain[40]. From these results, it was possible to estimate the contribution of the entropic elasticity to the forces tending to contract the extended polymer chain. In terms of order of magnitude, these forces are close to the energetic contribution by the elastic forces of the "kink" isomers (associated with the existence of a barrier to internal rotation) but have the opposite sign.

The variation of the free energy F of the partly extended chain as a function of the distance between its ends is illustrated in Fig.6[14] (p.129). The minimum free energy of the chain corresponds to a distance between its ends $r = (n-n_k)\sqrt{2}/3a$, where n is the total number of C–C bonds, n_k is the number of "kink" isomers, and a is the length of the C–C bond. If the ends of the chain are displaced from the equilibrium positions, then elastic forces arise which are associated with the hindered rotation of the *gauche*-bonds outside the plane of the zig-zag of the PE chain and the deformation of the *trans*-bonds in the plane of the zig-zag.

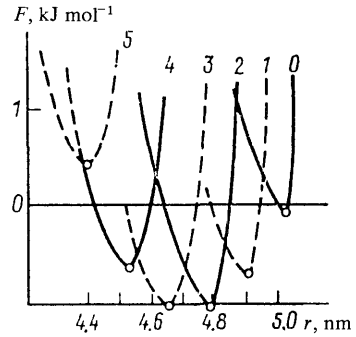

Figure 6. Variation of the free energy F of a partly extended PE chain with the distance r between its ends; the numerals against the curves represent the numbers of kink isomers[14] (p.129).

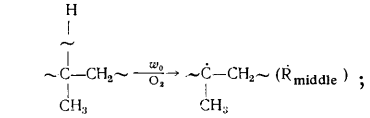
The modulus of the chain containing different conformers is specified by the expression

$$1/\bar{E} = \sum_i x_i/E_i ,$$

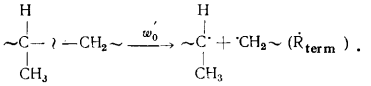
where E_i are the moduli of the individual conformers and x_i are their volume fractions. The smaller the content of *gauche*-conformers in the chain the greater the rigidity of the latter; the presence of only five "kink" isomers in the PE chain reduces the modulus from 200 to 9.5 GPa. It is seen from Fig.6 that, when the chain is extended, there are transitions between individual conformational states and the transition to the more extended conformation removes the axial stress from the section of the chain considered, i.e. it is a thermodynamically favourable process.

The results of a calculation by Darinskii and Neelov[39] and Pechhold[40] are extremely important for the interpretation of the experimental data obtained in the study of the kinetics of the oxidation of oriented and stressed polyolefins.



III. KINETICS AND MECHANISM OF THE OXIDATION OF STRESSED POLYMERS.

The discovery in 1950 by Kuz'minskii and co-workers of the phenomenon of the mechanical activation of the oxidation of raw and cured rubbers[1,2,41], the wisely familiar acceleration of the ozone-induced cracking of resins under a mechanical stress (see, for example, Refs.42–53), and the acceleration of the degradation of the C–C bonds in the macromolecular skeleton of mechanically stressed polymers[54] led to the idea that the oxidation reaction is as a rule accelerated under the influence of mechanical stresses. The onset of the breakdown of these traditional ideas dates back to the middle 1970's when studies on different polymeric objects and by different methods, showing that the acceleration of chemical reactions and particularly the oxidation reactions under the influence of mechanical stresses is by no means a universal phenomenon, were published independently and almost simultaneously[55–68]. This is associated with the fact that oxidation is usually a complex chain process whose individual stages vary differently in the stressed polymer. We shall consider the influence of mechanical stresses (1) on the kinetics of the oxidation of polyolefins under the influence of molecular oxygen and ozone and (2) on the kinetics of the ozonisation and oxidation of raw and cured rubbers.

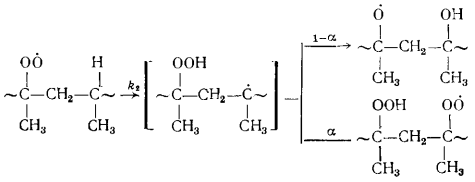


1. Kinetics and Mechanism of the Thermo-oxidation of Stressed Polyolefins under the Influence of Molecular Oxygen

The generally accepted mechanism of the chain oxidation of polyolefins is presented below.

Initiation:

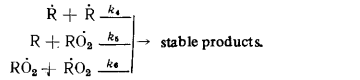
(0)



(0′)*

Chain propagation:

(1)



(2)*

Branching:

(3)*

Chain termination:

(4)
(5)
(6)

The asterisk denotes stages in which polymer chains may be degraded. The mechanism includes four main stages: initiation, propagation, degenerate branching, and termination of kinetic chains. The changes in the overall kinetics of the oxidation in stressed polyolefins occur as a result of the influence of mechanical stresses on the rate of each of the above stages. We shall consider in succession the data available at present concerning the influence of stretching stresses on the rate of each stage.

(a) Primary initiation. The primary initiation of radicals in stressed polyolefins can take place via two main pathways: reaction (0)—"direct" interaction of oxygen with macromolecules leading to the rupture of a C–H bond and the formation of internal alkyl macroradicals (this is the "usual" initiation stage in unstressed systems in which various admixtures such as the residues of the polymerisation catalysts apparently play a significant role[69]) and reaction (0′)—the rupture of C–C bonds in the macromolecular skeleton with formation of terminal macroradicals (this reaction proceeds only in stressed polymers).

The influence of structural stresses on the rate of reaction (0)—the rupture of C–H bonds under the influence of various hydrogen acceptors—has been investigated[62,63] for model compounds—unstressed and stressed cyclic paraffins. It has been shown[62] that the reaction of stressed cyclic paraffins with olefin is accelerated relative to the unstressed six-membered ring: by a factor of 48 for the eight-membered ring, by a factor of 89 for the nine-membered ring, and by a factor of 6 for the less stressed twelve-membered ring. An attempt has been made[64] at a quantitative interpretation of these results. The rate constant for the reaction with ozone depends on the excess energy of the ring subjected to stretching stresses, in conformity with the expression

$$\ln (k_i/k_0) = \gamma (E_{\text{exc}}^{\alpha}/RT) \ .$$

The authors[64] suggested that, in any reaction accompanied by the rehybridisation of the sp^3 carbon atom to the sp^2 state and hence by an increase of the valence angle, a stretching stress should reduce the activation energy: the increase of the valence angle under the influence of the stretching stress increases the energy of the molecule in the initial state by $E_{\text{init}} = 0.5C(\Delta\alpha)^2$. where C is a constant and $\Delta\alpha$ the radiation of the valence angle from the optimum value. During the abstraction of a hydrogen atom, the deviation of the angle from the optimum value diminishes and $E^{\neq}$ is therefore lower than E_{init}, which leads to a decrease of E_{act}. The above is valid also for reactions involving the abstraction of a hydrogen atom from polyolefin molecules.

This hypothesis has been tested experimentally[65] for the reaction of ozone with PP, high-density polyethylene (HDPE), and low-density polyethylene (LDPE). It was shown that the rate of accumulation of carbonyl groups in PP and PE increases linearly with increase of the stress. The rate of relaxation of the stress under the conditions of constant deformation differs significantly in oxygen and in ozone, the difference increasing with increasing stress, which indicates an increase of the rate of ozone-induced degradation of the macromolecule as the stress becomes more pronounced.

Studies on the ozone oxidation of the surfaces of isotropic PP films with different thermal histories[66] demonstrated the faster "combustion" of the bonds corresponding to the long-wavelength wing of the 973 cm^{-1} band in the absorption spectrum of PP. The authors interpreted this as a result of the faster reaction with ozone of the most overstressed C–H bonds. However, the long-wavelength wing of the band can correspond to bonds in other conformations rather than the overstressed bonds[70] and the result obtained by

Krisyuk[66] is thus a consequence of the different reactivities of different conformers. At the present time there are insufficient data for the solution of this problem.

The results of the above studies[62,64-66] have been surveyed by Popov et al.,[31] who demonstrated that the orientation and external load applied to oriented specimens have effects of different sign on the rate of the ozone oxidation of PP and PE. It was shown that the observed effects cannot be accounted for by a change in the degree of orientation, the degree of crystallinity, and the molecular dynamics of the polymers under load. Popov et al.[31] concluded that the main cause of the acceleration of the reactions of ozone with PP and PE under load is the stress-induced decrease of the activation energy for the abstraction of a hydrogen atom from the polymer chain. Unfortunately, the investigators[31,65,66] inferred the acceleration of reaction (0) in stressed polymers from the increase of the rate of acceleration of secondary products (carbonyl groups, breaks in macromolecules), which are produced as a result of subsequent reactions of the alkyl macroradicals generated in reaction (0).

However, the author's view[31,65,66] is apparently valid: additional (albeit also indirect) confirmation of the acceleration of reaction (0) in stressed PP has been obtained recently[71] (Fig.7). In the uninhibited oxidation of PP subjected to an external load there is a range of stresses in which the durability of the polymer is determined by the rate of the thermo-oxidative chain degradation and depends only slightly on the load[59,72,73] (Fig.7, curve *1*). In the inhibited specimen the chain oxidation process is suppressed, as a result of which in the region of low stresses its durability increases by more than an order of magnitude compared with the uninhibited specimen and is determined by the inhibitor consumption time, which depends on the rate of initiation (after the consumption of the inhibitor, the oxidative chain degradation leads to rapid decomposition of the specimen).

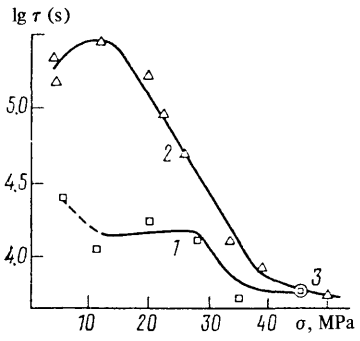


Figure 7. Isotherms of the durability in air of oriented PP ($\lambda = 7$), both uninhibited (curve *1*) and inhibited (curve *2*); inhibitor—Ionox; [InH] = 3×10^{-3} mol kg^{-1}; point *3* corresponds to the durability of the inhibited specimen *in vacuo*[71].

Fig.7 (curve *2*) shows that in the range of stresses 15–35 MPa the durability of the polymer falls exponentially with increase of the applied stress, which may indicate an increase of the rate of initiation [it will be shown below that in the range of stresses indicated the oxidation is initiated via reaction (0)]#. The causes of the increase of the rates of reaction may be associated with the fact that the rehybridisation of a carbon atom from the sp^3 to the sp^2 state as a result of the hydrogen atom abstraction reaction entails an increase in the length of the macromolecular fragment, which promotes the relaxation of part of the stress, and not with the deformation of the valence angles in the pre-start state (the absolute values of the applied stresses are fairly low—see Fig.7).

The second initiation reaction [reaction (0') involving the dissociation of a C–C bond in the macromolecular skeleton], leading to the formation of terminal macroradicals, takes place only in stressed polymers. Its rate increases exponentially with increase of the applied stress, as shown in numerous studies of Zhurkov's Leningrad School (see, for example, Regel' et al.[54]).

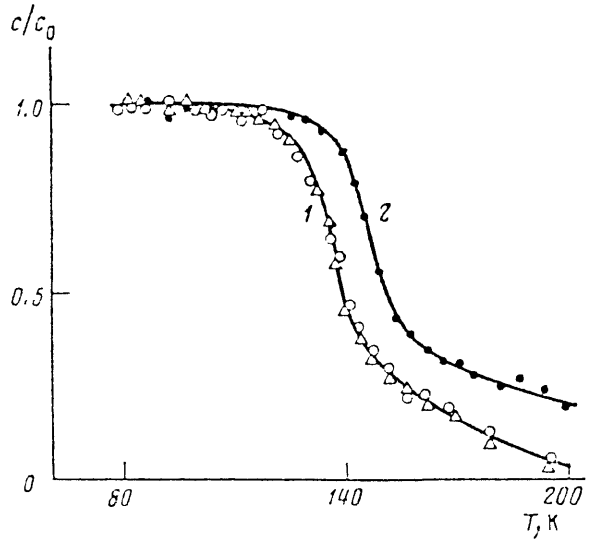

Figure 8. "Heating" curves for the reaction between Ṙ and NO in isotropic PP specimens (curve *1*) and specimens oriented with $\lambda = 9$ (curve *2*).[77]

(b) Propagation of the kinetic chains. The first kinetic chain propagation reaction involves the addition of oxygen to alkyl macroradicals [reaction (1)]. In polymers this reaction proceeds under microdiffusional conditions[74-76] and its rate is controlled by the rate of microdiffusion of oxygen via the polymer matrix. The decrease of the translational mobility of gases in PP as a result of orientational extension (see Fig.4 and Tochin et al.[28]) should lead to a decrease of the rate of reaction (1) in oriented PP. It follows from the data of Yakimchenko et al.[77] that this is indeed observed.

An unambiguous interpretation of these results is hindered by the fact that the oxidation under load is of a distinctly local character (see below): the concentration of the inhibitor in the region of the future break can be partly made good as a result of diffusional "suction" from neighbouring regions where it is consumed more slowly, the translational diffusion coefficient of the antioxidant depending on the applied stress[117].

The above investigators[77] studied the rate of reaction between $\dot{R}$ and NO (modelling the reaction of $\dot{R}$ and O_2) in isotropic and oriented PP. Fig.8 presents the "heating" curve for this reaction in isotropic and oriented ($\lambda = 9$) PP specimens and Fig.9 presents the kinetic curve for the destruction of the radicals $\dot{R}$ at a fixed temperature. Evidently alkyl radicals are destroyed more slowly in oriented PP than in the isotropic polymer. This is consistent with the shift of the spectrum of free energies of activation towards higher values.

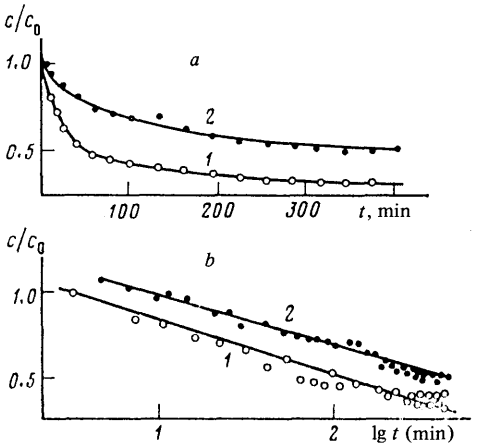

Figure 9. Kinetic curves for the destruction of alkyl radicals by the reaction between $\dot{R}$ and NO in PP (*a*) and the corresponding semilogarithmic plots (*b*)[77]; for legend, see Fig.8.

The application of an additional load to oriented specimens can entail a change in the diffusion coefficients of oxygen relative to the unstressed oriented specimens and the corresponding change in the rate of reaction (1); however, according to Iasuda and Peterlin[20,21], in the region of reversible deformations the scale of these changes is significantly smaller than on transition of the polymer from the isotropic to the oriented state. It may be expected that, in PP specimens maintained under isometric conditions (with the ends fixed), i.e. in the state of elastic deformation at the oxidation temperature (130 °C), the diffusion coefficient of oxygen is somewhat greater than in specimens subjected to shrinkage (for a degree of extension $\lambda = 9$ at 130 °C, the shrinkage is ~ 20%). However, the relevant experimental data are not available in the literature.

The changes in the translational diffusion coefficient of a bulky stable nitroxy-radical (the 4-methyl-2-spiro-cyclohexyl-2,3,3,4-tetrahydrofurano-1,2,3,4-tetrahydroquinoline-nitroxy-radical) in oriented PP subjected to a monoaxial load ($\lambda = 6$) at 120 °C have been investigated[74]. It was observed that, in a certain range of stresses, the diffusion coefficient of the radical increases with increase of the stress and then falls sharply, the difference between the maximum and minimum diffusion coefficients of the radical observed in the investigation amounting to approximately one order of magnitude. We have already mentioned that the influence of the deformation of the polymer on the diffusion coefficients of low-molecular-weight substances is greater the larger the size of the diffusant molecule. *D* decreases exponentially with increase of *V**, where *V** is the product of the cross-section of the diffusant molecule and the length of the jump in the activated diffusion model[20]. Naturally, for the diffusion of oxygen, the dependence of the diffusion coefficient on the load is significantly less (for example, the orientational stretching of PP to $\lambda = 7$ decreases the translational diffusion coefficient of a very large nitroxy-radical, namely the 2,2,6,6-tetramethylpiperidinoxy-radical, by a factor of approximately 100 at room temperature[29]), while the diffusion coefficient of nitrogen falls only severalfold under these conditions[28].

Thus one can assume that the influence of the external load on the diffusion coefficient of oxygen in oriented specimens [and hence also on the rate of reaction (1)] is small. It may be expected that, under the conditions of plastic deformation, the rate of reaction (1) increases. (It is known, for example, that, in the absence of a mechanical influence at 77 K, alkyl radicals are not converted into peroxy-radicals in an oxygen atmosphere; on the other hand, when various polymers are vibromilled at 77 K in an atmosphere of oxygen, peroxy-radicals are formed, which is evidently associated with the enforced acceleration of the diffusion of oxygen in the specimen[78].)

At fairly high oxygen pressures the rate of reaction (1) influences the kinetics of the oxidation of polyolefins only indirectly (see below) because the rate-limiting stage in the propagation of kinetic chains is reaction (2).

In polyolefins reaction (2) can proceed intramolecularly and intermolecularly. In PE and its low-molecular-weight analogues the main pathway in reaction (2) is apparently intermolecular. Indeed, according to Ivanchenko et al.,[79] the rate constant for the abstraction of a hydrogen atom from the PE macromolecule in solution (in the presence of the cumenylperoxy-radical as the acceptor) at 115 °C amounts to 0.12 litre mol^{-1} s^{-1}, which corresponds to a lifetime of the peroxy-radical in PE, relative to the intermolecular chain transfer reaction, of ~ 2.5×10^{-2} s. (Account is taken of the fact that the reactivity of the secondary peroxy-radical in PE is ~ 3 times higher the reactivity of the tertiary cumenylperoxy-radical, and the concentration of the reactive C–H bonds in block PE is 142 mol kg^{-1}.[80] This estimate for the "ideal" intermolecular reaction (2) was made without taking into account the specific features of the reactions in the solid phase where the constant may be significantly lower.)

The lifetime of the peroxy-radical of PE, in relation to the intramolecular radical substitution reaction, can be estimated from data obtained in a study[81] whose authors investigated the transition $RO_2^{\cdot} \rightarrow R^{\cdot}$ in PE–urea complexes, where it proceeds strictly intramolecularly. Extrapolation of the above data[81] to 115 °C yields the lifetime of the peroxy-radical PE in relation to the "ideal" intramolecular reaction (2), which amounts to ~ 3×10^2 s, i.e. higher by almost four orders of magnitude than the lifetime in relation to the intermolecular reaction. Such differences are apparently caused by the low probability of the activated complex with the optimum linear structure in the section of the chain having the *trans*-zig-zag conformation in PE–urea complexes. Examination of the possibility of reaction (2) in the *trans*-zig-zag PE model shows that the formation of a linear activated complex requires the distortion of the *trans*-zig-zag as a consequence of a change in the angles of internal rotation or the distortion of the valence angles. This factor probably determines the high activation energy for the intramolecular reaction (2) in the PE–urea complex (24.6 kcal mol^{-1}[81]), while in n-decane the activation energy for the abstraction of a hydrogen atom by the cumenylperoxy-radical is 17.5 kcal mol^{-1}.[80]

The preferentially intermolecular course of reaction (2) in PE is also indicated by the large fraction of the monomeric (not linked by hydrogen bonds) hydroperoxide formed on oxidation: whereas mainly bound hydroperoxide is formed in substituted poly-α-olefins (PP, poly-4-methylpent-1-ene-P-4-MP-1) on oxidation, in PE the concentration of the free hydroperoxide exceeds that of the bound form[82].

A necessary condition for the intermolecular transfer of kinetic chains is molecular mobility which ensures the encounter of the peroxy-macroradical with a neighbouring macromolecule. As shown in Sections II.3 and II.4, orientational stretching decreases the segmental mobility of the macromolecules in the amorphous phase, which can influence the rate of reaction (2). Indeed, according to the data of Rapoport et al.,[82] in the radiation-induced oxidation of PE at room temperature the parameter $k_2/k_6^{1/2}$ in oriented PE is lower by a factor of ~ 1.5 than in the isotropic monomer; this is evidently associated with a decrease of k_2, because the destruction of radicals is also controlled by molecular dynamics and for oriented PE the constant k_6 should be lower than for the isotropic polymer (see below).

In contrast to PE, in substituted poly-α-olefins and their low-molecular-weight analogues, reaction (2) proceeds mainly intramolecularly[11,83-85]. Examination of the probability of the intramolecular reaction (2) of a model of the PP macromolecule showed[55] that the reaction is virtually impossible if the radical is localised in the section of the macromolecule having an extended TGT conformation (the same as in PP crystallites): in this case the peroxy-radical is shielded from the neighbouring tertiary C–H bonds of the same macromolecule. Reaction (2) becomes sterically feasible only if the reaction centre undergoes the TGT → TGG evolution.

The formation of the conformation necessary for the reaction can be formally regarded as the "encounter" of a radical in the TGT conformation with a G conformer "diffusing" in the macromolecule. In reality the diffusion process constitutes a concerted transition of the type $\mathrm{TGTGTGT} \underset{k_{-r}}{\overset{k_r}{\rightleftharpoons}} \mathrm{TGGTGGT}$. The cooperative nature of the transition is due to the fact that the TT and GGG conformations in PP are forbidden (the former as a consequence of the "overlap" of the methyl groups and the latter due to the effect of the excluded volume). Attention should be drawn to the fact that the number of G conformers on the right-side of the scheme presented exceeds their number on the left-hand side, i.e. conformational transitions of this kind require the presence of "superfluous" G conformers in the macromolecule (compared with their number in the fully extended helical TGT sequence). The number of *gauche*-conformers in a given section of the macromolecule is determined by the ratio of its contour length to the distance between its ends and for each macromolecule in the amorphous phase of an amorphous-crystalline polymer is specified "genetically" at the instant of crystallisation or orientational extension.

Formally, reaction (2) can be considered from the standpoint proposed[86,87] for the kinetic description of bimolecular solid-phase reactions. Reaction (2) is described as a result of the reaction in the radical–GG conformer pair:

$$\mathrm{GG} + \mathrm{R\dot{O}_2} \underset{k_{-r}}{\overset{k_r}{\rightleftharpoons}} [\mathrm{R\dot{O}_2}(\mathrm{GG})] \xrightarrow{k_x} \mathrm{ROOH}\ .$$

Assuming that $k_r \cong k_{-r}$, we obtain the following expression for the rate of reaction (2) in the quasi-stationary approximation:

$$w_2 = \frac{k_x k_r}{k_x + k_r} [\mathrm{GG}] [\mathrm{R\dot{O}_2}] \equiv k_{\mathrm{eff}} [\mathrm{GG}] [\mathrm{R\dot{O}_2}]\ .$$

If the rate-limiting stage is the "encounter" of the GG conformer with the radical, then $k_{\mathrm{eff}} \cong k_r$; if the reaction in the pair is rate-limiting (i.e. not every collision of the radical with the GG conformer results in reaction), then $k_{\mathrm{eff}} \cong k_x$; in the intermediate case k_r and k_x are added together in accordance with the law of kinetic resistances.

In any case the rate of the intramolecular reaction (2) is proportional to the concentration of the GG conformers in the macromolecule. In the amorphous phase of amorphous-crystalline polymers there is always a distribution of sections of the macromolecules with respect to the contour length and hence a distribution with respect to the concentrations of the GG conformers§. In the oxidation of amorphous-crystalline polymers one should therefore observe a distribution with respect to the constants k_2 and the latter, determined on the basis of the overall kinetics of the oxidation reaction[89,90] (and incidentally also the constants k_1 and k_6) are effective average quantities for the given distribution.

The lowest constant k_2 is to be expected in the crystalline phase of PP where the unreactive TGT conformation predominates and constitutes "the elementary unit" of the helix and the characteristic reaction time is probably the expectation time for the formation of a defect in the helix at the site of the location of the radical. Reaction (2) in the crystalline phase of PP has been investigated[91] in the temperature range 270–300 K; an estimate of the effective value of k_2^{cr} from the results of this investigation yields ~ 2×10^{-5} s^{-1}, which is lower approximately by three orders of magnitude than k_{eff} for the amorphous phase of PP[89,90]. Such differences between the rates of reaction (2) in the crystalline and amorphous phases of PP are apparently a result of the "conformational inhibition" of the reaction in the crystalline phase[61]. The existence of a distribution with respect to the constants k_2 in PP is indicated by the results of a study[92] in which the kinetics of the destruction *in vacuo* of the peroxy-radicals of PP, obtained by γ-radiolysis at −78 °C and at room temperature, were investigated. The authors[91] fitted sets of three (irradiation at −78 °C) or two (irradiation at room temperature) exponential functions to the kinetic curves obtained. The plots of c/c_0 against lg τ, based on the results of the above study[92], are straight lines which may be evidence in support of the existence of a distribution function for the reactive species with respect to the constants k_2; the lowest constant k_2 agrees in order of magnitude with the value determined[91] for the crystalline phase of PP.

In the orientation stretching of polymers and following the application of an additional load to them, the conformers are redistributed (there is a decrease of the fraction of GG pairs and an increase of the fraction of TG pairs) and the overall concentration of the coiled conformers decreases (see below). As was to be expected, this results in a decrease of the average effective value of the constant k_2[89] by (a factor of 3–4 in oriented PP compared with the isotropic polymer). Although the absolute changes in the effective constant k_2 in oriented PP are small, the shift of the distribution towards lower values of the constants for the extended chains,

---

§ Attempts to establish the character of the distribution of sections of macromolecules with respect to length have been made[88]. Histograms of the concentrations of the free radicals formed in the stepwise deformation of PA-6 fibres were constructed. Unfortunately the results obtained are not unambiguous because it is still not clear whether there is a direct correlation between the concentration of the free radicals detected and the concentration of the ruptured macromolecules.

enriched in the unreactive TGT conformers, plays a decisive role in the strength of the material and its change during oxidative degradation, which are very important characteristics.

(c) Reaction (2) and the variation of the strength characteristics of PP in the oxidation process. The strength properties of amorphous-crystalline polymers are determined by the "tail" of the distribution of sections of the macromolecules in the amorphous phase with respect to lengths, which corresponds to the shortest and therefore the most extended chains incorporating the smallest number of coiled *gauche*-conformers. According to Kaush and De Vries[88], the fraction of fully extended macromolecules in PA-6 fibres, responsible for the modulus of elasticity and the strength properties of the specimen, is 1.1%, while 98.6% is the fraction of chains in the unextended state (see the preceding footnote concerning these results). The greater the degree of extension, the higher the fraction of the short-chain "tail" of the distribution, the greater the number of the fully extended macromolecules, and the higher the initial strength of PP[58]. It follows from the above that the probability of the intramolecular reaction (2) involving such macromolecules should be a minimum; reaction (2) in polyolefins results in the formation of hydroperoxy-groups whose thermal decomposition is usually accompanied by the degradation of the macromolecules and serves as the main source of the decrease of the molecular weight in autoxidation[93,94]. If reaction (2) proceeds intramolecularly, a hydroperoxide block is formed. According to Shlyapnikova and Shlyapnikov[94], the probability of the degradation of the macromolecule on decomposition of the hydroperoxide increases with increase of the length of the block:

$$\rho_d = 1-(1-\rho_1)^{\nu_{bl}},$$

where ρ_1 is the probability of the decomposition of a single hydroperoxy-group without the degradation of the macromolecule and ν_{bl} is the length of the block.

The presence of extended conformers prevents the intramolecular propagation of the kinetic oxidation chain; the more extended the chain, the smaller the number of GG conformers in it, and the lower the probability of the intramolecular reaction (2). Short hydroperoxide blocks or isolated hydroperoxy-groups would therefore be expected to form on the extended macromolecules [as a result of the intramolecular reaction (2), whose rate constant has been shown, in relation to low-molecular-weight analogues of PP, to be significantly lower even in the liquid phase than the intramolecular constant k_2 (Mill and Montorsi[11]]; the intermolecular reaction should be even slower in the solid polymer, where its rate is limited by the rate of encounters of the reactants, one of which is the stressed polymer chain, and, apart from diffusion-dependent obstacles, there is also steric hindrance to the reaction[13].

The isolated hydroperoxy-groups are decomposed several times more slowly than the block groups[84]. Consequently both the formation and the decomposition of the hydroperoxy-groups are retarded on extended macromolecules, which should lead to a sharp fall of the rate of the oxidative degradation of the extended macromolecules compared with the degradation of the coiled macromolecules. Since extended macromolecules are in fact responsible for the strength properties of the polymer, for the same degree of oxidation one should expect a smaller diminution of the strength of the specimens having a higher concentration of extended macromolecules, i.e. specimens which are more highly oriented. It has been shown[55] that this is indeed the case (Fig.10).

Formally, the amorphous phase of oriented PP can be divided into two unequal parts: in the larger part enriched in the coiled conformations (the "soft" part), there is rapid intramolecular propagation of the kinetic chains leading to the formation of hydroperoxide blocks, and degradative processes develop (this part of the polymer is responsible for the overall kinetics of the absorption of oxygen), while in the smaller ("hard") part, enriched in the extended conformations, the intramolecular propagation of kinetic chains is inhibited and their oxidative degradation is much slower; the absorption of oxygen by these macromolecules does not contribute appreciably to the overall oxidation kinetics but they are in fact responsible for the retention of the strength properties of the specimens undergoing oxidation. The retention of non-degraded extended macromolecules even for high degrees of oxidation of oriented PP has been confirmed in experiments involving the measurement of the repeated durability of unannealed and annealed PP specimens[61] (see below).

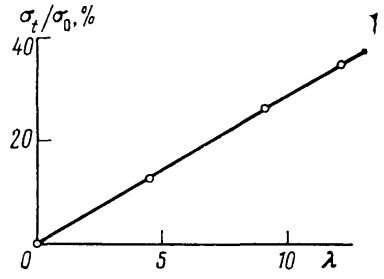

Figure 10. Dependence of the relative strength of PP on the degree of extension for absorption of O_2 at a concentration of 0.5 mol kg^{-1}.[55]

Thus a mechanical stress, leading to a decrease of the diffusional mobility of the polymer matrix and altering the set of conformations of the macromolecules in favour of the extended isomers, causes a decrease of the effective rates of both propagation reactions of the kinetic oxidation chains [reactions (1) and (2)].

(d) The branching of kinetic chains. The degenerate branching of kinetic chains in polyolefins takes place as a result of the thermal decomposition of the hydroperoxy-groups into radicals. Since side groups are decomposed in this reaction, a mechanical stress should not influence significantly the decomposition rate constant. Nevertheless, the rate of degenerate branching of kinetic chains in oriented PP proved to be significantly lower than in the isotropic polymer[57,95]. This is associated with the decrease of the yield of the branching agent—the hydroperoxide (calculated per mole of the absorbed oxygen).

Fig.11 presents the kinetic curves for the accumulation of hydroperoxide in the autoxidation of PP specimens with different degrees of orientational extension. Evidently a decreasing concentration of the accumulated hydroperoxide corresponds to the same amount of absorbed oxygen in the specimens with an increasing degree of extension. It has been shown[57] that this is not associated with the increase of the rate of the thermal decomposition of the hydroperoxide in the oriented specimens. The observed effect is caused by the induced decomposition of the hydroperoxy-group

under the influence of the alkyl macroradical present in it in the β-position—the isomerisation of the β-hydroperoxyalkyl radical [see the scheme below illustrating the sequence of reactions (2)]. The addition of oxygen to the alkyl macroradical, resulting in the formation of a "stable" hydroperoxy-group, competes with the isomerisation reaction. Within the framework of this mechanism, the yield of the hydroperoxide per mole of absorbed oxygen (α) is defined by the expression

$$\alpha = k_1[O_2]/(k_1[O_2] + k_5) ,$$

i.e. depends on the rate of reaction (1). Thus the rate of reaction (1) diminishes as a result of the orientational stretching of PP: the induced decomposition of the hydroperoxide begins to complete successfully with the addition of oxygen to the alkyl macroradical, which leads to a decrease of the parameter α. In this case the kinetic chain propagation reaction [reaction (2)] results in the preferential formation of an alcoholic hydroxy-group and an alkoxy-macroradical and not the branching agent (hydroperoxide) and an alkyl macroradical. The validity of the proposed interpretation is confirmed by the dependence of α on the oxygen pressure in the oxidation reaction[96-98].

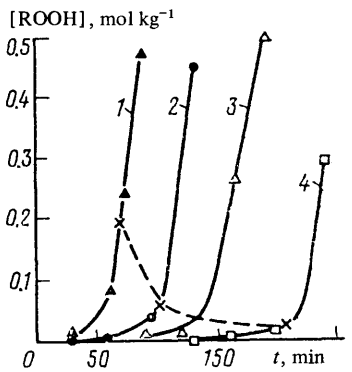

Figure 11. Kinetic curves for the accumulation of hydroperoxide in the autoxidation of PP with different degrees of extension (130 °C, p_{O_2} = 600 mmHg)[27]; the points corresponding to the absorption of oxygen at a concentration of 0.5 mol kg^{-1} are joined by a dashed line; λ: 1) 0; 2) 4.5; 3) 7; 4) 9.

The decrease of the yield of the hydroperoxide per mole of the absorbed oxygen in oriented PP specimens should lead to an increase of the induction period of the autoxidation relation, which has been observed experimentally[58] (see below).

(e) Termination of kinetic chains. In solid polymers the rate of destruction of macroradicals is limited by the rate of their encounters and is sensitive to the intensity of molecular movements[8]. In order to account for the experimentally observed high rates of destruction of macroradicals in solid polymers, the dependence of the rates of destruction on molecular mobility of the system, the anomalously high activation energies for the degradation process, and the compensation effect, several models have been proposed and have been examined critically[8].

In the amorphous phase of the isotropic PP the rate of destruction of peroxy-radicals ($k_6 \cong 10$ litre mol^{-1} s^{-1})[88,99] exceeds by 2–3 orders of magnitude that observed in the crystalline phase of PP even at room temperature[100] (the constant k_6 is undoubtedly an effective quantity; the activation energy is E_6^{PP} = 28.5 kcal mol^{-1}). Orientational stretching, which leads to a decrease of the average segmental mobility in the amorphous phase of the polymer, induces a decrease of the rate of destruction of the radicals[89, 101,102]. The data for PP[89] are presented in Fig.12. They correspond to the destruction of radicals in elastically deformed and entropically stressed PP. An entirely different dependence of the rate of destruction of radicals on the stress is to be expected in the case where the polymer undergoes plastic deformations: the enforced mixing of macromolecules under the influence of mechanical stresses increases the rate of their encounters and the rate of their destruction[103-105]. The destruction of radicals in the crystalline phase of PE and PP fibres at the instant of deformation of the crystallites¶ has been observed[104] (Fig.13).

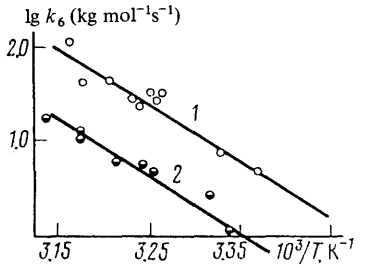

Figure 12. Temperature variation of the rate constant for the destruction of peroxy-radicals in PP: 1) isotropic; 2) oriented (λ = 8)[88].

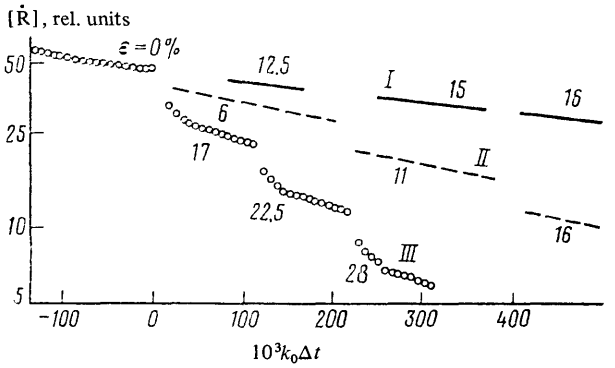

Figure 13. The influence of the degree of deformation of polymers ε on the destruction of radicals in irradiated and heat-treated PA-6 (I), PP (II), and PE (III) fibres; the reduced time is plotted along the abscissa axis; k_0 = rate constant for the destruction of radicals with zero deformation; Δt = time from the onset of deformation[14] (p.240).

¶ This is most probably associated with the formation and migration of defects in the crystal structure at the instant of deformation of the specimen.

An analogous effect has been investigated by Radtsig and Rainov[105], who showed that the reaction involving the destruction of the peroxy-radicals of polystyrene (PS) (which proceeds with a kinetic arrest at a temperature below T_g) can be restarted if the polymer is subjected to a brief plastic deformation at 77 K: the migrations of the macroradicals and macromolecules alter the local environment of the macroradicals and restore the initial distribution of the radicals with respect to reactivity. Thus the plastic deformation of the polymer should promote an increase of the rate of destruction of the macroradical. In PP this effect can be enhanced also by the fact that, as will be shown below, in the region of plastic deformations the initiation of kinetic chains proceeds preferentially via reaction (0) with formation of terminal macroradicals, which are more mobile and reactive than the internal macroradicals.

The results of the study of the influence of the stretching stresses on individual stages of the chain oxidation show that in the region of both elastic and plastic deformations the stresses accelerate the initiation reactions (0) and (0') and inhibit the kinetic chain propagation reaction (2), while reaction (1) and the kinetic chain termination reaction (6) are inhibited in the region of elastic deformations and are accelerated in the region of plastic deformations; the reaction involving the degenerate branching of the kinetic chains [reaction (3)] is inhibited in the region of elastic deformations.

The influence of stretching stresses on the rate of the overall oxidation depends on the role which each of the above stages plays in the overall chain process.

2. The Influence of Stretching Mechanical Stresses on the Overall Rate of Oxidation of Polyolefins

We shall consider initially the effects of orientational extension in the kinetics of the oxidation of polyolefins and then the effects of an external load applied to the oriented specimens and hence the problem of the durability and mechanism of the decomposition of polyolefins subjected to the joint action of mechanical stresses and an oxidising medium.

(a) The effects of orientational extension in the overall kinetics of the oxidation of polyolefins. This process has been studied in detail in a series of investigations[27,55–58,60,82,89,95,98,106] and has been examined critically in a review[26]. Here we shall deal briefly with the main results. Fig.14 presents the kinetic curves, for the absorption of oxygen in the autoxidation of unannealed and annealed PP films with different degrees of extension, and their linear forms. The kinetic parameters of the oxidation process are compared in Table 3 with the structural-mechanical parameters of the oriented specimens. The kinetics of the oxidation of the oriented PP are characterised by the following main features:

(1) the induction period in the oxidation of unannealed PP specimens increases exponentially with increasing degree of extension (Fig.14a) (an analogous relation has been observed for polyamide fibres[107]); (2) the differences between the initial rates of oxidation (reflected in the increase of the induction period with the degree of orientation) persist along the autocatalytic sections of the kinetic curves: the slopes of the linear forms of the curves diminish with increasing degree of extension (Fig.14c); (3) the maximum rates of oxidation are independent of the degree of extension; (4) starting with a specific duration of oxidation, the kinetic curves for the absorption of oxygen can be satisfactorily fitted by parabolas and the linear forms of the kinetic curves do not pass through the origin of coordinates [it has been suggested that the time interval t_0 obtained by extrapolating the linear forms of the curves (Fig.14c) to the abscissa axis be referred to as the true induction period of the uninhibited oxidation of PP[106]]; during the period t_0, the oxidation of the polymer develops at a very low rate; (5) annealing leads to the smoothing out of the differences between the oriented and isotropic specimens.

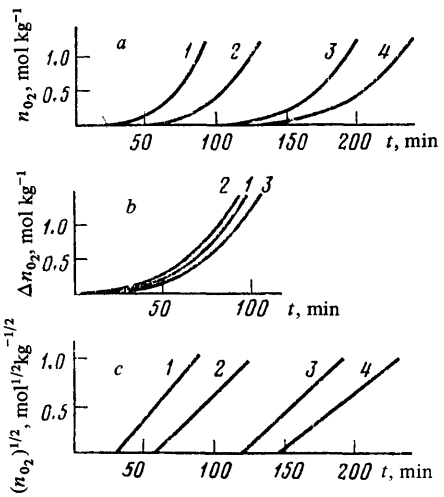

Figure 14. Kinetic curves for the absorption of oxygen in the autoxidation of PP: *a*) unannealed specimens; *b*) annealed specimens; *c*) linear plots corresponding to the kinetic curves; λ: 1) 0; 2) 4.5; 3) 9; 4) 12 (130 °C, p_{O_2} = 600 mmHg)[58].

The following main conclusions have been reached on the basis of the data presented.

1. The decrease of the initial rate of oxidation (the increase of the induction period) as a result of the orientational extension is not associated with a change in the degree of crystallinity, as is usually assumed (see, for example, Winslow et al.[108]): during annealing, the degree of crystallinity increases appreciably (from 64 to 76%), while the induction period of the oxidation reaction actually diminishes.

2. The changes in the oxidation kinetics are due to the presence of stressed extended macromolecules in the amorphous phase: annealing, leading to the relaxation of the internal stresses and the restoration of the compact conformations of the macromolecule[58,108], eliminates the differences between the oriented and isotropic specimens. Chemical relaxation of internal stresses, associated with the rupture of the extended macromolecules during the oxidation process itself, leads to the same result (this explains the equality of the maximum rates of oxidation for specimens with different degrees of extension).

Thus the main effect of orientational extension in the kinetics of the oxidation of PP is a significant increase of the induction period of the autoxidation reaction. An analogous phenomenon has been observed in the oxidation of oriented poly-4-methylpent-1-ene (P-4-MP-1)[110]. Differences between the kinetics of the absorption of oxygen by isotropic and oriented specimens were not observed in the autoxidation of PE at 130 °C,[82] which is natural because at this temperature relaxation processes take place vigorously in PE.

The data presented in the previous Section concerning the changes in the kinetic parameters of the individual stages of the chain oxidation of stressed PP show that, when PP is oriented, the effective rate constants for the propagation and termination of kinetic chains (k_2 and k_6) decrease in such a way that the parameter $k_2/k_6^{1/2}$, which determines the rate of the oxidation reaction at an advanced stage, diminishes slightly (by a factor of ~ 1.5 in the specimen with $\lambda = 4.5$, obtained by stretching an isotropic specimen subjected to preliminary oxidation). The changes in the initial rate of reaction exceed significantly the changes in the parameters $k_2/k_6^{1/2}$ (for example, the induction period of the oxidation reaction involving the specimen with $\lambda = 12$ increases by a factor greater than 4 compared with the isotropic specimen—see Table 3).

Table 3. Relation between the structural-mechanical parameters of oriented PP specimens and the kinetic parameters of their autoxidation (130 °C, p_{O_2} = 600 mmHg).[58]

λ	$10^3_s{}^0 r_{corr}$,	α_{cr}, %	σ, MPa	E, MPa	τ_{ind}, min	$10^6 b$, $mol^{1/2} kg^{-1/2} s^{-1}$	$10^4 w_{max}$, $mol\ kg^{-1} s^{-1}$
0	5.4/5.4	58/70	0	2	40/30	2.8/2.1	6.9/4.9
4.5	5.7/5.4	66/74	13	40	75/30	2.4/—	6.2/4.5
9.0	7.9/5.4	64/76	86	290	140/35	2.1/—	6.2/4.5
12.0	9.3/5.4	65/71	215	660	170/40	1.9/—	6.2/5.0

Note. The values for the unannealed and annealed specimens are given in the numerator and denominator respectively. Notation: τ_{corr} is the correlation time of the rotational movement of the probe radicals (the 2,2,6,6-tetramethylpiperidin-1-oxy-radical) at 60 °C, α_{cr} the degree of crystallinity, σ the stress in the orientational extension, $E = (2\lambda + 1)(d\sigma/d\lambda)$ the conventional rigidity, τ_{ind} the induction period of the autoxidation reaction, b the slope of the linear form of the kinetic curve for the absorption of oxygen in Fig. 14c, and w_{max} the maximum rate of absorption of oxygen.

The causes of the change in the induction period of the oxidation reaction during the orientational extension of PP have been examined[95,106]. However, before proceeding to their discussion, one must deal briefly with the question why an induction period arises at all in the uninhibited oxidation of PP and P-4-MP-1 or, in other words, why the kinetics of the initial stage of the oxidation reaction differ from the characteristics of the reaction at an advanced stage.

The derivation of kinetic information about the process occurring during the induction period presents considerable experimental difficulties, because the rates and degrees of oxidation are then very low. The absence of the necessary kinetic information does not at present permit unambiguous answers to the question posed. It has been shown[106] that the kinetic features characteristic of reactions with degenerate branching and quadratic termination of the kinetic chains are established only after the accumulation in the specimens of specific concentrations of the hydroperoxide (2×10^{-2} mol per kg of the amorphous phase, 80 °C, 760 mmHg O_2), which are approximately equal for the isotropic and oriented specimens (Fig. 15). It has been suggested[106] that at lower concentrations the hydroperoxide in PP has a low initiating capacity and is not the main source of radicals; the initiation reaction proceeds via the direct interaction between oxygen and the macromolecules [reaction (0)].

The results obtained recently in the study of the kinetics of the autoxidation of PP at elevated oxygen pressures[111] may serve as confirmation of the ideas described: it was found that the induction period decreases with increasing oxygen pressure over the entire range of pressures (from 0.02 to 4.24 MPa), while the maximum rate of accumulation of carbonyl groups virtually ceases to depend on the oxygen pressure already at $p_{O_2} \cong 0.45$ MPa. The activation energy for the induction period in the range 60–90 °C proved to be 24 kcal mol^{-1}. The low initiating capacity of the hydroperoxide formed in the initial stage of the oxidation reaction may be associated with the fact that its decomposition proceeds either as the unimolecular reaction

$$ROOH \xrightarrow{k_{s1}} R\dot{O} + \dot{O}H$$

(activation energy 35 kcal mol^{-1}, low values of k_3) or via the reaction

$$ROOH + RH \xrightarrow{k_{s2}} [R\dot{O} + \dot{R}] + H_2O \rightarrow \delta\dot{R}\ ,$$

in which rapidly recombining alkyl and alkoxy-macroradicals are formed (low degree of liberation of radicals from the cage, low values of δ). At higher concentrations the hydroperoxide apparently decomposes in intermolecular pairs linked by a hydrogen bond:

$$ROOH + ROOH \xrightarrow{k_{s3}} [R\dot{O}_2 + R\dot{O}] + H_2O \rightarrow \delta'\dot{R}\ .$$

The maximum rate of initiation corresponds to this reaction[86]. The increase of the initiation rate constant approximately by an order of magnitude with increase of the hydroperoxide concentration is observed also in the liquid phase: in the initial stage of the oxidation of n-decane and in the decomposition of t-butyl hydroperoxide[112].

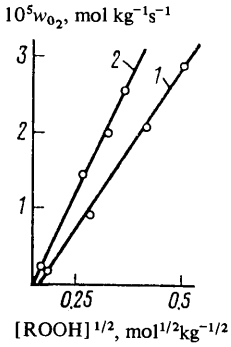

Figure 15. Dependence of the rate of absorption of oxygen on the concentration of the hydroperoxide for isotropic (line *1*) and oriented ($\lambda = 9$) (line *2*) PP films (80 °C, p_{O_2} = 760 mmHg)[107].

An alternative hypothesis concerning the causes of the induction period in the uninhibited oxidation of PP has been put forward[113]. It has been shown[114,115] by the EPR method that the rate of destruction of peroxy-radicals decreases with increase of the hydroperoxide concentration in PP subjected to preliminary oxidation: at room temperature k_6 falls from 170 to 5.2 kg mol^{-1} s^{-1} with increase of the hydroperoxide concentrations from 2.5×10^{-3} to 1×10^{-1} mol kg^{-1}, but, after the accumulation of hydroperoxide to give a concentration of 4×10^{-2} mol kg^{-1}, the constant k_6 changes only slightly. If it is assumed that the constant k_2 remains

unchanged during oxidation, then the changes in k_6 lead to an increase of the parameter $k_2/k_6^{1/2}$ with the degree of oxidation.

In principle, this can explain the difference between the kinetics of the initial stage and the advanced reaction. However, the induction period in the oxidation of PP is observed also at high temperatures (130 °C and above) where the constants k_6 are close to the "chemical" rate constant for the destruction of tertiary radicals in the liquid phase even for the oxidised polymer and it is difficult to expect higher values of k_6 in the initial stage. We therefore believe that the hypothesis of a low initiating capacity of the hydroperoxide formed in the initial oxidation stage is more likely. In one way or another, the establishment of the kinetic features characteristic of the advanced reaction is associated with the accumulation in the specimens of a hydroperoxide up to a specific concentration, which is virtually the same for isotropic and oriented specimens (Fig.15).

It was shown in Section III.1 that the rate of formation of the hydroperoxide falls when PP is oriented as a consequence of the decrease of the yield of the hydroperoxide per mole of absorbed oxygen. This factor is apparently the main cause of the increase of the induction period in the oxidation of PP subjected to orientational extension[95,106]. The decrease of the yield of the hydroperoxide is a consequence, in its turn, of the structural-physical changes occurring during the orientational stretching and is associated with the decrease of the rate of microdiffusion of oxygen in the polymer. This results in an increase of the rate of the induced decomposition of the hydroperoxide, which takes place without branching of the kinetic chains. We emphasise yet again that the oxidation of the entropically stressed specimens is slower than that of the unstressed specimens. The relaxation of stresses and the restoration of the compact conformations of the macromolecules in the amorphous phase of the oriented specimens smooth out the structural-physical differences between the isotropic and oriented specimens and increase the rate of oxidation of the latter (Table 3). This has important and interesting consequences for the kinetics of the oxidation and the durability of the specimens subjected to an external stretching load.

(b) The kinetics of the oxidation, durability, and mechanism of the decomposition of polyolefins subjected to an external stretching load. The mechanical load alters the structure of the molecular-dynamic properties of polymer matrices (see Section II); it is therefore natural to expect that the kinetics of the oxidation of polymers subjected to an external load will differ from the kinetics of the oxidation of specimens without an applied load. A series of studies devoted to this question have been carried out on oriented PP[59,72,73,116,117]. The specimens were maintained under different loads until rupture under the conditions of vigorous thermo-oxidative degradation and the durability of the polymer was compared with the concentrations and proportions of the oxidation products in the ruptured specimens. It was shown that, in the oxidation of PP subjected to an external stretching load, there exists a range of stresses in which the durability of the polymer depends only slightly on the load[59] and can actually increase as the latter is increased[117], but under these conditions the durability *in vacuo* is smaller by many orders of magnitude, i.e. is determined wholly by the rate of the thermo-oxidative degradation processes[71-73]. As an illustration, Fig.16 presents (on the basis of the data of Livanova et al.[73]), the durability isotherms (*a*) and curves relating to the rate of the steady creep to the stress (*b*) in oxygen and *in vacuo* for different PP specimens. The durability isotherms can be arbitrarily divided into three sections: along section I, the durability is determined by the rate of the thermo-oxidative chain degradation, along section II, by the sum of the rates of the mechanoinitiated and oxidative degradation, and along section III, solely by the rate of the mechanodegradation of the macromolecules carrying the load (which diminishes in a certain range with increase of the stress as a consequence of processes involving the orientational strengthening of the polymer). Accordingly, the durability increases significantly along section I after the introduction of inhibitors[60,71], while along section III it remains unchanged (Fig.7).

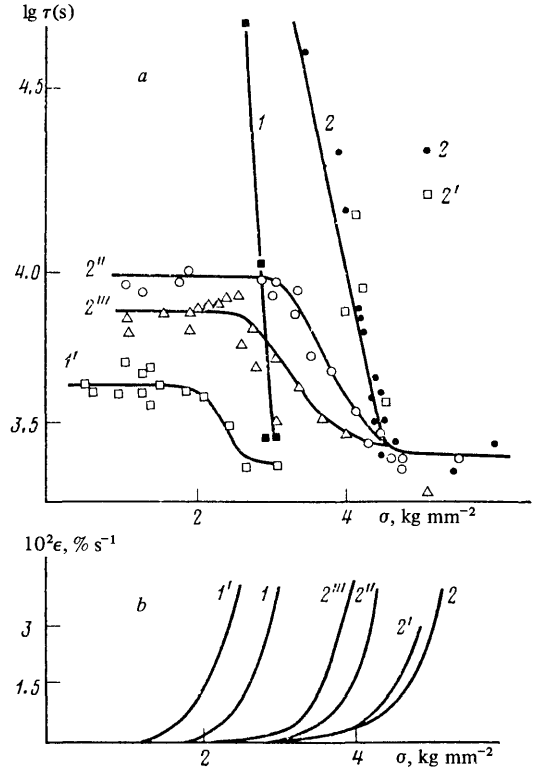

Figure 16. Durability isotherms (*a*) and the dependence of the rate of steady creep on the stress (*b*) at 130 °C for $\lambda = 5$ (curves *1* and *1′*) and 7 (curves *2* and *2′*–*2‴*) in oxygen (curves *1′*, *2″*, and *2‴*) and *in vacuo* (curves *1*, *2*, and *2′*) for unannealed (curves *1*, *1′*, *2*, and *2′*) and annealed (curves *2′* and *2‴*) specimens[73].

Fundamentally new results have been obtained[60,116] in a study of the concentration and distribution of the oxidation products in PP specimens oxidised under an external load. More than 100 specimens differing in the degree of extension, the initial structure (unannealed and annealed), and in the external stress (σ = 5–70 MPa) were investigated. In these studies the distribution of the oxidation products in the film was determined by scanning the specimen with a beam of infrared light focussed on to an area of 1 mm^2. We shall now describe the main results.

1. With increase of the applied stress, the transition from elastic deformations to creep deformations entails a change in the concentration and composition of the oxidation products

in the zone of the rupture of the specimens, indicating a change in the initiation mechanism: initiation via reaction (0) is gradually replaced by initiation via reaction (0'). This is accompanied by a decrease of the length of the kinetic oxidation chains and, under the conditions of fairly high stresses, the oxidation reaction passes from the chain to the non-chain regime. Fig.17 presents (on the basis of the data of Rapoport and co-workers[60,116]) the infrared spectra of the ruptured specimens in the region of the vibrations of the carbonyl and hydroxy-groups. For stresses corresponding to elastic deformations, the shape of the absorption band of the carbonyl groups in the stressed PP hardly differs from that of the band in the spectrum of the polymer oxidised without an external load; the band maximum at 1710 cm^{-1} corresponds to the C=O stretching vibrations in ketones (Fig.17*a*, spectrum *1*). With increase of the stress, the maximum shift towards higher frequencies, whereas for stresses corresponding to plastic deformations the maximum is observed at 1740 cm^{-1}, which indicates the predominant formation of aldehyde groups (Fig.17*a*, spectrum *3*).

The changes in the spectrum of the carbonyl groups occurring as the deformation regime is altered are accompanied by a sharp diminution of the concentration of hydroxy- and hydroperoxy-groups. In specimens oxidised under the conditions of plastic flow, where the aldehyde groups are virtually the only carbonyl oxidation products, the hydroperoxide cannot be determined iodometrically and the ratio of the concentrations of the aldehyde and hydroxy-groups is ~ 1:1, which corresponds to the ratio which should be obtained in the disproportionation of peroxy-radicals, one of which must be a terminal radical. This implies that in the region of plastic deformations the oxidation reaction virtually passes to a non-chain regime and consists in the formation, oxidation, and destruction of terminal macroradicals.

The data obtained indicate a change in the initiation mechanism: for small stresses, the initiation proceeds via reaction (0) and leads to the formation of middle macroradicals, whose subsequent chain reactions give rise to ketone, aldehyde, hydroperoxy-, and other groups. With increase of the stress, the mechanoinitiated rupture of C–C bonds, leading to the formation of terminal macroradicals, begins to play an increasing role. Evidently this is accompanied by a sharp increase of the rate of termination of the kinetic chains: the terminal radicals are more mobile than the middle radicals formed via reaction (0) and their destruction takes place in the plastically deformed matrix, which, as shown in section III.1, accelerates the process. The non-chain character of the oxidation under the conditions of high stresses is confirmed by the absence of the influence of inhibitors on the durability time in this region of stresses (Fig.7).

2. The fact that the oxidation process under a mechanical stress is local in character, observed by Rapoport and co-workers[60,116], is very important. At the site of the future break in the film, an oxidation centre arises and spreads in the specimen over a distance which depends on the stress in the oxidation reaction and on the structure of the specimen. This results in the establishment of a concentration gradient of oxygen-containing groups in the rupture zone. In the group of spectra *b* and *c* in Fig.17 the lower spectra correspond to the rupture zone of the specimens and the upper spectra to the "matrix" (sites remote from the rupture zone). For a fixed stress, the concentration gradient in the unannealed specimens is always greater than in the annealed specimens (Fig.18, curves *1* and *1a*). For specimens with a fixed structure, the concentration gradient increases sharply with increase of the stress in the oxidation process (Fig.18, curves *1–3*). As a result, the concentration of carbonyl groups, averaged over an area of 1 mm^2 in the rupture zone,

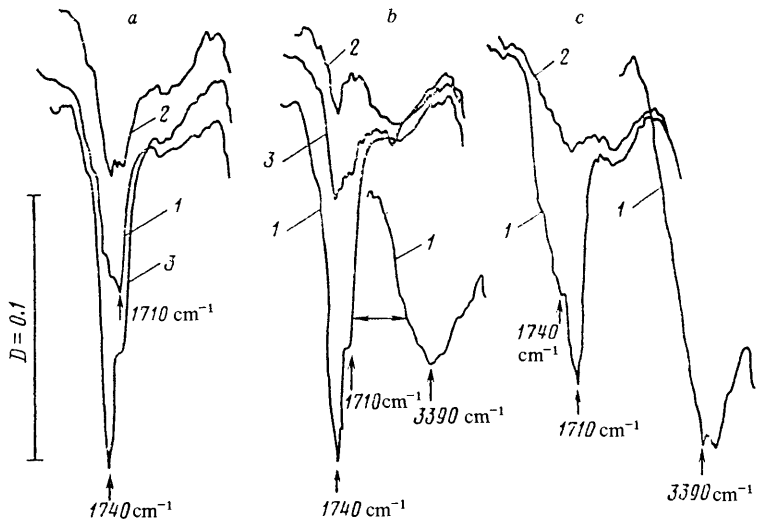

Figure 17. Infrared spectra of PP specimens subjected to an external load up to rupture; *a*) $\lambda = 7$, annealed specimen [σ(MPa): 1) 10; 2) 13; 3) 20]; *b*) the same specimen, $\sigma = 20$ MPa [1) rupture zone; 2) and 3) matrix]; *c*) $\lambda = 4$, unannealed specimen [1) rupture zone; 2) matrix][60,116].

decreases with increasing stress (Fig.19). For example, in unannealed specimens a change of the stress from 10 to 40 MPa (the region of elastic deformations) results in a decrease of the concentration of carbonyl groups in the rupture zone by a factor of 20. The same effect is observed in the annealed specimens. The durability of the specimens in the range of applied stresses 10–40 MPa are very similar. The data presented imply that the average rate of oxidation in the rupture zone diminishes with increasing stress. Since the rate of the initiation reactions increases with increasing stress and the rate of destruction of radicals falls in the region of elastic deformations (Section III.1), the decrease of the overall rate of oxidation with increasing stress can be a result of a decrease of the rate of propagation of kinetic chains induced by the additional enrichment of the amorphous phase of the polymer in macromolecules with extended conformations.

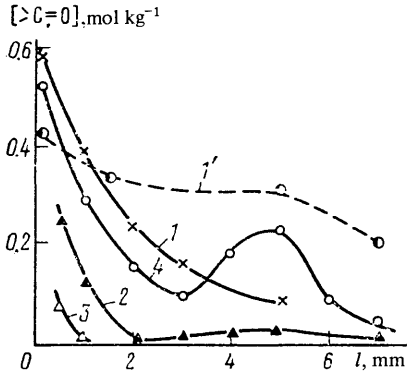

Figure 18. Carbonyl group concentration profile in PP specimens oxidised until rupture: 1)–4) unannealed specimen; 1') annealed specimen; oxidation temperature (°C): 1) and 1') 130; 2)–4) 120; λ: 1)–3) 8.5; 4) 4; σ (MPa): 1) and 1') 10; 2) 20; 3) 29; 4) 5.[60]

In the region of plastic deformations, the concentration of the non-chain oxidation products increases with the stress (Fig.19), which is associated with the increase of the rate of the mechanical initiation of the oxidation reaction. The decrease of the rate of propagation of kinetic chains under load and the increase of the rate of their rupture in the region of plastic deformations actually lead to the transition of the oxidation reaction to the non-chain regime.

3. In the rupture zone of the specimen, not only the concentrations but also the compositions of the carbonyl-containing groups can differ in the "matrix": starting from a specific stress, aldehyde groups predominate in the region remote from the rupture zone, while in the rupture zone ketones as well as aldehydes are often detected (Fig.17*b*). This is apparently associated with the fact that the rupture is preceded by the formation of a large number of microcracks, with relaxation of stress above and below such cracks; the oxidation process develops at these sites in an unstressed polymer, has a chain mechanism, and is accompanied by the formation of ketones. Comparison of spectra *2* and *3* in group *b* (Fig.17) shows that the compositions of the oxidation products differ at individual points in the matrix: in spectra *2* only aldehydes can be detected, while in spectra *3* ketones appear as well. On the basis of the data presented by Rapoport[60], it has been suggested that, at the "point" corresponding to spectrum *3*, a zone corresponding to the release of the load has appeared, which led to the development of chain oxidation and the formation of ketones. The appearance of release of load zones in the stressed polymer is associated with the formation of microcracks. The acceleration of the oxidation on the inner side of the arc-shaped microcracks, formed in the diffusional oxidation of annealed oriented PP specimens, has been observed[118]. Rapoport[60] suggested that the difference between the compositions and concentrations of the oxidation products formed in the stressed zones and in the zones where the load has been released be used as a basis for a method of defectoscopy for stressed PP undergoing oxidation; this possibility has been realised experimentally[116].

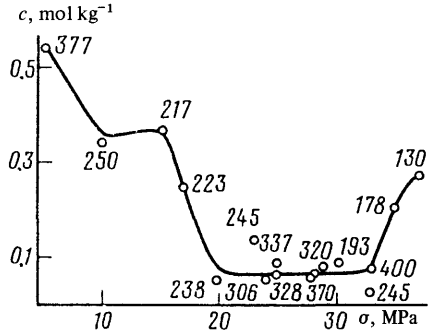

Figure 19. Dependence of the concentration of carbonyl groups in the rupture zone on the stress during oxidation; λ = 7.5; unannealed specimen; oxidation temperature 120 °C; the numbers against the points represent the lifetimes of the specimens in minutes[117].

4. It must be specially emphasised that oxygen-containing groups accumulate at significantly different concentrations at the instant of rupture in the matrices of specimens of different structures undergoing oxidation when subjected to different stresses. For example, the rupture of unannealed specimens frequently occurs when the matrix remote from the rupture zone is still in the induction period of the oxidation reaction (Fig.18, curves *2* and *3*); in the rupture zone profound oxidative degradation takes place under these conditions. On the other hand, at the instant of the rupture of annealed specimens the matrix is highly oxidised (Fig.18, curve *1'*). It is striking that the durabilities of the unannealed and annealed specimens are similar. It is even more striking that their repeated durabilities (the periods before rupture following a second application of the load to parts of the ruptured specimens) are also similar although in the annealed specimens the matrix has been oxidised to a much greater extent from the very beginning of the experiment. Rapoport et al.[116] consider the possible causes of the above effects: (a) the strictly local character of the oxidation of the unannealed stressed specimens; (b) the smoothing out of the structural differences between the annealed and unannealed specimens in the zone of a developing major crack; (c) profound oxidative degradation occurring in the annealed polymer without involving the extended macromolecules carrying the load, which are degraded more slowly and

in accordance with the same kinetic laws as the extended macromolecules in the unannealed polymer. This is an important argument in support of the ideas developed in Section III.1.

5. The significant differences between the concentrations of the oxygen-containing groups accumulating in the matrices of different specimens towards the instant of rupture show how carefully one must approach the development of criteria for macroscopic decomposition: it is very frequently suggested that the accumulation of carbonyl groups up to a specific concentration in the bulk of the specimens be employed as such a criterion for PP[119]; the results of Rapoport et al.[116] show that, as a consequence of the spatial localisation of the oxidation process in stressed PP, the employment of such a criterion would lead to major errors. It follows from the data obtained[116] that, in the study of the kinetics of the rupture of stressed polymers, one should not employ methods yielding values of the measured quantity averaged throughout the specimen.

The spatial localisation of the oxidation process observed in a stressed polymer[60,116] and the dependence of the reaction regime on the size of the stress posed new problems for investigators engaged in predicting the durability of polymer articles under operating conditions (when the polymer is subjected to the joint action of mechanical stresses, oxidising agents, ultraviolet light, etc.). Evidently, in describing the kinetics of such localised processes, one cannot employ the usual mathematical procedures developed for solid-phase reactions (even when account is taken of the distributions with respect to the rate constants). A key question becomes that of the causes and the instant of the spatial localisation of the oxidative degradation. It must be elucidated whether the localisation obtains from the very beginning of the oxidation of the stressed polymer or whether the process proceeds for a time uniformly throughout the bulk of the specimen. We believe that the localisation of the oxidation reaction is an "after-effect" of the opening of the sides of the microcracks and is associated with the acceleration of the oxidation process in the relaxed zones above and below the lips of the microcracks; up to this instant, the degradation can be regarded as proceeding "uniformly" throughout the bulk of the stressed polymer and the formation of a decomposition centre can be treated as a result of the accumulation of random ruptures. In the description of the kinetics of this process, one can therefore use successfully the method described in the literature[120,121].

We shall enumerate briefly the principal results of the studies of Rapoport and co-workers[60,116]: (1) a change in the mechanism of the initiation of the oxidation with increase of mechanical stress has been observed; (2) a change in the reaction regime—a transition from chain to non-chain oxidation—has been noted; (3) the limits of the ability of inhibitors to increase the durability of stressed polymers have been established; (4) the development of the oxidation process from a centre in the stressed polymer, requiring the application of local methods for the experimental study of the kinetics of the decomposition reaction, has been observed; (5) the possibility of the defectoscopy of the polymer undergoing oxidation under the influence of an external load, based on the difference between the concentrations and compositions of the oxidation products formed in the region of the crack and in the "undamaged matrix", has been demonstrated.

Two studies dealing with the kinetics of the oxidation of non-oriented PE[122] and PP[123] specimens subjected to an external load were published in 1982. In the first study[122] PE specimens in the form of "blades", whose widths in the wide and narrow parts differed by a factor of three, which corresponded to stresses differing by a factor of three in relation to the initial section, were oxidised. The ranges of the experimental stresses were 2.9–4 MPa at 70 °C and 1.9–3.1 MPa at 90 °C. The oxidation kinetics were followed from the accumulation of carbonyl groups in the wide and narrow parts of the specimens. For the highest and lowest stresses, no differences were observed between the rates of formation of carbonyl groups in the wide and narrow parts while for intermediate stresses the degree of oxidation of the wide parts of the specimens was always greater; the major crack and the degree of decomposition of the specimens increased in precisely this region, although the true stress was greater in the narrow part. In other words the specimens were not ruptured at the site of the maximum stress but at the sites of the minimum deformation, where the thermo-oxidative degradation developed faster. The results of this study[122] fully confirm the results and conclusions in other investigations[82,60,116]. The lower rate of oxidation of stressed PE in the narrow part is associated with orientation effects and its nature is apparently the same as that of the decrease of the rate of the radiation-induced oxidation of oriented PE[82]. A decrease of the rate of the photochemical oxidation of isotropic PP subjected to an external load has been observed[123].

Thus, under the conditions of orientational extension and an external load, the overall rate of the chain oxidation of polyolefins as a rule diminishes. For stresses which result in a transition of the reaction to a non-chain regime, the overall rate of oxidation increases with increase of the stress as a consequence of the increase of the rate of the mechanical initiation of the radicals.

3. The Influence of Mechanical Stresses on the Kinetics of the Oxidation of Raw and Cured Rubbers by Molecular Oxygen and Ozone

The influence of an external load on the ozone-induced ageing of polyolefins has been studied in the investigations[31,65,66] discussed above in Section III.1. In this Section we shall deal with the specific features of the oxidation of stressed raw and cured rubbers.

The majority of elastomers contain double bonds, which make them more reactive than polyolefins. Elastomers are rapidly oxidised in air and particularly in an ozone–oxygen mixture, which leads to the loss of their operating properties. In recent years this question has attracted increasing attention by investigators in connection with the pollution of the atmosphere and the increase of the content of corrosive components in air. The kinetics of oxidation processes in elastomers are influenced significantly by mechanical stresses[124,125], which was pointed out as early as 1950 by Kuz'minskii[1,2], who called this phenomenon "mechanical activation". The effect of mechanical activation was not related to the breaks in macromolecules, i.e. to mechanical degradation; on repeated deformations (amplitude 75%, frequency 250 cycles min^{-1}), the effect of mechanical activation proved to be much greater than in static deformations (degree of deformation 75%). However, there was no reason to attribute this effect solely to the mechanical activation of oxidation processes, because a dynamic load accelerated equally the rupture of vulcanised elastomers in oxygen and in an inert atmosphere; the effect was more likely to have been associated with the formation and development of microcracks.

Subsequently it was found that mechanical stresses can not only activate but can also inhibit chemical reactions in stressed elastomers[67,126] and the activation effect has been attributed to the decrease of the activation energy for oxidative and thermal processes, while the inhibition effect was attributed to the decrease of the pre-exponential factor.

The existing ideas about the mechanism of the ozone-induced cracking of stressed elastomers have been examined critically in Zuev's book[53]. In this review we are interested in the influence of mechanical stresses on the kinetics of the oxidative degradation of elastomers.

In the ozone-induced ageing of unsaturated vulcanised elastomers, the double bond dissociates. The influence of structural stresses on this process has been investigated on model compounds—cyclo-olefins[64], and a calculation[127] made it possible to explain quantitatively the results obtained by Popov and Zaikov[64]. During the dissociation of the double bond, a steric change takes place in the ~ C(1)–C(2)=C(3)–C(4) ~ unit associated with the rehybridisation of the C(2) and C(3) atoms from the sp^2 state to the sp^3 state; the C(2)–C(3) bond length increases from 1.333 to 1.534 Å, the valence angle decreases from 122.2° to 112.2°, and the angle of internal rotation diminishes from 0° to 60°. Fig.20 illustrates the changes in the distance l between the C(1) and C(4) atoms, not linked by valence bonds, as a function of the reaction coordinate for the *cis*- and *trans*-fragments ~ C(1)–C(2)=C(3)–C(4) ~. For the *trans*-configuration, the C(1)–C(4) distance only increases in the course of the reaction; for the *cis*-isomer, the above distance passes through a minimum. The rate of the ozonisation reaction should therefore be sensitive to the mechanical stress; stretching stresses should accelerate the reaction for the *trans*-configuration of the fragment and should inhibit it for the *cis*-configuration (in the latter case the energy of the transition complex can increase more under the influence of the stretching stress than the energy of the initial state, which should result in an increase of the activation energy for the ozonisation of the *cis*-isomer of raw rubber).

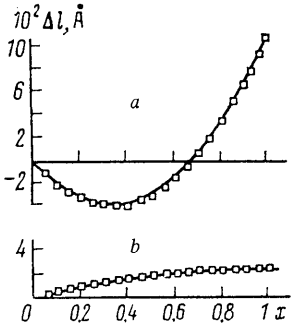

Figure 20. The changes in the C(1)–C(4) distances in the *cis*-forms (*a*) and *trans*-forms (*b*) of the ~ C(1)–C(2)=C(3)–C(4) ~ fragments in the $sp^2 \rightarrow sp^3$ transition of the C(2) and C(3) atoms[68]; x = reaction coordinate.

The ideas described served as a basis for the interpretation of the results obtained in the ozonisation of the unsaturated polymers obtained by vulcanising the *cis*- and *trans*-isomers of raw rubbers[68,128]; stretching stresses did indeed increase the rate of ozonisation of *trans*-1,4-polybutadiene, inhibited the ozonisation of *cis*-1,4-polyisoprene (for degrees of deformation exceeding 20%), and did not change the rate of reaction involving 1,2-polybutadiene in which the double bond is localised in a side group. From the standpoint considered here, the authors[68,128] proposed a new explanation for the existence of a critical deformation in the ozone-induced cracking of stressed cured rubbers, which had been known a long time but had not found an adequate interpretation. In the oxidation of elastomers, oxygen-containing functional groups accumulate in the latter and their decomposition is activated in the statically deformed cured rubbers[41].

The data presented in this review show that mechanical stresses interfere with the chain oxidation process at all its stages and can alter significantly the kinetics and even the regime of the oxidative degradation. Mechanical stresses can also lead to a very pronounced spatial localisation of the oxidation process in polymer specimens. They are frequently frozen in the material during its conversion into the finished article, are generated in the article during its use, and finally arise in the ageing process when the latter takes place in a diffusion regime. The oxidation of specimens uniformly throughout their bulk under real conditions is apparently more likely to be the exception rather than the rule. This poses new problems for investigators concerned with its prediction of the durabilities of polymer articles under real operating conditions, because the methods of homogeneous kinetics are inapplicable in this instance.

Phosphorylated Derivatives of Alkaloids and Nitrogen-containing Heterocycles—Cholinesterase Inhibitors

A.S.Sadykov, D.N.Dalimov, and N.N.Godovikov

The review deals with the synthesis and anticholinesterase activities of phosphorylated derivatives of certain alkaloids and nitrogen-containing heterocycles. It is shown that the conformational properties of the alkaloid and nitrogen-containing heterocycle residues in the composition of the organophosphorus inhibitor (OPI) molecule play an important role in the inhibition of the catalytic activity of cholinesterases. The type of inhibition of cholinesterases also varies as a function of chemical structure.
The bibliography includes 45 references.

I. INTRODUCTION

A characteristic feature of many esters of quinquevalent phosphorus acids is the ability to inhibit irreversibly cholinesterases. This process is known to proceed via two main stages: the sorption of the inhibitor on the active surface of the enzyme and phosphorylation of this centre. The capacity of an organophosphorus inhibitor (OPI) for sorption on the active surfaces of cholinesterases depends on the presence in their molecules of onium, dipolar, and hydrophobic groups. The second stage of the inhibition process is determined by the electrophilic phosphorylating capacity of the OPI, which depends on the character of the substituents linked to the phosphorus atom[1-14].

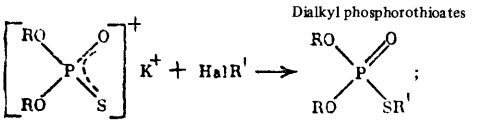
The majority of investigators of the relation between the structure of OPI and their anticholinesterase activity have concentrated their attention on the electrophilic phosphorylating capacity of these substances. Many attempts have been made to find a relation between the electrophilic phosphorylating capacity of OPI and their anticholinesterase properties. For example, relations have been sought between the hydrolysability of OPI, the inhibitor concentrations which reduce the activity of cholinesterases by 50% (I_{50}), and the inhibition rate constants k_2, on the one hand, and the Hammett (σ), Taft (σ^*), and Kabachnik (σ^{ph}) constants, on the other. However, only in a few instances has a direct relation been observed between these parameters[1-13].

It has been shown in studies by Kabachnik, Brestkin, Michelson, Rozengart, Godovikov, and co-workers[15-17] that the hydrophobic interactions of the OPI with the active surface of the enzyme play a decisive role in the inhibition of cholinesterases by OPI. However, hitherto no account has been taken of the role of the OPI conformation in their interaction with cholinesterases. Sadykov and co-workers have therefore undertaken studies on the synthesis and anticholinesterase activities of organophosphorus compounds containing alkaloid residues. Since alkaloids can exist in various stable conformations, this made it possible to estimate the influence of the conformations of OPI on their ability to inhibit cholinesterases.

II. SYNTHESIS

In order to be able to investigate the questions raised above, phosphorylated derivatives of alkaloids and nitrogen-containing heterocycles with a logically varied structure were synthesised and their anticholinesterase activities were investigated. Phosphorylated lupinine, epilupinine, anabasine, cytisine, decahydroquinoline, tetrahydroquinoline, 8-hydroxyquinoline, α-, β-, and γ-pipecolines, 2,6-dimethylpiperidine, piperidine, and morpholine were chosen as objects of the investigation. These substances were synthesised by standard methods (see Schemes 1-3).[18-25]

The corresponding methiodides of the majority of these compounds were obtained. The physicochemical constants of the substances synthesised are listed in Tables 1-4.



The anticholinesterase activities of the compounds synthesised were determined on enzyme preparations: acetylcholinesterase from human blood erythrocytes with a specific activity 2*E*/mg (EC 3.1.1.7) (ACE) and horse blood serum butyrylcholinesterase with a specific activity of 29*E*/mg (EC 3.1.1.8) (BuCE). The reversible and irreversible inhibiting activities were estimated in terms of the K_i (the reversible inhibition equilibrium constants) and k_2 respectively. These constants were found by standard methods described in the literature[26-28].

III. IRREVERSIBLE INHIBITION OF CHOLINESTERASES

The most characteristic feature of the interaction of OPI with cholinesterases is irreversible inhibition of these enzymes. As a rule phosphorothiolic esters give rise to the irreversible inhibition. A number of dialkyl phosphorothioates containing alkaloid residues in the thioester group were therefore synthesised and their antichlolinesterase activities were investigated.

Thus the study of the anticholinesteras activity of dialkyl phosphorothioates, obtained on the basis of the lupinine and epilupinine alkaloids [(I)-(XIV)] and their methiodides [(I')-(XIV')], showed that all the compounds

are powerful irreversible inhibitors of cholinesterases[29,30]. Tables 5 and 6 show that an increase in the length of the straight-chain alkyl groups from ethyl to n-pentyl in a series of both types of OPI [(I)-(XIV)] leads to an enhancement of the anticholinesterase activity in relation to acetylcholinesterase (by factor of 27 and 90 for lupinine and epilupinine derivatives respectively). This shows that the dependence of the inhibiting activity on the length of the alkyl groups in O,O-dialky *S*-lupinanyl phosphorothioates is weaker than for the analogous epilupinine derivatives.

(I)-(VII) (I')-(VII')

(VIII)-(XIV) (VIII')-(XIV')

Similar changes in k_2 as a function of the length of the alkyl moieties of the alkoxy-groups are observed also for the corresponding methiodides (I')-(XIV'). Comparison of the inhibiting activities of the bases (I)-(XIV) with those of their methiodides (I')-(XIV') shows that the values of k_2 for all the methiodides are higher by a factor of 2-8 than for their uncharged analogues. Such a comparatively small increase of the anticholinesterase activity of the methiodides is explained by the fact that at pH 7.5 used in the experiments these compounds are largely protonated[29].

* Nearly quantitative yield.

Tables 5 and 6 and Figs.1 and 2 show that there is a continuous increase of the anticholinesterase activity in relation to ACE of both series of OPI [(I)-(XIV)] with branched hydrocarbon moieties of the alkoxy-groups. A similar behaviour has been noted for the methiodides (I')-(XIV') but with higher constants k_2.

Table 5. The rate constants for the inhibition of ACE and BuCE (k_2, litre mol^{-1} min^{-1}) by *O,O*-dialkyl *S*-lupinanyl phosphorothioates (I)-(VII) and their methiodides (I') to (VII').[29,30]

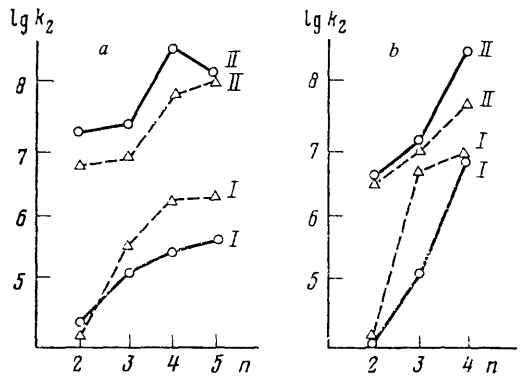

Figure 1. Dependence of $\lg k_2$ on the number n and degree of branching of carbon atoms in the alkyl moiety of the alkoxy-groups in the inhibition of ACE (continuous line I) and BuCE (continuous line II) by *O,O*-dialkyl *S*-lupinanyl phosphorothioates and in the inhibition of ACE (dashed line I) and BuCE (dashed line II) by *O,O*-dialkyl *S*-epilupinanyl phosphorothioates[29]; *a*) OPI with straight-chain alkyl groups; *b*) OPI with isoalkoxy-groups.

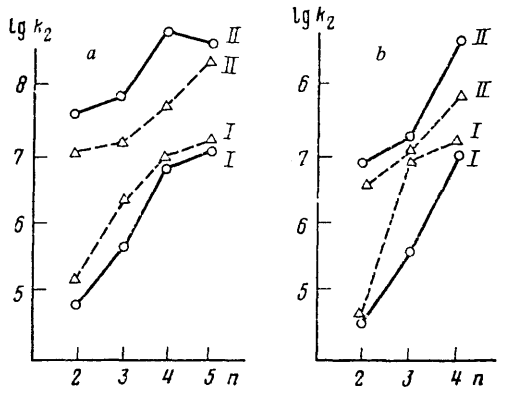
The greater inhibiting activity of these compounds in relation to BuCE than ACE is probably a consequence of the improved conditions for the hydrophobic sorption of the alkoxy-groups on the corresponding hydrophobic sections of BuCE. This effect is not associated with the inductive influence of the alkoxy-groups, since the pK_a of the corresponding tautomeric acids are very similar. The constants k_2 for the methiodides (I')-(XIV') in relation to BuCE are only slightly higher (by a factor of 1.5–3) compared with the k_2 for the bases (I)-(XIV).[29,30]



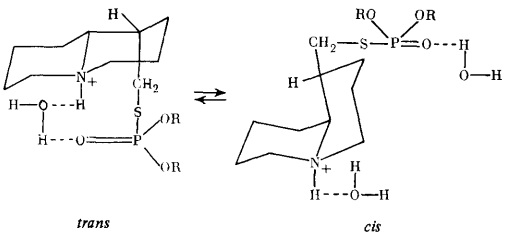


Figure 2. Dependence of lg k_2 on the number n and degree of branching of the carbon atoms in the alkyl moiety of the alkoxy-groups in the inhibition of ACE (continuous line I) and BuCE (continuous line II) by the methiodides of *O,O*-dialkyl *S*-lupinanyl phosphorothioates and in the inhibition of ACE (dashed line I) and BuCE (dashed line II) by the methiodides of *O,O*-dialkyl *S*-epilupinanyl phosphorothioates[29]: *a*) OPI with normal alkoxy-groups; *b*) OPI with isoalkoxy-groups.

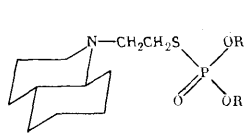
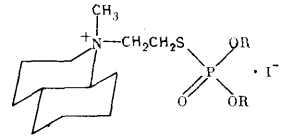
Comparison of the anticholinesterase activities of the OPI investigated in relation to ACE and BuCE is of definite interest. In comparing the data obtained for ACE and BuCE, one may note that the ability of both series of OPI [(I)-(XIV)] and their methiodides [(I')-(XIV')] to inhibit BuCE depends more on the length of the alkyl moieties of the alkoxy-groups than in the case of ACE. On the other hand, the appearance of an onium group in the OPI molecule results in a sharp increase of the inhibiting activity in relation to ACE. These data emphasise yet again the tendencies of BuCE and ACE to undergo hydrophobic and ion-ion interactions respectively[15]. All the compounds investigated exhibited selectivity in their activity in relation to BuCE. For the lupinine derivatives (I)-(VII), this effect is very marked and the greatest selectivity is shown by compounds with ethyl (by a factor of 1000), n-butyl (by a factor of 1500), and isopropyl (by a factor of 450) moieties in the alkoxy-groups. On the other hand, in the analogous epilupinine compounds (VIII)-(XIV) this effect is pronounced only for the ethyl (by a factor of 240) and isopropyl (by a factor of 235) derivatives.

Comparison of the inhibiting activities in relation to ACE of the epilupinine derivaties (VIII)-(XIV) with those of the lupinine derivates (I)-(VII) showed that the OPI of the (VIII)-(XIV) series exhibit a more powerful anticholinesterase activity than the analogous compounds of type (I)-(VII). The opposite dependence on the structure of the part of the OPI molecule which is split off is observed on comparing the anticholinesterase activities of the same series of compounds with one another in the inhibition of BuCE. Consequently *O,O*-dialkyl *S*-lupinanyl phosphorothioates and their methiodides exhibit a greater selectivity in their activity in relation to BuCE than their epilupinine analogues. Such specificity in the activity of lupinine derivatives is apparently associated with the fact that in solution the protonated form of the luipinine residue exists mainly in two conformational states: one having a *trans*-junction with the quinolizidine ring and an axial hydroxymethyl group and the other having a *cis*-junction with the quinolizidine ring and an equatorial hydroxymethyl group[31,32]. It may be that the *cis*-conformer is better adapted to sorption on the anionic centre of BuCE; as a result of such sorption, the equilibrium between the *trans*- and *cis*-forms shifts towards the formation of the latter, as a result of which one observes the specificity of the activity of the lupinine derivatives in relation to BuCE.



The fact that the methiodides of *O,O*-dialkyl *S*-lupinanyl phosphorothioates, which are known to have a *cis*-junction with the quinolizidine ring of the lupinine fragment and an equatorial thiophosphoryl group, exhibit an analogous specificity in their activity in relation to BuCE may serve as confirmation of the foregoing observations.

The *trans*-quinolizidine ring of the epilupinine derivatives remains unchanged on protonation or conversion into the methiodide and apparently approaches more closely the anionic centre of ACE. This results in a higher activity in relation to ACE.[33]



Thus one may note that the very high specificity of the activity of *O,O*-dialkyl *S*-lupinanyl phosphorothioates, and their methiodides is determined by the overall effect of the correspondence to the active centre of BuCE of the alkoxy-groups of the OPI molecule, on the one hand, and of the lupinine fragment on the other. The higher specificity of the activity of the epilupinine derivatives in relation to ACE compared with the lupinine derivatives is in all probability associated with the more effective sorption of the *trans*-quinolizidine ring of the epilupinine residue by the anionic centre of ACE rather than the *cis*-form of the quinolizidine ring in the lupinine derivatives.

As shown above, the inhibiting activities of compounds containing the lupinine and epilupinine derivatives depend significantly on the conformations of these fragments.

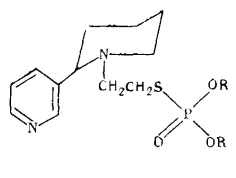
The anticholinesterase activitives of *N*-[β-(dialkoxyphosphinyl)mercaptoethyl]decahydroquinolines (XV)-(XXI) and their methiodides (XV')-(XXI') have been investigated; here the decahydroquinoline residue has a structure similar to those of the lupinine and epilupinine residues, but the nitrogen atom is located in one of the rings and not between two rings[33,34].

(XV)-(XXI)

(XV')-(XXI')

All the compounds investigated proved to be inhibitors of cholinesterases with an irreversible type of activity (Table 7). Table 7 shows that decahydroquinoline derivatives exhibit a powerful inhibiting activity in relation to ACE and that the length and degree of branching of the alkoxy-group have little influence on the inhibiting activity. Only the di-isopropoxy-derivative, which is less active by approximately two orders of magnitude than the remaining compounds, is an exception. An analogous behaviour has been observed also for the corresponding methiodides (XV')-(XXI').

Table 7. The rate constants for the inhibition of ACE and BuCE (k_2, litre mol^{-1} min^{-1}) by *N*-[β-(dialkoxyphosphinyl)-mercaptoethyl]decahydroquinolines (XV)-(XXI) and their methiodides (XV')-(XXI').[33,34]



Compound	R	$10^7 k_2$ (ACE)	$10^7 k_2$ (BuCE)	$\frac{k_2(\text{BuCE})}{k_2(\text{ACE})}$	Compound	$10^7 k_2$ (ACE)	$10^7 k_2$ (BuCE)	$\frac{k_2(\text{BuCE})}{k_2(\text{ACE})}$

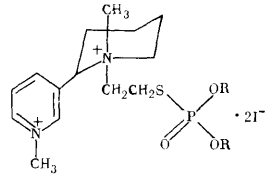
(XXI)	iso-C_5H_{11}	6.5	42	64	(XXI')	5.0	93	18.6

N-[β-(dialkoxyphosphinyl)mercaptoethyl]decahydroquinolines are more active in relation to BuCE than ACE. The dependence of the inhibiting activity on the length of straight-chain alkyl groups leads to a sharp increase of the anticholinesterase activity. An analogous behaviour has been observed also for the methiodides. It is noteworthy that the greatest selectivity in their activity is shown by the di-isoalkoxy-derivatives (by a factor of 582 for the di-isopropoxy-derivative, by a factor of 100 for the di-isobutoxy-derivative, and by a factor of 64 for the di-isopentoxy-derivative)[33]. Comparison of the anticholinesterase activities of the decahydroquinoline derivatives with those of the corresponding dialkyl phosphorothioates derived from lupinine and epilupinine shows that *N*-[β-(dialkoxyphosphinyl)mercaptoethyl]decahydroquinolines are stronger inhibitors in relation to ACE than *O,O*-dialkyl *S*-lupinanyl phosphorothioates. This difference between the inhibiting activities can apparently be accounted for by the difference between the structures and conformational states of the decahydroquinoline (*trans*) and lupinine (*cis*) residues. In relation to BuCE, the inhibiting activity of the decahydroquinoline derivatives with straight-chain alkoxy-groups is inferior to that of the analogous lupinine compounds. The opposite is observed in the series of OPI with isoalkoxy-groups[34].



Comparison of the constants k_2 for *N*-[β-(dialkoxyphosphinyl)mercaptoethyl]decahydroquinolines with those of the corresponding *O,O*-dialkyl *S*-epilupinanyl phosphorothioates shows that the anticholinesterase activities of both types of compounds (except the diethoxy- and di-isopropoxy-derivatives) in relation to ACE differ little. However, the methiodides of the decahydroquinoline derivatives are stronger ACE inhibitors than the OPI with the epilupinine fragment. This is apparently associated with the different basicities of the decahydroquinoline and epilupinine residues. *N*-[β-di-isoalkoxyphosphinyl)mercaptoethyl]decahydroquinolines are more active in relation to BuCE than the corresponding *O,O*-di-isoalkyl *S*-epilupinanyl phosphorothioates[33,34].

Thus the introduction of the bulky decahydroquinoline group in the β-position of the thioester group of the OPI instead of the lupinine and epilupinine groups led to a significant alteration of the inhibiting activity in relation to both types of cholinesterases. Comparison of the anticholinesterase properties of the decahydroquinoline derivatives with those of the dialkyl phosphorothioates derived from lupinine and epilupinine demonstrated yet again the sensitivity of the anionic centre of ACE to transoid saturated bicyclic systems. The change in the position of the nitrogen atom in the bicyclic system enhances the inhibiting activity in relation to ACE.

Whereas OPI containing residues of mononitrogen bases in the component which is split off were discussed above, we shall now deal with the anticholinesterase properties of the OPI containing the residue of the alkaloid anabasine [α-(β-piperidinyl)pyridine] in the β-position of the thioesters group and shall compare the data obtained with the inhibiting activities of the analogous decahydroquinoline derivatives[35].

(XXII)-(XXVIII)

(XXII')-(XXVIII')

All the compounds investigated proved to be irreversible cholinesterase inhibitors (Table 8).

Table 8. The rate constants for the inhibition of ACE and BuCE (k_2, litre mol^{-1} min^{-1}) by *N*-[β-dialkoxyphosphinyl)-mercaptoethyl]anabasines (XXII)-(XXVIII) and their methiodides (XXII')-(XXVIII').[35]

Compound	R	$10^5 k_2$ (ACE)	$10^6 k_2$ (BuCE)	$\frac{k_2(\text{BuCE})}{k_2(\text{ACE})}$	Compound	$10^6 k_2$ (ACE)	$10^7 k_2$ (BuCE)	$\frac{k_2(\text{BuCE})}{k_2(\text{ACE})}$

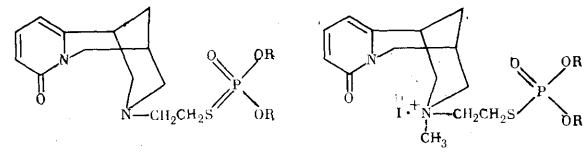
(XXVII)	iso-C_4H_9	18	10	5.5	(XXVII')	33	6.2	2
(XXVIII)	iso-C_5H_{11}	47	90	2	(XXVIII')	50	1.1	0.22

The irreversible inhibiting activity of *N*-[β-(dialkoxyphosphinyl)mercaptoethyl]anabasines in relation to ACE increases with increase of the length of the alkyl groups from ethyl to n-butyl. On further increase in their length, the activity falls.

The irreversible inhibiting activity of *N*-[β-(dialkoxyphosphinyl)mercaptoethyl]anabasines in relation to BuCE is higher than in relation to ACE. These differences depend to a

large extent on the length and degree of branching of the alkoxy-groups. The smallest difference is observed for the dibutyl derivatives (by a factor of two) and the highest for the di-isopropyl derivative (by a factor of 93).[17,35]



Thus the appearance of a second nitrogen-containing group in the thioester group of the OPI which is to be eliminated has a major influence on the anticholinesterase activity in the case of BuCE. This influence is determined to a large extent by the character of the hydrophobic alkyl moieties of the alkoxy-groups sorbed on the hydrophobic sections of the active surface of the enzyme in the region of the esterase centre.

One may conclude that the presence of two nitrogen-groups in the leaving part of the OPI molecule, which exists largely in the protonated form under the experimental conditions (pH 7.5), impairs the conditions for the hydrophobic sorption of the inhibitor; the alkoxy- and onium groups have a non-concerted influence, which decreases the inhibiting activity [35,36].

The compounds of the onium type which have been investigated show very slight differences in the inhibition of ACE and BuCE, the activities of the majority of them being similar in relation to both enzymes with the exception of the diazopropyl derivative, whose activity is selective in relation to BuCE, and the di-isopentyl derivative, which tends to be more active in relation to ACE (Table 8).[35]

Comparison of the anticholinesterase activities of the *N*-[β-(dialkoxyphosphinyl)mercaptoethyl]anabasines with those of the *N*-[β-(dialkoxyphosphinyl)mercaptoethyl]-decahydroquinolines investigated previously showed that the dialkyl phosphonothioates containing the anabasine group have an only slightly weaker inhibiting activity in relation to ACE than the analogous decahydroquinoline derivatives. *N*-[β-(Diethoxyphosphinyl)mercaptoethyl anabasine, whose anticholinesterase activity is inferior to that of *N*-[β-(dialkoxyphosphinyl)mercaptoethyl]decahydroquinoline by a factor of 10 and the activity of the corresponding methiodide is lower by a factor of 14, is an exception. The different sorbabilities on the anionic centre of ACE of the leaving components of the OPI compared probably have an effect in this instance. The fact that a further increase of the length of the alkoxy-groups smoothes out the differences between the inhibiting activities of decahydroquinoline and anabasine derivatives is apparently associated with the possibility that in the case of the decahydroquinoline analogues there may be an effect of the "non-concerted" sorption on the active surface of ACE,[36] as a result of which small differences between the constants k_2 are observed for these compounds as a function of the length and degree of branching of the alkyl moieties of the alkoxy-groups (by a factor of 2–4). However, since the anabasine fragment of the OPI molecule is less effectively sorbed on the anionic centre of ACE than the decahydroquinoline fragment, they may exhibit a tendency towards an increase of the anticholinesterase activity as a function of the length and degree of branching of the alkyl moieties of the alkoxy-groups (the activity increases by a factor of 30 on passing from C_2H_5 to C_4H_9). The slight differences between the inhibiting activities of the OPI of the two types (with the exception of the diethoxy-analogues) are associated with the increase in the length and the degree of branching of the alkoxy-groups, on the one hand, and with the difference between the structures of the alkanethiol components, on the other. Changes in the phosphoryl component of the molecules of *N*-[β-(diethoxyphosphinyl)mercaptoethyl]anabasines enhance the possibility of "productive" sorption, while similar changes in *N*-[β-(dialkoxyphosphinyl)mercaptoethyl]decahydroquinolines lead to an enhancement of the "unproductive" sorption on the active centre of acetylcholinesterase[17,33,35].

Comparison of the anticholinesterase properties of dialkyl phosphorothioates derived from anabasine with the analogous decahydroquinoline compounds in relation to BuCE shows that the activities of *N*-[β-(diethyoxyphosphinyl)mercaptoethyl]-anabasine and its methiodide are inferior (by a factor of 12 to 13) to those of the analogous decahydroquinoline derivatives. In all probability, the active centres of both ACE and BuCE respond to the differences between the structures of the leaving components of the molecules of the two types of OPI. An increase in the length of the alkoxy-groups results to some extent in a greater similarity of the inhibiting activities of the compounds compared. However, as for ACE, the anabasine derivatives are 4–5 times less active than the analogous dialkyl phosphorothioates derived from decahydroquinoline. Thus the appearance of a second nitrogen-containing group in the leading moiety of the OPI molecule influences the activity in relation to BuCE more than in relation to ACE. It was of interest to follow the variation of the anticholinesterase activities of *N*-[β-(dialkoxyphosphinyl)-mercaptoethyl] cytisines (XXIX)–(XXXIII) and their methiodides (XXIX′)–(XXXIII′), in which the conformational state of the cytisine residue differs sharply from those of lupinine, epilupinine, decahydroquinoline, and anabasine[37].

(XXIX)–(XXXIII) (XXIX′)–(XXXIII′)

Table 9 shows that all the compounds investigated proved to be inhibitors with a combined type of activity†. In relation to ACE, the irreversible inhibiting capacity increases with increase in the length of the alkyl groups up to the n-butyl derivative, after which there is a fall. The replacement of straight-chain alkyl groups by the isopropyl group results in a sharp decrease of the true degree of reversible inhibition of the enzyme by the inhibitor (k_a), which is apparently caused by the inadequate complementarity of the di-isopropoxy-derivative and the ACE active centre[33,37].

Table 9. The rate constants of the inhibition of ACE and BuCE by *N*-[β-(dialkoxyphosphinyl)mercaptoethyl]cytisines (XXIX)–(XXXIII) and their methiodides (XXIX′)–(XXXIII′)* [37]

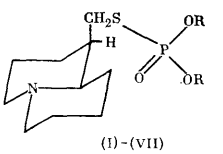
* For the significance of k_a, K_{ir}, and K_{is}, see Brestkin and Godovikov[36].

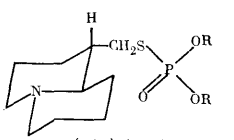
† A number of studies, reviewed by Brestkin and Godovikov[36], have been devoted to this type of inhibition.

In relation to BuCE, the test compounds are more active than in relation to ACE. An increase in the length of the alkyl moieties of the alkoxy-groups increases the inhibiting activity. In contrast to ACE, BuCE is relatively insensitive to the replacement of the straight-chain alkyl groups by the isopropyl group. It is noteworthy that *N*-[β-(di-isopropoxyphosphinyl)mercaptoethyl]cytisine shows the greatest selectivity in relation to BuCE (by a factor of 145). This selectivity is apparently associated with the less effective sorption of the di-isopropoxy-derivative on the active surface of ACE.



The reversible inhibiting activity in relation to ACE increases on passing from the ethyl to the propyl derivative, but a further increase in the length of the alkyl group has little influence on the reversible inhibiting activity of the organophosphorus compound investigated. It must be emphasised that the reversible inhibitors derived from cytisine exhibit selectivity in their activity with respect to BuCE.

The quaternisation of the nitrogen atom results in a slight increase of the anticholinesterase activity in relation to both enzymes (by a factor of 2–3), but the selectivity in relation to BuCE then falls. It follows from the foregoing that, compared with the previous compounds, *N*-[β-(dialkoxyphosphinyl)mercaptoethyl]cytisines and their methiodides proved to be significatnly weaker inhibitors with irreversible activity. The impairment of the inhibiting activity of cytisine derivatives may be associated with the steric hindrance of the cytisine residue in the sorption of the inhibitor on the active surface of the enzyme[37].



IV. COMPARISON OF THE ACTIVITIES OF THE OPI DERIVED FROM LUPININE AND EPILUPININE

Tables 10 present data for the effect on the cholinesterases of various species of mammals and arthropods by *O,O*-dialkyl *S*-lupinanyl phosphorothioates and *O,O*-dialkyl S-epilupinanyl phosphorothioates[30,38], which make it possible to discover a number of characteristic features. In the vast majority of cases, the OPI investigated proved to be stronger inhibitors of the ACE from the heads of files than of the mammalian ACE. This applies particularly to the first members of the series of compounds containing both straight-chain and branched groups. For example, the ACE from the heads of flies proved to be 15000 more sensitive to *O,O*-diethyl *S*-lupinanyl phosphorothioate than the ACE from human erythrocytes; the sensitivity in relation to the di-isopropyl derivative of lupinine was higher only by a factor of 250. In the case of epilupinine derivatives, the opposite relation between the sensitivities of the ACE from the heads of flies and human erythrocytes was observed, the increase in sensitivity being greater for the di-isopropyl compound (by a factor of 1000) than for the ethyl compound (by a factor of 550). It is noteworthy that some of the compounds investigated have the unique ability to suppress the ACE from the heads of flies: the absolute bimolecular inhibition rate constants reached approximately 10^8 litre mole^{-1} min^{-1}. An increase in the length of the straight-chain alkyl group in lupinine derivatives appreciably enhanced the anticholinesterase activity in relation to the mammalian enzyme. In contrast to this, the sensitivity of the ACE from the heads of flies to the OPI fell sharply with increase in the length of the alkyl group. Thus the compound with the C_5H_{11} group proved to be 120 times less active than the ethyl derivative. An increase in the length of the iso-groups increased the ability to suppress the mammalian ACE but had virtually no influence on the ACE from the heads of flies. In epilupinine derivatives an increase in the length of the straight-chain alkyl group had a very insignificant and indefinite influence on their ability to inhibit the ACE from the heads of flies. Indeed, the effect of epilupinine derivatives on the mammalian ACE did not differ from that of the analogous lupinine compounds. With increase in the length of both straight-chain and branched alkyl groups, the anticholinesterase activity increased significantly. This was manifested most clearly in relation to the ACE from human blood erythrocytes: on passing from C_2H_5 to C_5H_{11}, the activity increased by a factor of 90 and on passing from iso-C_3H_7 to iso-C_5H_{11} the activity rose by a factor greater than 500. The facts enumerated above indicate significant differences between the structures of the active surfaces of the cholinesterases from mammals and flies. It has been noted[39] that in the insect cholinesterase the distance between the anionic and esterase centres is greater than in the mammalian cholinesterase. However, it is difficult to account for the data obtained in terms of these differences alone. The results showing that the hydrophobic region around the anionic centre in the ACE from the heads of flies is more bulky and wider than in the ACE from human erythrocytes are of great interest. One canot rule out the possibility that this can justify the hypothesis of a greater complementarity between the bulky heterocyclic residue in the OPI investigated and the anionic centre of the fly cholinesterases compared with the mammalian enzyme. The fact that very small conformational differences between lupinine and epilupinine are sufficient to have a pronounced influence on the anticholinesterase effect of the OPI is quite probably also associated with precisely this factor. As regards the sharp decrease of the anticholinesterase activity of the OPI in relation to the ACE from the heads of flies with increase in the length of the hydrocarbon group, there is no doubt whatever that the cause lies in the difference between the hydrophobic environments of the esterase centres in the mammalian and insect enzymes. It may be that on this part of the active surface of the insect enzyme, the hydrophobic regions are not very large and that immediately beyond them there are hydrophilic regions which not only do not promote but actually actively hinder the sorption of large hydrocarbon groups, which leads to a pronounced decrease of the anticholinesterase effect.

V. REVERSIBLE INHIBITION OF CHOLINESTERASES

The reversible inhibition of the catalytic activity of cholinesterases is less characteristic of organophosphorus inhibitors. The purely reversible inhibition of cholinesterases by organophosphorus compounds was first demonstrated[40] in relation to a series of β-(2-pyridyl)ethylphosphine oxides and sulphides (Table 11).

Subsequently, it was shown that the alkyl esters of quinquevalent phosphorus oxyacids are capable of inhibiting cholinesterases only reversibly[41–44].

Pyridine	—	—	$1.2\cdot10^{-2}$	$2.5\cdot10^{-2}$

An analogous effect has been observed for substituted alkyl esters of phosphoric and methylphosphonic acids containing alkaloid and certain heterocyclic residues.

Thus the study of the anticholinesterase activities of diethyl phosphate derivatives of morpholine, piperidine, α-pipecoline, anabasine, tetrahydroquinoline, decahydroquinoline, cytisine, α-hydroxymethylpyridine, α-hydroxyethylpyridine, 8-hydroxyquinoline, lupinine, and epilupinine [compounds (XXIV)–(XLVI) except compound (XXXVII)] showed that all the compounds investigated are competitive reversible inhibitors of ACE (Table 12). The dependence of the inhibiting activity on the structure of the cationic group of the organophosphorus inhibitor appears to be extremely complex. Thus the morpholine derivative does not inhibit the catalytic activity of acetylcholinesterase at all, the inhibiting activity increasing on going over to the piperidine, α-pipecoline, and then anabasine derivatives. However, the condensation of cyclohexane and benzene rings with the piperidine ring (the decahydroquinoline and tetrahydroquinoline derivatives) does not alter significantly the anticholinesterase activity. In all these compounds the nitrogen atom is present in one ring, while its introduction into the position between two rings leads to a decrease of the inhibiting activity of the given substances (the lupinine and epiluinine derivatives). The 8-hydroxyquinoline derivative is the most active inhibitor in this series of substances. Its activity is apparently due to the correspondence of the distances between the phosphorus and nitrogen atoms in the inhibitor and between the carbonyl carbon atom and nitrogen in acetylcholine. Weak inhibiting properties in relation to acetylcholinesterase can apparently be explained by the fact that the phosphate group of the inhibitor is not complementary in relation to the active centre of this enzyme[25].

Table 12. The anticholinesterase properties of the esters of *O,O*-diethylphosphoric acid containing heterocyclic groups[25].

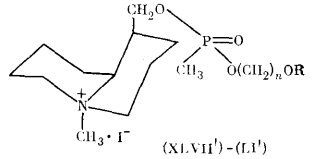
*The percentage inhibition at a concentration of 7.2×10^{-3} M is quoted.



**These substances proved to be irreversible inhibitors and were assessed in terms of the bimolecular interaction constants k_2.

It can be seen from the foregoing that phosphates are very weak reversible inhibitors of both types of enzymes. However, they in fact exhibit a definite selectivity in relation to butyrylcholinesterase. Therefore, bearing in mind that methylphosphoric acid derivatives have a more specific activity in relation to acetylcholinesterase, for which hydrophobic interactions are less typical, the anticholinesterase activities of derivatives of methylphosphonic acids containing a hydrophilic group in the non-leaving part of the molecule and the residues of the alkaloids anabasine, lupinine and piperidine in the leaving group were therefore investigated. It was assumed that the specific structure of the anabasine and lupinine residues, in which there is a considerable hydrophobic environment around the nitrogen atom, promotes the formation of comparatively stable enzyme-inhibitor complexes [17,18].

The study of the inhibiting activities of alkoxyalkyl lupinanyl methylphosphonates (XLVII)–(LI) showed that there is a tendency, albeit small, towards an increase of the inhibiting activity in relation to ACE and BuCE with increase of the length of the alkoxy-group (Table 13, and Fig. 3). [45]

(XLVII)–(LI)

(XLVII′)–(LI′)

There is every reason to suppose that the change in inhibiting activity noted above is associated with an increase of the ability of the OPI to be sorbed on the active surfaces of the enzymes via a hydrophobic mechanism. However, the presence of the hydrophilic oxygen atom in the alkyl moiety in the alkoxy-group hinders this process and thereby reduces the efficiency of the inhibitors.

The methiodides of (*O*-alkoxyalkyl)methylphosphinyllupinines are less active reversible inhibitors of ACE and BuCE than their uncharged analogues. Evidently, the

charge, interacting at the anionic site, does not ensure the most effective hydrophobic sorption (Fig.4). It is of interest to note that the inhibiting activities of both types of compounds depend not only on the distance between the oxygen and phosphorus atoms but also on the position of the former in relation to the alkyl moiety of the alkoxy-group. The presence of the oxygen atom in the β-position in the alkoxy-group to some extent interferes with hydrophobic sorption.

N-β-(ω-Alkoxyalkoxy)methylphosphinyloxyethylanabasines (LII)–(LVI) and their dimethiodides (LII')–(LVI') proved to be reversible inhibitors with competitive activity[45].

An increase in the length of the alkyl moiety of the alkoxy-group entails a small (three fold) increase of the inhibiting activity in relation to both acetylcholinesterase and butyrylcholinesterase.

An increase in the overall length of the alkoxy-group is accompanied by an increase of the inhibiting activity in relation to both enzymes, which is very low in the case of butyrylcholinesterase and is appreciable in the case of acetylcholinesterase (Table 14, Fig.5).

Table 14. The constants for the reversible inhibition of cholinesterases (K_i, mol litre^{-1}) by N-[β-(ω-alkoxyalkoxy)-methylphosphinyloxyethyl]anabasines (LII)–(LVI) and their methiodides (LII')-(LVI'). [17,45]

(LIX)	C_5H_{11}	2.06	1.015	(LIX')	0.677
(LX)	C_6H_{13}	1.55	0.307	(LX')	0.364

N-β-(Alkoxymethylphosphinyloxyethyl)piperidines (LVII)–(LX) are reversible competitive inhibitors of cholinesterases.

The activities of the test compounds in relation to butyrylcholinesterases are inferior to those of analogous anabasine and lupinine derivatives. The average K_i is 1×10^{-4} M, decreasing almost by a factor of 5 in the series of substances investigated (Table 15).

Piperidine derivatives are also weaker inhibitors of acetylcholinesterase than the corresponding anabasine and lupinine derivatives.

The methiodides of *N*-β-(alkoxymethylphosphinyloxyethyl)-piperidines (LVII')-(LX') have the same inhibiting effect on butyrylcholinesterases as their uncharged analogues (Table 15, and Fig.6).

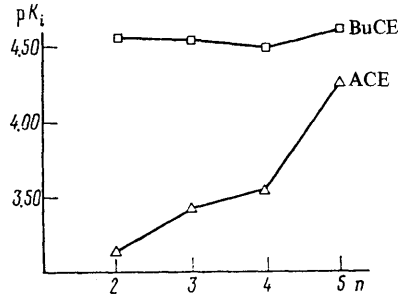

Figure 6. Dependence of pK_i on the length of the alkoxy-group in compounds of type (LVII)-(LX).[17,45]

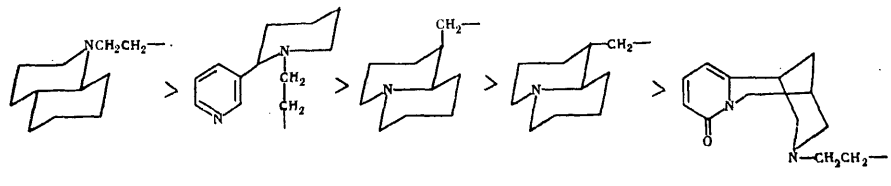
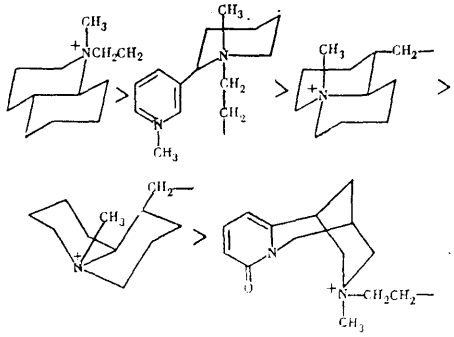


Thus the presence of an oxygen atom in the alkyl moiety of the reversible inhibitors, both with and without positive charges in the molecule, has an appreciable influence on the character of their interaction with cholinesterases. One should note that, for both the lupinine and anabasine derivatives, the characteristics of the changes in the anticholinesterase activity are similar. On this basis, one may conclude that the hydrophilic oxygen atom in the alkoxy-group of the reversible organophosphorus inhibitor in general reduces the inhibiting activity. Furthermore, one should also note that the reversible inhibiting activity depends significantly also on the structure of the heterocyclic residue present in the leaving component of the OPI molecule.

VI. CONCLUSION

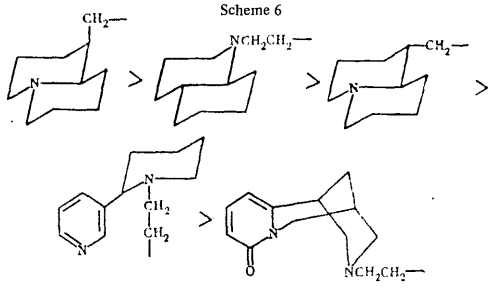
Thus, comparison of the anticholinesterase activities of the *O*,*O*-dialkyl phosphorothioates which we investigated, containing the residues of the alkaloids lupinine, epilupinine, anabasine, cytisine, and decahydroquinoline in the alkanethiol component of the organo phosphorus inhibitor, showed that all the compounds exhibit a greater tendency towards interaction with the horse blood serum butyrylcholinesterase than with the acetylcholinesterase from human blood erythrocytes. Similar properties of dialkyl phosphorothioates were known previously but in our studies the selectivity of the activity of the above substances in relation to butyrylcholinesterase depends not only on the structure of the phosphoryl component but also on the bulk and conformational possibilities in the leaving part of the inhibitor molecule. Dialkyl phosphorothioates containing the lupinine residue proved to be more highly specific inhibitors of butyrylcholinesterase than the epilupinine derivatives. Under the same experimental conditions and for identical structures of the phosphoryl component of the lupinine and epilupinine derivatives, the differences between the conformational states of the protonated forms of lupinine and epilupine in solution can be appropriately regarded as the cause of the selectivity of their activity in relation to butyrylcholinesterase[17,37]. The protonated forms of *O*,*O*-dialkyl *S*-lupinanyl phosphorothioates apparently exist in two conformational states, as in the case of acyl-lupinanes: having a *trans*-junction with the quinolizidine ring and an axial hydroxymethyl group and having a *cis*-junction with the quinolizidine ring and an equatorial hydroxymethyl group. These two conformers are in dynamic equilibrium. It may be that the *cis*-conformer is better adapted to sorption on the anionic centre of butyrylcholinesterase, as a result of which the sorption equilibrium is displaced towards the formation of the *cis*-form and this entails the observed specificity of the activity of lupinine derivatives in relation to butyrylcholinesterase. The conformation of the epilupinine derivatives under the experimental conditions at pH 7.5 to 7.8 remains unchanged, i.e. it has a *trans*-junction with the quinolizidine ring and an equatorial hydromethyl group[29,30-33,38].



Comparison of the anticholinesterase activities of the diethyl phosphorothioates containing the residues of the above alkaloids as well as cytisine, anabasine, and decahydroquinoline made it possible to set up a series based on the relative inhibiting activities as a function of the structure of the leaving components of the organophosphorus compounds investigated: the constants k_2 in relation to the ACE from the heads of flies are 9.3×10^5 for *N*-[β-(diethoxyphosphinyl)-mercaptoethyl]anabasine, 1.8×10^4 for *N*-[β-(diethoxyphosphinyl)mercaptoethyl]cytisine, and 1.3×10^6 litre mol^{-1} min^{-1} for *N*-[β-(diethoxyphosphinyl)mercaptoethyl]decahydroquinoline. In terms of the strength of the irreversible inhibition of human blood erythrocyte acetylcholinesterase, the inhibitors $(C_2H_5O_2)P(O)SR$ can be arranged in the following sequence as a function of the substituent R:

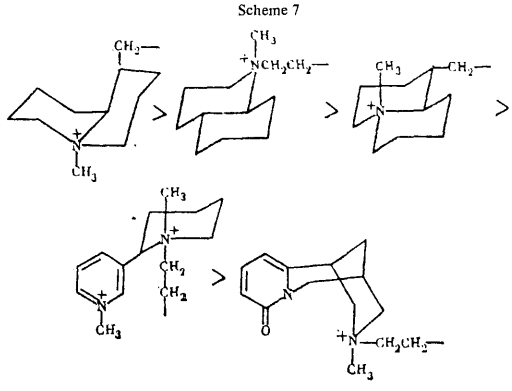
Scheme 4

On the other hand, the sequence of their methiodides is as follows:



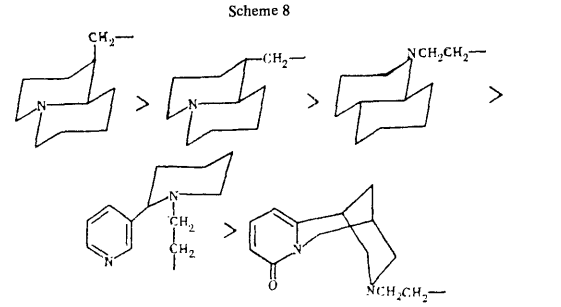
Scheme 5

It is seen from the above sequences that an increase in the complexity of the piperidine ring in the test substances results in a marked decrease of the irreversible inhibiting activity in relation to the erythrocyte acetylcholinesterase, which confirms the existence of a weakly hydrophobic framework around the anionic centre in the acetylcholinesterase from human erythrocytes. In the second sequence the methiodide of *O,O*-diethyl *S*-lupinanyl phosphorthioate is less active than the analogous epilupinine derivative, which is apparently due to the influence of the conformation change in the lupinine derivative on conversion into the methiodide[33].



Another picture is observed when the above inhibitors act on butyrylcholinesterase. Butyrylcholinesterase is known to tend to undergo hydrophobic interactions and the hydrophobic framework around the anionic centre in this enzyme is more extensive than in acetylcholinesterase. The given sequence shows that the anionic centre of butyrylcholinesterase has a definite boundary and tends to sorb labile bicyclic systems and transition to systems containing groups such as the pyridine and quinolizidine groups results in a sharp decrease of the reversible inhibiting activity:

Scheme 6



An analogous behaviour has been observed also for the methiodides of the test compounds:

Scheme 7

The compounds investigated proved to be very powerful inhibitors of the cholinesterase from the heads of flies with the exception of the cytisine derivative, which exhibited a very weak inhibiting activity in its interaction with all the enzymes investigated:

Scheme 8

Comparison of these series of relative inhibiting activities of the compounds, namely in their interaction with butyrylcholinesterase, shows that the first four compounds of the last sequence are very powerful inhibitors of both the acetylcholinesterase from the heads of flies and of butyrylcholinesterase. This suggests that in all probability the hydrophobic frameworks around the anionic centres of horse blood serum butyrylcholinesterase and the acetylcholinesterase from the heads of flies have a definite similarity in their steric structures[33].

The study of the acetylcholinesterase activities of *O,O*-dialkyl *S*-lupinanyl phosphorothioates and the corresponding epilupinanyl derivatives with straight-chain substituents in relation to the acetylcholinesterase from the heads of flies showed that the inhibiting activity of the lupinine derivatives decreases sharply with increase in the length of the alkoxy-groups in the inhibitor molecules; an analogous but less marked behaviour has been observed also for the epilupinine derivatives. The hydrophobic component in the region of the esterase centre of the acetylcholinesterase from the heads of flies is apparently small compared with the mammalian enzyme and immediately beyond it there are hydrophilic regions which hinder the sorption of large hydrocarbon groups, reducing the acetylcholinesterase activity. The investigations have yielded data which made it possible to discover differences between the structures of the active centres of mammalian cholinesterases and acetylcholinesterase from the heads of flies.

Carboxylic Acid Esters as Substrates of Cholinesterases

A.P.Brestkin, E.V.Rozengart, A.A.Abduvakhabov, and A.A.Sadykov

Data on the kinetics of the hydrolysis of various carboxylic acid esters by two main types of cholinesterases—acetylcholinesterase from human erythrocytes and buryrylcholinesterase from horse blood serum—are surveyed. It is shown that the rate of enzyme hydrolysis depends significantly on the structure of the acyl part of the ester molecule, the nature of the ester heteroatom, the structure of the alcohol component, and particularly the structure of the onium group. Esters based on natural products are of special interest as specific substrates of these enzymes. The role of the productive and non-productive sorption of the substrates in enzyme catalysis is demonstrated.
The bibliography includes 81 references.

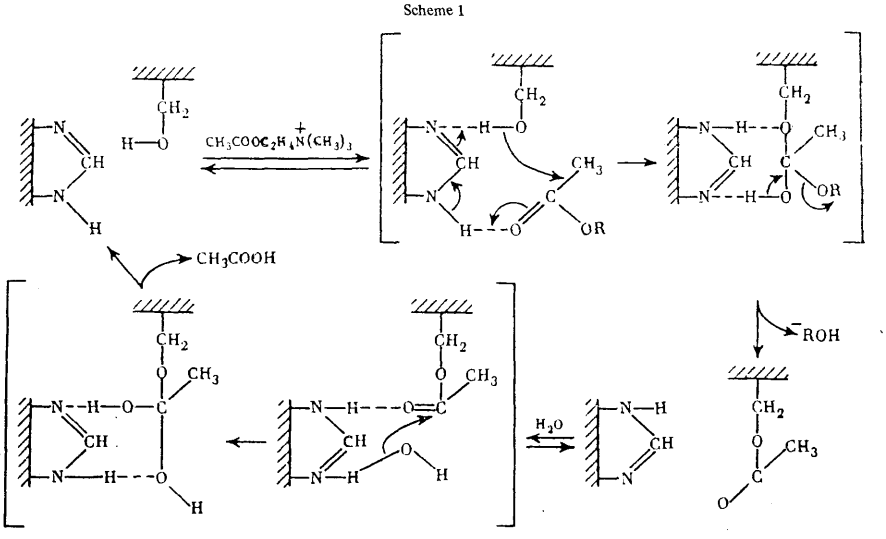
I. INTRODUCTION

Cholinesterases (CE) are enzymes which hydrolyse the choline esters of carboxylic acids at a higher rate than non-choline esters. A characteristic feature of these enzymes is the inhibition of their catalytic activity by low concentrations of tetra-alkylammonium compounds, certain organophosphorus compounds, and esters of substituted carbamic acids. The sensitivity to eserine at concentrations of 10^{-5} M and below is believed to be one of the most reliable criteria for the classification of an enzyme as a cholinesterase.

Two main types of cholinesterases have been most thoroughly investigated: acetylcholinesterase (ACE) or acetylcholine acyl-hydrolase (EC 3.1.1.7) and butyrylcholinesterase (BuCE)—a variety of acylcholine acyl-hydrolases (EC 3.1.1.8), which differ in their substrate specificity and sensitivity to various inhibitors. ACE hydrolyses acetylcholine (AC) at the highest rate, propionylcholine (PrC) and acetyl-β-methylcholine (MeC) somewhat more slowly, and has almost no influence on the rate of hydrolysis of butyrylcholine (BuC) and benzoylcholine (BzC). On the other hand, butyrylcholinesterase hydrolyses BuC at the highest rate, PrC, AC, and BzC somewhat more slowly, and does not influence the rate of hydrolysis of MeC. Furthermore, in contrast to BuCE, the catalytic activity of ACE is inhibited by high substrate concentrations.



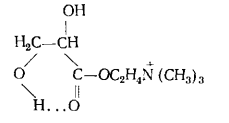
ACE of nerve tissue is directly involved in the transmission of nerve excitation from the nerve to the innervated cell. The biological role of BuCE as well as that of the ACE contained in the erythrocytes of many animals has not been elucidated.

Cholinesterases are the target of the inhibiting activity of certain medicinal preparations, organophosphorus and carbamate insectoacaricides, and organophosphorus poisons.

There exists an extensive literature on cholinesterases, which has been comprehensively surveyed in monographs[1-5] and a number of reviews[6-8].

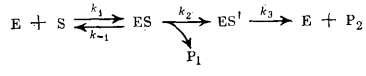
The extremely high catalytic activity of cholinesterases is due to the unique structure of their active surface. Apart from the esterase site, where the ester linkage is ruptured, at a distance of 4–5 Å from it on the surface there is an anionic site which is responsible for the specific binding of the ammonium group of AC and promotes a favourable orientation of the substrate molecule[2-4]. Apart from Coulombic interaction of the ammonium group with the anionic site of the enzyme, the orientation of substrates and inhibitors is

Scheme 1



greatly influenced by the hydrophobic interaction of their hydrocarbon groups with the hydrophobic sections located in the region of both the anionic and esterase sites[8].

It is suggested that the anionic site consists of the carboxylate anion derived from the dibasic glutamic or aspartic acid incorporated in the polypeptide chain of the enzyme. The esterase site on the active surface of the enzyme has a more complex structure. The serine hydroxyl, which is acylated on interaction with substrates and phosphorylated on interaction with organophosphorus inhibitors, plays the main role in it. According to modern ideas[9,10], this chemically inert hydroxyl is activated with the aid of the imidazole group of histidine located in its immediate vicinity. On interaction with the substrate, the activation process begins with formation of a hydrogen bond between its carbonyl oxygen and the imino-nitrogen of imidazole, which increases the basicity of the azole nitrogen and leads to the formation of a hydrogen bond between this nitrogen and the serine hydroxyl[9] (Scheme 1).



There is then a sharp increase of the nucleophilicity of the hydroxyl oxygen and its interaction with the central carbon atom is facilitated. The redistribution of electron density in the eight-membered ring of the enzyme–substrate complex formed results in the formation of a covalent bond between the serine oxygen and the acid group of the substrate and in the elimination of the alcohol group. The subsequent reaction of the acylated enzyme with water proceeds analogously, forming an intermediate acyl-enzyme–hydrate complex, which then decomposes to the initial enzyme and an acid. Thus the reactive form of the serine hydroxyl is produced at the instant of the oriented binding of the substrate molecule and does not precede it.

The mechanism of cholinesterase hydrolysis presented here is confirmed by a number of facts[4]. Cholinesterases do not catalyse the hydrolysis of choline esters containing thione sulphur (C=S) instead of carbonyl oxygen (C=O), since the sulphur atom is incapable of forming a strong hydrogen bond, which hinders the activation of the serine hydroxyl. For the same reason, organophosphorus compounds containing thione sulphur (P=S) do not phosphorylate cholinesterase, in contrast to their oxygen analogues. Glyceroylcholine, the cyclic structure of the acid group of which has been demonstrated by infrared spectroscopy[11], is not hydrolysed by ACE, because the carbonyl oxygen is already linked by a hydrogen bond to the hydroxy-group of the ester itself:

The hydrolysis of substrates (S) by an enzyme (E) is usually described by Scheme 2[4,12]:

Scheme 2

where ES is the Michaelis complex, ES′ the acylated enzyme, P_1 and P_2 are the alcohol and the acid respectively, and k_1, k_{-1}, k_2, and k_3 are the rate constants for the individual reaction states. Evidently, apart from the complexes ES and ES′, other intermediate complexes, for example, those occurring in Scheme 1, are also formed, but these additional complexes do not, generally speaking, vitiate the kinetic conclusions which follow from the three-stage scheme presented[12].

When the concentration of the substrate [S] in the reaction mixture is many times higher than the initial enzyme concentration $[E]_0$, it is believed that the enzyme hydrolysis proceeds under steady-state conditions where the concentrations of the complexes [ES] and [ES′] are established at almost constant levels. Under these conditions, the scheme leads to the familiar Michaelis–Menten equation

$$v=\frac{a_c[E]_0[S]}{K_M+[S]}=\frac{V[S]}{K_M+[S]}\ , \qquad (1)$$

where v is the rate of hydrolysis of the substrate by the enzyme, V is the maximum velocity of the reaction when the enzyme is fully saturated by the substrate, i.e. for $[S] \gg K_M$, whereupon Eqn.(1) becomes

$$v=V=a_c[E]_0'\ , \qquad (1a)$$

a_C is the activity of the catalytic centre of the enzyme linked to the rate constants of the individual reaction stages by the formula

$$a_c=\frac{k_2k_3}{k_2+k_3} \qquad (1b)$$

and K_M is the Michaelis constant expressed by the formula

$$K_M=\frac{[E][S]}{[ES]+[E']S}=\frac{(k_{-1}+k_2)\,k_3}{k_1(k_2+k_3)}\ . \qquad (1c)$$

When $[S] = K_M$, Eqn.(1) becomes

$$v=\frac{V}{2}\ , \qquad (1d)$$

and it follows from Eqn.(1c) that

$$\frac{K_M}{[S]}=\frac{[E]}{[ES]+[ES']}=1\ , \qquad (1e)$$

where [E] is the concentration of the free enzyme.

Hence it follows that K_M is numerically equal to the substrate concentration for which the rate of the enzyme reaction is smaller by a factor of two than the maximum rate defined by Eqn.(1d) and when half the enzyme is bound in the enzyme–substrate complexes [Eqn.(1e)].

The susceptibility of cholinesterases to irreversible inhibition by organophosphorus inhibitors (OPI) as a result of the phosphorylation of the active centres has been used to determine $[E]_0$ in the enzyme solution investigated[13]; $[E]_0$ is found from the minimum amount of a highly active OPI which fully inhibits the catalytic activity; $[E]_0$ makes it possible to calculate easily the activity of the catalytic enzyme centres a_C from Eqn.(1a): $a_C = V/[E]_0$.

The knowledge of a_C and V for one substrate ($a_{C,1}$ and V_1), for example, for AC, makes it possible to find a_C for another substrate ($a_{C,2}$) from the maximum rate of its enzyme hydrolysis V_2 for the same amount of the preparation of the given enzyme, i.e. for $[E]_{0,1} = [E]_{0,2}$:

$$a_{c,1}/a_{c,2}=V_1/V_2$$

It follows from Eqn.(1a) that a_C characterises the catalytic activity when the enzyme is fully saturated by the substrate, i.e. it does not take into account the first binding stage which has a significant influence on the ability of the enzyme to hydrolyse the substrate at low concentrations. To a first approximation, this stage is assessed in terms of the ratio

$$a_c/K_M : a_c/K_M=k_1k_2/(k_1+k_2)$$

because $k_2/(k_{-1} + k_2) < 1$, so that $a_C/K_M < k_1$.

The ratio a_C/K_M is an important kinetic parameter characterising the catalytic activity of the enzyme in relation to the given substrate when $[S] < K_M$, since under this condition Eqn.(1) becomes

$$v=\frac{a_c[E_0][S]}{K_M}\ . \qquad (1f)$$

Thus at high substrate concentrations the rate of enzyme hydrolysis is determined by the quantity a_C and at low concentrations by the quantity a_C/K_M.

Eqn.(1) is valid for the hydrolysis of the choline esters of carboxylic acids by ACE only at low concentrations of the esters, since at high concentrations the catalytic activity of the enzyme is inhibited. This, the so-called substrate inhibition is taken into account in the Haldane equation[14]

$$v = \frac{V[S]}{K_M + [S] + K_{SS}[S]^2} = \frac{V[S]}{K_M + [S] + (K_M/[S]^2_{opt})[S]^2} \quad (2)$$

where K_{SS} is the substrate inhibition constant.

The quantity K_{SS} is calculated from the formula

$$K_{SS} = K_M/[S]^2_{opt} \quad (2a)$$

where $[S]_{opt}$ is the substrate concentration for which the reaction rate has a maximum, i.e. the substrate concentration corresponding to the maximum on the v–[S] curve[14].

Haldane[14] believes that substrate inhibition is associated with the fact that at high concentrations [S] a second inactive enzyme–substrate sorption complex ES_2 is formed in addition to the ES complexes. At high electrolyte concentrations in the reaction mixture, substrate inhibition of ACE vanishes[15], which is difficult to reconcile with Haldane's hypothesis. Substrate inhibition is probably associated with the interaction of the substrate with an allosteric centre[15].

There is at present no reliable method for determination of the rate constants for the individual stages of the cholinesterase hydrolysis. The study of the kinetics of this reaction is restricted to the determination of K_M and V. One of the commonest procedures for the determination of these kinetic parameters is the Lineweaver–Burk method[16].

Table 1. The cholinesterase hydrolysis of the choline esters of carboxylic acids $RC(O)OCH_2CH_2\overset{+}{N}(CH_3)_3$ (the rate of hydrolysis of AC was assumed to be 100)[4].

II. DIFFERENT ANALOGUES OF ACETYLCHOLINE

The study of the kinetic parameters of the hydrolysis of various carboxylic acid esters by cholinesterases is necessary for the determination of the specificity of their catalytic activity and also for the elucidation of the mechanism of the cholinesterase hydrolysis and of the structure of the active surfaces of these enzymes.

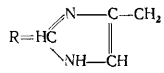
The cholinesterase hydrolysis of AC analogues, differing from the latter either by the structure of the acyl group [$R-C(O)OCH_2CH_2\overset{+}{N}(CH_3)_3$], or the nature of the ester linkage [$R-C(O)XCH_2CH_2\overset{+}{N}(CH_3)_3$], or the structure of the group between the ester oxygen and the onium nitrogen atom [$R-C(O)O-A-\overset{+}{N}(CH_3)_3$], or the structure of the onium group [$CH_3C(O)-OCH_2CH_2\overset{+}{N}R^1R^2R^3$], is discussed below.

1. Substrates Having the General Formula $RC(O)-OCH_2CH_2.\overset{+}{N}(CH_3)_3$

The enzyme hydrolysis of choline esters is known[2–4] to depend significantly on the structure of the acyl residue (Table 1). Among the choline esters of saturated straight-chain carboxylic acids ranging from formic (I) to oenanthic (VII), only the first three esters are hydrolysed by ACE, AC being hydrolysed at the maximum rate, while BuCE hydrolyses all seven esters, the rate of hydrolysis of BuC (IV) being highest.

In contrast to BuC, isobutyrylcholine (VIII), in which the length of the hydrocarbon group in the acyl component is the same as in PrC, is readily hydrolysed by ACE and not less effectively than PrC. It is striking that BuCE hydrolyses isobutyrylcholine less effectively than PrC and BuC, i.e. the branching of the hydrocarbon group impairs the susceptibility of the choline esters to hydrolysis by this enzyme. This is confirmed also by data for the enzyme hydrolysis of the choline esters of ethylmethylacetic (IX) and diethylacetic (X) acids which are hardly hydrolysed by BuCE, while the choline esters of the isomeric straight-chain acids—valeric (V) and caproic (VI)—are hydrolysed by this enzyme at a high rate.

The presence of a double bond in the acyl component reduces the susceptibility of choline esters to cholinesterase hydrolysis. Thus acryloylcholine (XI) is hydrolysed by BuCE and ACE more slowly by factors of almost two and five respectively than its saturated analogue (III). It has been shown in relation to the choline esters of crotonic acid that the influence of the double bond depends greatly on its position. The presence of the double bond in the α-position in compound (XII) reduces sharply the susceptibility of this ester to hydrolysis by BuCE, while the double bond in the β-position in compound (XIII) reduces the rate of hydrolysis of the ester by this enzyme only by a factor of 1.3 compared with BuC. Analogous data have been obtained in experiments with the choline esters of unsaturated analogues of valeric acid [compounds (XIV) and (XV)][4].



Unusual results have been obtained for the choline esters of aminoacids in which $R = NH_2(CH_2)_n$.[17] Under the influence of BuCE, the rates of hydrolysis of esters with $n = 3–4$ were lower by a factor of 15–20 than the rate of hydrolysis of AC and for $n = 6$ and 7 these esters were hydrolysed at the same rate as AC. The conversion of NH_2 into $\overset{+}{N}(CH_3)_3$ leads in all cases to a sharp reduction of the rate of enzyme hydrolysis[17].

It has been shown[18] that carbamoylcholine ($R = NH_2$) is not hydrolysed at all by BuCE.

Interesting data have been obtained[19,20] for the cholinesterase hydrolysis of fluoro-, chloro-, bromo-, and iodo-substituted AC derivatives. All these derivatives were hydrolysed faster by BuCE than AC (by a factor greater than 2.5), the bromo-derivative being hydrolysed at the maximum rate. The inhibition of catalytic activity by high substrate concentrations, which is atypical for BuCE, was observed for all the derivatives. The fluoro-derivative was hydrolysed by ACE like AC, while the remaining derivatives were hydrolysed more slowly by a factor of two, despite the fact that in all of them the strength of the ester linkage is much lower than in AC. Obviously the observed effect of the substitution of a hydrogen atom by a halogen is associated with the increase of the size of the acid group. This hypothesis is confirmed by the fact that the dichloro-derivative of AC is hydrolysed by ACE five times more slowly than AC, while the trichloro-derivative is not hydrolysed at all. It is surprising that BuCE, for which the steric factor should not play a

significant role in the given instance, does not hydrolyse these two esters.

The introduction into the acyl part of the AC molecule of the imidazole group[21]

and the pyridine group[22]

reduced the rate of hydrolysis by BuCE, while ACE altogether failed to hydrolyse these derivatives.

It is striking that imidazolylpropionylcholine

is hydrolysed by BuCE as effectively as BuC, i.e. 2.5 times faster than AC[21].

At high concentrations phenylpropionylcholine ($R=C_6H_5CH_2.CH_2$) is hydrolysed by BuCE almost twice as fast as AC and BzC, while at low concentrations it is hydrolysed faster by a factor greater than 40 owing to the lower value of K_M; it is not hydrolysed by ACE[23]. As for the imidazole derivatives, an increase of the distance between the carbonyl carbon and the phenyl group leads to an appreciable increase of the rate of enzyme hydrolysis.

The stereospecificity of cholinesterases has been investigated in experiments with lactoylcholine. The L(+)- isomer was hydrolysed by ACE faster than AC by a factor of 1.5, while the rate of hydrolysis of the D(-)-isomer was five times lower; the rate of hydrolysis of the racemate was 70% of that of AC[11]; BuCE did not exhibit stereospecificity: both isomers were hydrolysed by this enzyme 3.5 times faster than AC[24].

Thus the data examined in this section show that ACE is more sensitive than BuCE to changes in the structure of the acid components of the molecules of choline esters.

2. Substrates Having the General Formula $RC(O)XC_2H_4\overset{+}{N}(CH_3)_3$

Analogues of AC are known in which the ester oxygen has been replaced by S, Se, and NH. Among them, the greatest interest attaches to the thiocholine esters, whose study was begun as early as 1939[18]. Acetylthiocholine (ATC) and butyrylthiocholine (BuTC) have already been used for a long time in histological investigations in order to discover and locate cholinesterases in various tissues. These esters as well as propionylthiocholine (PrTC) and acetyl-β-methylthiocholine (AMTC) are also widely used in biochemistry in the study of the catalytic activities of cholinesterases; the thiocholine formed on their hydrolysis can be readily determined colorimetrically with the aid of the Ellman chromogen reagent[25]. This method for the determination of the cholinesterase activity is more sensitive than the potentiometric method.

Data according to which the rate of hydrolysis of thiocholine esters by cholinesterases is several times higher than that of the choline analogues have been presented in a series of reviews and monographs[2,3,5,6]. It has been demonstrated convincingly[26,27] that the available literature data are much too high, since the investigators who used the potentiometric titration method did not take into account the acid properties of the thiocholine formed on hydrolysis of these substrates.

Table 2 presents the results of a comparative kinetic study of the enzyme hydrolysis of choline and thiocholine esters by ACE and BuCE[27].

All the relations established for the oxygen analogues are valid for the cholinesterase hydrolysis of the thiocholine esters. Thus ATC is hydrolysed fastest by ACE, PrTC is hydrolysed more slowly, and BuTC is hardly hydrolysed at all. The rate of hydrolysis by BuCE decreases in the sequence BuTC > PrTC > ATC. The inhibition of enzyme activity by high concentrations of thiocholine esters is manifested only in experiments with ACE. There are also similarities between other substrate properties of thiocholine and choline esters—an S optimum and a pH optimum. It is striking that at high substrate concentrations ACE hydrolyses AC at a higher rate (in terms of a_C), while at low concentrations the rate of hydrolysis of ATC is higher (in terms of a_C/K_M). Butyrylcholinesterase hydrolyses ATC faster than AC at both high and low concentrations.

In contrast to its oxygen analogue, AMTC is hydrolysed comparatively effectively by BuCE and cannot therefore be used as a specific substrate of ACE[26,28].

Table 2. Kinetic parameters of the hydrolysis of choline and thiocholine esters by BuCE and ACE[27].

Substrate	BuCE			ACE		
	a_c, min^{-1}	K_M, mol $litre^{-1}$	a_c/K_M, litre mol^{-1} min^{-1}	a_c, min^{-1}	K_M, mol $litre^{-1}$	a_c/K_M, litre mol^{-1} min^{-1}
AC	$7.6\cdot10^4$	$9.1\cdot10^{-4}$	$8.4\cdot10^7$	$2.8\cdot10^5$	$1.9\cdot10^{-4}$	$1.5\cdot10^9$
PrC	$1.2\cdot10^5$	$5.5\cdot10^{-4}$	$2.2\cdot10^8$	$2.2\cdot10^5$	$2.8\cdot10^{-4}$	$8.0\cdot10^8$
BuC	$2.1\cdot10^5$	$7.7\cdot10^{-4}$	$2.7\cdot10^8$	0	—	—
ATC	$9.5\cdot10^4$	$5.4\cdot10^{-4}$	$1.8\cdot10^8$	$2.2\cdot10^5$	$1.0\cdot10^{-4}$	$2.2\cdot10^9$
PrTC	$1.2\cdot10^5$	$5.1\cdot10^{-4}$	$2.4\cdot10^8$	$1.2\cdot10^5$	$1.9\cdot10^{-4}$	$6.0\cdot10^8$
BuTC	$1.6\cdot10^5$	$4.3\cdot10^{-4}$	$3.8\cdot10^8$	0	—	—

The observed differences between the abilities of ACE and BuCE to hydrolyse choline and thiocholine esters are due to different causes: the different amounts of anhydride character in the ester linkages, the different configurations of the choline and thiocholine esters, and the different radii of the heteroatoms.

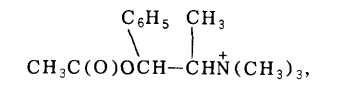
The selenium analogue of AC was hydrolysed by ACE at a lower rate than ATC[29]. It was believed that the amide analogue of AC (X = NH) cannot be hydrolysed by cholinesterases[4]. However, according to the latest data[30], this substrate is hydrolysed by ACE. In the study of the rate of hydrolysis of this amide one must bear in mind that the trimethylaminoethylammonium cation $(CH_3)_3\overset{+}{N}CH_2CH_2NH_2$ has pronounced basic properties and the traditional potentiometric titration method is not suitable for its determination.

3. Substrates Having the General Formula $RC(O)OAN(CH_3)_3$

The susceptibility of choline esters to hydrolysis by cholinesterases is greatly influenced by the structure of the group A between the ester oxygen and the onium nitrogen atom. Several AC derivatives in which the hydrogen atoms in the ethylene chain have been substituted by various hydrocarbon groups ($A = -CHR^1CHR^2$) have been synthesised. The β-methyl derivative of AC, which is relatively easily hydrolysed by ACE, is of greatest interest: the rate of its hydrolysis is smaller by a factor of three than that of AC[31] and it is hardly hydrolysed by BuCE (at least 20 times more slowly than AC[32]). Until recently, acetyl-β-methylcholine was therefore regarded as the only specific substrate

of ACE. The substitution of the hydrogen in the β-position by more complex hydrocarbon groups ranging from C_2H_5 to C_6H_{13} increases only slightly the rate of hydrolysis of esters by BuCE[18]. Unfortunately the hydrolysis of these AC derivatives by ACE has not been investigated.

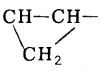
The specificity of ACE to the acyl residue of the β-methylcholine esters is the same as for choline esters: the propionate hydrolyses more slowly than the acetate, the rate of hydrolysis of the isobutyrate is lower still, and trimethylacetate is not hydrolysed at all[33].



Experiments with the optical isomers of acetyl-β-methylcholine established that the L-isomer is hydrolysed by ACE more slowly by a factor of two than AC, while the D-isomer proved to be a reversible inhibitor and not a substrate. As mentioned above, the racemate is hydrolysed by this enzyme approximately three times more slowly than AC.

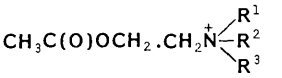
In experiments with butyryl-β-methylcholine it was shown that stereospecificity is characteristic also of BuCE: the L-isomer is hydrolysed by this enzyme 10 times more slowly than AC, while the D-isomer is not hydrolysed at all. It is striking that the stereospecificity of both enzymes is not shown in the hydrolysis of acetyl-β-methylcholine: both isomers are hydrolysed by BuCE more slowly by a factor of 1.5 than AC[34], while the rate of hydrolysis by ACE is the same as that of AC[33].

Thus the stereospecificity of cholinesterases is not manifested in all hydrolytic reactions of optically active substrates: it depends significantly on the position of the asymmetric carbon atom in the substrate molecule. The stereospecificity depends also on the nature of the enzyme. As stated above, ACE can distinguish between the D- and L-isomers of lactoylcholine, while BuCE cannot.



The replacement of two hydrogen atoms in the ethylene group by a methyl group in the α- and β-positions lowers the rate of hydrolysis of this ester by ACE[35]. Since there are two asymmetric carbon atoms in the acetyl-α,β-dimethylcholine molecule, this ester should exist in the form of four isomers, forming two pairs: the *erythro*-isomers and the *threo*-isomers, each pair constituting optical enantiomers. It was found that ACE hydrolyses only the *threo*-α(R), β(S)-dimethyl-AC racemate, while the rate of hydrolysis of *erythro*-α(R), β(S)-dimethyl-AC is zero[55].

The esters having the general formula



$$CH_3C(O)OCH(C_6H_5)-CH(CH_3)\overset{+}{N}(CH_3)_3,$$

which are synthesised from ephedrine and pseudoephedrine and are the α-methyl and β-phenyl derivatives of AC, are not hydrolysed by cholinesterases and behave as reversible inhibitors[36].

When the ethylene group in the AC molecule was replaced by the "rigid" cyclopropyl group (A = ), the optically active *trans*- and *cis*-isomers were obtained[37]. The rates of hydrolysis of the (+)- and (-)-*trans*-isomers by ACE were 96% and 59% of that of AC respectively. They were hydrolysed at a lower rate by BuCE: 61 and 33% respectively. The *cis*-isomers were not hydrolysed by these enzymes.

The data described here lead to the conclusion that BuCE is more sensitive to changes in the structure of the ethylene group in the AC molecule than ACE. This conclusion is also confirmed by the results of experiments with AC analogues in which the ethylene group has been replaced by a longer alkyl chain: $A = -(CH_2)_n-$. The ester with the trimethylene chain is hydrolysed by the rat brain homogenate ACE at 70% of the rate of hydrolysis of AC, while the ester with the tetramethylene chain is hydrolysed at 10% of the AC rate. On the other hand, under the influence of BuCE, the rates of their hydrolysis are 7.2 and 0.6% respectively[18,38,39]. Analogous data indicating a decrease of the catalytic activity of cholinesterases with increase of *n* have been obtained in experiments with ammonium and sulphonium compounds[40,41]. The high sensitivity of BuCE to an increase in the length of the alkyl chain has also been demonstrated in experiments with analogous BuC derivatives. The esters with the trimethylene and tetramethylene chains are hydrolysed by this enzyme respectively 5 and 70 times more slowly than BuC[42].

4. Substrates Having the General Formula

$$CH_3C(O)OCH_2.CH_2\overset{+}{N}(R^1)(R^2)(R^3)$$

The susceptibility of various analogues of AC to hydrolysis by cholinesterases depends also on the structure of the ammonium group. Thus the replacement of three methyl groups at the onium nitrogen in AC by ethyl groups resulted in a sharp decrease of the rate of their hydrolysis by BuCE but hardly affected the rate of hydrolysis by ACE[43].

It follows from the data in Table 3[44] that, among the compounds investigated, only the dibutylmethyl derivative (XXIX) proved to be an inhibitor and not a substrate of cholinesterases. Evidently such a large increase in the bulk of the ammonium group should result in a loss by AC derivatives of susceptibility to cholinesterase hydrolysis. Other AC derivatives, except compound (XXI), were hydrolysed by cholinesterases at high concentrations in the reaction mixture but at a lower rate than AC: this is indicated by the values of a_C listed in Table 3. According to the literature[43], a change in the composition of the ammonium group entails a more marked alteration of a_C in experiments with BuCE. Apparently the presence of a charge is most important for ACE, while a change in the structure of the ammonium group is less significant than for BuCE.

When the methyl groups in the AC molecule are replaced by ethyl groups, as in compound (XXVII), the parameter a_C decreases by a factor of 3 for BuCE and only by 1/3 for ACE. Analogous ratios were obtained also for other derivatives, except the pentyl derivative (XXIV), for which a_C in experiments with ACE fell by a factor of two compared with a_C for AC, while in experiments with BuCE the decrease was only by 1/4. It is of interest that the isopropyl derivative (XXV) is very similar to its unbranched analogue (XXII) as a substrate of BuCE and ACE.

The values of K_M for many compounds, with the exception of (XXI), (XXIV), (XXV), and (XXVII) in experiments with ACE and (XXVIII) in experiments with BuCE, proved to be lower than for ACE.

The observed differences between the values of a_C for cholinesterases in the enzyme hydrolysis of AC analogues as a function of the composition of the ammonium group conflict with Scheme 2 and Eqn.(1) which follows from it. Since all these compounds are acetate esters, the deacetylation rate constants k_3 for their ES′ complexes should be the same. The acetylation rate constants k_2 should also be virtually the same, since, according to quantum-chemical calculations, all the compounds are characterised by the same electron density at the carbonyl carbon atom and the strengths of the ester linkages should not therefore differ either. Thus, in conformity with this finding, when Scheme 2 is valid for all the compounds quoted, the values of a_C should also be identical in experiments with both ACE and BuCE. In fact these quantities vary within wide limits.

Table 3. Kinetic parameters of the hydrolysis of AC analogues having the general formula $CH_3C(O).OC_2H_4X$ by BuCE and ACE[44].

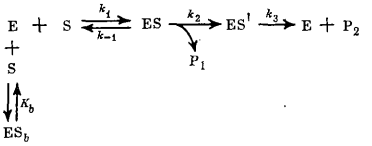
Note. K_M^* is the true Michaelis constant, K_b the equilibrium dissociation constant of the inactivated complex, and p a coefficient defining the fraction of productive binding of the substrate in enzyme hydrolysis.



[a] The reversible inhibition constant K_i is quoted.

The resulting contradiction can be readily resolved on the hypothesis of productive and non-productive binding[45-47]. According to this hypothesis, enzyme hydrolysis can occur only for the correct orientation of the substrate molecule on the active surface of the enzyme, i.e. under the conditions of productive binding where the carbonyl carbon atom of the substrate occupies a rigorously defined position relative to the serine hydroxyl, which attacks this carbon atom.

Evidently the probability of the correct orientation is not sufficiently high for all the AC analogues. If, following the binding of the substrate, its carbonyl carbon atom is not in the immediate vicinity of the serine hydroxyl, hydrolysis cannot occur. Such binding with an incorrect orientation is referred to as non-productive binding.

Taking into account non-productive binding, the scheme for cholinesterase hydrolysis becomes:

Scheme 3

where K_b is the equilibrium dissociation constant of the inactive complex ES_b. Scheme 3 leads to a modification of the Michaelis–Menten equation:

$$v=\frac{a_c[E]_0[S]}{K_M+[S]}=\frac{(k_2+k_3)/(k_2\cdot k_3)\cdot K_b/(K_b+K_M^*)[E]_0[S]}{(K_M^*K_b/(K_b+K_M^*))+[S]}=\frac{a_c^*p[E]_0[S]}{K_M^*p+[S]}\quad\ldots,\quad(5)$$

where K_M and a_c are the Michaelis constant and the activity of the catalytic centre, which are determined experimentally, K_M^* and a_c^* are the true values of these parameters expressed by Eqns.(1c) and (1b), and p is a coefficient which defines the fraction of the productive binding of the substrate in the enzyme hydrolysis:

$$p=\frac{[ES]+[ES']}{[ES]+[ES']+[ES_b]}=\frac{K_b}{K_b+K_M^*}\quad.\qquad(6)$$

If $K_b > K_M^*$, then $[ES_b] \to 0$ and $p = 1$, so that $a_c = a_c^*$ and $K_M = K_M^*$. In this case there is no non-productive binding and each substrate molecule sorbed on the active centre hydrolyses. On the other hand, if $K_b < K_M$, non-productive binding mainly takes place: $p = K_b/K_M^* \to 0$, $a_c = a_c p \to 0$, and under these conditions the ester is a reversible inhibitor and not a substrate. Probably at equal enzyme concentrations $[E]_0$ the differences between the experimental values of $a_c = a_c p$ [see Eqn.(5)] for the AC analogues are related mainly to the different values of the coefficient p; on the other hand, the true catalytic activities a_c for these substances should be the same for the reasons indicated above. In this case the ratio of the values of a_c for two substrates should be equal to the ratio of the coefficients p:

$$a_{c;1}/a_{c;2}=a_{c;1}^*p_1/a_{c;2}^*\cdot p_2=p_1/p_2\quad.\qquad(7)$$

The value of p for each AC analogue with a modified composition of the ammonium group can be estimated assuming that $p = 1$ in the enzyme hydrolysis of AC neglecting thereby the non-productive binding of AC on both ACE and BuCE:

$$p=a_c/a_c(AX)\quad.\qquad(8)$$

The values of p found for the acetates investigated make it possible to calculate for them the K_b and the true Michaelis constants K_M^*:

$$K_M^*=K/p\quad,\qquad(9)$$

$$K_b=K_M^*p/(1-p)\quad.\qquad(10)$$

The ratio a_c/K is of fundamental importance for the kinetics of enzymic reactions. Firstly, it does not depend on the non-productive sorption and, when account is taken of Eqns.(8), (9), and (10), we have

$$a_c/K_M=a_c^*\cdot p/K_M^*p=a_c^*/K_M^*=\frac{k_2k_3k_1(k_2+k_3)}{(k_2+k_3)(k_{-1}+k_2)k_3}=k_1\frac{k_2}{k_{-1}+k_2}\quad.\qquad(11)$$

Secondly, this ratio makes it possible to estimate the rate constant for the formation of the Michaelis complex—since $k_2/(k_{-1} + k_2) < 1$, it follows from Eqn.(11) that $k_1 > a_c/K$.

Thirdly, the ratio a_c/K_M characterises the rate of reaction for $[S] \ll K_M$, whereupon Eqn.(1) becomes

$$v = \frac{a_c}{K_M} \cdot [E]_0 [S] .$$

Calculations have shown that the markedly lower a_c for the butyrylcholinesterase hydrolysis of the AC analogues investigated compared with the acetylcholinesterase hydrolysis is associated with a more significant alteration of p. If compound (XXII) is excluded, then a_c is reduced by a factor less than two in experiments with ACE for all other AC analogues, while in experiments with BuCE the reduction is by a factor of three. When account was taken of non-productive binding, the true Michaelis constants K_M^* increased appreciably. In most cases they are inversely proportional to the ratios a_c/K_M, which, as stated above, characterise to a first approximation the rate constant for the productive binding of the substrate to the enzyme (k_1). Indeed substrates with the highest K_M^* are characterised by the lowest ratios a_c/K: (XII) and (XXV) in experiments with BuCE and (XXIII) and (XXVII) in experiments with ACE. The observed correlation between K_M^* and a_c/K_M shows that the changes in the true Michaelis constants K_M^* for the AC analogues investigated are associated mainly with the changes in k_1, while the rate constants for other steps in enzyme hydrolysis, namely k_2 and k_3, and possibly also k_{-1}, do not vary[45-47].

Compound (XXVIII), which can be logically regarded as an inhibitor, is not an exception. It is characterised by the highest K_M^* and the lowest ratio a_c/K_M in view of the extremely small contribution of productive sorption. On the basis of the idea of productive and non-productive binding, the calculated K_b should be smallest for substrates with the smallest p. Such a relation has been traced in relation to many AC analogues in experiment with BuCE: compounds (XXIV) and (XXVI) have the highest values of p and the highest K_b, while compounds (XXII), (XXIII), and (XXVII) have the lowest p and K_b. In experiments with ACE this relation is less clear-cut. The observed scatter of the calculated data is associated, firstly, with the assumption that $p = 1$ for AC and, secondly, with the inevitable errors in the experimental determination of V and K_M, particularly for ACE, whose catalytic activity is suppressed by high substrate concentrations. The question arises of the cause responsible for the alteration of the contribution of productive binding for the AC analogues investigated. In the cholinesterase hydrolysis of choline esters, the sorption of the latter is ensured in the first place by the ion–ion interaction of the ammonium group of the substrate with the anionic site of the CE. Furthermore, the hydrophobic interaction of the hydrocarbon groups of the "cationic head" of the substrate with the hydrophobic region surrounding the anionic centre plays a significant role.

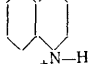
The complementarity of the substrate molecule in relation to the active surface of the enzyme, which is ultimately responsible for productive sorption, depends in general on the extent to which the ion–ion, ion–dipole, and hydrophobic interactions are concerted. When the interactions are concerted, the substrate molecule occupies a position on the active centre such that the necessary conditions are created for the formation of a reactive Michaelis complex (see Scheme 1). In such productive binding of the substrate, the activation of the serine hydroxyl, which executes a nucleophilic attack on the carbonyl carbon atom, is ensured.

When the above interactions of the substrate molecule with the active surface of the enzyme are not concerted, conditions, for the formation of the Michaelis complex are not created. An enzyme–substrate complex ES_b, inert with respect to the reaction, is formed instead.

In the light of this hypothesis, the enhancement of the hydrophobic interaction as a result of the introduction of more complex hydrocarbon groups into the substrate molecule should not always result in an increased contribution of the productive binding of the substrate to the enzyme. For example, in experiments with BuCE the parameter a_c decreases respectively by a factor greater than two, 2.7, and only 1.3 when the methyl group in the AC molecule is replaced by a propyl group [compound (XXIV)], by a butyl group [compound (XXV)], and by a pentyl group [compound (XXVI)].

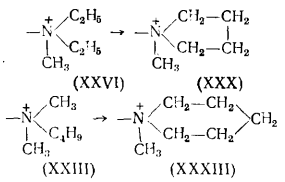
Theoretical conformational analysis showed that such an unusual alteration of a_c on gradual substitution of one methyl group at the onium nitrogen atom by more complex groups is associated with the alteration of the steric configuration of the substrate molecules occurring under these conditions. It has been shown that even a slight change in the ammonium group alters the number of stable conformations, among which only some are compatible with the active surface of the enzyme. Hence the change in the contribution of the non-productive sorption of the substrate is associated with the change in the quantitative ratio of the conformers, both complementary and non-complementary, in relation to the active surface of the enzyme[48].

III. ESTERS WITH A CYCLIC AMMONIUM GROUP IN THE ALCOHOL COMPONENT OF THE MOLECULE



Since 1939[18] numerous esters of this kind have been investigated. Among them, extremely valuable cholinesterase substrates have been discovered. This applies in the first place to the chomogen and fluorogen substrates, which differ significantly in their optical properties from their hydrolysis products[49]. The use of these substrates makes it possible to determine the activities of cholinesterases with a high accuracy even at very low enzyme and substrate concentrations.

This section deals with two types of acetates of cyclic aminoalcohols: esters in which the acetoxyethyl group is linked to an onium nitrogen [$CH_3C(O)OCH_2CH_2\overset{+}{N}$] and esters in which the acetoxy-group is linked to rings containing an onium nitrogen atom. In addition, certain thio-derivatives are also considered.



1. Esters Having the General Formula $CH_3C(O)OCH_2CH_2\overset{+}{N}$

These esters can be regarded as AC analogues. Their study was begun comparatively recently[47]. The compounds listed in Table 4 have been synthesised and the kinetics of their cholinesterase hydrolysis have been investigated by large teams of chemists and biochemists at the Institute of Bio-organic Chemistry of the Academy of Sciences of the Uzbek SSR, the Institute of Experimental Medicine of the Academy of Medical Sciences of the USSR, and the Sechenov Institute of Evolutionary Physiology and Biochemistry of the USSR Academy of Sciences[4,36,44,47,50-64]. Compounds (XXX)–(XXXIII) are of special interest, because the effect of the cyclisation of the ammonium group can be demonstrated in

Table 4. Kinetic parameters of the reactions of the cyclic aminoalcohol acetates $CH_3C(O)OC_2H_4X$ with BuCE and ACE.

relation to them:

(XXVI) (XXX)

(XXIII) (XXXIII)

These processes are accompanied by a sharp decrease of a_C for BuCE but hardly affect the reactions with ACE. The expansion from the five-membered ring in compound (XXX) to the seven-membered ring in compound (XLII) is accompanied by a gradual decrease of a_C by a factor of 3–4 for BuCE and less than two for ACE. The data presented demonstrate as a whole a greater sensitivity of BuCE to changes in the structure of the ammonium group. This conclusion is consistent with that based on the study of the substrates (XX)–(XXIX) in Table 3.

The introduction of a methyl group in the α-position of the piperidine ring [compound (XXXVIII)] reduces a_C for ACE, while the introduction of a methyl group in the γ-position [compound (XXXIX)] increases a_C for BuCE. On the other hand, the derivative with a pyridinium group in the α-position [the anabasine derivative (XLVIII)] is not hydrolysed by these enzymes. The replacement of the pyridinium group by the piperidinium group [compound (XL)] or by the rigid quinuclidinium group (XLI) results in a complete loss of susceptibility to hydrolysis by cholinesterases.

The increase in the bulk of the cyclic ammonium group [compounds (XLIV), (XLV), (XLVI), and (XLVII)] is accompanied by an appreciable decrease of a_C for ACE and BuCE. There is little difference between the substrate properties of the piperidinium compound and the more hydrophilic morpholinium compound (XXXVII). The *N*-ethyl derivatives (XXXI) and (XXXIV) are hydrolysed by BuCE much more effectively than their *N*-methyl analogues.

The constants K_M for the substrates investigated vary: by a factor of 35 for BuCE [compounds (XLII) and (XLVI)] and by a factor of 50 for ACE [compounds (XXXIX) and (XLV)]. As pointed out above, the constants K_M do not by themselves characterise the susceptibility of substrates to hydrolysis by cholinesterases. They are important in estimates of this susceptibility at low substrate concentrations, where the rate of hydrolysis is determined by the quantity a_C/K_M. It is striking that compound (XLVII), with the smallest values of a_C for these enzymes, has also the smallest value of a_C/K_M and that the maximum value of a_C/K_M corresponds to the maximum value of a_C: compound (XXXI) for ACE and compound (XXXV) for BuCE.

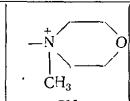
The fact that the tertiary analogues of the cyclic esters (XXXII), (XXXVI), and (XLIII) are not hydrolysed by ACE and BuCE is of special interest. Here it is appropriate to recall that dimethylaminoethyl acetate, a tertiary analogue of AC, is hydrolysed 1.5–3 times more slowly by BuCE and ACE than AC. According to the results of theoretical conformational analysis[65], the cyclic conformation of dimethylaminoethyl acetate with the C=O...H–N hydrogen bond is the most favourable. As stated above, the formation of a hydrogen bond between the carbonyl oxygen of AC and the imidazole ring of histidine in the active centre of the enzyme plays an important role in cholinesterase catalysis and such cyclic conformers are not therefore hydrolysed although their sorption on the catalytic surface is not ruled out.

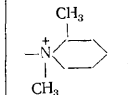
As regards the lack of susceptibility of the cyclic aminoalcohol tertiary esters (XXXII), (XXXVI), and (XLII) to cholinesterase hydrolysis, conformational calculations have shown that the structure of the acetoxyethyl component in the equatorial position relative to the nitrogen-containing ring is energetically favourable. This less compact conformation, compared with the axial conformation, should suffer from steric hindrance by the hydrophobic groups surrounding the anionic centre of the enzyme, which is an additional cause whereby one can explain their lack of susceptibility to hydrolysis by cholinesterases.

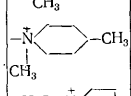
2. Esters Having the General Formula $RC(O)S(CH_2)_2R$

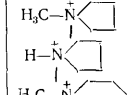
It follows from Table 2 that the replacement of the ester oxygen by sulphur in the choline substrate molecules does not entail a significant change in their susceptibility to cholinesterase hydrolysis. Large changes in such susceptibility are observed when O is replaced by S in acetyl-β-methylcholine (AMC). Whereas AMC itself is hydrolysed by BuCE at a very low rate ($a_C = 3 \times 10^3$ min^{-1}), its thiol analogue (AMTC) is hydrolysed by this enzyme 20 times faster ($a_C = 6.5 \times 10^4$ min^{-1}).[28] The parameter a_C for ACE increases only by a factor of two (1.0×10^5 and 2.1×10^5 min^{-1} respectively)[28]. The replacement of O by S in the AMC molecule therefore results in a sharp decrease of specificity: the ratios a_C(ACE)/a_C(BuCE) for AMC and AMTC are respectively 30 and 3.

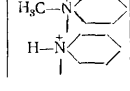
It was therefore of great interest to compare the substrate properties of the oxygen and thiol analogues of esters with a cyclic ammonium group[63,66]. Table 5 lists the kinetic parameters of the cholinesterase hydrolysis of carboxylic acid thioesters. Two groups of compounds attract attention in the first place: the morpholine derivatives (XLIX)–(LII) and the α-pipecoline derivatives (LIII)–(LVI). Like the choline esters (Table 2), the acetates (XLIX) and (LIII) are hydrolysed at the highest rate by ACE. However, whereas BuTC is not hydrolysed by ACE, among the morpholinium derivatives the butyrate is hydrolysed, albeit 20 times more slowly than the acetate. Furthermore, the valerate is also hydrolysed at an appreciable rate. On the other hand, the change in the catalytic activity of BuCE following an increase in the bulk of the acyl component is different from that in the choline esters. Among the morpholinium derivatives, the propionate (L) is hydrolysed at the highest rate, while among the α-pipecolinium derivatives the rate of hydrolysis of the acetate (LII) is highest. Hence it follows that the dependence of the susceptibility of esters to cholinesterase hydrolysis as a function of the increase in the bulk of the acyl component of the molecule depends on the nature of the onium group.

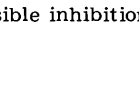


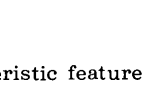












The hydrolysis by both enzymes of the protonated forms of the bases of the cyclic aminoalcohol esters (LX) and (LXII), in contrast to their oxygen analogues (see above), is of interest. Comparison of the values of a_C listed in Table 5 for the thioesters and those for their oxygen analogues (Table 4) reveals a definite regularity: when O is replaced by S, the rate of hydrolysis by BuCE either does not change or increases. The thio-substrates investigated therefore exhibit a lower specificity in relation to ACE. As shown below (Table 8), the replacement of O by S, as in the substrates (XXXII) and (XXXVII) resulted in a sharp decrease of specificity.

3. Esters of Cation-Containing Heterocycles

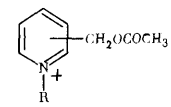
Table 6 lists the available comparative literature for the acetoxy-derivatives of ammonium-containing heterocycles as BuCE and ACE substrates. In contrast to all the compounds described above, the acyl residue in these esters is linked to

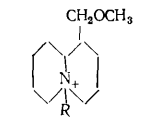
the onium nitrogen via a ring. The pyridinium derivatives (XXX)–(XXXV) are of great interest[67]. Despite the significant structural differences indicated, the rule that BuCE is more sensitive to changes in the alcohol component of the ester compared with ACE is valid for these compounds too. Thus a change in the position of the acetoxymethyl group in the methylated derivatives (XXX)–(XXXII) reduces sharply the rate of enzyme hydrolysis by BuCE but does not affect the hydrolysis by ACE. This was also observed for the ethylated derivatives (XXXIII) and (XXXIX). The high specificity of compound (XXXII) in relation to ACE is noteworthy.

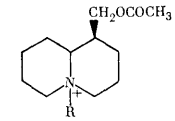
Table 5. The interaction of the thioesters $RC(O)S(CH_2)_2R'$ with BuCE and ACE[63,66].

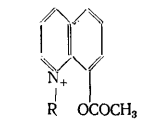
Compound	R	R′	BuCE		ACE	
			a_c, min^{-1}	K_M, mol litre^{-1}	a_c, min^{-1}	K_M, mol litre^{-1}
(XLIX)	CH_3		$6.6\cdot10^3$	$1.8\cdot10^{-4}$	$2.3\cdot10^4$	$6.0\cdot10^{-5}$
(L)	C_2H_5		$2.3\cdot10^4$	$8.9\cdot10^{-5}$	$1.6\cdot10^4$	$2.5\cdot10^{-4}$
(LI)	C_3H_7		$3.7\cdot10^3$	$7.8\cdot10^{-5}$	$1.2\cdot10^3$	$2.1\cdot10^{-4}$
(LII)	C_4H_9		$1.9\cdot10^3$	$1.9\cdot10^{-4}$	$8.8\cdot10^2$	$6.7\cdot10^{-4}$
(LIII)	CH_3		$3.6\cdot10^3$	$4.8\cdot10^{-4}$	$2.9\cdot10^4$	$2.4\cdot10^{-5}$
(LIV)	C_2H_5		$1.8\cdot10^3$	$4.8\cdot10^{-4}$	$4.4\cdot10^2$	$2.5\cdot10^{-4}$
(LV)	C_3H_7		$2.2\cdot10^2$	$8.3\cdot10^{-5}$	0	$1.4\cdot10^{-5}$ *
(LVI)	C_4H_9		0	$1.6\cdot10^{-3}$ *	0	$1.8\cdot10^{-5}$ *
(LVII)	CH_3		$1.1\cdot10^4$	$7.1\cdot10^{-5}$	$1.3\cdot10^4$	$7.4\cdot10^{-5}$
(LVIII)	C_2H_5		$2.5\cdot10^4$	$6.3\cdot10^{-5}$	$8.5\cdot10^3$	$4.0\cdot10^{-4}$
(LIX)	CH_3		$1.8\cdot10^4$	$5.3\cdot10^{-5}$	$1.4\cdot10^5$	$3.3\cdot10^{-5}$
(LX)	CH_3		$2.8\cdot10^3$	$1.2\cdot10^{-4}$	$7.0\cdot10^4$	$4.3\cdot10^{-4}$
(LXI)	CH_3		$4.4\cdot10^3$	$2.8\cdot10^{-5}$	$4.2\cdot10^4$	$2.4\cdot10^{-4}$
(LXII)	CH_3		$4.8\cdot10^2$	$2.4\cdot10^{-3}$	$1.4\cdot10^4$	$3.0\cdot10^{-4}$

* The reversible inhibition constant K_i is quoted.









A characteristic feature of the lupinine and epilupinine derivatives (XXXVI) and (XXXVII) is that both cholinesterases are insensitive to epimeric transformations, but ACE hydrolyses these esters faster than BuCE[52,68].

Quinolinium derivatives have found extensive applications in laboratory practice. Table 6 presents data solely for 8-acetoxyquinolinium (XXXVIII)[69]. Other derivatives have been investigated only with ACE from the electric organ of *Torpedo mormorato* [? *Electrophorus electricus*][70,71]. The rate of hydrolysis of compound (XXXVIII) can be determined with a high accuracy by colorimetric and fluorimetric methods. It is hydrolysed by ACE at an even higher rate than AC.

IV. ESTERS OF ALIPHATIC AND AROMATIC ALCOHOLS

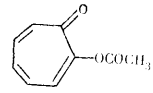
As early as 1949, it was established that cholinesterases are capable of hydrolysing not only the esters of cationoid alcohols but also the carboxylic acid esters of aliphatic alcohols[72–74]. Although the rates of hydrolysis were low, this fact was of fundamental importance. As for choline esters, on increase of the length of the acyl component of the molecule from the acetate to the butyrate, their rate of hydrolysis by ACE decreases while the rate of hydrolysis by BuCE increases. As regards the alcohol component, the carbon chain made up of four atoms is optimal for both enzymes. The branching of the alkyl chain has a major influence. The most complementary alkyl group for both cholinesterases is the 3,3-dimethylbutyl group, which is regarded as a carbon analogue of choline.

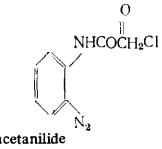
Table 6. The relative rates of hydrolysis v of the acetoxy-derivatives of certain ammonium-containing heterocycles by BuCE and ACE[72–74].

Compound	R	Position of CH_3OCOCH_3	Heterocycle	v*	
				BuCE	ACE
(LXIII)	CH_3	2		55	50
(LXIV)	CH_3	3		20	60
(LXV)	CH_3	4		3	50
(LXVI)	C_2H_5	2		125	35
(LXVII)	C_2H_5	4		10	35
(LXVIII)	C_3H_7	2		50	35
(LXIX) **	CH_2	—		7	21
(LXX)	CH_3	—		8	22
(LXXI)	CH_3			55	140

* The rate of hydrolysis of AC was adopted as 100.
** (LXIX) is lupinine, (LXX) is epilupinine, and (LXXI) is 8-hydroxyquinoline.

Carboxylic acid esters of aromatic hydroxy-compounds are frequently used in laboratory practice, namely those of phenol[75], nitrophenols, naphthols, and indole[76,77]. The esters of these aromatic alcohols are hydrolysed at a higher rate by cholinesterases. A whole series of resorufin and anthracene derivatives have been proposed for a highly sensitive fluorimetric method for the determination of cholinesterase activity[77].





Carboxylic acid esters of indophenol and its halogeno-derivatives occupy a special place among non-cationoid substrates[4,78]. They are widely used in colorimetric methods for the determination of the cholinesterase activity not only with the aid of instruments but also visually. This is because the esters have a pale-red colour and their hydrolysis products (indophenols) are intensely blue. It is striking that ACE hydrolyses only the unsubstituted indophenyl ester, while BuCE hydrolyses also the halogeno-derivatives.

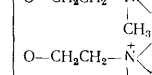
All the esters enumerated in this Section suffer from an important disadvantage: in contrast to the choline esters, they are readily hydrolysed by other esterases. In order to determine the cholinesterase activity of biological tissues with the aid of such chromogenic substrates, one finds initially the overall esterase activity and then, after treating

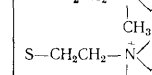
the tissue with a specific CE inhibitor, the esterase activity is remeasured. The difference between these two measurements characterises the activity of cholinesterases.

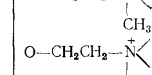
It should be noted particularly that certain types of cholinesterases do not hydrolyse all chromogenic substrates: the CE from the nerve ganglia of the cockroach do not hydrolyse *p*-nitrophenyl acetate, which is used to determine the activities of the carboxy-esterases of this insect[79].

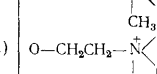
Table 7. The hydrolysis of new non-cationogenic substrates by the ACE from the electric organ of *Torpedo mormorato* [?*E. electricus*].

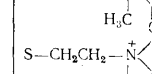
Compound	Substrate	a_c, min^{-1}	K_M, mol $litre^{-1}$
(LXXII)	AC	$9.8 \cdot 10^5$	0.4
(LXXIII)	vinyl acetate $CH_2 = CHOC(O)CH_3$	$10.5 \cdot 10^5$	67.0
(LXXXIV)	but-1-enyl acetate $CH_3CH_2CH = CHOC(O)CH_3$	$5.7 \cdot 10^5$	1.1
(LXXV)	propylidene diacetate $CH_3CH_2CH(OCOCH_3)_2$	$6.0 \cdot 10^5$	1.7
(LXXVI)	benzylidene diacetate $C_6H_5CH(OCOCH_3)_2$	$6.6 \cdot 10^5$	1.5
(LXXVII)	 tropolone acetate	$10.2 \cdot 10^5$	0.55
(LXXVIII)		$1.6 \cdot 10^4$	2.5
(LXXIX)	*o*-nitrochloroacetanilide *o*-nitrodichloroacetanilide	$1.2 \cdot 10^4$	0.6

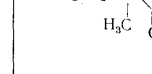


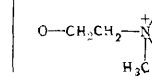












New unusual substrates of the ACE from the electric organ of *Torpedo mormorato* [? *Electrophorus electricus*] have been investigated recently[80]. Table 7 shows that these non-cationoid esters are hydrolysed by ACE a little less effectively than AC, while tropolone acetate (LXXVII) is actually more effectively hydrolysed. The alkylidene diacetates (LXXV) and (LXXVI), where the 2-acetoxy-groups are attached to a single carbon atom, are of interest. The usual dicarboxylic acid esters of dihydric alcohols are slowly hydrolysed by cholinesterases. For example, the hydrolysis of 9,10-diacetoxyanthracene by BuCE is much slower than that of 9-acetoxyanthracene, i.e. the second acetoxy-group interferes with the enzymic reaction[77]. In contrast to such dicarboxylic acid esters, alkylidene diacetates are hydrolysed by the ACE from the electric organ of *Torpedo mormorato* [? *Electrophorus electricus*] only 1.5 times more slowly than AC. One cannot rule out the possibility that the enzyme hydrolysis of the first acetoxy-group is followed by the spontaneous hydrolysis of the second. The possibility of the cholinesterase hydrolysis of the amide bond was demonstrated in the same study in relation to the non-cationoid acetanilides (LXXVI) and (LXXIX).

V. CONCLUSION

The data presented in this review indicate a limited specificity of the catalytic activity of ACE and BuCE. Both enzymes are capable of hydrolysing an extremely large number of choline and non-choline carboxylic acid esters. The difference between the specificities of these enzymes consists in the fact that ACE is more sensitive to the structure of the acid component of the esters, while BuCE is more sensitive to the structure of the alcohol component. It has been shown that ACE and BuCE are stereospecific in relation to optical isomers. Both enzymes are sensitive to the optical isomers of substrates in which the asymmetric carbon atom is in the β-position with respect to the choline component of the molecule. Furthermore, ACE is capable of distinguishing between the optical isomers of substrates in which the asymmetric carbon atom is in the acid component.

Apart from the specificity of the catalytic activity of cholinesterases, there exists also the concept of specific substrates. A specific substrate for a given enzyme is believed to be one whose rate of reaction under the influence of the given enzyme is greater by a factor of tens than the rate of its reaction under the influence of another enzyme. The specificity of the substrate can vary appreciably as a function of the enzymic process conditions: pH, ionic strength, and particularly substrate concentrations. As shown above, at high concentrations of the substrate its specificity with respect to the two cholinesterases is determined by the ratio $a_{c,1}/a_{c,2}$, while at low concentrations it is determined by the ratio $(a_c/K_M)_1/(a_c/K_M)_2$. Until recently only BuC and BeC for BuCE and AMC for ACE were believed to be specific substrates for these enzymes. The study of the acetates of cyclic aminoalcohols led to the discovery of several specific ACE substrates with a more pronounced selectivity (Table 8).

Table 8. The specificity of the acetates $CH_3C(O)X$ to ACE[48,81].

Compound	X	$\frac{a_c\ (ACE)}{a_c\ (BuCE)}$	$\frac{(a_c/K_M)\ (ACE)}{(a_c/K_M)\ (BuCE)}$
(XX)	$O-CH_2CH_2\overset{+}{N}(CH_3)_3$	5	12
ATC	$S-CH_2CH_2\overset{+}{N}(CH_3)_3$	2	11
(LXIII)	$O-CH(CH_3)CH_2\overset{+}{N}(CH_3)_3$	30	32
(LXIV)	$S-CH(CH_3)CH_2\overset{+}{N}(CH_3)_3$	3	10
(XXX)		20	15
(XXXIII)		65	5
(LXI)		10	1
(XXXVII)		50	30
(XXXVIII)		35	18
(LIII)		8	160
(XLII)		35	40

The most specific ACE substrates at high ester concentrations (in terms of the ratio of the parameters a_c) are compounds (XXXIII) and (XXXVII), for which the ratios are 65

and 50 and which are greatly superior to AMC as regards this parameter (the ratio of the a_C is 30).

The esters (XXXVII) and (XLII) proved to be highly specific ACE substrates at both high and low concentrations. Among the newly discovered specific substrates, the derivatives of piperidine (XXXIII) and morpholine (XXXVII) are widely used in laboratory practice.

As stated above, the thio-analogues of AC and AMTC exhibit a lower specificity in relation to ACE. This has been confirmed also for the piperidine derivatives (LII) and (LIII). As regards the α-pipecoline analogues (XXXVIII) and (LIII), the specificity fell only when their concentrations were high, while at low concentrations the specificity (the a_C/K_M ratio) increased sharply. The thioester (LXI) is so far the only thio-substrate which can be regarded as specific to ACE[63,66].

The data presented in this review, indicating an extremely high sensitivity of BuCE to changes in the structure of the ammonium group of the substrate, suggest that the dimensions of the anionic centre in BuCE are limited[48,81]. Presumably in the region of the anionic centre there is a pit whose shape and dimensions determine the limiting structures of the cationic group of such a substrate for which hydrolysis is still possible. Theoretical conformational analysis of AC derivatives with different structures of the ammonium group has shown that the substrate molecule exists in the form of a mixture of conformations separated as a rule by high potential barriers. If the substrate interacting with BuCE has a conformation whose dimensions exceed the limiting size of the pit in the anionic centre, non-productive sorption of the substrate takes place. The conformations of the ester in which the cationic group fits within the limits of the anionic centre of BuCE are susceptible to hydrolysis. Accordingly, the conformations of the same substrate can be divided into productive and non-productive. The analysis carried out here has demonstrated a very satisfactory correlation between the relative populations of the productive conformations of substrates and the rate of hydrolysis by BuCE.

At first sight it would seem that an increase in the size of the *N*-alkyl group should hinder sorption in the region of the anionic centre and hence reduce the rate of hydrolysis by BuCE. However, according to the results of theoretical conformational analysis, conformers with a more compact packing of the alkyl groups than in the propyl derivative (XXII) are characteristic of the pentyl derivative (XXIV).

Thus it is possible to explain the "anomalous" variation of the rate of hydrolysis in the sequence (XX), (XXII), and (XXIV); compound (XXII) is hydrolysed less effectively by factors of 3 and 2.5 than compounds (XX) and (XXIV) respectively. This can also be said of the *N*-alkylpiperidinium derivatives (XXXII), (XXXIV), and (XL), among which the isopropyl analogue (XL) proved to be more compact than the methyl derivative (XXXIII).

This new approach leads to the possibility of investigating the characteristics of the structure of the catalytic surface of cholinesterases by substrate analysis and permits direct recommendations for the synthesis of highly specific substrates.

Advances in the Chemistry of σ-Derivatives of Group IVB–VIB Transition Metals

G.A.Razuvaev and L.I.Vyshinskaya

A systematic account is given of the literature data on the methods of synthesis and reactivities of transition metal σ-derivatives R_nM and R_nMX_{m-n} (X = halogen, OR′, acac, or NR'_2; R′ = Me, Et, or Ph; n = valence of the metal) for transition metals in the Ti, V, and Cr subgroups. The influence of the nature of the central atom and of the character of the σ-substituents on the mode of thermal decomposition is discussed. The mechanisms of reactions involving insertion in the transition metal-carbon σ-bond are considered.
The bibliography includes 124 references.

I. INTRODUCTION

The chemistry of organometallic compounds (OMC) involving transition metals is at present one of the most rapidly and successfully developing branches of coordination chemistry.

The beginning of the development of the chemistry of σ-derivatives of transition metals was associated with attempts to obtain compounds of the type R_nM (R = Me, Et, or Ph; M = metal; n = valence of the metal), which were known for non-transition elements. The failure of these attempts led Krause and Grosse to postulate in 1937, in their detailed monograph on OMC chemistry, that transition metals with *d* orbitals cannot form a σ-bond with carbon.

However, studies carried out in the 1950's–1960's showed that R_nM (R = Me, Et, or Ph) derivatives of transition metals exist in solutions at low temperatures, decomposing when the temperature is increased. The results led to the erroneous hypothesis that the transition metal–carbon σ-bond is weak and that σ-derivatives of the type R_nM cannot be isolated. At this time attention was therefore concentrated on the study of the thermally stable complexes $R_nM.xL$ containing "stabilising" ligands such as CO, PR_3, or π-C_5H_5(Cp). The existing theory of the stability of the transition metal–carbon σ-bond postulated that the role of these ligands consists in increasing the energy of the σ-bond. However, subsequent numerous experimental data and their theoretical analysis demonstrated that the transition metal–carbon σ-bond is not weak. In his report at the Vth International Congress on Organometallic Chemistry, Wilkinson justified the view generally accepted at the present time; the thermal instability of the R_nM σ-derivatives is due to their kinetic instability associated with the low activation energy for the decomposition reaction. Since one of the main pathways leading to the decomposition is elimination of the alkene as a result of the transfer of a β-hydrogen atom to the metal atom, the compounds R_nM with σ-substituents which do not contain β-hydrogen atoms should be kinetically stable. Such substituents include the benzyl, neopentyl, trimethylsilylmethyl, mesityl, methyladamantyl, and other groups. The introduction of the electronegative perfluoroalkyl or perfluorophenyl σ-substituents into the molecule increases the activation energy for the decomposition reaction. In addition, it has been established that the successful isolation of the compounds R_nM depends on the correct choice of the method and conditions of the synthesis[1–4].

On the basis of the principles of kinetic stability, major advances have been achieved during the last decade on the isolation of individual σ-derivatives of transition metals of the type R_nM or R_nMX_{m-n} [X = halogen (Hal), OR′, acac, or NR'_2; R′ = alkyl or aryl]. They are as a rule extremely sensitive to oxygen and moisture but, in the absence of the latter, can exist for a long time at room temperature in the solid state or in solution without decomposition.

The reactivity of the transition metal–carbon σ-bond is being vigorously investigated. Attention has been concentrated on insertion reactions which take place in many catalytic processes. Instead of the compounds R_nM, many investigators have frequently used in the study of these reactions cyclopentadienyl derivatives of the type $Cp_2M(\sigma\text{-}R)_z$ (R = Me, Ph, CH_2Ph, or C_6H_5; z = 1 or 2) instead of the compounds R_nM. They are convenient objects of study, since the Cp_2M group is not involved in the reactions and the insertion products are fairly easy to identify.

The latest advances in the synthesis, isolation, and investigation of the chemical properties of individual σ-derivatives of Group IVB–VIB transition metals of the type R_nM or R_nMX_{m-n} (R = CH_2Ph, CH_2SiMe_3, CH_2CMe_3, Mes, adme, or C_6F_5; X = Hal, OR′, acac, NR'_2; R′ = alkyl or aryl; n = the valence of the metal; $m > n$)† will be examined in this review. The results of studies on the σ-derivatives of manganese, iron, cobalt and nickel as well as $Cp_2M(\sigma\text{-}R)_2$ will be resorted to in some cases in the discussions of the reactivity of the transition metal–carbon σ-bond.

II. THE SYNTHESIS OF σ-DERIVATIVES OF TRANSITION METALS

The main method of synthesis of the σ-derivatives involves the reaction of transition metal salts with organometallic compounds of lithium, magnesium, and zinc and, more rarely, mercury and aluminium. All these syntheses are usually carried out at low temperatures and with careful elimination of oxygen and moisture. The choice of the solvent has an appreciable influence on the yield of the product. The

† Mes = mesityl, adme = adamantylmethyl, and acac = acetylacetonate.

Table 1. Benzyl derivatives R_nM ($R = CH_2Ph$).

R_nM	Initial compounds		Conditions of synthesis		Yield, %	Characteristics of the substance		Refs.
	MX_n	R_nE	solvent	t, °C		m.p., °C	colour

alkylating agents cannot always be interchanged. The most reactive alkylating agents are organolithium compounds. With their aid and at fairly low temperatures, it is possible to obtain fully substituted derivatives R_nM. It is noteworthy that, when organolithium compounds are used, it is necessary to maintain rigorously the stoichiometry of the reactions, since an excess of the organolithium compound entails the formation of ate-complexes, which reduces the yield and hinders the isolation of R_nM in a pure form.

The magnesium derivatives RMgHal and R_nMg are most widely used as alkylating agents as a result of their ready availability. However, when RMgHal is employed, the transition metal is sometimes reduced owing to the presence in the reaction mixture of the partly soluble $MgCl_2$, which forms relatively unstable complexes with R_nM. To prevent this process, dioxane, which binds magnesium chloride in the insoluble complex $MgCl_2$.diox, is added to the reaction mixture. Virtually complete separation of $MgCl_2$ from R_nM, which remains preferentially in solution, is then achieved. Organozinc compounds behave as mild alkylating agents. They do not reduce the transition metal, but, even in the presence of an excess of R_2Zn, the complete alkylation of MX_n is not observed. They are therefore used successfully for the synthesis of alkyl(aryl)metal halides R_nMHal_{m-n} ($n = 1, 2, 3$; $m = 4, 5$).

The metal chlorides and their complexes with Et_2O or tetrahydrofuran (THF) are usually employed as the transition metal compounds. In some cases it is desirable to use metal alkoxides, which are more soluble in organic solvents than the corresponding halides.

Thus the decisive factors for the isolation of individual R_nM are the character of the initial transition metal compound and the alkylating agent, the reaction stoichiometry, the absence of Lewis acid impurities from the reaction mixture, and the nature of the solvent. In the present review the above factors were chosen as the basis for the discussion of various methods of synthesis of the σ-derivatives. In each Section the compounds are grouped in terms of types of σ-substituents and in each Subsection compounds of the highest valences of Group IV–VII metals are considered initially and then compounds of the lowest valences of the metals in the same sequence within the Groups.

1. Synthesis of R_nM

Benzyl Derivatives (Table 1)

The tetrabenzyl derivatives of metals of the titanium subgroup have been synthesised by the classical procedure—the double decomposition reaction of the metal chloride with a Grignard reagent in ether at a low temperature[5,6].

In contrast to this, the double decomposition reaction of VCl_4 with $PhCH_2MgCl$ is accompanied by a decrease of the valence of vanadium regardless of the initial reactant ratio, the nature of the solvent, and temperature[7]. The optimum method of synthesis of $(PhCH_2)_4V$ proved to be the reaction of VCl_4 with $(PhCH_2)_2Mg$ in Et_2O at −70 °C.[8–10] The benzyl derivatives of niobium have not so far been obtained. Benzylation of $NbCl_n$ ($n = 5, 4$) not only with a Grignard reagent but also with $(PhCH_2)_2M$ (M = Mg, Zn, or Hg) was accompanied by the formation of complexes of low-valence niobium[11]. Similarly, in the benzylation of $TaCl_5$ by $(PhCH_2)_2Mg$, tantalum(V) was reduced[12]. However, by selecting the appropriate conditions of synthesis, it was possible to obtain $(PhCH_2)_5Ta$. $TaCl_5$ is initially treated with $(PhCH_2)_2Zn$, which does not reduce the transition metal. The reaction results in the isolation of the mixed derivative $(PhCH_2)_3TaCl_2$. The subsequent substitution of the residual chlorine atoms by benzyl groups takes place under the influence of $(PhCH_2)_2Mg$ in toluene. The employment of toluene and the addition of dioxane enabled the authors to eliminate $MgCl_2$ completely from the reaction zone and to obtain $(PhCH_2)_5Ta$ in an almost quantitative yield[12].

The compound $(PhCH_2)_4Cr$ has been obtained only in solution and has been identified by its EPR spectrum[13]. The influence of the conditions of synthesis on the formation of the benzyl derivatives of molybdenum and tungsten has been studied in detail. It has been established that the tetrabenzyl derivatives of molybdenum and tungsten can be isolated as a result of the interaction of $MoCl_4.2Et_2O$ and $WCl_4.2THF$, which are readily soluble in ether, with $(PhCH_2)_2.Mg$.[14,15]

Organic σ-compounds of tervalent metals are known only for titanium, vanadium, and chromium. The probable explanation is that the initial low-valence derivatives are difficult to obtain for the remaining Group IV–IVB metals.

Table 2. Neopentyl and trimethylsilylmethyl derivatives R_nM and R'_nM ($R = CH_2CMe_3$; $R' = CH_2SiMe_3$).

R_nM, R'_nM	Initial compounds		Conditions of synthesis		Yield, %	Characteristics of the substance		Refs.
	MX_n	RE, R'E	solvent	t, °C		colour	m.p., °C	
R_4Ti	$TiCl_4$	RLi	hexane	—70	26	yellow	105[a]	[24, 25]
R_4Zr	$ZrCl_4$	RLi	hexane + Et_2O	0	68	colourless	108[a]	[24, 25]

R_4Cr	$CrCl_3 \cdot 3THF$	RMgCl	Et_2O	+20	30	chestnut	110	[13]
$R_4'Ti$	$TiCl_4$	R'MgCl	Et_2O	—20	65	yellow	+1	[26]
$R_4'Zr$	$ZrCl_4$	R'Li	Et_2O	0	89	colourless	10	[26]
$R_4'Hf$	$HfCl_4$	R'Li	hexane + Et_2O	0	96	colourless	10	[26]
$R_4'V$	VCl_4	R'Li	hexane	—60	10	green	42	[27]
$R_4'Cr$	$CrCl_3 \cdot 3THF$	R'MgCl	Et_2O	20	30	purple	40	[27]
R'_3Ti[b]	$R_4'Ti$	R'Li	toluene	0	50	yellow	—	[18]
$R'_3V.THF$	$VCl_3 \cdot 3THF$	R'MgCl	THF	—60	60	violet	75	[21]
$R_2'Cr$	$CrCl_3$	R'Li	hexane	20	97	dark violet	—[c]	[33]

Remarks: [a] melts with decomposition; [b] obtained in solution from R'_4Ti and EtLi; [c] m.p. not determined.

The possibility of synthesising $(PhCH_2)_3Ti$ by several procedures has been investigated. The double decomposition reaction of $TiCl_3.3THF$ or $Ti(acac)_3$ with an organomagnesium compound in Et_2O at −30 °C results in the formation of $(PhCH_2)_3Ti$. The attempts to isolate this compound lead to its decomposition at 0 °C.[16,17] Success was achieved by another method of synthesis involving the decomposition of ate-complexes:

$$(PhCH_2)_4Ti + EtLi \xrightarrow[0°C]{\text{xylene}} [(PhCH_2)_4\,TiEt]^-Li^+ \rightarrow$$
$$\rightarrow [(PhCH_2)_3TiEt] + PhCH_2Li$$
$$\downarrow \qquad\qquad CO_2\downarrow -78°C$$
$$(PhCH_2)_3Ti + [Et^\cdot]\ PhCH_2CO_2Li\ .$$

However, it has not so far been possible to isolate $(PhCH_2)_3Ti$ in a pure form; $(PhCH_2)_3Ti$ has only been obtained in the form of solutions in aromatic hydrocarbons[18,19].

The benzylation of $VCl_3.3THF$ or $V(acac)_3$ by $PhCH_2MgCl$, $(PhCH_2)_2Mg$, and $(PhCH_2)_3Al$ in Et_2O does not go to completion[17,20]. The reaction of $VCl_3.3THF$ with three moles of $PhCH_2Li$ in THF results in a complete exchange of chlorine atoms for benzyl groups. However, $(PhCH_2)_3V$ could not be isolated in a pure form: at 0 °C the compound decomposes rapidly in solution[21].

The attempts to synthesise $(PhCH_2)_3Cr$ have so far been unsuccessful[17].

Among the benzyl derivatives of bivalent metals, only $(PhCH_2)_2Ti.3Et_2O$ has so far been isolated; it is obtained on decomposition of the ate-complex formed from $Cp_2Ti(CH_2Ph)_2$ and $PhCH_2Li$.[22] The complex $(PhCH_2)_2Ti.3diox$ has been obtained by the oxidative-reduction symmetrisation of benzyl derivatives of titanium(III).[23]

The Neopentyl and Trimethylsilylmethyl Derivatives (Table 2)

These substituents belong to the single type CH_2EMe_3 (E = C, Si, Ge, or Sn) and are more bulky than the benzyl derivatives.

The neopentyl derivatives of the titanium subgroup are obtained by the double decomposition reaction of the metal halides MCl_4 with Me_3CCH_2Li.[24,25] The trimethylsilylmethyl derivatives of the titanium subgroup metals are formed as a result of the reaction of MCl_4 with both a Grignard reagent and an organolithium compound. It has been established that the best alkylating agent for $ZrCl_4$ and $HfCl_4$ is Me_3SiCH_2Li. A high yield of $(Me_3SiCH_2)_4M$ (M = Ti, Zr, or Hf) is achieved in the presence of a 5% excess of MCl_4. When the initial reactant ratio is exactly 1 : 4, the complexes $(Me_3SiCH_2)_4M.(Me_3SiCH_2)_2Mg$, which are difficult to separate, arise in the reaction mixture, while in the presence of an excess of MCl_4 greater than 5% the stable compounds $(Me_3SiCH_2)_3MCl$ are produced.[26]

Among the neopentyl and trimethysilylmethyl derivatives of the Group VB metals, only $(Me_3SiCH_2)_4V$ has been isolated[27]. It has been established that the preparation of niobium and tantalum derivatives is hindered by steric factors. When attempts were made to synthesise $(Me_3ECH_2)_5M$, the alkylidene or alkylidyne complexes of these metals were isolated[25,28,29]. It was possible to synthesise the compound $Me_3Ta(CH_2SiMe_3)_2$, since the small methyl substituents are distributed in its molecule around the Ta atom, together with the Me_3SiCH_2 groups[30].

Virtually the same features have been observed for the metals of the chromium subgroup as for the Group VB metals. The interaction of the ether-soluble $CrCl_3.3THF$ with four equivalents of Me_3ECH_2MgCl (E = C or Si) under identical conditions yields the tetrasubstituted derivatives $(Me_3ECH_2)_4.Cr$ (E = C or Si) with identical yields[13,27]. The reactions of molybdenum and tungsten halides ($MoCl_5$ and WCl_5) with Me_3SiCH_2MgCl in Et_2O at 20 °C result in the formation of the dimeric bridged complexes $(Me_3SiCH_2)_6M_2$.[27] An analogous complex with neopentyl ligands has been obtained from $MoCl_5$ and Me_3CCH_2Li in Et_2O at 20 °C;[25] after the exchange of all the chlorine atoms in WCl_6 for the neopentyl groups, the carbyne complex $(Me_3CCH_2)_3W(\equiv C-CMe_3)$ is obtained from WCl_6 with the aid of Me_3CCH_2Li.[31]

The trimethylsilylmethyl derivatives of tervalent titanium and vanadium have been synthesised. The compound $(Me_3SiCH_2)_3Ti$ has been obtained in solution in toluene on decomposition of the ate-complex $[(Me_3SiCH_2)_4TiEt]^-Li^+$.[18]

After the alkylation of $VCl_3.3THF$ with Me_3SiCH_2MgCl, the complex $(Me_3SiCH_2)_3V.THF$, which is stable at room temperature, was isolated in a pure state[21]. It has been established that the successful alkylation of $VCl_3.3THF$ depends on the nature of the solvent and temperature.

A considerable stabilisation of the tervalent states is attained when the substituents $(Me_3Si)_2CH$ are used. The reaction of $[(Me_3Si)_2CH]Li$ with a suspension of MCl_3 in Et_2O at −60 °C afforded low yields of the derivatives $[(Me_3Si)_2CH]_3M$ (M = Ti, V, or Cr).[32] An interesting fact has been observed in relation to vanadium—the coordination number of the metal depends on the bulk of the substituent: tricoordinate compounds are obtained with the bulky substituent $(Me_3Si)_2CH$, while tetracoordinate derivatives are isolated with the less bulky substituent Me_3SiCH_2.

Among the bivalent Group IV–IVB metal derivatives, only $(Me_3SiCH_2)_2Cr$ has been described hitherto. On the other hand a quadrivalent chromium derivative R_4Cr is obtained

Table 3. Mesityl, 1-methyladamantyl, and pentafluorophenyl derivatives (R = Mes; R′ = 1-adme; R″ = C_6F_5).

R_nM, R'_nM, R''_nM	Initial compounds		Conditions of synthesis		Yield, %	Characteristics of the substance		Refs.

Remarks: [a] yield not indicated; [b] melts with decomposition; PE = petroleum ether.

when $CrCl_3.3THF$ is treated with an excess of RLi or RMgCl (R = CH_2Ph or CH_2EMe_3),[13,27] while the reaction of $CrCl_3$ with a deficiency of Me_3SiCH_2Li results in the formation of $(Me_3SiCH_2)_2Cr$; the reaction mechanism has not been established[33].

The Mesityl Derivatives (Table 3)

The tetramesityl derivatives cannot be obtained by the usual double decomposition reaction between metal halides and a Grignard reagent or RLi. In view of the large bulk of the ligand, only three chlorine atoms are substituted in these reactions even in the presence of the arylating agents. A novel method of synthesis has been developed, consisting in the oxidation of the ate-complexes and the tervalent metals, which give rise to derivatives of the quadrivalent metals after careful choice of oxidation conditions[34–37]:

$$MCl_3 \cdot 3THF + 4MesLi \xrightarrow[20°C]{THF+Et_2O} [Mes_4M]^- Li^+ \cdot 4THF + 3LiCl$$
$$\downarrow \tfrac{1}{2}O_2$$
$$Mes_4M + LiO + 4THF$$

Derivatives of titanium, chromium, vanadium, and molybdenum have been obtained in this way. The difficulties in synthesising the tetramesityl derivatives of zirconium, hafnium, niobium, tantalum, and tungsten are associated with the fact that the initial MCl_3 are at present difficult to obtain.

Mesityl derivatives of tervalent metals have been obtained for vanadium and chromium. Unfortunately attempts to synthesise Mes_3Ti have not been described, although in the synthesis of Mes_4Ti the compound $TiCl_3.3THF$ was mesitylated[34]. Mes_3V was isolated in a pure form after the reaction of $VCl_3.3THF$ with three moles of MesMgBr, but not with MesLi, since interaction with the latter results in the preferential formation of the ate-complex of vanadium(III), rather than the neutral compound[38,39]. $Mes_3Cr.THF$, which cannot be converted into an arene complex because of the characteristic features of the mesityl group, proved to be easy to synthesise[40]. For the same reason, it has been possible to obtain and investigate the σ-mesityl derivatives of chromium(II).

The complex $Mes_2Cr.3THF$ can be obtained from anhydrous $CrCl_2$ and MesMgBr.[41] It is of interest that Mes_2Cr can give rise to complexes with coordination numbers ranging from 3 to 5. If the pentacoordinate complex $Mes_2Cr.3THF$ is dissolved in hexane at 20 °C. the colour of the solution changes, after 15–20 min from violet to green and a green deposit having the composition $Mes_2Cr.3THF$ is precipitated. Three molecules of the coordinated THF are readily substituted by one molecule of the bidentate bipyridyl ligand with formation of dark-blue crystals of the tetracoordinate chromium complex $Mes_2Cr.bipy$.[41] The formation of Mes_2Mo was unexpected; the authors[42] believe that the interaction of Mes_2MoO_2 with MeLi involves reduction:

$$Mes_2MoO_2 + 2MeLi \xrightarrow[0°C]{Et_2O} Mes_2Mo \cdot 2Et_2O + 2MeOLi$$

However, a change in the valence of molybdenum was not demonstrated analytically and the properties of this compound were not investigated.

The Adamantylmethyl Derivatives (Table 3)

The 1-adamantylmethyl (adme) ligand has a large bulk. It has been established that the peralkyl compounds R_nM incorporating this ligand decompose above 100 °C. In the synthesis of $(adme)_4M$ (M = Ti, V, or Cr), the alkoxides and not the halides were used as the initial transition metal compounds (the use of MCl_4 leads to an extremely low yield of the final products). The employment of soluble derivatives $M(OR)_4$ made it possible to carry out the reaction in saturated hydrocarbons at low temperature.

The compound $(adme)_4Ti$ crystallises in an analytically pure form from the $Ti(OPr\text{-}iso)_4$ + 4(adme)Li system in petroleum ether at 20 °C.[43] In view of the difficulty of obtaining the initial reagent $Zr(OPr\text{-}iso)_4$, $ZrCl_4$ was used in the synthesis of $(adme)_4Zr$. The isolation in a pure state of the compound $(adme)_4Zr$ obtained from $ZrCl_4$ and (adme)MgBr therefore requires repeated crystallisation in order to eliminate the admixture of magnesium halide salts[43].

Treatment of $V(OPr\text{-}iso)_4$ with an excess of (adme)Li gives the unexpected product $(adme)_4V$.[43] The attempts to obtain the peradamantylmethyl derivatives of niobium and tantalum ended in failure, whose only cause was the steric hindrance resulting from the disposition of the five bulky groups around the Nb and Ta atoms. Treatment of $Nb(OBu\text{-}t)_5$ with an excess of (adme)Li resulted in the formation of a mixture of the di- and tri-alkylated products. When $TaCl_5$ was allowed

to react with (adme)MgBr in Et_2O, only three chlorine atoms were substituted with formation of $(adme)_3TaCl_2$.[43]

The Pentafluorophenyl Derivatives (Table 3)

These derivatives have a much higher thermal stability than the phenyl compounds. While the Ph_4M (M = Ti, Zr, or V) derivatives cannot be isolated in a pure state, the corresponding pentafluorophenyl compounds are stable on heating to 100 °C and above.

The compound $(C_6F_5)_4Ti$ can be isolated in the form of the hexacoordinate complex $(C_6F_5)_4Ti.2Et_2O$ as a result of the double decomposition reaction between $TiCl_4$ and C_6F_5MgBr.[44] The best alkylating agent for the zirconium salt proved to be C_6F_5Li. In contrast to the titanium compound, the σ-derivative of zirconium can be isolated in the form of the pentacoordinate complex $(C_6F_5)_4Zr.Et_2O$.[45]

The interaction of VCl_4 with C_6F_5Li leads to the formation of the complex $(C_6F_5)_4V.2Et_2O$.[46] A brief communication (without description of experimental conditions) concerning the synthesis of the light-sensitive and volatile compound $(C_6F_5)_4Nb$ has been published[47].

The pentafluorophenyl derivatives $(C_6F_5)_3Ti.3THF$ and $(C_6F_5)_3V.THF$ have been synthesised by the reaction of $MCl_3.3THF$ with C_6F_5MgBr or C_6F_5Li. The authors of the present review established that the reaction conditions play a major role in the successful isolation of the compounds: the use of THF as the solvent, the optimum temperature range from 0° to +5 °C, and the order in which the reactants are added (it is essential that transition metal halide be added to the Grignard reagent)[21,48].

2. The Synthesis of Alkyl(aryl) Metal Halides

The main method of synthesis of organometallic halides involves the interaction of transition metal halides with alkylating (arylating) agents using different ratios of the initial reactants. The importance of the synthesis of compounds of the type R_nMHal_{m-n} is due to the possibility of their being used for the synthesis of other classes of substances.

The Benzyl Derivatives (Table 4)

The possibility of obtaining benzylmetal halides by the double decomposition reaction between MCl_4 and $PhCH_2MgCl$ has been investigated in relation to titanium. The reaction of $TiCl_4$ with different amounts of $PhCH_2MgCl$ in Et_2O at −20 °C leads to the reduction of titanium and the formation of bibenzyl[49]. Other methods of synthesis of benzyl titanium and benzylzirconium halides have therefore been used. A novel electrochemical method of synthesis of complexes of dibenzylmetal dihalides with bipyridyl or acetonitrile, having the general formula $(PhCH_2)_2MHal_2.L$ (M = Ti, Zr, or Hf; Hal = Cl, Br, or I; L = bipy or 2MeCN), has been proposed recently[51]. It consists in the chemical oxidation of the titanium subgroup metals in an electrolytic cell containing $PhCH_2Hal$ and acetonitrile or α,α-bipyridyl. The reactions are carried out in solution at a constant current of 30 mA (25 V). The process terminates with the precipitation of the insoluble complexes indicated above.

Benzylvanadium(IV) halides and benzylniobium(V, IV) have not been isolated in a pure state, since they decompose in the reaction solution at the instant of formation[7,52]. It proved possible to isolate certain benzyltantalum halides as a result of double decomposition reactions[10 12].

Particular attention has been devoted to the problem of the synthesis and investigation of the reactivities of benzyltitanium(III) halides, because it is believed that such titanium(III) derivatives enter into the decomposition of the active centres in various catalytic systems based on organotitanium compounds. In connection with the synthesis of $(PhCH_2)_n.TiHal_{3-n}$, a method for the substitution of the benzyl group in $(PhCH_2)_3Ti$ by a halogen involving treatment with HCl or I_2 was employed. The reaction of $(PhCH_2)_3Ti$ with gaseous HCl (in proportions of 1 : 1 and 1 : 2) was carried out in o-xylene at −20 °C. The reaction of $(PhCH_2)_3Ti$ with I_2 in toluene at −20 °C yields products with various degrees of alkylation depending on the initial reactant ratio[19]. It has been established that benzyltitanium(III) halides undergo quantitatively the oxidative-reductive disproportionation reaction on raising the temperature to 20 °C. However, the composition of the disproportionation products changes on passing from the chlorides to the iodides:

$$2\,(PhCH_2)_2\,TiCl \rightarrow TiCl_2 + (PhCH_2)_4\,Ti\,,$$
$$2\,(PhCH_2)_2\,TiI \rightarrow PhCH_2TiI + (PhCH_2)_3\,TiI\,.$$

The Trimethylsilylmethyl and Neopentyl Derivatives (Table 5)

The double decomposition reaction between $TiCl_4$ and Me_3SiCH_2MgCl or Me_3SiCH_2Li was used to synthesise $(Me_3SiCH_2)_nTiCl_{4-n}$ ($n = 1, 2, 3$); depending on the initial reactant ratio, it led to the isolation of $Me_3SiCH_2TiCl_3$ and $(Me_3SiCH_2)_2TiCl_2$.[53] The attempts at the synthesis of

Remarks: [a]m.p. not determined; [b]decomposes without melting; [c]stable at 25 °C.

$(Me_3SiCH_2)_3.TiCl$ were unsuccessful, since this compound readily disproportionates in solutions[53]:

$$2\,(Me_3SiCH_2)_3\,TiCl \xrightarrow[20^\circ C]{\text{hydrocarbons}} (Me_3SiCH_2)_4\,Ti + (Me_3SiCH_2)_2\,TiCl_2\ .$$

Trialkylmetal halides which do not undergo disproportionation have been synthesised using the $(Me_3Si)_2CH$ bulky substituent. The double decomposition reaction of MCl_4 even with an excess $[(Me_3Si)_2CH]Li$ always leads to the isolation of $[(Me_3Si)_2CH]_3MCl$ (M = Zr or Hf). When attempts were made to obtain the analogous titanium compound, reduction with formation of $[(Me_3Si)_2CH]_3Ti$ was observed[32]. Neopentylzirconium chlorides have been obtained recently[54]: the reaction of $ZrCl_4$ with two moles of Me_3CCH_2Li in Et_2O yields $(Me_3CCH_2)_2ZrCl_2.Et_2O$ in the form of an oil, while crystalline products are isolated on formation of complexes with phosphines and amines. Procedures whereby the symmetrical $(Me_3CCH_2)_2ZrCl_2$ is converted into mono- or tri-neopentylzirconium chloride are being investigated[54].

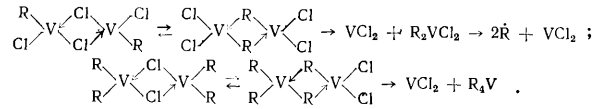
It has been shown that trimethylsilylmethylvanadium(IV) halides as well as $(PhCH_2)_nVCl_{4-n}$ are unstable in solution and decompose with formation of low-valence vanadium complexes[21].

Organozinc compounds can be used successfully to isolate a whole series of derivatives of the type $(Me_3ECH_2)_nMCl_{5-n}$ (M = Nb or Ta; E = C or Si; n = 1, 2, 3, 4). With the aid of organozinc compounds, it is possible to substitute in succession the chlorine atoms in MCl_5 for the Me_3ECH_2 groups[28,55–57]. For the Group IVB metals, only the molybdenum complex $(Me_3SiCH_2)_3MoCl.PMe_3$ has been isolated[58].

The methods of synthesis of the compounds $(Me_3SiCH_2)_n.TiCl_{3-n}$ have been investigated by analogy with $(PhCH_2)_n.TiCl_{3-n}$. It has been established that they exist in solutions at temperature not exceeding –5 °C. When attempts were made to isolate them, oxidative-reductive disproportionation to the titanium(II) and Ti(IV) complexes was always observed[59,60].

The Mesityl Derivatives (Table 6)

Attempts to obtain mesitylmetal halides have now been described for titanium(IV), niobium(V), tantalum(V), and vanadium(III). Mes_2Zn is the best arylating agent. The reaction of $TiCl_4$ with Mes_2Zn in proportions of 2 : 1 yields $MesTiCl_3$.[61]



Depending on the initial reactant ratio, it is possible, as for the Me_3ECH_2 substituents, to replace in succession the chlorine atoms by the Mes groups by the reaction of MCl_5 (M = Mb or Ta) with Mes_2Zn. $MesMCl_4$ and Mes_2MCl_3 have been obtained in this way[62]. The substitution of the third chlorine atom by the mesityl group is possible when MesLi is used. It has been established that the thermal stability of mesitylmetal chlorides diminishes with increase of the degree of arylation. Thus $MesTaCl_4$ sublimes without signs of decomposition, $MesNbCl_4$ decomposes in the solid state at 25 °C after several days, while Mes_2NbCl_3 decomposes faster than the monosubstituted product under these conditions: Mes_3TaCl_2 and Mes_3NbCl_2 always contain decomposition products[62].

The Pentafluorophenyl Derivatives (Table 6)

Compared with other compounds, the σ-C_6F_5-substituted derivatives have been investigated to only a fairly slight extent. A series of pentafluorophenylmetal chlorides have now been investigated for Group VB metals[63].

The reactions of MCl_5 (M = Nb or Ta) with C_6F_5Li in various proportions (ranging from 1 : 3 to 1 : 6) in hexane at −78 °C give rise to solid variable-composition products $(C_6F_5)_nMCl_{5-n}$, where n = 2, 3; the molecular weight is intermediate between those of the monomer and the dimer[64].

A detailed study has been made in order to synthesise alkylvanadium(III) chlorides R_nVCl_{3-n} (n = 1, 2) with substituents of different kinds (R = CH_2Ph, CH_2SiMe_3, Mes, or C_6F_5). For this purpose, the double decomposition reaction of VCl_3.3THF with RMgCl in proportions of 1 : 1 and 1 : 2 in Et_2O or THF as well as the reactions of R_3V.THF (R = CH_2. .$SiMe_3$ or C_6H_5) with gaseous HCl were investigated[21]. The attempts to isolate $RVCl_2$ and R_2VCl were unsuccessful. It has been established that the above derivatives undergo oxidative-reductive disproportionation in solutions at 0 °C. This process proceeds via a stage involving the formation of intermediate dinuclear complexes in which chlorine atoms are exchanged for the ligands R. The composition of the disproportionation products is determined by the ratio of the amounts of R and Cl in the initial reactant R_nVCl_{3-n}:

Evidently when a bulky ligand with structural rigidity is used, there is a possibility, on the one hand, that the monomeric form is stabilised and, on the other hand, that the exchange of a chlorine atom for a ligand R in the dinuclear complex, which subsequently decomposes, may be hindered. Such requirements are met by the mesityl ligand. Indeed the double decomposition reaction of VCl_3.3THF with MesMgBr in THF at a low temperature led to the isolation of the pure compound $MesVCl_2$.2THF, which is entirely stable on heating to 100 °C.[65]

3. The Synthesis of the Compounds R_nMX_{m-n} (X = OR', acad, or NR'_2; m = 3, 4, 5; n = 1, 2, 3)

The thermal stability of compounds of this type is determined not only by the characteristics of the σ-substituents considered in this review but also by the properties of the group X. The alkoxy-derivatives are thermally stable by virtue of the formation of dimers, since the R'O groups tend to associate. The acetylacetonate group reacts with the metal to form an intramolecular chelate. The R'_2N group promotes the coordination and saturation of the metal in the molecule. Furthermore, an increase of thermal stability is observed when bulky amide groups are used. The specific features of the above OR', NR'_2, and acac groups are responsible for the isolation of individual compounds containing methyl, ethyl, and phenyl groups (Tables 7 and 8).

The compounds $RTi(OPr\text{-}iso)_3$ (R = Me, Ph, or C_6H_5) and $R_2Ti(OEt)_2$ (R = CH_2Ph, or C_6H_{11}) have been obtained; they exist in the form of dimers[5,66,67,68].

The diphenoxides are monomeric and their thermal stability is determined to a large extent by the nature of the σ-substituent. The derivatives $(Me_3SiCH_2)_2Ti(OPh)_2$ is stable up to 100 °C, while the analogous dimethyl compound decomposes rapidly in solution at 20 °C.[69]

Studies of the synthesis of $(PhCH_2)_3TiOEt$, $RV(OR')_3$, and R_3VOR' have shown that they are readily symmetrised[5,70]. The compounds $R_2V(OR')_2$, which have been obtained in three different ways, proved to be thermally stable[70,71] (Table 7).

Remarks: [a]melts with decomposition; [b]decomposes in solution; [c]m.p. not determined. Pip = piperidine; CTS = octamethyl-2,4,6-trisila-1,3,5-triazacyclo-hex-1-yl.

The acetylacetonate derivatives have been investigated in relation to the zirconium and vanadium compounds (Table 7). While $(PhCH_2)_2Zr(acac)_2$ is fairly stable, $R_2V(acac)_2$ and also $RV(acac)_3$ undergo reductive elimination in solutions[72,73]. The derivatives $(Me_3SiCH_2)_3Zr(acac)$ and $R_3V(acac)$ are readily symmetrised. Systematic studies have been made of the synthesis and properties of mixed σ-derivatives of vanadium of the type R_nVX_{m-n} ($R = CH_2Ph$, CH_2SiMe_3, or C_6H_5; X = Cl, OBu-t, or acac; $n = 1, 2, 3$; $m = 3, 4$). It has been established that, regardless of the nature of the σ-substituent, the compounds RVX_3, RVX_2, and R_2VX_2 (X = Cl or acac) undergo reductive decomposition in Et_2O.[21] $RTi(OBu\text{-}t)_3$ and $R_2V(OBu\text{-}t)_2$ are exceptions owing to the large bulk and low electronegativity of the t-butoxy-groups. The derivatives RVX_3 are symmetrised, while the RVX_2 undergo oxidative-reductive disproportionation in solutions (regardless of the nature of X and R), which proceeds via a stage involving the formation of intermediate dinuclear complexes.

When the reaction mixture contains agents preventing the formation of dinuclear complexes and stabilising the monomeric form, stable products are isolated, for example, the compounds $RV(acac)_2.THF$, stabilised by the formation of the monomeric hexacoordinate complex, since the acetylacetonate group is a η^2-ligand.

Studies of a series of alkylamide derivatives of titanium established that the thermal stability of the compounds decreases in the sequence $RTi(NR'_2)_3 > R_3TiNR'_2 > R_2Ti(NR'_2)_2$. It was found that, in contrast to R_2TiX_2 (X = Hal or OR), the compounds $R_2Ti(NR'_2)_2$ readily disproportionate[74,75]:

$$3R_2Ti(NR'_2)_2 \xrightarrow[-20°C]{} 2RTi(NR'_2)_3 + R_4Ti \ .$$

The stabilisation of the symmetrical compounds has been achieved by employing rigidly fixed or bulky ligands (Table 8). X-Ray diffraction analysis of $MeHf[N(SiMe_3)_2]_3$ has shown that the $(Me_3Si)_2N$ groups are located in space in such a way that they fully shield the central atom from external influences[77]. By virtue of this spatial disposition of the $(Me_3Si)_2N$ groups, even the compound $Et_2Hf[N(SiMe_3)_2]_2$ (m.p. 65 °C) is thermally stable, although the ethyl derivatives of transition metals usually exist only at low temperatures because of the ease of β-elimination[78,79].

The amide derivatives of vanadium(IV) and vanadium(III) have been scarcely investigated. A single compound $Mes_3.VNPh_2$ has been synthesised by oxidising the corresponding ate-complex $[Mes_3VNPh_2]^-Li^+$.[81] The isolation of $MesV(NPh_2)_2$, formed by the reaction

$$VCl_3 \cdot 3THF + MesMgBr + 2KNPh_2 \rightarrow MesV(NPh_2)_2 \ ,$$

has been mentioned. No detailed description of the reaction conditions and the properties of the compounds is given[82].

III. THERMAL DECOMPOSITION OF THE σ-DERIVATIVES

The task of the study of the thermal decomposition of the individual σ-derivatives R_nM and R_nMX_{m-n} is the determination of the general features of this process as a function of the electronic configuration, coordination capacity of the central atom, and the decomposition conditions.

An attempt has been made at a theoretical justification of the modes of decomposition by analysing the correlation between the symmetry groups of the valence orbitals of the metal atoms in the initial σ-complex and its thermolysis products. On the basis of these correlations, the metal complexes with the electronic configurations $d - d^8$ should undergo reductive elimination. For the complexes with the electronic configurations d^0[Ti(IV), Zr(IV), and Hf(IV)] and d^1, d^2[V(IV), Cr(IV), Ti(III), and V(III)], the reductive elimination is prohibited and the σ-bond is homolysed[83]. The experimental results obtained by different workers are in good agreement with these theoretical postulates.

It has been established that reductive elimination is observed on thermolysis of the neophyl complexes of chromium(III) (d^3 system), Mn(II), Fe(III) (d^5 system), Fe(II), Co(III) (d^6 system), Co(II) (d^7 system), and Ni(II) (d^8 system) and leads to the formation of bineophyl and to a decrease of the valence of the central atom[84].

The elimination processes are varied. Apart from the reductive elimination, the complexes are decomposed via α-, β-, and γ-hydride elimination.

The classical compounds which decompose via α-elimination are the σ-derivatives of niobium and tantalum. The study of the kinetics of the thermal decomposition of $(PhCH_2)_5Ta$ in benzene at 40 °C in the presence of an initiator (azobisisobutyronitrile) or an inhibitor (the galvinoxy-radical) has shown that the decomposition of $(PhCH_2)_5Ta$ does not entail the homolysis of the M—C bond with formation of free radicals[85]. The authors believe that $(PhCH_2)_5Ta$ decomposes via intramolecular or intermolecular α-hydride elimination with formation of toluene and alkylidene complexes of quinquevalent tantalum. However, the individual compound could not be isolated in this instance. The neopentylidene complex $(Me_3CCH_2)_3Ta(CHCMe_3)$ proved to be thermally stable[28]. The analogous niobium complex is unstable. The authors[28] postulate the formation of the tantalum complex via the decomposition of the short-lived $(Me_3CCH_2)_5Ta$, whose molecules have a trigonal bipyramidal structure. Its relatively more acidic α-proton passes from the α-carbon atom of the equatorial alkyl group to the relatively more nucleophilic α-carbon atom of the axial alkyl group. This results in a rearrangement of the structure accompanied by the formation of Me_4C and the

final pseudotetrahedral complex. Schrock's investigations[12, 28,85] suggest that the decomposition of all the pentacoordinate niobium(V) and tantalum(V) complexes takes place via α-elimination with formation of tetracoordinate alkylidene complexes of formally quinquevalent niobium and tantalum[28].

The α-elimination process is dominant in the decomposition of alkylmolybdenum and alkyltungsten halides R_nMHal_{m-n} ($R = CH_2Ph$ or CH_2SiMe_3). The factor favouring this reaction pathway is the possibility of the stabilisation of carbenes on coordination to molybdenum and tungsten. The main evidence confirming the elimination of α-hydrogen is as follows: firstly, the Me_4Si formed on decomposition of $(Me_3.SiCH_2)_nMHal_{m-n}$ in deuterated solvents does not contain deuterium atoms and, secondly, the decomposition of the dry residues (after the decomposition of the compound) with heavy water results in the formation of considerable amounts of Me_3SiCHD_2 and $PhCHD_2$.[86-88]

Thus, in the decomposition of $Mes(Me)TaCl_3.PMe_3$ in toluene at 45 °C or of $Mes(Me)TaBr_3.PMe_3$ in $CHCl_3$ at 25 °C, the Me–Ta bond is cleaved homolytically and CH_4 is formed as a result of the abstraction of the γ-hydrogen from the Mes group. ^1H and ^{13}C NMR data made it possible to establish the formation of substituted benzylidene complexes and to put forward a γ-elimination mechanism[62]:

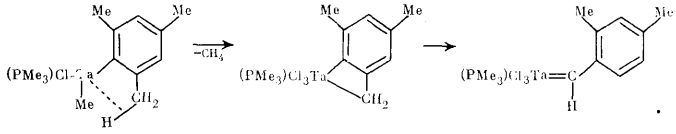

Table 9. Thermolysis of the benzyl and trimethylsilylmethyl derivatives of titanium, zirconium, and vanadium.

$(Me_3SiCH_2)_3V\cdot THF$	in ether (75)	2.0	[91]

Remarks: [a] the decomposition was carried out in a quasi-flow system permitting the removal of the eliminated ligand from the reaction zone.

It is nowadays regarded as generally accepted that the decomposition of the σ-derivatives of Ti, Zr, Hf, V, Cr, Mo, and W is accompanied by the homolysis of the σ-bond. The thermolysis of the benzyl derivatives $(PhCH_2)_4M$ (M = Ti, Zr, Hf, V, Mo, or W) in the solid state and in solutions entails the formation of mainly toluene. At the same time very small amounts of bibenzyl, benzene, diphenylmethane, methane, and ethane were detected. The metal-containing thermal decomposition products consist of dark involatile pyrophoric substances in which the metal is present in a low-valence state. Unfortunately quantitative data have been obtained only for titanium, zirconium, and vanadium[5,89,90,91] (Table 9).

The trimethylsilylmethyl and neopentyl compounds of the elements in the titanium and vanadium subgroups decompose to give Me_4E (E = C or Si) as the only volatile product. No detailed studies of the thermolysis of $(Me_3ECH_2)_4M$ (M = Ti, Zr, Hf) have so far been made. It has been established that the thermolysis of the trimethylsilylmethyl derivatives of vanadium(IV) and vanadium(III) under various conditions leads to the formation of black pyrophoric residues containing low-valence vanadium[91].

There are virtually no quantitative literature data on the thermolysis of mesityl derivatives. The high thermal stability of the compounds Mes_4M (M = Ti, V, Cr, or Mo), which decompose above 100 °C, has been noted[34-37]. The decomposition results in the formation of mainly mesitylene together with small amounts of xylene, toluene, and bimesityl. For example, in the decomposition of the Mes_4Ti the product ratios are $MesH : Me_2C_6H_4 : MeC_6H_5 : Mes_2 = 100 : 0.1 : 10 : 4.7$.[92] The decomposition of $Mes_3V.THF$ is accompanied by the elimination of THF followed by the splitting off of more than 90% of the σ-substituents. The decomposition products are mesitylene, xylene, toluene, and bimesityl in the proportions 100 : 6.3 : 2.3 : 6.3.[93]

Thus the first stage of the thermolysis is the homolysis of the R–M σ-bond regardless of the valence of the central atom. If the compound has a coordinated ligand, its decomposition usually begins with the elimination of the ligand molecule. It has been established by physicochemical methods that the eliminated σ-substituents do not become free radicals. Consequently their subsequent reactions take place intramolecularly or intermolecularly within a cage. The reaction products of the homolytic species are RH. The sources of hydrogen can be (1) the groups R bound to the metal, (2) the ligand coordinated to the central atom, and (3) the solvent molecules.

It has been established that Me_4Si is formed in the decomposition of the Me_3SiCH_2 derivatives only via the intramolecular or intermolecular elimination of the hydrogen atom from the groups R bound to the central atom. Neither the coordinated ligands nor solvent molecules serve as sources of hydrogen. After the elimination of THF in the first stage of the thermolysis of $(Me_3SiCH_2)_3V.THF$, a structural rearrangement takes place with formation of the dimer $[(Me_3SiCH_2)_6V_2]$. The large bulk of the Me_3SiCH_2 groups and the small radius of the vanadium atom hinder its coordination to THF or Et_2O in the dimer and also in $(Me_3SiCH_2)_4V$.[91,94]

The benzyl derivatives decompose in the solid state via the same mechanism as the Me_3SiCH_2 derivatives but in solutions a difference is observed. Since the $PhCH_2$ groups are less bulky than the Me_3SiCH_2 ligands, they do not hinder the coordination of the THF or Et_2O to vanadium. Although the thermolysis of the complexes $(PhCH_2)_4V.2Et_2O$ and $(PhCh_2)_3V.THF$ begins with the loss of the coordinated ligand, a mobile equilibrium exists in solutions:

$$(PhCH_2)_nV\cdot xL \rightleftharpoons (PhCH_2)_nV + xL \quad ;$$

$$n = 3, 4;\ L = Et_2O,\ THF;\ x = 1, 2 \quad .$$

The occurrence of the reversible reaction makes it possible to replace the ligand by a molecule of the solvent capable of coordination, which serves in its turn as a hydrogen donor. Consequently in the decomposition reaction in solutions, the sources of hydrogen for the formation of RH can be both the groups R bound to the metal and the molecules of the coordinated ligand. The occurrence of two pathways is confirmed by the quantitative yield of toluene and by the analysis of the solid residue. In the decomposition of organovanadium

compounds the solid residue contains the V–OR fragments which have arisen from secondary oxygen-containing ether groups. The study of the thermal decomposition of $(PhCH_2)_4V.2Et_2O$ in di-isopropyl ether by EPR revealed the formation of the intermediate derivative $(PhCH_2)_2V(OPr\text{-}iso)_2$.

The solvent is not involved in the formation of RH in the thermolysis of the benzyl derivatives of titanium and zirconium in hydrocarbons. This is confirmed by data for the decomposition of $(PhCH_2)_4Zr$ in $C_6D_5CD_3$, which does not result in the formation of $PhCH_2D$. The thermolysis of the equimolar $(PhCH_2)_4Ti + (C_6D_5CD_2)_4Ti$ mixture in heptane leads to the formation of toluene deuterated to different extents. This indicates the existence of an intermolecular pathway leading to the elimination of hydrogen. Unfortunately the decomposition of $(PhCH_2)_4M$ (M = Ti or Zr) in solvents capable of coordination (Et_2O, THF) has not been studied in detail and it is therefore difficult to reach a general conclusion concerning the influence of the nature of the solvent on the RH formation pathways.

The influence of the nature of the σ-substituent and of solvent character is clearly manifested in the thermolysis of the pentafluorophenyl derivatives of titanium and vanadium[48, 91,95] (Table 10). The titanium compounds decompose without fusion in the temperature range 120–130 °C, while the vanadium compounds decompose at 205–220 °C. The thermograms of the titanium complexes show that the coordinated ligands are split off initially. In contrast to this, the thermograms of the vanadium complexes have no peaks corresponding to the elimination of THF. The difference between the first stages of the decomposition determines also the difference between the subsequent decomposition pathways.

In compounds with the C_6F_5 ligands there is a possibility of the interaction of the unshared electron pair of the fluorine atom in the *ortho*-position with the *d* orbital of the metal. In the complexes $(C_6F_5)_4Ti.2Et_2O$, $(C_6F_5)_3Ti.3THF$, and $(C_6F_5)_4V.2THF$, the central atom is coordination-saturated and there is therefore initially no additional coordination of the fluorine to the metal. Experimental data show that the coordinated Et_2O or THF ligands are split off initially in the decomposition of the titanium derivative and one of the C_6F_5 groups is the first to be split off in the case of vanadium. This is probably followed by a rearrangement of the coordination sphere of the central atom associated with the fact that the vacant sites in the octahedral configuration are occupied by fluorine atoms. This additional coordination weakens both the $C-F_{ortho}$ and the C–M bonds. Both bonds are therefore ruptured in the thermolysis, which is accompanied by a transfer of the fluorine to the metal atom and the formation of metal fluorides. The fluorinated ligand is split off in the form of tetrafluorodehydrobenzene and the subsequent reaction pathways of C_6F_4 depend only on the nature of the solvent. C_6F_4 does not react with ethers and trimerises, but it does enter into a reaction with benzene of the type of diene synthesis with formation of 5,6,7,8-tetrafluorobenzobicyclo[2.2.2]octatriene.

The C_6F_5 groups eliminated from vanadium in the thermolysis of $(C_6F_5)_4V.2THF$ are converted mainly into C_6F_5H as a result of the abstraction of hydrogen from the coordinated THF molecules. A small proportion of the C_6F_5 groups dimerise. The formation of small amounts of C_6F_5H in the decomposition of $(C_6F_5)_4Ti.2Et_2O$ shows that the loss of coordinated ligands is accompanied by the partial homolysis of the C_6F_5–Ti σ-bond. On thermal decomposition in solutions, the compound $(C_6F_5)_3Ti.3THF$ remains coordination-saturated and for this reason one observes under the given conditions in the first stage the elimination of the C_6F_5 group, which is converted into C_6F_5H as a result of the abstraction of hydrogen from THF. Owing to the octahedral configuration, two vacant sites are produced and are occupied by the fluorine atoms from the two remaining C_6F_5 groups. The subsequent decomposition leads to the elimination of two C_6F_4 groups and the transfer of two fluorine atoms to titanium. However, $F_2Ti(OR)$ is formed instead of TiF_2, since the alkoxy-group produced due to the decomposition of the dehydrogenated THF adds to titanium. In $(C_6H_5)_3V.THF$ there is a possibility of the expansion of the coordination sphere to an octahedron as a result of the coordination of fluorine to vanadium. The C_6F_4 and not C_6F_5 is therefore split off in the decomposition of $(C_6F_5)_3V.THF$ and $VF_3.THF$ is formed.

Thus the mode of the thermal decomposition of the pentafluorophenyl derivatives is determined by the electronic configuration of the central atom and the possibilities for the rearrangement of the coordination sphere in the decomposition process.

Studies of the thermal decomposition of the compounds R_nMX_{m-n} have been published recently[7,63,96]. They are of interest because they make it possible to follow the influence of the second substituent on the reaction pathway. Under comparable conditions, studies have been made of the decomposition of the halogeno-derivatives R_nVCl_{4-n} having substituents of different kinds (Table 11). R_3VCl decomposition products show that symmetrisation takes place initially in accordance with the equation

$$R_3VCl \rightarrow {}^1/_2R_4V + {}^1/_2R_2VCl_2 \ .$$

When R = CH_2Ph or CH_2SiMe_3, the corresponding products R_4V do not decompose under the experimental conditions and

$(PhCH_2)_2V(OBu\text{-}t)_2$	heptane	90	0.70	—	V(III)+V(II) (0.75+0.15)
$Me_3SiCH_2V(OBu\text{-}t)_2.ClMgOBu\text{-}t$	solid[b]	200	0.89	—	V(IV) oxides (0.99)

Remarks: [a] amount of $(C_6F_4)_3$ found 0.60 mol/mol $(C_6F_5)_3VCl.THF$; [b] thermolysis in a quasi-flow system with removal of products from the reaction zone; iso-C_4H_{10} (0.45 mole), iso-C_4H_8 (1.95 mole) and t-BuOH (0.38 mole) were found. A dash indicates that the given compounds was not detected in the decomposition products.

can be isolated from the reaction mixture. The second symmetrisation product (R_2VCl_2) decomposes. The complex $(C_6F_5)_3VCl.THF$ also undergoes symmetrisation initially, but, since it decomposes at 198 °C and $(C_6F_5)_4V.2THF$ decomposes at 205 °C, in the given instance the processes are superimposed and a mixture of decomposition products of both compounds is obtained.

The study of the influence of the t-BuO group on the decomposition of alkylvanadium alkoxides (Table 11) makes it possible to establish that the reaction begins with the homolysis of the V–C σ-bond. At high temperatures (above 200 °C), the V–O and C–O bonds are cleaved. It is noteworthy that $V(OBu\text{-}t)_3$ and $V(OBu\text{-}t)_4$ decompose at 150° and 164 °C respectively. The amounts of RH formed in the decomposition of $R_2V(OBu\text{-}t)_2$ show that the neighbouring R ligands serve as a source of hydrogen. The formation of considerable amounts of CD_4 in the decomposition of $(CD_3)_2V.(OBu\text{-}t)_2$ may serve as confirmation of this finding. The formation of Me_4Si and the subsequent reactions can be represented schematically as follows:

The decomposition temperature determines the composition of the final vanadium-containing products. Below 100 °C, a mixture of alkoxides is produced, while at 200 °C the products consist of a mixture of vanadium oxides.

Regardless of the nature of R and R′, the thermolysis of the compounds $(RCH_2)_nTi(NR'_2)_{4-n}$ (n = 1, 2, 3; R = Ph or $SiMe_3$; R′ = Me or Et) leads to the formation of one mole of RH per RCH_2 group. The titanium remains quadrivalent in all cases[75] (Table 12). An ionic mechanism of the decomposition reaction with participation of the β-hydrogen of the NR_2 groups has been proposed[75]:

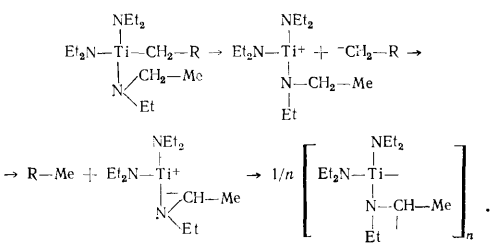

Table 12. Products of the decomposition of $(RCH_2)_n.Ti(NR'_2)_{4-n}$ in the solid state[75].

Compound	Decomp. temp.	RH, moles
$(PhCH_2)_3Ti(NEt_2)$	80	2.2
$(PhCH_2)_2Ti(NEt_2)_2$	80	1.5
$(PhCH_2)Ti(NEt_2)_3$	140	0.8
$(PhCH_2)Ti(NMe_2)_3$	105	0.8
$(Me_3SiCH_2)_2Ti(NEt_2)_2$	90	1.5
$(Me_3SiCH_2)Ti(NMe_2)_3$	90	0.9
$(Me_3SiCH_2)Ti(NEt_2)_3$	130	0.9

Data on the thermolysis of compounds containing bulky amide groups are consistent with the ionic mechanism[76]. The mechanism of the decomposition of the alkylamide compounds is significantly influenced by the presence of the alkylamide group and not by the character of the σ-substituent.

IV. REACTIONS INVOLVING INSERTION IN THE TRANSITION METAL–CARBON σ-BOND

The reactions of the σ-derivatives of transition metals with acids, alcohols, halogens, hydrogen halides, and metal salts have been investigated in fair detail. Numerous investigations established that the above reactions are independent of

the nature of the central atom—the M–C σ-bond is cleaved in all cases. The presence of bulky σ-ligands, such as the adamantyl, norbornyl, and mesityl groups, retards the bond cleavage but the reaction pathway remains unchanged.

An increasing number of studies on the chemistry of organic compounds of transition metals are nowadays devoted to the insertion reactions described by the general formula

$$M-[-R]_n + A \rightarrow M-[-AR]_n .$$

Many such reactions are known, since numerous monatomic and polyatomic species can be inserted in the M–C σ-bond. The reaction pathway is determined, on the one hand, by the nature of the transition metal–carbon σ-bond and, on the other, by the properties of the inserted molecules.

1. Reactions with Oxygen, Sulphur, and Selenium

Virtually all the σ-derivatives of transition metals are sensitive to molecular oxygen. Many compounds undergo spontaneous heating in air. However, if the substance contains bulky substituents, which shield the central atom from coordination with oxygen, it is usually resistant to oxidation. Indeed, Mes_4M and $(adme)_4M$ are not oxidised in air.

Organic compounds of non-transition metals are known to be oxidised via a radical mechanism with formation, depending on the conditions, of peroxides or alkoxides of the corresponding metals. Only preliminary data exist at present concerning the mechanism of the oxidation of organic compounds of transition metals. The oxidation of $(Me_3SiCH_2)_4.Ti(Zr)$ or $(PhCH_2)_4Zr(Hf)$ takes place at a higher rate at −78 °C. For example, the oxidation of $(PhCH_2)_4Hf$ in toluene for 3 min results in the quantitative formation of $(PhCH_2O)_4Hf$. In the presence of an excess of pyridine the initial rate of oxidation of $(PhCH_2)_4Zr(Hf)$ diminishes, one mole of oxygen is then absorbed (at −78 °C), and $(PhCH_2)_2Hf(OCH_2Ph)_2.Py$ is formed[97,98]. The authors suggest that organometallic peroxides are formed in the first stage of the oxidation reaction and either rearrange or react with another molecule of the organometallic compound, giving rise ultimately to alkoxides.

The insertion of elementary sulphur and selenium in the transition metal–carbon σ-bond has been described in only two instances. In contrast to the compounds RMgX, whose interaction with S_8 and Se yields the corresponding mercaptans and selenoalcohols, the compounds Cp_2NbR_2 (R = Me or α-thienyl) give rise to niobium(V) complexes and not insertion products on irradiation with ultraviolet light in benzene in the presence of S_8:[99]

$$Cp_2NbR_2 \xrightarrow[C_6H_6]{S_8,h\nu} Cp_2Nb\begin{matrix}R\\ \diagup\\ \diagdown\\ S\end{matrix}\!\!\begin{matrix}\\ \\ \\ S\end{matrix} .$$

An X-ray diffraction study of the complex $Cp_2Nb(S_2)Me$ showed that S_2 is a bidentate ligand and that the Mb–S distances are 2.515 and 2.432 Å.[100]

Analogously to Grignard reagents, a direct insertion of the Se atom in the M–C σ-bond has been observed for Cp_2MMe_2 (M = Zr or Hf). On refluxing with two equivalents of selenium, the derivatives thus produced give rise to a high yield of $Cp_2M(SeMe)_2$.[101]

2. Reactions with Carbon Monoxide

Numerous studies in this field during recent years established the mechanism of the coordination and subsequent insertion of the CO molecule as a function of the central atom and the character of the σ-substituent. The discovery of these features became possible when the cyclopentadienyl compounds $Cp_2M(R)X$, Cp_2TiR, and Cp_2MR_2 (R = Me, Ph, CH_2Ph, or C_6F_5; M = Ti, Zr, Hf, V, Nb, or Ta; X = Cl or OEt) were used[102–108]. It was established that the first stage involves the coordination of the CO molecule to the central atom. The secondary reactions leading to the final product depend on the nature of the central atom.

We shall consider how this situation arises in the few-reactions of compounds of the type R_nM with CO which have been investigated. The $(PhCH_2)_4Ti$ molecule absorbs only two CO molecules. The highest coordination number of titanium(IV) is six, so that only two ligands can be coordinated to the central atom in $(PhCH_2)_4Ti$ [in the analogous reaction of CO with the complex $(PhCH_2)_4Ti.NH(C_6H_{11})_2$, in which titanium-(IV) has a coordination number of 5, only one mole of CO is absorbed]. The infrared spectrum of the solution shows initially absorption bands at 1952 and 1873 cm^{-1}, which are characteristic of the coordinated CO group: subsequently these bands vanish and new bands due to the carbonyl group $\rangle C{=}O$ appear at 1640 and 1635 cm^{-1}. The acyl derivative $(PhCH_2)_2Ti(COCH_2Ph)_2$ was isolated as a result of the reaction. The process is reversible; when the solution is heated, CO is evolved and the initial compound $(PhCH_2)_4Ti$ reformed[109].

In contrast to $(PhCH_2)_4Ti$, the titanium(II) derivative $(PhCH_2)_2Ti.3Et_2O$ reacts slowly with CO in toluene (p_{CO} = 2 atm) at 20 °C and not more than two moles of CO are absorbed irreversibly. It has been established that 0.5 mole of CO is absorbed after 5 h, 1.0 mole after 10 h, and 2.0 moles after 24 h. The slow insertion is complicated by secondary reactions giving rise to a complex range of products[110].

The compound $(PhCH_2)_4Zr$ reacts with CO in decalin at 22 °C. Analysis of the zirconium-containing products demonstrated the presence of the Zr–CO–CH_2Ph, –Zr–O–C–CH_2Ph, and other fragments[111].

The vanadium(IV) and chromium(IV) compounds $(Me_3Si.CH_2)_4M$ and $(iso\text{-}Pr)_4Cr$ do not react with CO at 20 °C under normal pressure owing to the large bulk of the σ-substituents which obscure the central atom and prevent the coordination of the CO. However, at a CO pressure of 50 atm in THF, all the isopropyl groups are displaced from the $(iso\text{-}Pr)_4Cr$ molecule and $Cr(CO)_6$ is formed[27,112].

When the molybdenum complex $ClMo(CH_2SiMe_3)_3.PMe_3$ is acted upon by CO, two Me_3SiCH_2 groups are substituted by carbonyl groups and some of them migrate to a coordinated CO molecule, giving rise to an η^2-coordinated acyl group. The carbonylation product was identified on the basis of X-ray diffraction data as a dimer with hexacoordinate molybdenum $[ClMo(COCH_2SiMe_3)CO_2(PMe_3)]_2$.[58] The complexes $(C_6F_5)_2Co.2PR_3$ (R = Et, n-Bu, or Ph) combine reversibly with one CO molecule to form the pentacoordinate carbonyl complexes $(C_6F_5)_2Co.2PR_3(CO)$. An excess of CO induces the decomposition of the complexes accompanied by the formation of the dimer $[Co(CO)_3.PR_3]_2$.[113] When the dioxane complex is acted upon by CO, the dioxane is displaced and, in the presence of an excess of CO, cobalt is reduced to cobalt(I):[113]

$$(C_6F_5)_2Co\cdot 2diox \xrightarrow[-78°C]{CO} [(C_6F_5)_2Co(CO)_3] \xrightarrow[20°C]{CO} (C_6F_5)Co(CO)_4 .$$

When a stream of CO is passed through a tetrahydrofuran solution of $(C_6F_5)_2Ni.2diox$ for 8–10 h at 20 °C, the colour of the solution changes and the infrared spectra indicates the presence of a coordinated CO group. However, the attempts to isolate the carbonyl complex led only to the decomposition product $(C_6F_5)_2$ [114] (Table 13).

3. Reactions with Carbon Dioxide

Organolithium and organomagnesium compounds, which behave as sources of carbanions, readily react with various electrophiles, particularly with CO_2. This reaction can be formally represented as the insertion of the carbonyl group in the metal–carbon bond. This results in the formation of lithium or magnesium carboxylates, which give rise to the corresponding carboxylic acids after hydrolysis.

Table 13. Products of the reactions of R_nM with CO_2 and CO (p = 1 atm).

Initial compound	Reagent	Reaction conditions			Reaction products	Yield, %	Refs.
		solvent	t, °C	time, h			
$(PhCH_2)_2Ti\cdot 3Et_2O$	CO_2	THF	20	24	$(PhCH_2CO_2)_2Ti\cdot 3Et_2O$	99	[110]
$(PhCH_2)_4V\cdot 2Et_2O$	CO_2	pentane	0	96	$V(OCOCH_2Ph)_2$	95	[21]
$(PhCH_2)_4V\cdot 2Et_2O$	CO_2	Et_2O	−20	2	$V(OCOCH_2Ph)_3$	99	[21]
$(C_6F_5)_4V\cdot 2Et_2O$	CO_2	THF	20	150	$V(OCOC_6F_5)_3$	95	[21]
$(C_6F_5)_3V.THF$	CO_2	THF	20	150	$V(OCOC_6F_5)_3$	96	[21]
$(Me_2SiCH_2)_3V.THF$	CO_2	THF	−20	3	$V(OCOCH_2SiMe_3)_3$	83	[21]
$Me_2Ni.bipy$	CO_2	benzene	80	15	$Ni(OCOMe)_2\cdot bipy$	90	[117]
$Et_2Ni.bipy$	CO_2	benzene	50	15	$Ni(OCOEt)_2\cdot bipy$	52	[117]
$Et_2Hf[N(SiMe_3)_2]_2$	CO_2	pentane	20	24	$Et_2Hf[OCON(SiMe_3)_2]_2$	90	[78]
$(PhCH_2)_4Ti$	CO	pentane	−50	—[b]	$(PhCH_2)_2Ti(COCH_2Ph)_2$	80	[109]
$(iso\text{-}Pr)_4Cr$	CO	THF	20[a]	—[b]	$Cr(CO)_6$	66	[112]
$ClMo(CH_2SiMe_3)_3\cdot PMe_3$	CO	PE	20	—[b]	$[ClMo(COCH_2SiMe_3)\cdot (CO)_2(PMe_3)]_2$	99	[58]
$(C_6F_5)_2Co\cdot 2diox$	CO	hexane	20	—[b]	$(C_6F_5)Co(CO)_4$	60	[113]

Remarks: [a] p_{CO} = 50 atm; [b] time not indicated.

Systematic studies of the insertion of CO_2 in the transition metal–carbon σ-bond in derivatives of the type R_nM were begun quite recently. It was found that the compound $(PhCH_2)_4M$ (M = Ti or Zr) absorb slowly and irreversibly two moles of CO_2 per gramme-atom of the metal at 20 °C (p_{CO_2} = 13 atm), which is caused, as in the insertion of CO, by the coordinating capacity of Ti(IV) and Zr(IV). The hydrolysis of the reaction products yields in both cases $PhCH_2COOH$ as well as $(PhCH_2)_3COH$ as a result of secondary reactions[5]. The complex $(C_6F_5)_4Ti.2Et_2O$ does not react with CO_2 at 20 °C and p_{CO_2} = 2 atm.[44]

The derivatives R_3Ti (R = CH_2Ph or CH_2SiMe_3) are not carboxylated by gaseous CO_2 in toluene at −70 °C and p_{CO_2} = 1 atm.[21,48] The insertion of CO_2 in the Ti–C_6F_5 bond in $(C_6F_5)_3Ti$ has not been observed either at 20 °C (p_{CO_2} = 2 atm).[48]

It has been observed that, after 24 h at 20 °C (p_{CO_2} = 1 atm), the compound $(PhCH_2)_2Ti.3Et_2O$ absorbs two moles of CO_2 with formation of the complex $(PhCH_2CO_2)_2Ti.3Et_2O$. Analysis of the infrared spectrum showed that the carboxylate group in this complex has the η^1-coordination[110].

Detailed studies have been made of the character of the interaction of CO_2 with a series of vanadium(IV) and vanadium(III) compounds: $(Me_3SiCH_2)_4V$, $R_4V.2THF$ (R = CH_2Ph or C_6F_5), and $R_3V.THF$ (R = CH_2SiMe_3 or C_6F_5).[21] The compounds $(Me_3SiCH_2)_4V$ and $[(Me_3Si)_2CH]_3V$, in which the central atom is shielded, do not absorb CO_2.[21,32] The complexes $(PhCH_2)_4V.2Et_2O$ and $R_3V.THF$ (R = CH_2Ph or CH_2SiMe_3) absorb CO_2 at −20 °C, while $(C_6F_5)_4V.2Et_2O$ and $(C_6F_5)_3V.THF$ react slowly with CO_2 at +20 °C.

Experimental data have shown that at the beginning of the reaction the CO_2 molecule is coordinated to the vanadium atom, which is accompanied by the displacement of the Et_2O or THF ligand species. Subsequently the σ-substituent migrates to the carbon atom with formation of the carboxylate. The multistage insertion of CO_2 in vanadium(IV) and vanadium(III) derivatives as well as the reactions of the carboxylates formed, which behave analogously to the mixed compounds R_nVX_{m-n} examined above, has been investigated[21]. The carboxylation of the test compounds with an excess of gaseous CO_2 leads to the formation of $V(OCOR)_3$. Analysis of the infrared spectra has shown that the carboxylate group in these compounds has the η^2-coordination (Table 13). The reactivity with respect to CO_2 of the remaining σ-derivatives described above in Section II has not been investigated. There are in the literature isolated examples of the insertion of CO_2 in the M–C σ-bonds in metal complexes (M = Mn, Fe, or Ni). For example, after reaction with CO_2 (20 °C, 2 h), $[R_3Mn]^-Li^+$ and $R_3MnMgCl$ give rise to RCO_2H (R = Ph or Mes) in quantitative yields after hydrolysis[115]. The complex $(Me_3P)(H)Fe(CH_2PMe_2)$ reacts with CO_2 in THF at 20 °C and yields an unusual product of insertion in the Fe–C bond[116]. The nickel derivatives $R_2Ni.bipy$ (R = Me or Et) readily absorb two moles of CO_2 with formation of the carboxylates $(RCO_2)_2Ni.bipy$.[117]

Thus the results obtained hitherto demonstrate that the general character of the reactions with CO_2 is the same for the organic compounds R_nM of lithium, magnesium, and transition metals. It is noteworthy that the reactivity of the transition metal–carbon σ-bond depends on the nature and valence of the metal and also on the character of the σ-substituent.

It has been shown in relation to $Et_2Hf[N(SiMe_3)_2]_2$ that, when M–C and M–N bonds are present in the molecule, CO_2 is inserted in the M–N bond with formation of $Et_2Hf[OCON.(SiMe_3)_2]_2$.[78,118]

4. Reactions with Aldehydes and Ketones

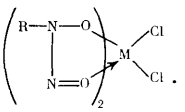
The addition of organolithium and organomagnesium compounds to the carbonyl group in aldehydes and ketones is one of the most important reactions in organic synthesis. The study of such reactions involving transition metal complexes is only just beginning.

It has been observed that $(PhCH_2)_4Ti$ readily interacts with one or two equivalents of ketones (acetone, benzophenone), yielding after hydrolysis the corresponding tertiary alcohols; the excess ketones do not react[119]. The reaction of $(PhCH_2)_2.Ti.3Et_2O$ with the above ketones results in the formation of the alkoxides $Ti[OCR_2(CH_2Ph)]_2$ (R = Me or Ph), which do not contain coordinated ether[110].

The reactivity of compounds of the type $R_nTi(OR')_{4-n}$ with respect to carbonyl compounds is lower than that of R_nTi. For example, $(PhCH_2)_2Ti(OME)_2$ does not react with acetone; one refluxing in Et_2O for 7 h, $PhTi(OPr\text{-}iso)_3$ reacts with PhCO to yield 19% of Ph_3COH after hydrolysis. At 20 °C the compound $PhTi(OPr\text{-}iso)_3$ reacts only with aldehydes[66,120,121]. Investigations have shown that the compounds $RTi(OPr\text{-}iso)_3$ (R = Bu or Ph) are more selective in relation to carbonyl compounds than the corresponding organolithium compounds [120–122]. In contrast to $PhTi(OPr\text{-}iso)_3$, $MeTi(OR')_3$ reacts with different ketones[120,123].

Like $(PhCH_2)_4Ti$, the compound $(PhCH_2)_4V$ reacts only with two moles of acetone, forming $(PhCH_2)_2V[OC(Me)_2CH_2Ph]_2$. It is known that $R_2V(OBu\text{-}t)_2$ derivatives do not react with acetone even on heating[21].

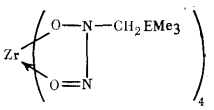
The data obtained for the titanium and vanadium compounds make it possible to put forward a general reaction mechanism. Analogously to organolithium and organomagnesium compounds, in the first stage oxygen is coordinated to the metal.



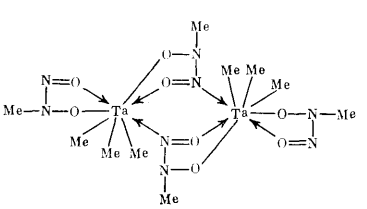
The alkoxy-groups formed are very bulky and tend to associate. These findings indicate the shielding of the central atom, so that coordination to the latter of other ketone molecules becomes virtually impossible. Steric effects are also responsible for the inertness of the compounds $R_2M(OR')_2$ (M = Ti or V) and $PhTi(OPr\text{-}iso)_3$ in relation to ketones. Bulky alkoxy-groups displace the coordinated Et_2O molecules from $(PhCH_2)_2Ti.3Et_2O$ in the alkoxide formation stage.

5. Reactions with Nitric Oxide

The mode of reaction with NO is determined by the nature of NO itself, which is a radical. Reactions with diamagnetic complexes lead to the formation of *N*-alkyl-*N*-nitrosohydroxylaminate derivatives[124]:



The compounds R_2MCl_2 (R = CH_2CMe_3 or CH_2SiMe_3; M = Ti or Zr) absorb four moles of NO in petroleum ether at 0 °C and give rise to octahedral complexes:



Analysis of the infrared spectra of these complexes indicates the *cis*-disposition of the Cl atoms relative to the metal atom and also the η^2-coordination of the two ON(R)NO groups. The compound $(Me_3CCH_2)_3TiCl$ absorbs six moles of NO, while $(Me_3SiCH_2)_4Ti$ absorbs eight moles of NO. Since titanium forms only hexacoordinate complexes, the ON(R)NO groups in the complexes are probably not equivalent; for example, $Ti[ON(CH_2SiMe_3)NO]_4$ has two chelate and two monodentate groups.

The reaction of $(Me_3ECH_2)_4Zr$ (E = C or Si) with NO results in the formation of monomeric octacoordinate complexes which are stable in air:

The observed difference between the structures of the products obtained from titanium and zirconium compounds is due to the different coordinating capacities of the above metal atoms.

Octacoordinate complexes are formed as a result of the reaction of Me_5Nb or Me_5Ta with NO. However, the nature of the central atom permits the existence of different structures of these metal complexes. It has been found that Me_5Nb gives rise to the monomeric complex $Me_2Nb[ON(Me)NO]_3$ with equivalent chelate ligands. A dimeric complex is formed from Me_5Ta and the following structure has been attributed to it on the basis of infrared and NMR spectra:

The paramagnetic complexes of transition metals with an unpaired electron at the metal atom react with NO to produce oxo-derivatives of the metals and azomethane[124]. The hypothesis that the initial stage in the reactions of paramagnetic complexes with NO involves the coordination of the NO molecule to the transition metal atom has been confirmed by the isolation of the complex $[(Me_3Si)_2CH]_3CrNO$, in which bulky ligands prevent further reactions[32].

---o0o---

It follows from the results of the analysis of the investigations carried out that considerable progress has now been achieved in the chemistry of the thermally stable σ-derivatives of transition metals. Extensive studies of the properties of the compounds R_nM and R_nMX_{m-n} have made a definite contribution to the development of theoretical organoelemental chemistry. The research prosecuted vigorously on these lines gives rise to good prospects for the practical utilisation of the σ-derivatives in metal complex catalysis, in the formation of biologically active preparations, and in the development of new methods for the preparation of protective coatings by the decomposition of organometallic compounds.

Platinum Metal Fluorides

A.V.Dzhalavyan, E.G.Rakov, and A.S.Dudin

The properties of the simple fluorides, oxide fluorides, and dioxygenyl compounds of the platinum metals have been reviewed. The most important fields of application and directions of study in the field of platinum metal fluorides have been outlined. The bibliography contains 185 references.

I. INTRODUCTION

The platinum metals are now widely used in chemical technology, chiefly as catalysts in petroleum reforming, and also in electrical technology, jewellery, and laboratory practice. The use of platinum metals as alloy components makes it possible to improve considerably the mechanical properties and increase the corrosion resistance of alloys, compared with the pure metals.

The fields of application of the platinum metal fluorides are determined directly by their physicochemical properties. The development of fluoride metallurgy is extending the possible applications of the volatile platinum metal fluorides in one of the most promising fields—the preparation of coatings, powders, alloys, or articles by reducing the volatile fluorides with hydrogen. For example, the preparation of iridium coatings by reducing IrF_6 with hydrogen has been described[1,2]. The simultaneous reduction of fluorides can be used to prepare alloys of platinum metals with refractory metals. The use of platinum metal fluorides to regenerate spent catalysts in the petrochemical industry appears promising[3].

Increasing quantities of platinum metals are accumulating in spent nuclear fuel, which can possibly be processed by subliming the fluorides. It has been estimated[4] that for 3% burnout, one ton of nuclear fuel gives 500 g of Rh and 1500 g of Pd. By the year 2000, the quantity of palladium produced in the reactors of atomic power stations will be about 250 tons, close to the required quantity of this metal. The quantities of rhodium and ruthenium obtained by nuclear fission will exceed the expected demand. Here it is necessary to solve the problem of removing the radioactive isotope ^{103}Ru,[5] and then the problem of isolating the other platinum metals.

The electronic configuration of the atoms Ru ($4d^75s^1$), Rh ($4d^85s^1$), Pd ($4d^{10}$), Os ($5d^66s^2$), Ir ($5d^76s^2$), and Pt ($5d^96s^1$) makes possible a variety of fluoride compounds, in which the oxidation state of the metal varies from +2 to +8. Simple platinum metal fluorides have coordination numbers from 2 to 7.

Thus platinum metal fluorides are already of considerable interest in both technology and chemistry.

Published reviews of the properties of platinum metal fluorides[6,7] are based on 15–20-year-old publications, and require to be bought up to date. A number of recent books and reviews have dealt with platinum metal fluorides among other fluorides[8–12], but they deal mainly with the properties of the fluorides of individual platinum metals, for example ruthenium,[9,12] iridium,[10] and osmium.[11] Data on the properties of fluorides are given in a number of reference books[13–16], but even the most complete of these[16] includes original publications only up to 1973.

The aim of the present review was to systematise the methods of synthesis, review published data on the physicochemical properties of the platinum metal fluorides, and define the most important directions of studies in this field.

II. SIMPLE FLUORIDES

1. Higher Fluorides

Among the platinum metals, a heptafluoride is known only for osmium. The higher fluoride OsF_7 was obtained by treating osmium powder with fluorine at 573–683 K and a pressure of 350–400 atm in a nickel bomb[17]. Osmium heptafluoride is obtained as a pale-yellow extremely hygroscopic powder, which partly loses fluorine at temperatures above 173 K, and on prolonged standing at room temperature decomposes quantitatively to OsF_6 and fluorine. Osmium heptafluoride has been characterised by mass spectrometry, magnetic susceptibility, and EPR and infrared spectroscopy at 93 K. The wavenumbers of vibrational bands in the infrared spectrum of OsF_7 are 715, 550, 483, 366, 336, and 282 cm^{-1}. Analysis of the infrared spectrum indicates that the OsF_7 molecule has D_{5h} symmetry[17]. A comparison of the enthalpies of formation of the fluorides of the elements from Hf to Re has been used to estimate the enthalpies of formation of gaseous OsF_7 and the hypothetical OsF_8: −1140 kJ $mole^{-1}$ and −980 kJ $mole^{-1}$ respectively[18].

The reported formation of RuF_8 [19] by the fluorination of ruthenium and its dioxide has not been confirmed. A study of the hydrolysis of ruthenium fluorides and the fluorination of ruthenium hydroxides revealed the formation of a volatile substance[20], whose infrared spectrum showed bands at 389 cm^{-1} and 1030 cm^{-1}, previously assumed erroneously[19] to be ruthenium octafluoride. This substance is the adduct $RuO_4(HF)_{10}$, which volatilises at temperatures above 273 K and an HF pressure above 150 mmHg.[20]

The most fully characterised platinum metal fluorides are the hexafluorides, of which only palladium hexafluoride was isolated only recently[21] and has been little studied. A general method for obtained the hexafluorides of ruthenium[22], rhodium[23], osmium[24], and iridium[25] involves the action of fluorine, diluted with nitrogen, on the metal powders, heated to 550–700 K, with subsequent rapid cooling of the reaction products. Platinum hexafluoride is obtained similarly, but under more severe conditions, by heating platinum wire electrically in a stream of fluorine to 1150–1300 K.[26,27] The synthesis of PtF_6 by the action of fluorine on spongy platinum at a pressure of 15 atm and a temperature of 470 K and a molar

ratio Pt : F_2 = 1 : 15, which gives a yield of 75%, has also been proposed[28].

A method for obtaining platinum metal hexafluorides in solution in KrF_2, anhydrous HF, or BrF_5 has been successfully developed and applied[29]. The solution of the metals, oxides, or lower fluorides in KrF_2 gives complexes $KrF_2.MF_5$ (M = Pt, Ru, Rh) and $KrF_2.2MF_5$ (M = Pt, Ru), which when heated slightly decompose vigorously with the quantitative formation of the corresponding metal hexafluorides, Krypton difluoride has a high fluorinating power, and acts as a fluoride ion donor, stabilising the higher oxidation states of the elements.

An effective method for the synthesis of thermally unstable platinum metal hexafluorides involves the use of atomic fluorine[30], which takes part in chemical reactions with an activation energy close to zero. The reaction of atomic fluorine with palladium powder at room temperature was in fact used to prepare PdF_6.[21] The fluorination of the platinum metals by atomic fluorine at low temperatures (below 370 K) is rapid. The yield of hexafluorides decreases in accordance with their thermal stability in the order OsF_6 > IrF_6 > PtF_6 > RuF_6 > RhF_6, and also depends on the composition of the starting material. The limiting stage of the fluorination of the platinum metals by atomic fluorine is the conversion of the pentafluorides to the hexafluorides. The fluorination of osmium and iridium oxides by atomic fluorine also gives the hexafluorides of these metals.

Table 1. Physical properties of platinum metal hexafluorides.

Property	RuF_6 [22, 34]	PhF_6 [23, 34]	OsF_6 [18, 24, 34, 35]	IrF_6 [25, 34, 35]	PtF_6 [27]

Note. Numbers in square brackets denote references (Ed. of Translation).

A study of the kinetics of the reaction of compact Ir and Pt with atomic fluorine in the range 1000–1450 K for iridium and 600–1430 K for platinum at a partial pressure of atomic fluorine of 0.005–0.06 mmHg [31] showed that the condensed films of lower fluorides of iridium and platinum formed on the metal surfaces do not decrease the rate of fluorination. The fluorination of osmium powder by molecular fluorine[32] takes place in two stages, and is described satisfactorily by the equation for a contracting sphere. The activation energy is 55.5 ± 2.1 kJ mole^{-1} for the first stage, and 17.4 ± 5.4 kJ mole^{-1} for the second. The order of the reaction is 0.5, so that it is assumed that the limiting stage of the fluorination of osmium is the dissociative adsorption of fluorine on the metal surface. The kinetics of the fluorination of ruthenium powder by molecular fluorine[33] in the temperature range 543 to 583 K at a fluorine partial pressure of 22.5–60 mmHg differs from that of the fluorination of osmium. This process is a single-stage process, the activation energy is 79.5 ± 7.1 kJ mole^{-1}, and the order of the reaction with respect to fluorine is 1. The rate of fluorination of ruthenium increases if the metal powder is heated beforehand in hydrogen.

The principal physical properties of the platinum metal hexafluorides are given in Table 1. The boiling points (T) and the enthalpies (ΔH^0) and entropies (ΔS^0) of fusion, volatilisation, phase transformation, and sublimation of the hexafluorides were obtained from the temperature dependence of the vapour pressure.

Linear correlations have been established between the enthalpies of fusion and volatilisation of the hexafluorides of W, Re, Os, Ir, and Pt and their melting and boiling points respectively[37,38]. The correlation of the enthalpy of fusion with the melting point indicates that the value of the enthalpy of fusion of OsF_6 given in Table 1 (7.5 kJ mole^{-1}) is about 2.7 kJ mole^{-1} too high. The value of the entropy of fusion of OsF_6 is also apparently too high. The correlation of the logarithms of the absolute values of the enthalpies of formation of the gaseous hexafluorides of W, Re, Os, and Pt with the stretching vibration frequency ν_1 was used[37] to estimate the enthalpy of formation of gaseous IrF_6 at 298.15 K—approximately −850 kJ mole^{-1}.

The hexafluorides crystallise in a body-centred cubic lattice at room temperature, and in an orthorhombic lattice at low temperatures[34]. The low-temperature form has the YF_3 structure, space group *Pnma*, and the number of formula units Z in the unit cell is 4. The high-temperature form (298 K) is isostructural with the cubic MoF_6 phase, Z = 2. The lattice parameters and densities for both phases of each hexafluoride are given in Table 2.

Table 2. Structural characteristics and densities of the crystals of the platinum metal hexafluorides[34].

Substance	Calculated density of the crystal, kg m^{-3}		Lattice parameters, A	
	cubic phase	orthorhombic phase	cubic phase	orthorhombic phase
RuF_6	3130	3500	6.11±0.01	*a* 9.44 *b* 8.59 *c* 4.98
RhF_6	3130	3620	6.13±0.02	*a* 9.40 *b* 8.54 *c* 4.96
OsF_6	4130	4770	6.25±0.02	*a* 9.59 *b* 8.75 *c* 5.04
IrF_6	4200	4820	6.23±0.02	*a* 9.58 *b* 8.73 *c* 5.04
PtF_6	4280	4900	6.21±0.02	*a* 9.55 *b* 8.71 *c* 5.03

The saturated vapour pressure over RuF_6 at 273.2, 277.8, 281.8, 284.2, 287.6, and 290.8 K has the values 23, 32, 40, 46, 56, and 67 mmHg,[22] and that over RhF_6 at 273, 278, 284, 289, and 293 K has the values 15, 19, 29, 40, and 49.5 mmHg respectively[23]. The vapour pressure (p, mmHg) is described

by the equations

for OsF_6 [35] $\lg p = 10.290 - 2284/T$ ($233.15 \leqslant T \leqslant 272.75$ K)
$\lg p = 8.726 - 1857.7/T$ ($272.75 \leqslant T \leqslant 307.15$ K)
$\lg p = 7.470 - 1472.8/T$ ($307.15 \leqslant T \leqslant 320.65$ K)

for IrF_6 [35] $\lg p = 10{,}000 - 2245.7/T$ ($223.15 \leqslant T \leqslant 273.55$ K)
$\lg p = 8.618 - 1867.5/T$ ($273.55 \leqslant T \leqslant 317.15$ K)
$\lg p = 7.952 - 1656.5/T$ ($317.15 \leqslant T \leqslant 327.15$ K)
for PtF_6 [27] $\lg p = 27.7758 - 3147.6/T - 6.09 \lg T$
($250.2 \leqslant T \leqslant 276.15$ K)
$\lg p = 20.6280 - 2528.7/T - 4.080 \lg T$
($276.15 \leqslant T \leqslant 334.45$ K)
$\lg p = 89.1496 - 5685.8/T - 27.485 \lg T$
($334.45 \leqslant T \leqslant 354.9$ K).

The vibrational spectra of the platinum metal hexafluorides have been the subject of a large number of experimental studies[23,39-42]. All the platinum metal hexafluorides have a regular octahedral configuration (O_h symmetry). For RuF_6 and OsF_6 the ν_2 and ν_5 frequencies are anomalously low, because of the dynamic Jahn–Teller effect[39-41]. The non-perturbed values of these frequencies were calculated for the first time[43] by interpolation from the dependence of the vibrational frequencies on the number of non-bonded electrons in the hexafluorides.

In this and later papers[44-47], the infrared and Raman spectroscopic data for the platinum metal hexafluorides were analysed and systematised.

The calculated vibrational frequencies in the infrared and Raman spectra of the platinum metal hexafluorides[43] and the interatomic distances (r_{M-F}), determined using Badger's rule[48,54], are given to Table 3. The force constants and mean-square amplitudes of the vibrations of the M–F bonds have been calculated[48,50-55].

Table 3. Calculated molecular constants of platinum metal hexafluorides[43].

Substance	Vibrational wavenumbers in the spectra of MF_6, cm^{-1}						r_{M-F}, Å
	ν_1 (a_{1g})	ν_2 (e_g)	ν_3 (f_{1u})	ν_4 (f_{1u})	ν_5 (f_{2g})	ν_6 (f_{2u})	
RuF_6	675	624	735	275	283	186	1.8775

*This band has been detected in the infrared spectrum of PdF_6.[21]
**Determined by electron diffraction in the gaseous state[49].

The ^{19}F NMR spectra of the hexafluorides of osmium, iridium, and platinum[56,57] show that in the low-temperature orthorhombic phase there is tetragonal distortion of the octahedra of the hexafluorides, and the chemical shifts of the axial and equatorial F atoms in PtF_6 are apparently the highest for all known fluoride compounds.

Thermochemical data[58,59] indicate that the electron affinity increases in the order $WF_6 < ReF_6 < OsF_6 < IrF_6 < PtF_6$, and for PtF_6 it is greater than 653 kJ $mole^{-1}$ (6.8 eV); the difference between two neighbouring terms is approximately constant, 84 kJ $mole^{-1}$ (0.9 eV). The spectra of the charge-transfer complexes between IrF_6 and liquid xenon in the near infrared range[60] have been used to estimate the electron affinity of IrF_6, 548.1 kJ $mole^{-1}$ (5.7 eV), which is close to the value obtained by other workers[58,59]. The electron affinity of PtF_6 at 0 K, calculated from effusion measurements, lies between 5.14 eV and 7.9 eV.[36] The physical properties and bonds in the molecules of the hexafluorides of osmium, iridium, and platinum have been studied theoretically[61-63]; earlier measurements of the electron affinity were examined critically, and new measurements of this quantity carried out[63]. The calculated values of the electron affinity and ionisation potentials of OsF_6, IrF_6, and PtF_6 are given in Tables 4 and 5. The values of the ionisation potentials of OsF_6 [62] are close to the data previously obtained from the photoelectron spectra[64].

Table 4. Electron affinity of MF_6, eV.

In spite of the fact that the hexafluorides of the platinum metals are often considered as a whole, their chemical properties show significant differences[66]. The hexafluorides of all the platinum metals except Os and Ir are thermally unstable and begin to decompose even at room temperature with the liberation of fluorine[22,23,67,68]; the rate of decomposition of PdF_6 under these conditions is much greater than that of the other hexafluorides, and amounts to 30% h^{-1}.[21] The tendency for the hexafluorides to decompose increases with increase in atomic number in each series, and the stability decreases more rapidly in the second than in the third series[6,69].

RuF_6 and RhF_6 react with Pyrex even at room temperature; the reaction with quartz is slower[22,23]; when heated with Pyrex, OsF_6 apparently forms OsO_3F and OsO_2F_2;[70] IrF_6 does not react with Pyrex up to 420 K,[25] but at 620 K it is reduced quantitatively by finely divided glass to iridium pentafluoride[68]; PtF_6 also decomposes slowly in contact with Pyrex or quartz[26].

The platinum metal hexafluorides are readily hydrolysed by even traces of moisture, undergoing disproportionation or reduction to give various products. For RuF_6 the chief product is $RuO_2.nH_2O$;[22] the hydrolysis of PdF_6 also gives the hydrated dioxide $PdO_2.nH_2O$, with the liberation of oxygen and ozone[21]. OsF_6 is hydrolysed according to equations[24]:

$$2OsF_6 \rightarrow OsF_6^{2-} + Os^{8+} + 6F^-,$$
$$OsF_6 + H_2O \rightarrow OsF_6^{2-} + 0.5O_2 + 2H^+.$$

The hydrolysis of IrF_6 gives $IrO_2.nH_2O$, with the liberation of ozone[25]; a PtF_6 specimen weighing less than 200 mg gives a yellow solution of H_2PtF_6 ($PtF_6 + H_2O \rightarrow H_2PtF_6 + 0.5O_2$), and quantities of more than 1 g give a black precipitate[27].

A study of the hydrolysis of solutions of platinum metal hexafluorides in hydrogen fluoride by accurately measured quantities of H_2O [71] showed that the products are the oxide tetrafluoride $OsOF_4$ for OsF_6, and for RuF_6, IrF_6, and PtF_6 the hydroxonium salts $H_3O^+MF_6^-$, or $(H_3O^+)_2PtF_6^{2-}$ for PtF_6 in an excess of H_2O. The hydrolysis of RhF_6 gives an unstable product, which could not be characterised. The difference between the results of the hydrolysis of OsF_6 and the hexafluorides of ruthenium, iridium, or platinum can be attributed to the greater electron affinity of the latter[71].

The reaction of the platinum metal hexafluorides with NO and NOF in most cases gives the ionic compounds $NO^+MF_6^-$.[58,72] In an excess of NOF, RhF_6 and PtF_6 give the salts $(NO)_2RhF_6$ and $(NO)_2PtF_6$.[72] With NO_2F and N_2O_4 with slow heating from 77 K to 298 K, platinum hexafluoride gives NO_2PtF_6 and $N_2O_3PtF_6$ respectively[73].

A study of the behaviour of the hexafluorides of osmium, iridium, ruthenium, and rhodium in redox reactions showed that OsF_6 and IrF_6 react vigorously with PF_3 with considerable liberation of heat to give mixtures of the metals, lower fluorides, and volatile PF_5.[74,75] In anhydrous HF at low temperatures, $Os(PF_3)_2F_4$ and IrF_4 were obtained, and for ruthenium the polymeric compound $[Ru(PF_3)_4]_n$ The hexafluorides OsF_6, IrF_6, and RuF_6 in anhydrous HF oxidise AsF_3 to AsF_5, forming adducts; Os is reduced to Os^V, and Ir and Ru to Ir^{IV} and Ru^{IV}. Unlike OsF_6, which does not react with SbF_3, iridium and ruthenium hexafluorides oxidise it at room temperature to SbF_5, and are converted mainly to the corresponding pentafluorides. Ruthenium hexafluoride oxidises BiF_3 to BiF_5 (this does not take place with OsF_6 and IrF_6) and oxidises ClF_3 to ClF_5, giving a mixture of $ClF_3.RuF_5$ and $ClF_5.RuF_5$.[75] The hexafluorides of osmium, iridium, and ruthenium react with CS_2 to give CF_4 and SF_4; and with hydrogen or the corresponding metal in anhydrous HF to give the pentafluorides; when heated to 370 K they are reduced by hydrogen in the presence of anhydrous HF to the metals[75]. RuF_6 also reacts with xenon[76]; with B_2O_3, ruthenium and iridium hexafluorides give the corresponding pentafluorides, and OsF_6 gives the oxide tetrafluoride $OsOF_4$.[77]

The few chemical reactions reported for RhF_6 do not make it possible to distinguish its oxidising power from that of RuF_6; however, since rhodium hexafluoride is thermally less stable than RuF_6,[6] it may be expected that it will be a stronger oxidising agent. Summarising all the above reactions, Burns and O'Donnell[75] arranged the hexafluorides in order of decreasing oxidising power: $RhF_6 > RuF_6 > IrF_6 > OsF_6$. This trend, which can be explained from thermodynamic data and an examination of the physical properties[6, 65,69,78,79], is confirmed by the data of other workers[74–77]. The oxidising power also increases in the transition metal sub-groups: $RuF_6 > OsF_6$; $RhF_6 > IrF_6$ (RhF_6 oxidises Xe,[76] but IrF_6 does not). PdF_6, prepared only recently, is also a very strong oxidising agent, apparently stronger than PtF_6 and RhF_6. Palladium hexafluoride is rapidly reduced on metal surfaces, and oxidises oxygen and xenon[21].

Platinum hexafluoride occupies a unique position, since it was used to synthesise the ionic compound $O_2^+PtF_6^-$ for the first time[80,81]. Bartlett, drawing attention to the similarity in the ionisation and potentials of xenon and oxygen, carried out the reaction of PtF_6 with Xe and obtained the yellow ionic solid $Xe^+PtF_6^-$, and discovered the chemistry of the noble gases[82]. Platinum hexafluoride reacts with KrF_2 at 273 K to give $KrF^+PtF_6^-$, whose Raman spectrum confirms its ionic structure[83]. The plutonium fluorides PuF_3 and PuF_4, when treated with PtF_6 below room temperature, are converted into PuF_6,[84] ClF_3 into ClF_5,[85] BrF_3 into BrF_5, and Np into NpF_6.[27] An infrared and NMR spectroscopic study of the solid product of the reaction of PtF_6 with $XeOF_4$ [86] showed that this reaction is accompanied by the formation of XeF_5^+, and the oxygen displaced from $XeOF_4$ is converted into O_2^+.

$OsCl_5$ was obtained for the first time by the reaction of OsF_6 with an excess of BCl_3 below room temperature[87]. The reaction of OsF_6 with liquid Br_2 gives solid $Br_2^+OsF_6^-$, and the dissolution of OsF_6 in liquid Cl_2 at 195 K gives a blue solution, from which a green solid of unknown composition separates on cooling[88].

The platinum metal hexafluorides are soluble in anhydrous HF; at 298 K the solubility of OsF_6 in hydrogen fluoride is 0.97 mole in 1000 g.[89]

An EPR study of the homogeneous recombination of fluorine atoms in OsF_6 and IrF_6 molecules at 293 K showed that the rate of recombination in these hexafluorides is the same as that of fluorine atoms in the MF_6 molecules for M = Os, Ir, and W.[90]

The reaction of volatile fluorides with graphite is now attracting considerable interest. Thus treatment of pyrolytic graphite with osmium and iridium hexafluorides gives the compounds $C_8^+OsF_6^-$ and $C_8^+IrF_6^-$, and the insertion of PtF_6 into graphite gives $C_{12}^{2+}PtF_6^{2-}$.[91] The electrical conductivity of the products of the insertion of OsF_6 and IrF_6 along the basal plane of graphite is a maximum for a composition of approximately $C_{24}MF_6$, for which it is 10 times that for the starting material; further insertion leads to a marked decrease in the electrical conductivity (the electrical conductivity of C_8MF_6 is comparable with that of the original graphite). This behaviour differs from that of graphite—AsF_5 systems, in which there is a steady increase in conductivity along the basal plane of graphite with increase in the AsF_5 concentration. The products of the insertion of PtF_6 into graphite are weakly conducting[91]. Examination of structural data and the physicochemical properties of platinum metal hexafluorides shows that they resemble to a considerable extent the hexafluorides of such metals as molybdenum, technetium, tungsten, and rhenium, they all form cubic crystals at room temperature, and orthorhombic crystals on cooling, with similar lattice parameters. The enthalpies of fusion and volatilisation have similar values (kJ $mole^{-1}$): 4.3 and 28.0 respectively for MoF_6; 4.5 and 30 for TcF_6; 4.1 and 25.9 for WF_6; and 4.5 and 28.3 for ReF_6.[16] All these hexafluorides have a regular octahedral configuration and approximately the same interatomic distances (from 1.82 Å in MoF_6 to 1.877 Å in RuF_6).

The main difference between the platinum metal hexafluorides and the corresponding compounds of molybdenum, technetium, tungsten, and rhenium is the higher reactivity of the former. This is revealed in the thermal instability of the platinum metal hexafluorides and in their more extensive hydrolysis (the platinum metal hexafluorides react with water to form the M^{IV} oxides, and MoF_6 and WF_6 give MoO_3 and WO_3 respectively). The platinum metal hexafluorides are also stronger oxidising agents than MoF_6, TcF_6, WF_6, and ReF_6; thus RuF_6, RhF_6, PtF_6, and PdF_6 oxidise even Xe, and platinum and palladium hexafluorides also oxidise oxygen.

2. Pentafluorides

The methods used to prepare the pentafluorides to a large extent are specific for each platinum metal. Pure ruthenium pentafluoride was first obtained by decomposing in a vacuum at 390 K the compound $RuBrF_8$, formed by the reaction of metallic ruthenium with BrF_3 at room temperature[92]. Ruthenium pentafluoride has also been synthesised by the direct fluorination of ruthenium powder with a mixture of F_2 and N_2 at 550–570 K,[93] by a mixture of HF and F_2 diluted with N_2,[94] and by fluorine at 470 K and a pressure of 4–5 atm in a nickel bomb[95].

The pentafluorides of ruthenium, osmium, and iridium have been obtained by the reaction of a solution of XeF_2 in anhydrous HF with $RuCl_3$ or RuO_2, or metallic Os or Ir.[96]

Rhodium pentafluoride is formed, together with RhF_6 and RhF_3, when rhodium wire burns in fluorine, and pure RhF_5 is obtained at a fluorine pressure of 6 atm and a temperature of 670 K.[97]

The reaction of $W(CO)_6$ with an excess of OsF_6 at 273 K gives a mixture of OsF_5, OsF_4, and Os, which can be separated by vacuum distillation (OsF_5 distils at 390 K).[67] Osmium pentafluoride is obtained by reducing OsF_6 with a solution of iodine in IF_5 [67,98] or by tungsten heated to a dull red heat[99].

IrF_5 and OsF_5 have been obtained in 100% yield by reducing IrF_6 and OsF_6 by hydrogen or Si powder in anhydrous HF at 298 K.[100–102] The rate of the process is increased when Pt gauze and ultraviolet irradiation are used. Iridium pentafluoride has been obtained[68] by heating a stoichiometric mixture of the elements in a Monel bomb; the bottom of the bomb was heated to 620–650 K, and yellow crystals of IrF_5 condensed on the lid of the reaction vessel.

**For crystalline RuF_4 at 298.15 K.

***At 915 K.[36]

The fluorination of spongy platinum or $PtCl_2$ by fluorine at 620 K gives PtF_5, which is readily separated from the more volatile O_2PtF_6 by vacuum distillation at 370 K.[80,103] The fluorination can be carried out under pressure[104].

The principal physical properties of the platinum metal pentafluorides are given in Table 6.

All the platinum metal pentafluorides form monoclinic crystals with the RuF_5 structure, space group $P2_1/c$, $Z = 8$. The unit cell parameters and densities of the crystalline platinum metal pentafluorides are given in Table 7.

X-Ray diffraction has shown that the structural unit of the platinum metal pentafluorides is an $(MF_5)_4$ tetramer with bridging F atoms in the *cis*-position. The metal has distorted octahedral coordination; each M atom is surrounded by six F atoms, but two *cis*-F atoms in the MF_6 group are joined to other M atoms. The average M–F distances for the terminal and bridging fluorine atoms are 1.81 Å and 2.01 Å respectively, and the MFM angle is 135°.[95,97,98,110,111] An analysis of the ^{19}F NMR spectra of the platinum metal pentafluorides in the temperature range 77–296 K confirmed that these compounds are polymeric[112].

Table 7. Structural characteristics and densities of the crystals of the platinum metal pentafluorides.

Calculated density of the crystal, kg m^{-3}	3920	4018	5570	5815

*Refinement of Ref. 110.

**According to Ref. 111, the lattice parameters of RhF_5 are: $a = 5.5173$, $b = 9.9177$, $c = 12.3376$ Å; $\beta = 100.42°$; density of the crystals 3950 kg m^{-3}.

The vapour pressure (p, mmHg) is described by the equations:

for RuF_5 (Ref. 94) $\lg p = 9.54 - 3329/T$ ($363.15 \leqslant T \leqslant 433.15$ K),
for OsF_5 (Ref. 106) $\lg p = 9.75 - 3429/T$ ($343.15 \leqslant T \leqslant 453.15$K).

The mass-spectrometric study of the composition of the saturated vapour of the platinum metal pentafluorides has shown[104,113,114] that close to room temperature, RuF_5, RhF_5, and IrF_5 form dimers, trimers, and tetramers, and OsF_5 and PtF_5 for dimers and trimers.

The vibrational frequencies of the two possible structural forms of the platinum metal pentafluorides, and the thermodynamic functions in the temperature range 298–3200 K, have been calculated[115]. The infrared spectrum of solid RuF_5, recorded in the range 400–1000 cm^{-1},[116] shows bands at 525, 645, 670, 715, and 750 cm^{-1}.

The chemical properties of the platinum metal pentafluorides have been less extensively studied. Ruthenium pentafluoride can be kept for a long time in nickel and quartz containers at room temperature, but begins to react slowly with Pyrex even at 370 K. When dissolved in water, RuF_5 is hydrolysed instantly to give a brownish–black solution and a precipitate of $RuO_2.nH_2O$; disproportionation also leads to the partial liberation of volatile RuO_4.[94] OsF_5 behaves similarly, forming $OsO_2.nH_2O$ and OsO_4 on hydrolysis[67]. Rhodium pentafluoride also reacts vigorously with H_2O, but the hydrolysis products could not be identified[97]. When PtF_5 is dissolved in water, PtO_2 is formed (25% of the total Pt), and the solution contains the rest of the platinum as the PtF_6^{2-} ion; in addition, O_2 is liberated[107].

The reaction of RuF_5 with CO in a flow system at 470 K gives a non-volatile solid product with the composition $Ru(CO)F_{3.5}$.[117] Iridium pentafluoride at 530–550 K reacts with CO to give a product with the composition $Ir(CO)_{2-3}F_2$.[118]

The reactions of molten XeF_2 with osmium and ruthenium pentafluorides give coloured crystalline adducts with the composition $XeF_2.OsF_5$, $XeF_2.RuF_5$, and $XeF_2.2RuF_5$.[119] The adducts $2XeF_2.MF_5$ and $XeF_2.MF_5$ (M = Ru, Os, Ir, Pt) and also $XeF_2.2MF_5$ (M = Ru, Ir, Pt) were obtained by the reaction of the corresponding platinum metal pentafluorides with a solution of XeF_2 in BrF_5.[120] Iridium pentafluoride forms adducts $2XeF_6.IrF_5$ and $XeF_6.IrF_5$.[121] The reaction of an equimolar mixture of Xe and PtF_5 with fluorine under pressure at a temperature of 450–490 K gave crystals of $XeF_5^+PtF_6^-$ and $Xe_2F_{11}^+PtF_6^-$.[109,122] A study of the crystal structure of these compounds[116,119–123] confirmed that they are ionic. The reaction of RuF_5 with KrF_2 in anhydrous HF also gives relatively stable adducts, as confirmed by the Raman spectra[124].

Osmium[106] and platinum[107] pentafluorides when heated disproportionate according to the equation

$$2MF_5 \rightarrow MF_4 + MF_6.$$

Platinum pentafluoride shows the properties of a relatively strong Lewis acid; it forms $NOPtF_6$ with NOF,[72] $2BrF_3.PtF_6$ with BrF_3, $2SeF_4.PtF_4$ with SeF_4, and $IF_5.PtF_5$ with IF_5.[107]

Comparison of the platinum metal pentafluorides with other known rare metal pentafluorides indicates that their properties are closer to those of the pentafluorides of molybdenum, niobium, and tantalum. The structural unit of all these pentafluorides is the tetramer $(MF_5)_4$, with bridging fluorine atoms in the *cis*-position and octahedral coordination of the metal. The average $M-F_{terminal}$ and $M-F_{bridging}$ distances in the tetramers of the pentafluorides of the platinum metals and molybdenum, niobium, or tantalum are similar; the values for the latter are 1.77 Å and 2.06 Å. These compounds are also polymerised in the gaseous state, and the platinum metal pentafluorides are also polymerised in the liquid state. The melting points and boiling points of MoF_5, NbF_5, and TaF_5 (340 and 487, 353.15 and 508, and 370.1 and 502 K respectively) and enthalpies of volatilisation (47.4, 51.0, and 54.3 kJ $mole^{-1}$) [16] are close to those for the platinum metal pentafluorides.

3. Tetrafluorides

All the platinum metals form tetrafluorides. The sandy-yellow RuF_4 is obtained by the reaction of an excess of RuF_5 with iodine in IF_5 [125] or by reducing RuF_5 with hydrogen in anhydrous HF.[75] The purple–red RhF_4 is obtained by the action of liquid BrF_3 on $RhBr_3$ or $RhCl_3$ with subsequent thermal decomposition of the adducts[126]. Red–brown PdF_4 has been synthesised by fluorinating PdF_3 with fluorine at a pressure of 7 atom and a temperature of 570–620 K.[127] Yellow–brown OsF_4 is formed, together with OsF_5, by the reaction of OsF_6 with $W(CO)_6$, and can be separated from the more volatile OsF_5 by vacuum distillation[67]. Osmium and iridium tetrafluorides are obtained by reducing their pentafluorides with hydrogen or powdered Si in anhydrous HF.[100,101] The rate of the process is increased by using Pt gauze or ultraviolet irradiation.

The reduction of IrF_6 using an electrically heated tungsten or iridium spiral in a Pyrex reaction vessel with walls cooled to 230 K gave red–brown IrF_4.[128] IrF_4 has also been synthesised by the reaction of IrF_6 with PF_3 in anhydrous HF.[74] Other reports of the synthesis of IrF_4 [25,129] have been refuted[68].

The action of an excess of BrF_3 on $PtCl_4$ or $PtBr_4$ at room temperature gives the adduct $(BrF_3)_2PtF_4$, which when heated in a vacuum to 450–470 K gives pale-brown PtF_4.[126] In this case, however, BrF_3 is not completely removed even by heating to 570 K, and further increase in temperature leads to decomposition of PtF_4. BrF_3 has been removed completely by treatment with fluorine at a low temperature[107]. The same paper described a method for preparing PtF_4 by heating $PtCl_2$ to 470–520 K in a stream of HF diluted with nitrogen. Platinum tetrafluoride is obtained by fluorinating spongy Pt and $PtCl_2$ with fluorine in a quartz apparatus at temperatures below 470 K.[103] The pure tetrafluoride is obtained by heating a $PtF_6 + PtF_x$ ($4 < x < 5$) mixture at 470 K for several hours and then removing the excess of fluorine in a vacuum[28].

There is almost no published information on the physical properties of the platinum metal tetrafluorides. RuF_4 does not melt up to 550 K.[125] OsF_4 melts at 403 K.[67] Iridium tetrafluoride begins to sublime at 450 K, and decompose at 670 K; the mass spectrum of IrF_4 showed that it is not associated in the vapour[128]. A thermodynamic study of gaseous PtF_4, formed by introducing fluorine into the effusion compartment of a mass spectrometer at 518–960 K, showed that for the reaction $Pt(solid) + 2F_2(gas) \rightleftharpoons PtF_4(gas)$ at 793 K, the change in the Gibbs free energy is −158 kJ $mole^{-1}$, and the enthalpy of formation of gaseous PtF_4 at 793 K is −214 kJ $mole^{-1}$.[130] A similar method in the temperature range 860–980 K using exchange reactions in the MnF_2–MnF_3–Pt system gave the enthalpy of formation of gaseous PtF_4. At 298 K, ΔH^0[form. $PtF_4(gas)$] = −410 ± 40 kJ $mole^{-1}$, and the dissociation energy $D^0(PtF_2-F_2)$ = 330 ± 40 kJ $mole^{-1}$.[131] The magnetic moments of RuF_4 [125] and RhF_4 [132] at 291 K are 3.04 B.M. and 1.1 B.M. respectively; PdF_4 and PtF_4 are diamagnetic[127,107].

An X-ray diffraction study of PdF_4, IrF_4, and PtF_4 [133] showed that they form monoclinic crystals, $Z = 8$, space group $Fdd2$ with lattice parameters $a = 9.35$, $b = 9.25$, $c = 5.84$ Å, $\beta = 90.7°$; $a = 9.61$, $b = 9.28$, $c = 5.71$ Å, $\beta = 92.0°$; $a = 9.64$, $b = 9.25$, $c = 5.67$ Å, $\beta = 92.7°$ respectively. A later and more accurate neutron diffraction study of PdF_4 [134] indicated that PdF_4 forms orthorhombic crystals ($Z = 8$, space group $Fdd2$, lattice parameters $a = 9.339$, $b = 9.240$, $c = 5.828$ Å) and is isostructural with IrF_4, previously studied by X-ray diffraction[133,135]. The Pd atom shows octahedral coordination; four F atoms are bridging (Pd–F distances 1.91 Å and 2.00 Å), and two are terminal, with the *cis*-arrangement (Pd–F distance 1.94 Å). The bridging angle PdFPd (134.0°) is close to the ideal value of 135° required for hexagonal closest packing of the octahedra. The ^{19}F NMR spectra of platinum and palladium tetrafluorides confirmed[136] that they show only octahedral coordination with non-equivalent F atoms. The crystal structure of RhF_4 has been studied[137]. The lattice parameters are $a = 9.71$, $b = 9.05$, $c = 5.63$ Å, $Z = 8$. According to Ref.133, RhF_4 is not isomorphous with PdF_4, PtF_4, and IrF_4, and the structure of RuF_4 is different from those of all the above tetrafluorides. The calculated densities of PdF_4 and PtF_4 crystals[16] are 4790 kg m^{-3} and 7070 kg m^{-3} respectively, and that of IrF_4 [133] is 7050 kg m^{-3}.

The vibrational frequencies of the platinum metal tetrafluorides have been calculated assuming T_d symmetry and M–F distances equal to those in the hexafluorides[115]. The experimentally determined vibrational frequencies in the infrared spectra of OsF_4 and IrF_4 are 719, 702, 660, 532 cm^{-1} and 691, 688, 545 cm^{-1} respectively[101]. According to Ref.74, the infrared spectrum of IrF_4 show bands at 685, 660, 609, 558, and 460 cm^{-1}.

The tetrafluorides of ruthenium[125], rhodium[126], and palladium[127] react vigorously with water to give $RuO_2.nH_2O$ and $RhO_2.nH_2O$ (the hydrolysis products of PdF_4 have not been identified). Osmium tetrafluoride dissolves in water to give a transparent yellow solution[67], and PtF_4 is hydrolysed slowly

to give a precipitate of PtO_2 and a solution containing the PtF_6^{2-} ion[107].

Rhodium tetrafluoride oxidises HCl to Cl_2; it does not react with ether or CCl_4 at room temperature[126]. Heating RhF_4 with an excess of SeF_4 gives $(RhF_4)_2SeF_4$.[138] The reaction of RhF_4 with CO gives $Rh(CO)_2F_3$, and the action of CO under pressure on PtF_4 gives the compound $Pt(CO)_2F_8$.[139]

Platinum tetrafluoride is reduced to the metal by hydrogen at 370 K, reacts with BrF_3 to give $(BrF_3)_2PtF_4$, and does not react with IF_5 and is insoluble in it. Evaporation of a solution of PtF_4 in SeF_4 in a vacuum gives $(SeF_3)_2PtF_6$.[107] Platinum tetrafluoride in acetone reacts at 273 K with a small quantity of H_2O, forming $H_2Pt(OH)_4F_2$, and with CH_3OH in acetone it forms the substance $PtF_2(OCH_3)_2$, which is explosive at 360 K.[140] Liquid XeF_2 at 410–420 K oxidised PtF_4, forming $Xe_2F_3PtF_6$.[141] A DTA study of the BrF_3–PtF_4 system detected the incongruently melting compounds $2BrF_3.PtF_4$ and $7BrF_3.PtF_4$.[142]

Palladium tetrafluoride is readily reduced to PdF_3, and decomposes to give the same compound when heated in a vacuum[127]. Compounds of different composition are formed by the reaction of PdF_4 with XeF_6 and XeF_2.[133,141]

4. Trifluorides

Brown RuF_3 has been obtained by reducing ruthenium pentafluoride with an excess of iodine at 420 K or with sulphur at 470 K.[143] Red RhF_3, contaminated by metallic rhodium, was first obtained by fluorinating rhodium or $RhCl_3$ with fluorine at a dull red heat (below 770 K).[144,145] Pure RhF_3 was synthesised by the reaction of RhI_3 with fluorine at 670–770 K.[146] Iridium trifluoride (black) was obtained by reducing IrF_6 with metallic iridium[146].

The physical characteristics of the platinum metal trifluorides have not been studied. An X-ray diffraction study of RuF_3, RhF_3, and IrF_3 [146] showed that they form orthorhombic crystals with the VF_3 structure, space group $R\bar{3}c$, $Z = 2$. The orthorhombic cell corresponds to a hexagonal pseudo-cell. The structural characteristics and densities of the crystalline platinum metal trifluorides are given in Table 8.

Table 8. Structural characteristics and densities of the crystals of the platinum metal trifluorides[146].

Trifluoride	Lattice parameters, Å, and angle F–M–F, °			Calculated density of the crystals, kg m^{-3}
	bimolecular rhombohedral cell	hexagonal cell, $Z = 6$	monomolecular rhombohedral cell	
RuF_3	a 5.408±0.001; α 54.67±0.01	a 4.967, c 13.756	a 3.672, α 85.13	5350 *
RhF_3	a 5.330±0.001; α 54.42±0.01	a 4.874, c 13.579	a 3.611, α 84.89	5690 *
IrF_3	a 5.418±0.002; α 54.13±0.03	a 4.940, c 13.819	a 3.666, α 84.72	8520

*Calculated in Ref. 12.

There are almost no published data on the chemical properties of the platinum metal trifluorides. RuF_3 is hydrolysed in water, but insoluble in it; it is also insoluble in dilute acids or alkalis[143]. When heated in a stream of fluorine, RuF_3 gives RuF_5.[147] Rhodium trifluoride is not hygroscopic, insoluble in water, and almost unaffected by hot concentrated HCl, HNO_3, HF (40%), or NaOH. When heated, it is reduced exothermally by H_2, NH_3, SO_2, P, Si, Fe, Al, Na, and Mg.[144,145]

Palladium trifluoride has been obtained by dissolving $PdBr_2$ or PdI_2 in bromine trifluoride, followed by thermal decomposition in a vacuum of the resulting adduct $PdF_3.BrF_3$,[126] or by fluorinating metallic palladium and its halides with fluorine[146]. Its magnetic properties were explained by assuming that this substance does not contain Pd^{III} but is $Pd^{2+}Pd^{4+}F_6$, whose effective magnetic moment (2.88 B.M.) corresponds to the moment of the d^8 configuration of Pd^{2+}.[127]

Measurements of the enthalpy of the reaction $PdPdF_6$(solid) + $3PF_3$(gas) = $3PF_5$(gas) + 2Pd in a bomb calorimeter gave ΔH^0(form.$PdPdF_6$(solid) 298.15 K) = −967.4 ± 7.3 kJ mole^{-1}.[148]

$PdPdF_6$ forms rhombohedral crystals, space group $R\bar{3}c$, $Z = 2$, with lattice parameters: $a = 5.5234 \pm 0.0005$ Å, $\alpha = 53.925 \pm 0.005°$. The calculated and measured densities of PdF_3 are 5315 kg m^{-3} and 5060 kg m^{-3} respectively. The structure of $PdPdF_6$ is related to the $LiSbF_6$ structure, and contains Pd^{II} and Pd^{IV} atoms surrounded octahedrally by F atoms (Pd^{II}–F distance 2.17 Å, Pd^{IV}–F distance 1.90 Å).[146,149]

A study of the influence of high pressure (up to 9×10^4 atm) on the properties of $PdPdF_6$ showed[150,151] that with increase in pressure there is a marked increase in the electrical conductivity, probably due to the electron transfer $Pd^{2+} + Pd^{4+} \rightarrow Pd^{3+}$. At 410–420 K, $PdPdF_6$ is oxidised by liquid XeF_2 to $XePdF_6$.[141]

A study of the reaction of Pt powder with fluorine at different temperatures established[152] that at 670–720 K the product is the fluoride $Pt^{2+}Pt^{4+}F_6$, which at 570–620 K is present in a mixture with PtF_4. The yellow hygroscopic $PtPtF_6$ powder decomposes to the elements at 460 K. The rhombohedral lattice parameters have been determined by X-ray diffraction: $a = 5.56$ Å, $\alpha = 53.85°$, space group $R\bar{3}$, density of the crystals (calculated) 7977 kg m^{-3}, $LiSbF_6$ structure.

5. Dichlorides

Only palladium difluoride is known and has been reliably characterised. Heating $BrF_3.PdF_3$ with SeF_4 gives $(SeF_3)_2.PdF_6$, which at 430 K decomposes rapidly to pale-violet PdF_2.[153,154] It can also be obtained by the direct reduction of $PdPdF_6$ with boiling SeF_4.[154] Fluorination of Pd powder gives a mixture of Pd and PdF_2, further treatment of which with fluorine at 770–1020 K gives PdF_2.[155]

Palladium difluoride crystallises with the tetragonal rutile structure, space group $P4_2/mnm$, $a = 4.956$ Å, $c = 3.389$ Å, $Z = 2$,[153,156] density of the crystals (calculated) 5760 kg m^{-3}.[16] At a pressure of 6×10^4 atm and 720 K in an argon atmosphere, the product is the violet–brown cubic form of PdF_2 (space group $Pa3$, $CdPdF_4$ structure, $a = 5.32$ Å), which is metastable at normal pressure[157]. PdF_2 obtained by the solid-phase reaction of a stoichiometric mixture of $PdPdF_6$ and dispersed Pd in an evacuated Pd tube at 870 K and a pressure of up to 9×10^4 atm undergoes a polymorphic transformation to give a phase isostructural with fluorite[151,158]. The electrical conductivity increases sharply (by a factor of 10^5).

Palladium difluoride is rapidly hydrolysed in moist air, and is decomposed exothermally by water[153].

ΔH^0[form. 198.15 K, PtF_2(gas)] = −80 ± 42 kJ mole^{-1}, and the dissociation energy $D^0(Pt–F_2)$ = 644 ± 42 kJ mole^{-1}.[130,131]

III. PLATINUM METAL OXIDE FLUORIDES

The platinum metals can form various oxide fluorides (Table 9), but these are known for only three metals—OsO_3F_2, OsO_2F_3, $OsOF_5$, $OsOF_4$, $RuOF_4$, and $PtOF_3$. The hypothetical $PtOF_4$ [101] was found to be O_2PtF_6.[80]

Orange OsO_3F_2 powder was first obtained by the reaction of Os with a mixture of F_2 and O_2 (2 : 1).[159] OsO_3F_2 has also been synthesised by heating a mixture of F_2 and OsO_4 (2 : 1, 570 K, 50 h).[70] OsO_3F_2 melts at 443–446 K.[79,159] The magnetic susceptibility and mass spectra of OsO_3F_2 have been recorded[160]. The principal vibrational frequencies in the infrared and Raman spectra of matrix-isolated OsO_3F_2 have been determined and assigned[161]: $\nu_1(A_1') = 946.5$, $\nu_2(E') = 928.5$, $\nu_3(A_2'') = 646$, $\nu_4(A_1') = 619$, $\nu_5(E'') = 348$, $\nu_6(E') = 316.5$, $\nu_7(A_2'') = 258$, and $\nu_8(E') = 206$ cm^{-1}. OsO_3F_2 has D_{3h} symmetry. The force constants of OsO_3F_2 have been calculated in a Urey–Bradley force field[162]. The thermodynamic functions of gaseous OsO_3F_2 in the temperature range 298–6000 K have been calculated in the rigid rotator–harmonic oscillator approximation[163]. The values of the heat capacity (C_p^0) and S^0, calculated at 298.15 K, are 96.631 J mole^{-1} K^{-1} and 327.18 J mole^{-1} K^{-1} respectively.

Table 9. Platinum metal oxide fluorides.

Oxidation state of the metal			
M (VIII)	M (VII)	M (VI)	M (V)
MO_3F_2	(MO_3F)	(MO_2F_2)	(MO_2F)
(MO_2F_4)	MO_2F_3	MOF_4	MOF_3
—	MOF_5	—	—

Note. Compounds whose existence is assumed are given in bracket.

Of the chemical properties of OsO_3F_2 it is known that it does not decompose on Pyrex, but is rapidly hydrolysed in the presence of moisture to OsO_4 and HF.[159]

Yellow-green OsO_2F_3 has been synthesised from an equimolar mixture of OsO_4 and OsF_6 (420 K, 17 h), and also from $OsOF_4$ and OsO_3F_2 (370 K, 12 h).[70,160] The magnetic susceptibility, mass spectrum, and EPR and Raman spectra of OsO_2F_3 have been recorded, and the vibrational frequencies assigned[160]. Solid OsO_2F_3 is polymeric, and probably has a structure containing tetrameric groups in which Os atoms with formal charges of 6+ and 8+ are joined by F-bridges.

OsO_2F_3 is sensitive to moisture, and is comparatively stable at room temperature, but it disproportionates at 330 to 350 K to give a mixture of $OsOF_4$ and OsO_3F_2; above 380 K, the equilibrium mixture also contains OsF_6 and OsO_4.[160]

The most fully studied platinum metal oxide fluoride is the emerald-green osmium oxide pentafluoride. It was obtained by heating Os in a stream of a mixture of O_2 and F_2 (1 : 2 by volume), and also by passing F_2, diluted with N_2, over OsO_2 and by heating Os in a Monel bomb with a mixture of O_2 and F_2 (1.0 : 2.5) at 570 K.[164,165] In all cases the product was a mixture of $OsOF_5$ (yield ~ 50%) and OsF_6, from which the more volatile OsF_6 was removed by vacuum distillation. $OsOF_5$ was obtained in more than 90% yield by the action of a slight excess of F_2 on anhydrous OsO_2 at 520 K.[165] $OsOF_5$ has also been synthesised by treating Os, placed in the atomic fluorine generation zone, with a mixture of O_2 and F_2 (1 : 3 by volume).[166]

The physical properties of $OsOF_5$ are given in Table 10.

The X-ray diffraction study of $OsOF_5$ [164,165,168] has shown that below 306 K it has the orthorhombic YF_3 structure, space group *Pnma*, $Z = 4$, density of the crystals (calculated) 4820 kg m^{-3}, lattice parameters $a = 9.540$, $b = 8.669$, $c = 5.019$ Å; above 306 K it is converted into a cubic form, $Z = 2$, $a = 6.14$ Å. Comparison of the structural data for $OsOF_5$ and the platinum metal hexafluorides (see Table 2) shows that they are isostructural. The fact that all the bonds formed by Os with neighbouring atoms in $OsOF_5$ are shorter than the Os–F bonds in the OsF_6 molecule (1.831 Å) is apparently due to the greater polarisation by Os in the first case[168].

Table 10. Physical properties of $OsOF_5$.[165]

Property	Value
M.p., K	332.35
B.p., K	373.75
$T_{p.t.}$, K	305.65
ΔH^0_{fusion}, kJ mole^{-1}	6.8
$\Delta H^0_{volatilisation}$, kJ mole^{-1}	36.6

$\Delta S^0_{volatilisation}$, J mole^{-1} K^{-1}	98
C_p^0 for the gas at 298.15 K, J mole^{-1} K^{-1}	118 *
S^0 for the gas at 298.15 K, J mole^{-1} K^{-1}	356 *
Magnetic moment μ, B.M.	1.47

*According to Ref. 167.

The $OsOF_5$ molecule has a slightly distorted octahedral structure with interatomic distances $r(Os–O) = 1.74$, $r(Os–F_{ax}) = 1.76$, and $r(Os–F_{eq}) = 1.80$ Å. The thermodynamic properties of $OsOF_5$ are also close to those of the platinum metal hexafluorides (Tables 1 and 10).

The vapour pressure (p, mmHg) of $OsOF_5$ is given by the equations[165]:

$$\lg p = 9.064 - 2266/T \quad (305 \leqslant T \leqslant 332\text{K}),$$
$$\lg p = 7.994 - 1911/T \quad (332 \leqslant T \leqslant 378\text{K}).$$

The infrared, Raman, and ^{19}F NMR spectra indicate that the $OsOF_5$ molecule belongs to the symmetry group C_{4v} [165,166,169,170]. The frequencies required for this configuration have been determined for gaseous $OsOF_5$: 962.6, 716.4, 644, 280.5, 645, 210, 332, 700.6, 263, 367, and 167 cm^{-1}.[170] The presence in the infrared spectrum of solid $OsOF_5$ of a band at 530 cm^{-1}, characteristic of the vibration of the Os–F–Os bridging bond, indicates that $OsOF_5$ is polymerised in the solid state[166]. The ^{19}F NMR spectrum indicates that the non-bonded *d* electrons are localised in the equatorial plane of the molecule[169].

$OsOF_5$ is stable in dry air, but decomposes in the presence of moisture to give OsO_4.[164] The oxidising properties of $OsOF_5$ are similar to those of OsF_6, but the former is a much weaker F^- acceptor[59].

Osmium oxide tetrafluoride was obtained by reducing $OsOF_5$ on an electrically heated tungsten wire[171] or by the reaction of OsF_6 with OsO_4 (2.5 : 1.0) at 450 K.[70] A general method for the synthesis of transition metal oxide fluorides, including $OsOF_4$, has been described, based on the exchange reaction of the corresponding hexafluorides with finely divided B_2O_3. A convenient method for synthesising $OsOF_4$ involves the hydrolysis of OsF_6 in hydrogen fluoride with an accurately measured quantity of H_2O.[71] $OsOF_4$ can be obtained by reducing $OsOF_5$ with finely dispersed Si powder in anhydrous HF.[166] The last two methods of obtaining $OsOF_4$ are preferred, since they do not require additional operations to remove the OsF_5 which usually accompanies it.

The orthorhombic lattice parameters of $OsOF_4$ [171] are $a = 5.56$, $b = 9.56$, $c = 12.83$ Å, the density of the crystals (measured) 5500 kg m^{-3}, $Z = 8$, space group $P2_122_1$.

The infrared spectrum of crystalline $OsOF_4$ has been studied[77,166]. According to Ref.166, the spectrum contains bands at 1010, 958, 707, 672, 649, and 535 cm^{-1}. The 1010 cm^{-1} band was assigned to the Os=O stretch, and the bands at 600–750 cm^{-1} to bridging Os–F–Os stretches. These bands in the range 500–600 cm^{-1} are characteristic of other transition metal oxide tetrafluorides and oxide pentafluorides[172], and indicate that they have a polymeric structure, in agreement with X-ray diffraction[171] and Raman spectroscopic[160] data. An electron diffraction study of $OsOF_4$ [166] showed best agreement with an equilibrium configuration with symmetry C_{4v} (a tetragonal pyramid with the oxygen atom in the axial position), previously established for $ReOF_4$ and WOF_4.[173] The existence of the four-fold axis in the $OsOF_4$ molecule was confirmed by photoelectron spectroscopy[174]. Analysis of the photoelectron spectra of the oxide tetrafluorides of tungsten, rhenium, and osmium shows an increase in the ionic character of the M–F bond in this order, and indicates that the multiplicity of the M–O bond must be close to 3, since the covalent bonding involves not 2 but 3 electron pairs, $(5a_1)^2$, $(5e)^4$. The last conclusion is confirmed by the results of electron diffraction studies[166] [r(Os–O) = 1.625, r(Os–F) = 1.835, r(O–F) = 2.825, r(F–F) = 2.466 Å], from which it follows that the Os–O bond in $OsOF_4$ is 0.115 Å shorter than the Os–O bond in $OsOF_5$. $OsOF_4$ is extremely sensitive to moisture, and dissolves in water and alkali solutions to give transparent yellow solutions with an odour of ozone (OsO_4 is apparently liberated)[77]. The fluorination of $OsOF_4$ at 450 K gives $OsOF_5$,[70] and heating an equimolar mixture of $OsOF_4$ and OsO_3F_2 at 370 K gives OsO_2F_3.[160]

The preparation of $RuOF_4$ by the reaction of metallic Ru with a mixture of BrF_3 and Br_2 (1 : 1) at room temperature has been described[94]. The source of oxygen was the wall of the reaction vessel. When the reaction was complete, BrF_3 was removed in a vacuum at 390 K, and the residue was heated in a sealed evacuated glass tube for 3–5 weeks at 310 K. According to Ref.94, $RuOF_4$ is a colourless substance, coloured pale green by impurities, which melts at 388 K, boils at 457 K, and has a heat of volatilisation of 50 kJ $mole^{-1}$. The vapour pressure (p, mmHg) is given by the equations

$$\text{for } RuOF_4\ [94]\ \lg p = 9.22 - 2857/T\ (293 \leqslant T \leqslant 373\text{K})$$
$$\lg p = 8.60 - 2616/T\ (393 \leqslant T \leqslant 433\text{K}).$$

Japanese workers who studied the behaviour of ruthenium during the sublimation of the fluorides to solve the problems of processing irradiated nuclear fuel[175–178] consider that the data in Ref.94 are erroneous, for the following reasons: 1) a stoichiometric reaction component ratio with respect to oxygen was not observed; 2) the presence of oxygen in the final products was not confirmed, and 3) the components of the gas phase were not analysed before the vapour pressure was measured. A study of the kinetics of the reaction of RuO_2 with fluorine in a flow reactor in the range 523–773 K at a fluorine partial pressure of 150 mmHg [175] showed that at temperatures above 670 K, RuO_2 is completely converted to $RuOF_4$, whose formation was confirmed by chemical analysis and from the mass and infrared spectra. The thermal decomposition of $RuOF_4$ was studied[176] by gas chromatography at 290–670 K, combined with chemical analysis and an infrared spectroscopic study of the solid residue and measurement of the vapour pressure by a transpiration method. Solid $RuOF_4$ decomposes to give O_2 and solid RuF_4, and the process takes place even at 293 K. With increase in temperature to 340 K, the decomposition rate increases to a maximum, and with further increase in temperature it decreases, although a small quantity of O_2 is liberated even at 670 K.

The authors cited[176] consider that the static method of measuring the vapour pressure of $RuOF_4$, used in Ref.94, is not suitable, because of errors associated with the liberation of oxygen. Moreover, at temperatures above 340 K, the RuF_4 formed prevents the normal volatilisation of $RuOF_4$. According to Ref.176, the equilibrium vapour pressure of $RuOF_4$ in the range 273–343 K is described by the equation $\lg p$ (mmHg) = 8.48 – 2740/T. It is pointed out that $RuOF_4$ vapour is stable, and that the instability of solid $RuOF_4$ is apparently related to the fact that the Ru^{VI} corresponds to an excited state. The bands at 1040 cm^{-1} and 720 cm^{-1} in the infrared spectrum of gaseous $RuOF_4$ were assigned to the Ru=O and Ru–F vibrations respectively. The spectrum of solid $RuOF_4$ does not show a band at 1040 cm^{-1}, but shows bands at 720, 630, and 520 cm^{-1}. The first of these was assigned to Ru–F stretches, the second to single bond Ru–O stretches, and the last to bridging Ru–F–Ru vibrations.

The fluorination of Ru with a mixture of F_2 and O_2 at 570–670 K gives RuF_5 (76–84%), $RuOF_4$ (16–24%), and small quantities of RuO_4.[178] These results differ from earlier data[19,179], and require confirmation.

Mass spectrometry, infrared spectroscopy, DTA, and TGA have established that at room temperature, a series of reactions involving the hydrolysis of $RuOF_4$, RuF_4, and RuF_5 followed by treatment of the hydrolysis products (mainly ruthenium hydroxides) with gaseous fluorine is accompanied by their almost complete conversion into RuO_4:[177]

$$Ru(OH)_4 \cdot n H_2O + (2+n) F_2 \rightarrow RuO_4 + 2(2+n) HF + n/2O_2.$$

Platinum oxide fluoride has been obtained by fluorinating PtO_2 at 470 K; it is nonvolatile, is slowly hydrolysed in moist air, and its behaviour towards water is the same as that of PtF_4.[107]

IV. DIOXYGENYL COMPOUNDS OF THE PLATINUM METALS

Dioxygenyl hexafluoroplatinate O_2PtF_6 was first obtained[103] by fluorinating spongy platinum or $PtCl_2$ at 620 K in a quartz apparatus, but was erroneously assumed to be $PtOF_4$. The true composition of the compound was determined soon afterwards[80].

Methods for preparing O_2PtF_6 have been described[81]. They include fluorination in quartz, the action of a mixture of F_2 and O_2 on Pt at 720 K, the reaction of OF_2 with Pt above 670 K, and the reaction of equimolar quantities of PtF_6 and O_2 at room temperature. The compounds O_2RuF_6 and O_2RhF_6 were obtained by heating the corresponding powdered metal with a mixture of F_2 and O_2 (3 : 1 and 4 : 1) for a long time (up to 60 h) at 570–770 K.[180] The fluorination of oxides of Ru, Rh, and Pt by atomic fluorine also gives dioxygenyl compounds[30]. According to Ref.21, the reaction of PdF_6 with O_2 gives an orange compound, apparently O_2PdF_6.

An X-ray diffraction study of O_2PtF_6 [80,81] showed that it forms cubic or orthorhombic crystals. The high-temperature cubic form, obtained by the reaction of OF_2 with Pt at a temperature above 673 K, has lattice parameter a = 10.032 ± 0.002 Å, space group $Ia3$, Z = 8, and calculated and measured densities 4480 kg m^{-3} and 4200 kg m^{-3} respectively. For the low-temperature orthorhombic form, obtained by the reaction of PtF_6 with O_2 in liquid N_2, a = 4.96 Å, α = 97.5°, density 4725 kg m^{-3}. For the cubic O_2RuF_6 lattice, a = 10.004 Å, and for rhombohedral O_2RhF_6, a = 5.05 Å, α = 97°.[180]

The chemical properties and infrared and ultraviolet absorption spectra indicate that dioxygenyl hexafluoroplatinate has an ionic structure. The lattice energy of $O_2^+PtF_6^-$ is about 500 kJ $mole^{-1}$. The composition of the compounds O_2MF_6 (M = Ru, Rh, Pt) was confirmed by the Raman and mass spectra[180,181].

O_2PtF_6 reacts vigorously with H_2O to give a pale-yellow solution containing PtF_6^{2-} ions and a black solid residue containing metallic platinum, with the liberation of oxygen and a gas with the odour of ozone[81]. The hydrolysis of O_2PtF_6 and O_2RuF_6 in 40% NaOH takes place according to the equation[182]:

$$O_2MF_6 + 2OH^- \rightarrow 1.5O_2 + MF_6^{3-} + H_2O.$$

O_2PtF_6 reacts with BrF_3, SeF_4, IF_5, and ClF_3 at room temperature to form various adducts[81]. The reaction of O_2RuF_6 at 298 K and of O_2RhF_6 and O_2PtF_6 at 379 K with an excess of NOF gives the nitrosyl compounds $NORuF_6$, $(NO)_2RhF_6$, and $(NO)_2PtF_6$.[72]

V. SUMMARY

The chemistry of the platinum metal fluorides has developed rapidly in the last 25 years. Discoveries such as the synthesis of O_2PtF_6 and $XePtF_6$ have been among the most significant in inorganic chemistry in recent decades. Nevertheless, the physicochemical properties and methods of synthesis of the platinum metal fluorides examined in the present review show that there are many "blank spots" in this field.

The most important task is still the development of simple and reliable methods for preparing platinum metal fluorides of sufficient purity. Existing methods are complicated by the fact that the isolation of individual substances requires a large number of additional operations to separate the compounds formed. High demands are also made of the purity of the starting materials, since for example traces of oxygen in the metal or fluorine leads to contamination of the hexafluorides with oxide fluorides[37]. Here, promising methods involve the use of solutions of KrF_2 and XeF_2 in anhydrous hydrogen fluoride, the use of atomic fluorine[29,30,96], and the use of selective sorption and selective reduction.

The lower fluorides of the platinum metals have been very little studied, and there are practically no data on their structure and chemical and thermal properties.

The most important problems in the field of platinum metal fluorides include the determination of the thermodynamic parameters, the lack of which makes it difficult to solve problems associated with the application of the platinum metal fluorides.

From the practical viewpoint, the platinum metal fluorides are of interest because of their high volatility and the consequent possibility of their use in processes of fluoride metallurgy[183,184]. This technology in principle has all the advantages of non-aqueous methods, and can simplify the existing multi-stage schemes for separating and purifying the platinum metals. The demand and the price of the platinum metals continue to increase[185], so that a change to short technological schemes and the associated marked decrease in losses are undoubtedly justified.

Fluorination may also prove extremely promising for the analysis of the platinum metals, which are difficult to dissolve quantitatively.

The present review has not examined the large number of complex fluorides of the platinum metals, which are also interesting materials for scientific study and which may find practical application, for example for the separation and purification of the platinum metals.

Metal-containing Monomers: Advances in Polymerisation and Copolymerisation

A.D.Pomogailo and V.S.Savost'yanov

The main advances in and problems of polymerisation, copolymerisation, as well as graft polymerisation of metal-containing monomers (MCM) are analysed. These are classified in terms of the type of bond between the metal and the organic component of the molecule into three principal groups, namely MCM with σ-, $n\nu$-, and π-bonded metal, are analysed. Attention is concentrated on the influence of the nature of the metal (both transition and non-transition) on the polymerisation process and on the properties of the products. A systematic account is given of the principal data for the polycondensation of metal-containing compounds. The applications of the metal polymer synthesised are considered.
The bibliography includes 215 references.

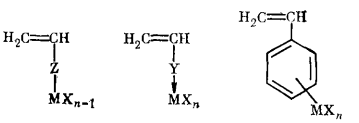
I. INTRODUCTION



Metal-containing polymers have found extensive applications in recent years in the preparation of various coatings with special properties, catalysts, as thermoplastic constructional materials, etc. At the same time clearly inadequate attention has been devoted to problems of the synthesis of metal-containing monomers (MCM) and the characteristic features of their polymerisation, copolymerisation, and graft polymerisation. Only ferrocene and certain other metallocene compounds are perhaps exceptions in this respect[1]. Although the first publications of the radical polymerisation of vinylferrocene date back to as early as 1955,[2] subsequently attention was concentrated on coordination polymers[3]; studies on the polymerisation of MCM developed more slowly, primarily owing to the difficulty of the synthesis of such MCM and also the specific features of their polymerisation and copolymerisation. The presence of metal atoms in molecules of this class leads to the formation of coordinate bonds in the polymerisation process and a redistribution of electron density at the growing centre, which has a significant influence on the polymerisation mechanism.

In recent years there has been an appreciable growth of interest in the polymerisation of MCM. Three international specialist symposia, devoted to the polymerisation of MCM and the study of the properties of organometallic polymers, have already been held in the USA.[4,5] Much attention has been devoted to these problems in the USSR in the investigations of Nesmeyanov and co-workers[6], Korshak and co-workers[7,8], Kabanov and co-workers[9], and certain others[10,38].

In the present review an attempt has been made to summarise the available data on the characteristic features of the polymerisation of MCM, to analyse the present state of the problem of the influence of the nature of the metal on the character of the polymerisation of such monomers, to discuss the advantages and disadvantages of the methods employed, and also to outline the most rational ways of developing this field. Attention has been concentrated on the MCM based on transition metals. As regards MCM based on non-transition metals, mention will be made of studies in which hypotheses have been developed or quantitative data are presented concerning the influence of the nature of the metal on the polymerisation or copolymerisation mechanism.

II. CLASSIFICATION AND PRINCIPAL SYNTHESES OF METAL-CONTAINING MONOMERS

In the literature there is at yet no clear-cut system of classification and nomenclature for MCM. In principle, one can employ for them the classification for traditional monomers based on the type of chain formed, the nature of multiple bonds, etc. as well as the classification based on the consideration of MCM as salts or other derivatives of the corresponding metal. However, such approaches do not reflect the specific features of the MCM and the corresponding terminology is cumbersome. From our point of view, the classification of MCM based on the type of bond between the metal and the organic component of the molecule is most convenient and yields the maximum amount of information about their structure. In terms of this principle, MCM can be divided into three main types: MCM with a covalently bonded (σ-bonded), coordinated ($n\nu$-bonded), and π-bonded metal atom, which can be illustrated by the most characteristic examples:

Here M is the metal atom, X the ligand, and Z and Y are functional groups. The first two types of MCM are characteristic of both non-transition and transition metals and the third is characteristic only of MCM incorporating Group VIA, VIIA, and VIII metals. We may note that only those π-bonded MCM in which there is a multiple bond not coordinated to the metal, in contrast to the usual fairly numerous π-complexes[11], possess the capacity for polymerisation. Metallocenes with a covalent bond between the transition metal atom and the unsaturated group have been classified as σ-bonded MCM. The type of bond has a marked influence

both on the stability of MCM and on their behaviour in polymerisation and copolymerisation processes.

The character of the polymerisation not only of organometallic monomers—compounds containing a metal–carbon bond (which is characteristic mainly of MCM of the third type)—but also a wider group of MCM incorporating metal–oxygen, metal–nitrogen, metal–phosphorus, etc. bonds is analysed in this review. The characteristic features of the polymerisation and copolymerisation of monomers incorporating both non-transition and transition metals are examined in succession for the MCM of the first and second types; as a rule, the order in which they are considered corresponds to the position of the given elements in the Periodic System.

The commonest methods of synthesis of MCM with a σ-bond involve the interaction of metal hydroxides or oxides with unsaturated acids, treatment of transition metal compounds with unsaturated alcohols, acids, and amines (see, for example, Feld and Cowe[12]), transesterification of metalloesters with an unsaturated alcohol or acid, reactions of MX_n with enolisable aldehydes or ketones, etc. Organometallic monomers are synthesised by methods involving the use of Grignard reagents containing multiple bonds in the hydrocarbon residue. We may note that methods of synthesis of MCM with a σ-bond have now been developed for almost all metals. Their stability depends both on the nature of the metal and on the structure of the MCM, procedures for the stabilisation of such compounds being known[174]. On the other hand, in contrast to MCM incorporating groups of the vinyl, allyl, and acetylene types, there are almost no literature data on MCM incorporating a metal σ-bonded to diene or allene groups.

The synthesis of MCM with a coordinate bond is based on the formation of donor–acceptor complexes of the compounds MX_n with monomers containing, apart from a multiple bond, also groups or atoms with an unshared electron pair. In terms of the nature of the coordinate bond, such MCM can be divided into compounds with nitrogen-containing ligands (vinylpyridines, vinylcarbazole, vinylimidazole, vinylbenzimidazole, vinylbenzotriazole, allyl- and diallyl-amines, acrylonitrile, etc.), oxygen-containing ligands (methyl methacrylate, methyl acrylate, vinyl acetate, methyl vinyl ketone, vinylpyrrolidone, allyl alcohol, etc.), phosphorus-containing ligands (dialkyl- and diphenyl-styrylphosphines, vinylphosphonic acids, esters, etc.), and sulphur-containing ligands (diallyl sulphide, etc.). The range of the coordination interaction energies is fairly wide and is determined by the nature of the reacting components[13]. The study of the characteristics of the formation of such MCM showed that their composition and structure do not as a rule differ from those of coordination compounds with the usual ligands. Although the donor–acceptor interaction leads to a redistribution of the electron densities of all the bonds of the monomer, a multiple bond does not usually undergo significant changes.

As regards the synthesis of MCM incorporating a π-bonded transition metal, two main methods have come to be widely used: (a) the introduction (via a series of consecutive reactions) of a vinyl, allyl, or acrylate group into the cyclopentadienyl or benzene ring; (b) the addition of MX_n to traditional monomers (for example, to styrene and its derivatives). In terms of the number of groups capable of polymerisation, the π-bonded MCM obtained can be both monosubstituted and disubstituted[4,14].

Among the non-traditional methods for the synthesis of MCM developed successfully at the present time, we may mention interesting syntheses of π-bonded MCM using the "bare" atom procedure[15]—the MCM are formed on interaction of vapours consisting of transition metal atoms at low temperatures with vinyl monomers. π-Bonded organometallic monomers, incorporating low-valence transition metal atoms, have been obtained[16] by the reductive substitution of MX_n in the presence of non-metallated monomers (for example, dienes). Metal-containing monomers of the nν- and π-types can be obtained, in principle, by a method based on the oxidative dissolution of the metals in the presence of the corresponding monomers[17]. The procedures indicated have extensive potential synthetic possibilities and their realisation will apparently make it possible to obtain a whole series of hitherto unknown MCM.

One may expect the appearance of new types of MCM, for example, those containing cyclic groups of the type of epoxy-groups, which are known at the present time for ferrocene derivatives[18] and organotin compounds[19]. The possibility of synthesising MCM with a polyfunctional type of bonding of the metal as well as polymetallic MCM appears to be promising.

Much less attention has been devoted to problems of the structure of MCM and problems of the stabilisation and destabilisation of their multiple bonds than to the synthetic aspects; however, the reactivities of multiple bonds and the methods for their activation are of outstanding interest for the polymerisation and copolymerisation of MCM.

III. HOMOPOLYMERISATION OF METAL-CONTAINING MONOMERS

MCM are polymerised (except in special cases) under the influence of a wide variety of initiators and are as a rule characterised by the same elementary steps as the polymerisation of traditional monomers. The differences are quantitative rather than qualitative. On the other hand, in an MCM–initiator system (the type of initiation can be various—radical or ionic or can involve the use of metal-complex Ziegler–Natta catalysts), the monomer can undergo reactions which are undesirable from the standpoint of the polymerisation process and can also influence significantly the active polymerisation centre.

1. Polymerisation of MCM with a σ-Bond

There are at present no publications devoted to the homopolymerisation and copolymerisation of MCM in which the vinyl group is linked directly to the metal, although such studies would be of great interest: they would be useful for the elucidation of problems concerning the influence of the metal atom on the vinyl centre, the stabilisation or destabilisation of the metal–carbon bond of the MCM in the polymer chain, etc. It may be that the difficulties are due to the elimination of a metal hydride in the polymerisation process[1]:

$$X_{n-1}M{-}CH{=}CH_2 \xrightarrow{\text{initiation}} \rightarrow\!\!- (-CH_2{-}\underset{\displaystyle MX_{n-1}}{\underset{|}{CH}}-)_t\!\!-\rightarrow X_{n-1}MH + -(-CH{=}CH-)_t\!\!- \quad .$$

On the other hand, as will be shown below, MCM with polymerisable groups of other types (allyl, acrylate, etc.) proved to be capable of polymerisation and the metal atom was retained in the resulting polymer.

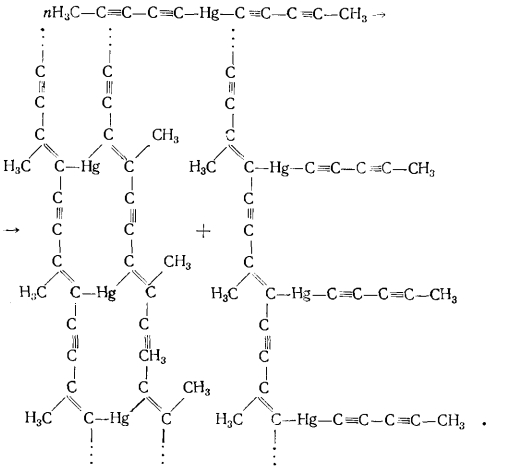
(a) Homopolymerisation of MCM Incorporating a Non-transition Metal

The comparatively early studies of the homopolymerisation and copolymerisation of MCM containing alkali and alkaline earth metals, in aqueous solutions and certain other polar media, have been described in detail in a monograph[9]. The

influence of the nature of the metal atoms (even isotypical metals) on the tendency of MCM towards homopolymerisation[20-22] can be illustrated in relation to the alkali metal salts of *N*-vinylsuccinamic acid: the lithium, sodium, and potassium salts do not polymerise in aqueous and methanol solutions in the absence of initiators up to 333–353 K, the formation of a polymer being observed only in the presence of an initiator (H_2O_2). On the other hand, the rubidium and caesium salts polymerise spontaneously already in the stage involving the synthesis of the MCM, which leads to the formation of mixtures of monomeric and polymeric salts. It is striking that the tendency of these MCM towards spontaneous polymerisation increases on passing from aqueous to methanol solutions. Overall, the salts of *N*-vinylsuccinamic acid can be arranged in the following sequence in terms of the rate of formation of the polymer: Cs > Rb > Na > K > Li.

The rate of polymerisation of potassium styrene-*p*-sulphonate, the molecular weight (MW) of the polymer, and the ratios $k_p/k_t^{1/2}$ increase with increase of the ionic strength of the solution; at the same time the activation energy for polymerisation falls (from 47.9 to 30.7 kJ mol^{-1}).[23] In the concentration range 0.12–0.3 M the initial rate of the process, the molecular weight of the polymer, and the ratios $k_p/k_t^{1/2}$ in the polymerisation of the calcium, strontium, and barium salts of styrene-*p*-sulphonic acid increase in the sequence of cations $Ca^{2+} < Sr^{2+} < Ba^{2+}$.[24] With increase in the ionic strength of the solution, the rate of polymerisation rises, but the influence of the nature of the cation diminishes, which enabled the authors[24] to explain this influence from the standpoint of the electrostatic interaction between the ionised monomers and the growing polymer radicals.

The monomers do not ionise in their solid-phase polymerisation, which is usually initiated by radiation or photochemistry. Thus, on γ-irradiation (at 196 K) of potassium and rubidium acrylates, triplet lines, typical for the majority of the irradiated vinyl monomers (at least when the latter dimerise) were observed in the EPR spectra[25]. The molecular mobility of the acrylate ion in the salts is correlated with the rate of their radiation-induced postpolymerisation and increases in the sequence Na < Li ≤ K < Rb.[26] The study of the radiation-initiated polymerisation of lithium, sodium, and potassium acrylates showed[27] that potassium acrylate is polymerised fastest: even at 273 K, it polymerises faster than the lithium salt at 374 K or the sodium salt at 393 K. The rate of polymerisation of potassium acrylate decreased rapidly during the process with increase of the degree of conversion (E_a = 70.1 kJ mol^{-1}); the degree of polymerisation was almost independent of the yield of the monomer and for potassium acrylate was higher by an order of magnitude than for the sodium and lithium salts.



The photopolymerisation of potassium acrylate takes place effectively[28] (250–300 nm): the yield of the polymer reaches 40% at 346 K and the molecular weight diminishes from 4.7 × 10^5 to 2.2 × 10^5 with increase of the degree of conversion from 15.8 to 43.6%.

It has been noted[29] that the solid-phase radiation polymerisation of anhydrous barium methacrylate is not observed up to its decomposition temperature; the formation of only oligomeric products has been observed[30]. However, with increase of pressure, the rate of polymerisation increased (in contrast to traditional monomers such as acrylamide or methacrylamide). This has been attributed[31] to preferential polymerisation in ideal crystals. Since the rate of polymerisation is much higher when the salt hydrates are employed, it was concluded[32] that the abundance of dislocations should facilitate polymerisation. Another explanation has also been given[33]: the radicals produced by the radiolysis of the salt hydrates (water of crystallisation) contribute significantly to the formation of the free radicals initiating the solid-phase polymerisation. The yield of the polymer depends to a large extent on the degree of hydration of the salt: the maximum rate of the process is observed when calcium acrylate hemihydrate is used[32,34]. The initial rate and the limiting yield of the polymer increase in the sequence dihydrate < anhydrous salts < hemihydrate; the activation energies are 84, 38, and 4 kJ mol^{-1} respectively. The question of the influence of oxygen on this process has not so far been elucidated. According to some data[35], the rate of polymerisation is independent of the presence of oxygen (barium methacrylate dihydrate); according to other data[34], complete inhibition of the process is observed (the polymerisation of calcium acrylate dihydrate and hemihydrate as well as the anhydrous salt was investigated.) There is a possibility of postpolymerisation for calcium and barium acrylates and methacrylates[30].

In the photoinitiated (250–300 nm) polymerisation of calcium acrylate[36] the process proceeds at a constant rate up to high degrees of conversion.

The formation of coordination polymers is more characteristic of MCM containing a metal of the zinc subgroup. Studies of the polymerisation of mercury-containing monomers with a σ-bonded metal have been surveyed[38]. We shall consider only the polymerisation of one of the few MCM of the acetylenic type—bis-(1,3-pentadiynyl)mercury[37] (Scheme 1): on heating to 373–473 K, 100% conversion was rapidly attained; on ultraviolet irradiation at room temperature, the rate of polymerisation proved to be appreciably lower, because the monomer is surrounded by the polymer, which does not transmit ultraviolet light. The polymers obtained contained diacetylenic groups and exhibited different degrees of branching and cyclisation.

Scheme 1

Poly-yne polymers containing other metals (Ni, Pd, Pt) in the main chain are considered below (Section VII).

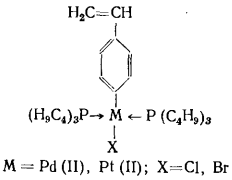
The formation of coordination polymers as well as a wide variety of condensation reactions leading to the appearance of high-molecular-weight products are more characteristic of Group III elements.

The homopolymerisation of MCM incorporating germanium, tin, and lead results as a rule in the formation of viscous oily or rubber-like products. Early studies on the polymerisation of MCM of this class have been surveyed in monographs[7,10]. Interesting results have been obtained in the investigation of the homopolymerisation of tributylstannyl methacrylate (TBSMA) in bulk (at 333 K) initiated by azobisisobutyronitrile (AIBN).[39,41]

The parameters $k_p/k_t^{1/2}$ and k_p have been estimated and compared with the corresponding parameters for methyl methacrylate (MMA): the ratios $k_p/k_t^{1/2}$ are 0.19–0.24 and 0.321, while the constants k_p (litre mol^{-1} s^{-1}) are 6.3×10^3–9.4×10^3 and 1×10^3 respectively. The fact that the rate constant for the propagation of the polymer chain is higher under comparable conditions for TBSMA than for MMA is noteworthy; this can be explained by the linear termination of the kinetic chains. Trimethylvinyltin and tributylvinyltin proved incapable of homopolymerisation[112].

The homopolymerisation of chlorodibutylstannyl acrylate is accompanied by the formation of a cross-linked polymer[42], which is probably caused by the disproportionation of the monomer, leading to dibutylstannyl dichloride and dibutylstannyl diacrylate (with polymerisation of the latter). A cross-linked polymer was also formed in the polymerisation of dimethylstannyl dimethacrylate. The polymer obtained from trimethylstannyl methacrylate was characterised by a comparatively high content of syndiotactic triads and was soluble in dimethylformamide (DMF) and methanol[43]. Triethylstannylmaleimide also polymerises via a radical mechanism[44] and, when initiating amounts of benzoyl peroxide are employed, there is no loss of the $Sn(C_2H_5)_3$ fragments from the polymer chain. At the same time a competitive interaction of the initiator with the initial monomer has been observed on increase of the concentration of benzoyl peroxide, accompanied by the cleavage of the Sn–N bond and the formation of triethyltin benzoate.

(b) Homopolymerisation of MCM Incorporating a σ-Bonded Transition Metal



The polymerisation of polymers incorporating polyvalent transition metals is characterised by a whole series of features from the standpoint of both kinetics and the properties of the polymers formed. An even greater variety in polymerisation behaviour is characteristic of them, depending on the type and valence state of the transition metal and on the nature of the ligand groups. Thus, on being kept for several days, di-isopropoxydivinyloxytitanium polymerised spontaneously and became insoluble in heptane, while tetrastyryloxytitanium polymerises only on heating to 423 K and dihexadienyloxydi-isopropoxytitanium polymerises only on heating to 498 K.[45]

On heating in benzene in the presence of 0.1% of benzoyl peroxide, allyloxytitanocene chloride is converted into a trimer with a molecular weight of 770.[46] Polymers with a low degree of polymerisation have been isolated[47,48] on heating solutions of titanocene derivatives of methacrylic acid in DMF up to 353 K (in the presence of benzoyl peroxide as the initiator). Dimethacryloyloxy-titanocene then produced a cross-linked polymer.

It has been noted[49] that tributoxytitanium methacrylate does not polymerise in the presence of 2% of benzoyl peroxide on heating to 353–373 K. This is associated with the preferential interaction between benzoyl peroxide and alkyl orthotitanate with formation of titanium acylates[49,50]. On the other hand, in the presence of 2% AIBN, tributoxytitanium methacrylate polymerises (on heating to 423 K for 5 h), while dibutoxytitanium maleate polymerises spontaneously[51] with formation of a product having a molecular weight of 2230 (corresponding to seven monomeric units) and soluble in many organic solvents.

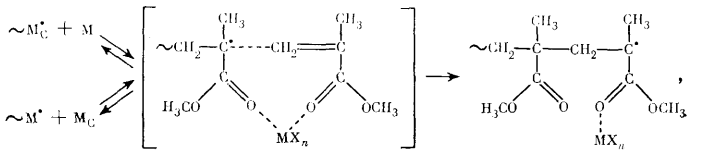
Among MCM with a σ-bond, containing other transition metals, copper and nickel acrylates[52] as well as zirconyl (ZrO^{2+}) methacrylate[53] proved to be capable of polymerisation. The solid-phase polymerisation of iron methacrylate takes place[54] under the influence of γ-radiation (dose rate 2.7 kJ $kg\ h^{-1}$, $T = 398$ K). Under the conditions indicated, a virtually quantitative yield of the polymer insoluble in methanol is attained after 12 h. Methacrylatopentamminecobalt(III) perchlorate polymerises with a high yield (pH 3, initiator—mixture of $K_2S_2O_8$ and $Na_2S_2O_3$).[55]

There is no information about the polymerisation of the few known σ-bonded MCM of the vanadium, chromium, and manganese subgroup metals. However, the radical polymerisation of *trans*-(4-vinylphenyl)bis(tributylphosphine)palladium chloride and bromide and the corresponding platinum compounds has been studied in comparatively high detail[56]:

M = Pd (II), Pt (II); X=Cl, Br

The polymerisation takes place under mild conditions (AIBN, 328–333 K) in benzene or toluene. White soluble polymers with molecular weights in the range 3600–10900 have been obtained, their yield depending on the polymerisation conditions. The attempts to polymerise the monomers with X = CN and C_6H_5 proved unsuccessful owing to their decomposition at the polymerisation temperature. On the other hand, their cationic polymerisation at a low temperature [in the presence of $B(C_4H_9)_3.O_2$ as the initiator] leads to the formation of polymers.

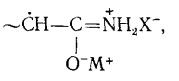
There are at present no data for the polymerisation of allene, diene, and acetylene σ-derivatives of transition metals.



2. Polymerisation of MCM Bound in Complexes

A new branch of the field of polymerisation, based on controlling the reactions via the formation of complexes of the initial monomer with metal salts, has arisen[57,58]. In principle, the interaction between the molecules of the monomer and the complex-forming agent can influence radically all the stages of the polymerisation process. The monomer then becomes "chemically activated" fairly frequently. The chemical activation can be associated both the intramolecular and intermolecular effects. As a consequence of this, there is as a rule an appreciable increase of the rate of polymerisation. In the problem considered, it is possible to distinguish three main components, each of which has its own specific features:
(a) polymerisation of vinyl monomers bound in complexes;
(b) polymerisation of allyl monomers bound in complexes;
(c) polymerisation of heterocycles bound in complexes.

(a) Characteristic Features of the Polymerisation of Vinyl Monomers Bound in Complexes



The influence of MX_n on polymerisation depends on the nature of the metal and the monomer, the method used to initiate polymerisation, and the ratio $[MX_n]/[\text{monomer}]$ in the system. $ZnCl_2$ is most frequently used as the complex-forming agent in the polymerisation of such MCM. Thus, is the polymerisation of MMA in the presence of $ZnCl_2$ or $AlCl_3$ (with initiation by AIBN at 323 K or by the photochemical decomposition of azo-compounds) in the presence of low contents of MX_n, the rate of the process increases linearly with the increase of the ratio $[MX_n]/[MMA]$ up to 0.2, after which there is some non-linear increase of the rate of polymerisation[59]. With increase of the ratio $[MX_n]/[MMA]$ under these conditions, k_p also increases, while k_t hardly changes; for $[MX_n]/[MMA] > 0.25$, k_p begins to diminish, while k_t falls sharply (by two orders of magnitude). An appreciable increase of the rate

of polymerisation of other vinyl monomers (4-vinylpyridine, 2-vinylpyridine, methylvinylpyridine, and acrylonitrile) has also been noted in the presence of $ZnCl_2$.[60] The complex-forming agent is regarded[59] as a "complementary species" involved in the formation of the transition complex (a coordination-radical mechanism of the propagation reaction obtains):

where M_c and M_c^* are the monomer and the growing radical bound in the complex respectively. One cannot exclude from consideration the possibility of the formation of organised aggregates of monomers bound in complexes (labile seeds) containing units with a suitable steric arrangement for polymerisation (an intermolecular effect)[61].

The importance of steric organisation is also confirmed by data for the solid-phase polymerisation of acrylamide and its *N*-alkyl derivatives bound in complexes with zinc halides. The polymerisation of the complexes is accompanied by an appreciable (by a factor of 1.5–2) increase of E_a.[104] This is attributed to the fact that the distance between the monomer molecules in the crystals of the pure monomer is much smaller than in the crystal of the complex. It is of interest that the polymeric complexes obtained have a linear structure, in contrast to the highly cross-linked polymers formed in the polymerisation of acrylamide derivatives not bound in complexes. The significant (by a factor of 3–5) increase of the rate of homopolymerisation of these monomers in the presence of lithium, calcium, and zinc salts is attributed to changes in the ratio $k_p/k_t^{1/2}$.[197] The increased activity of the radical incorporated in the complex has been explained[198] by the formation of the structure

characterised by an increase localisation of the unpaired electron at a carbon atom.

The homopolymerisation of vinyl monomers [particularly various vinylpyridines (VP)] bound in complexes with transition metal salts has been investigated in fair detail. Thus the complexes of cobalt and nickel chlorides were found to undergo solid-phase polymerisation[62]: $Co(4\text{-VP})_2Cl_2$ polymerised on heating to 380–405 K and in the presence of AIBN the reaction was appreciably accelerated; $Co(4\text{-VP})_4Cl_2$ and $Co(2\text{-VP})_2Cl_2$ polymerise on photochemical initiation. The polymerisation of adducts of $CoCl_2$ with various vinylpyridines (DMF, AIBN, 323 K) has also been studied[263]. Their polymerisation behaviour proved to be qualitatively similar to that of the $ZnCl_2$ complexes[64]. On the other hand, the nickel complexes show less tendency towards polymerisation: $Ni(4\text{-VP})_4Cl_2$ decomposes to $Ni(4\text{-VP})_2Cl_2$, which polymerises at 353–403 K on the surface of the crystals, forming a small amount of the polymer[62]. On heating to 353 K, the complexes $Cu(2\text{-VP})_2Cl_2$ and $Cu(2\text{-VP})Cl_2$ decompose with dissolution in their own ligand without any polymerisation, while $Cu(4\text{-VP})_2.Cl_2$ undergoes thermal polymerisation.

The interaction of tungsten, cobalt, and manganese carbonyls with 4-VP leads to the thermal polymerisation of the latter[65]. The possibility of the polymerisation of 4-VP bound in a complex with ruthenium(II) [of the complexes *cis*-$Ru(bipy)_2.(4\text{-VP})X^{n+}$, where $n = 1$ and X = Cl or $n = 2$ and X = CO or 4-VP] has been demonstrated[66]; the properties of the resulting polymers were not described in the above communication.

When vinylpyridines are polymerised in the presence of MX_n, the polymerisation of 4-VP and methylvinylpyridine is accelerated, while that of 2-VP is sharply retarded[63,64]. The accelerating effect in the first two instances has been attributed to the increase of k_p owing to the heterogenisation of the polymeric system, while steric effects, resulting in the shielding of the vinyl group, play a significant role for 2-VP.

For other MCM, we may note the radical polymerisation of bis(1-vinylimidazole)-manganese dichloride in aqueous methanol[67]. It is striking that $MnCl_2$ is a more effective complex-forming agent than HCl and CH_3I: when HCl in the complex was replaced by $MnCl_2$, the rate of polymerisation increased by a factor of 4.5†. It has been suggested[69] that, as a consequence of the intense dynamic conjugation of the π-electron systems of the vinyl group and the heterocycle, the coordination of vinylimidazole with $MnCl_2$ results in an increase of the polarity of the double bond and of the polarity factor *e*. An increase of the ratio $k_p/k_t^{1/2}$ has also been noted in the polymerisation of coordinated vinylimidazole, which may be due to the decrease of k_t owing to the increase of the molecular mobility of the polymer chains bound in a complex.

The synthesis of the polymeric complexes can be greatly facilitated as a result of the free-radical polymerisation of 1-vinylazoles in the presence of the corresponding metal chloride added to the reaction mixture[68,70]. In this case the complex formation and polymerisation reactions take place simultaneously. The composition of the polymer unit usually corresponded under these conditions to the ratio of the initial components. Thus in an alcoholic solution it was possible to obtain polymers from the following systems: vinylimidazole–$MnCl_2$, vinylimidazole–$NiCl_2$, vinylbenzimidazole–$NiCl_2$; vinylbenzotriazole–$NiCl_2$. Comparison of the effects of the nature of the ligands showed that polymerisation takes place more efficiently when vinylimidazole is used as a monomer.

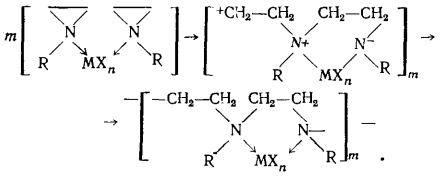
In an aqueous medium in the presence of copper, iron, nickel, cobalt, and manganese salts the polymerisation of MMA is accelerated[72]. It has been noted that the cation is of decisive importance in this effect, its activity varying in the sequence $Cu^{2+} > Fe^{2+} > Mn^{2+} > Ni^{2+} > Co^{2+}$, while the influence of the anion proved to be weaker. The results have been explained by the formation of the corresponding complexes. The homopolymerisation of complexes of palladium and nickel halides with vinylpyridine and phosphorus-containing monomers has been described[73].

---

†On the other hand, it had been shown in an earlier study[68] that the complexes $M(vinylimidazole)_4Cl_2$ (M = Mn, Co, or Ni) show a smaller activity in free-radical polymerisation than the non-coordinated vinylimidazole; for example, under identical conditions (4% AIBN, 343 K, alcohol), the degree of conversion of vinylimidazole reached 75%, while those of its complexes with the manganese and nickel chlorides reached only 60 and 35% respectively. Furthermore, analogous complexes with iron and copper chlorides could not be converted into polymeric products at all; evidently in this case the radicals formed are inhibited. The yields of the polymeric complexes obtained from $Ni(vinylbenzimidazole)_2Cl_2$ and $Ni(vinylbenzotriazole)_2Cl_2$ were low.

(b) Polymerisation of Allyl Monomers Bound in a Complex

The approach based on the polymerisation of compounds bound in complexes has been used particularly successfully in the case of allyl monomers. The polymerisation of allyl monomers is known[74] to involve considerable difficulties associated with the effective degradive chain-transfer, which results in the formation of the relatively inactive allyl radicals:

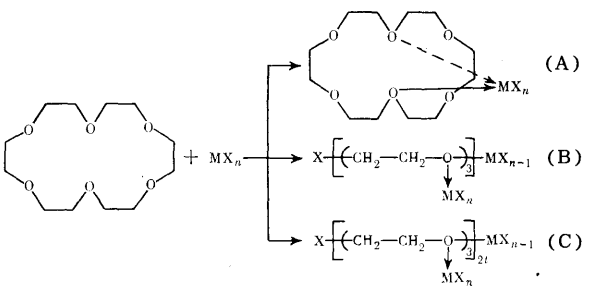


$$R^{\cdot} + H_2C{=}CH{-}CH_2X \rightarrow RH + H_2C{=}CH{-}C^{\cdot}HX \ .$$

On the other hand, the radical-initiated polymerisation of allyl monomers bound in complexes with metal salts proceeds at higher rates and with formation of polymers having high molecular weights. It has been suggested[75] that complex formation promotes the establishment of the steric conditions necessary for the reaction of the monomer and the radical, which are both ligands within the same coordination complex (intramolecular effect). Under these conditions, there is a possibility, firstly, of a decreased probability of the abstraction of a hydrogen atom by the growing radical and, secondly, the coordinated chain-transferring allyl radical formed in this instance may be capable of cleaving the double bond of the monomer (for example, as a consequence of the decrease of the rate of destruction of such species).

Various non-transition metal salts are used as complex-forming agents for allyl monomers[75-77]: LiCl, $LiNO_3$, Na_2SO_4, $MgCl_2$, $ZnCl_2$, and $ZnBr_2$. Among the few studies in which transition metal salts have been used as complex forming agents, we may mention one[78] on the radical polymerisation of allyl alcohol in the presence of chromium salts[78]. The rate of the process was found to decrease by a factor of 14.8 [$CrCl_3$, 348 K, $(NH_4)_2S_2O_8$]. The observed decrease of the reaction orders with respect to the initiator and the monomer (from 1.8 to 0.8 and from 0.5 to 0.4 respectively) has been attributed[78] to the involvement of the complex-forming agent in the elementary stages of the process and to the consequent increase of the probability of the transition from the degradative chain transfer to effective chain transfer.

(c) Polymerisation of Heterocycles Bound in a Complex



The redistribution of electron densities at the atoms and bonds in heterocycles as a consequence of complex formation, makes possible the occurrence of specific chemical reactions of the heterocycles in the coordination sphere of MX_n, which results in the formation of polymeric complex macromolecules. This can be demonstrated in relation to the $ZnCl_2$, $CdCl_2$, $PdCl_2$, $CoCl_2$, etc. complexes with ethyleneimine and and its derivatives[79-81]. Complex formation, the strain in the ethyleneimine ring increases by approximately 42 kJ mol^{-1}, which leads to a sharp decrease of the strength of the endocyclic bonds. Such complexes are capable of thermal polymerisation (both in bulk and in aprotic solvents) with opening of the heterocycle via a mechanism involving the heterolytic cleavage of the C–N bonds with formation of dipolar coordination ions:

The coordinate bonds are retained in the polymerisation process, which leads to the formation of polymeric chelate complexes. The characteristic features of such reactions are the presence in the initial complexes of at least two# heterocycles in the coordination sphere of the metal on the one hand, and the existence of "critical" temperatures for the dissociation of bonds in the heterocycles on the other.

The interaction of MX_n with macrocyclic crown-ethers takes place in an even more complex manner[82,83], involving the formation of three types of products (Scheme 2): (A)—the complexes of the $n\nu$ type produced by the exocyclic coordination of an MX_n molecule with two oxygen atoms; (B)—products of the opening of the crown-ether ring; (C)—polymers which are probably formed via a cationic polymerisation mechanism (the degree of polymerisation reaches 3–4).

Scheme 2

The amounts of fractions (A), (B), and (C) in the products of the reaction of dibenzo-18-crown-6 with $TiCl_4$, VCl_4, and $MoCl_5$ are respectively (wt.%) 87.5, 4.5, and 8.0 for (A), 60.0, 20.0, and 20.0 for (B), and 64.0, 24.0, and 12.0 for (C). It may be that similar reactions take place also for other types of heterocycles bound in complexes.

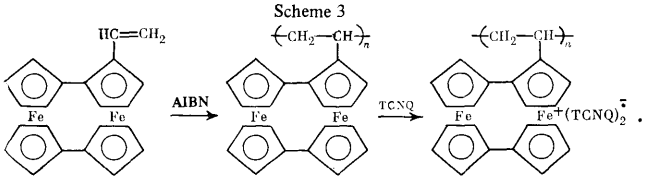
Thus the polymerisation of MCM bound in complexes is one of the most thoroughly investigated branches of the chemistry of MCM and not only theoretical but also practical possibilities of this field have already been outlined: the regulation of the molecular weights of the polymers obtained (which is particularly important for monomers of the allyl type), the acceleration of the process, the increased degree of conversion of the monomers, and the opening and polymerisation of heterocycles. There is every reason to believe that this field will develop vigorously in the future.

3. Homopolymerisation of π-Bonded MCM

In this class of MCM, the homopolymerisation (using different initiation methods) of vinylferrocene has been most fully investigated[1,4,5]. The principal conclusions reached in the study of the polymerisation of this monomer reduce to the following. With radical initiation in the presence of AIBN there is intramolecular electron transfer from the iron atom to the radical centre with formation of an Fe(III)-containing terminal group, which is accompanied by intermolecular chain termination. The order of the polymerisation reaction with respect to the initiator is therefore unity and the molecular

#The reactions of complexes containing one heterocycle in the coordination sphere terminate with the formation of cyclic dimers (piperazine derivatives); complexes incorporating a heterocycle and a primary or a secondary amine are incapable of polymerisation.

weight of the polymer does not increase with decrease of the initiator concentration. This has been explained[4] by the high chain transfer constant ($k_{tr}/k_p = 8 \times 10^{-3}$ compared with 6×10^{-5} for the polymerisation of styrene at 333 K); the high value of k_{tr} leads to the branching of the polymer formed.



Vinylferrocene provides an example of the influence of the transition metal in the MCM molecule on the character of its polymerisation. Thus the introduction of separating bridges between the ferrocenyl and active vinyl groups (as, for example, in ferroceynyl methacrylate) leads to the usual chain termination mechanism for which the dependence of the rate on the initiator concentration corresponds to a reaction order of 0.5.

The radical polymerisation of vinylcyclopentadienyltricarbonylmanganese[84] (benzene, AIBN) results in the formation of a polymer with MW > 2500. Its thermal polymerisation in bulk (at 443 K) leads to the formation of a glassy polymer. The unusual kinetic features of the polymerisation of this monomer in benzonitrile have been noted: the rate of polymerisation is given by the equation $w_{pol} = k_p[M]^2[AIBN]$ but an explanation for this has not yet been found.

η^5-Vinylcyclopentadienyldicarbonylmolybdenum and the corresponding tungsten compound are capable of homopolymerisation[85]. It is of interest that η^5-vinylcyclopentadienyldicarbonylcobalt does not polymerise owing to the decomposition of the organometallic component of the molecule, while the analogous iridium monomer gives rise to a homopolymer containing up to 50 wt.% of the metal.

The reasons why styryltricarbonylchromium does not polymerise either via a radical mechanism or in the presence of LiC_4H_9 have not as yet been elucidated; at any rate they are not steric. The transition state is probably stabilised in this instance by the strong (contact or resonance) interaction of the active centre with the $Cr(CO)_3$ group. On the other hand, η^6-(benzyl acrylate)-tricarbonylchromium readily polymerises in tetrahydrofuran (THF) (AIBN, 328–343 K), forming polymers with different molecular weights[86]. The homopolymer obtained in ethyl acetate had a molecular weight of 1.5×10^4. Among the η^4-dienylmetal tricarbonyl MCM, only η^4-(hexa-2,4-dien-1-yl acrylate)tricarbonyliron polymerises effectively (AIBN, benzene).[87] The considerable role of the reaction involving chain transfer to the polymer (particularly at high monomer concentrations), which leads to the formation of a polymer with a branched structure and a broad molecular weight distribution and partly to the formation of a microgel, has been noted. Among other MCM incorporating π-bonded iron, we shall mention the radical polymerisation of 3-vinylfulvalene(fulvalene)di-iron (Scheme 3) (solution in benzene, 343 K 24 h, yield 18%).[88] A characteristic feature of the polymer formed, which has a molecular weight of 5000 (average degree of polymerisation 18), is that, following its oxidation by tetracyanoquinodimethane (TCNQ), it acquires an exceptionally high conductivity for organic polymers, amounting to $(6–9) \times 10^{-3}\ \Omega^{-1}\ cm^{-1}$:

Scheme 3

More than 70% of the iron in the polymer is oxidised; the product consists of the mixed-valence salt $[Fe^{II}Fe^{III}][TCNQ]_2$. According to the results of physicochemical studies[88], the bisfulvalenedi-iron unit incorporating TCNQ constitute a delocalised system with only one type of iron atoms having a formal degree of oxidation of 2.5.

The homopolymerisation of η^5-(vinylcyclopentadienyl)-methyltricarbonyltungsten (AIBN, benzene, 333 K) has been investigated[89–91]. The operation of two different mechanisms of the polymerisation of this monomer was proposed initially: the traditional mechanism involving the vinyl bond and an unusual mechanism consisting in the initiation of the process by the $WCH_2^{\cdot}$ radical, formed via the intramolecular elimination of a hydrogen atom from the WCH_3 group. However, in a later study[85] the authors concluded that the traditional mechanism of vinyl polymerisation in fact operates. The process proceeds with difficulty up to molecular weights of 14000 with a high degree of consumption of the initiator, which corresponds to the kinetic process equation $w_{pol} = 1.13 \times 10^{-2}\ [AIBN]^{2.3}[M]^{0.8}$.[91] Such a high reaction order with respect to the initiator was not explained theoretically[91]. The calculated activation energy for chain propagation proved to be extremely high (338 kJ mol^{-1}).

A final conclusion concerning the influence of the metal atom on the elementary stages of the polymerisation of MCM apparently requires additional studies. The data available at the present time make it possible to conclude only that such influence is highly individual and depends on the type of bonding of the metal to the MCM, the nature of the metal itself, its ligand environment, and its valence state. As a rule, the MCM are highly active in chain transfer and termination reactions, although the mechanism of their action is still not clear. One can only conclude confidently that spatial separation of the multiple bond and the metal atom diminishes this effect. There are no direct data concerning the mutual influence of the metal atoms incorporated in the polymer chain.

There is virtually no information about the stereospecific polymerisation of MCM, although on general grounds it is not difficult to postulate that the metal atom is able to influence the orientation of the MCM molecule in the course of its addition to the growing chain and hence can influence the formation of stereoregular polymers.

IV. COPOLYMERISATION OF METAL-CONTAINING MONOMERS

A whole series of MCM incapable of homopolymerisation or polymerising with difficulty to oligomers are capable of copolymerising effectively with other monomers. One should note that there have been virtually no systematic studies of the radical polymerisation of MCM which would permit the calculation of the corresponding copolymerisation constants (r_1 and r_2) and the determination of the influence of the transition metal on their values and there have been no calculations of the parameters Q (a measure of the resonance stabilisation of the monomer during copolymerisation) and e (a measure of the polarity of the substituent at the double bond) in the Alfrey–Price mechanism. The only exceptions are the metallocene MCM [1,4] and the styryl-substituted palladium compound mentioned above[56].

1. Copolymerisation of σ-Bonded MCM Incorporating a Non-Transition Metal With Traditional Monomers

The rate of copolymerisation of MMA with alkali metal methacrylates (methanol, 333 K, AIBN) decreases with increase of the size of the cation[92]. It is striking that there is a clear-cut tendency towards the alternation of monomers in the MMA–lithium methacrylate copolymer: $r_1r_2 = 0.044$. An

alternating copolymer has also been obtained in the copolymerisation of acrylamide with sodium acrylate[93]. The composition of the copolymer obtained by the copolymerisation of the sodium salt of allenesulphonic acid with acrylonitrile in DMF was not described adequately[94]: apparently the parameters of the activity of the monomers varied with the initial molar ratio of the monomers.

The structure of such metal-containing polymers has been investigated. Thus it has been shown by Raman spectroscopy (absorption band in the range 166–170 cm^{-1}) [95,96] that, in the styrene–sodium methacrylate copolymer, the cations and anions are aggregated into clusters, particularly in the presence of a high metal content. Unfortunately the mechanism of their formation and the nature of the bonds in such aggregates have not so far been adequately studied.

The copolymerisation of alkaline earth metal acrylates with traditional vinyl monomers has been investigated in fair detail. Thus calcium, strontium, and barium acrylates have been copolymerised in aqueous solution with acrylamide and methacrylamide (mixture of $K_2S_2O_8$ and $Na_2S_2O_5$, 303 K).[97,98] The quantity r_2 varied in the sequence $Ba^{2+} < Ca^{2+} < Cr^{2+}$, while r_1 varied in the sequence $Ba^{2+} > Ca^{2+} \cong Sr^{2+}$. The overall rate of copolymerisation decreases with increase of the MCM concentration. Other conditions being equal, the rate of the process fell to a greater extent after the addition of barium acrylate than after the introduction of calcium and strontium acrylates. These facts have been attributed[97,98] to the electrostatic interaction between the growing macroradicals and the acrylate ions, which depends significantly on the interaction of the Ca^{2+}, Sr^{2+}, and Ba^{2+} cations with segments of the polyacrylamide chain in the macroradical (as for alkali metal acrylates). Similar results have been obtained also in the study of the emulsion copolymerisation of styrene with strontium acrylate initiated by $K_2S_2O_8$:[99] with increase of the MCM concentration to values exceeding 0.5%, the yield of the copolymer diminishes sharply. A reaction mechanism has been proposed in which account is taken of the growth of the macroradicals in different phases and the formation of the copolymer mainly as a result of the recombination of these macroradicals at the water–micelle interface is postulated.

The few studies of the catalytic copolymerisation of MCM merit special attention. For example, the copolymerisation of calcium acrylate with ethylene under the influence of the Ziegler–Natta catalytic systems $(RO)_2TiCl_2$–$Al(C_2H_5)_{1.5}Cl_{1.5}$, where R = n-C_4H_9, iso-C_4H_9, or iso-C_3H_7, has been investigated. For R = n-C_4H_9 or iso-C_4H_9, the yield of the copolymer did not change following an increase of the MCM concentration from 0.04 to 0.012 M, while for R = iso-C_3H_7 the yield fell appreciably. The reactivity of the calcium salt proved to be lower by a factor of two than that of the potassium salt. The calcium content in the copolymer depended on the structure of the alkoxy-group in $(RO)_2TiCl_2$ and increased in the sequence iso-C_3H_7O < iso-C_4H_9O < n-C_4H_9O. The observation of the influence of steric factors and allowance for this influence make it possible to diminish the effect of the polar monomer on the catalytic system in copolymerisation (this problem will be examined in greater detail below§).

The opposite examples, in which the rate of copolymerisation increased with increase of the MCM content in the reaction medium, are also known—for example[103] in systems comprising MMA, styrene, or 2-hydroxyethyl methacrylate, on the one hand, and the zinc or cadmium salt of ethylene methacrylate phthalate, on the other:

Notation: MAN = maleic anhydride, MA = methyl acrylate, EA = ethyl acrylate, BA = butyl acrylate, OA = octyl acrylate, AN = acrylonitrile, PMA = propyl methacrylate, BMA = butyl methacrylate, AMA = allyl methacrylate, GMA = glycidyl methacrylate, GA = glycidyl acrylate, N-MAA = *N*-hydroxymethylacrylamide, St = styrene, VPr = vinylpyrrolidinone, and VA = vinyl acetate.

§ We may note that catalytic systems based on alkoxy-derivatives of titanium combined with organoaluminium components generate free radicals under the influence of polar monomers (for example, MMA)[102]; the radicals can alter the polymerisation process.

In systems containing MMA, copolymerisation proceeds faster than in systems containing styrene: complete conversion is attained after several hours, but after 15–30% conversion gelling of the system takes place.

*Emulsion copolymerisation.
**Values obtained by averaging the data for glycidyl acrylate, glycidyl methacrylate, and *N*-hydroxymethylacrylamide.

The copolymerisation of tin-containing MCM, mainly trialkylstannyl acrylates, has been investigated in greatest detail, the copolymerisation constants for such monomers being summarised in Tables 1 and 2. The following features of the copolymerisation of tributylstannyl acrylate (TBSA) with alkyl acrylates have been discovered[105].

1. The rate of the process decreases with increase of the length of the alkyl chain of the alkyl acrylate and with the fraction of TBSA in the monomer mixture.

2. The alternation of units, confirmed by the S-shaped curves for the composition of the monomers and the values of r_1 and r_2 less than unity, is observed; such alternation is due to the negative polarisation of the double bond in the TBSA molecules and the positive polarisation in alkyl acrylates. The negative polarisation of the double bond in TBSA is due to the concentration of a considerable negative charge at the oxygen or tin atom, which is transferred inductively to the double bond, indicating a high polarity of the =–Sn bond:

3. The fraction of TBSA in azeotropic monomer mixtures increases with increase of the length of the alkyl chain of the alkyl acrylate owing to the decrease of activity in the series of alkyl acrylates.

It is of interest that TBSA and chlorodibutylstannyl acrylate have similar values of r_1 and r_2 in copolymerisation with methyl acrylate[42 105], which indicates the same influence of the C_4H_9 and Cl groups at the tin atom on the reactivity of the multiple bond.

The rate of copolymerisation of trialkylstannyl acrylates with maleic anhydride passes through a maximum for the equimolar composition of the monomer mixtures[19,71,114]. The constant $r_2 = 0$ for all the sytems, r_1 and Q decrease, and e_1 increases with increase of the length of the alkyl group in MCM. It has been suggested that the formation of the alternating copolymers is due to the interaction of the tin atom of the metal-containing monomer with the carbonyl group of maleic anhydride in the transition complex arising in the chain propagation reaction[19]. Under these conditions, the tendency of trialkylstannyl methacrylates to form complexes increases with increased length of the alkyl substituents at the tin atom, while the rate of their copolymerisation with maleic anhydride diminishes. It has been shown[44] that the copolymerisation of *N*-trialkylstannylmaleimide with styrene results in the formation of copolymers with a strict alternation of the monomeric units over a wide range of conversions and molar ratios of the monomers.

The following tin-containing terpolymers have also been synthesised: TBSA–vinyl acetate–vinylpyrrolidinone, TBSMA–vinyl acetate–vinylpyrrolidinone[107], TBSA–methyl methacrylate–acrylonitrile, TBSA–butyl methacrylate–acrylonitrile[111], TBSA–styrene–acrylonitrile, and TBSM–butyl methacrylate–acrylonitrile[108], the composition of the copolymers corresponding to the copolymerisation constants.

2. Copolymerisation of σ-Bonded MCM Based on Transition Metals

Tetramethylallyloxytitanium does not polymerise (either in the absence or presence of additives such as $SnCl_4$ and BF_4), but its copolymer with vinyl acetate has been obtained[115] (at room temperature without adding initiators), although the latter is incapable of homopolymerisation at room temperature. The same effect has been observed for the copolymerisation of trichlorotitanium acrylate with styrene (the reaction takes place explosively even in a dilute solution) or with isoprene[116]. The monomer itself is apparently a catalyst of cationic polymerisation in such cases. The copolymer of tetramethylallyloxytitanium with MMA has been obtained[115] in the presence of benzoyl peroxide at 338 K. The yellow solid polymer formed proved to be insoluble in solvents specific for poly(methyl methacrylate).

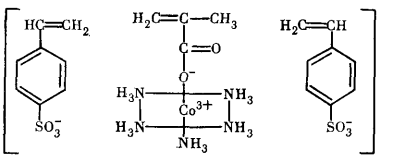
Tributoxytitanium methacrylate copolymerises (benzoyl peroxide, 363 K) with MA, while dibutoxytitanium dimethacrylate and dibutoxytitanium maleate copolymerise with styrene under the same conditions[51]. The possibility of the radical copolymerisation of a butenoxy-derivative of titanium with vinyl monomers has been noted[12]. The copolymerisation of allyloxytitanocene chloride[46] with styrene or MMA (monomer molar ratio 1:10, 0.5% of benzoyl peroxide, 373–393 K) leads to the formation of solid transparent orange copolymers with molecular weights of 22100 and 70000 respectively [the molecular weights of the polystyrene and poly(methyl methacrylate) obtained under the same conditions were 50000 and 90000 respectively]. These data confirm the conclusion that the MCM are highly active also in reactions involving the transfer of the growing chains. Infrared spectroscopic data indicate the retention of the titanocene structure in the copolymer[46]. The copolymerisation of methacryloyloxytitanocene chloride and also dimethacryloyloxytitanocene with the same monomers confirms these conclusions[48].

The copolymerisation of zirconyl methacrylate and acrylate[53] with styrene and various alkyl acrylates to form cross-linked copolymers insoluble in organic solvents and having a softening temperature higher than for the corresponding homopolymers, namely polystyrene and poly(alkyl acrylate), has also been reported[53]; however, quantitative data have not been published.

It has been noted[117] that the gelling of the ethylene glycol–chromium(III) methacrylate phthalate–styrene system (peroxide type initator, 328–373 K) beings already after 10–20%

conversion. Copolymers insoluble in the usual solvents were formed also in the radical copolymerisation of butoxy(methyl methacrylate)(ethylene glycol)titanium with styrene[118].

Data are available for the radical (comonomer–vinylpyrrolidinone, AIBN, solution in DMF, 323–353 K) and cationic (comonomer–α-methylstyrene, BF_3) copolymerisation of metalloporphyrin[119] and chlorophyll-containing[120] MCM.



The copolymerisation of *trans*-(4-vinylphenyl)bis(tributylphosphine)palladium chloride (benzene, AIBN, 328 K) has been investigated in detail[56]. The parameters $r_1 = 1.49$ (styrene) and $r_2 = 0.45$ were calculated by the Fineman–Ross equation for low degrees of conversion, which led to $Q = 0.41$ and $e = -1.4$ for the Alfrey–Price mechanism (the corresponding values for styrene are 1.0 and −0.8). The value of e_1 shows that, on the basis of the equation for the correlation between e and the Hammett constant, the σ-bonded palladium gro:p in *p*-substituted styrene is highly electron donating, of the type of *p*-amino- or *p*-methoxy-group in an aromatic ring. It might have been expected that *trans*-(4-vinylphenyl)bis(tributylphosphine)palladium dichloride would manifest a high reactivity in cationic polymerisation owing to the negative value of e, but BF_3 etherate did not induce its polymerisation, which was explained[56] by the interaction of the palladium group with BF_3, leading to the inhibition of the homopolymerisation.

Table 3. The copolymerisation constants and the parameters Q and e for the copolymerisation of methacrylatopentaamminecobalt(III) perchlorate (I) and *cis*-dimethacrylatotetra-amminocobalt(III) perchlorate (II) with methacrylic acid (aqueous solution, 303 K, $K_2S_2O_8 + Na_2S_2O_3$ initiator). [55]

Monomer	pH	r_1	r_2	Q	e
(I)	3	0.02±0.02	3.8±0.4	0.17	−0.91
(II)	3	0.001±0.001	2.1±0.5	0.17	−1.8
(I)	7	0.8±0.3	0.15±0.1	1.4	+0.46

Interesting features were observed[55] in a study of the radical copolymerisation of methacrylatopentamminecobalt(III) perchlorate and *cis*-dimethylacrylatotetramminecobalt(III) perchlorate with methacrylic acid. Table 3 shows that the pH of the medium has a significant influence on the copolymerisation process. This is probably associated with the fact that 90% of methacrylic acid is ionised at pH 7 and only 3% is ionised at pH 3. Accordingly, in the former case a positively charged monomer copolymerises with the methacrylate anion, while in the latter the monomer polymerises with unionised methacrylic acid. The copolymers obtained are sparingly soluble in water but readily dissolve in solutions of acids. Bearing in mind that Q and e for methacrylic acid and the methacrylate ion are 2.0, +0.7 and 0.9, −1.0 respectively, the presence of the cobalt-containing group leads to a decrease of Q_1 for both monomers and also of e_1 for *cis*-dimethacrylatotetramminecobalt(III) perchlorate. It is striking that the copolymer obtained at pH 3 contained a much larger isotactic fraction.

The copolymerisation (pH 1, 323 K, inert atmosphere, $K_2S_2O_8$) of methacrylatopentamminecobalt(III) perchlorate with sodium styrene-*p*-sulphonate has also been investigated[121]. After 12–24 h, the yield of the copolymer reached 5–10%. This resulted in the formation of a polyampholyte insoluble in water, DMF, and DMSO, consisting of an alternating copolymer (A–B–A), in which the molar content of the sodium salt of styrenesulphonate was independent of the composition of the reaction mixture and amounted to 60–70%. The copolymer obtained is characterised by a repeating unit as a result of the polymerisation of a transition structure:

Evidently, because of their hydrophobic character, the formation of such structures via the ionic interaction between the monomers is more probable than the formation of pairs of ionised monomers with a counterion. Generally speaking, by virtue of the wide variation of the values of Q and e, MCM provide greater possibilities than the usual monomers for the synthesis of alternating copolymers, but this problem has not been adequately analysed for MCM based on transition metals owing to the lack of experimental data.

3. Copolymerisation of MCM Incorporating a Coordination-Saturated Metal

We shall examine two cases: when one or both copolymerising monomers form complexes with metal compounds. In the former case the copolymerisation of MMA with vinylidene chloride, 2,6-dichlorostyrene, *p*-chlorostyrene, and styrene (AIBN or ultraviolet irradiation, 323 K) in the presence of $ZnCl_2$ or $AlBr_3$ leads to the formation of alternating copolymers[59] as a consequence of the rapid increase of the effective rate constants for cross chain propagation under the influence of the complex-forming agent. According to other data[122], in the copolymerisation of styrene with methyl acrylate in the presence of $ZnCl_2$ (spontaneous process or photoinitiated), the composition of the copolymer depended on the monomer ratio; alternation was observed only when the molar content of methyl acrylate in the initial mixture was <0.8. This has been attributed to the formation of two types of complexes: $ZnCl_2$–methyl acrylate and $ZnCl_2$–methyl acrylate–styrene; accordingly, the alternating copolymer is a product of the homopolymerisation of the second complex, while in the presence of an excess of methyl acrylate in the monomer mixture the two types of complexes copolymerise. The spontaneous compolymerisation of 1,3-cyclopentadiene with acrylonitrile in the presence of $ZnCl_2$ led to the simultaneous formation of a copolymer having a predominantly 1,4-*cis*-structure and a small amount of a cyclic adduct[123].

The characteristics of the radical copolymerisation of allylbenzene with methyl acrylate, acrylonitrile, methacrylonitrile, and fumaronitrile in the presence of $ZnCl_2$, $ZnBr_2$, ZnI_2, $Zn(SCN)_2$, $AlCl_3$, or $SnCl_4$ (333 K, AIBN) have been investigated[124]. In the allylbenzene–MMA and allylbenzene–fumaronitrile systems in the absence of the above salts polymerisation did not occur, while in the presence of $ZnCl_2$ alternating copolymers were formed. The values of Q and e have been calculated for acrylonitrile and MMA bound in complexes with $ZnCl_2$.

Alternating copolymers have also been obtained in the copolymerisation of monomers each of which is capable of the formation of complexes with MX_n—for example, acrylic acid and acrylamide in the presence of $ZnCl_2$ (AIBN, 318 K, benzene)[124].

It is noteworthy that, in the copolymerisation of allyl monomers with vinyl monomers (M_1), the presence of MX_n hardly influences r_2.[59] On the other hand, in copolymerisation with monomers each of which is capable of forming a complex (allyl acetate or allyl alcohol with MMA; $ZnCl_2$, $AlBr_3$), the parameters r_1 and r_2 become appreciably closer to each other. However, as shown for the MMA–acrylonitrile and methyl acrylate–acrylonitrile pairs of monomers[36], when $SnCl_4$ is used as the complex-forming agent, the corresponding ester is more reactive regardless of the ratio of the reactivities of the initial monomers.

The copolymerisation of styrene (M_1) with vinylpyridines (DMF, AIBN, 323 K) in the presence of $CoCl_2.6H_2O$ [64] leads to a considerable (approximately threefold) increase of r_1, compared with the same process in the absence of an additive, and to just as large a decrease of r_2 (for both 4-VP and 2-VP and methylvinylpyridine). The authors[64] attribute these effects to the formation of the corresponding complexes.

The copolymers of *cis*-$[Ru(bipy)_2(4\text{-}VP)X]^{n+}$ with styrene, MMA, and 4-VP (AIBN, 343–348 K, solvent—CH_3CN) have been described[66]. The structures of the polymers have been demonstrated by elemental analysis and infrared spectroscopy.

The vinylimidazole complexes of nickel(II), cobalt(II), iron(III), and copper(II) acetates copolymerise with vinylpyrrolidinone when divinylbenzene is added as the cross-linking agent (γ-irradiation, aqueous solution)[126]. After irradiation, the resulting polymer was ground and the metal ion as a "template" was removed by boiling the polymer powder in hydrochloric acid. It was found that each "template" polymer then adsorbed metal ions more effectively than pure polyvinylimidazole. The cobalt-containing "template" polymer adsorbed Co^{2+} ions most effectively, while selective adsorption was not observed for other "template" polymers

The radical copolymerisation of a series of cobalt-, nickel-, and palladium-containing complexes of styrylphosphines with styrene in various organic solvents has been reported[129].

We may note an interesting feature of the copolymerisation of MCM in complexes with olefins. In the copolymerisation of ethylene with vinylpyridines[130], acrylonitrile[131], or MMA,[132] the metal-containing monomer bound in complexes with VCl_4, $TiCl_4$, and $VOCl_3$ functions as a component of a metal complex catalytic system, on the one hand, and the formation of complexes by these monomers prevents the inhibiting effect of the heteroatoms on the anionic-coordination polymerisation of olefins and activates the double bond in the monomers, on the other. The mechanism of this process can be represented in the following form[132]:

$$VCl_4\cdot MMA + AlR_xCl_{3-x} \rightarrow VCl_4 + MMA\cdot AlR_xCl_{3-x}$$

$$VCl_4 + AlR_xCl_{3-x} \xrightarrow{C_2H_4} \rangle V\text{—}(\text{—}CH_2CH_2\text{—})_n\text{—} +$$

$$+ CH_2{=}C(CH_3)C{=}O \rightarrow AlR_xCl_{3-x} \rightarrow \rangle V\text{—}CH_2\text{—}C(CH_3)(\text{—}CH_2\text{—}CH_2\text{—})_n\text{—}$$

$$C(O \rightarrow AlR_xCl_{3-x})(O\text{—}CH_3)$$

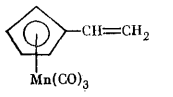
¶ It is of interest to note that a similar "adjustment" phenomenon was also observed in the formation of complexes of the corresponding cations with certain copolymers and subsequent cross-linking[127,128]. After the removal of ions there is in this instance an appreciable increase of sorption capacity and of the rate of sorption on the "adjusted" sorbents. However, in contrast to the study of Kato et al.[126], an increased selectivity in relation to the metal ion with respect to which the given sorbents had been "adjusted" was noted[127].

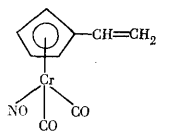
The formation of complexes of $Al(C_2H_5)_2Cl$ with polar monomers (acrylonitrile, acrylic acid, and potassium methacrylate) leads to similar results, which facilitates their copolymerisation with ethylene in the presence of the $VO(OC_2H_5)_3$–$Al(C_2H_5)_2Cl$ catalytic system[133]. The content of the polar monomer in such copolymers reaches 2.5 wt.%.

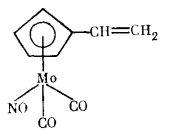
4. Copolymerisation of MCM With a π-Bonded Transition Metal

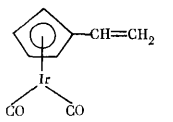
The copolymerisation of π-bonded MCM with classical vinyl monomers is apparently the most thoroughly investigated branch of the polymer chemistry of MCM. The results of the study of the copolymerisation of styrenetricarbonylchromium, η^5-vinylcyclopentadienyltricarbonylmanganese, η^6-(2-phenylalkyl acrylates)tricarbonylchromium, and η^4-(hexa-2,4-dien-1-yl acrylate)tricarbonyl with styrene, vinyl acetate, acrylonitrile, MMA, butadiene, and other monomers have been summarised in review[1,84]. Methylvinylcyclopentadienyltricarbonylmanganese (the 1,2- and 1,3-isomers) was copolymerised[109] with styrene and 1,4-divinylbenzene; the products contained 27–50 mole % of MCM.

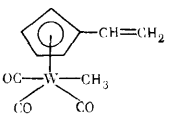
Two studies were devoted to problems of the copolymerisation of η^5-vinylcyclopentadienyltricarbonylmethyltungsten, η^5-vinylcyclopentadienyldicarbonylnitrosyl molybdenum, η^5-vinylcyclopentadienyldicarbonylnitrosylchromium, η^5-vinylcyclopentadienyldicarbonylnitrosyliridium, vinylruthenocene, and vinylosmocene[85,90]. Data on the copolymerisation parameters and the values of Q and e for the MCM considered are listed in Table 4. The copolymerisation of MCM with π-bonded metal is characterised by large negative values of e (from −1.6 to −2.1), which is associated with the powerful electron-donating character of the cyclopentadienyl ring and the conclusion[85] that the nature of the metal, the addition of the NO group and the two CO groups have little influence on the reactivity of the monomers is apparently quite justifiable.

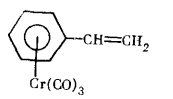


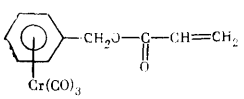


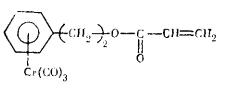


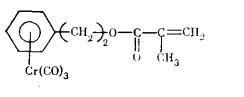












We may note also that $r_1 = 0$ has been obtained for the radical copolymerisation of tricarbonylstyrenechromium (M_1) with styrene or MMA,[134] i.e. the growing chain terminating in the M_1 group cannot combine with M_1, which is consistent with the inability of styrenetricarbonylchromium to undergo homopolymerisation.

A characteristic feature of the copolymerisation of η^6-(2-phenylethyl acrylate)tricarbonylchromium with styrene, MMA, and acrylic acid is the formation of polymers with a broad bimodal molecular weight distribution: MW > 10^6 for the high-molecular-weight fraction and 1×10^4–6×10^4 for the low-molecular-weight fraction. The high-molecular-weight fraction consists of a highly branched polymer, which is also observed with copolymers of η^4-(hexa-2,4-dien-1-yl acrylate)-tricarbonyliron copolymers. The copolymer containing 28 mole % of MCM has been obtained by the copolymerisation of 3-vinylbisfulvalenedi-iron with styrene (monomer ratio 1 : 4).[88] Its treatment with TCNQ in benzene, $CHCl_3$, or benzonitrile led to the oxidation of 88% of the initial amount of iron(II) and the formation of the mixed-valence salts $[Fe^{II}\text{—}Fe^{III}][TCNQ]_2^-$ analogous to homopolymer salts. However, their conductivity (2.5×10^{-5} Ω^{-1} cm^{-1}) was lower than for the homopolymer salts [$(6 - 9) \times 10^{-3}$ Ω^{-1} cm^{-1}].

5. Copolymerisation of Various MCM With One Another

Studies of the copolymerisation of various MCM in order to obtain bimetallic metal-containing polymers have been extremely limited although such products might apparently be of definite interest (for example, in metal complex catalysis).

Table 4. The copolymerisation constants and the parameters Q and e for the copolymerisation of π-bonded MCM*.

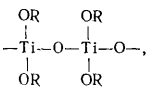
*For the notation, see Table 1.

Among the most significant advances in this field we may mention the copolymerisation of vinylcyclopentadienyltricarbonylmanganese with vinylferrocene (benzene, 343 K, AIBN), for which $r_1 = 0.44$, $r_2 = 0.49$, $e_1 = -2.6$, and $e_2 = -2.1$, while the polymer obtained had $\bar{M}_n = 7700$ and $\bar{M}_w = 13800$.[137]

The radical copolymerisation of η^6-(benzyl acrylate)tricarbonylchromium with ferrocenylethyl acrylate takes place readily in ethyl acetate[1].

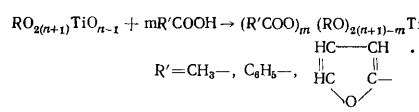
The polymer having the structure

was obtained only for a specific ratio of the monomers, i.e. η^5-vinylcyclopentadienyltricarbonylmanganese and η^5-vinylcyclopentadienyldicarbonylnitrosylchromium[138].



The copopolymerisation of two monomers incorporating iron and zinc methacrylates together with unsubstituted methacrylic acid had been reported[139]. It has been suggested that a long-range interaction transmitted via the polymer chain takes place between the iron and zinc atoms.

The copolymerisation of different MCM is not the only method of synthesis of bimetallic polymers. For this purpose, one can also use polycondensation methods (see below) and methods involving the polymerisation of bimetallic monomers for which there are virtually no experimental data, as mentioned above. However, an attempt has been made[140] to combine clusters with traditional monomers and to polymerise and copolymerise them. This method is believed to be promising although its application is complicated by the reactions of the initiator with the cluster and also by the large differences between the relative reactivities of the monomers in clusters and the traditional monomers.



Thus the copolymerisation of MCM with traditional monomers makes it possible to determine the influence of the nature of the metal in the MCM on the relative reactivities of the copolymerising monomers. Although this influence is difficult to treat systematically owing to specific factors even in MCM-homologues, nevertheless allowance for it makes it possible in many instances to act effectively on the copolymerisation process and on the properties of the products formed (see Section VIII).

V. POLYMERISATION AND COPOLYMERISATION OF OLIGOMERIC METAL-CONTAINING MONOMERS

Metal-containing oligomers as well as polymers incorporating multiple bonds are capable of polymerisation and copolymerisation. Oligomeric MCM are frequently formed already in the stage involving the synthesis of the monomers as the main or side products. Only the homopolymerisation of titanium-containing polymers of the type

in which some of the surrounding groups are unsaturated, and their copolymerisation with vinyl monomers have been investigated. Such compounds have been obtained by polymer-analogue reactions based on the ease of substitution of the alkoxy-groups in polyalkoxytitanoxanes by acyl residues with multiple bonds[7,49,141]:

Thus the interaction between polybutoxytitanoxane and

methacrylic as well as furylacrylic and cinnamic acids leads to the formation of waxy or rosin-like substances (depending on the amount of acid introduced). Polybutoxytitanoxane methacrylate behaved analogously to its low-molecular-weight analogue—tributoxytitanium methacrylate—because in the presence of bonzyl peroxide polymerisation did not take place even after prolonged heating, while on initiation with AIBN and heating at 423 K for 5 h there was an appreciable decrease of the number of double bonds[49]. Polybutoxytitanoxane furylacrylate and polybutoxytitanoxane cinnamate copolymerise with styrene (373 K, 1–2% of benzoyl peroxide); transparent red-brown copolymers are formed; in contrast to the initial polybutoxytitanoxane, they proved to be insoluble in solvents such as acetone, benzene, and toluene and did not react even with boiling water. Similar reactions have not been described for oligomeric products containing other metals. Here we may also mention the oligomeric π-complexes of tungsten[201] obtained by exchange reactions.

VI. GRAFT POLYMERISATION

There are few data concerning the graft polymerisation of MCM and almost all the publications on this question have appeared only in the last ten years. Only the results of studies on the radical graft polymerisation of MCM have been described and chemical initiation methods have been usually employed. MCM based on non-transition metal salts of acrylic acid have been largely used for grafting, evidently due to the ease of their synthesis and ready polymerisability.

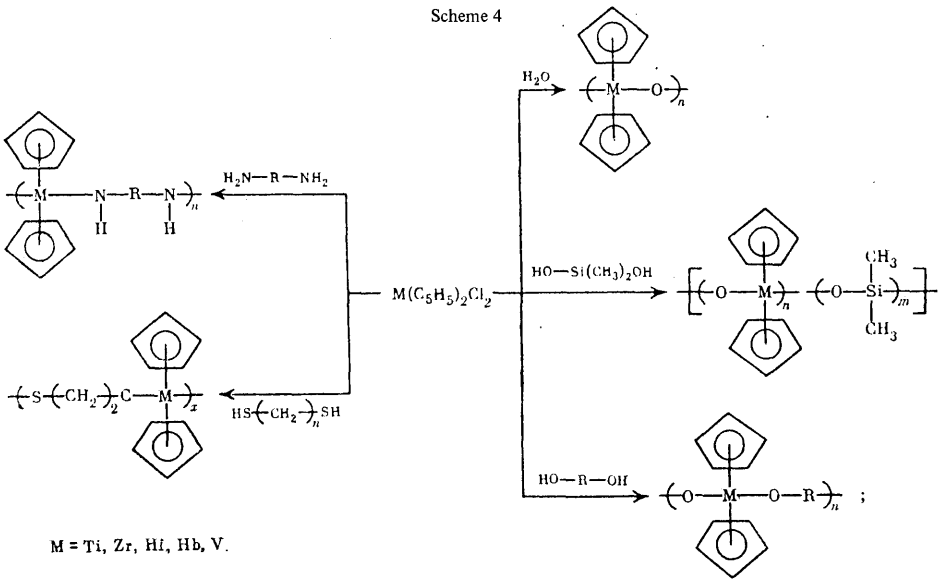
Thus the $(NH_4)_2S_2O_6$–$Na_2S_2O_3$ oxidation-reduction system[142] proved to be effective for the grafting of sodium acrylate to a polysaccharide and $(NH_4)_2S_2O_8$ was effective in the grafting of sodium acrylate and methacrylate to cellulose[143]. An interesting method for the grafting of acrylate and sodium ethylenesulphonate has been proposed[144]. Wool fibre was kept in an aqueous solution of the MCM after which it was treated with a gas discharge plasma, the yield of the graft copolymer reaching 2–5%. This method is extremely promising and can apparently be extended also to other MCM. The method of chemical initiation (by the Fe^{2+}–H_2O_2 oxidation-reduction system) has been used[145] also for the grafting of calcium acrylate to cellulose in aqueous solution. When a 20% solution was employed, the process took place at a high rate and terminated after 5 min. An increase of temperature from 292 to 353 K did not affect the yield of the graft copolymer, while a decrease of the MCM concentration to 16% sharply reduced it. Evidently, when 20–30% aqueous solutions of calcium acrylate are used, associated monomer species with an ordered molecular arrangement are involved in the grafting.

The grafting of zinc acrylate to polyolefins[146] and of the calcium and barium salts of acrylic and methacrylic acids to polypropylene and poly(vinyl chloride) fibres[147,148] has been reported.

However, the use of chemical grafting methods should lead to the formation of considerable amounts of the homopolymer together with the graft copolymer. The application of high-energy radiation (the radiation from the ^{60}Co isotope, an electron accelerator, and a glow discharge plasma) as the initiator of graft postpolymerisation has considerable advantages in this respect. The attempts at direct post-irradiation (accelerated electrons) grafting of sodium methylene- and styrene-sulphonates to a polyethylene film were unsuccessful[200]. On the other hand, these monomers were grafted after the preliminary hydrolysis of polyethylene.

The trapped radical method, involving contact between the grafting solution and a polymer support subjected to preliminary irradiation *in vacuo* has been used for the grafting of certain titanium- and vanadium-containing monomers to powdered polyethylene, polypropylene, polystyrene, and the ethylene–propene copolymer[149,150]. MCM of both acrylic and allylic series have been used. When $(C_5H_5)_2Ti(Cl).OCH_2CH{=}CH_2$, $(C_4H_9O)_2Ti[NH(CH_2CH{=}CH_2)]_2$, $Cl_3Ti(OCH_2.CH{=}CH_2)$, $(C_3H_7O)_3Ti(OCH_2CH{=}CH_2)$, and $CH_2{=}CHCH_2.OVOCl_2$ were grafted, the metal content in the graft copolymer did not exceed 0.10–0.12%, which is not surprising bearing in mind the low tendency of allylic compound towards polymerisation.

On the other hand, in the radiation-induced graft postpolymerisation of tributoxytitanium acrylate (preliminary irradiation dose *in vacuo* 200 kJ kg^{-1}) the maximum metal content also did not exceed the values quoted above[151]. This is apparently due to the steric hindrance to the chain propagation reaction associated with the large size of the $Ti(OC_4H_9)_3$ group. In the study of the temperature variation of the yield of the grafting process, a maximum was found in the region of 303 K, which can be accounted for by the superposition of two competing effects: the increase of the rate of chain propagation and the increase of the rate of destruction of the polymeric radicals with increase of temperature.



The grafting of monomers bound in complexes is an extremely promising branch of the graft polymerisation of MCM. The addition of the $ZnCl_2$, ZnI_2, or $AlCl_3$ salts proved to have an insignificant influence on the graft polymerisation of arcrylamide, MMA vinyl acetate, and styrene on 1,4-polybutadiene (benzene, 333 K, AIBN).[152] On the other hand, the grafting of MMA or styrene to 1,2-polybutadiene was greatly accelerated in the presence of these salts, which can be arranged in the following sequence in terms of their influence on the grafting parameters: $ZnCl_2 > AlCl_3 > ZnI_2$. The case considered is the only example illustrating the role of the steric structure of the polymeric support on the character of the grafting of MCM.

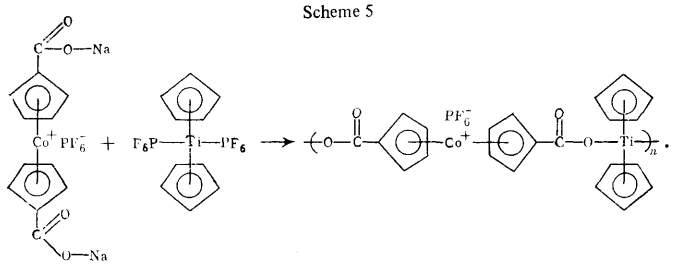
The possibility of grafting the complex of an organic or inorganic nickel salt with vinylpyridine (molar ratio from 0.1 : 1 to 1 : 1) to rubber in the presence of a radical initiator has been demonstrated[153].

All that has been said above concerning the polymerisation of allylic monomers bound in complexes holds also for their graft polymerisation. Allyl alcohol, allylamine, allyl acetate, allylmercaptan, etc. have been grafted to polyethylene, polypropylene, polystyrene, and poly(methyl methacrylate) in the presence of LiCl, CaCl, and $ZnCl_2$.[154,155] The method of joint irradiation has been used for this purpose. The rate of the graft polymerisation of allyl alcohol (AAl) increased by a factor of 5 for the molar ratio $[AAl] : [ZnCl_2] = 2 : 1$.[155] The graft copolymers of certain other allylic monomers have been obtained for the first time[154]. In addition, after the attainment of the same degree of grafting of vinyl monomers, the necessary irradiation dose increased considerably (by a factor greater than four).

The graft polymerisation of allylic monomers in the presence of certain transition metal salts has also been achieved. Allyl alcohol, allylamine, and diallylamine have been grafted to powdered polyethylene and polypropylene by the method of post-irradiation graft polymerisation (preliminary irradiation both *in vacuo* and in air) in the presence of $CoCl_2$, $Co(NO_3)_2.6H_2O$, NiI_2, and $CrCl_3.6H_2O$.[156] In the grafting of the complex $CoCl_2(AAl)$ (the dose in the preliminary irradiation of polyethylene in air was 200 kJ kg^{-1}; molar ratio $AAl : CoCl_2 = 3 : 1$, 343 K, inert atmosphere) the rate of the process is constant over a considerable time interval, as shown by the linear relation between the cobalt content in the copolymer and the reaction time. The activation energy for this process has been calculated as 40 kJ mol^{-1}. This procedure can probably be used also for the graft copolymerisation of MCM

Scheme 4

probably be used also for the graft copolymerisation of MCM with vinyl or allyl monomers and possibly also heterometallic MCM. There are no data concerning the graft polymerisation of π-bonded MCM.

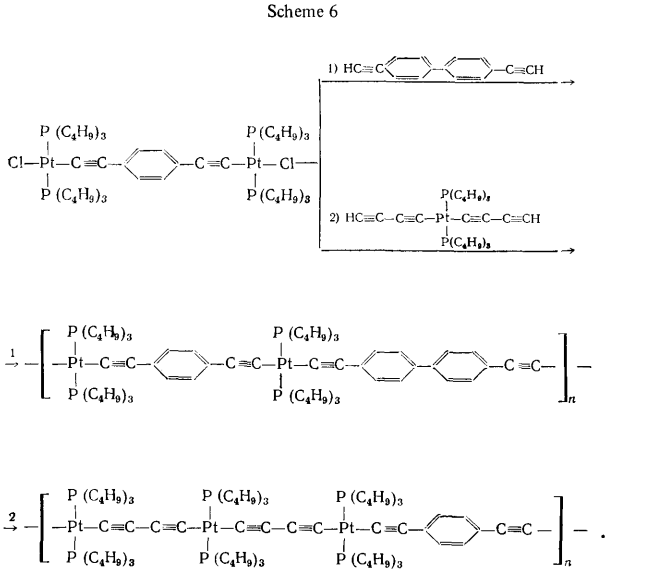


VII. POLYCONDENSATION REACTIONS OF METAL-CONTAINING COMPOUNDS

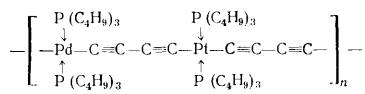
The condensation of metallocene compounds has been studied in fair detail; the comparatively early studies have been surveyed by Korshak[7] and Neuse and Rosenberg[157], while reviews of later work can be found in a number of other publications[158–164,203–205]. Reactions of this kind are presented in a general form in Scheme 4.

The degree of polycondensation in such products varies within wide limits—from 2 to 2000 depending on the nature of the reactants. A convenient method for the preparation of metallocene polymers by reaction with aldehydes has been described[165].

Polycondensation reactions of metallocenes, for example, between cobaltocene derivatives and titanocene[158] (Scheme 5), leading to the formation of a polymer chain incorporating different transition metal atoms, are known:



Scheme 5



Many of the reactions considered will probably prove to be promising for the synthesis of polymers based not only on metallocene derivatives but also on alkoxy-, amido-, amino-, and carboxy-derivatives of transition metals. For example, linear conjugated coordination polymers have been obtained by the condensation of tetrakis(salicylhaldehydo)zirconium(IV) with 1,2,4,5-tetra-aminobenzene or dicarboxybis(5,7-dichloro-8-quinolato)(triphenylphosphine)tungsten with quinoline-5,8-diol.[166] The molecular weight of the polymers reaches 50000 and their characteristic feature is the inclusion of octacoordinate metals. The formation of similar products can be expected also for molybdenum, niobium, rhenium, etc.; vigorous researches are being prosecuted on these lines.

An interesting series of studies[167–174] has been devoted to the polycondensation of acetylenic MCM. In the presence of copper(I) iodide or chloride, such MCM are capable of forming polymers with chloro-derivatives of nickel, palladium, and platinum and some can undergo copolycondensation with diethynylbenzene. A wide variety of poly-yne polymers containing nickel, palladium, or platinum atoms in the main chain have been synthesised in this way (Scheme 6).

Scheme 6

The poly-yne polymers are soluble in various organic solvents despite the fact that they possess a rigid rod-like structure in solution. Polymers containing different metals in the main chain, for example palladium and platinum, have been obtained in the same way[170]:

These polymers had molecular weights ranging from 8000 to 120000 and under certain conditions they depolymerised with formation of polynuclear complexes with a Pt–C bond. It is striking that in all cases the products formed can be regarded as alternating copolymers. The characteristic features of the polycondensation of acetylenic derivatives of the ferrocene type have been surveyed in a recent review[175].

VIII. APPLICATIONS OF METAL-CONTAINING POLYMERS

Metal-containing polymers are finding a wide variety of applications which are sometimes unexpected; such data have been published mainly in the patent literature. It is possible to note two main trends: applications involving the improvement of some properties of polymers and compositions based on them and applications based on the appearance of new properties due to the presence of the metal in the main or side chain of the polymer.

Thus the introduction of lithium, sodium, or potassium methacrylate units into PMMA greatly increases the thermal-stability of the polymer and to a greater extent for shorter PMMA blocks[176]. Intramolecular cyclisation reactions involving neighbouring side groups take place in this instance with formation of anhydride rings and the corresponding metal methoxide. The introduction of sodium methylallenesulphonate into polyacrylonitrile has an appreciable influence on the glass point (T_g) of the copolymer[177]: a relation with a maximum corresponding to an MCM content in the copolymer of 8 wt.% was observed. The increase of T_g is apparently associated with the increase of the rigidity of the chain as a result of the incorporation in the latter of more bulky polar groups. With high MCM contents, the intermolecular interaction of the nitrile groups weakens as a consequence of the loosening of the structure.

The addition of sodium or zinc polyacrylate to certain compositions[178] greatly increases their heat resistance and resistance to a corona discharge; the copolymers of sodium or potassium acrylate with unsaturated polyesters have a high impact strength, dimensional stability, and fire resistance[179]. The styrene–methacrylic acid–sodium methacrylate ternary copolymer is characterised by an increased yield point, which has been attributed[180] to an increased degree of neutralisation of the carboxy-groups. Titanium-containing polymers exhibit properties known as "anomalous fibre formation"[90]; their mass and initial dimensions change little under the conditions of heat treatment.

All the polymers based on MCM incorporating transition metals are as a rule stable up to 473–523 K. Even their low content in copolymers with traditional monomers, for example, those of zirconyl acrylate or methacrylate with alkyl acrylates[53], leads to the formation of a cross-linked polymer with enhanced thermoplastic properties and improved resistance to organic solvents. These properties are used, especially in the case of titanium-containing polymers, to obtain various coatings, frequently with enamel-like surfaces. We may also note the application of metal-containing polymers, obtained by the polymerisation or copolymerisation of MCM, as the main components in the preparation of foam plastics[181], hydrophilic finishing preparations for crease-resistant cotton fabrics[182], and as materials with effective slip[183]. Alkaline earth metal and copper acrylates and methacrylates are used as the principal components in the preparation of soil structure-forming agents designed for the stabilisation of soils[184–186], as water isolating agents in the recovery of petroleum[187], and as flocculants and coagulants[188,189].

One of the most promising applications of metal-containing polymers is their use as metal complex catalysts in numerous processes. Thus polymers obtained by the polymerisation of styrylphosphines bound in complexes with cobalt, nickel, and palladium salts catalyse hydroformylation reactions[129], while ferrocene-containing polymers catalyse dehydrogenation and dehydration processes[175].

As was to be expected, metal-containing graft polymers proved to be even more effective catalysts: for example, the grafted complexes of nickel salts with vinylpyridine on natural rubber catalyse the dimerisation of ethylene[153]; titanium- and vanadium-containing monomers grafted on powdered polyolefins catalyse the polymerisation and copolymerisation of ethylene[150]. The complex of $PdCl_2$ with 4-vinylpyridine grafted on the surface of ethylene proved to be an effective catalyst of the stereospecific polymerisation of acetylenic monomers[190,191] and also of the reductive *N*-alkylation of nitrobenzene and its reudction products by carbonyl compounds[192]. Data concerning the possibility of employing polymerisation, copolymerisation, and graft polymerisation processes involving MCM for the preparation of deposited catalysts to be used in various processes have been summarised in two communications[193,194]. The fixation of molecular nitrogen by manganese-containing metallopolymers has been reported[199]. Metal-containing polymers based on lead and tungsten metallocene monomers have been used as coatings for targets in laser-induced thermonuclear synthesis[202].

Many metal-containing polymers have bactericidal properties. Platinum-containing condensation polymers have been used in the treatment of tumours[195], the platinum complex being slowly split off in the course of biochemical hydrolysis, which leads to prolonged action of this drug. Polymers of η^5-vinylcyclopentadienyltricarbonylmanganese and its copolymers are used as inhibitors of fungal growth[137]. Germanium-containing polymers are employed in the treatment of fibrosis of the lungs[196].

The potential applications of metal-containing polymers in this field have not yet been fully investigated. The consideration of metal-containing polymers for the purpose of imparting specific operational properties to the compositions formed merits attention. This concerns the application of Group I–IV metal acrylate and methacrylate polymers as well as their copolymers with vinyl monomers as thermostabilisers for chlorine-containing resins, for example poly(vinyl chloride)[206–208].

The method of stabilisation of such polymers at the stage of their synthesis, for example, by the copolymerisation of tin-containing monomers with vinyl chloride, is of special interest[19]. In this case the stabilising centres in the copolymer are distributed in a sequence determined by the copolymerisation parameters and are not removed from the polymer during its use (constitutionally stabilised polymers). Stable and uniform constitutional colouring of polyolefins, based on the use as cocatalyst of the product of the interaction of titanium(IV), vanadium(III), and vanadium(V) with diazoacetylenic alcohols containing a multiple bond and a chromophoric group, was achieved by similar method[209].

On the other hand, thermal and photochemical degradation of a metal-containing polymer can result in the formation of metals or their oxides, which leads in the first place to the

generation of systems with new properties. Thus ultraviolet irradiation of films of the η^6-(2-phenylethyl acrylate)tricarbonylchromium–styrene copolymer was accompanied by the elimination of a CO group and the formation of Cr_2O_3 incorporated in cross-linked films[135]. This also applies to polymers obtained by the polymerisation of monomers containing iron[210]. The decomposition of certain polymers to the oxide takes place only at temperatures above 1000 K.

Among other applications of metal-containing polymers, one may name the formation of light-sensitive media for photocopying devices, adhesives, combustion moderators, flame extinguishers, electrically conducting materials[88] and semiconductors, and ion exchangers. The products of the polymerisation and polycondensation of MCM have been used as photosensitisers and materials for protection against heat and radiation. Photopolymerisation systems for the rapid dry production of an image have been developed and investigated. Barium acrylate has been used as their main component[211,212]. The radical copolymerisation of MMA with palladium, calcium, barium, and strontium methacrylates has been carried out to prepare photoresistors with a high sensitivity and a satisfactory resolving power, which are resistant to the action of high temperatures and corrosive media[213].

The applications of metal-containing polymers are apparently not restricted to these fields. Their considerable expansion may be expected, since the synthetic possibilities in this rapidly developing branch of polymer chemistry have not been fully elucidated as yet and have been by no means completely realised.

At the same time this field of study involves a whole series of problems whose solutions will make it possible to discover general characteristics. We believe that the most important of these are as follows: the search for methods of stabilisation of MCM (especially organometallic MCM), the synthesis of bimetallic and polymetallic MCM; the development of methods for the effective activation of the multiple bonds in MCM, new methods for the initiation of polymerisation processes, and a detailed analysis of the influence of the nature of the metal on the elementary stages of the polymerisation process; problems of the stereoregulation and supermolecular organisation of metal-containing polymers; characteristic features of the alternating copolymerisation of MCM with one another and with traditional monomers; the study of the structure of the chains of metallopolymers, the changes undergone by metals following their incorporation in the polymer matrix, and also the cooperative interaction between metal atoms; problems of catalysis and the elucidation of specific features of the chain structure of metal complexes and its manifestation in catalytic processes; the study of the reactivity of the multiple bonds in MCM in other reactions involving these bonds. Only the hydrogenation of monomers bound in complexes, whose rate, as in the case of polymerisation, is higher than in the absence of a complex-forming agent, has been investigated on these lines[214,215].

Although the analysis of the results of the study of the polymerisation and copolymerisation processes involving MCM indicates a considerable progress in the understanding of many aspects of this problem and also the intensity of the studies in this field, the elucidation of fairly general characteristics of these processes requires concerted studies by chemists specialising in the field of organometallic synthesis and in polymer chemistry.

Fluorine-containing Dyes

L.M.Yagupol'skii, A.Ya.Il'chenko, and L.Z.Gandel'sman

The methods of synthesis, properties, and applications of fluorine-containing dyes of all classes are examined. The influence of fluorine atoms and fluorinated substituents on the spectroscopic properties of dyes is discussed. It is shown that the introduction of fluorine-containing substituents makes it possible to obtain dyes which are resistant to oxidation, light, and other physical influences.
The bibliography includes 271 references.

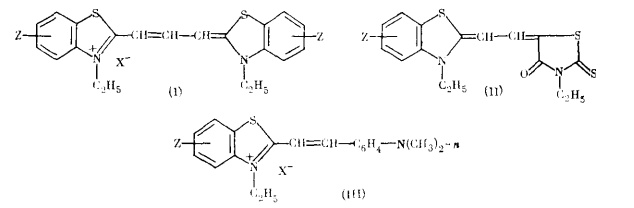
I. INTRODUCTION

The vigorous development of the chemistry of organofluorine compounds and the development of convenient methods for their synthesis[1-7] have made it possible to introduce fluorine atoms and fluorine-containing substituents into the molecules of various organic substances and hence to modify their properties within wide limits. Representatives of all classes of organic dyes with fluorine-containing substituents have now been synthesised. The influence of these substituents on the colour and other properties of the dyes has been investigated and dyes with properties of practical values have been discovered.

This review deals mainly with dyes which make it possible to elucidate the influence of fluorine-containing substituents on their colour and properties. Consideration of the available data will help in the development of a theory of the colour of organic dyes, in the expansion of experimental research in this field, and in the practical utilisation of fluorine-containing dyes.

The review covers the literature up to 1981 inclusive.

II. POLYMETHINE DYES



Fluorine-containing cyanine dyes were first synthesised by Kiprianov and Yagupol'skii in 1950.[8] Since then numerous communications dealing with the study of the influence of fluorine atoms and fluorine-containing substituents on the absorption spectra of dyes and their properties have been published. Some fluorine-containing-dyes have found important practical applications as cinefilm photosensitisers.

1. Dyes with Fluorine-containing Substituents in Heterocyclic Nuclei

The influence of fluorine atoms and fluorine-containing substituents in heterocyclic nuclei on the absorption spectra has been studied in detail in relation to benzothiazole derivatives—thiacarbocyanines (I), merocyanines (II), and styryl dyes (III) (Table 1).

Fluorine atoms and fluorine-containing substituents have been introduced into heterocyclic nuclei by methods dealt with in monographs and reviews[1-7]. The dyes (I)–(V) (Tables 1 and 2) were synthesised from the quaternary salts of substituted heterocyclic bases by the usual methods of the chemistry of cyanine dyes.

Table 1. The absorption maxima of dyes (I)–(III) in ethanol.

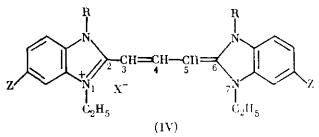
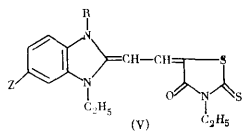
Monomethine di- and tri-carbothiacyanine dyes with the 6-F,[8] 5-CF_3,[9] 5-SCF_3,[15] and 6-SCF_3 [15] substituents, pentacarbothiacarbocyanines with the 5-CF_3, 6-CF_3, and 5-SO_2CF_3 substituents[19], thiacarbocyanines containing methyl and ethyl groups in the β-position in the chain and the 5-F or 6-F,[8,9]



5-CF_3,[9] 5 or 6-OCF_3,[13] 5- or 6-SCF_3,[15] 5- or 6-$NHCOCF_3$,[18] and 6-$SeCF_3$ [17] substituents in the nuclei, and dyes with a condensed 2-trifluoromethyloxazole ring in the 4,5-positions[20] have also been described. Certain asymmetric dyes[8,9,14,15,21,22] as well as thiacarbocyanines with two substituents in the nuclei [5-OCF_3 and 6-X (X = Cl, I, SCH_3, NH_2, or $NHCOCH_3$) [23] and 5,6-OCF_2O [24]] are known.

Fluorine atoms in benzothiazole nuclei have little influence on the absorption spectra of dyes but reduce their basicity[25] and lower the electron-donating capacity[26] (the Brooker basicity[27]) of the heterocyclic residues. The electron-donating capacity of the benzothiazole residues is reduced to an even greater extent under the influence of the electron-accepting substituents CF_3, OCF_3, SCF_3, SO_2CF_3, $NHCOCF_3$, and $NHSO_2CF_3$, which have positive σ_n constants[28]. As a result of this, the electronic asymmetry and the deviation in styryl dyes are reduced, while in merocyanines they are enhanced[26]. Fluorine-containing substituents in styryl dyes and merocyanines give rise respectively to greater and smaller bathochromic or hypsochromic effects than in the symmetrical carbocyanines.



For the dyes (I) substituted in the 6,6′-positions, a correlation has been found between their basicity (pK_a) and the σ_n constants of the substituents[25,29].

Table 2 presents the spectroscopic data for the benzimidazole dyes (IV) and (V).

Dyes of types (IV) and (V) containing the $SO_2CF_2CHF_2$, SO_2CF_2CHClF, $SO_2CF_2CHFCF_3$,[41] $SO_2CH_2CO_2CF_3$,[34] CH=CH–CF_3,[12] CF=CF–CF,[12,30] and N=N–CF_3 [18] substituents in the nuclei and the CF_3CHClF, CF_2CHFCF_3,[39,40] $C_6H_4SO_2.CF_3$-*p*, $C_6H_4CF_3$-*m* [42] substituents at the nitrogen atoms, dyes with two substituents in the 5,6-positions (F,F;[31] CF_3, $COOCH_3$;[38] CF_2OCF_2;[31] OCF_3, Cl;[30] SO_2CF_3, Cl;[30] SO_2CF_3, OCH_3;[30] CF_3, CN [44,45]) and the 5,7-positions (SO_2CF_3, Cl;[43] CF_3, CF_3 [43]), styryl dyes with the CF=CClF or CF=$CFCF_3$ substituents at the nitrogen atom of the benzimidazole ring[40,46], imidadicarbocyanines and imidatricarbocyanines with the SO_2CF_3 groups in the nuclei[35,47], imidacarbocyanines with two chlorine atoms and the CF_3 and SO_2CF_3 groups in the nucleus and the $(CH_2)_nCF_3$ (n = 1–3) group at the nitrogen atom[39,40,48], certain asymmetric dyes with the benzimidazole nucleus containing the CF_3 [22,49] and SO_2CF_3 [50] substituents, imidadicarbocyanine with the SO_2CF_3 substituent in the nucleus and a chlorine atom in the γ-position in the chain[51], and dyes of types (IV) and (V) in which all the hydrogen atoms in the benzene ring have been substituted by fluorine atoms[52] have also been described.

Fluorine-containing substituents are electron acceptors and, after the introduction into the benzene rings of symmetrical imidacarbocyanines (IV), give rise to a bathochromic effect [from 3–4 nm for the fluorine atoms and CF_3 groups to 25–30 nm for the most electron-accepting SO_2CF_3 and SO_2C.$(CF_3)_3$ groups]. The spectroscopic effects of the substituents are then as a rule greater than in the analogous dyes of the benzothiazole series.

The bathochromic effect of electron-accepting substituents in the series of benzimidazole dyes can be explained not only by an increase in the length of the chromophoric system but also apparently by the fact that the conjugation of the substituent with one of the nitrogen atoms of the benzimidazole ring increases the hypsochromic influence of this atom as an electron-donating substituent in the polymethine chain. According to the Förster–Knott–Dewar rule[53,54] (the FKD rule), electron-donating substituents in the even positions of the polymethine chromophore [see the numbering of the atoms in formula (IV)] have a hypsochromic effect on the colour of the dye while electron-accepting substituents have a bathochromic effect. The blue shift of the colour of imidacarbocyanines (IV) compared with the thiacarbocyanines (I) can be explained by the hypsochromic influence of the nitrogen atoms. The introduction of phenyl or polyfluoroalkyl groups (R = C_6H_5, CF_2CHF, etc.) at the nitrogen atoms of the dyes (IV) diminishes the electron-donating hypsochromic influence of the nitrogen atoms and induces a red shift of the colour than for R = C_2H_5.

Fluorine-containing substituents in benzimidazole nuclei as a rule reduce the basicity of the corresponding dyes[25,29] and a correlation is observed between the pK_a and the σ_n constants of the substituents in the nuclei[29].

For dyes containing two substituents in the nucleus, the spectroscopic effects and the pK_a are approximately additive[56,57], but, when steric hindrance displaces one of the substituents from the plane of the benzene ring, the influence of the latter on pK_a and λ_{max} diminishes[57,58].

Linear correlations between the absorption frequencies of the carbonyl groups and the σ_n constants of the substituents in the nuclei have been found for the merocyanine dyes (III) and (V).[59]

The introduction of electron-accepting substituents into the imidacarbocyanine molecule improves its sensitising properties[60]. Among imidacarbocyanines with fluorine-containing substituents (for example, SO_2CF_3), effective sensitisers have been discovered and these have found applications in the cine-photo industry[61].

Table 3 presents the absorption maxima of carbocyanines, merocyanines, and styryl dyes containing pyridine, 4-methylthiazole, quinoline, and 3,3-dimethylindolenine rings. Apart from carbocyanines, perfluoroalkyl-substituted di- and tricarbocyanines and derivatives of pyridine[62], quinoline[64], and indolenine[68] have been described.

Table 3 shows that the bathochromic influence of perfluoroalkyl groups on the absorption spectra of symmetrical carbocyanines is particularly pronounced in dyes where these substituents have been introduced directly into the heterocyclic nucleus. The substituents in condensed benzene rings usually also exhibit a bathochromic effect but it is weaker and in the case of indolenine derivatives they actually have a hypsochromic effect.

Table 3. The absorption maxima of dyes derived from pyridine (P),[62,63] 4-methylthiazole (T),[63] quinaldine (Q),[64–66] lepidine (L),[64,65,67] and 3,3-dimethylindolenine (I).[68]

*Δλ is quoted relative to the dye with the NCH_3 group.

The bathochromic effect of substituents increases when their electron-accepting properties are enhanced. The most electron-accepting group SO_2CF_3 in the 6,6′-positions of the lepidine and quinaldine dyes displaces the absorption bands towards longer wavelengths by 34 and 18 nm respectively.

Comparison of the spectroscopic effects of substituents in dyes with different heterocyclic nuclei (Table 4) shows that these effects are minimal in indolenine derivatives, increase on passing to benzothiazole, benzimidazole, and 2-quinoline derivatives, and are maximum in dyes derived from 4-quinoline.

Table 4. The spectroscopic effects (Δλ) of the fluorine-containing substituents Z in the *p*-position relative to the nitrogen atom.

Notation. The following abbreviations for heterocyclic nuclei are used in Tables 4–7 in the names and formulae of the dyes: BT = benzothiazole, BO = benzoxazole, BI = benzimidazole, BS = benzoselenazole, I = indolenine, Q = quinaldine, L = lepidine, R = ethyl- or methyl-rhodanine; the same abbreviations combined with the numeral 1 represent heterocyclic residues in their electron-donating form [see, for example, the formula of dye (VI) in the text]; S = styryl dye; C = carbocyanine; M = merocyanine (derivative of *N*-ethylrhodanine).

Merocyanine dyes, derived from rhodanine, usually exhibit positive solvatochromism, i.e. in polar solvents (alcohols) they have a colour corresponding to a lower frequency than in non-polar (benzene) or less polar (chloroform) solvents[62–67]. However, merocyanines with a benzimidazole nucleus, which exhibit negative solvatochromism, are exceptions[30,31].

2. Dyes with Fluorine-containing Substituents in the Polymethine Chain

The influence of substituents in the polymethine chain on the colour of cyanine dyes has been studied in particular detail in relation to derivatives of benzothiazole. Dyes with a fluorine atom in the α-position in the chain have been synthesised from quaternary 2-fluoromethylbenzothiazolium salts[69] by reactions usually employed to obtain cyanine dyes[69–72]. The dye (VI) can also be synthesised by the reaction of trifluoroacryloyl chloride with *N*-ethyl-*o*-aminothiophenol[73]:

β-Fluorothiacarbocyanine (VII) has been synthesised by the condensation of the dichloride of β,β-difluoroglutaric acid with *N*-methyl-o-aminothiophenol: [74]

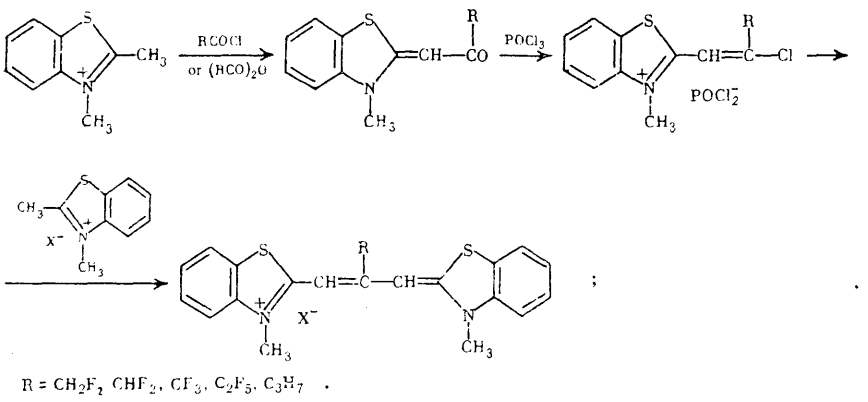
The synthesis of α,β-difluoro-substituted dyes has been achieved with the aid of 2-trifluorovinyl or (better) β-chloro-difluorovinyl-benzothiazole and the corresponding quaternary salts [75,76,79]. A dye with a fully fluorinated polymethine chain, namely α,β,γ-trifluorothiacarbocyanine (VIII), has been obtained from the same compounds [76,77,79]:

Other dyes containing fluorine atoms in the polymethine chain have been obtained by analogous procedures (Table 5).

The fluorine atoms in the polymethine chain influence the absorption spectra of the dyes to a much greater extent than those in the heterocyclic nuclei. The influence of the fluorine atom on the spectrum depends on its position in the chain: the introduction of fluorine atoms in the α- and α,γ-positions shifts the absorption band towards longer wavelengths, while the introduction of a fluorine atom in the β-position causes a hypsochromic shift. In conformity with the FKD rule, the electron-donating substituent exerts such an influence [84,85]. Consequently a fluorine atom in the polymethane chain behaves as an electron-donating substituent, which can be explained by the fact that the conjugation of the substituents in the chain exerts a stronger influence on the absorption spectra of the dyes than the inductive effect [84–86].

The introduction of a fluorine atom in the α-position in the heterocyclic residue enhances its electron-donating properties, which entails an increase of the deviation [from coplanarity?] in styryl dyes and a decrease of Δλ (compared with the effect in the symmetrical carbocyanine), while in merocyanine dyes the deviation diminishes and the bathochromic effect of the fluorine atom increases.

The thiacarbocyanine with a fully fluorinated polymethine chain absorbs light at longer wavelengths than the unsubstituted dye and its absorption intensity is higher, which indicates the possibility, in principle, of the existence of a new type of polymethine dyes with fully fluorinated chains.



Fluoroalkyl substituents have been introduced only in the β-position of the polymethine chains of cyanine dyes.

*Methyl groups are attached to the nitrogen atoms of the heterocycles; in the remaining cases the nitrogen atoms are combined with ethyl groups.

The thiacarbocyanine and selenacarbocyanine with the CH_2F group in the β-position have been obtained by the condensation of the corresponding quaternary salts with the iminoester of monofluoroacetic acid [71]. Acylmethylene derivatives and the β-chloroalkenyl-substituted quaternary salts of nitrogen-containing heterocycles have been used to synthesise dyes with other fluoroalkyl groups in the β-position, for example [74]:

$R = CH_2F$, CHF_2, CF_3, C_2F_5, C_3H_7 .

Dyes containing simultaneously fluorine atoms and trifluoromethyl groups in the chain have been synthesised analogously[87] (Table 6).

Table 6. The absorption maxima of cyanine dyes with fluoroalkyl groups in the polymethine chain.

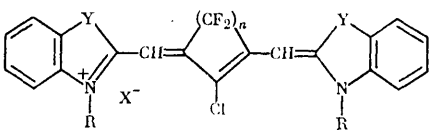
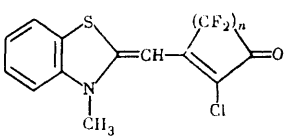
*See the footnote to Table 5.
**In nitromethane; dyes with the cyano-group are quoted for comparison.



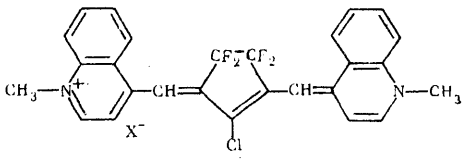
Electron-accepting substituents in the β-position of the polymethine chain of cyanine dyes should exert a bathochromic influence according to the FKD rule. Indeed, the electron-accepting trifluoromethyl groups cause a bathochromic shift of the absorption bands.

Table 6 shows that successive substitution of the hydrogen atoms in the methyl group by fluorine atoms entails a gradual bathochromic shift of the absorption maxima of thiacarbocyanines and merocyanines. In the series of thiacarbocyanines the CH_3 and CH_2F substitutents exhibit hypsochromic effects, while CHF_2, CF_3, C_2F_5, and C_3F_7 exhibit gradually increasing bathochromic effects. A correlation between the absorption frequency and the σ_i and σ_c constants of the substituents has been found for thiacarbocyanines containing substitutents in the β-position[84].

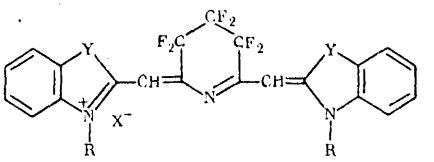


The fluoroalkyl groups in merocyanine dyes derived from benzothiazole exhibit a bathochromic effect, which reflects their electronic and steric influences. The steric hindrance generated by these substituents causes rotation of the predominantly double bond, which entails a bathochromic shift of the absorption bands[74]. In the analogous benzimidazole dye, in which a delocalised ionic structure predominates, the steric hindrance caused by the trifluoromethyl group is responsible for rotation about the predominantly single bond and therefore gives rise to a hypsochromic effect[74].

A spectroscopic effect of the interaction of the substituents is characteristic of cyanine dyes containing electron-donating substituents (fluorine atoms and methoxy-groups) in the α-position of the chain and electron-accepting substituents (trifluoromethyl or cyano-groups) in the β-position: the shift of the absorption band under the influence of two substituents of opposed electronic types exceeds the sum of the shifts induced by the individual substituents in the corresponding monosubstituted dyes[87,91,92]. The bathochromic influence of two electron-donating substituents (F, OH and OCH_3, OH) in the α,γ-positions and of one trifluoromethyl group in the β-position is particularly pronounced (in excess of 100 nm) (Table 6).



Cyanine dyes containing fluorinated rings in the polymethine chain have been described recently[94,95]:



R	Y	n	λ, nm	$\Delta\lambda^*$
CH_3	S	2	660	10
C_2H_5	CH=CH	2	700	-10
C_2H_5	CH=CH	3	758	48

n	λ, nm
2	471
3	500

λ = 773 nm, $\Delta\lambda^*$ = -40 nm

R	Y	λ, nm	$\Delta\lambda^*$
CH_3	CMe_2	572	
CH_3	S	573	9
C_2H_5	CH=CH	621	25

*relative to the dye unsubstituted in the chain.

The fluorinated bridges in the polymethine chains of these dyes can be regarded as electron-accepting perfluoroalkyl substituents, which usually exert a bathochromic influence in conformity with the FKD rule. A hypsochromic influence is observed only in the case of sterically hindered quinoline dyes.

3. Aromatic Azomethines and Azacyanines

The influence of fluorine atoms, trifluoromethyl groups, and other fluorine-containing substituents in the chains of azomethines and azacyanines has been investigated (Table 7). The azomethines (IX) and (X) have been synthesised in accordance with the scheme[96]

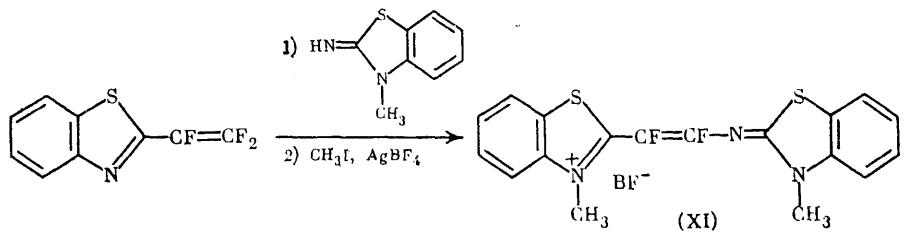


Table 7. The absorption maxima of azomethines and azacyanines with fluorine-containing substituents in the chain.

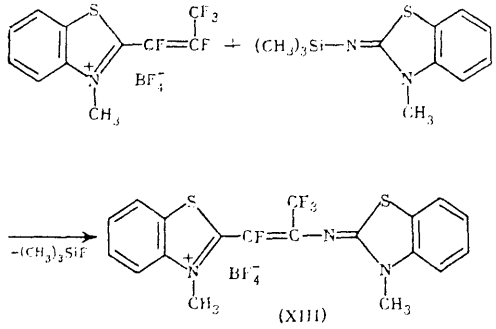
*In nitromethane.

Y = F, Cl ;

$R = CF_3, C_2F_5, C_3F_7$.



Azomethines with a CF_3 group have been synthesised by the Wittig–Staudinger reaction[96]:

$$ArCOCF_3 + (C_6H_5)_3P{=}NAr \rightarrow ArC(CF_3){=}NAr \ .$$

The azacyanine (XI) with two fluorine atoms in the chain has been obtained from 2-trifluorovinylbenzothiazole[97]: see page 998.

The dyes (XII) with perfluoroalkyl groups in the chain have been synthesised with the aid of the corresponding quaternary benzothiazolium salts[98,99]: see page 998.

The dye (XIII) has been obtained in accordance with the scheme[99]

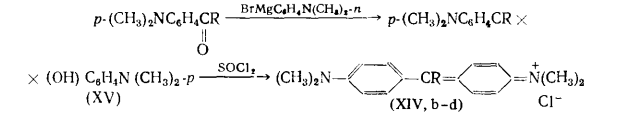
More complex azomethines with fluorine atoms and trifluoromethine groups in the aromatic nuclei[103] as well as triazacyanines with CF_3 groups in the heterocyclic nuclei[104] have been described. Certain azomethine dyes with CF_3 groups in the nuclei are used in the dyeing of polyester fibres[105,106]. The SO_2CHF_2 and SO_2CF_3 groups in aromatic nuclei have a marked bathochromic effect on the colour of azomethines. The introduction of a fluorine atom in the azomethine groups entails a hypsochromic shift of the absorption bands. The absorption intensity then increases, since the non-planar azomethine molecule usually approaches coplanarity more closely under these conditions[101]. This is probably caused by the fact that the fluorine atom is involved in conjugation with the azomethine linkage. The introduction of a CF_3 group at the methine carbon atom results in a bathochromic effect and reduces the light absorption intensity, since this group gives rise to steric hindrance and enhances the non-coplanarity of the molecule[102].

The sequence in which the ability of the groups to transmit conjugation (to effect the displacement of electrons from left to right) diminishes has been established by comparing the absorption maxima of azomethines containing various substituents in the chain[102]:

$$N{=}CH > N{=}C(CF_3) > CH{=}N > C(CF_3){=}N \text{ and } N{=}CF > N{=}CH > CH{=}N > CF{=}N \ .$$

The fluorine atoms in the chains of azacyanines influence the colour like electron-donating substituents, in conformity with the FKD rule, but their spectroscopic effects are weaker than in thiacarbocyanines[97–99]. The influence of perfluoroalkyl groups in the β-position in azathiacyanines depends mainly on the steric hindrance generated by them, which induces rotation of the predominantly single C–N bonds and hence a hypsochromic shift of the absorption bands[99].

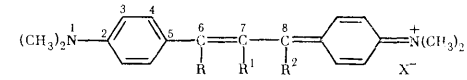
III. DIPHENYLMETHANE AND TRIPHENYLMETHANE DYES



1. Diphenylmethane Dyes

Diphenylmethane dyes containing a fluorine atom or fluoroalkyl groups at the methine carbon atom (compounds XIV, a–d) have been synthesised[86].

A dye with a fluorine atom has been obtained by treating Michler's ketone with difluorophosgene:



The dyes (XIV, b–d) with R = CHF_2, CF_3, and C_3F_7 have been obtained from the corresponding carbinols (XV):

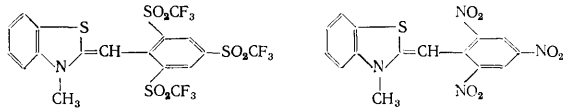
R	H	F	Cl	CH_2F	CF_3	C_3F_7	CN
λ_{max}, nm	607	588	626	665	693	703	716
$\Delta\lambda$, nm	0	−19	19	58	86	96	109

In accordance with the FKD rule, electron-donating substituents have a hypsochromic effect on the colour compared with the unsubstituted dye, while electron-accepting groups have a bathochromic effect. A fluorine atom at the methine carbon atom influences the absorption spectra like an electron-donating substituent, analogously to its influence in the chains of polymethine dyes. Like the cyano-group, fluoroalkyl groups give rise to a strong bathochromic shift of the absorption maximum. A correlation equation relating the absorption frequencies of the dyes to the electronic nature of the substituents (their σ_i and σ_c constants) has been found[86]. The conjugation effects of the substituents R have a preferential influence on the colour. Bulky substituents, for example the CF_3 group, lead to the breakdown of the coplanarity of the dye molecule, reducing the absorption intensity.

The bis(*p*-dimethylaminophenyl)trimethine dye with one or two fluorine atoms in the chain has been synthesised[107]:

	R	R^1	R^2	$\lambda(CH_3NO_2)$, nm	$\Delta\lambda$
	H	H	H	700	—
(XVI)	F	H	H	693	−7
(XVII)	F	F	H	746	+26

The dye (XVII) has been synthesised in accordance with the scheme

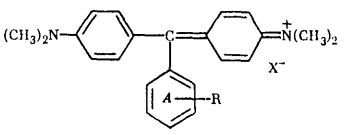


A fluorine atom in the chains of vinylene homologues of diphenylmethane dyes influences the colour like an electron-donating substituent, in conformity with the FKD rule: its effect on the colour is hypsochromic in the even positions within the chain and bathochromic in the odd positions. Both diphenylmethane and polymethine dyes of a new type with a

conjugated anion have been synthesised[108]:

λ_{max}=590 (n=0), 640 (n=1) nm (ethanol).

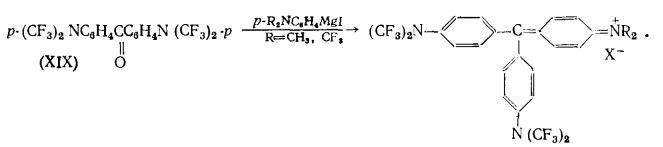
The analogous anionic dye with nitro-groups absorbs at longer wavelengths (at 622 nm for n = 0), since the SO_2CF_3 group, which is difficult to polarise, is a weaker auxochrome than the nitro-group[108]. This is also evident in relation to the following dyes[109]:



λ_{max} = 504 nm (benzene) λ_{max} = 522 nm (benzene)

2. Triphenylmethane Dyes

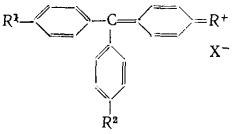
Triphenylmethane dyes (analogues of Malachite Green) containing a fluorine atom or a CF_3 group, have been obtained by the Grignard reaction[110,111]. The introduction of the CF_3 group increase the light stability[111]. Crystal Violet with a trifluoromethyl group in the m-position in one of the rings has been synthesised analogously[110].



Derivatives of Malachite Green containing one or two trifluoromethylgroups in the A ring [compound (XVIII)] absorb at a lower frequency, like the dyes with an NO_2 group, than the unsubstituted dye[111–113]:

(XVIII)

R	4-CH_3	H	3-CF_3	4-CF_3	4-NO_2	3,5-$(CF_3)_2$	F_5
λ_{max}, nm	616	621	634	637	645	647	658
$\Delta\lambda$	—5	0	13	16	24	26	37

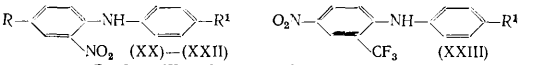


Triphenylmethane dyes containing two trifluoromethyl groups at the nitrogen atom have been synthesised[115]. The analogue of Crystal Violet with one $N(CF_3)_2$ group has been obtained from p-chloro-N,N-bis(trifluoromethyl)aniline and Michler's ketone by treatment with metallic sodium. A fluorine-containing analogue of Michler's ketone (XIX) has been used to obtain dyes with two and three $N(CF_3)_2$ groups:

(XIX)

The replacement of one $N(CH_3)_2$ group in the Crystal Violet by $N(CF_3)_2$ leads to a bathochromic shift of the long-wavelength absorption band by 42 nm. Further substitution of the $N(CH_3)_2$ groups by $N(CF_3)_2$ increases significantly the absorption frequency of the dyes, since the bis(trifluoromethyl)amino-group is a very weak auxochrome[115]. Triphenylmethane dyes containing 2,2,2-trifluoroethyl groups at the nitrogen atom in one or two rings have been proposed for the dyeing of polyacrylonitrile fibre[116].

Triphenylmethane dyes containing one and three $C_2H_5NCH_2.(CF_2CF_2)_nH$ groups, where n = 1, 2, have been synthesised[117]. The absorption maxima of such dyes with n = 1 and 2 hardly differ. The accumulation of the $C_2H_5NCH_2(CF_2CF_2)_nH$ groups in the dye causes a hypsochromic shift of the absorption maximum, although dyes with one such group absorb at a lower frequency, as in the case of $N(CF_3)_2$, than Crystal Violet. The $C_2H_5NCH_2(CF_2CF_2)_nH$ groups are fairly powerful auxochromes, which has been demonstrated also in relation to styryl dyes[117]:



R	R^1	R^2	λ_{max}, nm
$(CH_3)_2N$	$(CH_3)_2N$	$C_2H_5NCH_2CF_2CF_2H$	540, 594
$(CH_3)_2N$	$C_2H_5NCH_2CF_2CF_2H$	$C_2H_5NCH_2CF_2CF_2H$	540, 580
$C_2H_5NCH_2CF_2CF_2H$	$C_2H_5NCH_2CF_2CF_2H$	$C_2H_5NCH_2CF_2CF_2H$	578

IV. NITRODIPHENYLAMINE DYES

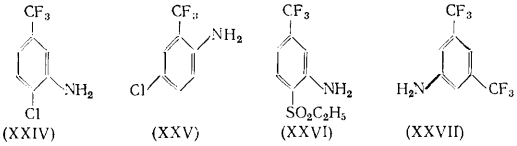
Nitrodiphenylamine dyes containing fluorinated groups have found applications as yellow disperse dyes for artificial and synthetic fibres. Dyes of this type have been obtained by the condensation of substituted chlorobenzenes containing the CF_3,[118–120] CF_3CO,[121] or CF_3SO_2 [119,122] groups with arylamines.

The dyes (XX)–(XXII) produce yellow coloure on acetate silk and Lavsan with a high stability in relation to light soap, and sublimation[121,124,125]:

(XX)–(XXII) (XXIII)

R=CF_3 (XX), SO_2CF_3 (XXI), $COCF_3$ (XXII);
R^1=H, CH_3O, C_2H_5O, Cl, CH_3, $NHCOCH_3$.

The fastness to light of trifluoroacetophenone (XXII) derivatives reaches 7 units, which is lower by 1–2 units than for the corresponding acetophenone derivatives; the stabilities in relation to soap, friction, and sublimation are different. The nitrodiphenylamine dye (XX, R = H) has a higher light stability than its isomer with the NO_2 group in the p-position[126]. The introduction of a second nitro-group into the dye (XX, R = H) in the 6-position lowers the fastness to light[127]. Electron-donating substituents R in 2-R-4-NO_2- and 4-R-2-NO_2-diphenylamines produce a bathochromic shift of the long-wavelength band, while electron-accepting substituents give rise to a hypsochromic shift of the absorption maximum[120,128,129]. Such influence of the substituents is consistent with the FKD rule:

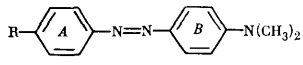


R	CH_3O	H	CF_3CO	CF_3	CF_3SO_2	NO_2
λ_{max}, nm (alcohol)	465	425	417 (benzene)	410	397	353
$\Delta\lambda$	40	0	—8	—15	—28	—72

The substituents R^1 in the dyes (XX) and (XXIII) have an analogous influence, but it is weaker than that of the substituent R.

Nitrodiphenylamine dyes exhibit positive solvatochromism, for example, for the dye (XX, R = H), λ_{max} is 432 nm in water, 410 nm in alcohol, and 401 nm in hexane.

V. AZO-DYES

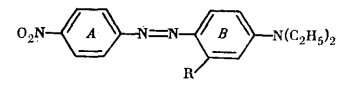


Azo-dyes with fluorine-containing substituents constitute a large group of disperse, cold, cationic, and active dyes. They are used to dye natural, artificial, and synthetic fibres and frequently exhibit a high stability in relation to light, oxidation, and other physical and chemical influences. Fluorine-containing substituents have been introduced into both diazo- and azo-components. The methods for their introduction have been satisfactorily developed[6,7,132]. The azoamines (XXIV)–(XXVII) with a trifluoromethyl group are used for the cold dyeing of cotton[130,131]. They are manufactured on an industrial scale.

(XXIV) (XXV) (XXVI) (XXVII)

These amines give rise to brilliant fast orange and red colours. The dyes based on the azoamines Brilliant Orange K (XXIV) and Brilliant Yellow G (XXV) are particularly brilliant and light-fast.

Table 8. The absorption maxima of dimethylaminoazo-dyes and their salts[133–137]



R	λ_{max}, nm		$\Delta\lambda$*	R	λ_{max}, nm		$\Delta\lambda$
	alcohol	alcohol + HCl			alcohol	alcohol + HCl	
CH_3O	497	555	148	CF_3	427	505	78
CH_3S	420	555	135	$(CF_3)_3CS$	444	512	68
CH_3	467	533	126	CHF_2SO	445	511	66
H	407	518	111	CF_3SeO	448	510	62
F	407	518	111	CF_3SO	447	507	60
Cl	417	522	105	$(CF_3SO_2)_2N$	449	507	58
CF_3O	419	512	93	CHF_2SO_2	463	503	40
CHF_2S	429	520	91	FSO_2	463	498	35
CF_3Se	430	517	87	NO_2	475	508	33
CF_3S	432	514	82	CF_3SO_2	476	500	24
CF_3SO_2O	424	508	84	$(CF_3)_3CSO_2$	485	500	15

*$\Delta\lambda = \lambda_{max}$(alcohol + HCl) − λ_{max}(alcohol).

Table 8 lists the absorption maxima of dimethylaminoazobenzenes (DAAB), containing fluorinated groups in the diazo-component of the dye. The absorption maxima of DAAB with electron-donating substituents give rise to a bathochromic shift of the absorption maximum, which is greater the more pronounced the electron-accepting properties. A fluorine atom does not influence the absorption spectrum. The CHF_2SO_2 and FSO_2 groups have effects similar to that of the NO_2 group, while the CF_3SO_2 and $(CF_3)_3CSO_2$ groups have a more marked influence and are the most powerful electron acceptors. When the molecules of azo-dyes are excited by light, electrons are displaced from the *B* ring to the azo-group and the *A* ring. Electron-accepting groups in the *A* ring and electron-donating groups in the *B* ring therefore as a rule cause a bathochromic shift in the colour of azo-dyes. The excitation of the molecules of salts of azo-dyes is accompanied by an electron shift in the opposite direction.

The absorption maxima of azo-dyes in an acid medium undergo a bathochromic shift after the introduction of electron-donating substituents into the *A* ring and electron-accepting substituents into the *B* ring (Table 8).[133,138,139] The influence of substituents in the *B* ring is illustrated below:

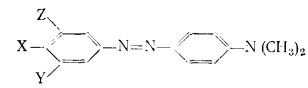
	R	CH_3O	CH_3	H	F	NO_2	CF_3	CN
λ_{max}, nm	alcohol	501	497	486	469	470	467	472
	alcohol + HCl	486	513	515	505	514	530	550
	$\Delta\lambda$	−15	16	29	36	44	63	78

(The difference between the absorption maxima of the DAAB derivatives and their salts is an indication of the halochroism of azo-dyes. It is linearly related to the Hammett σ constants of the substitutents:

$$\Delta\lambda = 125-101\sigma_p \ (r = 0.997); \quad \Delta\lambda = 115-70\sigma_m \ (r = 0.986).$$

Analogous equations have been obtained for *N*,*N*-di-(hydroxyethyl)aminoazo-dyes[133] and the bases of diazastyryl dyes (XXVII).[140]

The influence of substituents in the 6-position of the benzothiazole ring on the colour of the bases (XXVII) and the diazastyryl dyes (XXVIII)[140] is analogous to their influence in DAAB and their salts:

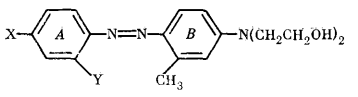


(XXVII) (XXVIII)

	R	CH_3O	CH_3	H	CF_3O	CF_3	CF_3S	CF_3SO	NO_2	CF_3SO_2
λ_{max}, nm	alcohol	511	510	509	518	526	529	536	548	546
	alcohol + HCl	610	600	508	596	598	588	584	584	562
	$\Delta\lambda$	99	90	89	78	62	59	51	36	16

The curves and the absorption maxima for the diazastyryl derivatives (XXVIII) and the hydrochlorides of the bases (XXVII) do not differ. This shows that the proton adds to the nitrogen atom in the benzothiazole ring and not the azo-group. Despite the difference between the structures of the diazastyryl dyes and DAAB, the influence of their substituents is of the same type.

The introduction of electron-donating substituents into DAAB leads to high values of $\Delta\lambda$ (Table 8). These dyes possess indicator properties. Lower values of $\Delta\lambda$ correspond to electron-accepting substituents. Such dyes are less halochromic and more suitable for the dyeing of fabrics and they are resistant to the gases in smoke. The introduction of highly electron-accepting fluorine-containing groups into the DAAB molecule makes it possible to observe the influence of negative halochroism—a hypsochromic shift of the absorption maximum in an acid medium[138]:



X	Y	Z	λ_{max}, nm		$\Delta\lambda$
			alcohol	alcohol + HCl	
NO_2	CF_3	—	487	503	16
CF_3	CF_3	CF_3	493	493	0
CH_3SO_2	CF_3SO_2	—	497	494	−3
CF_3SO_2	NO_2	—	522	490	−32

The negative halochroism can be explained by the fact that, in the case of strong electron-accepting substituents, the boundary resonance structures of the dye base approach energetic equivalence. Such dyes absorb at low frequencies.

After the introduction of electron-accepting substituents into the dye salts, there is a sharp increase of the contribution of the structure (which is dominant in any case) having a positive charge on the nitrogen atom of the dialkylamino-group, which causes a hypsochromic shift in the colour of the dye compared with the colour in a neutral medium.

A valuable quality of many fluorine-containing azo-dyes is high fastness to light in which the position and character of the fluorinated groups play a major role (Table 9).[141] When the electron-accepting properties of the substituents in the *o*- and *p*-positions in monosubstituted dyes (Nos.1–13) are enhanced, a bathochromic shift is observed. *p*-Substituted dyes (Nos.10 and 12) absorb at longer wavelengths than the *o*-isomers (Nos.11 and 13). Monosubstituted dyes with electron-donating and weak electron-accepting substituents (Nos 1, 2, and 4–9) are less light-fast than the unsubstituted dye (No.3). Electron acceptors (the nitro- and trifluoroethanesulphonyl groups) increase somewhat the light-fastness. No differences are observed between the light-fastnesses of monosubstituted dyes with the same substituent in the *o*- and *p*-positions.

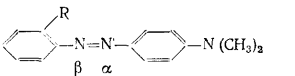


Table 9. The absorption maxima and fastness to light of fluorine-containing azo-dyes[141]

(XXIX)

No.	X	Y	λ_{max}, nm		Fastness to light, units

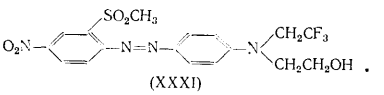
19	NO_2	CF_3SO_2	564	484	6–7

Among the isomeric disubstituted dyes Nos.14 and 15 and Nos.18 and 19, the dyes Nos.15 and 19 containing the CF_3 and CF_3SO_2 groups in the *o*-position, absorb at the lowest frequencies and show the greatest fastness to light. For the substituent in the *p*-position, the length of the chromophore chain has the greatest influence on the colour. The trifluoromethanesulphonyl group, which is a stronger electron acceptor than the nitro-group like all sulphur-containing substituents, has a tetrahedral structure. Conjugation does not therefore reach the oxygen atoms, being restricted to the sulphur atom by virtue of the involvement of its *d* orbitals and the conjugation chain is shorter than for the *p*-NO_2 group[147]. The conjugation of the *o*-NO_2 group is greatly influenced by steric factors. The breakdown of coplanarity for the CF_3SO_2 group does not affect significantly its conjugation with the dye chromophore. The fastness to light of the disubstituted dyes depends on the positions of the substituents. Dyes Nos.15 and 19 are more light-fast than dyes Nos. 16–18. This can be apparently explained by the fact that the bulky electron-accepting CF_3 and CF_3SO_2 groups in the *o*-position relative to the azo-group protect the latter against photochemical oxidation to a greater extent than the nitro-group. This is confirmed by the comparison of the absorption intensities of the salts of substituted DAAB.[145] Even a proton, which is small, adds to only an insignificant extent to the β-nitrogen atom of the azo-group in the presence of the CF_3 group in the *o*-position.

λ_{max}, nm (10^{-4} *E* given in brackets)



R	alcohol	alcohol + HCl
CH_3	410 (2.70)	520 (1.00)
H	407 (2.80)	518 (4.60)
CF_3	425 (2.98)	479 (0.008)
NO_2	440 (2.68)	500 (1.11)

In order to obtain light-fast dyes, it is necessary that two electron-accepting substituents be present in the *A* ring. A bulky fluorine-containing group in the *o*-position has a favourable effect. In those dyes where a trifluoromethyl group is already present in the *o*-position relative to the azo-group, the introduction of a bromine atom or a CF_3 group in the second *o*-position does not lead to a further increase of the fastness to light of the colour[146].

Among the dyes of type (XXIX) (Table 9), those where X = NO and Y = CF_3, C_2F_5, CF_2SO_2, or CHF_2SO_2 exhibit the highest light-fastness for different azo-components. Such dyes are of practical interest[146–164]. Stable colours on polyamide and polyester fibres have been obtained by dyeing the latter with disperse azo-dyes containing the fluorosulphonyl group[165–167]. The azoamines (XXIV)–(XXVII) [168–180] as well as their trifluoromethanesulphonyl analogues[181,182] are used to prepare pigments of cold, disperse, cationic, and azid azo-dyes. Disperse and cationic azo-dyes based on hereocyclic diazo-components, obtained from amino-derivatives of thiazole, thiadiazole, benzothiazole and pyrazole containing the CF_3 and $(CF_3)_2COH$ groups, are of practical interest for the colouring of artificial and synthetic fibres[183–190]. Certain disperse azo-dyes containing the CF_3 [191–196] and $COCH_3$ [197] groups have a low stability in relation to sublimation. Because of this "deficiency" they have found applications as dyes for thermal transfer printing on polyester and polyamide fibres. Dyes with the CHF_3, SO_2F, SO_2CHF_2, and SO_2CF_3 substituents in the benzoisothiazole ring, used for transfer printing on polyacrylonitrile and polyester fibres, are also mentioned in a patent[194].

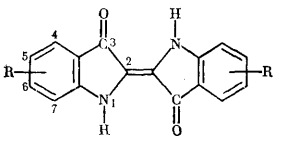
The arylamines $C_6H_5NRCH_2CH_2OH$ (XXX),[198] where R = $C_3F_7CH_2$, CF_3CH_2, CHF_2CH_2, $CH_3CF_2CH_2$, $CF_3CH_2CH_2$, $CHF_2CH_2CH_2$, $CH_3CF_2CH_3CH_2$, CH_2FCH_2, $CH_3CF_2CF_2CH_2CH_2$, or $CH_3CF_2CH_2CH_2CH_2$ are used as the azo-component. They have been obtained by the reaction of aniline with fluorine-containing alkyl bromides followed by treatment with epoxyethane[199,200]. The study of the properties of azo-dyes with azo-components of type (XXX) has shown that, with increase of the distance between the nitrogen atom and the carbon atom linked to the fluorine atom and with decrease of the number of fluorine atoms in the alkyl group, the colour of the dyes shifts bathochromically. The fastness to light increases with increase of the number of fluorine atoms in the *N*-alkyl group and as they come closer to the nitrogen atom[201]. The dye (XXXI) on acetate silk[201] and the dyes with the $N(CH_2)_nC_2F_5$ (n = 1, 2) groups in the azo-component on

polyester fibre[202–206] show an excellent fastness to light.

(XXXI)

Many new fluorine-containing azo-components $C_6H_5NRCH_2.(CF_2CF_2)_nH$ (XXXII, R = H, CH_3, C_2H_5, C_2H_4OH, or C_2H_4CN; n = 1, 2) have been synthesised by alkylating arylamines with the polyfluoroalkanesulphonates of fluorinated telomeric alcohols $H(CF_3CF_2)_nCH_2OH$ (FTA).[207,208]

The substituents R in disperse azo-dyes obtained from the azo-components (XXXII) can be arranged in the following sequence in terms of the bathochromic shift of the colour: $C_2H_5 \geq C_2H_4OH > CH_3 > C_2H_4CN$.[209] An increase in the number of difluoromethylene groups n leads to a hypsochromic shift of the absorption maximum by 6–7 nm. All the dyes exhibit a high fastness to light and some of them readily sublime and are suitable for thermal transfer printing.



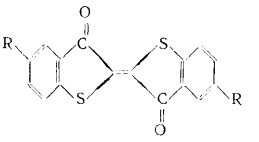
Dyes containing the CF_3 groups in the *o*-positions of the benzene ring of the azo-component are more light-fast than the corresponding dyes with the CH_3 group[140,210,217].

The absorption spectra and fastness to light of disperse azo-dyes derived from *N*-(2,2,2-trifluoroethyl)tetrahydroquinoline have been investigated[216].

The active dyes in which fluorine-containing groups, for example, a fluorine-substituted triazine or polyfluorocyclobutyl group[218–221], form a strong linkage with the fibre, are widely used, although certain fluorine atoms are then substituted and are no longer present in the dye on the fibre. If trifluoromethyl groups are present in the molecules of the azo-dyes forming part of the active dye[222–228], then such dyes give rise to light-fast colours.

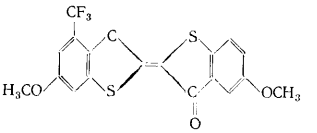
VI. INDIGOID AND THIOINDIGOID DYES

Isatins and indigoid dyes containing fluorine atoms and trifluoromethyl groups have been described[126,229–234]. Electron-donating substituents in the 5,5′-positions in indigo cause a bathochromic shift in the colour, while electron-accepting substituents cause a hypsochromic shift. The substituents in the 6,6′-positions act in the opposite manner.



λ_{max}, nm (tetrachloroethane)

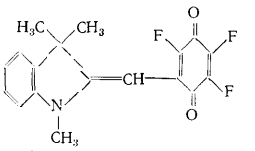
R	5,5′	6,6′	4,4′	7,7′
CH_3O	645	570	—	—
H	605	605	605	605
F	615	570	—	560
CF_3	—	—	605	580
NO_2	580	635	—	—



The fluorine atoms in the 5,5′- and 6,6′-positions influence the colour like electron-donating substituents. The inductive effect of the substituents in the 7,7′-positions has a marked influence. Fluorine atoms give rise to a greater hypsochromic shift of the absorption maximum of the dye than the CF_3 group. Comparison of the stabilities of the colours of 5,5′- and 7,7′-difluoroindigos with that of the colour of 5,5′-dibromoindigo showed that the fluoro-derivatives are more light-fast[234].

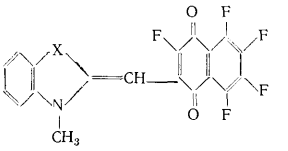
The replacement of the ethyl group in the vat dye diethoxyviolanthrone by the trifluoroethyl group causes a hypsochromic shift in the colour of the dye—the latter changes from green to blue[126]. Derivatives of thioindigo containing fluorine atoms and fluorinated groups have been obtained by oxidising the corresponding thionaphthenes[235–239]:

R	F	H	CF_3O	CF_3S	CF_3	NO_2
λ_{max}, nm (benzene)	559	545	549	548	535	513
$\Delta\lambda$	14	0	4	3	−10	−32



Electron-accepting substituents in the 5,5′-positions of thioindigo hinder the shift of electrons from the sulphur atom to the carbonyl group. This leads to a hypsochromic shift of the absorption maximum of the dye. $\Delta\lambda$ diminishes in the following sequence of substituents in the 5,5′-positions: C_2H_5O > I > F, Cl, Br > CH_3 > CF_3O > CF_3S > H > CF_3 > CH_3SO_2 > NO_2. 5,5′-Bis(trifluoromethyl)thioindigo derivatives exhibit a weak affinity for fibre[239]. Asymmetric dyes of the type

impart a bright red and fast colour to cotton, which makes them suitable for dyeing and printing[236].

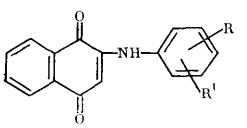


VII. BENZOQUINONE, NAPHTHOQUINONE, AND ANTHRAQUINONE DYES

The merocyanine dyes (XXXII) and (XXXIII) have been obtained by the reaction of methylene-substituted bases of nitrogen-containing heterocycles with the corresponding perfluoroquinones[240]:

(XXXII)

λ_{max}, nm	$\Delta\lambda$
692	+38

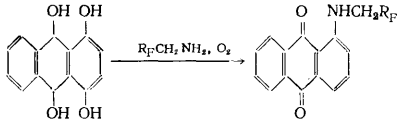


(XXXIII)

X	λ_{max}, nm	$\Delta\lambda$
$C(CH_3)_2$	635	+35
S	668	+53
CH=CH	685	+15

The introduction of fluorine atoms into the quinonoid nuclei of dyes leads to a considerable bathochromic shift. Like the corresponding compounds without fluorine, the dye (XXXII) with a perfluorobenzoquinone ring absorbs at longer wavelengths than the dye (XXXIII) with a perfluoronaphthoquinone residue. As the electron-donating properties of the heterocyclic residues are enhanced, the colour of the dye changes bathochromically.

Napthoquinone dyes (2-phenylamino-1,4-naphthoquinones) containing fluorinated groups in the benzene ring have been synthesised[241].

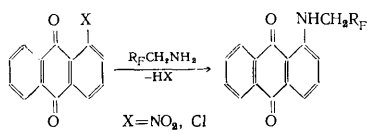


R, R′	λ_{max}, nm	R, R′	λ_{max}, nm
H, H	462	H, 3-CF_3	449
H, 4-F	460	H, 3-NO_2	443
H, 4-CF_3O	456	2-Cl, 5-CF_3	441
H, 4-CF_3S	454	2-NO_2, 5-CF_3	438
H, 4-CF_3SO_2	440	2-Cl, 5-CF_3SO_2	426

Fluorine-containing substituents shift the absorption maximum of the dye towards shorter wavelengths, since they withdraw electrons from the amino-group and prevent their transfer to the oxygen atom. Naphthoquinone dyes with fluorine-containing substituents are faster in relation to all kinds of treatment on Lavsan than dyes of the same series with non-fluorinated groups.

2-Trifluoromethylanthraquinone has been used as an intermediate in the synthesis of vat dyes[242]. 1-Isocyanato-5-trifluoromethylanthraquinone has been recently patented for the same purpose[243].

Dyes of the aminohydroxyanthraquinone series containing fluoroalkyl substituents at the nitrogen atom of the amino-group, have been obtained by treating leucoquinizarin with fluoroalkylamines and subsequent oxidation[244]:



Fluorine-containing alkyl substituents in the alkylamino-group induce a hypsochromic shift and increase the fastness to light of the dyes in the sequence $CH_3CF_2CH_2CH_2CH_2$, $CHF_2CH_2CH_2 < CH_3CF_2CH_2 < CHF_2CH_2$, CF_3CH_2, $CH_3(CF_3)CH$ (Table 10).

Table 10. The absorption maxima of anthraquinone derivatives containing polyfluoroalkyl groups[246].

No.	Ring substituents	λ_{max}, nm

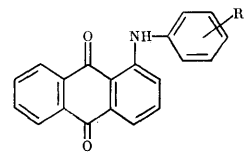
13	2-$OCH_2CF_2CF_2H$	328	330
14	1-NH_2-4-OH	528, 554	534, 570
15	1-$NHCH_2CF_2CF_2H$-4-OH	534, 570	537, 571
16	1-NH_2-4-Cl	472	484
17	1-NH_2-4-$OCH_2CF_2CF_2H$	476	496
18	1-NH_2-4-$OCH_2(CF_2CF_2)_2H$	476	496

α-Polyfluoroalkylaminoanthraquinone dyes have also been synthesised by the reaction of fluoroalkylamines with α-nitroanthraquinone[245] or α-chloroanthraquinone[246]:

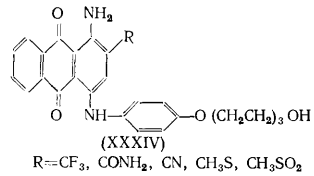
;



1,4-Bis(1′,1′,3′-trihydrotetrafluoropropyl)anthraquinone has been obtained by substituting two hydroxy-groups in leucoquinizarin by polyfluoroalkylamino-groups. The same product as well as β-polyfluoroalkylaminoanthraquinone has been synthesised by alkylating aminoanthraquinones by FTA sulphones[246,247]. When α- and β-chloroanthraquinones were treated with sodium alkoxides derived from FTA, polyfluoroalkoxyanthraquinones were obtained[246].

The substitution of the hydrogen atom of the hydroxy-group by a polyfluoroalkyl group influences the absorption maximum to a greater extent than the substitution of a hydrogen atom in the amino-group; the colour undergoes a hypsochromic shift to the extent of 50 nm. The β-polyfluoroalkylamino- and β-polyfluoroalkoxy-anthraquinones have colours in a shorter wavelength range than the corresponding α-derivatives.

The substitution of two hydrogen atoms in 1,4-diaminoanthraquinone (one in each amino-group) induces a bathochromic shift of the absorption band of the residue by 15 nm. However, dye No.8 (Table 10) has a colour corresponding to a much shorter wavelength than 1,4-bis(methylamino)-anthraquinone (No.7).

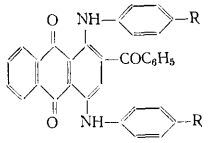


1-Amino-4-polyfluoroalkoxyanthraquinones (Nos.17 and 18) have only one absorption maximum in the visible region, in contrast to 1-amino-4-hydroxy- and 1,4-diamino-anthraquinones, because the polyfluoroalkoxy-groups are not involved in conjugation with the carbonyl group and in the formation of the hydrogen bond.

Arylaminoanthraquinone dyes containing fluorinated substituents in the benzene ring are suitable as disperse dyes for synthetic fibres. Electron-donating substituents in the benzene ring, like those introduced directly into the anthraquinone nucleus, induce a bathochromic shift of the absorption maximum of the dye, while electron-accepting substituents give rise to a hypsochromic shift[249].

R	λ_{max}, nm (alcohol)		
	p-	*m*-	*o*-
CH_3O	515	506	521
H	508	508	508
CF_3	496	492	486
NO_2	482	486	481

Dyes containing the CF_3 group impart to polyester fibre a red colour which is fast to light[248–251]. Comparison of the stabilities of the colours on acetate silk showed that the dye (XXXIV), containing the CF_3 group, has the highest fastness to light[244]:



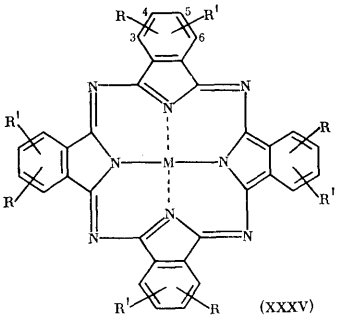
(XXXIV)

R=CF_3, $CONH_2$, CN, CH_3S, CH_3SO_2 .

The CF_3O group has been introduced into arylaminoanthraquinones in addition to the CF_3 group[252,253]. Colours more resistant to wet treatments and light have been obtained on polyester fibre than in the case of fluorine-free dyes. A series of 4-arylamino-1-hydroxyanthraquinones with substituents in the benzene ring [CF_3,[254,255] CHF_2,[256] OCF_2CHFX (X = H, F, or Cl),[257] CF_3O,[253] $C(CF_3)_2OH$ [258]] as well as pentafluorobenzamidoanthraquinone[259] have been patented.

1,4-Diarylaminoanthraquinones are obtained by arylating 1,4-diaminoanthraquinone. The substitution of the *p*-position in the benzene ring by the fluorine-containing groups CF_3CO and CF_3SO_2 leads to a hypsochromic shift of the long-wavelength absorption maximum as a consequence of the electron-accepting influence of such groups: $CF_3SO_2 > NO_2 >$

$CF_3CO > H > CH_3$:[260,261]



R	λ_{max}, nm (trichlorobenzene) ($\Delta\lambda$)	
CH_3	442 (10)	677 (11)
H	432	666
CF_3CO	440 (8)	617 (—49)
NO_2	448 (16)	612 (—54)
CF_3SO_2	419 (—13)	595 (—71)

These dyes impart to polyester fibre a bright green colour with high parameters of resistance to all physical and chemical influences. Patents describe 1,4- and 1,5-diarylaminoanthraquinone dyes containing the CF_3,[262–264] CF_3O, CF_3CO, CF_3SO_2,[260,261,265,266] $OCHF_2$, and OCF_2CHF_2 [267] groups in the benzene ring. They are used to impart fast blue and green colours to cellulose esters, polyesters, and polyamides.

VIII. PHTHALOCYANINE DYES WITH FLUORINE-CONTAINING SUBSTITUENTS

The introduction of fluorine atoms and fluorine-containing substituents into phthalocyanine dyes not only influences their absorption spectra but also increases their fastness to light, solubility, and resistance to the action of oxidants.

Table 11 lists the absorption maxima of metal-free phthalocyanines[268–270], copper-containing phthalocyanines (XXXV), and naphthalocyanines[270]:

(XXXV)

Table 11. The absorption maxima of fluorine-containing phthalocyanines (Pc) and naphthalocyanines (Nc).[268–270]

12	$[(CF_3)_3C]_4$-4-PcH_2	692, 655, 593	25	$(CF_3)_8$-6,7-NcCu	766, 714, 678
13	$[(CF_3)_3C]_4$-4-PcCu	672, 602			

*PcH_2 = phthalocyanine without a metal; PcCu = copper-phthalocyanine; NcCu = copper-naphthalocyanine.

The fluorine atoms in the 4-position in the phthalocyanines have virtually no influence on the absorption maxima and those in the 3-position induce a small bathochromic shift. A hypsochromic shift of the absorption bands is characteristic of tetrakis(trifluoromethyl)phthalocyanines (dyes Nos.5–7). The introduction of two or three trifluoromethyl groups in the 4- and 5-positions (dye No.8) or 3-, 4-, and 5-positions (dye No.11) does not induce a shift of the absorption maximum compared with the 4-substituted dye (No.7). The perfluoro-t-butyl group (dyes Nos.12 and 13) hardly affects the position of the long-wavelength absorption maximum. The trifluoromethylthio- and trifluoromethanesulphonyl-groups in dyes Nos.14–21 exhibit small bathochromic effects.

A bathochromic shift of the absorption band by approximately 100 nm is observed in the absorption spectra of naphthalocyanines (Nos.23–25) compared with the perfluoroalkylphthalocyanines.

The introduction of trifluoromethyl and perfluoro-t-butyl groups into phthalocyanine molecules greatly increases their solubility in organic solvents, reduces their basicity, and increases their resistance to oxidation[269].

It is seen from the above that investigations have led to the discovery of certain rules governing the influence of fluorine atoms and fluorine-containing substituents on the colour and properties of all classes of organic dyes. These data can be used for the specific synthesis of dyes with practically valuable properties.

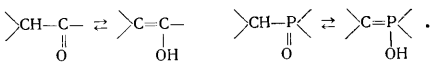
The Phosphorus-Carbon Prototropic Tautomerism

T.A.Mastryukova and M.I.Kabachnik



New types of prototropic tautomerism in which the proton migrates between a carbon atom and a phosphorus-containing functional group are examined. It is shown that in all cases the position of the tautomeric equilibrium is determined by the relative acidities of the different forms: the CH acidity of the forms in which the proton is located at a carbon atom and the PH or PXH acidity (X = O, S, etc.) of the tautomers with the proton in the phosphorus-containing group. The method for the estimation of the relative acidities of different forms with the aid of the σ^{ph} constants of the substituents at the phosphorus atom and the σ_C^- constants of the substituents at the central carbon atom, characterising the acidifying influence of these substituents, has attracted attention in this connection.
It has been shown that in all cases the equilibrium position is determined by the general characteristics of the protolytic acid - base tautomeric equilibrium.
The bibliography includes 75 references.

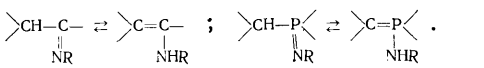
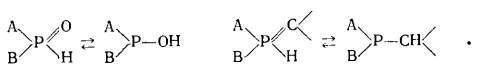
IV. Conclusion 1028



I. INTRODUCTION

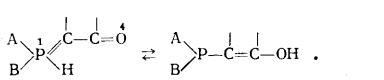
By phosphorus-carbon prototropic tautomerism, we understand the type of tautomerism in which the proton migrates between a carbon atom and a phosphorus-containing functional group. In principle, phosphorus-carbon tautomeric systems can be derived from their purely organic prototypes by replacing the group accepting a proton from the carbon atom by a phosphorus-containing group. Thus, the phosphoryl-hydroxy-ylide system can be derived from the keto-enol system:



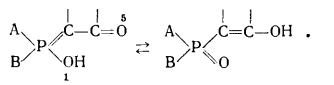
keto - enol phosphoryl - hydroxy-ylide

The phosphorimide–animoylide tautomerism can be derived similarly from the ketimine–enamine tautomerism:

Ketimine - enamine phosphorimide - aminoylide



Furthermore, by virtue of the ease with which phosphorus changes its covalence from 3 to 4, diad-tautomeric systems of the type of dialkyl phosphites and their numerous analogues are widely known in the chemistry of organophosphorus compounds. By means of the reverse analogy, involving the replacement of the heteroatom linked to phosphorus by a carbon atom, it is possible to derive the diad phosphorus–carbon tautomerism:

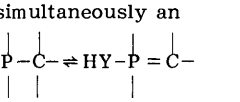


dialkyl phosphite tautomerism diad phosphorus - carbon tautomerism

It can be shown that all types of the phosphorus-carbon tautomerism constitute a single group of equilibria, a common feature of which is the transfer of a proton from the α-carbon atom to a phosphorus-containing functional group (Table 1).

Apart from the phosphorus-carbon diad and triad tautomeric systems, there is also a possibility of their vinylogue systems. Here, one can include, for example the tetrad system in which there is a proton 1,4-migration and not a 1,2-migration (diad migration):

Mention can also be made of a pentad system in which the proton is transferred from the 1-position to the 5-position:



Although formally these systems do not fit the definition quoted above (in the last system, for example, the proton is transferred from the oxygen atom of the phosphorus-containing functional group to the oxygen atom of the carbonyl group, the keto-form is in this instance simultaneously an ylide form and the type of transition  is retained for the phosphorus atom, which makes it possible to classify these complex systems conventionally as of the phosphorus–carbon type. Furthermore, as will be shown below, there is always a typical phosphorus-carbon 1,2- or 1,3-transition in such systems together with the pentad or tetrad transitions from an oxygen or phosphorus atom to an oxygen atom and conversely.

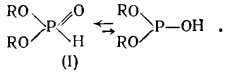
Table 1. A schematic arrangement of the phosphorus–carbon prototropic systems.

Y	Type of tautomerism	General formula
Electron pair	diad, dialkyl phosphite type of tautomerism	
O	triad, phosphoryl - hydroxy-ylide	
S	triad, thiophosphorly-mercaptoylide	
RN	triad, phosphorimide-aminoylide	
C	triad, carbon - phosphorus - carbon	

The position of any prototropic tautomeric equilibrium is known to be determined by the relative acidities of the different forms under the given experimental conditions, i.e.

$$K = c_1/c_2 = K_2/K_1 ,$$

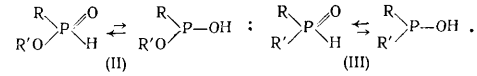
where c_1 and c_2 are the concentrations of forms 1 and 2 and K_1 and K_2 are their dissociation constants. In practice, a tautomeric equilibrium is observed in those cases where the dissociation constants of the forms differ by not more than 1–3 orders of magnitude (naturally this limit depends on the sensitivity of the method of analysis or calculation adopted for the tautomeric system). On the other hand, if the difference between the dissociation constants is large, the equilibrium is displaced almost completely towards the form whose dissociation constant is smaller.



If this criterion is applied to typical phosphorus-carbon systems, namely the diad $\backslash CH-P/$ or triad $\backslash CH-P(=O)-$ systems it is clear that conversion into the ylide forms $\backslash C=P-H$ or $\backslash C=P-OH$ will occur only if the acidity of the CH forms becomes comparable to or greater than the acidity of the PH or OH forms. At the same time it is known that the PH acidity and especially the OH acidity is usually higher than the CH acidity. For the CH acidity to become equal to or greater than the acidity of the XH forms, a sufficiently powerful acidifying influence of groups attached to the carbon atom is necessary. Ylide forms can therefore be observed in those cases where strongly electronegative groups such as COR, SO_2R, CN, etc. are attached to the α-carbon atom. Naturally, the ratio of the acid properties of the forms depends on many intermolecular and external factors. However, to a first approximation it may be sufficient to estimate the acidifying influences of the substituents attached to the carbon and phosphorus atoms. Such an approximate approach has helped to discover certain new types of tautomerism to which this review is devoted.

II. THE DIAD PHOSPHORUS-CARBON TAUTOMERISM

As already mentioned, the diad phosphorus-carbon system is structurally related to other diads: phosphorus-oxygen, phosphorus-sulphur, and phosphorus-nitrogen. Some important information about these systems is therefore initially presented below.

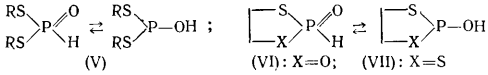


1. The Phosphorus-Oxygen, Phosphorus-Sulphur, and Phosphorus-Nitrogen Diads

Among all the types of diad tautomeric systems known in organic chemistry, the organophosphorus diads have been investigated to the greatest extent. They include in the first place dialkyl phosphites (I), the study of the tautomerism of which was initiated by A.E.Arbuzov[1] more than 75 years ago:

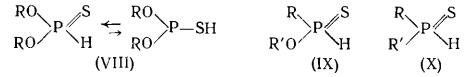
(I)

Although the conclusion that such tautomerism occurs had been reached a long time ago[2], proof of the existence of the hydroxy-form was obtained much later in kinetic isotope investigations[3,4]. Naturally, alkyl alkylphosphonites (II) and dialkylphosphonites (III) are included here also:



(II) (III)

In all the compounds of this type the tautomeric equilibrium is displaced towards the form with tetracoordinate phosphorus. Only in the case of bis(trifluoromethyl)phosphinite (IV) is the form with a tervalent phosphorus atom the only one present[5]:

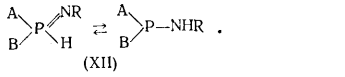


(IV)

It was later stated in the literature that the *S,S*-dialkyl phosphorodithioites (V) as well as the cyclic phosphorothiolites (VI) and (VII) are tautomeric mixtures of two forms[6–8]:

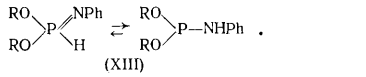
(V) (VI): X=O; (VII): X=S

O,O-Dialkyl phosphoromonothioites (VIII), the sulphur analogues of phosphites, were first investigated by the authors of this review at the beginning of the 1950's.[9] Here too the tautomeric equilibrium is displaced towards the thione forms under the usual conditions; the *O*-alkyl phosphonothioites (IX) and dialkylphosphinothioites (X) behave similarly:



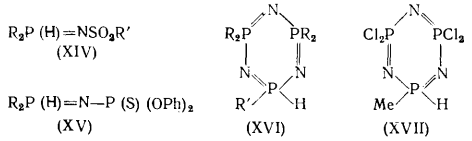
(VIII) (IX) (X)

According to an estimate, this equilibrium is displaced to an even greater extent than in dialkyl phosphites and only bis-(trifluoromethyl)phosphinothioite (XI) exists solely in the thiol form[10]:



(XI)

The proportions of the different forms of phosphoramidites and their analogues (XII) are different:



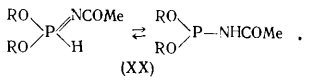
(XII)

Under the usual conditions, where A, B, and R are alkyl, aryl, or alkoxy-groups, the tautomeric equilibrium is displaced towards the amine form with a tervalent phosphorus atom[11]. This was first demonstrated by Kabachnik and Gilyarov[12] in relation to dialkyl N-phenylphosphoramidites (XIII).

(XIII)

In contrast to the oxygen and sulphur diads, in the case of phosphoramidites the second, i.e. the PH form could be detected for a much larger number of examples—for compounds (XIV),[13] (XV),[13] (XVI),[14] and (XVII):[15]

(XIV) (XV) (XVI) (XVII)



Instances of the tautomeric equilibria involving both forms have also been found[16,17]:

$$(RO)_2P(H)=N-SiMe_3 \rightleftarrows (RO)_2P-NH-SiMe_3 \ ;$$
(XVIII)

$$[Me_2N]_2P(H)=N-COMe \rightleftarrows [Me_2N]_2P-NH-COMe \ .$$
(XIX)

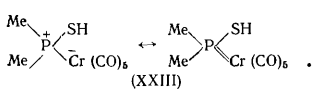
The PH forms of dialkyl phosphites (I) and their sulphur analogues (VIII) have much weaker acid properties than the OH and particularly the SH forms. The equilibrium is therefore as a rule displaced towards the PH forms. Only the introduction of two trifluoromethyl or cyclic ethylenedithiol groups at the phosphorus atom can increase the acidity of the PH form so much that it exceeds that of the OH or the SH forms, in the direction of which the equilibrium is in fact displaced[18].

The acidity of the NH forms of phosphoramidites and their analogues (XII) is lower than that of the PH forms; accordingly, the NH forms predominate in the equilibria. However, the difference between the acidities of the forms is not so great in this instance; when suitable substituents at the nitrogen and phosphorus atoms are used, it is easy to alter the relative acidities of the forms and thus influence the equilibrium position. For example, it is known that the equilibrium (XX) is displaced towards the amino-form[19]:

(XX)

However, if the strongly electron-accepting alkoxy-groups at the phosphorus atom are replaced by the more electron-donating dialkylamino-groups [see (XIX)], then the acid properties of the P–H bonds are diminished and the PH and NH forms can be detected in the tautomeric equilibrium[17]. On the other hand, if the trimethylsilyl group [see (XVIII)] is introduced at the nitrogen atom of the system (XX), then, as a result of the effect of the p–d conjugation

the nitrogen atom acquires a partial positive charge, the acidity of the N–H bond increases, and both forms again appear in the tautomeric equilibrium, which has been observed experimentally[16].

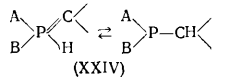


There are indications in the literature that the OH form of a dialkyl phosphite can be stabilised by incorporating it in a complex with a transition metal ion. For example, the complex (XXI), discovered in 1944 by Grinberg and Troitskaya[20,21]:

$$Pt\{P(OEt)_2OH\}_2 \cdot \{P(OEt)_2O\}_2 \ .$$
(XXI)

One can also refer to the complex $Mo(CO)_5[Ph_2POH]$ [22] and a number of others[23]. Dialkyl phosphorothioites form similar complexes in the SH form, for example, compound (XXII):[24,25]

$$Cr(CO)_5[Me_2PSH] \ .$$
(XXII)



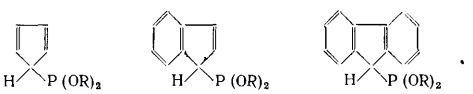
However, in discussing these and analogous complexes one must not forget that, instead of the free (solvated by solvent molecules) tautomeric forms with a tervalent phosphorus atom, one is dealing with compounds of another type [compounds (XXIII)], containing a tetracoordinate phosphorus atom:

(XXIII)

It is therefore illegitimate to consider examples such as those of "stabilisation" of phosphites with tervalent phosphorus.

2. Phosphorus–Carbon Diad Systems

As mentioned above, the phosphorus-carbon diad system (XXIV) is the carbon analogue of the dialkyl phosphite diad:



(XXIV)

This is the last of the four possible phosphorus diads:

(a) The phosphorus–carbon diads existing in the CH form. Dialkyl phosphonites $(RO)_2P-CHR'_2$, alkyl phosphinites $(RO)R'P-CHR''_2$, and tertiary phosphines $R_2P-CHR'_2$ containing an α-hydrogen atom belong in the first place to phosphorus–carbon diad systems. However, they had not been considered previously from the standpoint of the possibility of the the diad phosphorus-carbon tautomerism. Indeed, these substances are always represented in the CH forms with a tervalent phosphorus atom since the acid properties of the C–H bond are still less marked than those of the N–H bond, the shift of the equilibrium towards the CH forms is even greater in this instance. Very powerful influences on the C–H and P–H bonds are necessary for the appearance of the experimentally detectable phosphinomethylene PH form.

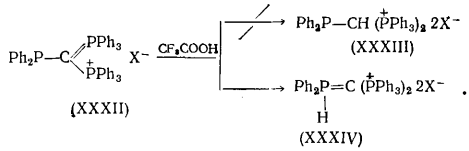
Attempts to achieve such an influence on the CH acidity of phosphonites and tertiary phosphines have been made. Thus one of the authors of the present review and Tsvetkov[26] investigated for this purpose cyclopentadienylphosphonites (XXV), indenylphosphonites (XXVI), and fluorenylphosphonites (XXVII).

(XXV) (XXVI) (XXVII)

However, these substances proved to be pure CH forms.

Kolodyazhnyi, Gololobov, and co-workers introduced at the α-carbon atom of the R_2PCH group two alkoxycarbonyl groups [compound (XXVIII)],[27,28] two sulphonyl groups [compound (XXIX)],[29] the protonated dimethyl sulphoxylide group [compound (XXX)],[30] and certain others:

(XXVIII) (XXIX) (XXX)



In all cases the groups R consisted of the simplest (unbranched) alkyl, phenyl, or alkoxy-groups. Only the CH forms of all these compounds could be detected in solutions by infrared spectroscopy, ^1H NMR, and NMR.[28] It has been stated[31] that the PH form of the phosphorylated acetaldehyde (XXXI) can exist in equilibrium with the CH and enol forms:

$$Ph_2P-CH_2-C(H)O \rightleftarrows Ph_2P-CH=CH-OH \rightleftarrows Ph_2P(H)=CH-C(H)O \ .$$
(XXXI)

However, the aldo-enol equilibrium has been demonstrated experimentally in this instance but the existence of a PH ylide form has been merely postulated.

(b) The phosphorus–carbon diad existing in the PH form. The first compound with the PH ylide structure was described in 1966 by Birum and Matthews[32]. When the phosphorany idene phosphonium salt (XXXII) was treated with trifluoro-

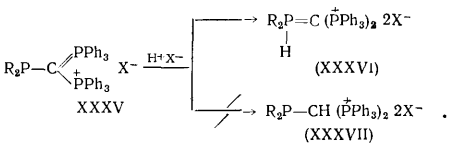
acetic acid, the formation of the ylide (XXXIV) with a P–H bond was observed:

(XXXII) (XXXIII) (XXXIV)

Two triphenylphosphonium groups attached to the central carbon atom proved to have such a powerful acidifying effect on the C–H bond in compound (XXXIII) that the proton added to the phosphorus atom with formation of the PH ylide (XXXIV) and not to the carbon atom.

Indeed, the triphenylphosphonium group belongs to the class of the most highly acidifying groups. In the study of the influence of this group on the tautomeric keto-enol equilibrium, we found[33] that its effect is significantly greater than that of, for example, the ethoxycarbonyl group, as can be seen from the following data: $MeCOCH_2COOEt$ (7% of enol); $MeCOCH(COOEt)_2$ (69% of enol); [34] $MeCOCH(COOEt)\overset{+}{P}Ph_3X^-$ (100% of enol). In the latter case, total enolisation is observed not only in solutions but also in the crystalline state[33,35].

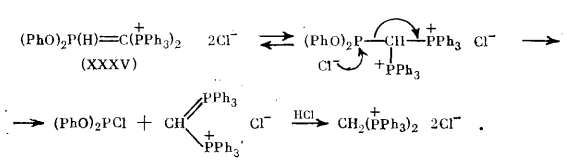
According to Issleib and Lindner[36], the triphenylphosphonium group is at the head of the series of substituents Y arranged in order of their decreasing acidifying influence on the CH acidity of the phosphonium salts $Ph_3\overset{+}{P}CH_2YX^-$:



$$Ph_3P^+ > PhCO > MeCO > CN > COOR > P(S)R_2 \approx P(O)R_2 > PPh_2 > Ph > H > Me .$$

In terms of the Hammett constants, the phosphonium groups are also among those with the most pronounced electron-accepting properties ($\sigma > 0.9$).

The authors of this review have made a detailed study of the protonation of substances of the type of compound (XXXII). The substituents at the tervalent phosphorus atom were varied in such a way that their σ^{ph} constants, characterising the acidifying effect of the groups at the phosphorus atom, gradually diminished[37]:



R	PhO	EtO	Ph	Me	Et	Bu
σ^{ph}	−0.06	−0.21	−0.59	−0.96	−1.10	−1.22

Phosphino-substituted phosphoranylidenephosphonium salts (XXXV) were protonated in various solvents by different acids (in an atmosphere of dry argon). According to $^{31}P\{^1H\}$ NMR data, only protonated PH forms (XXXVI) are formed in all cases[38]:

XXXV (XXXVI) (XXXVII)

These forms are characterised by a high constant J_{PH} = 450–700 Hz and other features (Table 2). All attempts to detect the CH form (XXXVII) in solution were unsuccessful. However, evidence has been adduced in support of the decomposition of compound (XXXV) with R = PhO under the influence of acids via the CH form[39]:

X-Ray diffraction analysis of compound (XXXVI, R = Bu, X = Br)[40] confirmed its structure (Fig. 1). The central carbon atom C(1) in this compound is markedly sp^2-hybridised (the sum of the angles between the bonds involving the carbon atom and the three phosphorus atoms is 359 °C), while the P(3) phosphorus atom is sp^3-hybridised, which undoubtedly indicates a PH structure.

Table 2. Parameters of the ^{31}P NMR spectra of the products (XXXVI) obtained by the protonation of the salts $R_2P^{\alpha}C[=P^{\beta}Ph_3]P^+Ph_3X^-$ (XXXV) by trifluoroacetic acid or hydrogen chloride in $CHCl_3$ or CH_2Cl_2.[38]

Certain PH ylides have been recently obtained by Kolodyazhnyi[41]. These are derivatives of phosphino-substituted malonic ester $RR'P(H)=C(COOMe)_2$, in which R = t-butyl and R′ are branched alkyl groups (for further details, see below).

(c) The phosphorus–carbon tautomeric diads. The starting point in the search for tautomeric phosphorus–carbon diad systems consisted of a comparison of the results of the

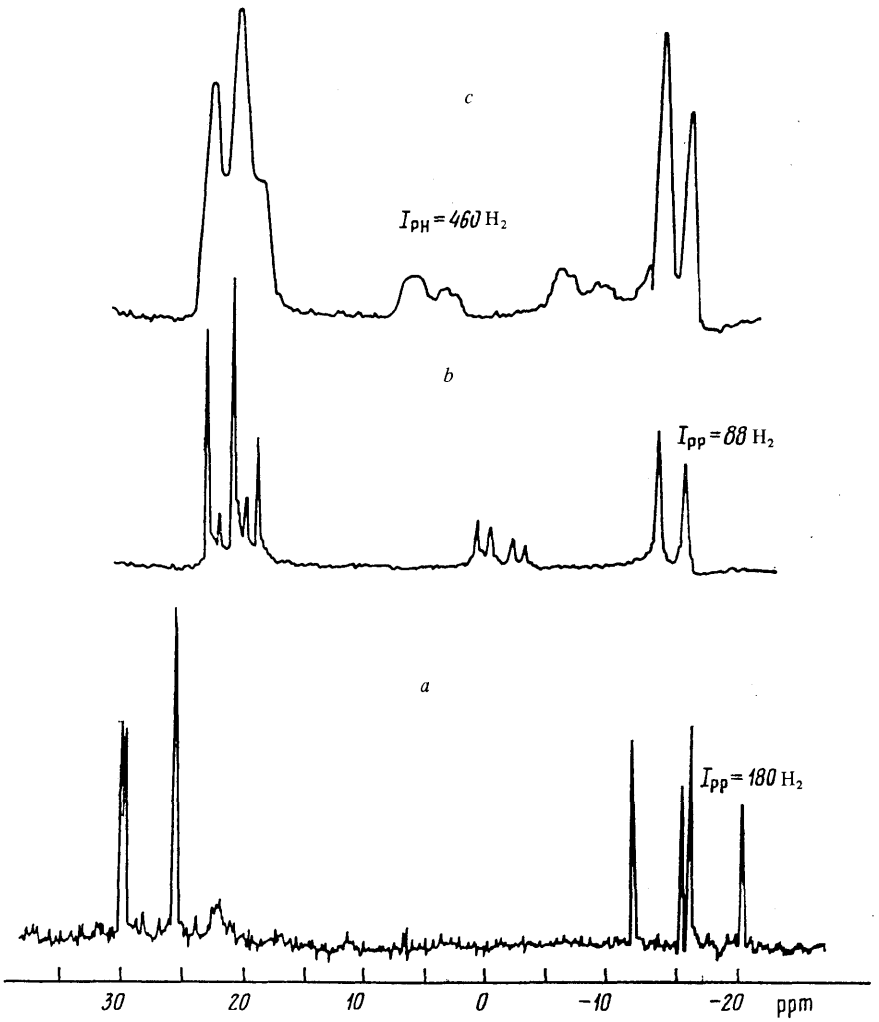
protonation of phosphino-substituted phosphoranylidenephosphonium salts (XXXV) and phosphino-substituted malonic esters (XXVIII). In the former case only the PH ylide (XXXVI) was found while in the latter only the CH acid (XXVIII) was discovered. In the former systems the CH acidity [of the (XXXVII) form] proved to be too high and the equilibrium was fully displaced towards the PH form (XXXVI). On the other hand, in systems of the second type the acidity of the CH form proved to be too small and the position of the phosphorus–carbon equilibrium was fully displaced towards this form. It was naturally postulated that, when one phosphonium and one ethoxycarbonyl group are introduced at the central carbon atom instead of two phosphonium groups [as in compound (XXXVII)] or two ethoxycarbonyl groups [as in compound (XXVIII)], one would expect the acidities of the two forms to be similar and that a true tautomeric equilibrium would result[42,43]. Naturally the equilibrium position should depend on the character of the substituents at the phosphorus atom because they also influence the relative acidities of the two forms.

The dibutylphosphinoethoxycarbonylmethylphosphonium salt (XXXVIII)

(XXXVIIIa) (XXXVIIIb)

proved to be a pure PH acid (XXXVIIIb). This ylide exists as a mixture of two conformers of the PH form, as shown by the doubling of the number of signals in the $^{31}P\{^1H\}$ NMR spectrum at a low temperature (Table 3). This kind of conformational isomerism of cisoid and transoid forms is already well known for unsubstituted alkoxycarbonylphosphinomethylenes[44,45]. It is also characteristic of the initial dibutylphosphinoethoxycarbonylmethylenephosphorane (XXXIX):

(XXXIX)



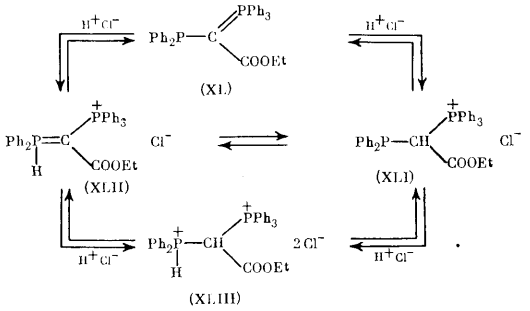


Figure 2. ^{31}P NMR spectrum of a solution of the $Ph_2PCH(\overset{+}{P}Ph_3)COOEt\ Cl^- \rightleftharpoons Ph_2P(H)=C(\overset{+}{P}Ph_3)COOEt\ Cl^-$ tautomeric mixture in CH_2Cl_2 at −80 °C: *a*) $^{31}P\{^1H\}$ NMR spectrum of the initial ylide; *b*) $^{31}P\{^1H\}$ NMR spectrum of the tautomeric mixture; *c*) ^{31}P NMR spectrum of the tautomeric mixture[42].

Consequently the acidity of the CH form again exceeded that of the PH form. However, the replacement of the two butyl groups at the tervalent phosphorus atom by two phenyl groups greatly increased the PH acidity and the protonated diphenylphosphinoethoxycarbonylmethylenetriphenylphosphorane proved to be a tautomeric substance. Its solution contains both the CH form (XLI) and the corresponding PH form (XLII). Overall, the acid-base and tautomeric transitions in this instance can be represented by the following scheme[40,42,43]:

The $^{31}P\{^1H\}$ NMR spectrum of the tautomeric mixture at −90 °C with the ratio ylide (XL) : HCl = 1 : 2 is fairly complex (see Table 3). It contains the signals of two conformers of the PH form (XLII) (four doublets at 21.4, 23.7, 0.5, and −2.4 p.p.m) and two doublet signals of the CH form (XLI) at −15.6 and 25.1 p.p.m. with $J_{PP} = 88$ Hz (Fig. 2).

Table 3. Parameters of the ^{31}P NMR spectra of the phosphinoylides $R_2P^{\alpha}C[=P^{\beta}Ph_3]COOEt$ and the products of their protonation with HCl.[40,42,43]

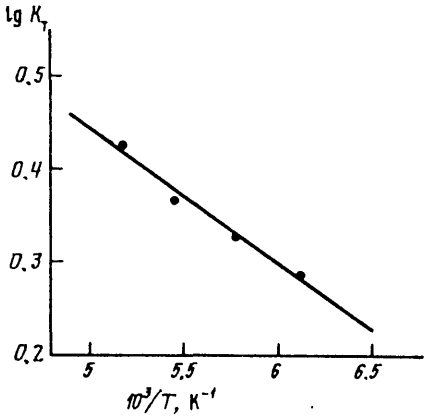
The validity of the assignment of the signals with δ = 0.5 and −2.4 p.p.m. to the conformers of the PH form is indicated by the high splitting constant $J_{PH} = 460$ Hz observed when the suppression is removed. On the other hand, the assignment of signals with the splitting constant $J_{PP} = 88$ Hz to the CH form was confirmed by the study of the ^{13}C NMR spectrum of a solution of the pure CH form in a 10 : 1 CH_2Cl_2–CH_3CN mixture at −80 °C (see below). Under these conditions, the signal of the α-carbon atom with the chemical shift δ = 38.1 p.p.m. has a triple doublet splitting. The doublet splitting with $J_{CH} = 139.7$ Hz is due to the interaction with the added proton (CH group), the second doublet splitting with $J_{CP} = 57.0$ Hz is caused by the interaction with the phosphonium atom, and the third doublet splitting with the constant $J_{CP} = 48.0$ Hz is associated with the spin-spin coupling with the tervalent phosphorus atom. Only in the case of the CH form is it possible to observe such triple doublet splitting of the signal in the ^{13}C NMR spectrum.

With increase in the HCl concentration, there is initially a change in the relative signal intensities, indicating an increase of the concentration of the CH form (XLI), after which (in the presence of a large excess of HCl) the spectrum becomes greatly simplified and is converted into the spectrum of the doubly protonated form (XLIII) with a sharply reduced J_{PP} (to 7.3 Hz).

The position of the tautomeric equilibrium (XLII) ⇌ (XLI) depends on many factors. An increase of temperature favours the CH form (XLI). It has been found from the dependence of $\lg K_T$ on $1/T$ (Fig. 3) that the PH form is slightly more stable (by 0.65 kcal mol^{-1}) under these conditions than the CH form (Table 4); apparently an increase of the HCl concentration also acts like the increase of the polarity of the medium. It is of interest to note that only the CH form is present in the 10 : 1 CH_2Cl_2–CH_3CN mixture in the presence of two moles of HCl at −80 °C (see above).



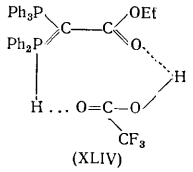


Figure 3. Temperature variation of the $Ph_2PCH(\overset{+}{P}Ph_3)_3COOEt\ Cl^- \rightleftharpoons Ph_2P(H)=C(\overset{+}{P}Ph_3)COOEt\ Cl^-$ tautomeric equilibrium constants.

Table 4. Dependence of the position of the tautomeric equilibrium between the PH and CH forms [(XLII) ⇌ (XLI)] on the solvent composition [−80 °C, (XL) : HCl = 1 : 2].[40]

Content of CH_3CN in CH_2Cl_2, %	Content of PH form, %	Equilibrium constant K_T = [PH]/[CH]
0	30	0.43
3.20	14	0.16
6.25	5	0.05
9.10	0	0

One PH form is observed in trifluoroacetic acid or in CH_2Cl_2 with an excess of CF_3COOH. It may be that trifluoroacetic acid stabilises the PH form, forming long hydrogen

bonds with the latter [see formula (XLIV)]:

(XLIV)

The next example of the phosphorus–carbon diad tautomerism was discovered somewhat later by Kolodyazhnyi[41]. It was noted above that the diphenylphosphino-derivatives of malonic ester (XXVIII) consist of 100% CH forms[27,28]. This applies also to the previously investigated derivatives of tervalent phosphorus (XXVIII) containing lower unbranched alkyl groups, the phenyl group, or an alkoxy-group at the phosphorus atom.

Continuing his persistent search for PH ylides, Kolodyazhnyi[41] investigated the analogous derivatives (XLV) and (XLVI) containing branched alkyl groups at the phosphorus atom, namely the t-butyl, s-butyl, isobutyl, and isopropyl groups, i.e. those characterised by the greatest $\pm I$ effect:

$$\underset{\text{(XLV)}}{RR'P{-}CH(COOMe)_2} \rightleftarrows \underset{\text{(XLVI)}}{RR'P(H){=}C(COOMe)_2}\ .$$

The study showed that in the crystalline state these substances are PH ylides (XLVI), where R = t-Bu, R' = iso-Pr, s-Bu, or Me_3SiCH_2. Their infrared spectra show only the absorption bands of the PH ylide. On fusion or dissolution of compounds (XLVI), bands appear in their infrared spectra in the region of 1700–1800 cm^{-1}, which are characteristic of saturated carboxylic acid esters and indicate the partial conversion of compound (XLVI) into (XLV). The ^{31}P NMR spectra also indicate the simultaneous presence of the PH ylide form (doublet with the constant J_{PH} = 435–440 Hz) and the CH form (singlet, δ = 12.5–35.5 p.p.m., depending on the nature of the alkyl groups). Integration of the signals in the NMR spectra and of the infrared bands made it possible to determine the constants K_T for the tautomeric equilibrium (XLVI) ⇋ (XLV). It was found that they depend not only on the character of the substituting groups at the tervalent phosphorus atom but also on the temperature and the nature of the solvent. It was observed that an increase of temperature shifts the equilibrium towards the CH form and the dependence of $\lg K_T$ on $1/T$ showed that the CH form is less favoured by energy factors (approximately to the extent of 2 kcal mol^{-1}). The influence of the solvent on the position of the tautomeric equilibrium is not very clear in this instance: the following series of solvents increasing the content of the PH form has been published[41]: C_6H_{14} < THF < C_6H_6 < CH_2Cl_2 < $CHCl_3$.

As regards the influence of the substituents at the phosphorus atom (Table 5), the author[41] assumes that the bulk of the substituting group plays a decisive role. He believes that bulky groups favour the formation of the planar system $HP{-}C^{-}(COOMe)_2$, which reduces the steric hindrance in structures (XLV) as a consequence of the interaction of the COOMe groups with the bulky substituents at the tervalent phosphorus atom. However, it is difficult to agree with his explanation. If one uses the data presented in Table 5, it can be readily seen that the (XLV) ⇋ (XLVI) tautomeric equilibrium constants obey satisfactorily the Hammett equation when one employs the constants σ_I^{Ph} characterising the influence of the groups attached to the phosphorus atom. The following values were then obtained for a solution in $CHCl_3$†: $\lg K_T^0 = -6.55$, $\rho = -2.351$, and $r = 0.979$ for $s = 0.14$ and $s_\rho = 0.25$ (Fig.4). On the other hand, if an attempt is made to set up a correlation between $\lg K_T$ and the Taft steric constants E_S, then the points cover the entire field of the graph and no reasonable relation can be seen.

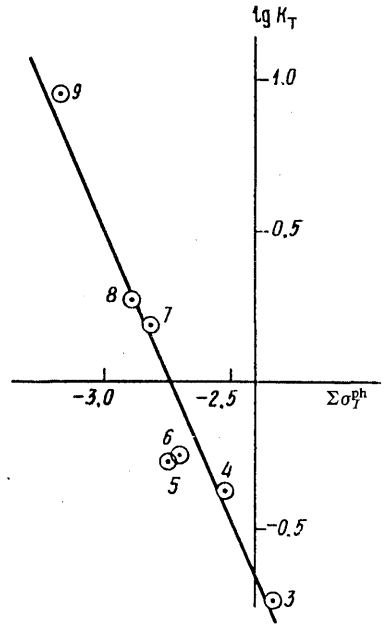

Figure 4. Dependence of the RR'PCH(COOMe)$_2$ ⇋ RR'P(H) = C(COOMe)$_2$ tautomeric equilibrium constants on $\sum \sigma_I^{ph}$ for the groups R and R' (the numbers of the points correspond to the number of the compounds in Table 5).

Table 5. The RR'PCH(COOMe)$_2$ ⇋ RR'P(H) = C(COOMe)$_2$ tautomeric equilibrium (20 °C, $CHCl_3$).[41]

№	R	R'	$\Sigma\sigma_I^{ph}$	Content of PH form, %	K_T
1	t-Bu	Me_2N	−1.28	0	0
2	t-Bu	Et_2N	−1.73	0	0
3	Bu	Bu	−2.44	15	0.18
4	iso-Pr	iso-Pr	−2.60	30	0.43
5	t-Bu	iso-Bu	−2.85	33	0.49
6	t-Bu	n-Bu	−2.79	35	0.54
7	t-Bu	iso-Pr	−2.85	61	1.56
8	t-Bu	s-Bu	−2.91	65	1.86
9	t-Bu	Me_3SiCH_2	−3.15	90	9.00

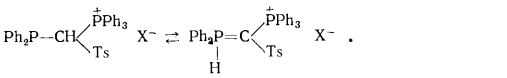
The parameters of the above correlation permit also other interesting conclusions. It is possible to calculate the position of the tautomeric equilibrium in the same systems but with other substituents at the phosphorus atom for which no

† The calculation was based on six points: 3,4, 6, 7, 8, and 9 (Table 5).

tautomeric relations had been observed earlier[27]. Such a calculation shows that in $CHCl_3$ the Et_2P group ($\sum\sigma^{ph} = -2.2$) should lead to an approximately 4% content of the PH form, the Ph_2P groups should give rise to less than 10^{-4}%, and the $(EtO)_2P$ group should produce an even smaller amount. This also applies to compounds with dialkylamino-groups: the content of the PH form should be ~0.3% for R = t-Bu and R' = Et_2N and ~0.08% for R = t-Bu and R' = Me_2N. Naturally the PH forms were not detected in solutions of these substances.

Thus the position of the diad prototropic equilibrium between the PH and CH forms in the series of phosphino-derivatives of malonic ester as well as the other instances investigated depends on the polar influences of the substituents which determine the acid strength of the CH and PH forms and thus the position of the tautomeric equilibrium.

In order to infer reliably the influence of the substituents at the α-carbon atom and at the phosphorus atom on the position of the proton, a quantitative approach to the estimation of the acidifying effect of these substituents is necessary. As mentioned above, one can use the constants σ_I^{ph} for the substituents at the phosphorus atom. The application of the Issleib and Lindner[36] series given above to the substituents at a carbon atom makes it possible to estimate the acidifying capacity of these groups only qualitatively. The authors of this review therefore recently developed a system of σ_C^- constants whereby one can carry out a correlation analysis of the dissociation constants of CH acids with a satisfactory accuracy[46]. This correlation system is naturally based on the Hammett σ^- constants and it was found that the numerical value of the constant depends on the number of substituents at the central carbon atom of the CH acid. Since there can be one, two, or three such substituents, each substituting group was characterised by three constants: $\sigma^-_{CH_3}$ for a primary carbon atom, $\sigma^-_{CH_2}$ for a secondary carbon atom, and σ^-_{CH} for a tertiary carbon atom#. The use of these constants made it possible to obtain excellent correlations of the pK_a for CH acids using the Hammett equation§. Thus it became possible to infer the acidifying influence of substituents on the strength of CH acids from the sum of the substituent constant σ_C^-¶. Table 6 lists certain constants σ_C^- characterising the acidifying influence of the groups at the carbon atom.

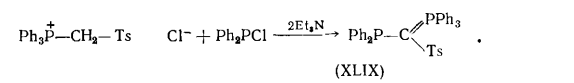


In conformity with the foregoing, for the above three types of compounds containing two identical groups at the phosphorus atom (phenyl or butyl), the sum $\sum\sigma^-_{CH}$ is 1.24 for the first type [compound (XXVIII)], 1.68 for the second type [compounds (XXXVIII) and (XLI)], and 2.16 for the third type [compound (XXXIII)]. The acidifying effect when the sum of the constants is 1.24 is insufficient for the transfer of a proton from C to P (it is insufficient for two phenyl groups at the phosphorus atom and almost insufficient for two butyl groups). The sum $\sum\sigma^-_{CH} = 1.68$ for two butyl groups gives rise to the PH structure (the CH acidity is then too great) and in the presence of two phenyl groups the CH⇌PH tautomeric system is produced. Finally, for the sum $\sum\sigma^-_{CH} = 2.16$, the proton is firmly held at the phosphorus atom (the CH acidity is too great).

Table 6. The $\sigma^-_{CH_2}$ and σ^-_{CH} constants characterising the acidifying influence of the groups on the CH acidity[46].

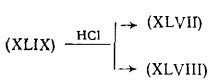
Group	$\sigma^-_{CH_2}$	σ^-_{CH}	Group	$\sigma^-_{CH_2}$	σ^-_{CH}
Me	0.12	0.13	COMe	0.88	0.66
Ph	0.365	0.26	COPh	0.98	0.78
p-$NO_2C_6H_4$	0.74	0.52	$PhSO_2$	0.77	0.71
COOMe	0.72	0.62	p-$MeC_6H_4SO_2$	—	0.70
COOEt	0.725	0.60	NO_2	1.26	1.12
CN	0.80	0.75	$Ph_3\overset{+}{P}$	1.22	1.08

One must bear in mind that the constants ρ of the correlation between the CH acidity and σ_C^- are fairly large (usually 10–25), which means that small changes in $\sum\sigma_C^-$ can give rise to large changes in the CH acidity.



Next, studies were made on the (XLVII)⇌(XLVIII) systems with tosyl groups[47]:

(XLVII) (XLVIII)



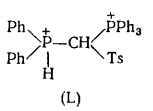
It was assumed that investigation would reveal either a tautomeric or an ylide system (XLVIII), since the sum of the constants $\sum\sigma^-_{CH} = 1.78$ is characterisitc of the form (XLVII), exceeding the corresponding sum (1.68) for the (XLI) ⇌ (XLII) tautomeric system (investigated previously) with an ethoxycarbonyl group at the α-carbon atom; however, it is significantly smaller than $\sum\sigma^-_{CH} = 2.16$ for the PH ylide diphosphonium structure (XXXVI).

The necessary compounds were synthesised in accordance with the scheme[47]

(XLIX)

Next, the ylide (XLIX) was protonated:

On treatment with trifluoroacetic acid or HCl in a slight excess, only the PH form (XLVIII) is observed. The $^{31}P\{^1H\}$ NMR spectrum (in a 3:1 $CHCl_3$–CH_2Cl_2 mixture) shows a typical AB quartet with $\delta_1 = -2.1$ p.p.m. and $\delta_2 = 19.8$ p.p.m. (with the constant $J_{PP} = 37$ Hz). When the suppression of the spin–spin coupling between the phosphorus and the protons is removed, the signal with $\delta = -2.1$ p.p.m. is converted into a characteristic doublet with $J_{PH} = 490$ Hz, which undoubtedly indicates the presence of the PH bond. Only the PH form



---

A single reaction series can include terms with $\sigma^-_{CH_3}$, $\sigma^-_{CH_2}$, and σ^-_{CH}.

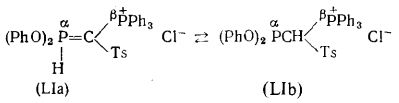
§ For the limitations of this correlation system, see Kabachnik and Mastryukova[45].

¶ Naturally, in estimating the CH acidity from the influence of the acidifying group, account must be taken also of the influence of the phosphorus-containing group. However, for many of these the values of σ_C^- are unknown and only comparisons for constant substituents at the phosphorus atom are therefore strictly legitimate.

(XLVIII) was observed also under other protonation conditions. Treatment with a large excess of HCl at −95 °C leads to the doubly protonated dication (L):

(L)

The positions of the signals in the ^{31}P NMR spectrum then change only slightly, but there is a sharp decrease of the spin-spin coupling constant: $J_{PP} = 6$ Hz (compared with 37 Hz for the monoprotonated compound). The dication is stable only at a low temperature and, on heating, the NMR spectrum of the dication is converted into that of the monocation (XLVIII).

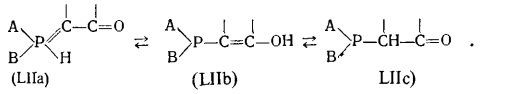


Thus the CH acidity induced by the presence of the triphenylphosphonium and tosyl groups proved to be too high and the proton migrated to the diphenylphosphino-group. However, when the phenyl groups at the tervalent phosphorus atom were replaced by phenoxy-groups, whose acidifying effect is incomparably greater ($\sigma_I^{ph} = +0.27$ for Ph and +2.83 for PhO), the PH acidity increased and an experimentally observable equilibrium between the two forms of (LI) again appeared (Table 7).

Table 7. ^{31}P NMR spectroscopic data (−80 °C, CH_2Cl_2) for the tautomeric system.

(LIa) (LIb)

Substance	$\delta_{P\alpha}$ (d), p.p.m.	$\delta_{P\beta}$ (d), p.p.m.	J_{PP}, Hz	J_{PH}, Hz
Initial ylide	173.2	16.4	14.6	—
PH form (LIa)	49.1	16.8	29.3	697
CH form (LIb)	149.5	20.0	7.4	—



(LIa) (LIb)

The results obtained in the study of the diad phosphorus–carbon tautomerism can be summarised as follows. Table 8 lists the substituents X and Y at the carbon atom in order of decreasing acidifying capacity expressed by the sum of the constants σ_{CH}^{-}. The substituents at the phosphorus atom (on the left) are arranged from above downwards in order of increasing sum of the constants σ_I^{ph}, i.e. of increasing acidifying influence. Thus Table 8 lists on the left hand side the strongest CH acids and at the bottom the strongest PH acids. The upper left-hand corner represents the region of PH forms; here the carbon atom readily gives up a proton and the phosphorus atom readily accepts it. The lower right-hand corner represents the region of the CH form (the phosphorus atom readily gives up a proton and the carbon atom readily accepts it). The region of compounds with a distinct tautomeric equilibrium lies along the diagonal of Table 8. In this region the strengths of the CH and PH acids are similar and both forms are observed in the equilibrium.

3. The Tetrad Phosphorus–Carbon Tautomerism (A Vinylogue of the Diad Tautomerism)

As mentioned above, tetrad systems can be derived as vinylogues of the diad systems. The simplest examples of such tetrad tautomerism of compounds (LII) can be represented as a combination of the phosphorus-carbon diad and keto-enol tautomerisms:

(LIIa) (LIIb) LIIc)

The two tautomeric forms produced when the proton is fixed at the phosphorus atom [structure (LIIa)] and oxygen atom [structure (LIIb)] must be supplemented by the third form (LIIc), which can be produced when the proton is fixed at the α-carbon atom (as in diad tautomerism).

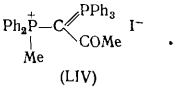
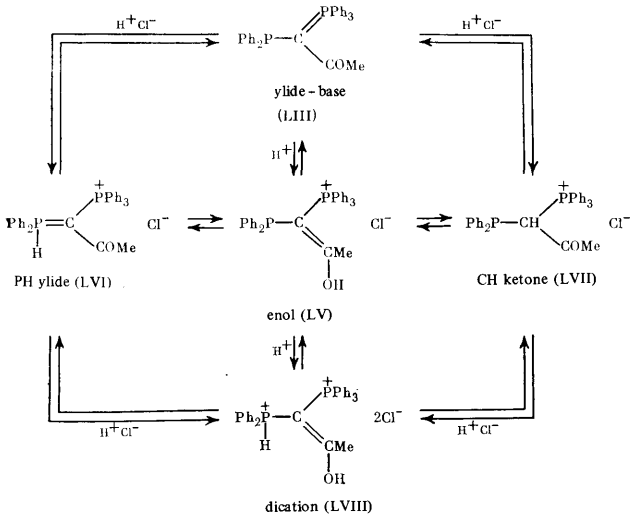
* Data expected on theoretical grounds are enclosed in brackets.



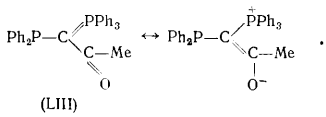
Diphenylphosphinoacetaldehyde (XXXI) (see above) could be regarded as a tautomeric substance of this kind if the existence of the PH ylide form could be demonstrated.

The products of the protonation of the diphenylphosphino-derivative of acetylmethylenetriphenylphosphorane (LIII) were investigated as the first tetrad system[48]. The phosphorane was obtained by the reaction of Ph_2PCl with acetylmethylenetriphenylphosphorane:

(LIII)



We may note that the spin-spin coupling constant in the $^{31}P\{^1H\}$ NMR spectrum of the ylide (LIII) is $J_{PP} = 184$ Hz (in CH_2Cl_2 at 20 °C). When the ylide (LIII) is methylated at the tervalent phosphorus atom, the product is the ylide (LIV) whose spectrum shows an AB quartet at 16.9 p.p.m. and 18 p.p.m. with $J_{PP} = 46$ Hz:



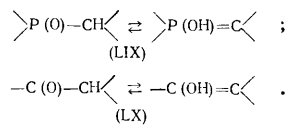
(LIV)

After extensive cooling, the multiplicity of the spectrum was found to be doubled owing to conformational isomerism.

The study of the prototropic transformations on protonation of the ylide (LIII) led to the following pattern of the acid-base and tautomeric transitions[48]:

The addition of a solution of HCl in CH_2Cl_2 to compound (LIII) at −80 °C in an argon atmosphere leads initially (in the presence of a small amount of the acid and immediately after its addition) to the enol form (LV). Its $^{31}P\{^1H\}$ NMR spectrum ($\delta_1 = -20.4$ p.p.m., $\delta_2 = 24.6$ p.p.m., and $J_{PP} = 144$ Hz) differs little from the spectrum of the ylide-base (LIII) ($\delta_1 = -18.8$ p.p.m., $\delta_2 = 25.2$ p.p.m., $J_{PP} = 184$ Hz). This is quite natural, because the electronic structure of the molecule of the initial ylide-base (LIII) differs little from that of the *O*-protonated form (LV):

(LIII)



With increase of the HCl content in the reaction mixture (to 2 and 3 moles of HCl), six doublet signals with three splitting constants, equal in pairs, appear immediately. Two doublet signals are identical with those in the spectrum of the enol (LV) and therefore indicate its presence in the mixture; the other two doublets ($\delta = 2.6$ and 18.5 p.p.m., $J_{PP} = 51$ Hz) correspond to the PH form, since, after the removal of suppression the doublet at −2.6 p.p.m. splits into further two doublets with the constant $J_{PH} = 500$ Hz; furthermore, the splitting constant J_{PP} is in this case close to the constant found for the methylated derivative (LIV); the remaining two doublets refer to the CH form, which has been confirmed by repeated cross comparisons.

On further increase of the HCl concentration, the spectrum simplifies both as regards the positions of the signals (four doublets) and the character of J_{PP} and J_{PH}—it can be easily assigned to the dication (LVIII).

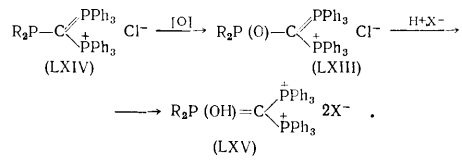
III. THE TRIAD PHOSPHORUS–CARBON TAUTOMERISM

1. The Phosphoryl–Hydroxy-ylide Tautomerism

The possibility of the phosphoryl–hydroxy-ylide tautomerism (LIX), which is analogous to the keto–enol tautomerism (LX), was first suggested by Arbuzov and Razumov in 1929 in connection with the discussion of the alkylation reactions of diethoxyphosphorylacetic acid ester[49]:

(LIX)
(LX)

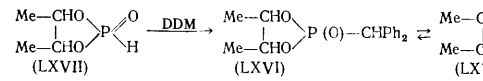
In conformity with the views adopted at the time, they attributed a tautomeric behaviour to metal (sodium) derivatives of these substances:



Arbuzov returned to this question in 1934 [50] and in 1947 [51], but naturally no evidence, apart from the dual reactivity of the alkali metal derivatives, was available at the time for the phosphoryl-hydroxy-ylide tautomerism.

A letter to the Editors by Kolodyazhnyi was published in 1976 [52] in which the tautomerism of phosphorylated di(benzenesulphonyl)methane (LXI)⇌(LXII) was reported:

(LXI) (LXII)

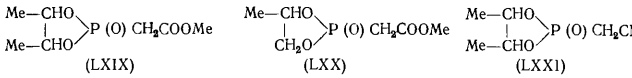


On acidification with hydrochloric acid, the sodium salt of compound (LXII) is converted into the free acid in the hydroxy-ylide form (LXII), whose structure was clearly confirmed by infrared spectroscopy. The acid crystallises from solution in benzene as the phosphoryl CH form (LXI) with an altered infrared spectrum. When the CH form is dissolved in $CHCl_3$, both forms are produced and their ratio varies with increase of temperature in favour of the phosphoryl CH form.

The authors of the present review and their co-workers[39] investigated simultaneously the protonation of phosphoryl-substituted phosphoranylidenephosphonium salts (LXIII) obtained by oxidising the corresponding phosphino-substituted salts (LXIV) with potassium permanganate; the formation of the hydroxy-ylide forms (LXV) was then observed:

(LXIV) (LXIII) (LXV)

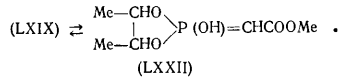
When fluorosulphonic acid is protonated, the signals in the $^{31}P\{^1H\}$ NMR spectrum referring to the triphenylphosphonium phosphorus atoms do not undergo any significant changes, while the signals due to the phosphorus in the phosphoryl group undergo a downfield shift of 12.3 p.p.m. The protonation of phosphoryl groups is known to be accompanied as a rule by a similar change in the position of their NMR signal[53, 54].



The next communication about the phosphoryl–hydroxy-ylide transitions was by Kazan chemists[55]. The authors reported that the cyclic diphenylmethylphosphonate (LXVI), obtained from the corresponding cyclic phosphite (LXVII) by reaction with diphenyldiazomethane (DDM) and subsequent oxidation, consists of the (LXVI)⇌(LXVIII) tautomeric mixture:

(LXVII) (LXVI) (LXVIII)

Unfortunately the authors did not present experimental data justifying this interesting and unexpected conclusion.

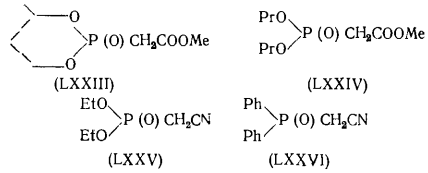


The phosphoryl–hydroxy-ylide tautomerism naturally obeys the same general laws which govern prototropic tautomerism in general. The conversion of a phosphoryl compound with an α-CH group into a hydroxy-ylide requires a powerful acidifying influence by the substituents at the central carbon atom which would equalise the strength of the CH acid with that of the P–OH acid, which is the hydroxy-ylide form. Here one must naturally take into account the influence of all the substituents—both at the carbon atom and at the phosphorus atom. From this standpoint, the butylenedioxyphosphinyl group in the CH acid (LXVI) should exert a powerful acidifying influence, while the influence of the phenyl group is moderately strong or even weak. The hydroxy-ylide form (LXVIII) contains at the phosphorus atom the butylenedioxy-group, which is a powerful electron acceptor. This form should be a fairly strong acid. Thus it would seem that one should expect the dominant form to be the phosphoryl CH form (LXVI), which is a weaker acid. On the other hand, if proton transfer nevertheless takes place despite the above reasoning, then one must accept that the influence of the butylenedioxy-group affects the CH acidity (LXVI) form to a much greater extent (increasing it sharply) than the OH acidity of the (LXVIII) form, which is enhanced to a lesser extent (a hypothesis which is in general unlikely). Further studies confirming the presence of the ylide form (LXVIII) are evidently necessary.

Other relations may be expected (and such are observed in reality) for the cyclic ethoxycarbonylmethylphosphonates (LXIX) and (LXX) or the corresponding nitriles (LXXI):

(LXIX) (LXX) (LXXI)

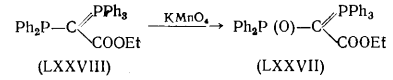
Here the methylene group has an environment analogous to that in the malonic ester and the manifestation of an appreciable CH acidity may be expected even in the absence of the dioxaphospholan ring; if the CH acidity becomes equal to or even approaches the OH acidity of the hydroxy-ylide form (LXXII) under the influence of the butylenedioxyphosphoryl group, then one can postulate the occurrence of the phosphoryl-hydroxy-ylide tautomerism (LXIX)⇌(LXXII), which is apparently actually observed[56]:



(LXXII)

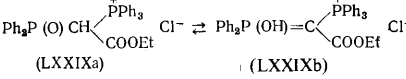
Indeed the ^{1}H NMR spectrum of compound (LXIX) in CCl_4 contains the doublet signal of the P–CH_2 protons at 3.2 p.p.m. with the splitting constant $J = 21$ Hz, the doublet signal of the proton in the P=CH group at 2.9 p.p.m. with the same splitting constant, and the broad signal of the OH proton at 6.8 p.p.m.†

The ^{31}P NMR spectra also show the signals of the phosphoryl and hydroxy-ylide forms. In aqueous alcohol the equilibrium is fully displaced towards the ylide. The infrared spectrum confirms the ^{1}H NMR data. Analogous behaviour has been observed also for compounds (LXX) and (LXXI).



Five-membered cyclic methoxycarbonylmethylphosphonates proved to be strong acids ($pK_a = 2.71$–2.79 in 50% alcohol). The derivative of the six-membered dioxaphosphorinane (LXXIII), which has an analogous structure, is a weaker acid ($pK_a = 9.64$ and 11.05 for the two geometrical isomers), while the corresponding acyclic derivative (LXXIV) is weaker still ($pK_a = 12.10$). These substances are not tautomeric. The cyanides (LXXV) and (LXXVI) are likewise not tautomeric and their acid strengths are low ($pK_a = 11.58$ and 11.09 respectively):

(LXXIII) (LXXIV) (LXXV) (LXXVI)



Thus in the presence of the usual acyclic substituents at the phosphoryl group, the acidifying effect of the methoxycarbonyl group COOMe ($\sigma^-_{CH} = 0.72$) and the cyano-group ($\sigma^-_{CH_2} = 0.80$) is insufficient to impart to the phosphoryl CH form an acid strength comparable to that of the hydroxy-ylide OH form, which is necessary for tautomeric behaviour. Only in the presence of an adjoining dioxaphospholan ring, as in compounds (LXIX)–(LXXI), is this condition fulfilled and prototropic transitions are observed. Incidentally, the nature of the influence of the dioxaphospholan ring is not clear (see above).

Tautomeric behaviour is to be expected when groups which cause a greater increase in the CH acidity are introduced at the α-carbon atom. This was achieved in a study by one of the present authors and his co-workers[57] after the simultaneous introduction of the triphenylphosphonium ($\sigma^-_{CH} - 1.08$) and ethoxycarbonyl ($\sigma^-_{CH} = 0.60$) groups at the α-carbon atom[57]. The synthesis of ethoxycarbonyldiphenylphosphinylmethylenetriphenylphosphorane (LXXVII) was achieved by oxidising the corresponding ethoxycarbonyldiphenylphosphinophosphorane (LXXVIII):

(LXXVIII) (LXXVII)

The phosphorane (LXXVII) is protonated by HCl with formation in solution of α-phosphorylated phosphonium salts having the CH structre (LXXIXa) and the OH structure (LXXIXb):[57]

(LXXIXa) (LXXIXb)

The salt forms crystals melting at 123–125 °C and containing the pure hydroxy-ylide form (LXXIXb) according to infrared spectroscopic data. The infrared spectrum showed a band at 1660 cm^{-1} due to the conjugated ethoxycarbonyl group (i.e. COOEt at a carbanionic centre) and a broad diffuse band due to the OH group (at 1500–2200 cm^{-1}). On dissolution in chloroform, an additional band appears in the infrared spectrum at 1730 cm^{-1} (non-conjugated ethoxycarbonyl group), which indicates the tautomeric equilibrium (LXXIXa)⇌(LXXIXb).

The ^{1}H NMR spectrum in CH_2Cl_2 contains the signals of both the CH form (LXXIXa) (a triplet at 1.12 p.p.m. and a quartet at 3.55 p.p.m. due to the protons of the exthoxy-group) and the signals of the OH form (LXXIXb) (a triplet at 0.49 p.p.m. and a quartet at 3.49 p.p.m due to the protons of the ethoxy-group; in both cases the spin-spin coupling constant $J_{HH} = 7$ Hz; in addition a broad singlet signal due to the proton of the OH group with $\delta = 10.7$ p.p.m. is observed. Evidently the signal of the CH proton is masked

† New data concerning the acid properties of compounds (LXIX) and (LXXIII) in ethanol have been published recently (O.Larsen and G.Aksnes, Phosphorus and Sulphur, 1983, 15, 219, 229). In contrast to the data quoted by Ovchinnikov et al.[56], compounds (LXIX) and (LXXIII) proved to be weak CH acids with virtually identical strengths (pK_a = 19.90 and 19.95).

in the case of the CH form by the signals of the aromatic protons). The ratio of the tautomeric forms (LXXIXa) : (LXXIXb) = 1 : 1.8 follows unambiguously from the ratio of the signal intensities[57].

The ^{31}P NMR spectra also confirm the above conclusion. They contain the signals of the two conformers of the OH form and the signals of the CH form:

	δ_1, p.p.m.	δ_2, p.p.m.	J_{PP}, Hz
OH form, conformer 1:	44.5 p.p.m.	19.1	41
OH form, conformer 2:	41.0	20.0	44
CH form	28.1	23.9	7

We may note that the low value of J_{PP} is characteristic of the structures of the type of (LXXIXa). The position of the tautomeric equilibrium in the system investigated depends on the nature of the solvent and the temperature[57].

An analogous study has been carried out for compounds similar to those described previously but with the replacement of the ethoxycarbonyl group by the tosyl group[58]. The phosphorane (LXXX) with the tosyl group has been synthesised by oxidising the phosphinophosphorane (LXXXI). Next, the entirely stable hydroxy-ylide (LXXXII) with m.p. 193 to 195 °C was obtained in 92% yield by treatment with HBr in ether:

$$Ph_2P{-}C(PPh_3)(Ts) \xrightarrow[(CH_2Cl_2,\ Me_2CO)]{KMnO_4} Ph_2P(O)C(PPh_3)(Ts) \xrightarrow[Et_2O]{HBr} Ph_2P(OH){=}C^{+}(PPh_3)(Ts)\ Br^-$$

(LXXXI) (LXXX) (LXXXII)

The structure of the bromide salt of the hydroxy-ylide was investigated by X-ray diffraction (Fig. 5). The central carbon atom C(1) has in this case a planar trigonal structure (its displacement from the plane towards the bromide anion is 0.118 Å) and the (C(1)–P(1) and C(1)–P(2) bonds are shortened (1.751 and 1.764 Å), compared with the single C–P bonds, which shows that they have a bond order of 1.5. The C–SO_2 bond is also somewhat shortened (1.728 Å compared with 1.772 Å for C_{ar}–S), which shows that the sulphur atom adjoins the anionic centre. Finally, there is the O...H...Br hydrogen bond with a length of 3.078 Å. The infrared spectrum of the crystalline ylide confirms its structure.

The situation does not change when the hydroxy-ylide (LXXXII) is dissolved in deuterochloroform. The ^1H NMR spectrum of the solution shows a singlet signal due to the CH_3 proton at 2.27 p.p.m. and a broad singlet signal of the OH proton at 11.2 p.p.m., the ratio of the integral intensities is 3 : 1, which indicates the absence of the CH form of compound (LXXXIII):

$$(LXXXII) \rightleftharpoons Ph_2P(O)CH(PPh_3)(Ts)\ Br^-$$

(LXXXIII)

The ^{31}P NMR spectrum shows only two doublet signals at 18.2 p.p.m. and 46.4 p.p.m. with the splitting constant J_{PP} = 29 Hz. Tautomerism of the type (LXXXII) ⇌ (LXXXIII) is not observed[58].

Thus the combination of the triphenylphosphonium and ethoxycarbonyl groups leads to the phosphoryl–hydroxy-ylide tautomerism and the replacement of the ethoxycarbonyl group by the tosyl group shifts the tautomeric equilibrium completely towards the hydroxy-ylide form in both the crystalline state and in solutions. An explanation of this phenomenon should be sought in the stronger acidifying influence of the tosyl group ($\sigma^-_{CH} = 0.70$) compared with the ethoxycarbonyl group ($\sigma^-_{CH} = 0.60$) on the CH acidity. The difference of 0.10 of a unit between the values of $\sum\sigma^-_{CH}$ combined with the steep slope of the relation between the CH acidity and $\sum\sigma^-_{CH}$ naturally increase sharply the CH acidity of the (LXXXIII) form and thus fully displace the equilibrium in the direction of the (LXXXII) form.

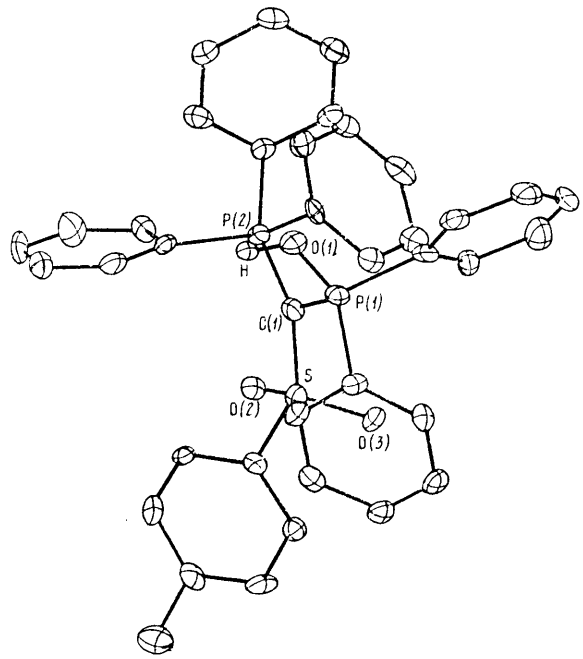


Figure 5. The structure of the cation of the bromide salt $Ph_2P(OH){=}C^{+}(PPh_3)Ts\ Br^-$; angles: P(1)C(1)P(2) = 122°; P(1)C(1)S = 121°; P(2)C(1)S = 115°.[58]

As shown above, a single alkoxycarbonyl group ($\sigma^-_{CH_2} = 0.72$) at the central carbon atom is insufficient for the tautomeric transfer of a proton to the oxygen atom of the phosphoryl group; the combination of the alkoxycarbonyl group with the triphenylphosphonium group ($\sum\sigma^-_{CH} = 1.68$) proved to be entirely sufficient for the manifestation of the tautomeric transition; on the other hand, the combination of the triphenylphosphonium group with the tosyl group ($\sum\sigma^-_{CH} = 1.78$) and also the combination of two triphenylphosphonium groups ($\sum\sigma^-_{CH} = 2.16$) lead to a "redistribution" of the CH acidity: the tautomeric equilibrium proved to be displaced in the direction of the hydroxy-ylide form.

It was therefore of interest to investigate the influence of two tosyl groups ($\sum\sigma^-_{CH} = 1.40$) at the central carbon atom in the structures (LIX) considered. Two tosyl groups should lead either to the CH form or to tautomerism between the CH and OH forms. This question has been recently elucidated by Kolodyazhnyi[60], who investigated the influence of the substituents X on the position of the tautomeric equilibrium in the

(LXXXIV)⇌(LXXXV) system:

$$Ph_2P(O)-CH(SO_2C_6H_4X)_2 \rightleftarrows Ph_2P(OH)=C(SO_2C_6H_4X)_2$$
(LXXXIV) (LXXXV)

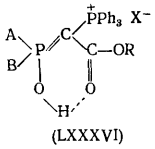
In a pure state these substances consist of colourless crystals, which are very stable in air. They have the structure of the CH forms (LXXXIV), as can be seen from their infrared spectra, which contain bands at 1200–1210 cm^{-1} (P=O), 1160 to 1170 cm^{-1} (sym.SO_2), 1340–1350 cm^{-1} (asym.SO_2), and 2820 to 2840 cm^{-1} (CH). They are all strong acids (Table 9). However, in solution both forms, (LXXXIV) and (LXXXV), are present, differing in the chemical shifts in their ^{31}P NMR spectra (these are 21–24 p.p.m. and 47–49.5 p.p.m. respectively). The protons of the CH and OH groups are not manifested in the ^1H NMR spectra at the usual temperature but they can be detected on cooling—the signals of the OH protons are at 10–11 p.p.m. and those of the CH protons at 6–7 p.p.m. These are doublet signals (J_{PH} = 13 Hz); at −7.5 °C they lose the doublet structure and at +30 °C they disappear.

Table 9. The influence of substituents X on acidity and the tautomeric equilibrium[60].

$Ph_2P(O)-CH(SO_2C_6H_4X)_2 \rightleftarrows Ph_2P(OH)=C(SO_2C_6H_4X)_2$ [60]
(LXXXIV) (LXXXV)

X	σ_n	K_T (THF, 25 °C)	pK_a, (50% CH_3OH)
p-Cl*	+0.227	1.20	3.55
H	0	0.25	3.60
p-Me	−0.17	0.11	3.62
p-MeO	−0.268	0.04	3.68

* K_T = 1.32 at 20 °C and 1.98 at 30 °C.



The infrared spectra of the solutions are also different for the CH and OH forms. The spectrum of the CH form (LXXXIV) shows bands at 1200 cm^{-1} (P=O), 1170 cm^{-1}, and 1350 cm^{-1} (SO_2 attached to an sp^3-hybridised carbon atom); the spectrum of the OH form (LXXXV) shows bands at 1300 cm^{-1} and 1290 cm^{-1} (SO_2 attached to an sp^2-hybridised carbon atom). Table 9 lists the (LXXXIV)⇌(LXXXV) equilibrium constants as a function of the substituent X. Using the data in Table 9, it can be shown that the tautomeric equilibrium constants obey satisfactorily the Hammett equation when the usual constants σ_p are used:

$$\lg K_T = -0.51 + 2.867\,\sigma_p \quad (r = 0.994;\ s = 0.08;\ s_p = 0.21).$$

An increase of temperature increases the relative content of the (LXXXIV) form, which indicates a greater stability of the hydroxy-ylide form (LXXXV). The equilibrium position depends on the nature of the solvent, the content of the (LXXXV) form increasing in the sequence

$$CH_2Cl_2 < CHCl_3 < CCl_4 < THF .$$

In conclusion of this section, mention must be made of the striking stability of the hydroxy-ylide forms. They are apparently stabilised by hydrogen bonds, which can be both intramolecular, as in structure (LXXXVI), and intermolecular:

(LXXXVI)

Apart from the oxygen atoms of the COOR or SO_2Ar substituents, halide ions can also function as proton acceptors in the hydrogen bonds. This problem has so far been little investigated, but the existence of the hydrogen bonds has been demonstrated. They reduce the acidity of the OH forms and hence displace the equilibrium in their direction.

2. The Thiophosphoryl–Mercaptoylide Tautomerism

This type of triad phosphorus–carbon tautomerism (LXXXVII)⇌(LXXXVIII) is the phosphorus analogue of the thioketo-enethiol tautomerism (LXXXIX)⇌(XC):

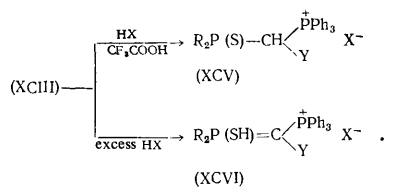
$$>P(S)-CH< \rightleftarrows >P(SH)=C< \qquad -C(S)-CH< \rightleftarrows -C(SH)=C< .$$
(LXXXVII) (LXXXVIII) (LXXXIX) (XC)

All the thiophosphoryl-compounds known previously, namely tertiary phosphine sulphides $R_2P(S)-CHR'R''$, phosphinothionates $(RO)R'P(S)CHR''R'''$, and phosphonothionates $(RO)_2P(S)CHR'R''$, are thione derivatives, i.e. correspond to structure (LXXXVII). Owing to the low basicity of the thiophosphoryl group (this is equivalent to a high acidity of its protonated form), a rarer appearance of the mercaptoylide form (LXXXVIII) than of the corresponding hydroxy-ylide form was to be expected for the thiophosphoryl-mercaptoylide system (LXXXVII)⇌(LXXXVIII). In other words, the transfer of a proton from the (LXXXVII) forms to the (LXVIII) forms requires a greater CH acidity of the (LXXXVII) forms than was the case for the phosphoryl-hydroxy-ylide transitions (see the previous section).

The first representative of a thiophosphoryl compound with the (LXXXVIII) structure was obtained[61] by the authors of this review and their co-workers. When the thiophosphorylated phosphoranylidenephosphonium salt (XCI) was protonated by fluorosulphonic acid, the mercaptoylide form (XCII) was obtained:

$$Me_2P(S)-C(PPh_3)(\overset{+}{P}Ph_3)\ X^- \xrightarrow{FSO_2OH} Me_2P(SH)=C(\overset{+}{P}Ph_3)(\overset{+}{P}Ph_3)\ 2X^- .$$
(XCI) (XCII)

S-Protonation was detected from the characteristic downfield shift of the signal in the $^{31}P\{^1H\}$ NMR spectrum by 7.2 p.p.m. (cf. Skvortsov et al.[54]).



Later the same workers investigated the thiophosphoryl-mercaptoylide tautomerism in greater detail[62] and obtained unexpected results. Various thiophosphoryl-substituted phosphinomethylenes (XCIII) have been synthesised by adding sulphur to the corresponding phosphino-derivatives (XCIV):

$$R_2P-C(PPh_3)Y \xrightarrow{S} R_2P(S)-C(PPh_3)Y ;$$
(XCIV) (XCIII)

	(a)	(b)	(c)	(d)	(e)	(f)	(g)	(h)	(i)
R	Ph	Bu	EtO	PhO	Ph	Bu	Ph	Bu	Bu
Y	Ts	Ts	Ts	Ts	COOEt	COOEt	$\overset{+}{P}Ph_3Cl^-$	$\overset{+}{P}Ph_3Cl^-$	$\overset{+}{P}Ph_3Br^-$

These compounds were protonated by various acids under different conditions. Of the two types of protonation—at the sulphur atoms, as in structure (XCVI), and at the carbon

atom, as in structure (XCV)—only one type has been invariably observed as a function of the initial compound, the protonating agent, and the reaction conditions:

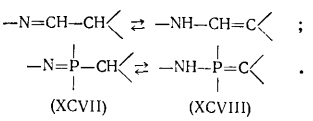
(XCV)

(XCVI)

Thus the protonation of compounds (XCIII, a–f) by hydrogen halides in equimolar proportions or in the presence of an excess of the latter leads only to the CH forms (XCV, a–f). The signal of the triphenylphosphonium phosphorus in the $^{31}P\{^1H\}$ NMR spectrum then undergoes a downfield shift by 1.5–7 p.p.m. and the constant J_{PP} diminishes significantly, amounting to 32–42 Hz before protonation and to 1–2 (at most 6) Hz after protonation, which is extremely characteristic of CH protonation. Frequencies corresponding to the SO_2 and COOEt groups attached to an sp^3-hybridised carbon atom are observed in the infrared spectrum. Apart from the signals due to the protons of the butyl, phenyl, and tosyl group, the ^1H NMR spectrum of the salt (XCVb) contains doublets with $\delta = 8.8$ p.p.m. and $J_{PCH} = 12.1$ and 13.6 Hz, which indicates unambiguously the CH structure (XCV). The ratio of the integral intensities of the signals of the CH proton and the CH_3 protons of the tosyl group is then 1 : 3. Protonation of the thiophosphorylylides (XCIII, e and f) by trifluoroacetic acid is also directed solely to the central carbon atom. The hydrochlorides (XCV, a–c), formed on protonation by HCl, are crystalline substances; they are all very strong acids which readily lose HCl on storage in air, the chlorides being less stable than the bromides.

Thus in this group of compounds the strength of the SH acids exceeds significantly that of the CH acids, although the latter are fairly strong.

A different behaviour is observed on protonation of compounds (XCIII, g–i), since this should entail the protonation of extremely strong acids. Indeed, on treatment of the thiophosphoryl ylides (XCIII, g–i) with HCl in CH_2Cl_2 (even with a large excess of HCl) or on treatment with an excess of trifluoroacetic acid, the addition of a proton is not always observed at the usual temperature. Only at temperatures between −70° and −85 °C in CH_2Cl_2 on treatment with an excess of hydrogen halide or on dissolution in fluorosulphonic acid is protonation observed, but in these instances only at the suphur atom.

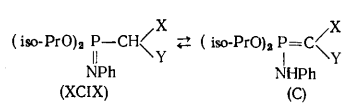


Thus, when compounds (XCIII, g and h) are treated with HSO_3F, doublet signals with the chemical shifts $\delta = 3.67$ p.p.m. for compound (XCVIg) and 3.05 p.p.m. for compound (XCVIh) and the splitting constants $J_{PSH} = 10$ and 8 Hz respectively appear in the ^1H NMR spectra. Spectra of this kind are very characteristic of thiophosphoryl compounds protonated by fluorosulphonic acid[63].

In the ^{31}P NMR spectra the signal of the thiophosphoryl phosphorus atom shifts downfield by 1–5 p.p.m. compared with the non-protonated compounds. The spin–spin coupling constant J_{PP} not only does not diminish under these conditions, as in the previous instance of C protonation, but actually increases somewhat.

Thus a system in which the (LXXXVII) and (LXXXVIII) forms are in an experimentally observed tautomeric equilibrium has been found for thiophosphoryl compounds of type (LXXXVII). If the acidity of the CH form is insufficient [the sum of the constants of the substituents at the central carbon atom $\sum\sigma^-_{CH} = 1.78$ for compounds (XCV, a–d) and, especially, 1.68 for compounds (XCV, e and f)], then only the CH form is produced. If the acidity of the CH form is high [$\sum\sigma^-_{CH} = 2.16$ for compound (XCVI, g–i)], then the proton is transferred to the sulphur atom and we detect exclusively the SH form. Apparently the region of the thiophosphoryl-mercaptoylide tautomerism involving thiophosphoryl compounds should occur for values of the sum of the constants $\sum\sigma^-_{CH}$ of the substituents at the central carbon atom between 1.78 and 2.16. The synthesis of thiophosphoryl compounds with such substituents at the α-carbon atom and the study of their thiophosphoryl-mercaptoylide tautomerism are matters for the future.

3. The Phosphorimide–Aminoylide Tautomerism



The phosphorimide–aminoylide tautomerism is the phosphorus analogue of the well known azomethine tautomerism:

(XCVII) (XCVIII)

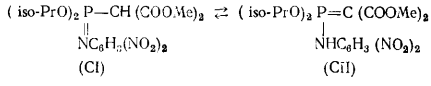
Compared with previous cases—the phoshoryl-hydroxyylide tautomerism (LIX) and the thiophosphoryl–mercaptoylide tautomerism (LXXXVII) and (LXXXVIII)—there is not in this instance such a sharp difference between the polarities of the ends of the N = P = C triad; the relative acidities of the CH and NH forms can therefore change significantly under the influence of substituents at the nitrogen and carbon atoms. This type of tautomerism has been investigated by the Kiev chemical school[64–67]. Referring to it, in conformity with the nomenclature of the phosphorus-nitrogen compounds adopted in Kiev, as the phosphazo-ylide tautomerism, Kolodyazhnyi, Kukhar', Gololobov, and others investigated thoroughly both the methods of analysis of the tautomeric mixtures and the factors influencing the position of the phosphorimide-aminoylide equilibrium. It was established that the imide (XCVII) and iminoylide (XCVIII) forms can be clearly distinguished by means of infrared spectra and also ^1H and ^{31}P NMR. Thus, when there are two COOR groups at the carbon atom of the (XCVIII) form, the ^{31}P NMR spectrum shows a signal in the vicinity of 50 p.p.m., while for the corresponding (XCVII) form the signal is at 0 p.p.m. The ^1H NMR spectra of the (XCVII) forms contain a doublet due to the CH group in the range 3.5–4 p.p.m., while the spectra of the (XCVIII) forms contain the doublet of the NH group at 7–13 p.p.m. In the infrared spectra the vibration frequency of the COOR group at the α-carbon atom depends on the state of hybridisation of the latter and amounts to 1700–1760 cm^{-1} for the sp^3 hybridisation and to 1600–1700 cm^{-1} for the sp^2 hybridisation.

Thus the presence or absence of the tautomeric equilibrium has been established and in many instances its constants have been determined. The sharp influence of substituents at the nitrogen and carbon atoms on the equilibrium is noteworthy. Thus, in the presence of two isopropoxy-groups at the phosphorus atom, i.e. in the (XCIX) ⇌ (C) system

(XCIX) (C)

the equilibrium position (in CCl_4 at 28 °C) changes as follows:

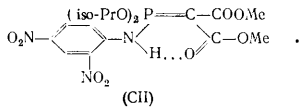
X, Y	$\Sigma\sigma_C^-$	Content of NH form, %
$(COOMe)_2$	1.24	100
COOMe, Ph	0.88	0
COOMe, H	0.72	0



If the NH acidity is reduced by replacing the phenyl group at the nitrogen atom by the methyl group, then 100% of the NH form will be present not only in the first case for $\sum\sigma_C^- = 1.24$ but also for $\sum\sigma_C^- = 0.88$; even for $\sum\sigma_C^- = 0.72$, its content will still be 90%. On the other hand, if the NH acidity is increased by introducing the 2,4-dinitrophenyl group at the nitrogen atom instead of the phenyl group, then in the first case ($\sum\sigma_C^- = 1.24$) only 30% of the NH and not 100% is observed and, finally, the greatest increase of the NH acidity, resulting from the introduction of the tosyl group at the nitrogen atom, leads to the complete disappearance of the NH form in all the three instances considered. Thus the results obtained by the Kiev chemists[64-67] can be readily interpreted from the standpoint developed in the present review.

The nature of the solvent has an appreciable influence on the phosphorimide–aminoylide equilibrium. The content of the aminoylide form increases in the following series of solvents from left to right:

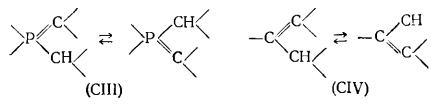
$$CCl_2{=}CCl_2 < CCl_4 < CH_3OH < CH_3CN < CHCl_3 \quad .$$



This series is apparently determined by the simultaneous operation of several factors.

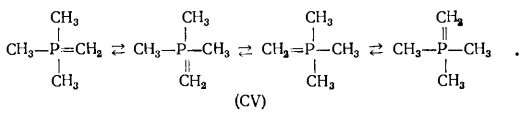
An increase of temperature favours the imide form (XCVII). Thus the study of the temperature variation of the equilibrium in the (CI) ⇌ (CII) system

(CI) (CII)



showed that $\Delta H = -5.9 \pm 0.5$ kcal mol^{-1} and $\Delta S = -21$ e.u. for a 0.2 M solution in CCl_4. The aminoylide form (CII) is energetically more favourable and more stable than the imide form (CI). The high entropy of the conversion of the ylide into the imide is noteworthy; this enabled the author of the study quoted above to postulate that the ylide form has a more rigid structure as a consequence of an intramolecular hydrogen bond:

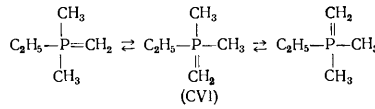
(CII)



4. The Carbon–Phosphorus–Carbon Tautomerism

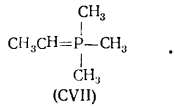
Here we are dealing with the phosphorus analogue (CIII) of the three-carbon tautomerism (CIV):

(CIII) (CIV)



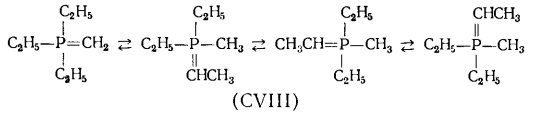
The first data on the degenerate tautomerism of this kind were published by Schmidbaur and Tronich[68], who found that the ^{1}H NMR spectra of solutions of trimethylmethylenephosphorane (carefully freed from impurities) depend on temperature and that at 100 °C the signals of the methyl and methylene protons merge owing to the degenerate tautomeric migrations of the proton in system (CV):

(CV)



The activation energy for such transformations was estimated as 20 kcal mol^{-1}. The transformation is catalysed by added methanol, water, silanol, and in general proton donors. When traces of CH_3OH are introduced, a singlet signal is observed in the ^{1}H NMR spectrum already at −30 °C.

Tautomeric transitions (also degenerate) analogous to those of methylenetrimethylphosphorane have been observed for ethyldimethylmethylenephosphorane (CVI)[68]:



(CVI)

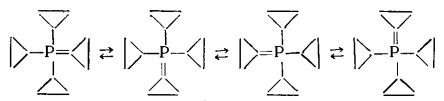
In the absence of catalysis by methanol, the ethyl group is not involved in the tautomerism, while the presence of methanol, the methylene protons of the ethyl group are involved in the merging of the signals, which indicates the appearance of the fourth tautomeric form (CVII), which is in equilibrium with the three previous forms:

(CVII)

The ^{1}H NMR spectrum of the compound $(C_2H_5)_3P{=}CH_2$ undergoes no temperature-induced changes below 100 °C, but, after the addition of methanol, the equilibrium of the four forms in system (CVIII) is immediately established[68]:

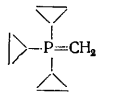
(CVIII)

Strictly speaking the conversion of the first form specified into any one of the other three constitutes a non-degenerate tautomeric transition. However, the differences between the energy relations of the forms are in this instance very small and the system approaches a degenerate state. An analogous situation (with complete degeneracy) has been observed for triethylethylidenephosphorane $(C_2H_5)_3P{=}CHCH_3$, whose ^{1}H NMR spectrum is independent of temperature. The addition of only traces of methanol induces a rapid proton migration. As regards the mechanism of the catalytic action of methanol, it has been suggested that methanol reacts with the ylide to form phosphonium methoxide (CIX) by the reversible reaction[68]



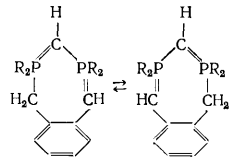
(CIX)

Next, the familiar transylidation process takes place.



The application of ^{1}H NMR spectroscopic methods made it possible to discover many analogous instances of the degenerate tautomerism of ylides. Thus one may quote as an

example tricyclopropylcyclopropylidenephosphorane (CX) [69]:

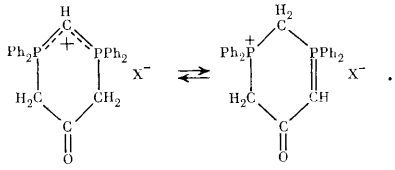


(CX)

It is of interest that the replacement of one cyclopropyl substituent by the methyl group immediately fixes the structure (CXI), as the more favourable, and proton migration ceases:

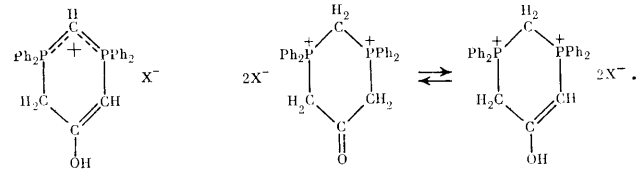
(CXI)

We may mention also the pentad system of type (CXII) [70]:



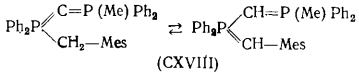
(CXII)

The introduction of strongly electron-accepting substituents into the methylene and methyl groups of trimethylmethylenephosphorane significantly reduces the barrier to tautomerisation. Thus the merging of the signals of the methylidyne and methylene groups in system (CXIII) takes place in $CDCl_3$ at −40°– −50 °C, while for a solution in SO_2 the merging takes place at −20 °C [71]:



(CXIII)

The number of known cases of non-degenerate tautomerism in the triad $CH-\overset{|}{P}=C$ is much smaller. The first example of this kind was the tautomerism of 3,3,5,5-tetraphenyl-3,5-diphosphacyclohexenone, (CXIV) ⇌ (CXV), investigated by the authors of this review and their co-workers[72,73]:

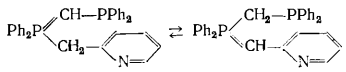


(CXIV) (CXV)

According to infrared spectroscopic data, the substance in the crystalline state has the structure (CXV): the infrared spectrum of a mull in hexachlorobutadiene shows bands at 1540–1550, 1345, and 880 cm^{-1} associated with the ν_1, ν_2, and ν_3 vibrations of the acylphosphinomethylene system, while OH bands are absent; according to NMR and infrared spectra, a solution in $CHCl_3$ contains simultaneously also the (CXIV) form (again at a low relative concentration). It is of interest that the enol form (CXVI) is not detected in the equilibrium mixture at all, while in the saturated system (CXVII) there is a distinct keto-enol equilibrium according to ^1H NMR and infrared spectroscopic data[74]:

(CXVI) (CXVII)

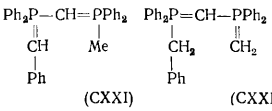
Interesting examples of the non-degenerate tautomerism (CXVIII), (CXIX), and (CXX) in the $C=\overset{|}{P}-CH$ triad have been described recently[75]:



(CXVIII)

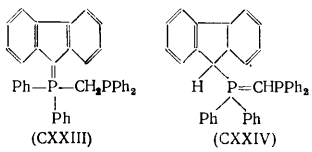
(3 : 1 ratio of different forms);

(CXIX)



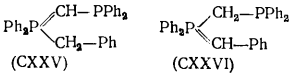
(3 : 2 ratio of different forms);

(CXX)



(3 : 1) ratio of different forms).

In the degenerate carbon–phosphorus–carbon tautomerism the forms involved are identical, their acidities are equal, and their contents in the equilibrium mixture are the same. For certain small differences between the structures of the forms, which are reflected in their relative CH acidities, a non-degenerate tautomerism is observed where the less acid form naturally predominates in the equilibrium mixture. On the other hand, if the structural differences become more significant, then the difference between the CH acidities increases and the equilibrium is almost completely displaced to one side. Thus the derivative (CXXI) is not tautomeric; it has the structure (CXXI) and not (CXXII):



(CXXI) (CXXII)

The fluorenylidene derivative is also non-tautomeric, having the structure (CXXIII) and not (CXXIV):

(CXXIII) (CXXIV)

If the α-pyridyl substituent in system (CXX) is replaced by the phenyl substituent, which has a lower acidifying capacity, then the equilibrium is fully displaced towards the (CXXV) form and tautomerism with the (CXXVI) form is not manifested:

(CXXV) (CXXVI)

Such a sharp response of the position of the carbon–phosphorus–carbon tautomeric equilibrium to seemingly small changes in the character of the substituents at the CH groups can be explained by the very high slopes of the linear

correlations between the pK_a for the different forms and $\sum\sigma_{CH}^-$. Indeed the values of ρ in the expressions for the pK_a for non-tautomeric CH acids ($pK_a = pK_a^0 - \rho\sum\sigma_C^-$) vary from 10 to 25 as a function of the solvent, the counterion, etc.[46]

Small changes in $\sum\sigma_C^-$ induce large changes in the pK_a for the different forms. The difference between them ($\Delta pK_a = pK_1 - pK_2$) can then increase markedly, whereupon the position of the tautomeric equilibrium ($pK_T = \Delta pK_a$) is sharply altered.

IV. CONCLUSION

Not so long ago there was no information about the existence of PH ylides, P(OH) ylides, P(SH) ylides, etc. Studies in the 1970's led to the discovery of this new extensive field of organophosphorus chemistry. In this review we were concerned only with problems of the tautomerism of such ylides with the corresponding derivatives of tervalent phosphorus or phosphoryl, thiophosphoryl, etc. compounds. The prototropic migrations could be reliably treated in this instance from the standpoint of the theory of the tautomeric acid–base protolytic equilibrium. This is naturally extremely important. At the same time, it is essential to note that the proton transitions constitute only a part of the extensive chemistry of the new systems. There exists yet another very interesting field of dual reactivity of the corresponding ambident species, which can be negatively charged like the usual anions, but the corresponding neutral species are also possible if the initial protonated forms carry a positive charge. We were naturally unable to deal with this extremely interesting field of the chemical properties of new phosphorus ylides. There is a possibility also of other interesting and important reactions, for example, rearrangements, decomposition reactions, etc. Their elucidation has not so far proceeded very far, although interesting results have already been obtained. However, this is a subject for another article.

The Arbuzov Rearrangement with Participation of Halogenoacetylenes as a Method of Synthesis of Ethynylphosphonates and other Organophosphorus Compounds

A.A.Petrov, A.V.Dogadina, B.I.Ionin, V.A.Garibina, and A.A.Leonov

The Arbuzov rearrangement with participation of halogenoacetylenes is examined and its possible application in the synthesis of a wide variety of hitherto inaccessible organophosphorus compounds is discussed.
The bibliography includes 50 references.

IV. The electronic structure and physical characteristics of ethynylphosphonates 1034

I. INTRODUCTION

The Arbuzov rearrangement, discovered at the beginning of the century, has served for decades as one of the principal methods of synthesis of compounds with a phosphorus–carbon bond and has been an important method for the investigation of substances capable of nucleophilic substitution and addition reactions. Studies carried out in the Department of Organic Chemistry of the Lensovet Leningrad Technological Institute showed in 1962 that halogenoacetylenes with the halogen attached to the triple bond can be used successfully in this reaction[1]. The discovery of the Arbuzov rearrangement involving halogenoacetylenes not only revealed a new pathway to the synthesis of a wide variety of acetylenic phosphonates and other organophosphorus compounds based on them but also attracted attention to the study of the reactivities of halogenoacetylenes in relation to nucleophiles.

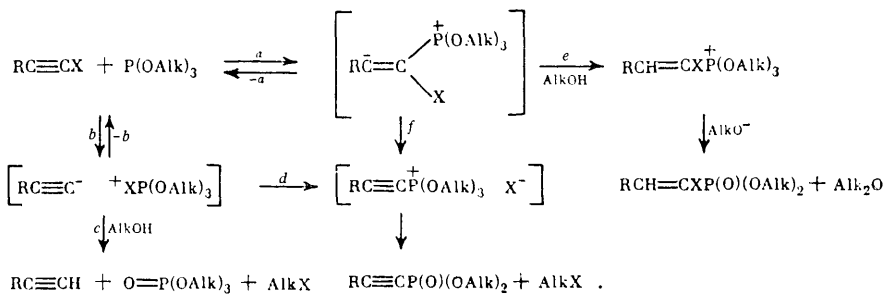
Although many halogenoacetylenes have long been known and convenient preparative methods for the synthesis of a series of compounds of this type have been proposed, for a long time they did not find applications in organic synthesis. At the beginning of the 1960s only a few reactions involving the nucleophilic substitution of the halogen in halogenoacetylenes were known[2] and on the whole it was assumed that their reactivity in relation to nucleophiles is low. It was postulated that, as in hypohalites, the halogen in halogenoacetylenes is "positive" and that this should promote oxidation-reduction processes and not nucleophilic substitution with elimination of the halogen as an anion. In reality, it was found that, at least in those cases where the second carbon of the halogenoacetylenes is linked to a group containing a multiple bond, to an aromatic ring, or to a heteroatom, the nucleophilic substitution of the halogen—the Arbuzov rearrangement leading to the formation of "normal" products (ethynylphosphonates and halogenoalkanes)—takes place readily and with a high yield[3-7]:

$$R{-}C{\equiv}C{-}X + P(OAlk)_3 \longrightarrow R{-}C{\equiv}C{-}P(O)(OAlk)_2 + AlkX \quad (X=Cl, Br)$$

During the past two decades, various investigators achieved the syntheses of a wide variety of ethynylphosphonates, including those hitherto inaccessible, studied the reaction mechanism, and demonstrated the possibility of employing the compounds obtained for the synthesis of various organophosphorus products based on them.

II. SYNTHESIS OF ACETYLENIC PHOSPHONATES

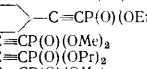
Among halogenoacetylenic compounds, bromoethynyl- and chloroethynyl-benzenes[1,2], conjugated bromoalkenynes[3,6], and bromoalkadiynes (1-bromopenta-1,3-diyne and 1-bromohexa-1,3-diyne)[4] were made to undergo the reaction successfully. Alkylhalogenoacetylenes are much less reactive and react only on heating, forming mixtures of products which are difficult to separate[5]. Nevertheless, when 1-bromo-oct-1-yne reacts with triethyl phosphite, the corresponding phosphonate is formed in a yield up to 20%; however, the authors showed that the reaction of 1-bromoalkynes with sodium dialkyl phosphites, which takes place at a reduced temperature (−70 °C) in tetrahydrofuran with a yield up to 75%,[7] constitutes a more suitable method of synthesis of alkylethynylphosphonates.



The rearrangement of trialkyl phosphites by halogenoacetylenes, containing a group with a metal belonging to the Fourth Period as the second substituent, has been achieved successfully. This not only permitted the synthesis of exotic dihetero-substituted acetylenes but also led to the discovery of a simple method of synthesis of unsubstituted ethynylphosphonate, which is otherwise difficult to obtain, and also of bromoethynyl phosphonate[9,10]:

$$Alk_3M{-}C{\equiv}C{-}X + P(OAlk)_3 \rightarrow Alk_3M{-}C{\equiv}C{-}P(O)(OAlk)_2 \rightarrow \begin{cases} \xrightarrow{\text{hydrolysis}} HC{\equiv}CP(O)(OAlk)_2 \\ \xrightarrow[(M=Sn)]{Br_2} BrC{\equiv}CP(O)(OAlk)_2 \end{cases} ; \quad M=Sn, Si$$

The rearrangement involving dichloro- and dibromo-acetylenes is especially interesting. Depending on the ratio of the dihalogenoacetylene and the phosphite, one or both halogen atoms can be substituted[5,11,12]:



$$X{-}C{\equiv}C{-}X \xrightarrow{P(OAlk)_3} X{-}C{\equiv}C{-}P(O)(OAlk)_2 \rightarrow \xrightarrow{P(OAlk)_3} (AlkO)_2P(O)C{\equiv}CP(O)(OAlk)_2 .$$

This reaction has been used to synthesise symmetrical and mixed phosphonates[13]. The employment of this method for the synthesis of ethynylphosphine dioxides, which are of interest as dienophiles, has been reported[14]. In the presence of an excess of dihalogenoacetylene, highly reactive halogenoethynylphosphonates were obtained—they are convenient intermediates in the synthesis of previously inaccessible substituted ethynylphosphonates and derivatives of phosphonoacetic acid.

Ethynylphosphonates obtained by the Arbuzov rearrangement with participation of halogenoacetylenes, which were not indicated in a previous review[8], are listed in Table 1.

Table 1. Ethynylphosphonates obtained by the Arbuzov rearrangement from halogenoacetylenes*.

Compound	Yield, %	B.p., °C (*p*, mmHg)	*t*, °C	n_D^t, °C	d_4^t
