Chemically Induced Radio-frequency Emission and Chemical Radiophysics

A.L.Buchachenko and V.L.Berdinskii

Chemical reactions involving free radicals can yield molecules with inverted populations of the nuclear Zeeman levels and able to store energy in the nuclear Zeeman reservoir. These molecules produce a radio-frequency electromagnetic field which induces radiative transitions between the Zeeman levels resulting in the conversion of the stored energy into radio-frequency emission from the molecules. The dependence of the recombination probability of the radicals on their spin state allows the elementary acts of radical reactions to be controlled by the application of radio-frequency electromagnetic fields ("chemical" radio receiver). The generation and reception of r.f. radiation in chemical reactions are the object of a new field of science: chemical radiophysics. 29 references.

I. INTRODUCTION

Chemical reactions are used to produce either new substances and materials or energy. The chemical energy released during a reaction "heats up" the translational, vibrational, and rotational motion of the molecules, and excites their electron shells. The emission of heat and light by the reacting system is a result of this "pumping" of energy into the molecules. More "organised" methods of converting chemical energy into radiation (chemical lasers) have been studied in recent years, and the mechanisms of the chemical action of laser radiation have been determined[1]. In the whole of that work the energy of the chemical reactions was emitted in the visible or infrared region of the spectrum.

We have recently observed emission at radio frequencies[2] from chemical reactions, resulting from the energy pumping of the Zeeman nuclear levels which act as an energy reservoir for the molecule. This new phenomenon (chemically induced radio-frequency emission) offers a bridge between the previously unrelated sciences of chemistry and radiophysics.

The aim of this review is to examine the physicochemical foundations and the theory of this new phenomenon, to establish the present state of knowledge on the effect of radio-frequency fields on the elementary acts of chemical reactions in solids, liquids, and gases, and to discuss the chemical consequences and the prospects of new developments in physical chemistry arising from this phenomenon. Problems of fundamental importance in chemical radiophysics

include: firstly, the role of the spin degrees of freedom of the molecules and radicals in chemical reactions, and the mechanism of the chemical pumping of the nuclear Zeeman levels; secondly, the way and the conditions under which the energy stored in the Zeeman reservoir is converted into the energy of radio-frequency emission; thirdly, the conditions and the mechanism which enable a radio-frequency field, acting on the spins of electrons and nuclei, to influence the chemical behaviour of atoms, molecules, and radicals.

II. CHEMICAL PUMPING

Transitions between nuclear Zeeman levels are accompanied by reorientation of the nuclear spins and magnetic moments which interact with the external magnetic field. Hence the pumping of the Zeeman reservoir (i.e. the creation of an excess or even an inverted population of the upper Zeeman levels) is equivalent to creating a negative polarisation of the nuclei. The mechanisms of chemically induced nuclear polarisation are well known[3-5], and the phenomenon of chemical polarisation of the nuclei (CPN) was discovered[6,7] in 1967. It was found that in chemical reactions involving paramagnetic particles (free radicals) a non-equilibrium population of the nuclear Zeeman levels is developed in the product molecules, resulting in nuclear polarisation (positive if the excess population resides in the lower Zeeman level, and negative if the population excess, or even inversion, affects the upper level). The non-equilibrium occupancy of the levels manifests itself in the nuclear magnetic resonance spectra of the product molecules as an anomalously strong absorption (for positive CPN) or induced emission (for negative CPN). Some examples of CPN are shown in Fig.1.

Chemical polarisation of the nuclei is created during the elementary acts of the interaction between radicals: their recombination, or their disproportionation. It arises from spin-forbidden processes in chemical reactions. The simplest physical interpretation of this phenomenon is the following. Spin (i.e. the momentum of rotation of the electrons and nuclei) is conserved in chemical reactions, and therefore reactions involving a change of spin are rigidly forbidden. Thus when two radicals collide their electronic spins can either be added (total spin of the pair $S = 1$, triplet state) or subtracted ($S = 0$, singlet state). The products of the recombination of radicals are usually diamagnetic, i.e. they have zero spin, and therefore they must have been formed from singlet radical pairs. Triplet pairs do not recombine. However, triplet–singlet conversion of the pair can take place during the lifetime of the triplet pair under the influence of the external magnetic field and of the internal (hyperfine, or Fermi) interaction between electrons and nuclei. The rate of conversion depends on the orientation of the spins and of the magnetic moments of the nuclei: for some orientations the rate is high, and radical pairs having these orientations are rapidly converted into the singlet state and recombine, giving reaction products.

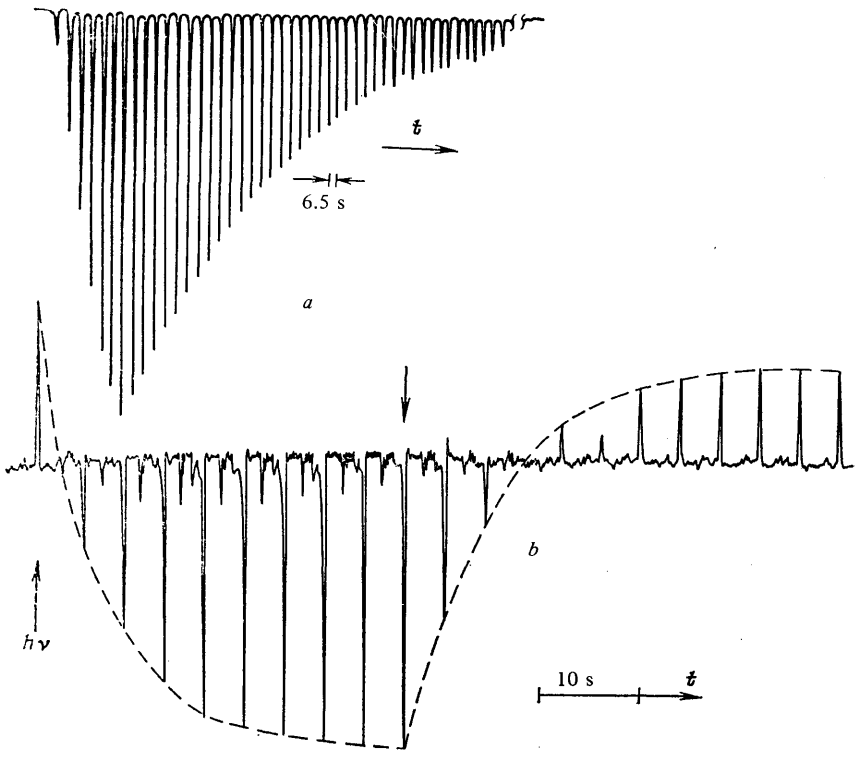

Figure 1. Chemical polarisation of ^{31}P nuclei in trimethylphosphate during the reaction with cyclohexylperoxydicarbonate (*a*), and of the protons in the CH_2 groups of dibenzylketone during photolysis (*b*). The arrows denote the switching on and off of the light.

In the radical pairs with the opposite nuclear orientation the triplet–singlet evolution is hindered, and the radicals in these pairs give different products. In this way the chemical reaction can "sort" the radicals for nuclear spin orientation and direct the radicals with a given type of nuclear orientation towards certain products and those with the opposite type towards other products. In this way some reaction products acquire a positive nuclear polarisation while others acquire a negative polarisation. As a rule, because of differences in chemical shift, the nuclei in the various products are characterised by different NMR frequencies, and therefore CPN is easily detected by NMR.

The sign of the CPN depends on the initial spin state of the radical pair, on the difference between the g-factors of the radicals, and on the sign of the hyperfine electron–nucleus interaction, but the CPN is invariably of opposite signs in the products of radical recombination and in the products of other radical conversions (without recombination). Obviously, the sign of the CPN is determined by the chemical nature of the radicals and by the type of chemical reaction involving the radical pair.

The sorting of nuclei with respect to orientation as a CPN mechanism is characteristic of reactions taking place in strong magnetic fields (about 10^3 Oe).[3] In weak magnetic fields (including the Earth's field) the reaction orients the nuclei as well as sorting the nuclei according to orientation. The electron–nucleus magnetic interaction couples the electrons and the nuclei into a single system in which the total angular momentum (spin) is conserved, so that the change in spin of one particle (electron) can be compensated by the change in spin of another (nucleus). Therefore the triplet–singlet conversion of the radical pair is accompanied by nuclear polarisation: the nuclei are transferred from the lower to the upper Zeeman level and are oriented against the field, producing an excess population of the upper level and a negative polarisation. In this mechanism of CPN the sign of the nuclear polarisation is again dependent on the initial spin state of the radical pair.

Thus the chemical interaction of radicals, being selective with respect to the electron spin of the radical pair, is also selective with respect to nuclear spin, since the two spin systems (electrons and nuclei) are coupled through the magnetic hyperfine interaction.

In principle, any nucleus having a non-zero magnetic moment can be polarised during the reaction, but CPN is most often observed in the widely distributed isotopes with a nuclear spin of $I = 1/2$, such as ^{1}H, ^{13}C, ^{19}F, ^{31}P, ^{119}Sn, etc.

Since radical recombination takes place in all radical reactions, CPN may be found in practically all reactions involving a free-radical step, and it may be treated as unambiguous proof of the existence of such a step. Therefore CPN has become an important method of establishing the mechanism of chemical reactions, and is now widely used for this purpose.

The magnitude of the CPN is measured by the polarisation coefficient P. Under Boltzmann equilibrium conditions the populations of the upper and the lower Zeeman level are n_-^0 and n_+^0 respectively, and under non-equilibrium conditions (i.e. in the presence of polarisation) the quantity P is defined by the expression

$$P = \frac{n_+ - n_-}{n_+^0 - n_-^0} , \qquad (1)$$

where n_+ and n_- are the non-equilibrium occupancies of the lower and the upper level. The polarisation coefficient is a measure of the factor by which the non-equilibrium occupancy difference created in the molecules at the instant of their generation from the radical pair exceeds the equilibrium value. With positive polarisation $n_+ > n_-$ and $P > 0$, whereas with negative polarisation we have a population inversion of the Zeeman levels and $P < 0$.

The quantity P depends on the spin and magnetic moment of the nucleus, on the electron–nucleus interaction energy, on the difference between the g-factors of the radicals in the pair, and on the strength of the magnetic field, i.e. on all the magnetic parameters which determine the rate of the triplet–singlet transitions of the radical pairs (spin dynamics). Furthermore P also depends on the diffusional mobility of the radicals (the molecular dynamics of the pair) and on the lifetime of the radicals (chemical dynamics), which jointly determine the time during which the pair must exist in order to undergo triplet–singlet conversion. Knowing the parameters of the spin, the molecular, and the chemical dynamics of the radical pair we can calculate the parameter P (see Refs.3 and 4 for a more detailed discussion).

The energy stored in the Zeeman reservoir as a result of nuclear polarisation is easily calculated. The ratio of the equilibrium occupancies is

$$n_+^0/n_-^0 = \exp(\hbar\gamma_n H_0/2kT) \approx 1 + \hbar\gamma_n H_0/2kT , \qquad (2)$$

where $\hbar\gamma_n H_0$ is the energy of the radio-frequency quantum, i.e. the excess energy of the nucleus in the upper Zeeman level (γ_n is the gyromagnetic ratio of the nucleus, and H_0 is the magnetic field intensity), and kT is the thermal energy. From this expression we obtain the Zeeman energy of N polarised nuclei in a magnetic field H_0:

$$E_z = -\frac{1}{2} PN(\hbar\gamma_n H_0)(\hbar\gamma_n H_0/2kT) , \qquad (3)$$

For example, in a field of 15000 Oe the Zeeman energy of 1 mole of protons with a polarisation coefficient $P = -10^3$ is $\sim 10^{-4}$ J at 30 °C. The energy of the Zeeman reservoir is proportional to the nuclear polarisation coefficient, and therefore the chemically induced emission of radio frequencies is most likely to be found in reactions with strong nuclear polarisation.

The large absolute value of the polarisation coefficient $|P|$ is a striking feature of CPN: values of 10^2–10^4 are common. However, in some reactions the coefficient $|P|$ can be even larger and approach the limiting value $P_{\lim}$:

$$|P_{\lim}| = (2kT/\hbar\gamma_n H_0) . \qquad (4)$$

Thus in the photolysis of cyclododecanone in the liquid phase at 20 °C in a field of 125 Oe a coefficient $|P| > 3.6 \times 10^6$ was observed for the protons of this molecule, and the probability of transferring the proton to the upper Zeeman level by the absorption of one quantum of photochemically active light[8] was greater than 0.3, i.e. the quantum "yield" of the nuclear polarisation was ≥ 0.3.

In the photosensitised decomposition of cyclohexanone diperoxide in solution at 20 °C in a field of ~200 Oe, a coefficient $|P| > 4 \times 10^5$ was observed[9] in the resulting cyclohexane, with a quantum "yield" of ~0.036 for the nuclear polarisation. Though this value is an order of magnitude lower than in the previous case, it is surprisingly large, and well beyond the range accessible by using existing methods of orienting nuclei in the condensed phase (for example, the Oberhauser effect).

Thus chemical reactions can generate large amounts of nuclear polarisation and store large amounts of energy in the Zeeman reservoir of the reaction products.

III. SELF-EXCITATION OF CHEMICALLY INDUCED RADIO-FREQUENCY FIELDS

A population inversion of the Zeeman levels is a necessary but by no means sufficient condition for the emission of the Zeeman energy stored in the reaction products in the form of radiation. The frequencies of the transitions between the nuclear Zeeman levels depend on the strength of the external magnetic field and correspond broadly to the radio-frequency range (from super-long to ultra-short waves). In this range the probability of spontaneous radiative transitions between levels is very small. For example, for a proton in a magnetic field of 7500 Oe this probability is 10^{-25} s^{-1}, corresponding to an emission time of 10^{17} years[10]. This is enormously greater than the spin–lattice nuclear relaxation time (1–100 s), after which the occupancy of the Zeeman levels reverts to the equilibrium thermal (Boltzmann) distribution and the energy of the Zeeman reservoir is irreversibly converted into thermal energy of the lattice. Therefore it is important to establish the conditions under which the Zeeman energy of the reaction products is emitted as r.f. radiation instead of being converted into heat by the spin–lattice relaxation processes.

The magnetic moments of the negatively polarised nuclei (μ_n) can be combined into an overall magnetisation vector **M** oriented in opposition to the outer magnetic field. The reaction products will generate r.f. radiation, i.e. they will create the necessary electromagnetic field, only when self-excitation of the Larmor precession of the nuclear magnetisation vector **M** round the direction of the external field H_0 can take place (Fig.2). The antiparallel orientation of the vector **M** with respect to the field H_0 is unstable, and as a result of random fluctuations the vector **M** can deviate from this orientation and begin to rotate round the direction of the field H_0 (i.e. to precess). Once the precession has started the vector **M** begins to induce an electromagnetic field which forces it to deviate still further from the external field H_0 (Fig.2).

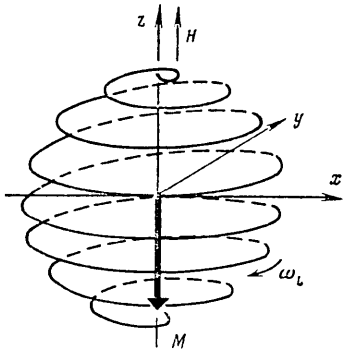

Figure 2. Precession of the magnetisation vector of negatively polarised nuclei. The tranverse components M_x and M_y are oscillating in the xy plane at the precession frequency ω_L.

The self-excitation of the precession of the vector **M** ensures the presence in the ensemble of molecules (reaction products) of transverse variable components of the total magnetisation $M_x(t)$ and $M_y(t)$, oscillating at the Larmor frequency $\omega_L = \gamma_n H_0$ in a plane perpendicular to the direction of H_0. The longitudinal component M_z varies slowly in chemical reactions. Therefore the radio-frequency electromagnetic field in the region surrounding the sample is generated only by the transverse component of the magnetisation, $M_\perp = (M_x^2 + M_y^2)^{1/2}$. If the sample containing chemically polarised reaction products is placed inside an induction coil the precessing vector **M** induces a high-frequency e.m.f. in the coil. This process is the exact analogue of the generation of an e.m.f. in the winding of any electrical generator, the only difference being that in this case the magnet is rotation (and not the rotor): the role of the rotating magnet is played by the transverse component of the nuclear magnetic moment. This is the simplest, classical account of the generation of a chemically induced radio-frequency field.

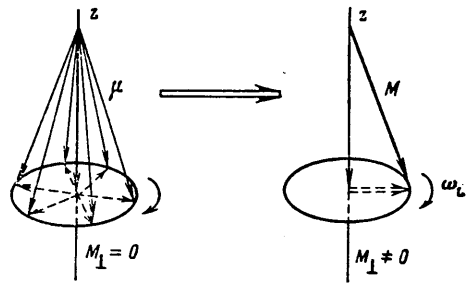

Figure 3. Transition from non-coherent motion to coherent precession of negatively polarised nuclear magnetic moments (frequency ω_L).

Self-excitation of the precession of the overall vector **M** denotes the appearance of spontaneous synchronisation (coherence) in the motion of the nuclear magnetic moments of the product molecules (Fig.3). In the absence of coherence the magnetic moments of the individual nuclei orientated against the field H_0 precess independently of each other, their precession phases are random, and the transverse components of the magnetisation are randomly "strewn" in the precession plane. As a result there is no net transverse magnetisation ($M_\perp = 0$). The r.f. electromagnetic field generated by the reaction acts on the magnetic moments of the nuclei and compels them to precess consistently, synchronously, and coherently, so that all the precessions are in phase, and the transverse components become aggregated in an overall vector $M_\perp \neq 0$. In other words the resulting coherent electromagnetic field induces a further avalanche-like increase in the synchronisation of the precession of the nuclear magnetic moments. The amplified electromagnetic field takes control of the precession of **M**, and as a result the (initially) negatively oriented magnetisation vector tends to become oriented along the field direction (Fig.2). This intrinsic coherent electromagnetic field induces forced radiative transitions between the Zeeman levels. The probability of forced transitions is very much greater than the probability of spontaneous emission, and therefore the energy of the Zeeman reservoir can be radiated instead of being dissipated as heat.

Thus the situation is similar, in principle, to that in a laser, where the emission of radiation is a forced (stimulated) process. It is therefore legitimate to treat the chemical reaction as a chemical quantum generator of radio frequencies: a raser (by analogy with the laser).

The coherence is perturbed by transverse magnetic relaxation processes through the random local fields H_{loc} which cause a scatter in the frequencies and phases of the precessing magnetic moments of the individual nuclei: the transverse components of the magnetisation vector become "dispersed", opposing the development of coherence (Fig.3). To ensure coherence, the field H^* created by the chemical reaction products, which "collects" the transverse components of the magnetisation, must be greater than H_{loc}: $H^* > H_{loc}$. In other words the coherence time T_2^* must be less than the nuclear transverse relaxation time T_2, i.e. the rate of development of coherence must be greater than the rate at which coherence is perturbed.

Thus two conditions must be fulfilled for the self-excitation of electromagnetic radiation in chemical reactions: negative polarisation of the nuclei, to allow energy to be stored in the Zeeman reservoir, and coherence of the nuclear spin system, to "rescue" the Zeeman energy from thermal relaxation and to stimulate its emission in the form of radiation. These two conditions are closely bound together: if the Zeeman energy is small, i.e. if the magnetisation vector M is small, the electromagnetic field induced by the precession of M and its coherence will both be weak, and they will be unable to compete with the transverse nuclear relaxation processes which perturb the coherence. Therefore in order to excite raser generation we need to achieve a well defined critical level of chemical nuclear polarisation (the vector M_z) corresponding to an amount of stored Zeeman energy called the generation threshold. A theoretical analysis of the self-excitation conditions and of the generation threshold is given in Section V.

IV. EXPERIMENTAL OBSERVATIONS OF RADIO-FREQUENCY GENERATION

Chemically induced radio-frequency emission was first observed in the photochemical reaction between porphyrin and quinone[2,11], and somewhat later in the thermal decomposition of benzoyl peroxide[12].

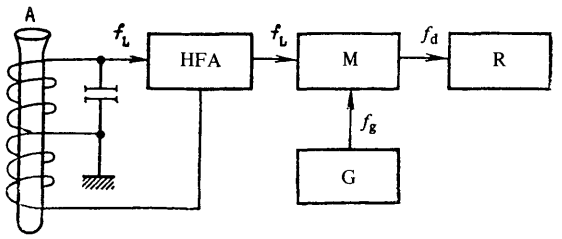

Figure 4. Block diagram of the radio circuit used to detect the chemically induced radio-frequency field: A is a tube containing the polarised reaction products, HFA is a high-frequency amplifier, M is a mixer, G is a standard generator, R is a recorder. The magnetic field H_0 is perpendicular to the coil axis[2].

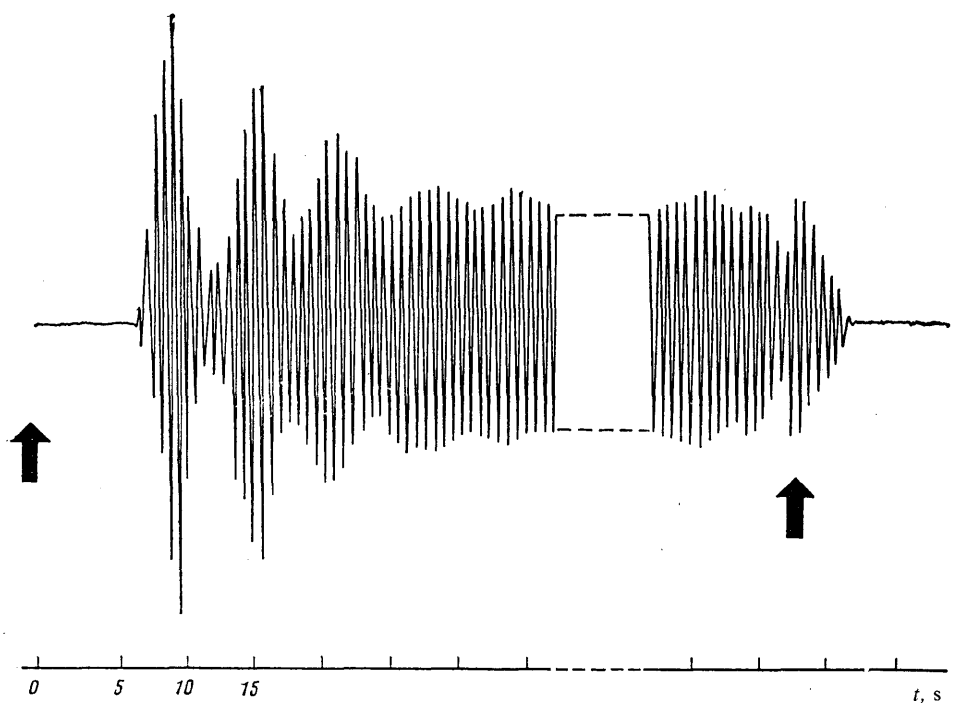

Figure 5. Chemically induced radio-frequency emission from polarised quinone molecules (signal recorded at the low frequency f_d; H_0 = const); the arrows denote the switching on and off of the light[2].

The reaction between porphyrin and *p*-benzoquinone is

$$\Pi \xrightarrow{h\nu} \Pi^*$$
$$\Pi^* + Q \xrightarrow{H^+} \Pi^{\dot{+}} + \dot{Q}H$$
$$\Pi^{\dot{+}} + \dot{Q}H \rightarrow \Pi + Q + H^+ ,$$

where Π is a porphyrin molecule (octamethyltetraphenylporphyrin), Q is the quinone, $\dot{Q}H$ is the semiquinone radical, and $\Pi^{\dot{+}}$ is the porphyrin cation radical. The ion radicals produced by the electron transfer reaction undergo disproportionation to give quinone molecules with negatively polarised protons. The result is a continuous pumping of

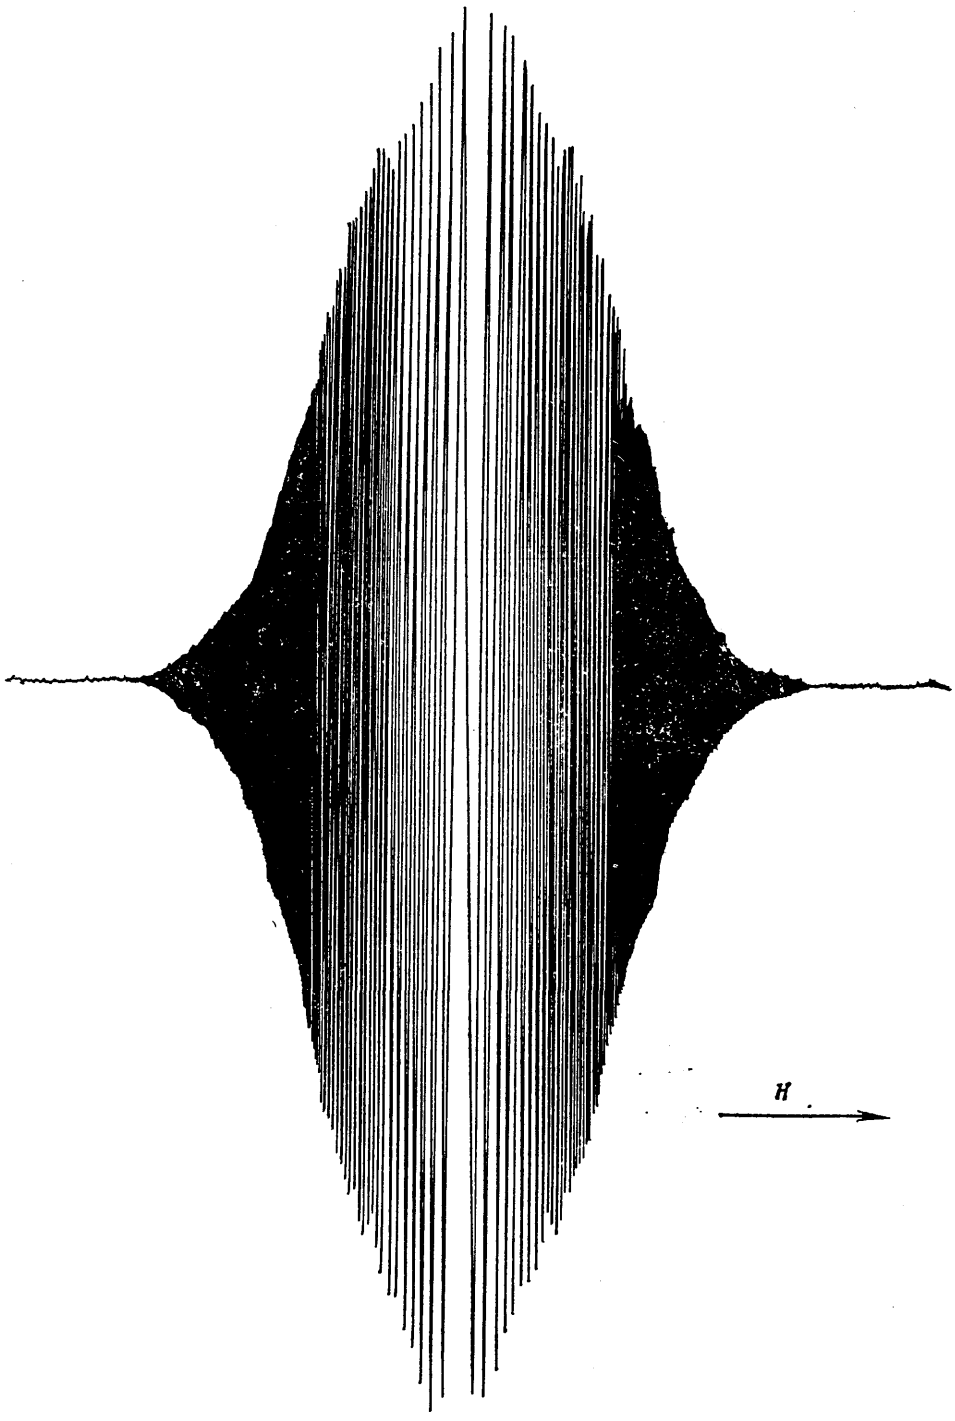

Figure 6. Chemically induced radio-frequency emission from polarised quinone molecules. Signal recorded with periodic variations in the field H_0.

the Zeeman energy reservoir of the protons in the quinone molecule, with a magnetisation vector oriented against the field H_0.

The reaction was carried out in a tube surrounded by the coil of an oscillator circuit, and initiated by light in the absorption band of the porphyrin (λ = 546 nm). The circuit was tuned to the frequency of the Larmor precession of the nuclear magnetisation vector of the quinone molecule (f_L = 100 MHz) in a field $H_0 \cong$ 24000 Oe, corresponding to an emission wavelength of 3 m. A block diagram of the radiation detection circuit is shown in Fig. 4. In order to lower the generation threshold the Q-factor of the oscillator circuit was increased by additional feedback from the high-frequency amplifier. After amplification of the signal from the chemically induced radio-frequency field a low-frequency signal is obtained at the difference frequency $f_d = f_L - f_g$ (where f_g is the frequency of the reference generator), and this is amplified by a low-frequency amplifier and displayed on a recorder and an oscilloscope. The self-excitation of the precession was additionally monitored at the high frequency f_L by an h.f. oscilloscope connected to the output of the high-frequency amplifier. A record of the chemically induced signal is shown in Fig. 5. Generation begins 5–10 s after the admission of light and the onset of the reaction, i.e. when the system reaches the generation threshold. After this short initial transient a steady-state regime is established: this regime can be maintained for a long time, because the reaction is almost ideally reversible. The radio-frequency generation stops when the light is switched off and the reaction comes to an end. The generation process can be repeated several times with the same sample by switching the photochemical pumping system on and off.

Fig. 6 shows a record of the radio-frequency generation obtained by slowly varying the field H_0 (by 10^{-3} Oe) with the recorder carriage connected to the field scan. Changes in field strength produce a change in the generation frequency f_L, and hence in the detected difference frequency f_d. Thus $f_d = 0$ at the centre of each bundle of signals, where the Larmor precession frequency coincides with that of the reference generator f_g, and f_d increases towards the edges of the bundle. This behaviour of f_d shows unequivocally that the signal is due to chemically induced radiation.

In another series of experiments[11] the radio-frequency field was detected in a crossed coil system (Fig. 7). The auxiliary coils are connected to the output of the high-frequency amplifier, and the generation signal is connected to the input of the same amplifier. As in the previous experiment, $H_0 \cong$ 24000 Oe, and the precession frequency is 100 MHz.

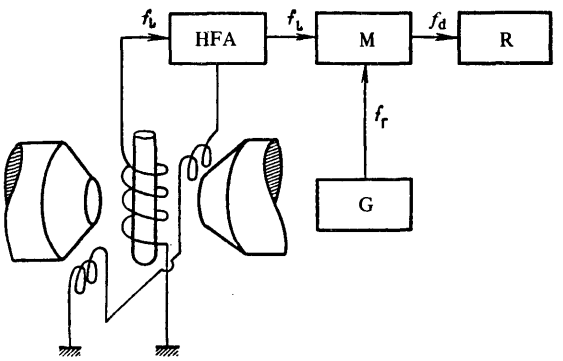

Figure 7. Block diagram of the apparatus used to detect the chemically induced radio-frequency field with crossed coils: HFA is a high-frequency amplifier, M is a mixer, G is a standard generator, R is a recorder[12].

The generation signals detected in this way from the photochemical reaction between porphyrin and quinone are shown in Fig. 8. The signals were recorded by amplitude detection with a constant field H_0. In this case steady-state generation is not established after the initial transient, and the emission consists of regularly spaced short bursts of radiation. In this regime the reaction system behaves like a radio-frequency "chemical pulsar".

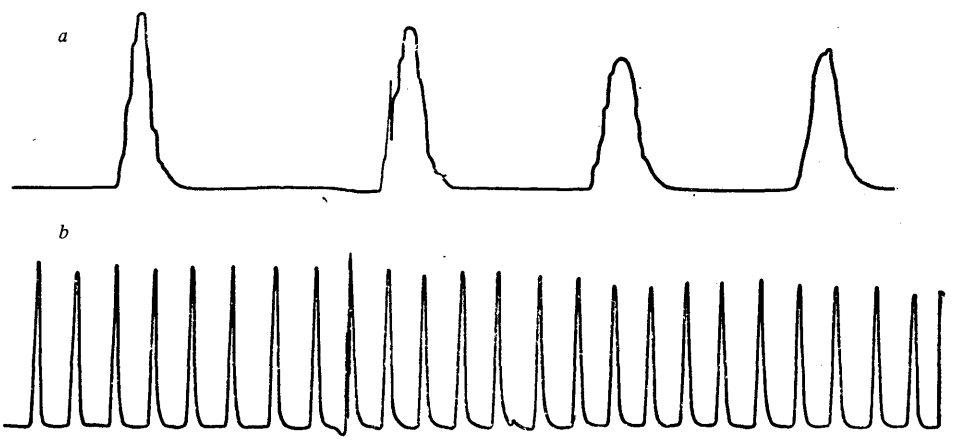

Figure 8. Chemically induced radio-frequency emission from quinone molecules in a constant field H_0 ("chemical pulsar" regime): *a*) duration of record 50 s, *b*) duration of record 250 s.[12]

The strength of the r.f. fields generated by the reaction products has been measured in experiments on the self-excitation of the precession of the total nuclear magnetisation vector **M** in a rotating system of coordinates[12], involving a non-resonant magnetic field H_1 rotating in a plane perpendicular to the constant field $\mathbf{H}_0$. The r.f. field was generated in the negatively polarised protons of the benzene molecules produced by the thermal decomposition of benzoyl peroxide in cyclohexanone (120 °C, peroxide concentration 0.5 M). The reaction involves free-radical steps, and is accompanied by strong negative polarisation of the benzene protons. From the CPN kinetics the effective rate constant of the reaction

$$(PhCO_2)_2 \xrightarrow{k} C_6H_6 \ ,$$

was determined ($k = 2 \times 10^{-2}$ s^{-1}), for which the polarisation coefficient is $P = -400$. Under these conditions the negative polarisation of the protons is retained for 3–4 min after the onset of the reaction. In these experiments the e.m.f. produced in the coil was measured: it was found to be ~2 μV, corresponding to a magnetic component of the electromagnetic field generated by the reaction of ~1.6×10^{-7} Oe. From this we can estimate the emission temperature as $T_{em} \cong 10^{28}$–10^{29} K, so that the energy of the non-equilibrium emission from the reaction is 25–27 orders higher than the energy of the equilibrium (Boltzmann) radio-frequency emission. In comparison we note that the energy of the radio-frequency radiation from one of the best known cosmic emitters (the OH radical maser) is only ~10^{13} K, i.e. the chemical radio-frequency generators are "brighter" than their cosmic analogues. However, the absolute efficiency of the chemical generator is negligibly small, because the heat capacity of the spin systems is low and only a very small fraction of the energy of the chemical reaction can be accomodated in the Zeeman reservoir.

V. THEORY OF THE CHEMICAL RASER

We have based a theoretical analysis[13] of the chemical radio-frequency generator on the standard Bloch equations which describe the behaviour of the nuclear magnetisation vector[14]:

$$\begin{aligned}
\frac{dM_x}{dt} &= \omega M_y - \gamma_n M_z H_y - 2\pi\Delta f M_x \\
\frac{dM_y}{dt} &= -\omega M_x + \gamma_n M_z H_x - 2\pi\Delta f M_y \\
\frac{dM_z}{dt} &= \gamma_n (M_x H_y - M_y H_x) - \frac{M_z - M_0}{T_1} + P\frac{dM_0}{dt} \ ,
\end{aligned} \qquad (5)$$

where M_x, M_y, and M_z are the components of the magnetisation vector, M_0 is the equilibrium magnetisation, H_x and H_y are the components of the variable magnetic field generated in the coil by the chemical reaction products, T_1 is the spin–lattice relaxation time of the nuclei, Δf is the half-width of the NMR line at half height, and γ_n is the gyromagnetic ratio for the nuclei of interest. Eqns.(5) differ from the conventional Bloch equations only in the term $P(dM_0/dt)$, which characterises the rate of generation of nuclear magnetisation by the reaction, i.e. the rate of chemical pumping.

The self-excitation threshold for the precession of the chemically induced nuclear magnetisation vector is defined by the condition

$$|M_z| > \Delta f/\gamma_n \eta q, \qquad (6)$$

where η is the filling coefficient of the coil and q is the Q-factor of the circuit. Of course, the parameter M_z should be negative. If the condition (6) is obeyed we expect self-excitation of the precession of the vector **M** (Fig.3). Under these conditions we observe a transverse component of the magnetisation, $M_\perp = (M_x^2 + M_y^2)^{1/2}$, whose value increases exponentially, and a high-frequency e.m.f. is induced in the coil. Its amplitude is given by

$$u = (4\pi/c)\, q w s \eta \omega_L M_\perp \ ,$$

where w is the number of turns in the coil, s is its cross-sectional area, and c is the velocity of light.

For unimolecular reactions of the type of A → B, with a rate constant k and polarisation coefficient P, the self-excitation condition becomes

$$\frac{(1 - PkT_1)^{1/(1-kT_1)}}{(1-P)^{kT_1/(1-kT_1)}} > 1 + \frac{\Delta f}{\gamma_n \eta q M_0} \ , \qquad (7)$$

where some of the quantities (P, k, M_0) are "chemical" parameters, others (Δf, η, T_1, q) are radiophysical.

The generation dynamics are illustrated in Fig.9: they were obtained by solving the system (5) on an analog computer. In the case of pulsed chemical pumping the generation consists of a single signal (Fig.9*a*): the parameter M_z quickly reaches the generation threshold, and then the transverse component $M_\perp$ appears. The relationship between M_z and $M_\perp$ (the phase diagram of the nuclear magnetisation) consists of a single loop (see insert in Fig.9*a*). In this case the chemical pumping pulse is accompanied by a single generation pulse.

With strong and sustained chemical pumping the radio-frequency emission takes the form of a regular series of pulses (Fig.9*b*). During the intervals between the pulses the chemical reaction in the system continues to create magnetisation, which reaches the generation threshold after some time. The phase diagram consists of many superimposed loops. This generation regime was demonstrated in Fig.8 (the chemical "pulsar"). If the rate of chemical pumping is lowered the pulse regime may change into continuous steady-state generation (see experiment in Fig.5).

In decaying reactions, i.e. with damped chemical pumping, we observe a smooth transition from one generation regime to the other (Fig.9*c*): the pulsed generation regime changes to continuous generation, which in turn decays as the chemical reaction comes to an end. Depending on the kinetics of the chemical reaction, i.e. on the kinetics of the chemical pumping of the Zeeman reservoir, different generation regimes can be established. Several of these have been demonstrated experimentally (see Section IV).

We have so far discussed only the radiation generated in a reacting system located in the coil of a tuned oscillator circuit. However, excitation of a chemically induced radio-frequency field is possible, in principle, even in the absence of special resonance circuits, i.e. in "free" space. The conditions for excitation of this type have been studied[15], and the generation threshold was found to be determined by the condition

$$|M_z| v = \frac{3c^3}{2\gamma_n T_2 \omega_L^3} \ , \qquad (8)$$

where ν is the volume of the sample containing the polarised reaction products, and T_2 is the characteristic time for the "disruption" of the coherence. From formula (8) we can obtain the minimum volume ν_{min} of reaction products with the maximum nuclear polarisation coefficient consistent with self-excitation of the precession in free space. For a concentration of polarised protons $N = 10^{-2}$ mole litre^{-1}, $T_2 = 10$ s, and $f_L = \omega/2\pi = 100$ MHz, we find that $\nu_{min} \cong 10$ litre. If we increase the frequency, ν_{min} decreases as ω_L^{-3}.

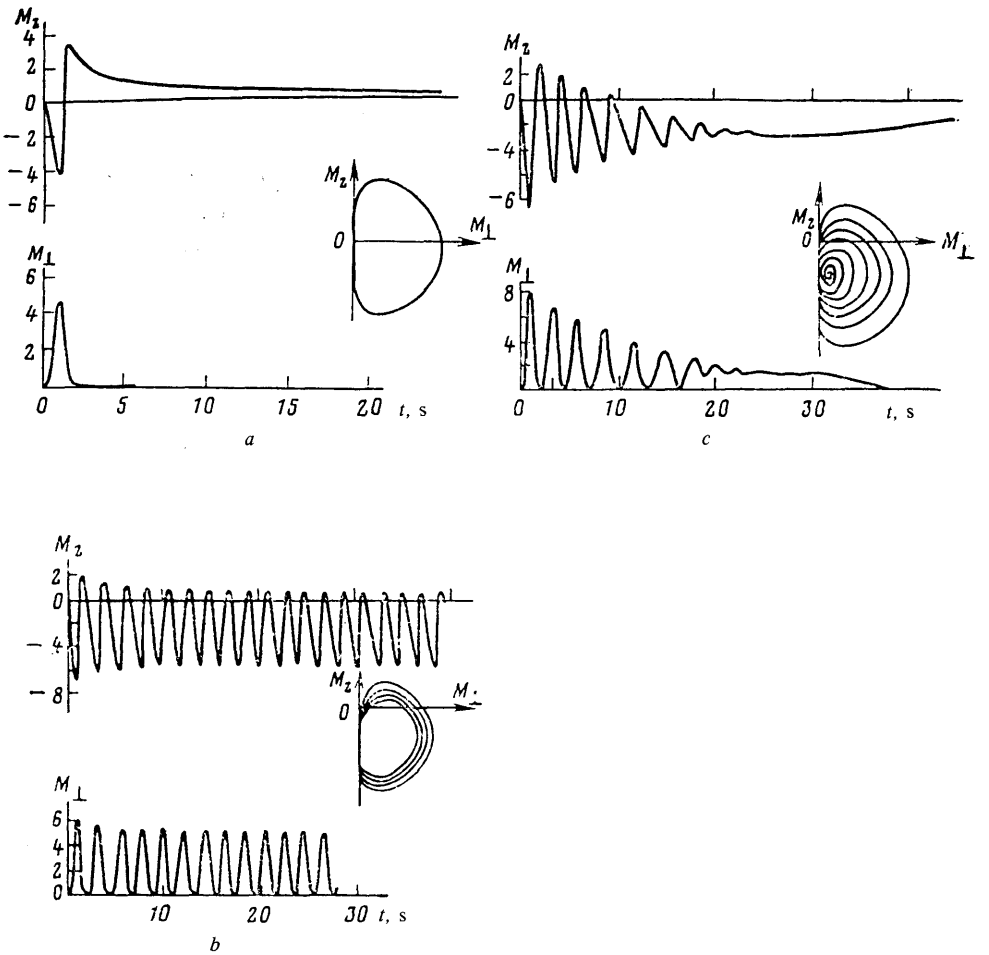

Figure 9. Radio-frequency generation dynamics of the chemical raser: *a*) for a fast reaction, *b*) for a reversible photochemical reaction, *c*) for a slow unimolecular reaction. In each case the "phase diagram" of the nuclear magnetisation in $M_\perp$, M_z coordinates is shown as an insert. The intensity of radio emission is proportional to $M_\perp^2$.[13]

Throughout this review we have dealt with the radio-frequency emission generated by the precessing total magnetic dipole of chemically polarised nuclei. The electromagnetic field of this type of dipole can be arbitrarily divided into three components[16]: the short-range field, decreasing as R^{-3} (where R is the distance from the source); the intermediate range field, decreasing as R^{-2}; the long-range field, decreasing as R^{-1}. In all the experiments discussed above the short-range region was detected. The electromagnetic field in the long-range region (which is often assumed to be the relevant region in discussion of radio emission) has not so far been experimentally explored because its strength is very low. However, in principle this field can be observed by using extremely sensitive instruments (similar to those employed in radio astronomy).

VI. CHEMICAL "RADIO RECEIVER"

We have shown that a chemical reaction can generate r.f. radiation. It is therefore legitimate to ask whether, conversely, r.f. radiation can affect chemical reactions, or in other words whether a chemical reaction can act as a receiver and detector of radio emission. An answer in the affirmative is suggested by the known effect of a radio-frequency field on the spin systems of reacting species, which can alter the rate of a chemical reaction or the yield of products by allowing previously spin-forbidden transitions. Several experimental realisations of this type of "chemical" radio receiver have been described.

A clear example is the effect of an electromagnetic field on reactions involving paramagnetic species (radicals and triplet excitons) in solids[17-20]. Using this phenomenon

(i.e. the sensitivity of the elementary acts of chemical reactions to an external electromagnetic field) the authors[17–20] have developed a new radio-spectroscopic method of detecting paramagnetic intermediates in reactions, which they have called RYDMR (Reaction Yield Detected Magnetic Resonance).

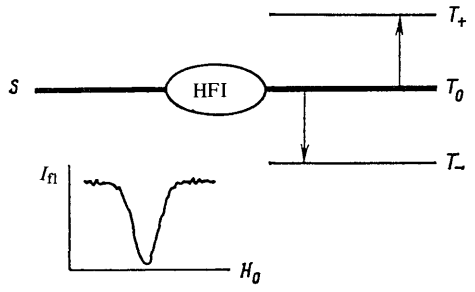

Figure 10. Principle of detection by the RYDMR spectrum, recorded for the fluorescence of the molecules formed in ion-radical recombination reactions. The hyperfine interaction (HFI) induces singlet–triplet transitions, and the external electromagnetic field at the ESR frequency induces a "loss" of radical pairs to the T_+ and T_- states. The result is an increased yield of triplet molecules, a decreased yield of singlet (fluorescing) molecules, and a decrease in the fluorescence intensity. The vertical arrows denote the transitions between T_0 and $T_\pm$ levels at the ESR frequency.

The basic idea of the method is shown in Fig.10. Assume that the interaction between two radicals (the cation M^+ and the anion M^-) takes place by electron transfer:

$$M^{\cdot+} + M^{\cdot-} \rightarrow (M^{\cdot+}M^{\cdot-}) \rightarrow M^* + M \ ,$$

so that one of the molecules (M*) is formed in an excited state. If the electron transfer occurs in a singlet ion-radical pair the excited M* molecule will be in a singlet (S) state, and it will fluoresce. In the ion-radical pair ($M^{\cdot+}M^{\cdot-}$) the hyperfine electron–nucleus interaction (HFI) induces singlet–triplet conversion of the pair into the T_0 state (see Fig.10), from which a triplet (non-fluorescing) M* molecule is obtained. The S–T_0 transitions are reversible, with characteristic times of 10^{-8}–10^{-10} s. If the ion-radical pair experiences a variable field which induces resonant transitions from the T_0 to the T_+ and T_- states, the decrease in the number of pairs in the T_0 state produces an increased "loss" of singlet pairs. The yield of singlet M* molecules falls, and the yield of triplets increases. The frequency of the field which produces a change in the relative yield of singlet and triplet product molecules corresponds to ESR transitions in the radical pair, and therefore the dependence of the intensity of fluorescence on the magnetic field H_0 can be used to detect the ESR spectrum of the ion-radical pair (optical detection of ESR). The decrease in fluorescence associated with the decreased number of singlet pairs occurs at resonance values of the steady magnetic field, for which the splitting of the levels (T_0–$T_\pm$) corresponds to the frequency of the oscillating field.

The RYDMR spectra of excited charge transfer complexes in molecular crystals were first obtained in this way[17]. In this case the external electromagnetic field affects the probability of transitions between spin states in a pair consisting of two triplets, and it alters the rate of annihilation of the triplets with formation of an excited singlet fluorescing molecule. The RYDMR spectra of the radical + triplet exciton pair have also been observed[21].

A method of obtaining the RYDMR spectra of ion-radical pairs in liquids has recently been developed[22,23], and the ESR spectra of various ion-radicals have been obtained. The RYDMR technique has been used also to investigate the nature of the ion-radical pairs formed in the primary act of photosynthesis[25].

Another application of the RYDMR technique is in the detection of the magnetic resonance spectra of short-lived pairs of paramagnetic species, and in the measurements of their lifetimes (10^{-6}–10^{-10} s). The method offers a high sensitivity, often several orders better than the sensitivity of traditional magnetic resonance methods. Thus in the RYDMR detection of ion-radical pairs in liquids by fluorescence measurements a sensitivity of 20–100 pairs in the sample has been claimed[22]. Some estimates of sensitivity are given in Ref.20: in particular, for the annihilation of a triplet pair in molecular crystals a variable field in which the amplitude of the magnetic component is $H_1 = 1$ Oe produces a change of 10^{-5} in the rate of the process. In general, in order to allow an electromagnetic field of amplitude H_1 to influence the spin state of a pair of paramagnetic particles during the lifetime τ of the pair, we must satisfy the condition

$$\gamma_e H_1 \tau \approx \pi \ , \qquad (9)$$

where γ_e is the gyromagnetic ratio of the electron. Thus for pairs with $\tau \simeq 10^{-8}$ s we need $H_1 \simeq 20$ Oe. The RYDMR effect is a consequence of the influence of an external electromagnetic field on the course of chemical reactions in a condensed phase, and it can be detected not only from changes in the yield of singlet and triplet molecules under the influence of a variable field, but also from the relative yields of recombination and dissociation products of the pairs, from photocurrents, etc.

Zhitnikov and coworkers[26–28] have shown that a resonant radio-frequency field can affect the elementary acts of chemical reactions in the gas phase (for example, the ionisation by collision of helium and alkali metal atoms). As in the previous examples this effect of the r.f. field can be explained by the presence of spin-forbidden physicochemical processes which can be controlled by varying the spin state of the interacting particles.

Consider, for example, the ionisation of helium atoms. In the ground state (1^1S_0) the helium atom is diamagnetic, since the spins of the two electrons are compensated and their orbital moment is zero. When excited (for example, by a high-frequency gas discharge) the helium atoms pass into a metastable triplet state (2^3S_1) characterised by a total electron spin $S = 1$ and a lifetime of several microseconds. The energy of the metastable state is 19.77 eV, and its ionisation potential is 4.7 eV. Under normal conditions one of the two helium atoms with triplet excitation passes into the ground state (as a result of inelastic collisions), and the other atom is ionised. This produces an electron–ion plasma, easily detected by changes in the luminescence and in the electrical conductivity of the medium. Irradiation of the sample with circularly polarised light in a magnetic field H_0 causes optical orientation of the metastable helium atoms, i.e. it favours the occupancy of one of the three Zeeman sublevels of the triplet state. Very high degrees of

polarisation can be achieved in this way, and a very large fraction of the excited helium atoms have their magnetic moments in the same orientation with respect to the field H_0.

Optical orientation is found to have a large effect on the ionisation of the atoms by the collision reaction

$$\mathrm{He}(2^3S_1) + \mathrm{He}(2^3S_1) \rightarrow \mathrm{He}(1^1S_0) + \mathrm{He}^+(1^2S_{1/2}) + e^- ,$$

where e^- denotes a free electron. The total spin of the particles formed by this reaction is 1. Therefore this reaction is forbidden by the law of spin conservation (i.e. the law of conservation of angular momentum) in the case of two colliding helium atoms with electron spins in the same direction, since their combined spin is 2. As a result of the spin requirement the polarised helium atoms can only undergo elastic collisions, which do not lead to ionisation (in spite of the energy gain offered by the ionisation process). Thus the polarisation of the helium atoms results in a decrease in the density of free electrons and helium ions. Experimentally this effect is detected as a decrease in electrical conductivity and in luminescence intensity of the electron–helium plasma following optical orientation of the atoms.

A radio-frequency field affects the collisional ionisation of helium atoms by inducing resonant transitions between the Zeeman sublevels of the triplet state, thus lessening the polarisation of the atoms. The result is an increase in the number of collisions between metastable helium atoms, whose electron spins are in different orientations and for which inelastic processes are "allowed", leading to ionisation of one of the atoms. Therefore a radio-frequency field should increase the experimentally observed electrical conductivity of an electron–helium plasma. Formally this phenomenon can be described by postulating an additional participant to the reaction, whose presence ensures equality of the total spins of the reacting and the resulting particles. The role of this additional particle (with a spin $S = 1$) is played by the quantum of the radio-frequency field, whose absorption causes reorientation of the electron spins of the metastable helium atoms.

Very interesting experiments[28] on the influence of radio-frequency fields on the collisional ionisation of optically oriented alkali metal atoms (e.g. rubidium or caesium), and of excited helium atoms, have been reported. Since the ionisation potentials of alkali metal atoms are much lower than the excitation energy of the helium atom, inelastic collisions in the gas phase usually cause ionisation of the metal atoms and deactivation of the helium atoms:

$$\mathrm{He}(2^3S_1) + \mathrm{Rb}(5^2S_{1/2}) \rightarrow \mathrm{He}(1^1S_0) + \mathrm{Rb}^+(4^1S_0) + e^- .$$

The total spin of the resulting Rb^+ ion, helium atom in the ground state, and free electron is 1/2. However, if the magnetic moments of the colliding helium and rubidium atoms have the same orientation their total spin is 3/2. Therefore if the colliding helium and rubidium atoms have parallel spins the inelastic collisions accompanied by ionisation are spin-forbidden. Collisional ionisation is possible only when the spins of the colliding atoms are pointing in opposite directions. Indeed, it is experimentally found that the concentration of free electrons and ions decreases when the helium and alkali metal atoms have the same orientation. Perturbing the polarisation of these atoms by the application of a resonant radio-frequency field increases the number of inelastic collisions and the concentration of electrons and ions, as shown by a change in the observed electrical conductivity of the plasma.

However, the effect of radio-frequency fields on the spin systems of colliding and interaction atoms is not merely to equalise the occupancies of the Zeeman and hyperfine levels: these fields also create coherence in the spin systems. As we showed in Section II, coherence implies the existence of transverse components of the total magnetisation vector, precessing at the Larmor frequency around the direction of the external field H_0. It so happens that this radio-frequency coherence has the same effect as orientation on the collisional ionisation (atom polarisation). Since the transverse components of the electron spins of the helium and rubidium atoms have different Larmor precession frequencies, they will periodically show a parallel orientation, and under these conditions their collisional ionisation is spin-forbidden, only elastic collisions are possible, and the electrical conductivity of the plasma decreases. After some time the spins of the helium and rubidium atoms are found to point in opposite directions (owing to the difference in precession frequency), collisional ionisation is no longer forbidden by the law of conservation of spin (or of its transverse component), and the electrical conductivity of the plasma increases. The two types of process (elastic and inelastic collisions) alternate at a frequency equal to the difference between the precession frequencies of the magnetic moments of the excited helium and rubidium atoms. As a result the electrical conductivity of the plasma is modulated at this difference frequency. These experiments[28] are the first demonstration of the effect of electromagnetic fields and of radio-frequency spin coherence on the elementary acts of chemical reactions.

Various examples of the influence of variable electromagnetic fields on the rate and direction of chemical reactions have been considered above. In every case the chemical reaction acts as a "receiver" of electromagnetic radiation. The physical explanation of the change in reactivity of the atoms, triplet molecules, and ions lies in the partial relief from spin restrictions given by the external radio-frequency field. Similar effects should be observed in the interaction of alternating electromagnetic fields with nuclear (as opposed to electronic) spin systems. Partial control of the rate and direction of a chemical reaction should be possible by using a radio-frequency field to modulate the nuclear spin state of the participating radicals or radical pairs.

VII. CHEMICAL RADIOPHYSICS

Chemically induced radio-frequency emission is a new phenomenon, which allows the radiophysical properties of radical reactions to be observed. These properties allow new approaches to the study of the reactions themselves, and they offer new (radiophysical) methods of detecting the radical steps. They also suggest new ways of designing technological devices such as magnetometers and masers in which the working substance is the product of a chemical reaction incorporating an inverted population of Zeeman levels.

Radio-frequency emission can be generated, in principle, in a system of negatively polarised electrons and radicals. The special features and properties of this chemically induced emission of the energy of the Zeeman electronic reservoir are discussed in Ref.16.

The self-excitation of the precession of the nuclear magnetisation vector and the development of coherence in the nuclear spin system of the reaction products are equivalent to a transition from a disordered to an ordered state, i.e. to a non-equilibrium phase transition (similar to a phase transition of the second kind). In this transition the quantity equivalent to the order parameter is the modulus of the transverse components of the precessing nuclear magnetisation vector of the reaction products. The

observations reported in Refs.2, 11, and 12 are the first examples of magnetic phase transitions caused by chemical reactions.

The discovery of chemically induced radio-frequency emission and of the effect of radio-frequency electromagnetic fields on the elementary acts of chemical reactions has laid the foundation of a new branch of science: chemical radiophysics, whose object is to study the generation and detection of radio waves at the chemical (molecular) level, to investigate the radiophysical properties of chemical reactions, and to analyse the chemical and radiophysical consequences of coherence effects in spin systems[29]. Radiophysical properties may also be found, in future, in biochemical reactions and processes.

Metal Complexes of Porphine and Azaporphine Compounds as Catalysts of Reactions Involving Oxidation by Molecular Oxygen

N.S.Enikolopyan, K.A.Bogdanova, and K.A.Askarov

The results of studies of the catalytic action of the metal complexes of porphines and azaporphines in reactions involving oxidation by molecular oxygen are surveyed. Various mechanisms of the action of the metal-porphine catalysts are analysed and a relation between the characteristics of the structures of these compounds and the spectrum of their activity is demonstrated. In terms of the problem of the preparation of new catalysts for the selective oxidation of organic compounds under mild conditions, possible ways of seeking systems in which the metal-porphines function as oxygen transferring agents are outlined.
The bibliography includes 161 references.

I. INTRODUCTION

Porphyrin compounds enter into the composition of many biologically important substances, including a series of oxidative enzymes such as oxidases, peroxidases, and others. The biological activity of porphyrins and their participation in a wide variety of the vital processes of living organisms have aroused much interest in these compounds[1-23]. The characteristic features of the structures of metalloporphines†, which consist of planar cyclic molecules with an extensive π-conjugation system, are responsible for their catalytic activity. In the planar molecules of metalloporphines the fifth and sixth coordination sites of the central metal ion are available for the coordination of the molecules of reactants in the reaction being catalysed and the extensive π-conjugation system facilitates a redistribution of the electron density within the reaction complex, which lowers the activation barrier to the reaction.

We believe that the problem of the modelling of the enzymtic catalytic activity of metalloporphyrins and of the formation on their bases of new catalytic systems for the oxidation of organic substrates under mild conditions, selective with respect to the reaction products, urgently requires solution at the present time. This review deals with the catalysis by metalloporphyrins of reactions involving oxidation by molecular oxygen in terms of the mechanisms of the action of the catalyst.

The studies on these lines were initiated by those of Cook[24-26] and Paquot[27-31] on metallophthalocyanines (M-Pc). Later these catalysts were investigated in other studies[32-68]. The synthesis of metallopolyphthalocyanines (M-Poly-Pc)[69,70] led to an interesting modification of phthalocyanine catalysts with a still more developed π-conjugation system and permitting the introduction of different metal ions into the same catalyst molecule. As a rule M-Poly-Pc exhibits a higher catalytic activity[37,71-80] than the corresponding monomeric analogues. The catalytic activity of metalloporphyrins (M-P) began to be studied comparatively recently[43,81-102], which is apparently due to their lower availability and lower stability compared with M-Pc.

The mechanisms of the catalysis by metalloporphines of oxidations by molecular oxygen have not as yet been finally elucidated. However, the available data show that metalloporphines can act via alternative mechanisms: via a donor mechanism in which an oxygen molecule is activated and via an acceptor mechanism in which the substrate undergoing oxidation is activated. A third mechanism, according to which metalloporphines catalyse the decomposition of the hydroperoxides present in the substrate undergoing oxidation in the form of impurities and thus initiate the free-radical chain auto-oxidation, is also discussed in the literature.

We shall consider each of these mechanisms in greater detail.

II. THE MECHANISM OF THE ACTIVATION OF OXYGEN

In the majority of systems[32-39,44,45,47,51,59-61,67,68,71,74-79,81,83,85,86,88-90,99-102] one is to some extent justified in postulating that molecular oxygen is coordinated to the metal ion of the metalloporphine and that either partial charge transfer from the catalyst to the oxygen,

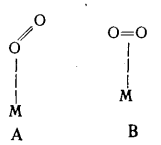
$$P\text{-}M + O_2 \rightleftharpoons P\text{-}M^{\delta+} \ldots O_2^{\delta-},$$

or the transfer of one electron,

$$P\text{-}M + O_2 \rightleftharpoons P\text{-}M^{+} \ldots O_2^{\cdot-},$$

or two electrons,

$$P\text{-}M + O_2 \rightleftharpoons P\text{-}M^{2+} \ldots O_2^{2-},$$



take place with formation of a superoxo- or peroxo-complex respectively.

Although direct evidence for the presence of metalloporphine-oxygen complexes in the catalytic reaction system has not so far been obtained, there are a number of indirect indications in support of the oxygen activation mechanism. One of these is the existence of 1:1 oxygen—metalloporphine complexes established by EPR and optical spectroscopy[103-125]. Under the influence of the field of the transition metal ion,

† The metalloporphine compounds include metalloporphyrins and metallophthalocyanines. The molecular skeleton of porphyrins is based on the porphyrin ring; phthalocyanines are derivatives of azaporphine.

the energy levels of the doubly degenerate antibonding π* orbitals of the oxygen molecule are split, the electrons are located at the more stable of the two orbitals, and their spins are paired; this entails the formation of a vacant orbital, which leads to the enhancement of the electron-accepting properties of the oxygen.

Two types of addition in mononuclear complexes of the type M...O_2 are known[126]: inclined terminal addition of oxygen in which the metal atom is linked to only one of the two oxygen atoms and the M–O–O angle is approximately 120° (A) and symmetrical addition of oxygen in which the metal is coordinated to the double bond of the oxygen molecule (B):

A B

In the first case a σ-bond is formed between one of the unshared electron pairs of oxygen and the vacant d_{z^2} orbitals of the metal and in the second it is formed between the occupied bonding π orbital of the oxygen molecule and the unoccupied d_{z^2} orbital of the metal. In both cases reverse donor interaction takes place with transfer of electron density from one of the doubly occupied d_{xz} (or d_{yz}) orbitals of the metal ion to the antibonding vacant π* orbital of the oxygen molecule, the reverse donor interaction predominating over the coordination σ-bonding, since the energy of the π* level of oxygen is lower than the energy of the *d* levels of transition metals.

The electronic configuration and the geometrical structure of the oxygen complexes of metalloporphines apparently depend both on the nature of the central metal ion[127] and on the nature of the porphin ring (Table 1). It is nowadays believed that the structure of the oxygen complexes of Co(II) Co(II)-porphyrins has been established[88,104,107–110,112]. These are octahedral complexes having one unpaired electron located at the coordinated oxygen. According to X-ray diffraction data, inclined terminal addition of the oxygen molecule occurs[115].

Three versions of the electronic structure are considered for the diamagnetic P-Fe...O_2 complexes[110,115,127,128]:

(1) $Fe^{2+}...O_2^*$—the oxygen molecule is present in the singlet state;

(2) $Fe^{2+}...O_2 \leftrightarrow Fe^{4+}...O_2^{2-}$—the quasi-neutral oxygen is involved in a resonance equilibrium with the peroxide ion;

(3) $Fe^{3+}...O_2^-$—a single electron of the iron ion is transferred to the oxygen molecule and the unpaired spins of the iron and oxygen electrons are paired.

The last two structures make it possible to explain the stabilisation of the oxygen complexes of Fe-P by polar solvents.

The oxygen complexes of Mn-P and Mn-Pc are pentacoordinate compounds. The peroxide structure TPP-$Mn^{4+}...O_2^{2-}$ has been proposed[119,120] for the tetraphenylporphine complex on the basis of the set of available experimental data (EPR and optical spectroscopy) and theoretical considerations, and symmetrical addition of oxygen was postulated by analogy with the peroxide complex of titanium-octaethylporphyrin[129]. The superoxide structure Pc-$Mn^{3+}...O_2^-$ has been proposed for the manganese-phthalocyanine complex[121–123].

In the case of Cr(II)-TPP(Py) irreversible addition of oxygen takes place. Infrared spectroscopic data indicate the superoxide structure of the complex $Cr^{3+}...O_2^-$,[130] while theoretical considerations indicate the peroxide structure $Cr^{4+}...O_2^{2-}$.[127]

The oxygen complex formed in the catalytic reaction system interacts with the substrate undergoing oxidation and as a rule initiates the free radical chain oxidation, but in certain cases the oxidation proceeds via a non-chain mechanism.

Table 1. The structure of the oxygen complexes of metalloporphines.

M-P	Structure	*S*	Geometry	References
Co(II)-TPP(Py)	$Co^{3+}...O_2^-$	1/2		[88, 104, 107—110, 112, 115, 127]
Fe(II)-P	$Fe^{2+}...O_2^*$ $Fe^{2+}...O_2 \leftrightarrow Fe^{4+}...O_2^{2-}$ $Fe^{3+}...O_2^-$	0		[110, 115, 127, 128]
Mn(II)-TPP	$Mn^{4+}...O_2^{2-}$	3/2		[119, 120, 127]
Mn(II)-Pc	$Mn^{3+}...O_2^-$	—	—	[121—123]
Cr(II)-TPP(Py)	$Cr^{3+}...O^-$ $Cr^{4+}...O_2^{2-}$	1		[130, 127]

Notation: *S* = overall spin quantum number; TPP = α, α′, α″, α‴-tetraphenylporphine; Py = pyridine.

$$[M\text{-}P]^{1/2},$$

Table 2. The composition (%) of the cyclohexene autoxidation products.

Catalyst	*t*, °C	Cyclohex-1-en-3-one	Cyclohex-1-en-3-ol	Epoxycyclohexane	References

1. Initiation of the Free-Radical Chain Oxidation

The set of facts such as the inhibition of the process by radical inhibitors[39,82,86,88], products characteristic of chain autoxidation (Table 2), and kinetic data indicate the initiation by metalloporphines of the free-radical chain autoxidation in the majority of systems.

Comparison of the experimental equations for the rates of oxidation of acetaldehyde, benzaldehyde, cyclohexene, and 2,5-dihydrofuran[75,77–79,85,88],

$$-d[O_2]/dt = k[RH]^{3/2}[O_2]^{1/2}.$$

where RH is the substrate undergoing oxidation, with the theoretical equation

$$-d[O_2]/dt = k_p/(2k_t)^{1/2} \quad (1)$$

obtained on the basis of the generally accepted mechanism of

chain autoxidation,

$$RH \xrightarrow{k_i} R^{\cdot},$$
$$R^{\cdot} + O_2 \rightarrow RO_2^{\cdot},$$
$$RO_2^{\cdot} + RH \xrightarrow{k_p} ROOH + R^{\cdot},$$
$$2RO_2^{\cdot} \xrightarrow{k_t} \text{non-radical products},$$

assuming a fairly long kinetic chain and a fairly high partial oxygen pressure, leads to an expression for the rate of initiation

$$v_i = k_i[RH][O_2][M\text{-}P],$$

which makes it possible to represent the initiation stage in the following manner:

$$P\text{-}M + O_2 \overset{K_{O_2}}{\rightleftharpoons} P\text{-}M^+ \ldots O_2^-,$$
$$P\text{-}M^+ \ldots O_2^- + RH \xrightarrow{k_i'} P\text{-}M^+ \ldots O_2H^- + R^{\cdot},$$

where K_{O_2} is the equilibrium constant of the reaction involving the formation of the oxygen complex (for brevity we shall refer to it as the oxygenation constant).

Table 3. The rate constants for the overall reaction and for the autoxidation chain initiation in systems catalysed by metalloporphines.

Substrate	Catalyst	t, °C	$10^3 k_p$, litre$^{3/2}$ × mol$^{-3/2}$ × s^{-1}	$10^3 k_i$, litre^2 × mol^{-2} × s^{-1}	Refs.
DHF	Co-T(p-CH_3-P)P	30	2.22—2.50	—	[85]

* Estimated by us from the data of Ohkatsu and Tsuruta[85] and Ohkatsu et al.[78] respectively.

** Solvent—ethyl isobutyrate.

*** Benzene, in the remaining cases—ethyl acetate.

Remarks: DHF = 2,5-dihydrofuran; CH = cyclohexane; CH-diene = cyclohexadiene; Co-T(p-CH_3-P)P = cobalt-tetra(p-tolyl)porphine; the equation for the rate of oxidation of acroleine is more complex than Eqn.(1), since in this case the rate-limiting stage is the reaction of the acyl radical with oxygen (this is associated with the stabilisation of the acyl radical of acroleine as a result of conjugation with the double bond); $k_i = k_i' K_{O_2}$.

The superoxide complex initiates the autoxidation chain, abstracting the mobile oxygen from the molecule of the substrate being oxidised. It is assumed[85] that the complex $P\text{-}M^+\ldots O_3^-$ can rupture C–H bonds whose energy does not exceed 79 kcal mole^{-1}. In the oxidation of unsaturated hydrocarbons there is also the possibility of the initiation of autoxidation by the addition of the superoxide complex to the double bond:

$$P\text{-}M^+\ldots O_2^- + \rangle C{=}C\langle \rightarrow -\overset{|}{\underset{|}{C}}-\overset{|}{\underset{O-O-M^+-P}{C}}-.$$

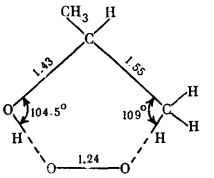
The oxidation chain propagation and termination and the regeneration of the catalyst can be represented as follows:

$$R^{\cdot} + O_2 \rightarrow RO_2^{\cdot} \text{ (chain propagation)},$$
$$RO_2^{\cdot} + RH \rightarrow R^{\cdot} + ROOH$$
$$RO_2^{\cdot} + \rangle C{=}C\langle \rightarrow -\overset{|}{\underset{OOR}{C}}-\overset{|}{C}-$$
$$2RO_2^{\cdot} \text{ —non-radical products (chain termination)},$$
$$P\text{-}M^+\ldots O_2H^- \rightarrow M\text{-}P + HO_2^{\cdot} \text{ (catalyst regeneration)}.$$

The radical nature of the superoxide complex is manifested to a large extent in the chain oxidation reaction, which is indicated by the attack by the complex $P\text{-}M^+\ldots O_2^-$ on the hydrocarbon undergoing oxidation at the sites with maximum electron density[85].

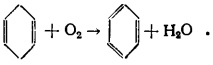
The constants for the overall reactions and chain initiation have been estimated for a number of systems (Table 3).

2. Catalysis of Non-Chain Oxidation



Data on the catalysis of non-chain oxidation by metalloporphines are of special interest for the solution of the problem of the selective oxidation of organic substrates by molecular oxygen.

The reverse donor interaction observed in the formation of an oxygen-metalloporhine complex, consisting in the transfer of electron density from one of the occupied d orbitals of the central metal ion to the antibonding vacant π^* orbital of the oxygen molecule, weakens the O–O bond, which is indicated by the increase of the distance between the oxygen atoms in the complex to 1.24–1.26 Å compared with the corresponding distance of 1.2074 Å in the free O_2 molecule[126]. The interaction with the substrate being oxidised can entail the complete rupture of the weakened O–O bond and the oxidation of the substrate either as a result of the insertion of an oxygen atom in the substrate molecule or as a result of the abstraction of hydrogen atoms from the latter[131,132].



The second mechanism has been put forward for the gas-phase oxidation of propan-2-ol and propane-2-thiol, catalysed by M-Pc (M = Cr, Mn, Fe, Ni, or Cu) at 200–400 °C:[51,59,60]

$$CH_3{-}CHOH{-}CH_3 + {}^1/_2O_2 \rightarrow CH_3{-}CO{-}CH_3 + H_2O,$$
$$2CH_3{-}CHSH{-}CH_3 + {}^1/_2O_2 \rightarrow (CH_3)_2{-}CHSSCH{-}(CH_3)_2 + H_2O.$$

The following geometrical structure of the transition complex in the reaction has been suggested for the oxidation of propanol[59] (the bond lengths are given in ångstroms):

The oxidative dehydrogenation of cyclohexadiene by atmospheric oxygen, catalysed by M-Pc (M = Fe, Co, Ni, Cu, or Zn) at 250 °C, takes place analogously[19]:

The complex salts of certain porphyrins enter into the composition of oxidative enzymes as coenzymes. The attempts to model enzymic catalytic activity were unsuccessful for a long time—only radical chain autoxidation was observed. However, reports have now appeared that in certain homogeneous liquid-phase systems metalloporphines can function as agents transferring oxygen to the substrate being oxidised.

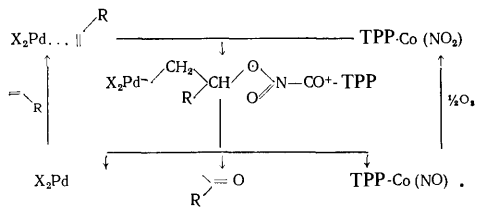
Data have been presented concerning the modelling of the functions of the monoxygenating enzyme cytochrome P.450 [81, 86,92,98] capable of catalysing the hydroxylation of saturated and aromatic hydrocarbons and the epoxidation of unsaturated hydrocarbons in the cells of living organisms. The coenzyme of cytochrome P-450, namely haemin, contains cysteine as an axial ligand. The maintenance of the enzyme in the reduced state is achieved as a result of the functioning of the microsomal respiratory chain[133].

The following modelling systems have been proposed:

(1) Iron-protoporphyrin (haemin) and an excess of thiosalicylic acid for the oxidation of cyclohexane by atmospheric oxygen in an aqueous acetone medium (the reaction products are cyclohexanol and cyclohexanone in proportions of 2 : 1); [81]

(2) TPP-MnCl and an excess of sodium tetrahydroborate for the oxidation of cyclohexane by atmospheric oxygen in a benzene-ethanol mixture (the reaction products are cyclohexanol and cyclohex-2-en-1-ol in proportions of 4 : 1); [86]

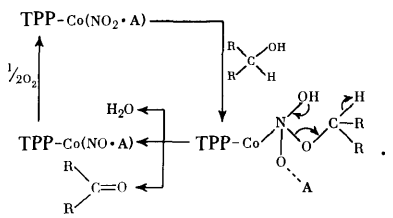
(3) TPP-MnCl–H_2–colloidal platinum in benzene with added imidazole or its derivatives for the oxidation of cyclohexene to epoxycyclohexane and cyclohex-2-en-1-one in proportions of 15 : 1 and of adamantane to adamantan-1-ol, adamantan-2-ol, and adamantan-2-one in proportions of 14.7 : 1.7 : 1; [98]



(4) haem-NAD (or NADP) for the hydroxylation of aniline in an alkaline medium (pH > 11) with formation of *p*-aminophenol[92] (NAD = nicotinamide-adenine dinucleotide; NADP = nicotinamide-adenine dinucleotide phosphate).

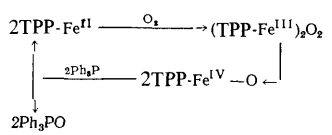
These systems contain an excess of the reducing agent, have products whose composition is characteristic of autoxidation, and are insensitive to the action of radical inhibitors.

It has been suggested[81,86] that one of the atoms of the oxygen molecule activated by the metalloporphyrin is capable of being inserted in the C–H bond on interaction with an unsaturated hydrocarbon, forming an alcohol, while in the reaction with an olefin it adds to the double bond, forming an epoxy-compound. It has been assumed[98] that the complex TPP-MnO, analogous to that observed in the M–P–iodosobenzene oxidising systems[134–141], is the hydroxylating and epoxidising species. When sodium tetrahydroborate is used as the reductant, the primary oxidation product is epoxycyclohexane, which is reduced by the excess $NaBH_4$ is cyclohexanol.



The TPP-MnCl–$(NBu_4)BH_4$ system in solution in methylene chloride catalyses the selective oxidation of olefins (cyclooctene, styrene, oct-1-ene, and phenylprop-1-ene) to the corresponding ketones, which are partly reduced by the excess $(NBu_4)BH_4$ to alcohols[98]. The products of the oxidation of cyclohexene are cyclohexanol and cyclohex-2-en-1-ol in proportions of 2 : 1.

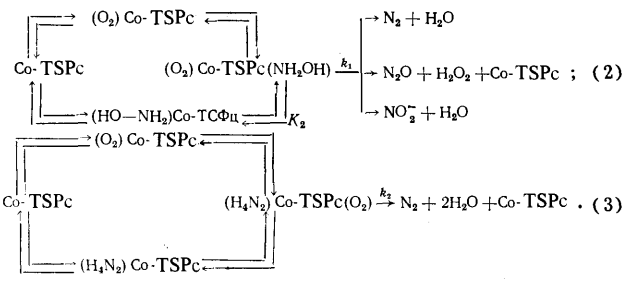
Nitro- and nitroso-complexes of Co-TPP, namely (Py)Co-TPP(NO_2) and Co-TPP(NO), were used as oxygen transferring agents in a new catalytic system proposed for the selective oxidation of olefins: ethylene and propene were oxidised to acetaldehyde and acetone respectively[87]. The nitro-complex can be formally regarded as a species containing the monoanionic ligand $Co^+...NO_2^-$, capable of functioning as a weak nucleophile. In order to activate the olefin undergoing oxidation with respect to nucleophilic attack, it was coordinated to bivalent palladium. One of the oxygen atoms in the NO_2 ligand is then apparently transferred to the olefin and the resulting nitroso-ligand is oxidised by the oxygen supplied to the system in accordance with the scheme



where X is the palladium counterion.

In the presence of Lewis acids [$BF_3.(C_2H_5)_2O$; $LiPF_6$], the complexes (Py)Co-TPP(NO_2) and Co-TPP(NO) also catalyse the selective oxidation of primary and secondary alcohols: benzyl alcohol and cycloheptanol are oxidised to an aldehyde and a ketone respectively[97]. It has been suggested that the Lewis acid (A) is coordinated to the oxygen of the nitro-group, increasing its electrophilicity. The oxidation can proceed via the formation of an ether-like intermediate which decomposes via a non-radical mechanism into a carbonyl product, water, and a nitroso-complex of Co-TPP:

Yet another pathway leading to the activation of oxygen is observed in the oxidation of triphenylphosphine catalysed by Fe-TPP in solution in toluene at 25 °C.[91] In the presence of molecular oxygen Fe-TPP is oxidised to the bridged peroxo-dimer $(TPP\text{-}Fe)_2O_2$, the first stage of the spontaneous decomposition of which involves the formation of the oxo-complex TPP-Fe^{II}–O. This complex is in fact the agent transferring oxygen to the Ph_3P molecule:

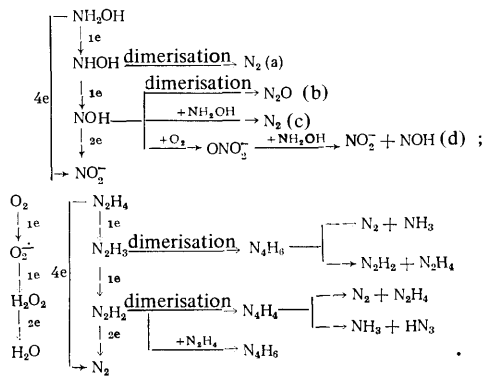


However, the oxo-complex also reacts with $(TPP\text{-}Fe)_2)_2$ and TPP-Fe...O_2:

$$TPP\text{-}Fe^{IV}\text{—}O + (TPP\text{-}Fe)_2O_2 \rightarrow (TPP\text{-}Fe)_2O + TPP\text{-}Fe...O_2 ,$$
$$TPP\text{-}Fe^{IV}\text{—}O + TPP\text{-}Fe...O_2 \rightarrow (TPP\text{-}Fe)_2O + O_2 ,$$

which leads to the deactivation of the catalyst and the cessation of the reaction; in the inactive reaction system the porphyrin compound is present only in the form of the bridged oxo-dimer. A conclusion concerning the mechanism of the oxidation of Ph_3P was reached on the basis of the analysis of the kinetics of the spontaneous decomposition of $(TPP\text{-}Fe)_2O_2$ and its reduction by Ph_3P.

The oxidation of hydroxylamine and hydrazine, catalysed by cobalt-tetrasulphophthalocyanine (Co-TSPc) in an alkaline medium, proceeds, according to Wagnerova et al.[67,68], within the coordination sphere of the ternary complex of Co-TSPc with O_2 in the substrate formed in the first stage of the



reaction:

This is supported by a series of facts. In an alkaline medium Co-TSPc forms a 1:1 complex with N_2H_4. The addition of hydrazine to the oxygen complex of Co-TSPc, which has two absorption bands at 626 and 670 nm, leads to their disappearance and the appearance of new bands at 450 and 680 nm. Subsequent passage of oxygen restores the initial spectrum.

The change of the reaction order with respect to N_2H_4, NH_2OH, and O_2 from 1 to 0 with increase of the reactant concentration also shows that N_2H_4, NH_2OH, and O_2 react in the coordinated state and the theoretical rate equations, derived for mechanisms (2) and (3), agree with the experimental equations. The constants $k_1 = 25\ s^{-1}$ and $k_2 = 2.0 \times 10^3$ have been estimated for hydroxylamine.

Analysis of the products of the oxidation of NH_2OH and N_2H_4 shows that the process takes place within the coordination sphere of the complex without the release of free radicals into space. The states in the successive oxidation of substrates and the reduction of oxygen are presented below together with their possible subsequent reactions, regardless of whether they are free radicals or enter into the composition of the complex:

If after the transfer of one or two electrons the radicals formed pass into space, then the NH_2OH oxidation products should contain more of the radical dimerisation products, in particular N_2O, and, as a result of the competing reaction (c), the relative NO_2^- content should increase or remain unchanged with increase of the initial NH_2OH concentration. In reality, the main NH_2OH oxidation product is NO_2^- (60%) and the amount of N_2O formed is very small. Furthermore, an increase of the initial NH_2OH concentration leads to a decrease of the relative content of NO_2^- in the products. All these findings support electron transfer within the complex. Molecular nitrogen is formed[68] when the complex Co-TSPc.(NOH) interacts with NH_2OH:

$$\text{Co-TSPc(NOH)} + NH_2OH \rightarrow N_2 + 2H_2O + \text{Co-TSPc} \quad .$$

Similarly the presence of only traces of ammonia, the radical recombination product, in the hydrazine oxidation products also indicates an intracoordination mechanism of electron transfer.

The electron transfer from the substrate to oxygen probably proceeds via the central cobalt ion with participation of the π-electron system of the phthalocyanine ring and the process can proceed in more than one stage.

Despite the fundamental similarity of the mechanisms of the oxidation of NH_2OH and N_2H_4 in the presence of Co-TSPc, the detailed electron transfer mechanisms are apparently different. Thus the amount of hydrogen peroxide formed in the oxidation of hydrazine increases in the course of the reaction, which can be explained by assuming that the oxidation proceeds in two stages, i.e. that oxygen displaces H_2O_2 from the intermediate ternary complex:

$$\text{(O}_2\text{) Co-TSPc(N}_2\text{H}_4\text{)} \rightarrow \text{(H}_2\text{O}_2\text{) Co-TSPc(N}_2\text{H}_2\text{)} \rightarrow$$
$$\xrightarrow{O_2} \text{(O}_2\text{) Co-TSPc(N}_2\text{H}_2\text{)} \rightarrow H_2O_2 + N_2 + \text{Co-TSPc} \quad .$$

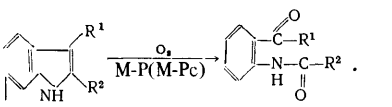
According to our data[99-101], the oxidation catalysed by metalloporphyrins in an aqueous medium involves the generation of a free superoxide radical-anion. One can put forward two possible mechanisms:

(1) dissociation of the oxygen complex of the metalloporphyrin with formation of O_2^-:

$$\text{P-M}^+ \ldots O_2^- \rightleftarrows \text{P-M}^+ + O_2^- \quad ;$$

(2) electron transfer from the substrate S undergoing oxidation to oxygen within the coordination sphere of the ternary complex of M-P with O_2 and S:

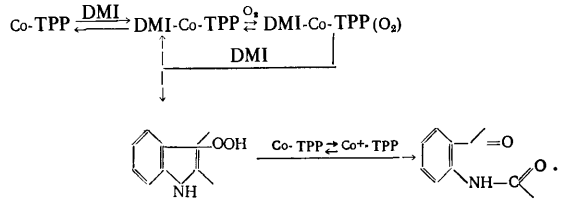
$$\text{S}\ldots\text{M-P}\ldots O_2 \rightarrow \text{M-P} + S^+ + O_2^- \quad .$$



The first reaction involves the formation of the oxidised form of the catalyst and the completion of the catalytic cycle requires a catalyst regeneration stage via the interaction with the substrate or with one of the intermediate products of the reaction.

A typical example of the process with a "superoxide" mechanism is the oxidation of adrenalin in an aqueous medium, catalysed by porphyrin complexes of cobalt: Co-α, α', α'', α'''-tetra(*p*-sulphophenyl)porphine and Co-mesoporphyrin[99,100]. The oxidation process is inhibited by superoxide dismutase and is not catalysed by metal-free porphyrins. The kinetic data indicate the operation of the first mechanism in this system and the catalyst is regenerated via the reaction with the peroxide ion O_2^{2-}:

$$\text{Co}^+\text{-P} + O_2^{2-} \rightarrow \text{Co-P} + O_2^- \quad .$$



The coordination of the substrate to the metalloporphyrin is not essential in all cases. This is indicated by the catalysis of the oxidation of the Fe^{2+} ion (a substrate which cannot behave as an axial ligand) by cobalt-porphyrin to Fe^{3+}.[102]

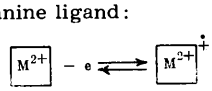
The dimethyl ether of metalloprotoporphyrin TPP-M (M = Co, Cu, or Ni) in solution in methylene chloride[83,95] and Mn-Pc in solution in dimethylformamide (DMF)[142] catalyse the dioxygenation of alkyl derivatives of indole with formation of the corresponding ketoamides:

The formation of a ternary complex of the catalyst with O_2 and indole is indicated by the results of ultraviolet spectroscopic and EPR studies. In the case of Mn-Pc, it has been suggested[142] that one such complex of an indole derivative interacts with the oxygen of another complex—the reaction is of second order with respect to Mn-Pc. In the case of

Co-TPP it is believed[95] that the interaction of the ternary complex with a dimethyl indole (DMI) molecule results in the formation of 2,3-dimethylindolyl hydroperoxide—its presence in the reaction system has been demonstrated by NMR. The next reaction stage involves the decomposition of the hydroperoxide, which is also catalysed by Co-TPP:

It must be emphasised that the study of the non-chain oxidation processes in the presence of metalloporphines is of great interest from the standpoint of the understanding of the mechanisms of the operation in biological systems of oxidative enzymes containing porphyrin structures. Another important aspect of these investigations is the creation of new catalytic systems for the selective non-chain oxidation of organic compounds by molecular oxygen under mild conditions. We believe that investigations where the reaction is carried out in the presence of a suitable reductant capable of regenerating the catalyst in the course of the reaction and which involve, together with the activation of molecular oxygen on the metalloporphine, the additional activation of the substrate being oxidised with respect to nucleophilic attack by its coordination to a suitable complex-forming agent are the most promising. Bimetallic porphine systems containing electron-donating and electron-accepting active centres may prove to be effective for the simultaneous activation of oxygen and the substrate being oxidised.

3. The Influence of Various Factors on the Catalytic Activity of Metalloporphines



It is of interest to compare the influences of various factors—the nature of the metal, the porphine ring, and the trans-ligand —on the catalytic activities of metalloporphine compounds and on their oxygen affinity (K_{O_2}) in systems involving the oxygen activation mechanism. When oxygen complexes are formed by metalloporphines, electron density is transferred to the oxygen molecule and the oxidation potential of the latter can be conveniently selected as the parameter characterising the influence of the above factors on the properties of M-P.

(a) *The nature of the metal.* Table 4 shows that the lower the oxidation potential of the metalloporphine M-P, the higher its oxygenation constant K_{O_2}. Mn-TPP, for which K_{O_2} is smaller by several orders of magnitude than might have been expected on the basis of the potential, is an exception. This may be associated either with the fact that the oxygen complex of Mn-TPP has a peroxide structure, in contrast to the superoxide complexes of other metalloporphyrins M-P or with the fact that the complex Mn-TPP(O_2) is tetrahedral, while the complexes of other metalloporphyrins M-P are octahedral (it has been shown for Co-porphyrins that the electron-donating *trans*-ligands greatly accelerate the oxygenation[109]).

We shall follow the influence of the nature of the metal on the catalytic activity of metalloporphines in various systems. In the oxidative dehydrogenation of cyclohexadiene by atmospheric oxygen at 250 °C, a clear-cut correlation can be traced between the oxidation potentials of the metallophthalocyanines M-Pc and their activity (Fig.1). For the series of metals Fe, Co, Ni, Cu, and Zn, the oxidation potentials of Mn-Pc as well as M-TPP (Table 5) have a maximum at the point corresponding to Ni, which is associated with the change in the oxidation mechanism. The iron and cobalt complexes are oxidised via the central metal ion:

and the copper and zinc complexes are oxidised via the porphyrin or phthalocyanine ligand:

(The rectangle denotes a π-electron porphine system).

Table 4. The oxidation potentials $E_{1/2}$ of the metalloporphyrin complexes[143] and their oxygenation constants at −78 °C.[115]

Complex		$\lg K_{O_2}$	$E_{1/2}$, V
Co-TPP(Py)	(in toluene)	−1.7	+0.13
Co-T(p-OCH_3-P)P(N-CH_3-Im	(in toluene)	−0.8	+0.11
Fe-T(piv-P)P(N-CH_3-Im)	(solid)	6 4	−0.11
Mn-TPP	(in toluene)	~2.1	−0.27
Cr-TPP(Py)	(solid)	*	−0.86

* Cr-TPP(Py) combines irreversibly with O_2.

Remarks: K_{O_2} is expressed in mm^{-1}; $E_{1/2}$ is the potential measured in DMSO relative to the saturated calomel electrode; T(piv-P)P = meso-tetra(α, α', α'', α'''-*O*-pivalimidophenyl)porphine; N-CH_3-Im = *N*-methylimidazole.

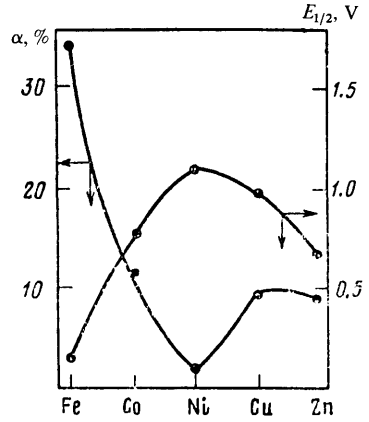


Figure 1. Dependence of the catalytic activity (α is the degree of conversion) in the oxidative dehydrogenation of cyclohexadiene by air and of the oxidation potentials $E_{1/2}$ of M-Pc on the nature of the central metal ion[19].

In the case of nickel both processes take place at the same potential.

The catalytic activity of metalloporphines varies in opposition to the oxidation potentials and is a minimum for Ni-Pc; Cu-Pc exhibits a higher catalytic activity than might have been expected on the basis of its oxidation potential. A similar anomaly has been also observed in other systems. This is apparently associated with the specific features of the interaction of copper complexes with molecular oxygen. The nature of this interaction in terms of the electronic structure can only be postulated, but it is striking that the most important metalloenzymes, catalysing the reduction of oxygen in biological systems, contain iron and copper.

Table 5. The first oxidation potentials of metalloporphines (OEP = octaethylporphyrin) relative to the saturated calomel electrode (in volts).

M	Electronic configuration of M	TPP (Ref.143)	TPP* (Ref. 144, 145)	OEP (Ref.143)	Pc** (Ref. 144, 145)
Cr^{2+}	d^4	−1.06 ***	—	−1.14 ****	—
Mn^{2+}	d^5	−0.23 *****	—	−0.42 ****	−0.11
Fe^{2+}	d^6	−0.19 ****	−0.32	−0.24****	+0.16
Co^{2+}	d^7	+0.32	+0.52	—	+0.77
Ni^{2+}	d^8	+1.04	+1.01	+0.73	+1.10
—	—	+0.95	+1.00	+0.81	—
Cu^{2+}	d^9	+0.90	+0.99	+0.79	+1.00

* In benzonitrile.

** In 1-chloronaphthalene.

*** In methylene chloride.

**** In DMSO.

***** In acetonitrile. In the remaining cases the solvent was butyronitrile.

Table 6. Data on the oxidation of indole derivatives in solution in methylene chloride[83,95].

Catalyst	$E_{1/2}$, V	3-Methylindole		2,3-Dimethylindole	
		τ, h	α, %	τ, h	α, %
Co-TPP	+0.32	5	70	1	50
Ni-TPP	+1.04	20	traces	20	traces
Cu-TPP	+0.90	20	50	3	40

Remarks: The values of $E_{1/2}$ in butyronitrile[143] are quoted relative to the saturated calomel electrode; τ = reaction time; α = conversion of substrate.

The activity of M-TPP in the liquid-phase oxidation reactions of indole derivatives is also correlated with the oxidation potential of the catalyst and is a minimum for Ni-TPP (Table 6). In the oxidation of adrenalin in an alkaline medium, Co-T(*p*-sulpho-P)P is also more active than Ni-T(*p*-sulpho-P)P.[99]

Co-TPP deviates (is less active) from the correlation between the catalytic activity of M-TPP in the acetaldehyde oxidation reaction (Table 7) and their oxidation potentials.

In the gas-phase oxidation of propane-2-thiol and propan-2-ol at 250–350 °C, manganese-phthalocyanine exhibits a lower activity (Table 8) than suggested by its oxidation potential. This can be associated with the oxidation of the Mn^{2+} ion at high temperatures[146]. The copper complex shows, as usual, an anomalously high activity. Ni-Pc is more active in the oxidation of propanol than might have been expected. In order to account for the activity series obtained for metallophthalocyanines, the authors resorted to the molecular orbital and ligand field theories[51,61].

(b) *The nature of the porphine ring.* It follows from Table 9 that the greater the basicity (the quantity bearing an inverse relation to pK_a) of the free porphyrin base, the lower the oxidation potential of the corresponding metalloporphyrin and the higher its oxygen affinity. Octaethylporphyrin (OEP) is an exception.

Table 7. Kinetic data for the autoxidation of acetaldehyde (0.5 M) in solution in ethyl acetate catalysed by M-TPP (5×10^{-3} M at 10 °C).[89]

Catalyst	$E_{1/2}$, V	$-10^6\, d[O_2]/dt$, mol litre^{-1} s^{-1}	$10^6\, k_i$, litre^2 × mol^{-2} s^{-1}
Mn-TPP	−0.23	3.5	11.2
Co-TPP	+0.32	2.6	6.2
Ni-TPP	+1.04	3.1	8.8
Cu-TPP	+0.90	3.4	10.6

Remarks: The potentials $E_{1/2}$ in butyronitrile[143] (in acetonitrile for Mn-TPP) are quoted relative to the saturated calomel electrode; the k_i were estimated from the data of Ohkatsu and Osa[89].

Table 8. The activation energies (kcal mole^{-1}) for the gas-phase oxidation reactions of propanol and propanethiol catalysed by M-Pc.[51,59–61]

M	Mn	Fe	Co	Ni	Cu	Zn
$E_{1/2}$, V	−0.11	+0.16	+0.77	+1.10	+1.00	+0.68
Propane-2-thiol	15—18	12—14	16—20	30	14—17	23—28
Propan-2-ol	15	10	23	14	9	—

Remarks: The potentials $E_{1/2}$ in 1-chloronaphthalene[144,145] are quoted relative to the saturated calomel electrode.

An analogous relation is observed also between the catalytic activity of metalloporphines and the basicity of the corresponding porphine bases. Thus the cobalt complex of the more basic dimethyl ether of protoporphyrin (Co-DME-proto-P) is a more active catalyst of the oxidation of indole derivatives [3-methylindole (I), 3-methoxypropionylindole (II), and 3-methoxybutyrylindole (III)] than the corresponding complex of the less basic TPP (Table 10). The catalytic activity of tetrasubstituted copper-phthalocyanines in the cumene oxidation reaction at a temperature below 100 °C increases with enhancement of the π-donor properties of the substituents: $NO_2 < C_5H_5N < H < Br < Cl$.[36]

(c) *The nature of the substituents in the phenyl groups of tetraphenylporphine.* The electron-donating and electron-accepting properties of *para*-substituents in the phenyl groups of Co-TPP have a weak influence on its oxidation potential[143] and oxygenation constant[148] (Table 11), which is apparently associated with the fact that the benzene rings

are arranged at right angles to the plane of the porphyrin nucleus and do not therefore contribute significantly to its π-conjugation system.

Table 9. The influence of the basicity of the free porphyrin base on the oxidation potential of Mn-P [146] and the oxygenation constant of Co-porphyrins (−45 °C). [147]

Porphyrin ligand	pK_a	$E_{1/2}$, V	Im	Py	Pip	N-CH_3-Im
OEP	6	—	24.5	1.41	1.78	23.4
DME-meso-P	5.8	−0.19	32.4	—	—	—
DME-deutero-P	5.5	−0.14	—	—	—	—
DME-proto-P	4.8	−0.11	14.4	14.4	4.47	20.0
T(*p*-OCH_3-P)P	>3	—	—	0.76	1.4	6.5
TPP	~3	+0.01	1.58	—	—	—

Remarks: K_a = dissociation constant of the protonated free porphyrin base: $H_3\text{-}P \rightleftarrows H^+ + H_2\text{-}P$; the potentials $E_{1/2}$ in acetonitrile are quoted relative to the standard hydrogen electrode; the values of 10^3 K_{O_2} (mm^{-1}) are quoted in the remaining columns for different axial ligands in solution in toluene; Pip = piperidine.

Table 10. Data on the oxidation of indole derivatives in solution in methylene chloride[83,95].

Substrate oxidised	Catalyst	τ, h	α, %
(I)	Co-DME-proto-P	3	80
(I)	Co-TPP	5	70
(II)	Co-DME-proto-P	20	40
(II)	Co-TPP	30	50
(III)	Co-DME-proto-P	18	40
(III)	Co-TPP	24	60

Table 11. The influence of the substitutents X in Co-T(*p*-X-P)P on $E_{1/2}$, [143] K_{O_2} at −38 °C, [148] and the catalytic activity in the acetaldehyde (0.5 M) oxidation reaction in solution in ethyl acetate at 10 °C. [89]

X	$E_{1/2}$, V	$\lg K_{O_2}$	$-10^6\, d[O_2]/dt$, mol litre^{-1} s^{-1}
OCH_3	0.33	1.65	4.2
CH_3	0.35	1.61	81.0
H	0.39	1.48	2.8
Cl	0.40	1.45	1.2

Remarks: The values of $E_{1/2}$ in butyronitrile are quoted relative to the saturated calomel electrode; K_{O_2} (for Py)Co-T(*p*-X-P)P (mm^{-1}) refers to a solution in toluene; catalyst concentration 5×10^{-3} M; $P_{O_2} = 1$ atm.

The only reaction for which the influence of the nature of the substituents in the phenyl groups of the catalyst has been studied is the oxidation of acetaldehyde in the presence of Co-T(*p*-X-P)P. [89] The tetramethyl-substituted catalyst exhibits an anomalously high activity in this system (Table 11).

At the present time the above finding cannot be explained and the lack of data for other reactions would make premature any conclusions concerning the influence of the nature of the substitutent X in M-T(*p*-X-P)P on the catalytic activity.

(d) *The nature of the trans-ligand.* A general correlation between the basicity of the axial ligand L in the complex (L)Co-P and the oxygenation constant of the latter has not been observed[105,106,109,115,147] (Fig. 2). However, for a series of structurally similar axial bases [substituted pyridines (Fig. 2) and substituted phosphines[149]], a linear relation can be traced between K_{O_2} and pK_a. The lack of a general correlation is associated with the fact that the parameter pK_a characterises only the σ-donor properties of the ligand but does not take into account its π-donor properties. However, π-donor *trans*-ligands should enhance the reverse donor interaction of (L)M-P with O_2 and hence should increase its oxygen affinity. Indeed, Fig. 2 shows that powerful π-donors such as imidazole and DMF increase the oxygenation constant.

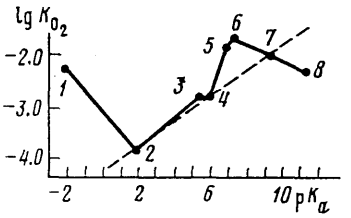

Figure 2. Relation between $\lg K_{O_2}$ (toluene, −45 °C) for (L)Co-DME-proto-P and the pK_a of the axial ligand L: [115] *1*) dimethylformamide; *2*) 4-cyanopyridine; *3*) pyridine; *4*) 4-butylpyridine; *5*) imidazole; *6*) 1-methylimidazole; *7*) 4-aminopyridine; *8*) piperidine.

Table 12. The values of K_{O_2} and the oxidation potentials of the complexes (L)Co-T(*p*-OCH_3-P)P. [147]

L	$-\lg K_{O_2}$	$E_{1/2}$, V
N-Methylimidazole	1.72	−0.48
4-Picoline	2.20	−0.23
5-Chloro-*N*-methylimidazole	2.26	−0.24
Piperidine	2.28	−0.31
3,4-Lutidine	2.35	−0.22
Pyridine	2.46	−0.20

Remarks: The values of K_{O_2} are expressed in mm^{-1} (obtained at −65 °C in toluene); the potentials $E_{1/2}$ were obtained in DMF; L = axial ligand.

In connection with the foregoing, it would apparently be more useful to compare the K_{O_2} with the oxidation potentials of the metalloporphyrins M-P having an axial ligand (Table 12). Despite the existing deviations, a general trend can be seen, namely an increase of the oxygenation constant with decrease of the oxidation potential of (L)Co-T(*p*-OCH_3-P)P.

The influence of electron-donating additives on the rate of the catalytic oxidation has been studied in a series of systems. The rate of oxidation of acetaldehyde catalysed

by Co-T(p-CH_3-P)P passes through a maximum as a function of the relative content of the additive (pyridine or DMF) corresponding to the ratio [additive]/[catalyst] = 1 (Fig. 3). It has been shown by EPR that, depending on the amount of added pyridine, a 1 : 1 or 1 : 2 Co-TPP-pyridine complex is formed. Consequently the axial base occupying the fifth coordination site in the catalyst molecule increases its catalytic activity. However, in the presence of large amounts of the additive, the latter occupies both coordination sites of the catalyst and prevents the coordination of oxygen, which lowers the rate of reaction.

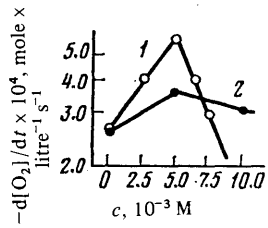

Figure 3. The influence of added pyridine (line *1*) and dimethylformamide (line *2*) on the rate of oxidation of acetaldehyde catalysed by Co-TPP in solution in ethyl acetate at 10 °C. [89]

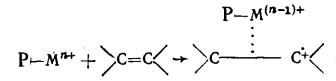


An analogous accelerating effect of basic additives (acetone, benzamide, urea, pyridine, acridine, aniline, and piperidine) has been demonstrated in the oxidation of benzaldehyde in the presence of Co-T(p-CH_3-P)P [89] and it has been shown that the higher the basicity of the additive the smaller its amount required to increase the rate of reaction.

It has been stated that catalytic amounts of pyridine have an accelerating effect in the oxidation of cumene in the presence of metallopolyphthalocyanines[74,75].

Thus analysis of data concerning the influence of various factors on the catalytic activity of metalloporphines reveals the following tendency: factors increasing the oxygenation constants of metalloporphyrins as a rule increase also their catalytic activity in oxidation reactions proceeding via an oxygen activation mechanism.

III. THE MECHANISM OF THE ACTIVATION OF THE SUBSTRATE UNDERGOING OXIDATION

In the systems examined above, metalloporphines function in accordance with a donor mechanism, transmitting electron density to the oxidant molecule. The presence of an extensive π-conjugation system in the metalloporphines, capable of stabilising different valence states of the central metal, gives rise to the possibility of the operation (under certain conditions) of an alternative mechanism of the catalysis—an acceptor mechanism characterised by partial or complete transfer of an electron from the oxidised substrate to the catalyst:

A similar mechanism has been postulated in the oxidation reactions of cyclohexene in solutions in nitrobenzene and benzene[84,93] and of squalene in solution in benzene[94] in the presence of Co(III)-OEP on the basis of the following data: firstly, the diamagnetic Co(III)-OEP cannot activate oxygen, since it does not form complexes with it, and, secondly, an EPR signal ($g = 2.0060$, $A_N = 14.33$, $a_H = 8.5$) has been detected in the Co(III)-OEP-cyclohexene system by the "spin trapping" method using nitrosodurene, which the authors[84] attributed to the cyclohexene radical-cation. We may add that there are indications in the literature of the formation of complexes by metalloporphines with unsaturated hydrocarbons[19,38,50] and, as shown in relation to the cyclohexa-1,4-diene-Co-Pc system, the complex formation equilibrium constant ($K_{cyclohexadiene}$) increases after the introduction of electron-accepting substituents into the phthalocyanine ring[19] (Table 13).

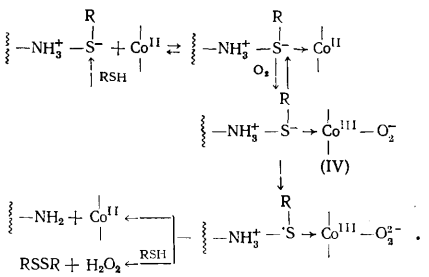
Table 13. The catalytic activity of substituted Co-Pc in the cyclohexa-1,4-diene-nitrobenzene system at 240 °C and the equilibrium constants (litre mol^{-1}) for the complex formation reactions between the catalyst and reactants[151].

Catalyst	α, %	K_{TNB}	$K_{CH\text{-}diene}$
Co-Pc	14	586	2.1
Co-Pc(F)$_4$	5	36	8.5
Co-Pc(F)$_{16}$	71	0.295	45

Notation: α = yield of benzene; K_{TNB} and $K_{CH\text{-}diene}$ are the equilibrium constants for the complex formation reactions of the catalyst with trinitrobenzene and cyclohexadiene respectively.

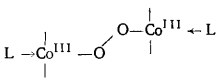
An acceptor mechanism of the catalysis has also been demonstrated for the oxidation reactions of thiols in an alkaline medium[52–58,62–66]. The catalysis of these reactions[54,57,58] consists of the coordination of the RS^- anion to M–Pc, the alternate reduction of M(II)-Pc by the thiol and the oxidation of the resulting M(I)-Pc by oxygen:

$$RSH + OH^- \rightarrow RS^- + H_2O ,$$
$$M(II)\text{-}Pc + RS^- \rightarrow M(I)\text{-}Pc + RS^{\cdot} ,$$
$$4M(I)\text{-}Pc + O_2 + 4H^+ \rightarrow 4M(II)\text{-}Pc + 2H_2O ,$$
$$2RS^{\cdot} \rightarrow RSSR .$$



It has been shown by spectroscopy in the visible region[54] that in a phosphate buffer (pH 8.5–10.0) cysteine reduces the tetrasodium salt of cobalt(II)-4,4,4,4-tetrasulphophthalocyanine [Co(II)-Pc(SO_3Na)$_4$] to Co(I)-Pc(SO_3Na)$_4$. Subsequent introduction of oxygen into the system leads to a spectrum similar to that of Co(II)-Pc(SO_3Na)$_4$ when the reaction product is cysteine. Apparently Co(II)-Pc(SO_3Na)$_4$ forms a complex with cysteine.

The rate of oxidation of thiols usually depends on the M-Pc and O_2 concentrations but is independent of the thiol concentration[58], which shows that the thiolate anion reacts in the coordinated state. However, according to Kundo et al.[53], the rate of oxidation of cysteine is proportional to the cysteine and catalyst concentrations. Such conflicting data may be due to the difference between the ratios of the concentrations of the reactants used in different studies.



The coordination of the RS^- anion to the M-Pc during the reaction is also indicated by the decrease of the rate (up to the cessation of the reaction) caused by the addition of a strong complex-forming agent (the cyanide ion) in the oxidation of cysteine[57] and ethanethiol[58].

Effective catalysts have been proposed recently for the oxidation of thiols, the catalysts containing oxidation centres and basic groups involved in a cooperative interaction[62-66]. Such bifunctional catalysts consist of Co(II)-Pc(SO_3Na)$_4$ and a polymeric base (for example polyvinylamine or polyacrylamide modified by amino-groups) and exhibit a higher activity in the oxidation of 2-mercaptoethanol than the NaOH/Co(II)-Pc(SO_3Na)$_4$ low-molecular-weight system.

It has been suggested that RSH forms a complex with the polymeric base. The thiolate ion in this complex, which is a powerful π-donor, forms a complex with Co(II)-Pc(SO_3Na)$_4$, which coordinates an oxygen molecule, whereupon an electron is transferred within the coordination sphere from RS^- to O_2:[63]

The higher catalytic activity of polymeric catalytic systems compared with low-molecular-weight systems is associated with the fact that in the former case the very reactive mononuclear superoxo-complex (IV) is the effective species, while in the latter case dimerisation results in the formation of the less reactive dimericperoxo-complex (V):

(V)

Thus metalloporhines can catalyse oxidation-reduction reactions via two alternative mechanisms. The alteration of the electron-donating and electron-accepting properties of metalloporphines by the introduction of the appropriate substituents in the porphine ring can lead to the inversion of the mechanism of the catalysis in the same system. A similar phenomenon has been observed in the gas-phase oxidative dehydrogenation of cyclohexa-1,4-diene by nitrobenzene[151]. The metallophthalocyanines M-Pc catalyse this reaction by activating the oxidant, which is indicated by a series of facts—in particular by the increase of catalytic activity with decrease of the oxidation potentials of M-Pc (M = Mn, Fe, Co, Ni, Cu, or Zn) and with increase of the constants for their complex-formation reaction with trinitrobenzene. The enhancement of the electron-accepting properties of Co-Pc by the introduction of 16 fluorine atoms into its molecule changes the mechanism of the catalysis (Table 13). Depending on the number of fluorine atoms (from 0 to 16) in the phthalocyanine ring, the catalytic activity passes through a minimum; the oxidative dehydrogenation of cyclohexadiene in the presence of Co-Pc($F)_{16}$ takes place also in the absence of nitrobenzene; with increase of the number of fluorine atoms in the catalyst molecule, the constant for its complex formation reaction with trinitrobenzene diminishes and that for the reaction with cyclohexadiene increases.

IV. CATALYSIS OF THE DECOMPOSITION OF HYDROPEROXIDES

The presence of a variable-valence metal ion in metalloporphines gives rise to the possibility of yet another mechanism of the catalysis. They can initiate the autoxidation chain, catalysing via the Haber—Weiss mechanism[152] the decomposition of the hydroperoxides present in the substrate as impurities:

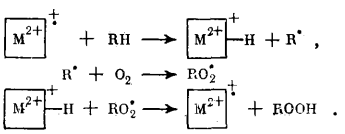
$$ROOH + M^{n+} \rightarrow RO^{\cdot} + OH^- + M^{(n+1)+} ,$$
$$ROOH + M^{(n+1)+} \rightarrow RO_2^{\cdot} + H^+ + M^{n+} . \qquad (4)$$

This mechanism usually operates at elevated temperatures. According to a number of studies[32-36], it predominates in the liquid-phase oxidation of cumene and a number of other hydrocarbons in the presence of M-Pc at temperatures above 105 °C; below 100 °C, the M-Pc activate oxygen. A change in the mechanism of the catalysis in the range 100–105 °C is indicated by the break in the temperature variation of the rate constant represented by a plot of $\lg k$ against $1/T$ as well as the lack of constancy of the ratio of the hydroperoxide formed to the oxygen which has reacted, observed above 105 °C. According to the results of other investigators the M-Pc catalyse the decompostion of cumenyl hydroperoxide also at 60–100 °C.[41,42,153].

In systems involving the oxygen activation mechanism, there is a possibility of the parallel catalysis of the decomposition of the hydroperoxides formed in the course of the reaction.

The composition of the cumene oxidation products in the presence of M-Pc at 80 °C and the catalytic activity of M-Pc depend on the nature of the metal (Table 14). In the case of Mn-, Fe-, and Co-Pc, the main reaction products result from the decomposition of cumenyl hydroperoxide: carbinol and acetophenone; in the case of Cu-, Zn-, and Mg-Pc, cumenyl hydroperoxide is virtually the only product; in the presence of Ni-Pc, the main product is cumenyl hydroperoxide but a certain amount of carbinol and acetophenone is also formed.

Table 14. The compositions (%) of the products of the oxidation of cumene catalysed by M-Pc at 80 °C over a period of 10 h.[154]



M	Mn	Fe	Co	Ni	Cu	Zn	Mg
Conversion of cumene	63.1	70.3	77.1	42.2	12.9	14.2	10.3
Hydroperoxide	17.9	12.4	5.8	31.7	12.9	14.2	10.3
Carbinol	31.8	40.8	50.0	9.0	0	0	0
Acetophenone	13.4	17.1	21.3	1.5	0	0	0
Selectivity with respect to hydroperoxide*	28.4	17.6	7.5	7.5	>98	>98	>98

* The content (%) of cumenyl hydroperoxide in the oxidation products.

The Mn-, Fe-, and Co-Pc catalysts are extremely active, since, together with the activation of oxygen, they also catalyse the decomposition of hydroperoxides; Cu-, Zn-, and Mg-Pc are capable of activating oxygen but do not catalyse the decomposition of hydroperoxides; Ni-Pc occupies an intermediate position—it is involved to some extent in reaction (4). These data can be interpreted from the

standpoint of the influence of the central metal on the mechanism of the oxidation of M-Pc (see Section II). The variable-valence metal ion necessary for the catalysis of the decomposition of hydroperoxides is present only in Mn-, Fe-, and Co-Pc, whose oxidation-reduction cycle proceeds via the central metal ion, and in Ni-Pc, whose oxidation-reduction takes place partly by the same mechanism; Cu- and Zn-Pc cannot catalyse the decomposition of hydroperoxides because their oxidation-reduction cycle proceeds only via the phthalocyanine ligand.

According to Manassen[155], the M-Pc whose oxidation involves a change in the valence of the metal ion catalyse the oxidation of cumene at elevated temperatures via the decomposition of the hydroperoxide, while the M-Pc whose oxidation proceeds via the ligand act as chain carriers:

Both mechanisms are possible for Ni-Pc.

V. CONCLUSION

The presence of an extensive π-conjugation system and of the central variable-valence metal ion in metalloporphine molecules gives rise to the possibility that they catalyse oxidation-reduction reactions via two alternative mechanisms: the donor mechanism, in which an electron is transferred in the course of the reaction from the catalyst to the oxidant, and the acceptor mechanism characterised by electron transfer from the substrate being oxidised to the catalyst molecule. The ratio of the oxidation-reduction potentials of the metalloporphine and the reactants of the reaction catalysed determines the mechanism of the catalysis in each specific system.

The presence of a variable-valence metal ion in the metalloporphine molecules also permits the initiation of the chain in the free-radical autoxidation by catalysing the decomposition of hydroperoxides via the Haber–Weiss mechanism.

Although porphyrin structures enter into the composition of oxidative enzymes and are active oxygen transferring agents in biological systems, synthetic metalloporphines catalyse under laboratory conditions as a rule the free-radical chain autoxidation. However, in certain systems the functioning of metalloporphines as agents transferring oxygen to the molecules of the substrate being oxidised is postulated. The search for such systems is of interest both from the standpoint of the elucidation of the mechanisms of enzyme catalysis and from the standpoint of the creation of new catalysts for the oxidation reaction which are selective as regards products.

We believe that studies in which the reaction is carried out in the presence of a suitable reductant, maintaining the catalyst in the reduced state, and the substrate being oxidised is activated with respect to nucleophilic attack by being coordinated to a suitable complex-forming agent merit attention. The employment of bimetallic porphyrin systems of the type obtained in a number of studies[156–161], one of the metallic centres of which (the donor) activates oxygen and the other (the acceptor) activates the substrate being oxidised, may also prove promising.

Primary Photoprocesses in Colorant Molecules

V.E.Korobov and A.K.Chibisov

A survey is made of primary photoprocesses in dye molecules in solution—photophysical processes in excited singlet and triplet states (absorption from an excited level, vibrational and rotational relaxation, lifetimes, quantum efficiencies of fluorescence, intersystem and internal conversions, deactivation and quenching of the triplet state, etc.) and primary photochemical reactions (*cis-trans*-isomerisation, electron transfer, etc.). A list of 309 references is included.

CONTENTS

I. Introduction 27
II. Photophysical processes in molecules in a singlet excited state 27
III. Photophysical processes in molecules in a triplet state 31
IV. Primary photochemical reactions of dyes 34

I. INTRODUCTION

Organic colorants are widely employed in various fields of science and technology—in the textile industry, colour and black-and-white photography, printing, etc.—absorbing light radiation efficiently and then transforming the resulting electronic excitation into various other forms of energy. Investigation of the interaction of intense light pulses with dye solutions led to the production of optical quantum generators having a tuned generation frequency (dye lasers). As traps for electronic excitation energy colorants can be used for the photostabilisation of polymeric materials. Finally, considerable interest has been aroused by study of the photosemiconductor properties of colorants with the aim of "sensitising" electrographic layers.

The development of experimental technique produced a substantial expansion of research on photoprocesses in colorant molecules. Laser sources enabled light pulses to be obtained of high intensity (~10^{13} W cm^{-2}) and short duration (10^{-9}–10^{-12} s). The use of such pulses to excite molecules made it possible to investigate primary photoprocesses lasting as little as 10^{-12} s.

Research on the photophysical and photochemical properties of organic dye molecules was last reviewed (1967) in a monograph[1]. Since then, an immense number of papers have appeared on the photonics of such molecules. The present Review covers the main results of research on primary photoprocesses in colorant molecules in solution published during the past decade.

II. PHOTOPHYSICAL PROCESSES IN MOLECULES IN A SINGLET EXCITED STATE

The processes occurring in colorant molecules in a singlet excited state (a lower excited state is implied) are extremely diverse. On absorption of a light quantum a molecule usually passes into upper vibrational sublevels of an electronically excited state. The processes following absorption include vibrational and rotational relaxation. The molecule can pass from the singlet excited state to the ground state with emission of a light quantum (fluorescence) or without emission (internal conversion), as well as to a triplet state (intersystem crossing) (Fig.1).

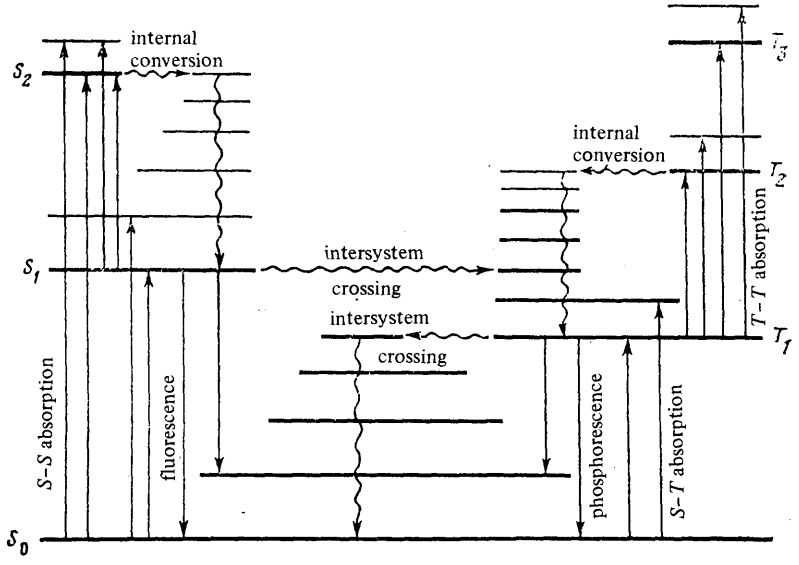

Figure 1. Scheme of energy levels in dye molecules and transitions between them.

Electromagnetic radiation of definite frequency induces forced transitions either to the ground state (amplification of light) or to a higher excited state (absorption of light). These unimolecular processes of deactivation of the singlet excited state may compete with bimolecular processes—energy or electron transfer—stimulated by transitions to ground and triplet states, formation of excimers and excited complexes, etc.

1. Singlet–Singlet Absorption

Absorption from a singlet excited level corresponds to $S_1 \rightarrow S_n$ transitions in the dye molecule (Fig.1). Their experimental investigation has been made possible during recent years by the development of picosecond laser spectroscopy. Spectra or effective $S_1 \rightarrow S_n$ absorption cross-sections have now been determined for several rhodamine[2–7] and cyanine[8–14] dyes, Cresyl Violet[15,16], Acridine Red[17], Nile Blue[6], etc.

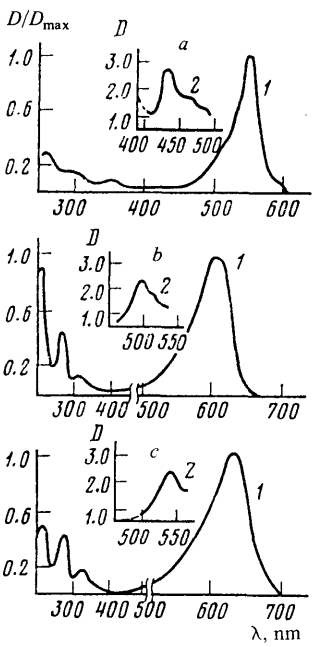

Figure 2. Absorption spectra[6] of ethanolic solutions of: *a*) Rhodamine 3B; *b*) Cresyl Violet; *c*) Nile Blue corresponding to the transitions: 1) $S_0 \rightarrow S_n$; 2) $S_1 \rightarrow S_n$. Optical densities D expressed in relative units.

Thus the $S_1 \rightarrow S_n$ absorption spectra of Rhodamines 6G and 3B in ethanol contain a maximum at 430 nm, but in that of Nile Blue the maximum occurs at 540 nm [6] (Fig.2). The corresponding spectrum of cryptocyanine has a band at 550 nm,[8,9] representing the energy difference between the S_2 and S_1 levels. For Cresyl Violet in methanol and in glycerol the maximum lies at 490–500 nm [6,15] and 430 nm [16] respectively. Here the energy of the $S_1 \rightarrow S_n$ transition does not correspond to any final state involved in absorption from the S_0 ground level. This was explained[15] by a symmetry difference between S_0 and S_1 states, which imposes restrictions on the probability of electron transitions. The absorption spectra of molecules in a singlet excited state give fresh information on the structure of the energy levels in colorant molecules.

2. Vibrational and Rotational Relaxation in a Singlet Excited State

Vibrational relaxation was first recorded in Rhodamine 6G by picosecond laser excitation[18]. The vibrational relaxation time was $\tau_{vibr} \cong 6$ ps, and a similar value 8 ± 3 ps was obtained later[19]; for Rhodamine B $\tau_{vibr} < 2$ ps. Subsequent studies have shown[20–24] that for these two colorants in ethanol, methanol, and water $\tau_{vibr} < 1$ ps, which is apparently the most reliable value.

The vibrational relaxation time for Rhodamine 6G dissolved in glycerol lengthens by only 50% over the temperature range 40–20 °C, while the viscosity increases more than thousandfold[25]. The lack of correlation between this time and the solvent viscosity indicates primarily that vibrational relaxation is due to interaction between solute and solvent molecules. In "isolated" molecules the time of "pure" vibrational relaxation is ~10^{-8} s.[26,27] A relation has been detected also with the quantum efficiency of fluorescence[25]: for Rhodamine B as example the quantum efficiency falls to 0.5 on passing from glycerol to ethanol, while the vibrational relaxation time shortens from 4 ± 1.4 to 0 ± 1.4 ps. The effect on the time was attributed to a difference in mobility of the terminal diethylamino-groups of the dye molecule in the two solvents[25]. An important part in the vibrational relaxation of rhodamines is played by hydrogen bonds between dye and solvent molecules. For the fluorescein group of xanthen colorants (fluorescein, eosin, erythrosin) $\tau_{vibr} < 10$ ps.[28]

The use of picosecond lasers has also enabled rotational or orientational relaxation in colorant molecules to be investigated[29–39]. Most of the measurements of rotational relaxation times have been made on Rhodamine 6G in various solvents. This time is directly proportional[29] to solvent viscosity (as follows from the Debye–Stokes–Einstein hydrodynamic model) and to hydrodynamic volume. Thus for Rhodamine 6G in ethanol the time τ_{rot} fluctuates from 70 to 300 ps according to various workers[29,33,34]. In viscous solvents it increases to 2800 ps [29,31] (or even to 6500 ps [32]) in undecanol and to 2100 ps in ethylene glycol[29,31]. Rotational relaxation times have been measured for Rhodamine 4S in ethanol (250 ps [38]), for Rose Bengal in several organic solvents varying in viscosity (in acetone and ethanol respectively 70 and 450 ps [37]), and for 3,3'-diethyloxadicarbocyanine (160 ps in ethanol[35]). Despite some divergence in the results, it can be accepted that, for the colorants investigated in low-viscosity media at room temperature, orientational equilibrium with the solvent is established before the act of emission.

3. Lifetime and Quantum Efficiency of Fluorescence

The lifetime of a singlet excited state τ_S^* is an important parameter determined by the aggregate of processes deactivating excited molecules. The use of picosecond lasers has enabled it to be found both from the decay of $S_1 \rightarrow S_n$ absorption intensity (for non-fluorescent molecules) and from the decay of fluorescence intensity. Such lifetimes have been measured for rhodamine[32,33,40–44,47,49], xanthen[28,32,41,54–57],

thiazine[58,129,149] azine[44,110], triphenylmethane[57,62,63], indigoid[54–67], coumarin[68,69], polymethine (cyanine)[13,35,70–84,110], and other colorants (Table 1).

Table 1. Lifetime τ_S^* and quantum efficiency ϕ_{fl} of fluorescence of dyes.

Dye	Solvent	τ_S^*, ns	φ_{fl}
Rhodamine 6G	methanol	3.7 [40]; 6.5 [41]	—
	ethanol	3.7 [33]; 4.5 [42, 44]	0.88 [42, 46]
	water	4.0 [44]	0.89 [46]; 0.96 [45]
	acetone	—	0.78 [46]
Rhodamine B	ethanol	3.4 [42]	0.81 [111]; 0.61 [42]; 0.72 [50]
	ethanol + HCl	2.5 [47]	0.49 [48]
	ethanol + KOH	3.1 [47]	0.71 [48]
Rhodamine 3B	ethanol	3.4 [42]	0.7 [111]; 0.68 [42]; 0.42 [46]
	water	—	0.37 [46]
NN'-Diethylrhodamine	ethanol	—	0.94 [42]
Fluorescein	ethanol	—	0.97 [54]
	water	4.0 [41]	—
	water (neutral dye)	—	0.14 [51]; 0.20—0.25 [52]
	water (monoanion)	—	0.26 [51]; 0.25—0.35 [52]
	water (dye cation)	—	0.9—1.0 [52]
	water, pH 9	—	0.92 [53]
	water, 0.05*N* NaOH	4.4 [32]; 3.9 [28]	—

Note. Numbers in square brackets denote references (Ed. of Translation).

For rhodamine dyes in various solvents (water, methanol, ethanol, glycerol, etc.) the lifetimes lie in the range 2–6 ns. Variations are due to the experimental conditions. For example, τ_S^* falls from 4 to 2 ns with increase in the concentration of Rhodamine 6 G in water from 10^{-5} to 10^{-2} M,[41] which can be explained by singlet–singlet energy transfer from monomers to non-luminescing association complexes[40]. Lifetimes for rhodamine dyes became shorter on heating[85] owing to temperature quenching of fluorescence[86]. Later, however, it was concluded[87] that the excited singlet lifetime did not vary with temperature. Variation has been observed in the presence of detergents[88,89] and also with change in solution acidity[47,90].

Xanthen dyes of the fluorescein group have excited singlet lifetimes of the same order as those of the rhodamine group[28, 32,41,54], except for erythrosin and Rose Bengal, for which they are only around one-tenth[28,54–57]. Such a difference is due not only to the internal effect of the heavy atom[54] but also to a specific solvent effect. Thus these lifetimes for Rose Bengal in proton-donor solvents are some 20% of those in aprotic solvents[91], a difference attributed to the influence of hydrogen bonds on non-radiative transitions.

The shortest excited singlet lifetimes, a few picoseconds, are typical of triarylmethane dyes (Malachite Green, Crystal Violet)[62,63]. The decisive role in ultra-rapid electronic relaxation processes in such molecules belongs to internal conversion and conformational changes[16,63].

Brief lifetimes of singlet excited states have been found also in many polymethine dyes, apparently as a consequence of their capacity for *cis–trans*-photoisomerisation. The lifetimes increase in viscous media[70,71,78]. They depend on the length[92] of the polymethine chain $[CH:CH]_n$, changing approximately tenfold with increase in n from 1 to 3; further increase in n shortens the lifetime, to 50 ps for $n = 5$. The latter effect is explained by narrowing of the energy gap between S_0 and S_1 states and increase in the probability of non-radiative transitions.

An important characteristic of singlet excited states of molecules is the quantum efficiency of fluorescence ϕ_{fl}, which is determined from the singlet lifetime and the fluorescence rate constant k_{fl} by the formula $\phi_{fl} = k_{fl}\tau_S^*$.

Rhodamine dyes exhibit intense fluorescence, with quantum efficiencies exceeding 0.5 for most of them[42] (Table 1), which is explained by favourable relative positions of singlet and triplet energy levels[93]. The efficiency is affected by structural features of the rhodamine molecules[94] and also by such experimental conditions as the solvent[47,90], exciting wavelength[95,96], etc. It depends on the temperature: thus for Rhodamine B in alcohol the efficiency increases from 0.4 to 1.0 when the solution is cooled, and falls to a few percent on heating to 78 °C.[97]

The quantum efficiency ϕ_{fl} of the fluorescein group of xanthen dyes varies within wide limits as a consequence both of ionisation of the molecule (with change in solution pH) and of the effect of heavy atoms contained therein (Table 1). It is affected by hydrogen bonding between dye molecule and solvent[98], temperature[99], and deuteration[100].

For triarylmethane dyes the quantum efficiency of fluorescence is low ($\sim 10^{-4}$) in non-viscous media. However, it increases rapidly with the viscosity η, in conformity with the empirical relation $\phi_{fl} = c\eta^{2/3}$,[112] in which c is constant for a given dye.

Research on the spectral luminescent properties of cyanine dyes[75,77,80,84,101,102,110] has revealed a dependence of efficiency on the length of the polymethine chain analogous to the above relation for singlet lifetime[92]. The presence of *meso*-substituents in the chain usually lowers the efficiency. Introduction of a heavy atom into the heterocycle has little

effect[102]. Since polymethine dyes are capable of *cis–trans*-photoisomerisation, the effect of several factors on efficiency is in most cases a consequence of variation in the tendency to photoisomerisation.

Table 2. Quantum efficiencies of intersystem crossing and internal conversion ϕ_{is} and ϕ_{ic} and corresponding rate constants k_{is} and k_{ic} for dyes.

Dye	Solvent	φ_{is}	k_{is}, s^{-1}	φ_{ic}	k_{ic}, s^{-1}
Rhodamine 6G	ethanol	$2\cdot10^{-3}$ [114]; $5.5\cdot10^{-4}$ [111] *	$6.5\cdot10^{6}$ [42]; $1.6\cdot10^{6}$ [113] $4.2\cdot10^{5}$ [114]; $3.2\cdot10^{6}$ [115] $1\cdot10^{5}$ [111, 117] * $6\cdot10^{5}$ [116]	0.17 [119, 120]	$3\,1\cdot10^{7}$ [119, 120]

* At 77 K.

Note. Numbers in square brackets denote references (Ed. of Translation).

The fluorescence spectrum is characteristic of each dye. With almost all dyes the emission spectrum is located at the longer-wavelength edge of the principal absorption band. In addition to the usual fluorescence arising on transition from a lower singlet excited state to the ground state, a radiative transition from higher excited states is also possible, whose spectrum is displaced to shorter wavelengths (short-wave luminescence). The low quantum efficiencies and short lifetimes make detection of such luminescence difficult For dyes its observation therefore became possible after the creation of powerful laser sources of excitation. Short-wave luminescence has been investigated in solutions of Rhodamines 6G,[103–108], 3B,[109] and B,[104,109] cryptocyanine[78], etc. For these dyes it is characterised by low efficiencies $\phi_{fl} \cong 10^{-4}-10^{-6}$, while the excited states responsible for it are short-lived (~20–0.03 ps).

4. Intersystem Crossing and Internal Conversion

In the absence of processes tending to quench fluorescence and photochemical reactions involving a singlet excited state the non-radiative processes competing with fluorescence are intersystem crossing to a triplet state and internal conversion (Fig.1). Knowledge of quantum efficiencies or rate constants for these processes is necessary mainly because of the involvement of triplet states of colorants in various photoreactions. Methods elaborated for determining quantum efficiencies ϕ_{is} [59] have enabled values to be found for rhodamine[111,114,119,121–125], xanthen[53,60,61,126], thiazine[60,127], polymethine[77,80,110,131–134], and other dyes[59,61,128] in liquid solutions. Efficiencies ϕ_{is} together with rate constants $k_{is} = \phi_{is}\tau_S^{*-1}$ are listed in Table 2 for several dyes.

The efficiency ϕ_{is} of Rhodamine 6G has been determined from measurements of laser generation characteristics[135,136], triplet–triplet absorption[114,120–123,137], phosphorescence[111,117], and yields of photochemical reactions[138], but in several cases results obtained by different methods differed greatly. Those obtained from direct actinometric measurements[114] and by comparison with a standard[121–124] are apparently the most accurate (Table 2). Values of ϕ_{is} remain almost unchanged on passing from alcohol to water[114,123,124], but are appreciably lower in acid media (pH 1.4).[122] A significant increase is observed in media containing heavy atoms[119], as well as when the dye molecules are associated[120,139,140], in the latter case to 0.5. Both effects are due to strengthening of spin–orbit interaction.

The internal effect of a heavy atom in increasing the efficiency ϕ_{is} is especially clear in the series of xanthen dyes of the fluorescein group (Table 2). Thus passing from fluorescein to eosin (tetrabromofluorescein) and erythrosin (tetraiodofluorescein) increases the efficiency by factors of ~35 and ~50 respectively[60].

Low efficiencies $\phi_{is} \cong 10^{-2}-10^{-4}$ characterise many polymethine dyes in non-viscous solutions. Intersystem conversion to a triplet state has *cis–trans*-photoisomerisation as an effective competitor[131–134]. The quantum efficiency ϕ_{is} is significantly higher for dyes containing *meso*-substituents in the polymethine chain[131–134], because of steric hindrance to the competing process. An appreciable increase in efficiency has been observed in viscous media, in which *cis–trans*-isomerisation is likewise hindered[131].

Internal conversion competes with an intersystem transition to a triplet state. In the absence of photochemical reactions involving the singlet excited state the quantum efficiencies in the quenching of fluorescence conform to the relation

$$\varphi_{fl} + \varphi_{is} + \varphi_{ic} = 1 \qquad (1)$$

which enables the quantum efficiency of internal conversion ϕ_{ic} to be found from the observed efficiencies ϕ_{fl} and ϕ_{is}. Table 2 includes values of ϕ_{ic} and the rate constant of internal conversion k_{ic} for xanthen, thiazine, polymethine, and other dyes. It is evident that internal conversion is almost completely absent from fluorescein-group dyes in polar media:

an appreciable contribution by its efficiency has been observed only with fluorescein itself in dimethyl sulphoxide, dimethylformamide, and formamide[98]. The rate constant k_{ic} increases exponentially with decrease in the energy ΔE corresponding to the 0–0 band in the $S_0 \rightarrow S_1$ transition, which is governed by intermolecular interaction in the solute–solvent system[54,98]. Internal conversion is greater in rhodamine dyes, which also can be explained, apparently, in terms of the energetics of intermolecular hydrogen bonding[54].

Internal conversion makes a significant contribution to energy degradation of singlet excited molecules in the case of thiazine, acridine, triarylmethane, and polymethine dyes. It is especially effective in triarylmethane dyes, for which $\phi_{ic} \cong 1$, and $10^{-11}k_{ic}$ is respectively 5 and 2 s^{-1} for methanolic Malachite Green[63] and ethanolic Crystal Violet[62].

5. Quenching of Singlet Excited State

Dynamic quenching of fluorescence can occur mainly as a result of energy transfer, electron transfer, internal conversion or intersystem crossing under the influence of a quenching agent, formation of excimers and excited complexes, and other causes.

Quenching of singlet excited states of dye molecules by compounds having lower S_1 levels results from energy transfer by an inductive–resonance mechanism. Thus energy transfer has been established[141,142] between fluorescein and eosin, and correspondingly erythrosin and Rose Bengal. Picosecond laser technique has enabled such transfer to be investigated between Rhodamine 6G and 3,3'-diethylthiacarbocyanine[143], as well as Malachite Green[144–146]. For the Rhodamine 6G–Malachite Green system the critical energy-transfer radius $R_0 = 53$ Å and the transfer rate constant $k = 3.1 \times 10^{11}$ M^{-1} s^{-1}; for the Rhodamine 6G–3,3'-diethylrhodamine system in water $R_0 = 59$ Å. The efficiency of energy transfer is increased by the presence of a surface-active agent—sodium dodecyl sulphate[143].

Effective quenching of the fluorescence of dyes (Acridine Yellow, Magdala Red, phenosafranine, Rhoduline Red, etc.) by inductive–resonance energy transfer takes place in the presence of rare-earth metals (neodymium, erbium, praseodymium, etc.)[147,148]; the transfer radius is $R_0 = 10–13$ Å.

Many dyes undergo molecular association with increase in concentration[1]. Fluorescence quenching of monomeric dye molecules results from transfer of singlet excitation energy to non-luminescent association complexes. Detailed investigation of such concentration quenching has been made on rhodamine dyes[150–152].

Quenching of fluorescence accompanied by charge-transfer complex formation is assumed in the interaction of singlet excited rhodamine dye molecules with anthracene and its alkyl derivatives[153], as well as of xanthen dyes, Acridine Orange, and 7-hydroxycoumarin with oxygen[154]. Fluorescence quenching of Oxonine by allylthiourea increases the quantum efficiency of intersystem crossing to a triplet state[155], whereas that of Rhodamine 6G by diethylaniline makes internal conversion more probable[156]. Formation of a singlet excited complex is assumed in the fluorescence quenching of Pyronine by potassium iodide[157].

6. Effect of Association on Properties of Molecules in Singlet Excited State

With increase in concentration dyes may associate, which influences the properties of singlet excited states[1]. Thus raising the concentration of Acridine Orange to 0.1 M lengthens the singlet lifetime τ_S^* from 1.7×10^{-9} to 1.6×10^{-8} s.[158] For a pseudocyanine the formation of I-aggregates leads to shortening of this lifetime to 3.5×10^{-11} s, owing to migration of excitation energy within the aggregate[159]. Shortening of the lifetime has been observed also on the aggregation of rhodamine dyes[40,160].

Energy transfer by an inductive–resonance mechanism is possible for associated dye molecules. Such transfer has been observed between *NN'*-dioctadecyloxacyanine and *NN'*-dioctadecylthiacyanine[161]. Formation of excimers has been recorded also for polymethine dyes[162,163].

III. PHOTOPHYSICAL PROCESSES IN MOLECULES IN A TRIPLET STATE

Triplet states of dye molecules have an important role in the degradation of electronic excitation energy and are involved in various photochemical reactions. Triplet–triplet energy transfer is often used to populate the triplet level of molecules having low intersystem quantum efficiencies. Molecules in a triplet state have significantly longer lifetimes than singlet excited dye molecules, so that their spectra can be recorded by flash photoexcitation[164]. Triplet states of dyes are detected also from phosphorescence[1,111,165] and electron spin resonance[165–171] spectra.

1. Triplet–Triplet Absorption

Triplet–triplet (T–T) absorption corresponds to permitted transitions between triplet states (Fig. 1). Early work on flash photolysis involved detailed examination of T–T absorption spectra of xanthen dyes of the fluorescein group[172]. During recent years great interest has been taken in triplet states of rhodamine dyes in view of their widespread use in laser technique. The first direct determinations[137] of the corresponding spectrum of Rhodamine 6G with sensitised occupation of the triplet level of the dye molecules in butanol were soon confirmed[120,173]. The spectra of this dye in aqueous and alcoholic solution have been obtained by direct flash photoexcitation[114,116,122–124,140,174]. The T–T absorption band at 600–620 nm, where the laser emission by Rhodamine 6G is located, is accompanied by two additional T–T absorption bands, in the blue and in the infrared (Fig. 3).

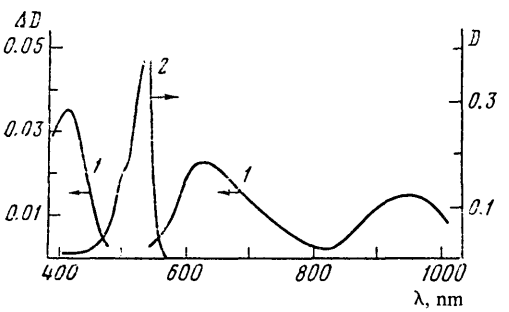

Figure 3. Absorption spectra[123] of aqueous Rhodamine 6G corresponding to the transitions: 1) $T_1 \rightarrow T_n$; 2) $S_0 \rightarrow S_n$.

The triplet–triplet absorption spectra of polymethine dyes have been investigated in detail in connection with their use as active media for optical lasers[11,130,131,133,175–181]. Because

of the low intersystem quantum efficiencies the spectra were obtained for most of these dyes with sensitised excitation. Such spectra have been determined for thiazine dyes (Thionine[182–185], Methylene Blue[186–190], Methylene Green[187]), acridine dyes (Acridine Orange, Acridine Yellow)[191–194], indigoid dyes (thioindigo, 6,6′-diethoxythioindigo)[195,196], coumarin dyes (coumarin, 7-hydroxycoumarin, 7-diethylamino-4-methylcoumarin)[197–199], and other dyes.

2. Deactivation of Triplet States

In photoreactions of dyes the quantum yield of the primary product is directly proportional to the lifetime of the molecule in any triplet state involved. Hence knowledge of the characteristics of processes effecting deactivation of such triplet states is extremely important for assessing the efficiency of photochemical reactions.

A distinction must be made between uni- and bi-molecular deactivation processes. The former include phosphorescence, intersystem crossing, and thermally activated delayed fluorescence (delayed fluorescence of type *E*/200). Among the second are triplet–triplet annihilation fluorescence (delayed fluorescence of type *P*/200), concentration quenching, and electron transfer on disproportionation of two triplet molecules and on interaction of a triplet with an unexcited molecule, as well as deactivation of a triplet state by various quenching agents.

Unimolecular deactivation processes. The lifetime of a molecule in a triplet state is determined by the totality of deactivation processes. In the absence of triplet–triplet annihilation and of concentration and other quenching processes this lifetime is given by

$$\tau_T = (k_{ph} + k_e + k_0 + k_q[Q])^{-1}$$

which takes into account the unimolecular (pseudounimolecular) deactivation processes

$$T \xrightarrow{k_{ph}} S + h\nu_{ph} \qquad (2)$$

$$T \xrightarrow{k_e} S^* \qquad (3)$$

$$T \xrightarrow{k_0} S \qquad (4)$$

$$T + Q \xrightarrow{k_q} S + Q\ . \qquad (5)$$

In most cases phosphorescence (2) cannot be recorded in liquid dye solutions at room temperature, owing to rapid non-radiative deactivation of the triplet state (4) and (5). It has been recorded in solutions of rhodamine dyes in the presence of bromoform (20–30 vol.%), which facilitates transition to a triplet state[209,212,229], the quantum efficiency of phosphorescence being (2–6) × 10^{-5}.[209] Systematic measurements of phosphorescence have been made for xanthen dyes at 77 K.[203,208,230] The longest triplet lifetimes occur in solid matrices—solutions at low temperatures or films (e.g. polyvinyl alcohol)—and are determined from the kinetics of the decay of phosphorescence[203,208], triplet–triplet absorption[198], and the e.s.r. signal[166,169,202,231,232]. Values of τ_T for most colorants under these conditions lie in the range 0.1–1.0 s (Table 3).

Several colorants (e.g. xanthen dyes) exhibit delayed fluorescence of type *E*. This process (3) involves vibrational excitation of T_1 to an isoenergetic level S_1 followed by an intersystem transition at S_1 and loss of excitation by fluorescence (Fig.1). Delayed fluorescence of this type is observed with compounds having small singlet–triplet separation (2000–3000 cm^{-1}), as well as at high temperatures.

Table 3. Lifetime τ_T and deactivation rate constants of triplet state of dyes.

In deoxygenated liquid solutions the chief processes deactivating a triplet state are non-radiative degradation (4) and quenching by uncontrollable impurities (5). Table 3 lists rate constants k_0 and $k_1 = k_0 + k_Q[Q]$ for various classes of dyes, and Table 4 gives positions of the triplet level E_T for the molecules. Several conclusions follow from these data: (i) k_1 exceeds k_0 for all the compounds investigated (the difference between them is due mainly to quenching by residual oxygen, whose concentration is estimated as $(1-2) \times 10^{-7}$ M); (ii) k_0 and k_1 increase with the number of heavy atoms in xanthen dye molecules in the sequence—fluorescein < eosin < erythrosin—and also in polymethine dyes (internal heavy-atom effect)[102]; (iii) k_1 for the rhodamine group of xanthen dyes is greater in media containing heavy atoms, e.g. bromoform (external heavy-atom effect); (iv) protonation of thiazine and acridine dye molecules increases k_1, as a consequence of the position of the triplet level in protonated molecules; (v) the high values $k_1 \cong (2-3) \times 10^8$ s^{-1} for thioindigoid dyes are due to the involvement of the triplet state in photoisomerisation; and (vi) k_1 for triarylmethane dyes increases on passing from a solid matrix to a solution, as conformational changes and additional rotational modes become possible.

Triplet–triplet annihilation and concentration quenching. Bimolecular processes include triplet–triplet interaction (at high concentrations of triplet molecules) and concentration quenching. Provided that the singlet–triplet splitting in the molecule is less than the separation between triplet and ground levels, excitation energy can be transferred between two triplet molecules with transition of one of them to a singlet excited state followed by fluorescence (delayed fluorescence of type *P*). Other possible results of triplet–triplet interaction may be non-radiative degradation[200, 233] and electron transfer[59,234]:

$$T + T \xrightarrow{k_{TT}} \begin{cases} \rightarrow S^{*} + S & (6) \\ \rightarrow \tilde{S} + S & (7) \\ \rightarrow R^{+} + R^{-} \cdot & (8) \end{cases}$$

The triplet–triplet interaction rate constant k_{TT} is usually found from the rate of decay of triplet–triplet absorption intensity. Table 3 gives values of k_{TT} for individual xanthen, acridine, and polymethine dyes; high values indicate that triplet–triplet interaction is occurring in the diffusion range.

Delayed fluorescence of type *P*, resulting from triplet–triplet annihilation, is observed in liquid dye solutions. That of butanolic Rhodamine 6G in the presence of bromoform[229] is assumed to involve formation of a ternary complex of two triplet dye molecules and one bromoform molecule. With photoexcitation sensitised by triplet–triplet energy transfer account must be taken also of delayed fluorescence due to triplet–triplet annihilation of mixed type[224,235].

Concentration quenching of triplet states arises from interaction of a triplet with an unexcited molecule. Its mechanism has not been finally established, but it apparently results from formation of a vibrationally excited molecule in the ground state[236], excimer phosphorescence[59], and electron transfer[59,172,234]:

$$T + S \xrightarrow{k_{TS}} \begin{cases} \rightarrow \tilde{S} + S & (9) \\ \rightarrow [T_2] \rightarrow S + S + h\nu & (10) \\ \rightarrow R^{+} + R^{-} & (11) \end{cases}$$

Table 3 includes concentration-quenching rate constants k_{TS} for several dyes. Comparison of k_{TS} and k_{TT} indicates that concentration quenching is substantially less effective than triplet–triplet interaction.

3. Quenching of the Triplet State

A distinction is made between static and dynamic quenching of triplet states. The former involves a decrease in concentration of triplet molecules unaccompanied by change in their lifetime. Static quenching corresponds to equilibrium between molecules unperturbed by the quenching agent and those that have been affected by the quencher (complex formation with the latter, association, etc.) and have a lower intersystem quantum efficiency ϕ_{is}. Dynamic quenching of the triplet state occurs in encounters of triplet with quencher molecules and shortens their lifetime.

A distinction is made also between "physical" and "chemical" quenching: the former yields the initial molecules in a ground (vibrationally excited) or an electronically excited state, but the latter gives intermediate products, e.g. free radicals. Physical quenching includes triplet–triplet interaction, concentration quenching, and quenching by heavy atoms; quenching by electron donors and acceptors, etc. must be regarded as chemical.

The chief processes for quenching the triplet state of dye molecules are triplet–triplet energy transfer, electron transfer, quenching by an "external" heavy-atom mechanism, and paramagnetic quenching.

Triplet–triplet energy transfer is one way in which the triplet state of a donor is quenched by an energy acceptor[233, 237]. Measurements of such transfer have revealed that the rate constant depends on the separation ΔE_T between the triplet levels of donor and acceptor. With large $\Delta E_T \geq 1500$ cm^{-1} the rate constant remains almost unchanged, close

to the diffusion constant; with decrease in the separation the rate constant k_q decreases; and with $\Delta E_T < 0$ there is a linear dependence of $\ln k_q$ on ΔE_T.[238,239]

Energy acceptors in the quenching of triplet states of dyes include oxygen molecules, aromatic hydrocarbon molecules, and inorganic ions. Quenching by oxygen has been studied in the greatest detail: it is generally accepted that quenching results in the formation of singlet oxygen[237], but electron transfer is also possible[204,249]. Table 5 gives triplet-quenching rate constants for various energy acceptors.

Compounds containing heavy atoms (bromobenzene, bromoform, alkali-metal bromides and iodides, hetero-organic compounds of tin, lead, mercury, etc.) facilitate intersystem transitions and lead to triplet quenching in both liquid and solid solutions[59]. Those in Table 6 can be arbitrarily divided into two groups according as k_q lies in the ranges 10^2–10^5 and 10^7–10^9 M^{-1} s^{-1}. Differences in the values of k_q are due to different quenching mechanisms: weak quenching (by bromoform, bromobenzene, caesium chloride, lithium bromide) is caused by direct spin–orbit interaction, but effective quenching by potassium iodide and by mercury(II) and thallium(I) chlorides involves electron transfer.

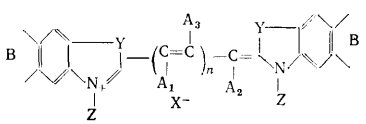
4. Triplet States of Association Complexes

At high dye concentrations association complexes are formed in polar solvents, in micellar solutions by interaction with macromolecular compounds, and also in mixtures of a polar and a non-polar solvent[1]. Association is accompanied by change in the spectral luminescent properties of the molecules.

Triplet states of association complexes have been investigated mainly on the rhodamine group of xanthen dyes[120,140,210,250–254]. Association of Rhodamine 6G in tetrachloromethane, cyclohexane, benzene, etc. in the presence of 0.1–0.2% of a polar solvent (association complexes of type I), as well as in aqueous solution in the presence of polymethacrylic acid (association complexes of type II) increases significantly the quantum efficiency of intersystem crossing in the triplet state relative to that of the dye monomers (ϕ_T respectively ~0.2 and ~0.5 for types I and II). The quantum efficiency of internal conversion also increases, and that of fluorescence decreases. The increase in ϕ_T accompanying association of Rhodamine 6G may be due to strengthening of spin–orbit interaction on aggregation and narrowing of singlet–triplet separation[252].

The triplet state of associated Rhodamine 6G is deactivated in uni- and bi-molecular processes. In 0.2% butanol–99.8% tetrachloromethane mixtures both delayed fluorescence of type *E* and phosphorescence are observed[250,251]. Measurements of the lifetime of the triplet state have shown that the deactivation rate constant k_1 increases from 200 to 3000 s^{-1} on passing from type II to type I association complexes[254]. The longer lifetime for the former is probably due to stabilisation of the complexes by the polymer. An analogous stabilising effect of polymethacrylic acid has been found for monomeric Rhodamine 6G.[140] The rate constant k_1 depends on the nature of the polar component of the mixture (viscosity and capacity for hydrogen bonding)[140,254]. Associated Rhodamine 6G can undergo triplet concentration quenching and triplet–triplet interaction[254], the latter accompanied by delayed fluorescence of type *P*.[210]

Many dyes are ionic compounds[1]. At certain solution concentrations charged dye ions are able to form ionic association complexes with a gegenion. Photophysical processes have been investigated in ionic association complexes of xanthen dyes of the fluorescein series with transition and rare-earth metal ions[256–261]. The measured phosphorescence lifetimes of the dye complexes with rare-earth metal ions in ethanol at 77 K indicate transfer of the triplet excitation energy to the metal ion. Sensitised luminescence of the trebly charged ytterbium cation has been detected in associated dyes in liquid solutions. The nature of the gegenion influences the relative quantum efficiencies of fluorescence and phosphorescence in the association complexes: thus the phosphorescence of eosin completely vanishes in complexes with the ytterbium(III) cation, whereas its quantum efficiency increases in the presence of trebly charged europium, gadolinium, terbium, and cerium cations.



IV. PRIMARY PHOTOCHEMICAL REACTIONS OF DYES

Dyes undergo various photochemical reactions in solutions[1]. Primary photochemical processes can occur at any stage in degradation of the energy of singlet and triplet excitation.

Three types of reaction can be distinguished, independently of the multiplicity of the excited state[262]: reactions of type A take place in a vibronic state immediately after absorption of a light quantum, those of type B follow vibrational relaxation, and type C occur after transition to a vibrationally excited level of the ground state, or to a triplet state. Type A reactions, proceeding from an unrelaxed vibrationally excited state, should have rate constants exceeding 10^{11}–10^{13} s^{-1}; they include photodissociation and photoisomerisation. Such reactions are unimolecular, with kinetics depending on temperature and exciting wavelength. Type B—electron, proton, etc. transfer—are of great interest for the photochemistry of dyes. The main factors influencing the reactivity of molecules are energy, multiplicity, distribution of electron density, and orbital symmetry.

1. *cis–trans*-Photoisomerisation

cis–trans-Photoisomerisation has been studied in greatest detail on cyanine (polymethine) dyes of structure

Y=O, S, $C(CH_3)_2$; Z=CH_3, C_2H_5; A_1, A_2=H, CH_3, F; A_3=H, F, CH_3, C_2H_5, OCH_3, NH_2; n = 0, 1, 2, 3; B = H, 5-NO_2, 5-H_2CO, 6-$N(CH_3)_2$, 6-Br, 6-NH_2OH, OCH_3, I, NO_2; X=I, CH_3SO_4, Br, ClO_4

It has been investigated in solid matrices[265] and in liquid solutions with flash (microsecond)[130–132,134,175,180,263,264,268,270] and laser (nanosecond[266,267,269,273–276] and picosecond[176,271,272]) excitation.

In the ground state polymethine dye molecules may occur in either the *trans* or the *cis* form. Photoexcitation may correspondingly involve *trans* → *cis* or *cis* → *trans* transitions. Thus 3,3'-diethylthiacarbocyanine, which has an unsubstituted polymethine chain, on excitation passes from the *trans* into the *cis* form[264]. *trans–cis*-Isomerisation takes place about the $C_{(2)}$–$C_{(8)}$ bond in the unsubstituted and 10-substituted polymethine chain, and about the $C_{(8)}$–$C_{(9)}$ bond in *meso*-substituted dyes[270].

cis–trans-Photoisomerisation of polymethine dyes takes place in the singlet state S_1,[266,277] as indicated primarily by triplet–triplet energy transfer results. Sensitised population of the triplet level of these dyes gives a triplet–triplet absorption spectrum markedly different from that of the photoisomers[130,131,134,175,180,264,269,273]. Furthermore, the fluorescence of 3,3'-diethylthiacarbocyanine decays and its *cis*-isomer accumulates within the same time (300 ps).[272] However, *cis–trans*-photoisomerisation from the triplet state is possible with 8,9-difluorothiacarbocyanine[274].

On excitation in the $S_0 \rightarrow S_n$ transition band, isomerisation follows internal conversion $S_n \rightarrow \tilde{S}_1$ and vibrational relaxation $\tilde{S}_1 \rightarrow S_1$.[267,278] However, picosecond laser excitation enabled isomerisation to be recorded in the S_2 state of 3,3'-diethyl-2,2'-thiacarbocyanine[12]. The rate constant in methanol is 3.2×10^{10} s^{-1}, which ensures that isomerisation can compete successfully with internal conversion ($k_{ic} = 1.8 \times 10^{10}$ s^{-1}).

Fig. 4 shows the transitions in substituted thiacarbocyanines when the initial form is a *cis*-isomer. The absorption and fluorescence spectra of isomers usually differ insignificantly, with shifts of 5–20 nm. Extinction coefficients are also closely similar[176,266,272].

Polymethine dyes are usually characterised by high quantum efficiencies of photoisomerisation ϕ_{isom}. Table 7 lists quantum efficiencies ϕ_{fl}, ϕ_{is}, and ϕ_{isom}, rate constants of triplet deactivation k_1 and relaxation of the photoisomer k_{relax}, and also activation energies of relaxation E_a for 3,3'-diethylthiacarbocyanine and its substituted derivatives. It is evident that non-radiative degradation of the energy of singlet excited states is effected mainly by isomerisation with characteristics (ϕ_{isom}, k_{relax}, E_a) depending on the presence in the polymethine chain of substituents capable of offering steric hindrance to rotation on isomerisation. Replacement of one hydrogen atom at position 8 or 9 by a fluorine atom does not produce significant steric hindrance, so that long-lived photoisomers are formed (lifetime 10^{-3}–10^{-2} s) with an angle of rotation of the chain $\alpha = 180°$. Replacing two or three hydrogen atoms leads to marked steric hindrance, with the angle decreasing to 90°, the photoisomer relaxation rate constant increasing abruptly, and the activation energy of relaxation simultaneously diminishing. Analysis of Stuart–Briegleb models shows that similar changes in k_{relax}, E_a, and α always accompany steric hindrance[273]. If such hindrance is sufficiently great, photoisomerisation may be completely suppressed[279].

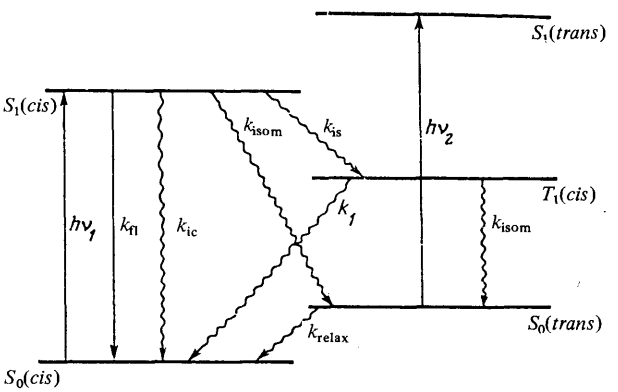


Figure 4. Scheme of energy levels and transitions between them for *cis*- and *trans*-isomers of thiacarbocyanines.

Replacement of hydrogen atoms in polymethine dyes by halogens leads to a redistribution of probabilities of singlet deactivation of excited states as a consequence not only of steric hindrance but also of an internal heavy-atom effect. Thus for 9-iodothiacarbocyanine $\phi_{is} = 1$ but $\phi_{isom} \cong 0$.[102].

Photoexcitation of indoleninedicarbocyanines initially in *cis*-form gives long-lived *trans*-isomers together with short-lived di-*cis*-isomers (k_{relax} respectively ~10^2 and ~10^6 s^{-1}).[132,269]. The latter are sterically hindered and are found in low quantum yields (0.01–0.1). Dyes having a shorter polymethine chain can also form sterically hindered di-*cis*-photoisomers[275].

The efficiency of photoisomerisation effected by rotation of large fragments of the molecule is substantially dependent on the viscosity of the medium: increase in viscosity diminishes the probability of formation of a photoisomer[131,272] and its rate of relaxation[276]. Photoisomerisation is influenced also by the temperature[276] and the solvent[271,279]. Thus a ketocyanine isomerises in a non-polar solvent ($\phi_{isom} = 0.5$) but

not in alcohol[279], owing to predominance of the non-polar structure of the photoisomer.

Merocyanine dyes, like carbocyanines, are capable of photoisomerisation[280–282]. From a singlet excited state both short- and long-lived photoisomers are formed (k_{relax} respectively ~100 and ~1 s^{-1}), whereas a triplet state yields only the latter[280,281]. They are formed by rotation about the $C_{(2')}$–$C_{(8')}$ and $C_{(5)}$–$C_{(9')}$ bonds respectively[281]. The photoisomerisation rate constant depends on the proton-donor power and the polarity of the solvent[282].

Table 7. Influence of substituents in polymethine chain of 3,3'-diethylthiacarbocyanine on quantum efficiences, rate constants, and activation energies of *cis–trans*-photoisomerisation[131–134,175,264,274].

Substituents	Isomer	φfl	$\varphi$is	φisom	k_1, s^{-1}	k_{relax}, s^{-1}	E_a, kcal $mole^{-1}$
None	*cis*	0.05	<0.001	0.95	$4.6 \cdot 10^2$	$1.6 \cdot 10^2$	15

Thioindigo and its derivatives are capable of *cis–trans*-photoisomerisation[65,66,195,196,227,283–287]. With thioindigo and 6,6'-diethoxythioindigo the reaction involves a triplet state common to *cis*- and *trans*-forms. In the triplet state fragments of the molecule are turned through 90° relative to the ethylenic bond[196]. Involvement of the triplet state of thioindigo in isomerisation follows from results on sensitised population of the triplet level of the dye molecule[286] and on inhibition of the *trans* → *cis* transition by oxygen[227,287], as well as from comparison of rates of triplet deactivation and photoisomer accumulation[196]. However, recent work[307,308] on the mechanism of the photoisomerisation of *trans*-thioindigo using a picosecond laser casts doubt on involvement of a triplet state in isomerisation.

Azomethine dyes undergo *syn–anti*-isomerisation about the carbon–nitrogen double bond[288]. Two mechanisms are possible, one (torsion) consisting in rotation about this bond, and the other (inversion) in rotation of a fragment in the plane of the molecule through 120° about the nitrogen atom. Experimental results indicate that both mechanisms operate[289], isomerisation occurring in both singlet excited and triplet states[290,291]. In azo-dyes of the Picramine R group[292] *cis–trans*-photoisomerisation takes place from a singlet excited state[191].

2. Electron Transfer

Electron transfer is the most common photochemical reaction of dyes[234]. It can occur in both singlet excited and triplet states. Interaction of excited molecules with electron donors or acceptors will inevitably produce additional paths for degradation of the excitation energy. Thus a consequence of electron transfer is to shorten the lifetime of excited molecules in the presence of a quenching additive, in conformity with the Stern–Volmer equation. Thus the singlet lifetime τ_S^* of Thionine is shorter in the presence of iron(II) chloride or sulphate in aqueous solution at pH 2.[129]

Study of the quenching of singlet excited states usually involves measurement of the relative fall in efficiency or intensity of fluorescence. If the dye molecules do not form non-luminescent complexes with quenching additives, the fall in efficiency and the shortening of the lifetime τ_S^* are described by the same Stern–Volmer formula. A fall in fluorescence efficiency has been found for Thionine in the presence of iron(II), manganese(II), cerium(III), and caesium(I) in water at pH 2.5,[293] Rhodamine 101 in the presence of methanolic amines[294], and Methylene Blue in the presence of iron(II) in 0.01 M hydrochloric acid[149]. The rate constant for the quenching of singlet excited states of Thionine molecules by iron(II) cations is $k_q = 3.5 \times 10^9$ M^{-1} s^{-1},[129] identical with the 3.6×10^9 M^{-1} s^{-1} calculated from the Stern–Volmer dependence for the fall in fluorescence efficiency[293] and for the lifetime of these singlet states[129]. Thus quenching of fluorescence in the Thionine–iron(II) system is due solely to electron transfer. Formation of complexes in the ground state is possible between Thionine and the sulphate anion[293].

Table 8. Rate constants k_q for quenching of the triplet state of dyes by electron donors and acceptors.

Dye	Solvent	Donor	Acceptor	k_q, M^{-1} s^{-1}	Ref.
Eosin	water, pH 7.1	(-)-tryptophan	—	$8.4 \cdot 10^8$	[247]
»	water, pH 6.2	—	ferricyanide	$7.5 \cdot 10^8$	[246]
»	water, pH 7.2	edta	—	$5.0 \cdot 10^5$	[60]

»	propanol	—	*m*-dinitro-benzene	$2.2 \cdot 10^9$	[181]
»	propanol	—	methylviologen	$1.4 \cdot 10^8$	[181]

Quenching of triplet states by electron donors and acceptors has been investigated in thiazine[171,182–189,215,218,220,247,248,295,296], xanthen[59,60,116,124,246,247,297], acridine[192–194], polymethine[131,181,225], and other dyes[234] (Table 8).

The Stern–Volmer type of linear dependence found experimentally between the relative shortening of the lifetime of singlet and triplet molecules and the concentration of the

quenching additive is a direct indication of the possibility of electron transfer. It must be borne in mind that this type of relationship is satisfied by other processes, e.g. energy or hydrogen transfer. Electron transfer involving excited dye molecules is characterised firstly by the formation of solvated radical-ions (or radicals) and secondly by a correlation between the quenching rate constant and the donor or acceptor properties of the quencher.

Flash and laser photolysis have been used to determine the absorption spectra of one-electron oxidation and reduction products of fluorescein[297], rhodamine[116,123,124,298], thiazine[182-185,187-189,295], acridine[182,228], polymethine[131,181,225], and other dyes.

In polar media electron transfer between a triplet dye molecule (acceptor) and a quencher molecule (donor) leads to formation of a solvent-separated radical-pair[234]:

$$A(T) + D \underset{k_{21}}{\overset{k_{12}}{\rightleftharpoons}} A(T)\ldots D \underset{k_{43}}{\overset{k_{34}}{\rightleftharpoons}} A^{\dot{-}}\ldots D^{\dot{+}} \begin{cases} \xrightarrow{k_{30}} A + D \\ \xrightarrow{k_{34}} A^{\dot{-}} + D^{\dot{+}} \end{cases}$$

This either dissociates into solvated radical-ions or recombines with formation of the original reactants in the ground state; involvement of a triplet excited complex has also been suggested[184,248,301].

The quenching rate constant is given by the formula[301]

$$k_q = k_{12}\left[1 + \frac{k_{21}}{k_{30}}\exp\left(\frac{\Delta G_{23}^{\neq}}{RT}\right) + \frac{k_{21}}{k_{30}+k_{34}}\exp\left(\frac{\Delta G_{23}}{RT}\right)\right]^{-1}, \qquad (12)$$

The relation between the free energy of activation $\Delta G_{23}^{\neq}$ and the change in free energy of electron transfer ΔG_{23} is established by means of the correlation[299]

$$\Delta G_{23}^{\neq} = \frac{\Delta G_{23}}{2} + \left[\left(\frac{\Delta G_{23}}{2}\right)^2 + (\Delta G_{23}^{\neq}(0))^2\right]^{1/2} \qquad (13)$$

in which $\Delta G_{23}^{\neq}(0)$ is the free energy of activation when $\Delta G_{23} = 0$. It follows from (12) and (13) that k_q is independent of ΔG_{23} for exothermic reactions ($\Delta G_{23} < 0$), whereas $\ln k_q$ decreases linearly with increase in ΔG_{23} for endothermic reactions ($\Delta G_{23} > 0$). Good agreement has been found between the experimental and the calculated dependence of k_q on ΔG_{23} over wide ranges of the latter for Thionine[185,300], Methylene Blue[189,220], eosin[255], Acridine Orange[194,301] and its 10-methyl derivative[194], and *o*-methylfluorescein methyl ester[185], which confirms the electron-transfer mechanism of quenching of the triplet state.

Electron transfer can occur in both singlet excited and triplet states. With dilute solutions and low concentrations of quenching additives it takes place solely in the triplet state. Evidence of involvement of this state of dye molecules in electron transfer is provided by quenching results and by kinetic analysis of its deactivation and the accumulation of radical-ions (or radicals), which are products of electron transfer[234]. The role of the triplet state has been demonstrated in one-electron oxidation and reduction reactions of Thionine[171,182-184,215,248], Methylene Blue[185-189,218,295], fluorescein[59,204,297], eosin[204,246], erythrosin[59], Safranine T,[172] phenosafranine[172], Oxonine[296], Acridine Orange[192-194], Rhodamine 6G,[116,123,124] polymethine dyes[131,181], etc.

Electron transfer can occur not only as a result of diffusional encounters of a triplet dye molecule with an unexcited partner molecule (exogenous electron donor or acceptor) but also in the absence of foreign donor or acceptor molecules. In the latter case the partner may be another triplet molecule [triplet–triplet interactions (8)] or an unexcited molecule of the same dye [triplet–singlet interaction (11)]. Electron transfer by reactions (8) and (11) has been established for fluorescein[204], eosin[204], Rhodamine 6G,[116,123,124], and thiazine[187,204] and polymethine[131,222] dyes.

3. Other Reactions

Proton phototransfer involving dye molecules has been considerably less studied. The acid–base properties in both ground and electronically excited states are characterised by the protolytic equilibrium exponent pK. Values of $pK_{S_0,T}$ in ground and triplet states are usually determined from the pH dependence of the $S_0 \to S_n$ and $T_1 \to T_n$ absorption spectra, and those of pK_{S*} in the singlet excited state from that of the fluorescence spectra. Determinations of pK_{S_0}, pK_{S*}, and pK_T have been made on xanthen, thiazine, azine, and other dyes[59]. It follows from Table 9 that excitation of thiazine dye molecules to a triplet state appreciably facilitates proton addition to the cation with formation of the protonated form. Data on acid–base equilibrium constants for thiazine dyes and the relative proton affinities estimated therefrom for molecules in ground and triplet states are confirmed by calculations of the distribution of electron density for Thionine in ground, singlet excited, and triplet states[302]. These show that the basic properties of Thionine are significantly stronger in the triplet than in the unexcited state, with the singlet excited state occupying an intermediate position. A similar situation is found for other thiazine dyes.

Table 9. Acid–base equilibrium constants of dye molecules in ground, singlet excited, and triplet states[59].

Dye	pK_{S_0}	pK_{S*}	pK_T
Fluorescein (monoanion)	6.7	—	7.0
Eosin (monoanion)	4.3	—	<4
Erythrosin (monoanion)	5	—	5
Thionine	−0.33	3.1	6.3
Methylene Blue	<1	—	6.7
Methylene Green	<1	—	7.5
New Methylene Blue	<1	—	7.5
Azure	<1	—	7.7
Safranine T	0.1	—	6
Phenosafranine	0	—	6

A substantial difference between pK_T and pK_{S_0} is observed also with azine dyes (Safranine T, phenosafranine). Their example also reveals a higher basicity of molecules in the triplet state than in the singlet states S_0 and S_1. However, the above rule does not hold for xanthen dye molecules: pK_T and pK_{S_0} have closely similar values (Table 9).

Laser excitation has been used[303] for the direct determination of kinetic parameters of proton transfer involving triplet Thionine. The rate constant is found to be close to the diffusion constant[303,304].

Among little investigated but important photoreactions of dyes is photodissociation. It has been shown for leuco-cyanides of triarylmethane dyes (Malachite Green, Brilliant Green) that a coloured form—the dye cation—appears on ultraviolet exposure of solutions in polar media[305,306]. From direct measurements of the rate of formation of the cation of Malachite Green[305] and data on the sensitised population of the triplet level of the leuco-cyanide of Brilliant Green[306] it is concluded that a singlet excited state is involved in photodissociation.

Photodissociation of the *p*-azido-derivative of Malachite Green has been studied in an alcohol–ether matrix at 77 and 300 K.[309] At the latter temperature the quantum efficiency

of the photoelimination of nitrogen increases from 0.001 to 0.1 with change in the exciting wavelength from 600 to below 350 nm. A predissociation mechanism of rupture of the nitrogen–nitrogen bond is regarded as the most probable.

---oOo---

Thus laser techniques have permitted the investigation in dye molecules of many primary photoprocesses lasting as little as 10^{-12} s. The laws of photophysical and primary photochemical reactions established for dyes of various classes are common to many organic compounds and biologically active substances. Research on primary photoprocesses in dye molecules constitutes an important branch of photochemistry–molecular photonics.

Bimetallic Transition Metal Hydride Complexes

G.L.Soloveichik and B.M.Bulychev

The literature data on bimetallic transition metal hydride complexes containing metal-hydrogen bonds and non-transition metal atoms are described systematically and discussed. The principal methods of synthesis of these compounds and ways of stabilising them in the lowest oxidation state by cyclopentadienyl and other electron-donating ligands are considered. The characteristics of the changes in the transition metal-non-transition metal and metal-hydrogen bond types as a function of the electronic configuration and the ligand environment of the metal atoms forming part of the bimetallic hydride complex are noted. The influence of complex formation on the geometrical parameters and spectrochemical characteristics of the metal-hydrogen bond are discussed.
The bibliography includes 191 references.

I. INTRODUCTION

The successful preparation of catalytic systems of the Ziegler–Natta (Z–N) type for the hydrogenation and isomerisation reactions of olefins at the beginning of the 1960s led to a rapid increase in the number of publications, mainly patents, devoted to studies and applications of a wide variety of catalysts and cocatalysts for these reactions. At the present time there is no doubt that the active centres of the catalysts contain metal–hydrogen bonds[1–3]. The individual hydrides of Group VIII metals catalysing the hydrogenation of olefins have been studied in fair detail, particularly the rhodium, iridium, and ruthenium compounds. Their structures and the mechanisms of their hydrogenation have been considered in a number of reviews[4–6].

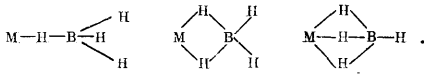
At the same time the reaction mechanism and the structure of the active centres of the classic Z–N system have not so far been finally elucidated.

This is because of the high sensitivity of the systems to oxidation and the consequent considerable scatter and poor reproducibility of the experimental data. Furthermore, several catalytic reactive complexes containing the transition metal (TM) in the lowest oxidation states[3] are as a rule formed in the course of the reaction[7,8].

It has been suggested that the low-valence state is stabilised as a result of the formation of a complex with the cocatalyst—a non-transition metal compound[3,9]. Since usually alkyl or hydride derivatives of aluminium and more rarely lithium alkyls and Grignard reagents are used as the cocatalyst, the active centres in such cases may be bimetallic hydride complexes (BHC) containing both a transition and a non-transition metal.

Complexes of this type have been studied in solutions. A comparatively small number of BHC have been isolated in a pure state and investigated. However, on the basis of the available data one cannot reach any definite conclusion concerning the relation between the structure of the BHC and their catalytic activity because the individual compounds have not as a rule been used in catalytic processes.

In monographs[10] and review articles[4,5] devoted to transition metal hydrides and also the application of the Z–N catalysts in the hydrogenation reactions of unsaturated compounds[2,3] little attention has been devoted to the BHC. Admittedly, recently a detailed review has been published on transition metal hydroborates belonging to the class of BHC.[11] In the present study these comparatively thoroughly investigated compounds will therefore be considered only in relation to the hydroaluminates. It is noteworthy that the M–H–B bridge bond in the transition metal hydroborate is not apparently involved in the catalytic steps and the activity of the compounds $M(BH_4)_nL_m$ or the MX_n–$M'(BH_4)_m$ systems is probably related to the products of their reactions or decomposition with formation of the M–H bond[12].



II. CLASSIFICATION OF BIMETALLIC HYDRIDE COMPLEXES

As regards the nature of the metal–hydrogen bond, BHC can be divided into four main types. In the first three the transition metal is linked to the non-transition metal via a hydrogen atom, while in the fourth there is a direct linkage.

The first type includes ionic or similar "inorganic" transition metal tetrahydroaluminates having the general formula $M(AlH_4)_m$, for example, $Y(AlH_4)_3$ [13] and $Nb_2(AlH_4)_5$.[14] The

tetrahydroaluminate group in these compounds consists of a more or less distorted isolated $[AlH_4]^-$ tetrahedron. This type includes also the ionic complexes of Group VIII metals such as $L_nFe^+[AlH_2X_2]^-$.[15]

An increase in the strength of the M–H bond leads to the formation of covalent three-centre bridge bonds. The most striking representative of the second type of BHC are the thoroughly investigated transition metal tetrahydroborates. All the possible varieties of bridges with one[16], two, and three[11] hydrogen atoms are known for these compounds:

Among the aluminium-containing BHC, compounds are known with both single bridges, such as $[Cp(C_5H_4).TiHAlEt_2]_2$ [17] and $Cp_2Ta(H)_2HAlMe_3$,[18] and double bridges, such as $Cp_2TiH_2AlEt_2$ [19] and $Cp_2NbH_2AlH_2$.[20]

A further increase in the strength of the M–H bond together with a weakening of the H–E bond lead to the formation of ionic compounds of the third type containing a transition metal linked to hydrogen atoms in the anion ($Cp_2TiH_2^-MgHal^+$) [21] or the cation $\{[L_mNiH]^+[AlCl_4]^-\}$.[22]

The fourth type includes complexes containing direct (covalent or donor–acceptor) metal–metal bonds, such as, for example, the "inorganic Grignard reagents" $Cp_2Mo(H).MgBr.2THF$ (THF = tetrahydrofuran) [23] or the adducts of Cp_2MoH_2 with halogenoalanes[24].

Naturally the proposed classification of BHC is fairly arbitrary. The real compounds may contain features of two types [for example, the compounds $M(AlH_4)_n$ have the features of both the first and second types] or may contain different types of bonds [for example, there are both terminal and bridging hydrogen atoms in $Cp_2Zr(H)BH_4$].[25]

III. METHODS OF SYNTHESIS OF BIMETALLIC HYDRIDE COMPLEXES

The sources of hydride hydrogen in the formation of the M–H bond in BHC may be individual hydrides of transition and non-transition metals, molecular hydrogen, alkyl groups, etc. The M–H bonds are then formed directly during the synthesis of the BHC or as a result of the substitution of alkyl groups, halogens, etc. in the bimetallic non-hydride complexes by the hydrido-ligand.

1. Reactions Involving Individual Transition Metal Hydrides

Stable binary transition metal hydrides MH_x, where x is usually 0.5–2, with a "metallic" metal–hydrogen bond are inactive in the synthesis of BHC. A directed two- or three-centre M–H bond is formed only in compounds containing stabilising electron-donating ligands (phosphines, carbon monoxide, cyclopentadienyl groups, etc.). However, since phosphine and carbonyl complexes are as a rule coordination-saturated, they are involved only extremely rarely in complex formation reactions with transition metal compounds (see Section VII below).

The cyclopentadienyl compounds Cp_2MH_n, whose interaction with Lewis acids leads to the formation of BHC of various types, constitute an exception.

The reaction of $(Cp_2ZrH_2)_x$ with $AlMe_3$ in benzene gives rise to a compound having the composition $(Cp_2ZrH_2.AlMe_3)_2$,[26] which may contain terminal Al–H bonds in the anion $[AlHMe_3]^-$:

$$(Cp_2ZrH_2)_x + xAlMe_3 \xrightarrow{20°,C_6H_6} \frac{x}{2}[Cp_2ZrH(HAlMe_3)]_2 \quad (1)$$

BHC containing the M–H–Al bridge bond have been obtained by an analogous reaction with participation of Cp_2TaH_3:[8]

$$Cp_2TaH_3 + AlEt_3 \xrightarrow{20°,C_6H_6} Cp_2Ta(H_2)HAlEt_3 \quad (2)$$

Direct M–E bonds are formed on interaction of Lewis acids with compounds of Group VI and VII metals having an unshared pair: Eqn.(3),[27] Eqn.(4),[24–28] and Eqn.(5).[29,30] The reduction of the metal to a lower oxidation state does not then take place:

$$Cp_2WH_2 + AlEt_3 \xrightarrow{20°,C_6H_6} Cp_2W(H)_2AlEt_3 \quad (3)$$

$$Cp_2ReH + BF_3 \xrightarrow{33°,\text{several days}} Cp_2Re(H)BF_3 \quad (4)$$

$$Cp_2MoH_2 + ZnCl_2 \rightarrow Cp_2MoH_2ZnCl_2 \quad (5)$$

Sometimes reactions of this kind are accompanied by the elimination of a hydrocarbon:

$$Cp_2MoH_2 + \text{iso-PrMgBr} \xrightarrow[-C_6H_6]{Et_2O} [Cp_2Mo(H)Mg(\text{iso-Pr})(\mu\text{-}Br)_2Mg(OEt_2)]_2 \xrightarrow{THF} 2Cp_2Mo(H)MgBr\cdot 2THF + 2\ \text{iso-PrMgBr} \quad (6)$$

A non-transition metal hydride may be involved in such reactions: Eqn.(7),[31] Eqn(8),[32] and Eqn.(9):[24]

$$(Cp_2TiH)_2 + B_2H_6 \xrightarrow{0°,THF} Cp_2TiBH_4 \quad (7)$$

$$(Cp_2ZrH_2)_x + x\,HAl(\text{iso-Bu})_2 \xrightarrow{20°,C_6H_6} Cp_2Zr(H)_2HAl(\text{iso-Bu})_2 \quad (8)$$

$$Cp_2MoH_2 + AlH_{3-n}Cl_n \xrightarrow{C_6H_6} Cp_2Mo(H)_2AlH_{3-n}Cl_n \quad (9)$$

2. Reactions with Participation of Non-Transition Metal Hydrides

This constitutes the most effective and promising methods of synthesis of BHC. Non-transition metal (mainly aluminium) hydrides undergo exchange reactions and addition reactions with transition metal salts or complexes to form BHC. With a rare exception[33], these reactions are carried out in ethyl ether or THF. Transition metals in the highest oxidation states are then usually reduced, for example, Fe^{III} is reduced to Fe^{II} [Eqn.(10)],[34] Ta(V) is reduced to Ta(IV) [Eqn.(11)],[35] and Ti(IV) is reduced to Ti(III) [Eqn.(12)]:[36,37]

$$FeCl_3 + LiAlH_4 \xrightarrow{-80°,Et_2O} Fe(AlH_4)_2\downarrow + H_2 + AlH_3 + LiCl\downarrow \quad (10)$$

$$TaBr_5 + LiAlH_4 \xrightarrow{-80°,Et_2O} [TaH_n(AlH_4)_{4-n}\cdot n\,AlH_3]\downarrow + H_2 + AlH_3 + LiBr \quad (11)$$

$$Cp_2TiCl_2 + LiAlH_4 \xrightarrow{20°,Et_2O} Cp_2TiAlH_4 + AlH_3 + LiCl \quad (12)$$

When the salts of transition metals in the lowest oxidation states are employed, the usual exchange reactions [reactions (13) [38] and (14) [39,40]] take place:

$$Li_2MnBr_4 + LiAlH_4 \xrightarrow{-80°,Et_2O} Mn(AlH_4)_2 + LiBr \quad (13)$$

$$(Cp_2TiCl)_2 + NaAlH_4 \xrightarrow{20°,THF} Cp_2TiH_2AlH_2 + NaCl \quad (14)$$

The 1,1′-methylenebiscyclopentadienyltitanium hydroaluminate $CH_2(C_5H_4)_2TiH_2AlH_2$, which is almost insoluble in ethyl ether and THF, has been obtained in a pure state only via the exchange reaction[41]

$$CH_2(C_5H_4)_2TiBH_4 + LiAlH_4 \rightarrow CH_2(C_5H_4)_2TiAlH_4\downarrow + LiBH_4 \quad (15)$$

Other hydroaluminates, insoluble or only slightly soluble in organic solvents, for example, $Zr(AlH_4)_4$, can also be obtained by this method.

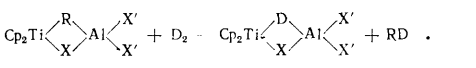
The interaction of $Al(iso\text{-}Bu)_3$ and $AlH(iso\text{-}Bu)_2$ with Cp_2TiCl_2 or Cp_2VCl_2 leads to the formation of $Cp_2TiHClAl(iso\text{-}Bu)_2$ and $Cp_2TiH_2Al(iso\text{-}Bu)_2$ even for the ratios Al/Ti = 2 : 1 and 3 : 1:[42–47]

$$Cp_2Ti(V)Cl_2 + HAl(iso\text{-}Bu)_2 \rightarrow Cp_2Ti(V)H_2Al(iso\text{-}Bu)_2 + H_2 + ClAl(iso\text{-}Bu)_2. \quad (16)$$

It has been suggested that these compounds are formed either owing to the presence of admixtures of hydrides in AlR_3 or as a result of the disproportionation reaction

$$Al(C_2H_5)_3 \rightleftarrows AlH(C_2H_5)_2 + C_2H_4 \quad . \quad (17)$$

$Cp_2TiH_2AlMe_2$ has been obtained in a different way, via the reaction of $(Cp_2TiCl)_2$ with $NaAlH_2Me_2$ in ArH.[48,49]



Reactions involving the addition of the aluminium hydride derivatives $AlH_nX_{3-n}.mL$, where $n = 1–3$, $m = 0$ or 1, and X = Hal, to biscyclopentadienyltitanium chloride, which are carried out in inert and, more rarely, solvating solvents, have been described[36,45,50,51]:

$$Cp_2TiX + AlH_nX_{3-n}\cdot L \xrightarrow{Et_2O,\ ArH} Cp_2TiH_nAlX_{4-n}\cdot L \quad . \quad (18)$$

These BHC are formed as intermediates in the interaction of Cp_2TiCl_2 with $LiAlH_4$.[37]

3. Activation of Molecular Hydrogen

It has been noted in a number of studies that the formation reactions of BHC in catalytic systems based on Cp_2TiCl_2 and alkali metal[52] and aluminium[44] alkyls are appreciably accelerated in a hydrogen atmosphere. The role of molecular hydrogen as a source of hydride hydrogen has been confirmed by experiments with deuterium[44] and in the hydrogenation of olefins in the presence of the $(Cp_2TiCl)_2$–$LiAlH_4$ system[53]:

$$+ RD \quad . \quad (19)$$

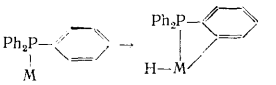
Reaction (19) can be regarded as the model reaction of the regeneration of the active centre in the catalytic hydrogenation of olefins.

4. The Cleavage of the Metal–Alkyl Bond

The cleavage of the M–Alk bond with formation of the M–H bond and an olefin [reaction (20)] has, with rare exceptions [for example, reactions (21) and (22)], no preparative value in the synthesis of BHC:[54,55]

$$M\text{–}Alk \rightleftarrows M\text{–}H + \text{olefin}; \quad (20)$$

$$(C_{10}H_8)(CpTiH)_2 + Al(C_2H_5)_3 \xrightarrow{C_6H_6} (C_{10}H_8)[CpTi(H)H_2Al(C_2H_5)_2TiCp] + C_2H_4; \quad (21)$$



$$Cp_2TiCl_2 + C_2H_5MgCl \rightarrow Cp_2TiH_2^-MgCl^+ + MgCl_2 + C_2H_4 + C_2H_6 \quad . \quad (22)$$

However, reaction (20) plays an important role in catalytic isomerisation, polymerisation, and possibly metathetical reactions of olefins[56,57]. The alkyl groups are the source of hydride hydrogen in these substances[56]. It has been suggested that the $Cp_2TiH_2^-$ anion is formed via a stage involving the formation of the unstable anion $Cp_2TiR_2^-$.[58] Indeed a complex having the composition $[Na(THF)_x]^+[Cp_2TiR_2]^-$ has been obtained recently by the reduction of Cp_2TiR_2 with sodium naphthalide in THF.[59]

5. Transfer of Hydrogen from the Ligands to the Metal Atom

When Cp_2TiCl_2 is reduced with metallic magnesium in the presence of MgI_2 and also by lithium and sodium naphthalides in ether or THF, BHC with a double hydrogen bridge are formed[60–62]. The source of hydride hydrogen is in this instance the C_5H_5 group[61]. The formation of Cp_2TiH_2MgCl has also been noted in the reduction of Cp_2TiCl_2 with metallic magnesium in ethyl ether[58]. The reaction with metallic sodium in THF in the presence of $AlCl_3$ leads to the formation of $Cp_2TiH_2AlCl_2$ in 60% yield[63]. The same compound is formed on reduction of Cp_2TiCl_2 with metallic aluminium in THF.[64]

The reaction involving hydrogen transfer from the ligand is known to lead to the formation of "metallocene" hydrides {the "stable titanocene" $(C_{10}H_8)(CpTiH)_2$ and the "niobocene" $[Cp(C_5H_4)NbH]_2$} and also BHC such as $[Co(C_5H_4)TlHAlEt_2]_2$[17] and $(C_{10}H_8)[(C_5H_4)TiHAlEt_2]_2$.[54] These reactions proceed as a rule at elevated temperatures and lead to the formation of compounds with σ-π-linked cyclopentadienyl rings. The reaction mechanism is in all cases obscure. An analogous reaction has been described for arylphosphine complexes of transition metals[65]:

(23)

6. Reactions with Participation of the Solvent

In the extensive reduction of transition metals the source of hydrogen used for the formation of the M–H bond may also be the solvent, for example, ethyl ether in the reduction of Cp_2TiCl_2 with metallic magnesium [reaction (24)] and in the interaction of LiC_2H_5 with "metastable titanocene" [reaction (25)]:[58]

$$2Cp_2TiCl_2 + 5Mg + 4(C_2H_5)_2O \rightarrow 2Cp_2TiH_2^-MgCl^+ + MgCl_2 + 2Mg(OC_2H_5)_2 + 4C_2H_4; \quad (24)$$

$$(Cp_2Ti)_2 + 4C_2H_5Li + 2(C_2H_5)_2O \rightarrow 2Cp_2TiH_2^-Li^+ + 2LiOC_2H_5 + 5C_2H_4 + C_2H_6. \quad (25)$$

Nor can one rule out the possibility that the solvent "supplies" the hydride hydrogen in the synthesis of $Cp_2TiH_2AlCl_2$ from Cp_2TiCl_2 and Na in the presence of $AlCl_3$ in THF.[63]

IV. TRANSITION METAL TETRAHYDROALUMINATES

Transition metal tetrahydroaluminates without stabilising organic ligands, having the general formula $M(AlH_4)_n$, are known for Cu, Ag, Ce, V, Ti, Zr, Nb, Ta, Mn, Fe, and possibly Co.

The general method of synthesis of these compounds involves the exchange reactions of the salts with $LiAlH_4$ in ethyl ether at low temperatures (between −110° and −80 °C). Since the $M(AlH_4)_n$ are insoluble in ethyl ether, like LiCl, the products investigated in the early studies were mixtures of two substances[66,67]. Pure transition metal tetrahydroaluminates were obtained using MBr_n or the bromide complexes Li_mMBr_{n+m}:

$$Li_mMBr_{n+m} + n\,LiAlH_4 \xrightarrow{\sim 110°,\ Et_2O} M(AlH_4)_n + (n+m)\,LiBr \quad . \quad (26)$$

In certain cases the starting materials were perchlorates[68,69] and tetrahydroborates[70]. Transition metal tetrahydroaluminates are substances insoluble in organic solvents, whose colour varies from yellow to red-brown with increase of the number of *d* electrons. The $M(AlH_4)_n$ are as a rule readily

oxidised and on contact with air ignite spontaneously [$Y(AlH_4)_3$ [13] and tantalum[35] and niobium[14] compounds]. They are vigorously hydrolysed by water with evolution of the entire hydride hydrogen. An exception is the tantalum tetrahydroaluminate $TaH_2(AlH_4)_2$, in which the metal–hydrogen bonds are retained after hydrolysis according to infrared spectroscopy data [ν(M–H) = 1650 cm^{-1}]. The residual hydrogen (three atoms per tantalum atom) is evolved on treatment with alkali[35].

When $NbCl_5$ is made to react with an excess of $LiAlH_4$, tetrahydroaluminates in different oxidation states are formed depending on the temperature. The yellow complex $LiNb_2 \cdot (AlH_4)_7$ was obtained in the range between −120° and −70 °C, being converted into the dark-red $LiNb_2(AlH_4)_5$ on raising the temperature[67]. The reaction at room temperature leads to the formation of the brown niobium(II) complex $LiNb \cdot (AlH_4)_3$.[67,71] Analogous binary compounds are formed also with LiCl.[72] A complex formation reaction with LiBr has likewise been noted for yttrium and ytterbium tetrahydroaluminates[72].

Zirconium tetrahydroaluminate apparently forms anionic complexes too, since a white deposit of this compound dissolves in an excess of zirconium(IV) tetrahydroborate[70]. However, it is noteworthy that the complex-forming atom in this instance can also be the aluminium atom which is known to form complex anions, for example, $[Al(BH_4)_4]^-$.[73]

The decomposition of the majority of the tetrahydroaluminates $M(AlH_4)_n$ begins already at −50° and below. This accounts for the virtually complete lack of data concerning the synthesis of the tetrahydroaluminates of metals such as V, Cr, Au, and Ag as well as data on the chemical and physicochemical properties of other compounds. The relatively stable tantalum and yttrium tetrahydroaluminates are an exception. The thermal stability increases consistently on passing from the First to the Third Series of transition elements (within a single Group), for example, Ti < Zr and Nb < Ta, although there is no explicit regularity on passing from Group to Group. One can only note that the stability of the tetrahydroaluminates varies in parallel with the thermal stability of the corresponding tetrahydroborates and that its maximum corresponds to Groups I–V.

The use of differential thermal analysis (DTA) in combination with gas-volumetric measurements made it possible to determine the mechanisms of the thermolysis of certain tetrahydroaluminates. The instances described in the literature can be combined in four groups.

1. The reduction of the metal to the lowest oxidation states with retention of the metal–tetrahydroaluminate group bond:

$$M^{n}(AlH_4)_n \rightarrow M^{n-m}(AlH_4)_{n-m} + m\,AlH_3 + \frac{m}{2}\,H_2 \quad (27)$$

Examples are provided by the reduction of Nb(V) to Nb(III) [14] or Nb(II).[71] It has also been suggested that the synthesis of iron(II) and tantalum(IV) tetrahydroaluminates proceeds via a stage involving the formation of the unstable $Fe(AlH_4)_3$ [34] and $Ta(AlH_4)_5$.[35,66,67]

2. The decomposition to the free metal and aluminium hydride is most frequently encountered:

$$M(AlH_4)_n \rightarrow M + n\,AlH_3 + \frac{n}{2}\,H_2 \quad (28)$$

Certain niobium tetrahydroaluminates[67,71], $AgAlH_4$,[68] $Fe(AlH_4)_2$,[74] and possibly $Zr(AlH_4)_4$ [70] decompose in this way.

3. The decomposition to the free transition metal and aluminium has been observed for $Ce(AlH_4)_3$,[75] $Mn(AlH_4)_2$, $Co(AlH_4)_2$,[38] and $AgAlH_4$.[69] However, it is known that thoroughly dispersed transition metal powders catalyse the decomposition of aluminium hydride:

$$M(AlH_4)_n \rightarrow M + n\,Al + 2n\,H_2 \quad (29)$$

It is therefore extremely likely that reaction (29) proceeds via a stage involving the formation of AlH_3, which is unstable under the given conditions, and is a special case of reaction (28).

4. The decomposition to the transition metal hydride and aluminium hydride, which takes place without a change in the valence state of the transition metal, has been observed for tantalum [Eqn.(30)] [35] and copper[38] tetrahydroaluminates:

$$Ta(AlH_4)_n \rightarrow TaH_2(AlH_4)_2 + 2AlH_3 \quad (30)$$

The individuality of $CuAlH_4$ has been confirmed by the synthesis from it of an Na_3AlH_6 analogue—copper(I) hexahydroaluminate Cu_3AlH_6—by the low-temperature (−40 °C) treatment of the tetrahydroaluminate with THF.[76]

There are no literature data concerning the direct or indirect determination of the structures of transition metal tetrahydroaluminates. The only physicochemical method used in the study of these compounds is infrared spectroscopy, but the data thus obtained are very scanty. This is evidently associated with the considerable difficulties in the low-temperature measurement of the spectrum. The infrared spectra of the transition metal tetrahydroaluminates contain absorption bands in the range 1500–1850 cm^{-1} which can be assigned to the stretching vibrations of the terminal Al–H bonds. The wave numbers ν for these vibrations in $Nb_2(AlH_4)_5$ (1500 cm^{-1}) [72] (1850 cm^{-1}),[67] $Ti(AlH_4)_4$ (1615 cm^{-1}),[77] $TaH_2(AlH_4)_2$ (1600 cm^{-1}), $Fe(AlH_4)_2$ (1690 cm^{-1}), $Y(AlH_4)_3$ (1840 cm^{-1}), and $Yb(AlH_4)_2$ (1800 cm^{-1}) [72] are close to the values of ν(Al–H) for ionic lithium (1780 cm^{-1}), sodium (1680 cm^{-1}), tetramethylammonium (1660 cm^{-1}),[78] and magnesium (1850 cm^{-1}) [79] tetrahydroaluminates.

Bearing in mind the physical and spectroscopic characteristics of the transition metal tetrahydroaluminates $M(AlH_4)_n$, one can assume that, in contrast to the corresponding tetrahydroborates, these are compounds with predominantly ionic M–AlH_4 bonds and slightly distorted tetrahedral anions $[AlH_4]^-$, i.e. apparently have structures similar to those of alkali and alkaline earth metal tetrahydroaluminates.

V. BISCYCLOPENTADIENYL BIMETALLIC HYDRIDE COMPLEXES

The biscyclopentadienyl complexes of transition metals, which can be regarded as products of the addition of transition metal biscyclopentadienyl hydrides[80,81] to Lewis acids or bases are most interesting from the theoretical and practical points of view.

Two types of transition metal biscyclopentadienyl hydride derivatives have been described in the literature: the biscyclopentadienyl hydrides proper with the general formula $(\eta^5\text{-}C_6H_5)_2MH_n$ and the so-called "metallocene hydrides" in which the metal–hydrogen bond is formed as a result of a rearrangement in an unstable "metallocene" Cp_2M with transfer of a hydrogen atom from the Cp ring to the metal atom.

According to quantum-chemical calculations on Cp_2ML_n molecules, where n = 1–3,[82–85] the metal atom in the Cp_2M fragment with inclined rings has three hybrid orbitals, used in the formation of bonds with ligands and located in a plane with yz symmetry.

The 18 electron rule holds for the majority of the compounds investigated[85].

1. Group IVA

BHC of the first three types are known for the elements of the titanium subgroup. The greatest number of compounds have been described for titanium owing to the vigorous

studies of the Cp_2TiCl_2–reductant systems with catalytic activity in the fixation of molecular nitrogen and the polymerisation and hydrogenation of olefins. However, one should note that in the vast majority of cases individual compounds were not isolated and they were identified solely by indirect methods, mainly by EPR. Only recently have studies been published in which these substances and systems have been investigated by other physicochemical methods.

Thus it has been shown[39,40] that the interaction of $(Cp_2TiCl)_2$ with $NaAlH_4$ in THF leads to the formation of Cp_2TiAlH_4 [Eqn.(14)]. Indeed, according to calorimetric titration (CT) data, this reaction proceeds in a single stage, whose heat is 140 kJ mol^{-1}, terminates following the attainment of the ratio Al : Ti = 1 : 1,[86] and differs from the analogous reaction involving $LiBH_4$ [reaction (31)], which leads to the formation of a complex with the ratio B : Ti = 2 : 1:[87]

$$Cp_2TiCl + LiBH_4 \xrightarrow{Et_2O} LiCl + Cp_2TiBH_4 \underset{-LiBH_4}{\overset{LiBH_4}{\rightleftarrows}} Li[Cp_2Ti(BH_4)_2] \quad . \quad (31)$$

However, in a study of the catalytic properties of the $(Cp_2TiHal)_2$–$LiAlH_4$ system[53] it was established that the reaction results also in the formation of a catalytically active unstable BHC having the composition $(Cp_2Ti)_2AlH_4Cl$, which is not manifested on the CT curves.

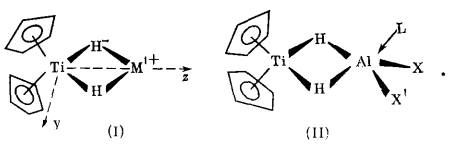
The reaction of $(Cp_2TiCl)_2$ with the chloroalanes AlH_nCl_{3-n} [Eqn.(18)], proceeds according to CT data, with a heat change of 171 kJ mol^{-1} for n = 3 and 92 kJ mol^{-1} for n = 2.[36] In the latter case the reaction proceeds in two stages and terminates for the ratio Al : Ti = 2 : 1 with formation of the unstable complex $Cp_2TiH_2AlCl_2.AlH_2Cl$.[51] The study of the interaction in the $(Cp_2TiCl)_2$–AlH_2Cl system by dielectrometric titration[36,51] showed that $Cp_2TiH_2AlCl(H)$ is formed also via an intermediate stage involving the formation of an unusual conducting compound with the ratio Al : Ti = 1 : 3.

Analogous complexes, also detected by the CT method, exist likewise in the $(Cp_2TiCl)_2$–$AlH_nCl_{3-n}.L$ systems with n = 0 and 1.[88] The heats of reaction (32) are 58.5 kJ mol^{-1} for n = 0 and 44.9 kJ mol^{-1} for n = 1:

$$3Cp_2TiCl + AlH_nCl_{3-n}\cdot L \xrightarrow{C_6H_6} (Cp_2Ti)_3AlH_nCl_{6-n}, \; n = 0, 1 \quad . \quad (32)$$

Since the dipole moments of these complexes are close to zero[88], the latter apparently have symmetrical structures with a hexacoordinate aluminium atom in the centre of an octahedron, i.e. they resemble the structures of the known complexes of Cp_2TiCl with zinc, beryllium[89,90], and manganese[91] chlorides having the composition $(Cp_2Ti)_2M'Cl_4$. The proposed model has been confirmed by EPR [64,88] and infrared spectroscopic[50] data. Although further interaction of $(Cp_2Ti)_3AlH_n.Cl_{6-n}$ (n = 0 and 1) with $AlH_nCl_{3-n}.L$ does take place, it does not entail a heat change[88]. The EPR signal characteristic of the BHC $Cp_2TiH_2AlCl_2$ gradually appears in reaction (32) with an excess of dichloroalane in solution[51,88], i.e. a reaction analogous to reaction (33) takes place[42,43]:

$$Cp_2TiCl_2AlR_2 \underset{-ClAlR_2}{\overset{+HAlR_2}{\rightleftarrows}} Cp_2TiCl(H)AlR \underset{-ClAlR_2}{\overset{+HAlR_2}{\rightleftarrows}} Cp_2TiH_2AlR_2 \quad . \quad (33)$$



Solutions of the BHC Cp_2TiH_2M', where M' = Li, Na, MgHal, or AlX_2 have the intense violet colour characteristic also of other titanium(III) compounds containing two hydrogen bridges in the molecule—$(Cp_2TiH)_2$ [31] and $Cp_2TiH_2BH_2$.[92] In contrast to the halide and alkyl bridges, the hydride bridges are not decomposed by Lewis bases, which indicates their high strength. This is also confirmed by the displacement of the equilibrium in reaction (33) to the right even in the presence of a 50–100-fold excess of AlR_3 [42] and by direct thermochemical measurements.[37,51,86,88] The most informative method for the study of the paramagnetic BHC of titanium(III), vanadium(IV), iron(I), etc. in solution is EPR. The EPR spectra of BHC with the mixed bridges  are doublets as a consequence of the splitting by a single ^1H nucleus (J = 1/2) with a hyperfine coupling constant (HFC) a_H = 3.5–9.1 G (Table 1). The hyperfine structure (HFS) of the spectra of BHC with a double hydrogen bridge is due to the interaction of the unpaired electron with two equivalent hydrogen nuclei, which gives rise to the splitting of the spectral lines into a triplet in which the intensity ratios are 1 : 2 : 1 (observed, for example, in the spectra of magnesium-containing BHC [21,49,52,60,61]), and with the magnetic nucleus of the non-transition metal. The fundamental motif in the EPR spectrum is then a quartet for the lithium- and sodium-containing compounds ($J_{^7Li} = J_{^{23}Na}$ = 3/2) [40,52,58,60,95] and a sextet for the hydroaluminate complexes Cp_2TiH_2AlXX' ($J_{^{27}Al}$ = 5/2). The form of the spectrum is determined by the ratio of the HFC constants a_H and a'_M. In certain cases it is impossible to resolve the HFS of the spectrum despite the presence of hydrogen bridges, established by independent methods, for example, for the BHC with tetrahydroborate groups[53], $CH_2(C_5H_4)_2TiH_2AlH_2$,[41] and $(Cp_2Ti)_2AlH_4Cl$.[99] In the last case this is attributed to an intramolecular exchange interaction[99].

The correctness of the interpretation of the EPR spectrum can be readily (in most cases) checked by substituting the hydride hydrogen by deuterium. An increase in the number of components (J_2D = 1) [21,61] is then observed for the sodium- and magnesium-containing BHC of titanium(III) [for example, when $(C_5H_5)_2TiCl_2$ is replaced by $(C_5D_5)_2TiCl_2$, the reduction with sodionaphthalene gives rise to a 20-component multiplet instead of the 11-component multiplet[61]]. On the other hand, the HFS of Cp_2TiD_2AlXX' due to the nuclei is usually unresolved and the EPR spectrum shows a well-resolved sextet[39,51] (Table 1).

In some cases, it has proved possible to resolve the super-HFS of the EPR spectrum of Cp_2TiH_2M' due to the protons of the C_5H_5 groups (a_{HCp} = 0.2–0.6 G) and also the ^{47}Ti(J = 5/2) and ^{49}Ti(J = 7/2) nuclei, manifested as "satellites" at the edges of the spectrum.

The form and parameters of the EPR spectra of the isotypical BHC in inert and solvating solvents differ only slightly. Since the Lewis base is not removed on crystallisation of the BHC, there is no doubt that the latter are solvated also in solutions. One can therefore postulate that the molecules of the solvating solvent are not linked to the Ti atoms but are coordinated to the Al atom.

It follows from the data presented that all the BHC Cp_2TiH_2M', where M' = Li, Na, MgHal, or AlX_2, have in solution a structure of type (I) and (II) with two bridging H atoms occupying two equivalent orbitals of the Ti atom:

The non-transition metal atoms lie on the z axis of the Cp_2Ti fragment. The question of the orientation of the orbital occupied by the unpaired electron (on the z axis[40] or at right angles to it, as for the orbital with the unshared electron pair[100]) remains open.

Table 1. Parameters of the EPR spectra of bimetallic cyclopentadienyltitanium complexes.

It has also been suggested[63] that the TiH_2Al bridge may be asymmetric, as in the molybdenum complexes $[Cp_2MoH_2CuI]_2$.[101] The greatest strength of the hydride bridges compared with other types of bonding is consistent with the increase of the spin density of the unpaired electron at the aluminium atom in the sequence $Cp_2TiCl_2AlR_2 < Cp_2TiHClAlR_2 < Cp_2TiH_2 \cdot AlR_2$.[43,46,47] The amount of ionic character of the compounds increases in the sequence $M' = AlH_2 < AlCl_2 < MgBr < Li < Na$, which should apparently lead to an increase of the H–Ti–H angle[40].

One must note that the successive replacement of the terminal atoms in $Cp_2TiX_2AlX'_2$ by more electron-accepting ligands leads to a linear increase of the HFC constants a_{Al} and to a decrease of a_H for the BHC, the constants being linked by the simple relations $a_H = a_{Al}$ for $X = X' = H$,[38,39,51] Et,[44] or iso-Bu,[43] $a_H = \frac{2}{3}a_{Al}$ for $X' = X = Me$,[48,49] $a_H = \frac{1}{2}a_{Al}$ for $X = H$ and $X' = Br$,[51] and $a_H = \frac{1}{3}a_{Al}$ for $X = X' = Cl$[49,58,90] or Br.[51] The linear variation of properties such as the dipole moment μ and the standard enthalpy of formation ΔH_f^0 with increasing n was noted previously for $AlH_nCl_{3-n} \cdot L$,[102,103] where $n = 0$ and 3 and $L = NR_3$, Et_2O or THF.

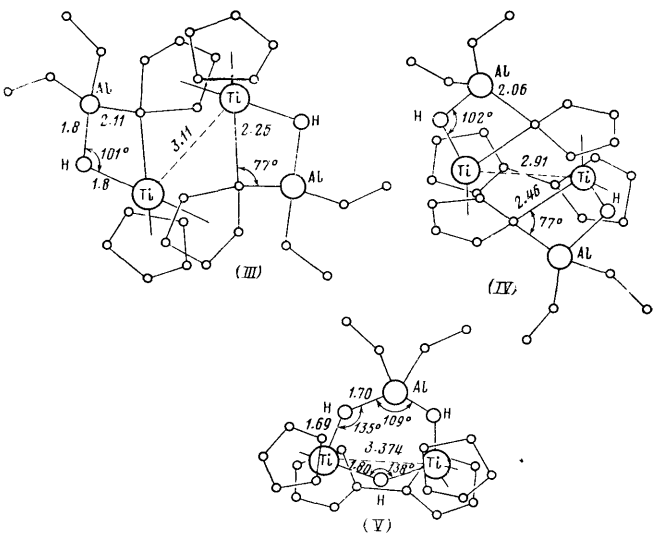
Very few BHC of this type have been isolated in a pure state, although the alkyl derivatives $Cp_2TiX_2AlR_2$, where $X = Cl$ or Me,[104] and the complexes $Cp_2LnR_2AlR_2$ with similar properties, where Ln = Y, Yb, Sc, or Ho, are known[105]. The isolation of $Cp_2TiH_2Al(iso\text{-}Bu)_2$ in the form of a red-violet oily substance[40] has been reported but none of its characteristics are quoted in the above communication.

When an excess of $AlEt_3$ was allowed to act on Cp_2TiCl_2[104,106] or on Cp_2TiPh_2 and Cp_2TiCl,[17] a red diamagnetic substance was obtained, melting without decomposition at 169–191 °C and readily soluble in water and hydrocarbons. It has been established by X-ray diffraction that in this compound the titanium and aluminium atoms are linked by hydrogen bridges and the compound is described by the formula $[Cp(C_5H_4) \cdot TiHAlEt_2]_2$.[17] A further two compounds are formed on

treating the "stable titanocene" with triethylaluminium. BHC with the compositions $[(CpTi)_2H.(H_2AlEt_2)](C_{10}H_8)$ and $[(C_5H_4)TiHAlEt_2]_2(C_{10}H_8)$ crystallise at 20° and 100 °C respectively[54]. Analogous compounds are also formed when $AlEt_3$ is replaced by $AlMe_3$.[107]

"Zirconocene" reacts in a more complex manner and the composition of the products of the addition of $AlEt_3$ to it has not therefore been established[107].

The structures of the BHC considered (Fig.1) are derivatives of two types of structures: the structure of "niobocene" containing π,σ-linked $\eta^5:\eta^1$-C_5H_4 groups (III) and the structure of "titanocene" containing the fulvalene ligand $\eta^5:\eta^5$-$C_{10}H_8$ (V). In the BHC (IV) the features of both types of structures are observed. The close relation between "titanocene" and the BHC obtained from it is also indicated by the finding that they are formed with a high yield on treating compounds (V) with an equivalent of water[54]. The Ti–Ti distance in these compounds (2.91–3.37 Å) is significantly greater than the sum of the covalent radii (2.72 Å), which indicates the absence of a direct metal–metal bond [with the possible exception of compounds (IV)]. Consequently, the titanium in these compounds is in the +3 oxidation state. The diamagnetism of the BHC considered is evidently of the same type as in "titanocene" and its derivatives[108]. The Al–C and Ti–C distances are close to the sums of the covalent radii (1.95 Å and 2.13 Å), i.e. the Ti–C_{ring}–Al bond can apparently be described as a three-centre bond analogous to, for example, the Al–C–Al bond in Al_2Me_6.



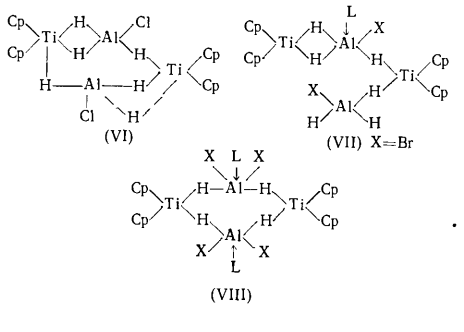


Figure 1. The structures of the bimetallic hydride complexes $[Cp(C_5H_4)TiHAlEt_2]_2$ (III), $(C_{10}H_8)[(C_5H_4)TiHAlEt_2]_2$ (IV), and $(C_{10}H_8)[Cp_2Ti_2(H)(H_2AlEt_2)]$ (V) according to X-ray diffraction data[17,54].

The ^1H NMR data for these compounds agree well with the results of X-ray diffraction analysis (Fig.1). The chemical shift of the protons in the Ti–H–Al bridge is in the range 16.6τ–21.6τ, whereas the chemical shift of the protons in the homonuclear Ti–H–Ti bridge is significantly greater and equal to 31.8τ.[17,54]

The interaction of zinc aryls and alkyls with titanium(IV) biscyclopentadienylalkyls (or the corresponding aryls) and the "metastable titanocene" leads to the formation of the diamagnetic complexes $(C_{10}H_8)(C_5H_4)(C_5H_3R)Ti_2(H)(R')Zn$, where R = H or Ph and R′ = Ph or Me.[109] The presence of the metal–hydrogen bond is confirmed by the formation of HD in the reaction with DCl, although the ν(Ti–H) bands were not observed in the infrared spectra. Structural formulae incorporating bridge or terminal Ti–H and Ti–R bonds and a dicoordinate zinc atom have been proposed for these compounds[109]. We believe that these formulae are unlikely bearing in mind the fact that the compounds are non-solvated. The "stable titanocene", which has two bridging hydrogen atoms[110], decomposes $ZnPh_2$ to metallic zinc and benzene, evidently as a result of the decrease of the stability of the complex on passing from the alkyl hydride to zinc hydride[109].

When the complexes $Cp_2TiAlH_nHal_{4-n}.L$ (n = 2–4, L = NEt_3 or OEt_2) are isolated from solutions, rearrangements take place and are in some cases accompanied by the loss of hydrogen (n = 4).[104] The structure (II) persists apparently only for $Cp_2TiH_2AlHal_2.NEt_3$.[111] The compounds obtained contain 0.5 or 1 (n = 2) mole of a Lewis base per gram atom of titanium and are paramagnetic intensely coloured substances moderately soluble in ethyl ether and benzene and extremely sensitive to oxidation and hydrolysis[111,112]. Infrared spectroscopic study of these compounds revealed the presence of three groups of ν(M–H) absorption bands, one of which was assigned to the vibrations of the terminal Al–H bonds (1750–1900 cm^{-1}) and the other two to vibrations of different types of hydrogen bridges, apparently the double TiH_2Al bridges (1150–1260 cm^{-1}) and the single TiHal bridges (1350–1500 cm^{-1}).[111] The halogen atoms are in all cases terminal[111]. The tendency towards rearrangements diminishes with decrease of n, on replacement of Cl by Br and of OEt_2 by NEt_3, and also on reducing the temperature of the synthesis. $Cp_2TiAlH_3.0.5OEt_2$ apparently contains $\eta^1:\eta^5$-C_5H_4 groups and its structure resembles structure (III). The structural formulae (VI)–(VIII) have been proposed[111] for the compounds $Cp_2TiAlH_3.OEt_2$ and $Cp_2TiAlH_2Hal.OEt_2$ on the basis of EPR and infrared spectroscopic data[51,111], as well as CT data[37,51]. The authors[111] do not rule out the possibility of the dimerisation of compounds (VI)–(VIII) via bridging $\eta^5:\eta^1$-C_5H_4 groups, as in the study of Tebbe and Guggenberger[17]:

On crystallisation of $Cp_2TiAlH_nCl_{4-n}.L$ with n = 0 and 1, only Ti : Al = 3 : 1 complexes with chloride bridges mixed with the solvates $AlCl_3.L$ (n = 0) or complexes of unknown composition with AlHCl.L (n = 1) were detected in the solid phase by infrared spectroscopy[89]. The compounds $Cp_2TiH_{2-n}.AlX_{2+n}$ are formed as intermediates also in the more complex reaction involving the reduction of Cp_2TiCl_2 by lithium tetrahydroaluminate[37]. According to EPR and CT data, the reaction then proceeds via a series of intermediate stages[34–37]

and terminates with formation of the unstable compound $Cp_2TiH_2.AlH_2.AlH_3$, which decomposes in accordance with Eqn.(38):

$$Cp_2TiCl_2 + LiAlH_4 \rightarrow [Cp_2TiH_2AlCl_2 \cdot Cp_2TiCl] + LiCl + H_2 \; ; \quad (34)$$

$$Cp_2TiH_2AlCl_2Cp_2TiCl + LiAlH_4 \rightarrow [Cp_2TiH_2AlH(Cl)]_2 \; ; \quad (35)$$

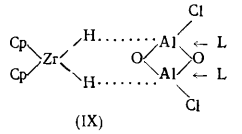
$$[Cp_2TiH_2AlHCl]_2 + LiAlH_4 \rightarrow [Cp_2TiH_2]_2\,Al_2H_3Cl + AlH_3 + LiCl \; ; \quad (36)$$

$$[Cp_2TiH_2]_2\,Al_2H_3Cl + AlH_3 + LiAlH_4 \rightarrow 2Cp_2TiH_2AlH_2 \cdot AlH_3 + LiCl \; ; \quad (37)$$

$$Cp_2TiH_2AlH_2 \cdot AlH_3 \rightarrow Cp_2TiH_2AlH_2 + Al + \tfrac{3}{2}H_2 \; . \quad (38)$$

Isagawa et al.[113] believe that the final product of these reactions is the complex $Cp_2Ti(AlH_3)_2$, but they do not take into account the instability of the entire system with respect to decomposition reaction and $Cp_2Ti(AlH_3)_2$ can therefore be regarded also as a partly decomposed form of $Cp_2TiH_2AlH_2.AlH_3$.

In contrast to the titanium compounds, the BHC of zirconium(IV) and hafnium(IV) are not reduced by complex hydrides, so that only BHC containing the metal in the +4 oxidation state (mainly zirconium) have been described in the literature, although one can assume that in the future zirconium compounds analogous to the titanium(III) BHC examined above will be obtained (for example, on the basis of "zirconocene" isomorphous with the stable "titanocene"), namely $(C_{10}H_8)(CpTiH)_2$.[114]



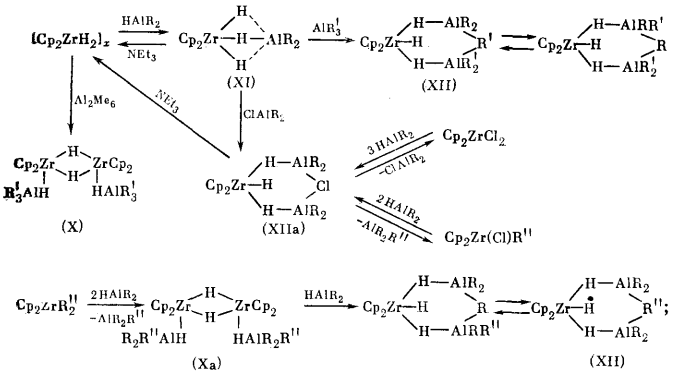
Biscyclopentadienylzirconium(IV) hydride tetrahydroaluminate has been obtained by the exchange reaction[115]

$$[Cp_2Zr(H)Cl]_x + x\,LiAlH_4 \xrightarrow{THF,\,C_6H_6} [Cp_2Zr(H)AlH_4]_x + x\,LiCl \; . \quad (39)$$

The solubility of the compound thus obtained is higher than that of the polymeric zirconium hydride complexes $[Cp_2Zr(H)X]_x$, where X = Cl or Me,[115] which may indicate a lower degree of association of the tetrahydroaluminate.

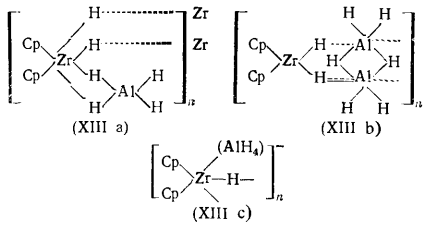
The reaction of $LiAlH_4$ with $(Cp_2ZrCl)_2O$ [Eqn.(40)], which terminates with the formation of the polymeric $(Cp_2ZrCl)_2O$,[115] may proceed via a stage involving the formation of the unstable complex (IX), decomposing on crystallisation:

$$(Cp_2ZrCl)_2O + LiAlH_4 \rightarrow 2/x\,[Cp_2ZrH_2]_x + LiCl + 1/2\,\{AlOCl\} \; ; \quad (40)$$



(IX)

The interaction of $(Cp_2ZrH_2)_x$ with Al_2Me_6 [26] leads to the formation of the molecular dimeric adduct $[Cp_2ZrH_2AlMe_3]_2$, which is fairly soluble in benzene. The adducts of $[Cp_2Zr.(H)Cl]_x$ with Al_2Me_6 are much less stable[26].



Several BHC of zirconium have been isolated in the form of pale-blue or pale-violet oily substances on treatment of biscyclopentadienyl compounds of zirconium(IV) with di-isobutylaluminium hydride[32]. The BHC of zirconium obtained were identified and their structure postulated on the basis of measurements of molecular weights and NMR data (Scheme 1):[26,32,115]

Scheme 1

R = t-Bu, R′ = Me, R″ = neohexyl.

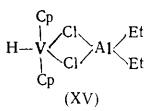
Two models of the structure of biscyclopentadienylzirconium hydride tetrahydroaluminate have been proposed[115]: the bridged tetrahydroaluminate (XIIIa) (bidentate AlH_4 group) and the adduct with aluminium hydride (XIIIb):

(XIII a) (XIII b)

(XIII c)

The model (XIIIb) is inconsistent with the frequency ν(Al–H) (1790, 1700 cm^{-1}), which is characteristic of a tetracoordinate and not hexacoordinate aluminium atom[116]. Bearing in mind the method of synthesis of $[Cp_2Zr(H)AlH_4]_x$,[115] one can postulate that the polymeric skeleton of $[Cp_2Zr(H)Cl]_x$ persists [the frequencies ν(Zr–H–Zr) are respectively 1425 and 1390 cm^{-1}]. Since the bidentate AlH_4 group is a four-electron ligand like the BH_4 group[117], the zirconium atom in compound (XIIIa) has formally a 20-electron configuration. On the other hand, its tetrahydroborate analogue $Cp_2Zr(H)BH_4$ is monomeric and has an 18-electron configuration[25]. Although the 20-electron complexes of zirconium and hafnium are known, for example, $Cp_2Hf(BH_4)_2$ [118] and Cp_3ZrH,[119] it is also necessary to consider the 18-electron analogue (XIIIa) with a monodentate or ionic AlH_4 group, as in model (XIIIc). This is also indicated by the absence of the ν(Zr–H–Al) absorption bands in the range 1100–1500 cm^{-1},[26,115] which are characteristic covalent titanium tetrahydroaluminates[111].

The signal of the methyl protons in $(Cp_2ZrH_2AlMe_3)_2$ (0.41τ) is displaced downfield relative to Al_2Me_6 as a consequence of the formation of the Al–H bond[26]. The frequency of ν(Al–H) in the spectrum of the BHC (1780 cm^{-1}) corresponds to a tetracoordinate Al atom[116] and H in the terminal position. NMR data show that the CH_3 groups are also terminal[26]. Consequently, the zirconium atoms in both $[Cp_2Zr(H)AlH_4]_x$ and $[Cp_2ZrH_2AlMe_3]_2$ are linked by two hydride bridges and each is joined to the $AlHMe_3$ or $(AlH_4)^-$ group by an ionic bond, as in (XIVb).



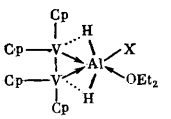
The butyl complex $(Cp_2ZrH_2Al(iso\text{-}Bu)_2C_6H_{13})_2$ evidently has a structure analogous to (Xa).

The chemical shift of the hydride protons in compounds (X)–(XII) (10.3τ–11.2τ for Zr–H and 12.0τ–12.9τ for Zr–H–Al) hardly changes, i.e. the nature of the Zr–Al bond is probably the same in all the complexes. The NMR data are satisfactorily consistent with the structural formulae (X) to (XII),[32] (Scheme 1) in which the zirconium atoms are coordination saturated.

The zirconium tetrahydroaluminate complexes are thermally unstable and decompose at room temperature[26,32], while $[Cp_2Zr(H)AlH_4]_x$ decompose above 60 °C in solution[107]. The main gaseous decomposition product of the latter is hydrogen, while in the case of $[Cp_2Zr(D)AlD_4]_x$ almost pure HD is formed[107]. According to infrared spectroscopic data, the Zr–H–Zr linkages are then retained, while the ν(Al–H) vibrations disappear. Consequently the tetrahydroaluminate and cyclopentadienyl groups participate in the elimination of H_2 and an $Al–C_5H_4$ σ-bond is then formed, as in the case of $[Cp(C_5H_4)TiHAlEt_2]_2$.[17] Hydrogen and methane are evolved on decomposition of $[Cp_2ZrH_2AlMe_3]_2$, but the Cp groups are apparently not involved[26].

2. Group VA

The biscyclopentadienyl BHC of vanadium are almost unknown. In the study of the $Cp_2VCl_2–AlH(iso\text{-}Bu)_2$ system by EPR, it was noted that, after the introduction of a small amount of oxygen to the system containing reduced vanadium, an eight-component EPR signal appears with broadened (ΔH = 30 G) lines[44]. The authors explained the broadening by the presence of an unresolved HFS associated with the splitting by two protons and the aluminium atom (as in the $Cp_2TiH_2AlR_2$ complexes[40,42–44]) and the EPR signal is attributed to the complex $Cp_2VH_2Al(iso\text{-}Bu)_2$, i.e. one can assume that BHC having the compositions $Cp_2VHClAl(iso\text{-}Bu)_2$ and $Cp_2VH_2Al(iso\text{-}Bu)_2$ with structure (I) are formed in the $Cp_2VCl_2–AlH(iso\text{-}Bu)_2$ system. BHC are also formed in the $Cp_2VCl_2–Et_2AlCl$ system in an amount of approximately 10% of the initial Cp_2VCl_2 concentration. Differentiation of the EPR spectrum showed that each line of the octet ($J_{^{51}V}$ = 7/2) with a_V = 41.1 G is split into a doublet (a = 5.7 G), which may be due to the interaction of the unpaired electron of vanadium(IV) with a proton[98]. The following structural formula was attributed[88] to the BHC observed on the basis of data for the anisotropic splitting:



(XV)

The physical and physicochemical properties of biscyclopentadienylvanadium(III) tetrahydroborate Cp_2VBH_4 are very close to those of Cp_2TiBH_4, although the former compound is less stable[121]. The tetrahydroaluminate complexes obtained by the reaction of Cp_2VCl with lithium tetrahydroaluminate in diethyl ether are also less stable in solution[122]. The reaction proceeds in two stages: the first stage proceeds up to the ratio $Cp_2VCl : LiAlH_4 = 2 : 1$ and involves a heat change of 126.7 kJ mol^{-1}, which is close to the heat of the analogous reaction involving Cp_2TiCl (140 kJ mol^{-1}),[37] while the second stage, leading to the complete removal of chlorine from solution, is not accompanied by the evolution of heat.

The evolution of 0.5 mole of H_2 per mole of Cp_2VCl in the first stage indicates the reduction of vanadium(III) to vanadium(II). It has been suggested[122] that the vanadocene formed gives rise to a diamagnetic complex with monochloroalane:

$$2Cp_2VCl + LiAlH_4 \xrightarrow{Et_2O} (Cp_2V)_2AlH_2Cl + LiCl + H_2 . \quad (41)$$

According to infrared spectroscopic data, this substance contains bridging hydrogen atoms and a terminal chlorine atom [$\nu(Al–Cl_{term})$ = 440 cm^{-1}] and has the composition $(Cp_2V)_2AlH_2Cl.OEt_2$. The structural formula (XVIa) has been proposed for this substance. The unstable complex (XVIb) with aluminium hydride is apparently formed in the second stage of the reaction:

(XVII)

(a) X=Cl;

(b) X=H.

A series of BHC are known for niobium(III) and niobium(IV), these being formed on interaction of aluminium, gallium, and zinc alkyls with biscyclopentadienylniobium and biscyclopentadienyltantalum hydrides[123]:

$$Cp_2TaH_3 + MEt_n \underset{20°}{\overset{C_6H_6}{\rightleftharpoons}} Cp_2Ta(H)_2HMEt_n,\ M=Al,\ Ga,\ Zn,\ Cd ; \quad (42)$$

$$Cp_2NbH_3 + AlEt_3 \underset{-50°}{\overset{C_6H_5CH_3}{\rightleftharpoons}} Cp_2Nb(H)_2HAlEt_3 ; \quad (43)$$

$$Cp_2Nb(L)H + AlEt_3 \xrightarrow{20°,\ C_6H_6} Cp_2Nb(L)HAlEt_3,\ L=C_2H_4,\ CO,\ PMe_3 ; \quad (44)$$

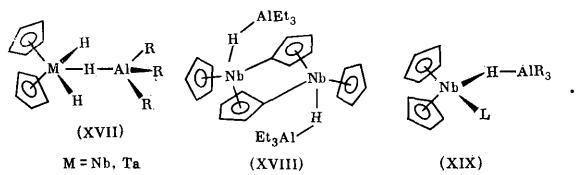
$$[Cp(C_5H_4)NbH]_2 + 2AlEt_3 \xrightarrow{20°,C_6H_6} [Cp(C_5H_4)NbHAlEt_3]_2 . \quad (45)$$

The BHC have been isolated in a crystalline form. They are readily soluble in benzene, which made it possible to demonstrate the correspondence between the molecular weights and the proposed formulae, decompose in the light at room temperature, and are stable in the dark in the course of a week. The complexes with gallium, zinc, and cadmium alkyls are less stable and exist in equilibrium with the initial compounds only in solution; on crystallisation, equilibrium (42) shifts to the left. In contrast to tantalum, niobium(V) is reduced by metal alkyls and the adducts $Cp_2NbH_3.MEt_n$ have been detected by NMR only between −40° and −50 °C, splitting off alkanes on raising the temperature and giving rise to the BHC of niobium(III):[56]

$$Cp_2Nb(H_2)HAlEt_3 \xrightarrow{C_6H_6} Cp_2NbH_2AlEt_2 + C_2H_6 ; \quad (46)$$

$$2Cp_2Nb(H_2)HZnEt_2 \xrightarrow{C_6H_6} (Cp_2NbH_2)_2Zn + ZnEt_2 + C_2H_6 . \quad (47)$$

The BHC of this type are also formed on interaction of Cp_2NbCl_2 with $Na(Li)AlH_4$ and its derivatives $NaAlH_2X_2$ (X = Et or $OCH_2CH_2OCH_3$) [reaction (47)].[20] The reaction may proceed via a stage involving the disproportionation of the unstable niobium(IV) hydride[20]:



$$Cp_2NbCl_2 + NaAlH_2X_2 \xrightarrow{C_6H_6,\ THF} \begin{matrix} Cp_2NbH_2 + HAlX_2 + NaCl \\ \downarrow \qquad\quad \downarrow \\ Cp_2NbH_3\ \ Cp_2NbH \quad AlHX_2 \end{matrix} \rightarrow Cp_2NbH_2AlX_2 . \quad (48)$$

The interaction between Cp_2TaCl_2 and $NaAlH_2(OCH_2CH_2.OCH_3)_2$ proceeds analogously[124]. Although the intermediates have not been isolated, hydrolysis results, as in the study of Labinger and Quai Sam Wong,[20] in a satisfactory yield of Cp_2TaH_3.[124] In contrast to the tetrahydroborate Cp_2NbBH_4, the compounds $Cp_2NbH_2AlX_2$ do not react with

PR_3, CO, and C_2H_4 and do not form the complexes $Cp_2Nb.(H)L$.[20] The signal due to the hydride hydrogen atoms gradually appears in the benzene solution of $Cp_2NbD_2AlD_2$, which has been explained by the H/D exchange between the C_5H_5 rings and the AlD_4^- group. Only the bridging hydrogen atoms are exchanged and in THF the exchange is retarded evidently owing to the blocking of the coordination site by the solvent.

Treatment of a solution of Cp_2TaH_3 in toluene with LiBu [124] give rise to an insoluble orange substance containing, together with Ta–H bonds, apparently also Ta–Li bonds and having chemical properties resembling those of the BHC $[Cp_2Mo(H)Li]_4$ (see subsection 3 below).

The coordination of a non-transition metal alkyl or hydride leads to an upfield shift of the hydride proton signal by 3–7 p.p.m. and to a bathochromic shift of ν(M–H) (Table 2). In the case of the coordination-saturated trihydrides Cp_2MH_3 the shift is selective, i.e. mainly the signal of the central proton A (in the AB_2 system) is displaced[20,124]. Consequently, the structure of the BCH with the composition $Cp_2MH_3.AlR_3$ can be described by the structural formula (XVII) incorporating a single M–H–Al hydrogen bridge. Single hydrogen bridges are evidently present also in the BHC based on the "niobocene" (XVIII) and the hydrides $Cp_2Nb(L)H$ (XIX),[123] whereas structures with double hydrogen bridges of type (I) are more likely in the complexes of Cp_2NbH with aluminium and zinc hydrides[20,123]. This has been confirmed by NMR data, which have been satisfactorily interpreted on the hypothesis that the non-transition metal atom is located on the symmetry axis *z* of the Cp_2NbH_2 fragment[123].

(XVII) M = Nb, Ta (XVIII) (XIX)

Table 2. ^1H NMR and infrared spectroscopic data for the biscyclopentadienyl BHC of vanadium, niobium, and tantalum.

The reduction of "niobocene" with sodium naphthalide yielded the red anionic complex $Na_2[CpNb(\eta^1:\eta^5\text{-}C_5H_4)H]_2$.[128] An analogous complex containing cyclopentadienyl rings linked via a siloxane bridge has been obtained by the reduction of $[C_5H_4Si(Me_2)OSi(Me_2)C_5H_4]NbCl_2$ with sodium in toluene and subsequent treatment with diethyl ether. According to X-ray diffraction data, it retains the geometry of "niobocene" with isolated sodium ions solvated by two diethyl ether molecules. The Nb–Nb distance then increases (to 3.93 Å) and the Nb–H distance decreases together with an increase of the ν(Nb–H) frequency.

In the BHC of niobium(III) having an unshared electron pair, there is a possibility of the formation, in addition to the Nb–H–Al bridge bonds, also of a direct Nb → Al donor–acceptor bond. Indeed, according to the X-ray diffraction data for the unusual BHC $Cp_2Nb(CO)HZn(BH_4)_2.0.5C_6H_6$, obtained in accordance with Eqn.(4),[120,125,129] the niobium atom in this compound is linked to the electron-deficient molecule of zinc tetrahydroborate via both the Zn–H–Nb hydrogen bridge and the direct Nb–Zn bond (the Nb–Zn distance is close to the estimated sum of the covalent radii, namely 2.7 Å) (Fig.2). The stretching vibration frequency of the metal–hydrogen bond in compound (XX) undergoes a bathochromic shift on complex formation by ~350 cm^{-1}:[125]

$$NbCl_5 + CpNa + Zn \xrightarrow{THF,\,CO} \{Cp_2Nb(CO)ZnCl_2\} \xrightarrow{NaBH_4} Cp_2Nb(CO)HZn(BH_4)_2 \quad (49)$$

(XX)

An analogous complex containing niobium and iron and having the composition $Cp_2Nb(CO)HFe(CO)_4$ (XXI) has been obtained on treatment of Cp_2NbH_3 with $Fe(CO)_5$.[130] In view of the short metal–hydrogen bond distances (Fig.2), the authors postulate the presence of the Nb–H–Fe linkages and not of the direct Nb–Fe bond. The similarity of the spectroscopic characteristics of the Nb–H bond in $Cp_2Nb(CO)HFe(CO)_4$ to the analogous parameters in the monomeric $Cp_2Nb(CO)H$ (Table 2) and also the application of the 18 electron rule indicate a low probability of the existence of the Nb–H–Fe bridge. A terminal Nb–H bond has been postulated in the complex $Cp_2Nb(H)(\eta\text{-}C_5H_4)Fe(CO)_2$.[127]

(XX) (XXI)

Figure 2. The molecular structures of $Cp_2Nb(CO)HZn(BH_4)_2$ (XX) [129] and $Cp_2Nb(CO)HFe(CO)_4$ (XXI).[130]

3. Groups VIA and VII

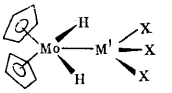
As a consequence of the filling of all the unoccupied orbitals by the unshared electron pairs on formation of the metal–hydrogen bond, the biscyclopentadienyl derivatives of Group VIA (Mo, W) and VIIA (Te, Re) metal hydrides are bases and readily form 1 : 1 adducts with Lewis acids (H^+, boron and aluminium alkyl and halides, transition metal salts, etc.).

The adducts of magnesium and transition metal compounds with the halides of boron (diborane and BMe_3 do not react) and aluminium are almost insoluble in diethyl ether and aromatic hydrocarbons. The complexes with transition metals are

soluble in THF, dimethyl sulphoxide (DMSO), dimethylformamide (DMF), and pyridine[30] and those with aluminium alkyls are soluble also in aromatic hydrocarbons[27,82,131]. According to cryoscopic data, the latter are monomeric in solution[27]. As in the protonation reaction[126,132], Cp_2ReH combines with only one molecule of the Lewis acid[28,133].

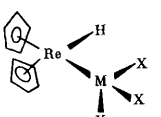
The unstable adduct $Cp_2WH_2.AlH_3$ is apparently formed on interaction of Cp_2WH_2 and aluminium hydride[27], but all attempts to isolate it as well as the complex $Cp_2WH_2.AlHMe_2$ were unsuccessful. The reaction does not proceed at all with gallium hydride, although $GaMe_3$ gives rise to an unstable adduct[131].

The more stable complexes of Cp_2MoH_2 with aluminium halides and dihalogenoalanes have been obtained by the reaction[24]



$$Cp_2MoH_2 + AlHal_{3-n}H_n \cdot OEt_2 \rightleftarrows Cp_2MoH_2 \cdot AlHal_{3-n}H_n + Et_2O,\ n = 0, 1. \quad (50)$$

Reaction (50) has been investigated in solvents with different solvating capacities and it has been concluded that the basicity of Cp_2MoH_2 exceeds only slightly that of diethyl ether[24]. The earlier view that the basicities of Cp_2MoH_2 and pyridine are comparable[82] is apparently wrong.



The equilibrium in the reaction of Cp_2MH_2 with transition metal compounds is fully displaced to the right, which can be accounted for either by the greater acidity of these compounds or by the formation of a different type of bond between the components.

These adducts as a rule crystallise from solutions in strongly solvated solvents in the form of the monosolvates $Cp_2MH_2.M'X_n.L$.[29,30,134–136]

The spectroscopic characteristics of the M–H bonds in the adducts $Cp_2MH_2.M'X_n$ are presented in Table 3. It follows from these data that the parameters of the metal–hydrogen bond hardly change on formation of adducts with compounds of Group IIIA elements. The chemical shift of the methyl protons (there is a downfield shift[26]), in $Cp_2MH_2.AlMe_3$ and the frequencies ν(B–Hal) in the complexes with $BHal_3$ correspond to tetracoordinate aluminium and boron atoms[27,28]. Hence it follows that in the adducts obtained the transition metal has two terminal hydrogen atoms and is linked to the non-transition element (B and Al) by a direct donor–acceptor bond (BHC of the fourth type):

(XXIIa)

(XXIIb)

A bathochromic shift of ν(Al–H) has been observed for the complexes of Cp_2MoH_2 with dihalogenoalanes[24] (Table 3) and is apparently associated either with a change in the C.N. of aluminium to 5 (the halogen bridge bond) or, what is more likely, with a significant decrease of the strength of the Al–H bond.

The adducts of $Cp_2Mo(W)H_2$ with aluminium alkyls are thermally unstable and gradually decompose in solution with liberation of alkanes and precipitation of solid products. As was to be expected, tungsten compounds are more stable than molybdenum compounds and the methyl complexes are more stable than the ethyl complexes[132].

The decomposition of $Cp_2WH_2.AlMe_3$ can proceed simultaneously via two pathways: the elimination of hydrogen from the Cp group formation of an Al–C σ-bond, and the elimination of the hydride hydrogen atom from tungsten with formation of a direct W–Al bond[132]. These reactions are common to strong alkylating agents—aluminium and lithium alkyls and Grignard reagents.

When the reaction between Cp_2MoH_2 and Al_2Me_6 is carried out in toluene at 80 °C, the orange crystals of the compound $C_{25}H_{35}Al_3Mo_2$ (XXIIIa) are formed[137]. Cp_2WH_2 reacts similarly, giving rise to the yellow crystals of $C_{25}H_{35}Al_3W_2$, which, however, is not isomorphous with the molybdenum compound[138]. Prolonged refluxing of the reagents makes it possible to obtain the yellow crystals of the compound $C_{26}H_{34}Al_4Mo_2$ (XXIIIb) (Scheme 2)[137].

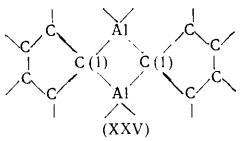
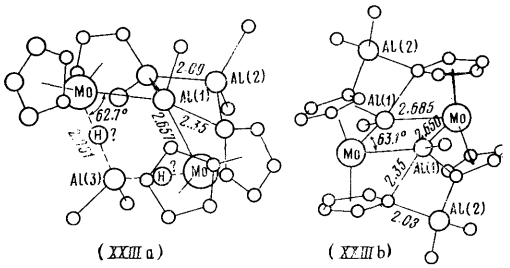
*ν(Al–H) = 1910 cm^{-1}. **ν(Al–H) = 1890 cm^{-1}. ***Solution in DMF.



The structure of both molybdenum complexes was established by X-ray diffraction (Fig.3).[139,140] Although it was not possible to establish the positions of the hydrogen atoms, the larger Mo–Al distance (2.95–3.00 Å) compared with the Mo–Al distance in the "non-hydride" component of the molecule (2.65 Å) and the presence of an absorption band at 1825 cm^{-1} in the infrared spectrum enabled the authors[137,139,140] to postulate that the hydrogen atoms are located between the Mo and Al(3) atoms [formula (XXIIIa)], which are thus linked by hydrogen bridges. However, ν(M–H) is closer to ν(Mo–H) in Cp_2MoH_2 (1853 cm^{-1}) than to ν(Al–H) (1750

cm^{-1}) [116] and is not characteristic of bridging hydrogen atoms. One can therefore assume that terminal hydrogen atoms linked to molybdenum are present in the $C_{25}H_{35}Al_3Mo_2$ structure. The Mo–Mo distance (4.75 Å) is entirely sufficient to accommodate two hydrogen atoms [formula (XXIV)].

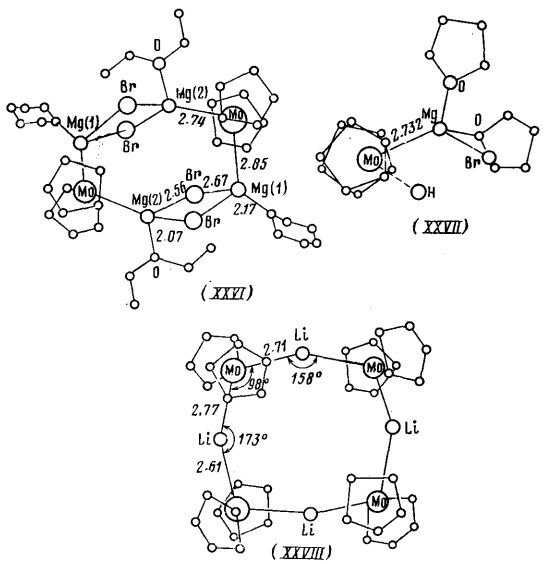


(XXIV)

It is of interest that the cyclopentadienyl group C_5H_4 is tridentate, as in aluminium titanium hydrides[17,54], forming, apart from the σ-bond with the transition metal atom, also a four-centre σ-bond with two aluminium atoms [formula (XXV)].

(XXV)

All the aluminium atoms and the C(1) carbon atom are then in one plane[139,140]. An analogous type of bond has been observed in the ferrocenylalanes $Me_2Al(\mu\text{-}Cl)(\mu\text{-}\eta^5\text{-}C_5H_4Fe\text{-}\eta^5\text{-}C_5H_5)AlMe_2$.[141,142]

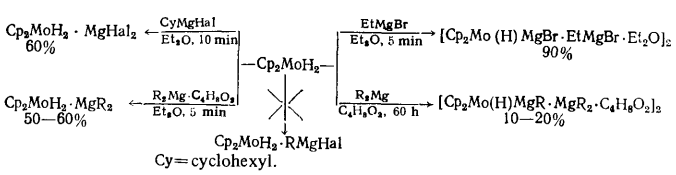


(XXIII a) (XXIII b)

Figure 3. The structures of the $C_{25}H_{35}Al_3Mo_2$ (XIIIa) and $C_{26}H_{34}Al_4Mo_2$ (XXIIIb) molecules according to X-ray diffraction data[139,140].

When solutions of $Cp_2MoH_2(Cp_2WH_2)$ interact with an excess of a Grignard reagent RMgX in ether, yellow crystals of $[Cp_2Mo(H)Mg(R)\text{–}\mu\text{-}X_2Mg(OEt_2)]_2$ (XXVI) are deposited[138,143,144]. An X-ray diffraction study has been made of the compound with R = cyclohexyl [144] (Fig.4). The positions of the hydride hydrogen atoms have not been established. The infrared spectrum of the compound contains absorption bands at 1740 and 1720 cm^{-1}, which are displaced to 1260 cm^{-1} on deuteration. It has been suggested that the terminal hydrogen atoms are in the Mg_aMoMg_b plane, i.e. as in the complex with trimethylaluminium[73], and do not form a bond with the Mg atom. All three orbitals of Cp_2Mo are used up in the formation of bonds with hydrogen and two magnesium atoms (the length of the covalent Mo–Mg bond is shorter by ~0.1 Å than the coordinate bond)[144].

A Lewis base stronger than Cp_2MoH_2, for example, THF, displaces it from the complex with RMgX. Thus, when the BHC $[Cp_2Mo(H)Hg(Br)\mu\text{-}Br_2Mg(OEt_2)]_2$ was dissolved in THF, a red solution was formed, from which the monomeric BCH $Cp_2Mo(H)MgBr.2C_4H_8O$ (XXVII) was isolated[23,145,146]. X-Ray diffraction study of this compound demonstrated the presence of a direct Mo–Mg bond (Fig.4). The magnesium atom is solvated by two THF molecules and has C.N. = 4. The hydride hydrogen atoms are not localised, but ν(Mo–H) = 1850 cm^{-1} is very close to ν(Mo–H) for Cp_2MoH_2 (1853 cm^{-1}).[23] It has been suggested[108] that analogous compounds are formed on interaction of Cp_2MH_2 with RMgX in proportions of 1 : 1. According to Aripovskii et al.[143], the interaction of Cp_2MH_2 with Grignard reagents can proceed via three pathways (Scheme 3), depending on the conditions, with formation of solvated or non-solvated substances, but never leads to the formation of the adducts $Cp_2MH_2.RMgX$. The reaction of Cp_2MH_2 with BeX_2 in ether is significantly reversible.



(XXVI) (XXVII) (XXVIII)

Figure 4. The molecular structures of $[Cp_2Mo(H)Mg(C_6H_{11}).(\mu\text{-}Br)_2Mg(OEt_2)]_2$ (XXVI),[144] $Cp_2Mo(H)MgBr.2C_4H_8O$ (XXVII),[23,145] and $[Cp_2Mo(H)Li]_4$ (XXVIII).[148]

Treatment of $Cp_2Mo(W)H_2$ with butyl-lithium in toluene at 50 °C gives rise to the yellow-orange crystals of $[Cp_2Mo(W).(H)Li]_4$ (XXVIII).[147]

Scheme 3

Cy = cyclohexyl.

It was established by X-ray diffraction that complex (XXVIII) is tetrameric and that association takes place via lithium bridges (Fig.4). The Li–Mo–Li angle (97–98°) is unduly large and suggests that hydrogen atoms are present in its bisector plane[148].

The fulvalene complex $[CpMo(H)]_2(\mu\text{-}C_{10}H_8)$ reacts analogously with LiBu, forming the lithium derivative $[CpMo(Li)]_2(\mu\text{-}C_{10}H_8)$, whose properties are similar to those of $[Cp_2Mo.(H)Li]_4$.[149] Like the magnesium derivatives, the compounds

$[(Cp_2Mo(W)(H)Li]_4$ are powerful nucleophiles whose properties are similar to those of organolithium compounds[147]. When they interact with $R_3M'Hal$ (M' = Ge or Sn; R = Me or Et), the BHC $Cp_2Mo(W)(H)M'R_3$, with a direct M–M' bond, are formed[150].

The compound Cp_2MH_2 react with ZnR_2 (R = Et or Bu) to form the polymeric complexes $[(Cp_2M)_2Zn]_n$ without M–H bonds[140]. Like all the BHC of molybdenum and tungsten with direct M–M' bonds, they regenerate the initial dihydride on hydrolysis[138,147,149].

A characteristic feature of the structures of the compounds formed by Cp_2MH_2 with compounds of non-transition Group IIIA and in certain cases Group IIA metals is the formation of a direct M–M' bond and the absence of hydrogen bridge bonds. The situation changes significantly on passing to Lewis acids formed by heavy transition metals.

Weakly soluble or insoluble adducts of Cp_2MH_2 with Zn, Cu, Ag, Co, Fe, Mo, and Rh compounds have been obtained in DMF, THF, diethyl ether, and benzene[29,30,134–136]. The reaction with strong bases results as a rule in the formation of the solvated complexes $Cp_2MH_2.M'Hal_{2-n}.L$ (n = 0 or 1); non-solvated substances crystallise from diethyl ether and benzene.

Table 3 shows that the formation of complexes by Cp_2MH_2 with the transition metal and zinc compounds investigated leads to a significant bathochromic shift of the ν(M–H) band (50–250 cm^{-1} and in the compounds with AgCl and $MoOCl_3$ not less than 350 cm^{-1}, since these bands are then masked by the bands of the solvents and the Cp rings) and its splitting into the ν_s and ν_{as} components[29,135], while τM–H is displaced upfield [$\Delta\tau_{M-H}$ = +5.5–+5.8 p.p.m. for $Rh(RPh)_3$].[136] This is undoubtedly characteristic of the formation of hydrogen bridge bonds analogous to the M–H–B bonds in transition metal hydroborates[11].

Table 4. Structural characteristics of the adducts of Cp_2MH_2 with transition metal and zinc compounds.

$Cp_2WH_2 \cdot Rh(PPh_3)_2$	—	—	—	—	—	2.16	—	[136]

X-Ray diffraction study of the compounds $Cp_2WH_2Rh(PPh)_3$,[136] $Cp_2MoH_2ZnBr_2.DMF$,[134] $[Cp_2MoH_2CuI]_2$,[101] $Cp_2MoH_2FeI_2.THF$,[151] and $[(Cp_2MoH_2)Cu].CuCl_2$ [152] confirmed the conclusions reached in other investigations[29,30,135] concerning the presence in these compounds of the bridge bonds

M' and, in contrast to the "classical" symmetrical bridge[11], in the last four compounds asymmetric hydrogen bridges were discovered (Table 4 and Fig. 5; the coordinates of the hydrogen atom were not determined by Alcock et al.[136], while Grotty et al.[134] determined them with a large error).

The question of the degree of involvement of the d^2 electrons of the Mo and W atoms in the formation of a bond with the M' atoms remains open. On the basis of the theoretical model of Alcock and Green[85,86], some investigators[101,151,152] suggest that not only the interatomic distance but also the H(1)MH(2) angle is a measure of the degree of direct M–M' bonding. In compounds with an angle H(1)MH(2) > 90° (A), a direct intermetallic bond is formed preferentially (adducts with halogenoalanes). When the H(1)MH(2) angle is 80–90° (B) and for the corresponding interatomic distance, both a donor–acceptor bond and a hydrogen bridge bond can be formed, whereas in the case of an H(1)MH(2) angle less than 80° (C) the hydrogen bridge bond makes the main contribution to the bonding of the components and the complexes formed are of the chelate type (Cp_2MH_2 is a bidentate ligand) in which the d^2 electrons of the M atom occupy a non-bonding orbital. There is no doubt that the extreme cases are unlikely. Most probably both types of bond obtain to some extent in the compounds considered:

A B

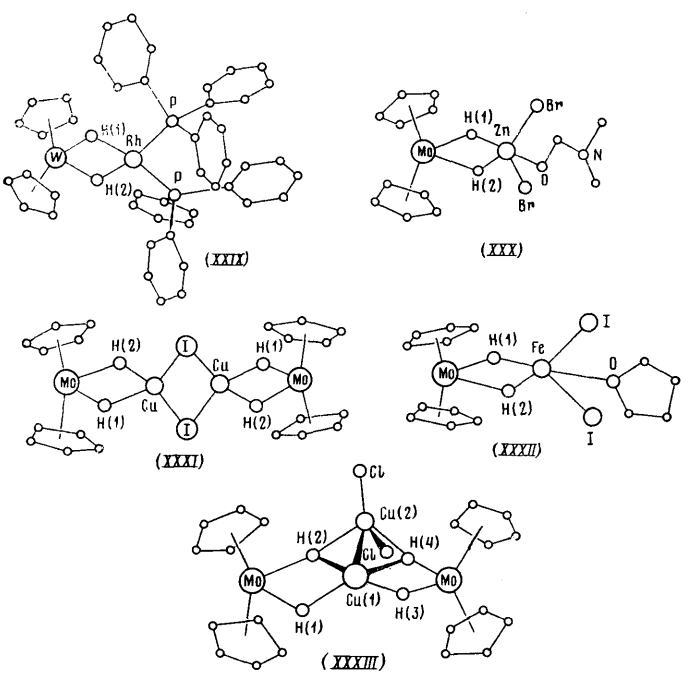

Figure 5. The molecular structures of $Cp_2MoH_2Rh(PPh_3)_2$ (XXIX),[136] $Cp_2MoH_2ZnBr_2.DMF$ (XXX),[134] $[Cp_2MoH_2CuI]_2$ (XXXI),[101] $Cp_2MoH_2FeI_2.C_4H_8O$ (XXXII),[151] and $[(Cp_2MoH_2)_2.Cu]CuCl_2$ (XXXIII).[152]

VI. MONO- AND TRIS-CYCLOPENTADIENYL BIMETALLIC HYDRIDE COMPLEXES

The introduction of even one π-C_5H_5 group into the coordination sphere of a transition metal atom increases significantly the stability of hydride compounds. The monocyclopentadienyl BHC have apparently a structure similar to that

of the biscyclopentadienyl complexes, although their stability is lower.

When $CpTiCl_3$ is reduced with metallic magnesium in the presence of MgI_2, the EPR spectrum exhibits a triplet with the intensity ratios 1 : 2 : 1, analogous to the signal of the compound $Cp_2Ti\begin{smallmatrix}H\\ \diagup\ \diagdown\\ H\end{smallmatrix}MgI$ [60] and apparently corresponding to the BHC $Cp(Cl)TiH_2^-MgI^+$. As in the case of the biscyclopentadienyl complex, the source of the hydride hydrogen is the Cp rings, since the EPR signal does not appear when $CpTiCl_3$ is replaced by $(C_5Me_5)TiCl_3$.[60]

The possibility of obtaining monocyclopentadienyltitanium BHC stable under ordinary conditions has been confirmed by the results of the calorimetric titration of $CpTiCl_3$ with lithium tetrahydroaluminate in diethyl ether: the reaction proceeds via the same stages as that involving Cp_2TiCl_2 and the enthalpy changes are similar[37]. It is of interest that the stage involving the substitution of the last chlorine atom by a hydrogen atom is not accompanied by an enthalpy change in this instance, as in the case of $(Cp_2V)_2ClAlH_2$.[122] The final reaction product is the complex $CpTi(AlH_4)_2.AlH_3$, which is extremely unstable and decomposes after 10–20 min with the complete evolution of hydrogen.

In the study of the polymerisation of ethylene in the presence of the Cp_4Zr–$AlEt_3$ system, the BHC (XXXV), stabilised by three C_5H_5 groups, was isolated[153]:

$$Cp_4Zr \xrightarrow[-C_2H_4]{AlEt_3} Cp_3ZrEt \xrightarrow[-C_2H_6]{AlEt_3} Cp_3ZrCH_2AlEt_2 \xrightarrow[-C_2H_4]{AlEt_3} Cp_3ZrCH_2CH\begin{smallmatrix}AlEt_2\\ \diagdown\\ AlEt_2\end{smallmatrix}$$

$$Cp_3ZrH\cdot Al(Et)CH{=}CH_2 \rightleftarrows (XXXIV) \rightleftarrows Cp_3ZrH + {}^1/_2(AlEt_3)_2. \qquad (51)$$

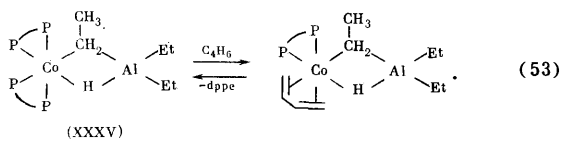
The formula $Cp_3Zr{-}H{-}AlEt_3$ (XXXIV) was proposed on the basis of the chemical properties and preliminary X-ray diffraction data (Zr–Al = 3.66 Å). It may be that similar BHC are also formed in the Cp_2ZrX_2–$AlEt_3$ system[154,155].

Triscyclopentadienyluranium(IV) forms bimetallic complexes in solution with alkyl groups and halogen bridges of the type $Cp_3U\begin{smallmatrix}R\\ \diagdown\\ Al\\ \diagup\\ U\\ \diagdown\\ R\end{smallmatrix}R$,[156] but the BHC could not be isolated in a pure state owing to the rapid reduction of uranium(IV) to uranium(III).[157]

VII. BIMETALLIC TRANSITION METAL HYDRIDE COMPLEXES STABILISED BY OTHER ELECTRON-DONATING LIGANDS

Apart from the fairly numerous and comparatively thoroughly investigated biscyclopentadienyl BHC, there are extremely few data on BHC stabilised by other electron-donating ligands such as alkyl groups, olefins, and phosphorus- and oxygen-containing Lewis bases. The conclusion concerning the structure of the majority of the complexes formed under these conditions is exceptionally tentative and we shall therefore consider only briefly the available literature data on this question.

Thus the stabilisation of the transition metal hydride complexes has been noted in complex multicomponent catalytic systems of the Ziegler–Natta type, where the stabilisers are solvents, the substrate, and non-transition metal compounds.



Although the majority of the transition metal hydrides obtained at the present time contain organophosphorus ligands, the BHC stabilised by phosphines or phosphites are almost unknown. The only reliably characterised BHC of this group is the compound $\{Ta[H_2Al(OC_2H_4OMe)_2](dmpe)_2\}$, where dmpe = bisdimethylphosphinoethane $Me_2PCH_2CH_2PMe_2$ obtained by reaction (52).[158] The complex is a dimer linked by Al–O–Al bridges:

$$TaCl_2(dmpe)_2 + NaAlH_2(OC_2H_4OMe)_2 \xrightarrow{Et_2O} [Ta\{H_2Al(OC_2H_4OMe)_2\}(dmpe)_2]_2 + NaCl + H_2 + AlH(OC_2H_4OMe)_2, \qquad (52)$$

The P_4TaAl atomic group is a distorted square pyramid (as a consequence of the formation of the TaH_2Al bridge, the angle between the normal to the P_4 plane and the Ta–H bond is 16°). The H atoms are not localised but the infrared spectrum shows two equally intense bands at 1605 and 1640 cm^{-1}, which the authors attribute to the presence of two bridging hydrogen atoms.

A series of BHC have been obtained in Ziegler–Natta systems modified by phosphines. BHC having the composition $[Fe(dppe)_2]^+[AlH_2R_2]^-$ are formed in the $Fe(acac)_3$–$AlEt_3$–dppe system, where dppe = bisdiphenylphosphinoethane $Ph_2PCH_2CH_2PPh_2$ and acac = acetylacetone[15]. In contrast to the complex $[Fe(dppe)_2]^+[AlCl_2R_2]^-$, which has a similar composition, this compound does not decompose on treatment with diethyl ether[15], which indicates a more complex Fe–AlH_2R_2 interaction than was suggested on the basis of the ionic mechanism.

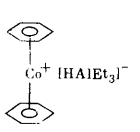
The codimerisation of ethylene and butadiene in the presence of $CoCl_2$–$AlEt_3$–dppe is believed to proceed in the presence of complex (XXXV), which readily splits off phosphines[159]:

(XXXV) (53)

The BHC having the general formula $[HNiL_n]^+AlX_4^-$ are formed in the NiX_2–$AlR_3(AlX_3')PR_3'$ systems, which are active in the dimerisation of olefins[22,160–162]. The non-transition metal compound plays the role of the Lewis acid and can be replaced by, for example, $TiCl_4$.[22]

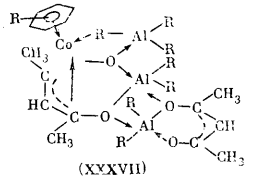
The proposed structure of the BHC has been confirmed by specific synthesis from $HNiCl(PPr_3)_2$ and $AlCl_3$ [in this process $\nu(Ni{-}H_{ter})$ = 1937 cm^{-1} shifts slightly towards longer wavelengths[160]] and also from $Ni(dppe)_2$ and $HAlCl_4$.[163]. It is noteworthy that $\nu(Ni{-}H)$ = 1949 cm^{-1} and τ_{Ni-H} = 23 for the complex with dppe hardly change when the $AlCl_4^-$ anion is replaced by BF_4^-.[163] The isolation of the stable (up to 125 °C) BHC having the composition $Cp_2FeH^+AlCl_4^-$ has also been reported[164]. Only the BHC containing nickel(II) are active in the $NiCl_2$ + $AlEt_3$ + PR_3 system.[161,162] The formation of BHC has also been postulated in the $CoCl_2$–RMgCl–dppe system[165].

In the fixation of nitrogen in the presence of the $TiCl_3.(VCl_3)$–Mg–THF system, the nitride complex $[MNMg_2Cl_2.THF]$ is formed and reacts with H_2 in the presence of Mg to form the BHC $[TiH_2NMg_3Cl_{1.5}.(THF)_x]$.[166,167] The reduction of VCl_3 with magnesium in THF in an argon atmosphere gives rise to a BHC having a similar composition, namely $[VHMg_2.Cl_{1.5}(THF)_x]$, while reduction in an H_2 atmosphere results in the formation of $[VH_2MgCl(THF)_2](THF)_2$.[167,168] The $\nu(M{-}H)$ absorption band has not been observed in the infrared spectra of the two complexes[166]. Analogous BHC are apparently formed also in the MX_n–Mg systems for compounds of other transition metals[168]. These compounds catalyse the hydrogenation of olefins. It is of interest that the introduction of aluminium chloride into the VCl_3–Mg system up to the ratio Al : V = 1 : 1 increases the rate of hydrogenation[167], which is believed to be due to the substitution of Mg by aluminium in the BHC.



BHC containing a Group VIII metal and magnesium are formed in Ziegler–Natta systems with Grignard reagents. Thus the $FeCl_3$–PhMgBr system absorbs hydrogen, which is attributed to the formation of BHC of the second type[169]. Subsequently the complex $FeH_2MgX_4(THF)_8$ was isolated in a pure state in the form of a yellow crystalline substance[170]:

$$FeCl_3 + 7PhMgBr + 6H_2 \xrightarrow{THF} \tfrac{1}{2}\,Ph{-}Ph + 3MgX_2 + 6C_6H_6 + FeH_6Mg_4X_4(THF)_8. \quad (54)$$



The existence of the catalytically active BHC with Co–H–Al bridge bonds and stabilised by THF has been postulated in the $CoCl_2$–$NaAlH_2(OMe)_2$ system prepared in an H_2 atmosphere[171].

A complex dihydride, active in the hydrogenation of olefins, is formed in the cobalt(nickel, iron) stearate–RMgX systems in diethyl ether; it is believed to be stabilised by the products of the interaction of the stearate and a Grignard reagent[172,173].

The interaction in cobalt chelates–AlR_3(LiR, RMgX) systems gives rise to a series of cobalt(I) and zerovalent cobalt complexes stabilised by aromatic hydrocarbons and transition metal compounds[174,175]. The formation of the BHC (XXXVI) [174] and of the alkyl complex (XXXVII),[175] which in the course of hydrogenation apparently gives rise to compounds (XL), has been postulated:

(XXXVI)

(XXXVII)

An unusual BHC, stabilised by an olefin and THF and having the composition $(COD)_{1.5}NiLi_2H_2(THF)_x$ (COD = cyclo-octadiene) has been obtained in accordance with Eqn. (55). The complex reacts with CO, liberating cyclo-octadiene but not H_2.[176] As regards chemical properties, it behaves as a lithium hydride transferring agent, its reaction with $AlEt_2$, for example, yielding $Li[AlHEt_3]$, but, in contrast to pure LiH, it reacts with olefins, forming lithium alkyls:

$$(COD)_2Ni + 2Li \xrightarrow{THF,\ -30^\circ} (COD)_2NiLi_2(THF) \xrightarrow{+H_2,\ -60^\circ} (COD)_{1.5}NiH_2Li_2(THF)_x. \quad (55)$$

It is of interest to consider the possible ways of seeking new BHC, which evidently involves their stabilisation by effective ligands other than the C_5H_5 groups. As stated above (Section III, Subsection 5), the stability of the transition metal tetrahydroaluminates $M(AlH_4)_n$ varies in parallel with the stability of the corresponding tetrahydroborates. The same behaviour has been observed also for other BHC: stable tetrahydroaluminates correspond to the stable monocyclopentadienyltitanium tetrahydroborate[177] and biscyclopentadienyltitanium, biscyclopentadienylzirconium, biscyclopentadienylvanadium, and biscyclopentadienylniobium tetrahydroborates[11]. Consequently stable transition metal tetrahydroborate complexes can be regarded as models in relation to the tetrahydroaluminate complexes. However, it is noteworthy that, since the coordinating capacity of the aluminium atom is greater than that of the boron atom and the AlH_4^- group is a stronger reductant than BH_4^-, it is to be expected that the structure of the tetrahydroaluminate BHC differs significantly in most cases from that of the tetrahydroborate BHC (see, for example, Erofeev et al.[122] and Marks and Kennelly[178]).

Transition metal tetrahydroborates stabilised by phosphines and also arsines have been described for cobalt, nickel, ruthenium, rhodium, iridium, palladium, copper, and silver[11] as well as molybdenum[179]. Carbonyl compounds are also known: the stable salt $[(Ph_3P)_4N]^+[Mo(CO)_4BH_4]^-$ and the unstable complex $Mn(CO)_5BH_4$.[11] The stable trisdialkylaminotitanium(IV) [180] and trisdialkylaminothorium(IV) [181] tetrahydroborates and uranium(III) tetrahydroborate, stabilised by crown-ether[182], are noteworthy.

Bearing in mind the synthesis in recent years of a large number of stable transition metal alkyls with substituents not containing β-hydrogen atoms, one may expect the synthesis of BHC containing such alkyl groups. Thus a series of zinc tetrahydroaluminate complexes having the general formula $MZn_nMe_{2n}AlH_4$, where M = Li, Na or K and n = 1 or 2, which are stable in solution in THF, have been obtained by Ashby and Watkins[183–185].

Another possible method of synthesis of stable BHC involves the interaction of non-transition metal compounds with molecular transition metal hydrides. Among these, we may note the familiar pentahydrides $MH_5(dmpe)_2$ of niobium[186] and tantalum[187], whose chemical properties resemble closely those of Cp_2MH_3: they catalyse the H–D exchange between D_2, on the one hand, and C_6H_6 and C_2H_4, on the other, and form the complexes $NHL_2(dmpe)_2$ with CO and C_2H_4. Analogous complexes having the composition $MH_3(dmpe)$ have also obtained for titanium and zirconium[188]. The synthesis of $CpNb(PPh_3)_2(CO)H_2$, isoelectronic with Cp_2MoH_2,[189] and of $CpMo(dppe)H_3$, isoelectronic with $CpNbH_3$,[190] has been reported. The chemistry of BHC involving the study of the complex-formation reactions of Cp_2MH_n and the isoelectronic compounds Cp_2NbH, $(PR_3)_4MH_4$,[191] etc. with transition metal compounds will apparently be fairly fruitful.

Synthetic Methods for Cyclohexa-1,3-dienes

V.A.Mironov, A.D.Fedorovich, and A.A.Akhrem

The review gives a systematic account of the methods of synthesis of cyclohexa-1,3-diene, its homologues, and derivatives with functional groups. The purity of the preparations obtained by each method is considered on the basis of modern data. The bibliography includes 221 references

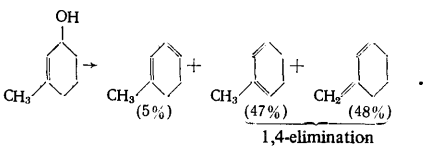
III. Synthesis of cyclohexa-1,3-dienes 62
IV. Conclusion 75



I. INTRODUCTION

Substituted cyclohexa-1,3-dienes are important intermediates in the synthesis of many physiologically active compounds, including terpenes, carotenoids, and steroids. Cyclohexa-1,3-diene (I) itself has been used as the starting material in one of the schemes for the stereoselective synthesis of 11-deoxyprostaglandines[1]. It is a promising monomer for the manufacture of aromatisable polymers. Both the diene (I) itself and the vast majority of its derivatives (with the possible exception of α-terpinene and α-phellandrene) are obtained solely by synthesis. Despite the importance of this class of compounds, there is no review literature on the methods of their synthesis. The aim of the present review is to fill this gap†. The methods of synthesis of the diene (I), its homologues, and derivatives with functional groups are relatively varied. The principal methods can be divided into five groups in the majority of which the starting material contains the cyclohexane ring. The synthesis of the diene (I) and in the first place its homologues and derivatives involves certain experimental difficulties. Many of the synthetic methods result in the formation of side products, including isomeric dienes. The high reactivity of cyclohexadienes, particularly their tendency to dimerise, polymerise, aromatise, and oxidise, may also be the cause of the reduced yield of the desired products and the appearance of impurities. The principal causes of the possible inhomogeneity of cyclohexa-1,3-dienes are considered below.

II. THE AMBIGUITY OF THE REACTIONS AND THE PRINCIPAL SIDE PROCESSES

1. The Mode of Elimination and the Admixture of 3-Methylenecyclohexenes

The formation of the second double bond in the cyclohexadiene ring is usually achieved with the aid of elimination reactions (the elimination of hydrogen halides, water, alcohol, etc.) which can occur via different pathways even under mild conditions: via 1,2- and 1,4-elimination mechanisms[2]. The 1,4-elimination product can predominate, which is confirmed by the data in Tables 1 and 2 (see below). The dehydration of substituted cyclohex-2-en-1-ols leads as a rule to mixtures of two dienes with endocyclic double bonds and, in the presence of an alkyl group in the 1- and 3-positions, is accompanied by the formation of an admixture of 3-methylenecyclohex-1-enes. The amount of the latter in the mixtures can be very considerable (in excess of 40%), for example[3]:

The elimination of two water molecules (from cyclohexanediols) or two hydrogen halide molecules (from dibromocyclohexanes) evidently proceeds with intermediate formation of the allyl system and hence should also obey the rule mentioned above.

2. Admixture of Cyclohexa-1,4-dienes

When two water molecules are split off from cyclohexane-1,3-diols or cyclohexane-1,4-diols, cyclohexa-1,4-diene is formed as a side product in an amount of 20% and above (see below). It is reasonable to suppose that isomers with isolated double bonds can also be present in the dehydrobromination products of 1,3- and 1,4-dibromocyclohexanes (particularly the latter). Cyclohexa-1,4-dienes can also be formed as the products of the isomerisation of the corresponding 1,3-dienes in an alkaline medium.

3. Isomerisation

The isomerisation of cyclohexa-1,3-dienes can occur as a result of a 1,5-shift of hydrogen (above 250 °C), a 1,5-shift of substituents (400–500 °C), and a change in the nature of the substituent (500–600 °C).[4] The processes lead to the formation of a mixture of isomers with different positions of the double bonds and under the conditions of pyrolysis complex mixtures of skeletal isomers are produced.

In the presence of strong bases (for example, solutions of alkali metal alkoxides in the corresponding alcohols or dimethyl sulphoxide, (DMSO), cyclohexa-1,3-diene itself is partly converted into the 1,4-isomer (see, for example, Refs.5–8). The amount of the latter in the mixtures formed depends greatly on the nature of the base, the solvent, and other isomerisation conditions, varying in the range 0–34%;

† The literature up to 1945 is excluded from consideration.

cyclohexa-1,4-dienes is capable of isomerising quantitatively to the corresponding conjugated dienes under the influence of the same bases in ammonia, amines, and other solvents.

4. Aromatisation

A specific feature of the cyclohexa-1,3-diene derivatives is the ease with which they are aromatised. The conversion of dienes of the above series into benzene derivatives takes place as a result of two related reactions—dehydrogenation and disproportionation—with the simultaneous formation of cyclohexenes.

Cyclohexa-1,3-dienes can be dehydrogenated on heating in the liquid or gaseous phase with substances capable of absorbing hydrogen or with oxidants; the most thoroughly investigated hydrogen absorbing agents are palladium on charcoal[9–15] and elemental sulphur[16,17]. In the vapour phase above 400 °C, the dehydrogenation of cyclohexa-1,3-diene takes place in the absence of catalysts with evolution of molecular hydrogen[2,18–20]. The degree of conversion is then considerable (approximately 50%) only at 500 °C. Thermal aromatisation of the 5,5-disubstituted cyclohexa-1,3-dienes takes place via dealkylation (with evolution of a gaseous alkane) at 550 °C [21,22] and above.

It is generally known that the disproportionation of cyclohexa-1,3-dienes can occur as a heterogeneous process—as a result of contact with catalysts: palladium, platinum, nickel, and iron at 50–100 °C or alumina at 250–400 °C.[23] Homogeneous disproportionation takes place when dienes interact with strong bases under exceptionally mild conditions. Thus, when cyclohexadienes come into contact with a solution of potassium t-butoxide in DMSO (55 °C, 24 h) [7] or t-butyl alcohol (60°, 3h),[24] the dienes are quantitatively converted into a mixture of equal amounts of aromatic and mono-olefinic compounds. Sodium amide in liquid ammonia in the presence of a proton donor (for example, ammonium chloride) exhibits a powerful disproportionating activity[8]. Thermal disproportionation of the diene (I) takes place when it is heated for a long time at 150–200 °C in the absence of a solvent or catalyst during dimerisation[25] or polymerisation[26–28], the overall yield of benzene or cyclohexene reaching 20%.

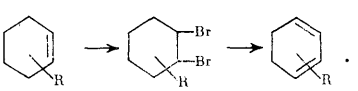
5. Dimerisation and Polymerisation

Dimerisation via the diene condensation mechanism (see, for example, Refs. 25, and 29–31) and thermal polymerisation (see, for example, Refs. 27, 28, 32, and 33) take place as parallel reactions on heating cyclohexa-1,3-diene at 170 to 200 °C; the process is completed by the complete disappearance of the monomer in the course of approximately 10 h. The polymerisation of the diene (I) is catalysed by Lewis acids and takes place even at −80 °C in the presence of titanium tetrachloride[34–39], tin tetrachloride[34], or boron trifluoride[38,39]. On treatment with n-butyl-lithium, the polymerisation takes place at 30–60 °C.[36,37,40].

6. Oxidation

Cyclohexa-1,3-diene[41,42] and its derivatives[42] are oxidised by oxygen, particularly readily in the light, to endoperoxides even at room temperature; under the same conditions, not only the oxidation but also the aromatisation of dienes is observed[43].

7. Practical Recommendations



The foregoing shows that, in selecting a scheme for the synthesis of a substituted cyclohexa-1,3-diene, one must take into account many factors which can be reflected in the purity of the preparation. In the synthesis of cyclohexa-1,3-dienes, prolonged heating at 170 °C and above is undesirable (dimerisation, polymerisation, and disproportionation) and even brief heating at 250 °C can be damaging (isomerisation), while temperatures of 400 °C and above (dehydrogenation) must be completely ruled out. In synthetic methods the use of Lewis acids is inadmissable (polymerisation) and contact with strong bases (isomerisation and disproportionation), alumina, particularly at an elevated temperature (disproportionation), and atmospheric oxygen (oxidation and dehydrogenation) can have undesirable consequences.

The number of specimens of substituted cyclohexa-1,3-dienes described in the literature is very large but the purity and isomeric composition of the preparations have been checked only in studies during the last two decades. Analysis of the early literature data shows that the vast majority of the cyclohexadiene specimens could not have been homogeneous and hence the employment of these data in synthetic practice requires a preliminary aasessment of their reliability.

III. SYNTHESIS OF CYCLOHEXA-1,3-DIENES

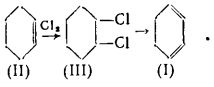
1. Synthesis from Cyclohexenes

(a) *Bromination–dehydrobromination.* The most frequently employed scheme for the synthesis of cyclohexadienes from cyclohexenes involves bromination–dehydrobromination:

The bromination of cyclohexene (II) or its homologues is carried out at −5–0 °C in chloroform[32], carbon tetrachloride[44], or glacial acetic acid[45]; in all cases the reaction leads to the corresponding 1,2-dibromo-derivatives in yields of 80–85%. In the method ensuring the maximum yield of the dibromo-derivative (95%),[46] carbon tetrachloride with added absolute ethanol was used as the solvent.

Quinoline at the boiling point was widely used in early studies as the dehydrobromating reagent; the dienes were isolated from the reaction mixture by distillation (yield 45 to 65%). It has been shown by Raman[47] and ultraviolet[48] spectroscopy and also by gas-liquid chromatography (GLC) [35] that the composition of the preparation obtained by this method incorporates 40–50% of the diene (I), 40–50% of cyclohexene (II), and approximately 20% of benzene. It is extremely difficult to separate these compounds (b.p. 80.5°, 83°, and 80 °C respectively) by fractional distillation. The isolation of the pure diene (I) via its complex with silver nitrate[49] is suitable only for small batches of the diene.

The above method was used in early studies to obtain cyclohexadienes from 1-methyl-, 5-methyl-, 1,3-dimethyl-, and 1,4-dimethyl-cyclohexenes. The compositions of the dienes enumerated above were not monitored but it was shown by ultraviolet spectroscopy[50] that "5-methyl-cyclohexa-1,3-diene" obtained by this method contains 58% of toluene. According to Domnin's data[51], the dehydrobromination of 1,2-dibromo-1-chlorocyclohexane by quinoline led to chlorocyclohexadiene considerably contaminated by chlorocyclohexene and chlorobenzene. From the above, all the preparations of substituted cyclohexadienes obtained by the method described

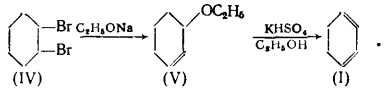


should contain not more than 50% of the main substance. Furthermore, as a result of the different pathways followed in the elimination of the second molecule of hydrogen bromide, there is a possibility of the formation of mixtures of isomers.

It has been suggested that 1,2-dibromocyclohexane be dehydrobrominated[44] by the readily available sodium alkoxide derived from ethylene glycol (at 220–230 °C) with the distillation of the reaction products; the yield of the hydrocarbon fraction is then 60%; according to infrared spectroscopic data, the resulting mixture contains 81% of the diene (I), 4% of the benzene, and 15% of cyclohexene (II). Despite the only slight increase of the yield and purity of the preparation obtained, this method has an advantage over that described above, since the expensive quinoline is replaced by the readily available sodium hydroxide and ethylene glycol. It is known[52] that, when sodium hydroxide is replaced by potassium hydroxide, the yield of the diene (I) increases to 71%, but its purity was not estimated. Presumably the specimen obtained is also not free from benzene and cyclohexene as impurities.

It has been suggested that a solution of sodium isopropoxide in aprotic solvents (for example, in the dimethyl ether of triethylene glycol) be used as the dehydrobrominating agent at 110–115 °C with distillation of the products *in vacuo*[53]. The yield of the diene (I) is then 35–40%. It is known[53] that an increase of the reaction temperature leads to the contamination of the product by benzene and cyclohexene. It has been established[54] that the application of a similar method (involving the use of sodium methoxide), for the synthesis of substituted cyclohexadiene leads to extremely complex mixtures of products.

Thus a change in the nature of the dehydrobrominating agent has still not permitted the synthesis of individual cyclohexadienes by means of the scheme described.

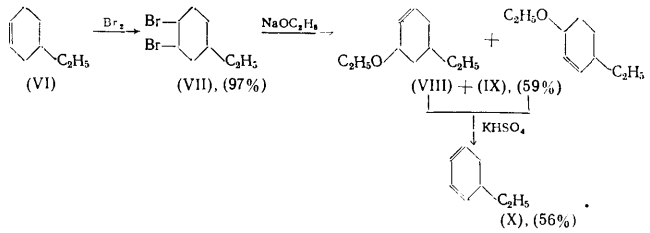


(b) *Chlorination–dehydrochlorination.* A scheme based on the chlorination of cyclohexene with subsequent thermal[55] or catalytic[56] dehydrochlorination of the resulting 1,2-dichlorocyclohexane (II) has been considered as a method of industrial synthesis of the diene (I):

(II) (III) (I)

The addition of chlorine to cyclohexene takes place readily in both liquid and gas phases. According to patent data[57,58], the dehydrochlorination of the dichloro-derivative (III) can be achieved in 89% yield when it is treated with sodium hydroxide in poly(ethylene glycol); the preparation obtained is contaminated by an admixture of 3-chlorocyclohexene[57]; the similarity of the dehydrohalogenation method to that described above suggests that the preparation should contain also benzene and cyclohexene. In order to achieve a continuous process, it has been suggested[56] that the vapour of the dichloro-derivative (III) be passed over alumina and silica gel, deposited on activated charcoal, at 300 °C and a pressure of 100 mmHg. The yield of the diene (I) is 33%, but, according to GLC data, the preparation is contaminated by benzene (10%), methylcyclopentadienes (7%), and methylcyclopentenes (3.5%). A patent has been taken out[55] for the pyrolytic (230–480 °C) dehydrochlorination of the dichloro-derivative (III), which results in a 34% yield of the diene (I) together with 7% of benzene and small amounts of cyclohexene and cyclohexa-1,4-diene. Thus the scheme described requires extensive further elaboration for its practical realisation.

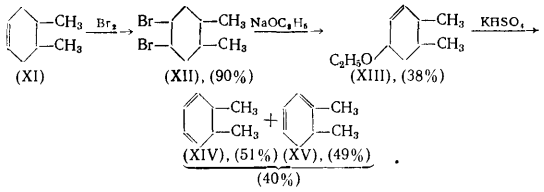
(c) *The Hofmann–Damm method.* The scheme proposed by Hofmann and Damm[32] for the dehydrobromination of 1,2-dibromocyclohexane is extremely widely used:



(IV) (V) (I)

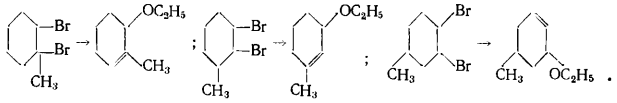
Treatment of the dibromo-derivative (IV) with a boiling alcoholic solution of sodium ethoxide leads to a 40–70% yield of 3-ethoxycyclohexene (V) accompanied by the formation of 15–30% of the diene (I). Distillation of the ether (V) from sodium bisulphate makes it possible to split off an alcohol molecule which gives rise to a 60–90% yield of the diene (I). The formation of a mixture of the ether (V) and the diene (I) on treatment of the dibromo-derivative (IV) with sodium ethoxide constitutes a definite disadvantage of the scheme, since this mixture requires separation which inevitably entails losses. The method has been frequently tried and improved[59]. According to Raman spectroscopic data, the preparation obtained is free of admixtures of benzene and cyclohexene.

In one of the versions of this scheme, it has been suggested[60] that sodium ethoxide be replaced by the methoxide (the yield of 3-methoxycyclohexene is 69%) and that methanol be split off by heating (155–160 °C) with orthophosphoric acid in triethylene glycol. The yield of the diene (I) in the last stage is 82%. According to the data of Zupancic and Wucherpfennig[60], the diene (I) formed is chromatographically homogeneous. Sodium isopentoxide has been suggested for the same purpose. A considerable acceleration of the reaction (IV) → (V) (at 130 °C it is almost instantaneous) and the easier elimination of isopentyl alcohol in the second stage have been pointed out as advantages of the above reagent. However, the diene (I) formed under these conditions contains an appreciable amount of cyclohexene as an impurity.



Using the Hofmann–Damm method[32], 1-methyl-,[54] 4-methyl-,[54] 1-ethyl-, 3-ethyl-, and 4-ethyl-,[61] 1-n-propyl-, 1-isopropyl-, 1-n-butyl-, 1,4-dimethyl-, and 4,4-dimethyl-,[21] 4,5-dimethyl,[61] 4-ethyl-4-methyl-,[62] and 1-phenyl- and 1,2-dibromo-cyclohexenes[63] have been converted into substituted cyclohexadienes. The reaction conditions and the yields at different stages reproduce fairly closely those described above for the diene (I) itself. The structure of the preparations of substituted cyclohexadienes obtained was established only in a small number of instances. It is known[61] that the reaction applied to 4-ethylcyclohexene (VI) leads to a fairly homogeneous (approximately 98%) 5-ethylcyclohexa-1,3-diene (X), i.e. there is virtually no migration of the double bonds under the elimination conditions:

(VI) (VII), (97%) (VIII) + (IX), (59%) (X), (56%)

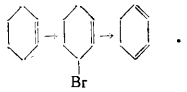


On the other hand[61], under analogous conditions, a mixture of approximately equal amounts of the isomeric dienes (XIV) and (XV), which correspond to different elimination

pathways, is formed from 4,5-dimethylcyclohexene (XI):

(XI) (XII), (90%) (XIII), (38%) (XIV), (51%) (XV), (49%) (40%)

It was later established reliably by GLC and ^1H NMR [64] that the interaction of the methyl-substituted dibromocyclohexenes (XVI)–(XVIII) with sodium ethoxide proceeds via one of the two possible pathways with a selectivity of 95–97%:



(XVI) (XIX), (51%) (XVII) (XX), (43%) (XVIII) (XXI), (62%)

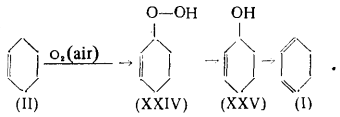
On the other hand[64], heating of the ethers (XIX)–(XXI) with potassium hydrogen sulphate at 100 °C leads to extremely complex mixtures of hydrocarbons and, apart from the two possible elimination pathways, the mixture composition is complicated also as a result of the isomerisation of the dienes formed. The results of the above study[64] were subsequently reproduced[65].

Thus the above procedure for the synthesis of substituted cyclohexa-1,3-dienes can be of interest only when the starting materials are 4-substituted or 4,4-disubstituted cyclohexenes, since only then do both reaction pathways lead to the same diene. Consequently among the preparations enumerated above, only the 5-methyl-, 5-ethyl-,[61] 5,5-dimethyl-,[21] and 5-ethyl-5-methyl-cyclohexadienes[62] can be relatively homogeneous.

(d) *The Ziegler method.* Cyclohexenes were converted into cyclohexadienes in accordance with the following scheme[66]:

(II) (XXII) (I)

The bromination of cyclohexene with *N*-bromosuccinimide in carbon tetrachloride leads to a 70–85% yield of 3-bromocyclohexene (XXII), whose dehydrobromination with the aid of quinoline at 190 °C results in a 50–70% yield of the diene (I); this method has been frequently employed. According to GLC data[35,40], the preparation obtained is not less than 99% pure and contains only traces of cyclohexene, which appears doubtful on the basis of the comparison with the data presented above. A mixture of 1- and 2-chlorocyclohexa-1,3-dienes was obtained in the same way from 1-chlorocyclohexene[67] and a mixture of 1-methoxycarbonyl-2-methyl- and 1-methoxycarbonyl-6-methyl-cyclohexa-1,3-dienes was obtained from 4-methoxycarbonyl-3-methylcyclohexene[68]. The diene has been synthesised analogously from the nitrile of cyclohexene-1-carboxylic acid[69]. Collidine[49], triethylamine[68], sodium methoxide[69], and potassium t-butoxide[70] have also been used as dehydrobrominating agents, but in all the instances indicated above a decrease of the yield of the desired product was observed.



Thus one can assume that the method has no advantages over that discussed above, particularly as regards the synthesis of substituted cyclohexadienes, since the formation of mixtures of isomers from the individual substituted cyclohexene has been demonstrated experimentally in this instance [67,68]. Thus "2-cyanocyclohexa-1,3-diene" [69] and "5-methylcyclohexa-1,3-diene" [71] obtained in this way are most probably mixtures of isomers.

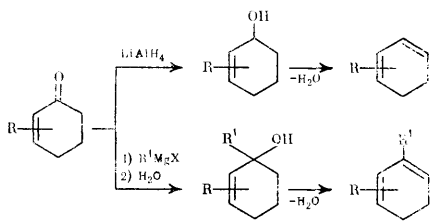
A version of the given scheme is the allyl chlorination of cyclohexene[72] by t-butyl hypochlorite in the presence of benzoyl peroxide (yield 77%) with subsequent dehydrochlorination of 3-chlorocyclohexene by dimethylaniline at 180 °C; the yield of the diene (I) is 80%, but the purity of the preparation has not been established. However, it forms an adduct with maleic anhydride in 93% yield. Bearing in mind that the dehydrochlorination of chlorocyclohexene proceeds much more readily than that of dichlorocyclohexane, this process can be regarded as the most likely industrial scheme for the synthesis of the diene (I) using the high-temperature allyl chlorination of cyclohexene in the first stage (by analogy with the thoroughly investigated propene chlorination process). However, this question has not so far been investigated.

(e) *The allyl oxidation.* The oxidation of cyclohexene with selenium dioxide in acetic anhydride leads to a 50% yield of 1-acetoxycyclohex-2-ene (XXIII). Two distillations of the acetate (XXIII) from potassium hydrogen sulphate at 145 to 155 °C give rise to a 60–70% yield of the diene (I), whose relative homogeneity has been confirmed by the fairly satisfactory agreement of its constants with those of a preparation known to be pure.

In order to convert acetates of type (XXIII) into cyclohexadienes, they were pyrolysed at 420 °C;[73] however, it has been shown for 3-methoxycarbonylcyclohex-1-en-2-yl acetate that the reaction product is a mixture of the possible isomers of methoxycarbonylcyclohexadiene, which is apparently contaminated by the corresponding aromatic compounds, i.e. this method cannot be recommended.

One of the most promising schemes for the industrial application of the syntheses of the diene (I) is[74]

(II) (XXIV) (XXV) (I)



Cyclohexene is usually oxidised by atmospheric oxygen at 150 °C and 25–75 atm. This reaction is known to be autocatalytic[74–77]. The employment of cumenyl hydroperoxide as the catalyst[78] makes it possible to carry out the process under milder conditions (90–100 °C, 6–10 atm). As a rule[75,76,77], the degree of conversion is not high (15–30%) and the unreacted cyclohexene is readily separated by distillation and can be reused. The decomposition of the cyclohexenyl hydroperoxide (XXIV) may entail the formation of cyclohex-2-en-1-one and epoxycyclohexane; their minimal amount (3 to 10%) is obtained when the oxidation product is treated with 1 *N* NaOH at 40 °C [76] or with iron sulphate in alcohol[77]. The conditions for the dehydration of cyclohex-2-en-1-ol, are described below.

Thus the application of the schemes described in this section to the synthesis of cyclohexa-1,3-diene derivatives is undesirable in view of the formation of complex mixtures of isomers. On the other hand, cyclohexene is the most readily available starting material for the synthesis of the diene (I) itself. Among the methods discussed above, the Hofmann–Damm method can yield the purest preparation of cyclohexa-1,3-diene. However, the simplest procedure involving bromination–dehydrobromination with the aid of quinoline or the more readily available alkoxide derived from ethylene glycol

has not lost its importance despite the low purity of the diene obtained, since the impurities do not interfere with many reactions (for example, the diene condensation). The oxidation of cyclohexene and the dehydration of the resulting enol (XXV) are apparently beyond competition at the present time as regards their application on an industrial scale.

2. Synthesis from Cyclohex-2-en-1-ones

Cyclohexenones, which are relatively readily available as a result of a wide variety of condensation and cyclisation reactions, are the most common and apparently some of the most promising starting materials in the synthesis of substituted cyclohexa-1,3-dienes. The main schemes of such syntheses are as follows:

The frequent use of these schemes is due to the fact that their main disadvantage (inhomogeneity of the dienes obtained) was discovered only towards the beginning of the 1960's after the development of the chromotographic and spectroscopic analytical techniques.

(a) *Synthesis via secondary alcohols.* The literature data on the reduction of cyclohexenones and the dehydration of the unsaturated alcohols formed are presented in Table 1. The reductant employed is mainly lithium tetrahydroaluminate in boiling ether[2,21,80,82,85]; the yield of alcohols is 70–90%. The allyl alcohols formed are thermally stable and are readily purified by distillation.

The main method for the industrial dehydration of the enol (XXV) itself considered in the literature involves the passage of its vapour over alumina[23,86–88] and the optimum yield of the diene (I) (up to 85%) can be achieved at 270 °C. It has been established[86] that the reaction is accompanied by the formation of cyclohexene, cyclohexane, and benzene, the latter being absent from the first portions of the catalytic reaction mixture[23]; the amount of impurities is 2–5% and increases with contact time. In order to diminish the role of side processes, it has been suggested[88] that the vapour of compound (XXV) be diluted with water; for the optimum molar component ratio of 2 : 1 respectively, the degree of conversion is 77% and the purity of the product is 99%. According to patent data[89,90], when a specially prepared catalyst based on alumina is used, it is possible to achieve a yield of 94% combined with a purity of diene (I) of 96.5% (the rest is cyclohexene).

It has been reported[91,92] that calcium and magnesium phosphates are effective catalysts of the vapour-phase dehydration of compound (XXV); at 250–280 °C and for a contact time of 18–30 s, the diene (I) can be obtained in 70–85% yield with a purity of 97–99% according to refractometric data, which is doubtful. The application of an aluminium boride catalyst for this purpose in a fluidised bed at 250–280 °C has been described[93] (yield up to 93%, purity according to GLC 99.3%, the residue consisting of 0.6% of benzene and 0.1% of cyclohexene).

The dehydration of substituted cyclohexenols over alumina at 300 °C [21] or 350 °C [85] has been described (yield approximately 60%); it must be supposed that the dienes formed under these conditions are contaminated by their disproportionaton products.

Table 1. Synthesis of cyclohexadienes via the reduction-dehydration of cyclohexen-1-ones.

* A = *p*-$CH_3C_6H_4SO_3H$; B = $CuSO_4$; C = $[(C_6H_3O)_3PCH_3]^+I^-$; D = $KHSO_4$.

Distillation of cyclohexenols in the presence of catalytic amounts of toluene-*p*-sulphonic acid[2,82], potassium hydrogen sulphate[94], magnesium chloride[75], or iodine[78] or refluxing with anhydrous copper or magnesium sulphate[95] has been widely used in laboratory practice for this purpose (Table 1). According to GLC data[2,80], the cyclohexadienes obtained by these methods are free of disproportionation products. The relatively low reaction temperature in this instance apparently makes it possible also to prevent the thermal isomerisation of the cyclohexa-1,3-dienes formed[2,80].

For the dehydration of cyclohexenols itself and 5,5-disubstituted cyclohexenols, it has recently been suggested[79,96] that the secondary alcohol be heated briefly at 50 °C with methyl triphenoxyphosphonium iodide in hexamethylphosphoramide; the dienes formed under these conditions in yields of 60–80% are free from impurities. However, in those cases where there is a possibility of different pathways in the elimination process, the reactions were not investigated.

Table 1 demonstrates the existence of different pathways in the dehydration of substituted cyclohexenols; in many cases the preferred reaction pathway is 1,4-elimination, which in the presence of an alkyl substituent in the 3-position leads to the formation of considerable (up to 40%) amounts of dienes with an exocyclic double bond. Homogeneous preparations can be obtained as a result of this reaction in only two cases:

(1) If any of the dehydration pathways leads to the same substance (this happens in the presence of one substituent in the 2-position or of two substituents in the 5-position, or of two identical substituents in the 2- and 5-positions).

(2) On geminal substitution in the 4,4- and 6,6-positions whereupon there is a possibility of only one reaction pathway.

Thus, despite its simplicity and convenience, this method of synthesis of substituted cyclohexadienes leads as a rule to mixtures of dienes (in the general case three-component mixtures) which are difficult to separate.

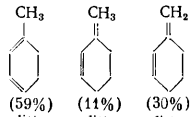
(b) *Synthesis via tertiary alcohols.* The interaction of cyclohexenones with organomagnesium and organolithium compounds followed by the dehydration of the tertiary unsaturated alcohols is apparently the most frequently employed method of synthesis of cyclohexadienes. The literature data on the application of this scheme are presented in Tables 2 and 3. In all the studies mentioned in the above tables, the organomagnesium compounds were synthesised and made to react with ketones in ether under standard conditions.

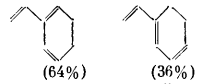
Attention should be drawn to the fact that the interaction of a Grignard reagent with cyclohexenones may be complicated by 1,4-addition which leads to saturated ketones[2,97]. This reaction lowers the yield of the dienes, sometimes to a considerable extent. With increase of the bulk of the substituent introduced into the molecule, the contribution of 1,4-addition increases sharply and can reach 70%;[97] copper(I) chloride catalyses this side reaction[97,124].

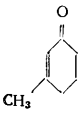
The tertiary alcohols formed as a result of the main reaction are as a rule unstable and are readily dehydrated, particularly in an acid medium. When the reaction mixture remaining after the organomagnesium synthesis is treated with acids (for example, with 6–10% sulphuric acid), the above alcohols cannot be isolated and the reaction products are diene hydrocarbons[104]. Traditional treatment of the reaction mixture with ammonium chloride also does not permit the isolation of the alcohols in many instances. Treatment with water makes it possible to isolate the alcohols only if the reaction mixture is poured into an ice–water mixture; the reverse order of mixing leads directly to the dienes[125]. The instability of the alcohols obtained complicates their purification and makes it desirable to dehydrate the residue after removing the ether from the hydrolysis products of the organomagnesium compounds (without drying the extract).

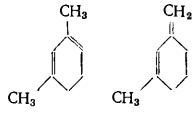
The dehydration of unsaturated tertiary alcohols can be achieved by their simple distillation (at 80–120 °C).[2] The addition of acid catalysts (oxalic[11] and toluene-*p*-sulphonic acids[2] and potassium hydrogen sulphate[118]) greatly accelerates the process, but the yield of dienes is then somewhat reduced. The composition of the dehydration products on distillation in a neutral medium and in the presence of toluene-*p*-sulphonic acid is virtually the same[2]. The application of phosphoryl chloride in pyridine for this purpose has been described[103] (yield 62%). The use of severe conditions, such as passing the vapour of the tertiary alcohol over alumina at 300 °C,[121] is evidently superfluous.

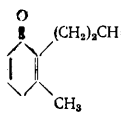
The composition of the mixtures of dienes obtained by the above procedure has been established reliably in an extremely limited number of cases[2,21,104,125]. In a number of studies the inhomogeneity of the product (the presence of an admixture of a diene with an exocyclic double bond) was suggested tentatively[106,109,117,118]. It has been postulated[109] that in some reactions the "transoid" dienes predominate in the mixtures produced. As a rule, the dienes obtained were regarded as homogeneous substances.

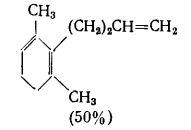


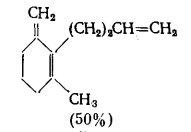


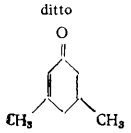


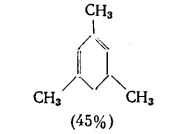


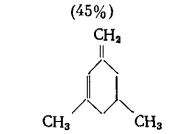


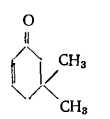


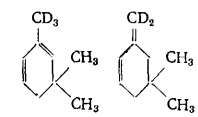












The data presented in Table 2 show that, when a methyl group is introduced by the given procedure into the molecule,

exceeds 30%. If a secondary alkyl group is introduced, such dienes are present in the mixture in still greater amounts. The presence of an alkyl substituent in the 3-position in the initial ketone increases the yield of the "transoid" diene to 45–55%.[3,21,104,125]. If the substituents in the 1- and 3-positions of the diene formed differ, the formation of two isomeric dienes with an exocyclic double bond is to be expected.

Finally, 1,4-elimination can lead to the appearance in the reaction products of a cyclohexadiene with a different disposition of the double bonds than would be expected from a formal inspection of the reaction scheme. This has been observed, for example, by Mironov et al.[2]

Thus the above reaction involving cyclohexadienes leads to complex mixtures of products and the literature data on this question contain numerous errors.

Table 2. Synthesis of cyclohexadienes from cyclohex-2-en-1-ones via organomagnesium and organolithium compounds (the composition of the reaction products has been established reliably).

** o-, m-, and p-isomers.

The isolation of the individual cyclohexadienes from the mixtures obtained requires the application of preparative GLC. 1,3-Diphenylcyclohexa-1,3-diene[14] (homogeneous according to the method of synthesis) and other polyphenylcyclohexadienes[11,12,115,116], which can be readily purified by crystallisation, are apparently and exception. However, one should bear in mind that in this case too it is difficult to predict unambiguously the positions of the double bonds in the diene obtained. For example, it is known[116] that the application of the above scheme in the examples quoted yields the same substance (the second isomer may be lost in the course

of the purification by crystallisation):

Furthermore, in analogous schemes[11], when one of the substituents is p-$C_6H_5C_6H_4$ and the other is C_6H_5, dienes with identical melting points are formed.

Thus, despite its wide-scale application, the method described is suitable only in a limited number of instances.

(c) *Dauben's method.* In 1968 Dauben et al.[126] suggested that cyclohexenones be converted into cyclohexadienes by the reaction of the tosyl hydrazones of these ketones with methyl-lithium in a benzene–ether mixture; the literature data on this method are compiled in Table 4.

It has been reported[129] that in this process methyl-lithium can be replaced by n-butyl-lithium, but, according to Dauben et al.[126], such replacement results in a decrease in the yield of the diene and in addition the use of *n*-butyl-lithium results in the contamination of the diene produced by mono-olefinic compounds. A considerable advantage of the method under discussion is that hydrogen is eliminated exclusively from the α-position relative to the hydrazone group. In combination with the low temperature of the experiment, this makes it possible to obtain cyclohexadienes having a specified structure with a high degree of purity.

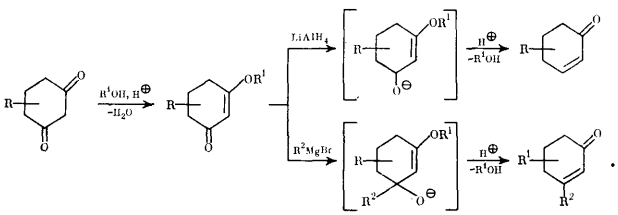
(d) *Plieninger's method.* A relatively convenient method of synthesis of substituted cyclohexadienes (XXVIII) involves the coupled dehydration–decarboxylation of 1-hydroxy-cyclohex-2-ene-4-carboxylic acids (XXIV):

(XXVI) (XXVII) (XXVIII)

The hydroxyacids (XXVII) are synthesised by the reduction of the relatively readily available ketoacid esters[16,133] with sodium tetrahydroborate in ethanol[16]; the dehydration-decarboxylation (as a rule without the isolation of the hydroxy-acids) is achieved on treatment of the acids with 4–5 *N* sulphuric acid at 20 °C. The overall yield of the dienes[16] is 14–60%. It has been suggested[134] that zinc tetrahydroborate in benzene be used as the reductant in the above scheme (yield of hydroxyacid 60–90%) and that the dineopentyl acetal of dimethylformamide be employed as the dehydrating agent at 20–70 °C in a non-polar solvent (α-methylnaphthalene), serving simultaneously as a "cushion" in the distillation of the diene. This procedure made it possible to increase the yield of dienes in the last stage to 50–85%. It is striking that this scheme yields dienes with a homogeneous isomeric composition free from extraneous impurities, which has been

shown convincingly[134]. The known instances of the application of this scheme are presented in Table 5. This is undoubtedly one of the promising methods of synthesis of substituted cyclohexadienes, but the conditions for the dehydration-decarboxylation of the hydroxyacids (XXVII) require further improvement; in particular the dehydrating agent (dineopentyl acetal of dimethylformamide) should be replaced by one more readily available.

Table 5. Synthesis of cyclohexa-1,3-dienes by the dehydration-decarboxylation of 1-hydroxycyclohex-2-ene-4-carboxylic acids.



Substitution in initial ester (XXVI) (R^1–R^3) and in the diene (XXVIII) obtained				Reduction conditions	Yield of hydroxy-acids, %	Reaction conditions*	Yield of diene, %	References

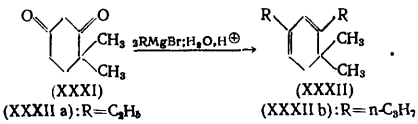
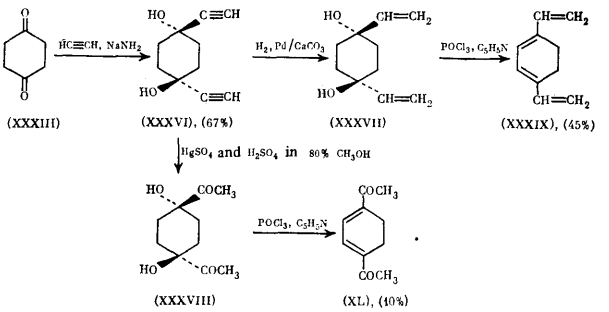
3. Synthesis from Cyclohexanediones and Cyclohexanediols

(a) *Starting materials.* The relatively readily available cyclohexane-1,3-diones in many instances serve as the starting materials for the synthesis of cyclohex-2-en-1-ones in accordance with the mechanisms (see, for example, Gannon and House[135]):



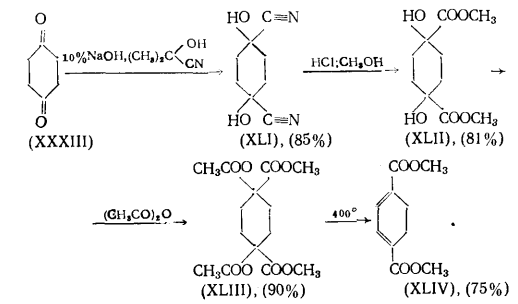
Cyclohexane-1,3-diols and cyclohexane-1,4-diols can be prepared by hydrogenating the corresponding diones or the available aromatic diols. Cyclohexane-1,2-diols are formed on oxidation of the corresponding cyclohexenes.

(b) *The substitution reaction.* When cyclohexane-1,3-dione is treated with phosphorus pentachloride in chloroform, it is possible to obtain 1,3-dichlorocyclohexa-1,3-diene (XXX) in approximately 60% yield, whose reduction with sodium in moist ether gives rise to the corresponding hydrocarbon containing an admixture of cyclohexene:



This reaction has also been described for 2-methyl-,[136] 5,5-dimethyl-, 5-phenyl-, and 2-methyl-5-phenyl-cyclohexane-1,3-diones. The yield of dichlorocyclohexadienes is 50–80%, but their purity has not been estimated.

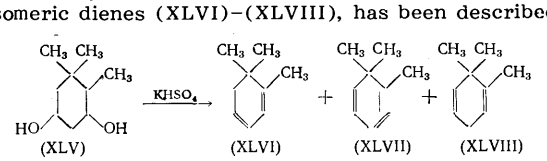
(c) *Synthesis via tertiary alcoholds.* The interaction of hexanediones with two equivalents of a Grignard reagent followed by the dehydration of the resulting dione[137] leads to the diene fraction (XXXII) in approximately 50% yield;



According to GLC data, the dienes formed are inhomogeneous, but the stretching vibration frequencies of the double bonds in the Raman spectra suggest that 1,3-dienes predominate in the mixtures. The synthesis of diphenylcyclohexadiene from cyclohexane-1,4-dione (XXXIII) has been achieved using an analogous scheme; organomagnesium synthesis under standard conditions led to a mixture of *cis*- and *trans*-1,4-diphenylcyclohexane-1,4-diols, whose dehydration with 20% sulphuric acid gave a 55% yield of 1,4-diphenylcyclohexa-1,3-diene (XXXIV), which was homogeneous according to the authors[138]. However, subsequent data[139] showed that the specimen contained 1,4-diphenylcyclohexa-1,4-diene (XXXV) (from 25 to 75% depending on the time of contact between the mixture of diols and the acid). Such mixtures are not susceptible to separation[139], but their treatment with potassium t-butoxide in t-butyl alcohol and subsequent crystallisation permit the isolation of the individual diene (XXXIV).

(d) *Synthesis via interaction with acetylides.* The interaction of dione (XXXIII) with sodium acetylide in liquid ammonia, leading to *trans*-1,4-diethynylcyclohexane-1,4-diol (XXXVI), from which divinylcyclohexa-1,3-diene (XXXIX) and diacetylcyclohexa-1,3-diene (XL) were obtained by means of the standard methods illustrated in the scheme below, has been described[140]:

1,4-Bis(2-phenylethyl)cyclohexadiene has been synthesised in accordance with an analogous scheme using phenylacetylene[141]. The positions of the double bonds in the dienes and also their homogeneity, which is particularly important for liquid divinylcyclohexadiene, have not been determined; it must be supposed that the preparations were not free from 1,4-isomers.

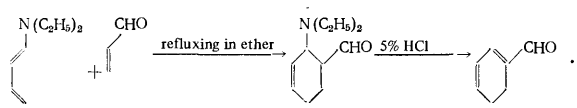


A related scheme has been used[142] to obtain dimethyl cyclohexadiene-1,4-dicarboxylate (XLIV):

A deficiency of this scheme is the use in the last pyrolytic stage of the diacetate (XLIII) at 400 °C, which is accompanied by a partial (18%) dehydrogenation of the substance. The homogeneity of the diene obtained relative to the positions of the double bonds has been confirmed by GLC data and the preparation of the adduct of the diene (XLIV) with maleic anhydride in a high yield. Evidently the given isomer predominates in the corresponding equilibrium mixture. The schemes presented above are not general and it is desirable to employ cyclohexanediones mainly for the synthesis of other starting materials—principally cyclohexenones.

(e) *Dehydration of cyclohexane-1,2-diols.* It has been shown by a large series of studies (see, for example, Refs. 143–145) that the dehydration of cyclohexane-1,2-diol cannot serve as a method of synthesis of cyclohexadiene, since its main products are cyclohexanone and formylcyclopentane. The synthesis of cyclohexane-1,2-diyl diacetate and its pyrolysis (540–660 °C) have been described[146] as a method of synthesis of cyclohexadiene, the yield in the last stage amounting to 84% according to the data presented[146]. However, the cyclohexadiene formed must be greatly contaminated by benzene. It is known that the products of the pyrolysis of 1-methylcyclohexane-1,2-diyl diacetate, obtained from 1-methylcyclohexene, contain a large amount of 3-methylenecyclohexene. Furthermore, the diene obtained should undergo isomerisation and aromatisation under the experimental conditions. Evidently the application of this extremely widely used scheme for the synthesis of dienes from monoolefinic compounds to the synthesis of cyclohexadienes is undesirable.

(f) *Dehydration of cyclohexane-1,3-diol.* The dehydration of cyclohexane-1,3-diol by 80% sulphuric acid gives rise to a mixture of cyclohexa-1,3-diene and cyclohexa-1,4-diene in proportions of approximately 5 : 1. The dehydration of *cis*-5,5-dimethylcyclohexane-1,3-diol[149,150] on distillation from phthalic anhydride leads to a 50% yield of 5,5-dimethylcyclohexa-1,3-diene, containing, according to GLC data, 8% of 3,3-dimethylcyclohexene and 8% of 4,4-dimethylcyclohexene, which can be readily removed by fractional distillation. Under the same conditions, *trans*-2,2-dimethylcyclohexane-1,3-diol[150] yields a complex mixture of products, which contains less than 10% of cyclohexadiene hydrocarbons. The dehydration of 5,5,6-trimethylcyclohexane-1,3-diol (XLV) on distillation with potassium hydrogen sulphate and resulting, according to Raman spectroscopic data, in a mixture of the isomeric dienes (XLVI)–(XLVIII), has been described[120]:

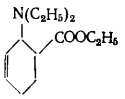


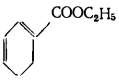
(g) *The elimination of water from cyclohexane-1,4-diol.* The elimination of water from cyclohexane-1,4-diol on treatment with 80% sulphuric acid gives a 44% yield of a mixture of cyclohexa-1,3-diene and cyclohexa-1,4-diene in proportions of 1 : 4. When the 1,4-diol is distilled from potassium hydrogen sulphate, the 1,4-isomer also predominates in the resulting mixture of dienes. The employment of anhydrous magnesium sulphate as the dehydrating agent[106] makes it possible to obtain a 40% yield of a mixture of dienes, in which the amount of the diene (I) is much greater. When cyclohexane-1,4-diol is distilled with phthalic anhydride (at 200 °C),[19] it is possible to obtain an 88% yield of a mixture consisting of 66% of the diene (I) and 34% of its 1,4-isomer according to GLC data. These mixtures can be readily separated by fractional distillation. Dehydration of cyclohexane-1,4-diol in a mixture with methanol in the vapour phase over alumina at 240–250 °C has been described[151]; the yield of the mixture of hydrocarbons was 48%. The main mixture component is apparently the diene (I), which has been isolated by column distillation and forms an adduct with maleic anhydride in a satisfactory yield.

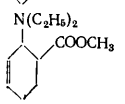
The replacement of the dehydration of cyclohexane-1,4-diols by their conversion into diacetates with subsequent pyrolysis must be regarded as undesirable, since aromatisation takes place to a considerable extent (up to 28%) under the experimental conditions (450–500 °C).[152]

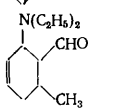
The data presented show that the synthesis of cyclohexa-1,3-dienes from cyclohexanediols leads as a rule to mixtures of the dienes and their 1,4-isomers.

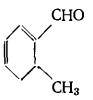
4. Condensation and Cyclisation Reactions

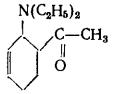


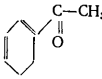


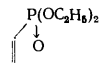


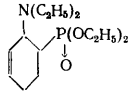


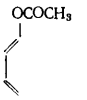


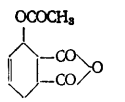


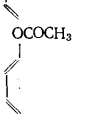


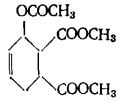


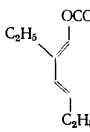


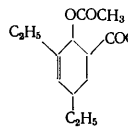


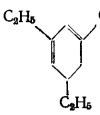


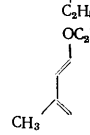


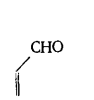


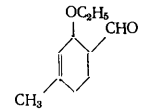


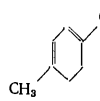


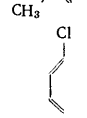


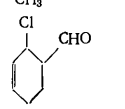


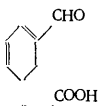


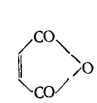


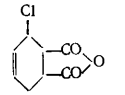


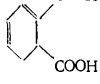


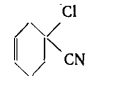




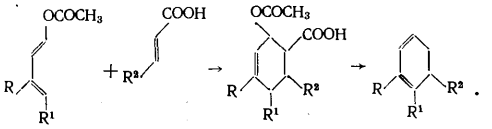








(a) *Diene condensation.* One of the preparatively important reactions for the formation of the cyclohexadiene ring is the diene condensation of acyclic dienes with dienophiles of the ethylene series when one of the addends (the diene or dienophile) contains a substituent which can be subsequently readily eliminated, for example[153]:



Examples of the employment of this scheme are compiled in Table 6. Dialkylamino-, acetoxy-, and alkoxy-groups, as well as the chlorine atom have been used as the substituents to be eliminated. The specific features of the diene condensation reaction limit the scope of the above scheme solely to the synthesis of cyclohexadienes containing electron-accepting groups, mainly carbonyl and carboxy-groups. The purity and the isomeric composition of the dienes obtained, described in Table 6, were in the vast majority of cases not determined. However, presumably the elimination took place preferentially via the pathway represented, since it corresponds to the elimination of the most mobile hydrogen atom from the α-position relative to the electron-accepting group, whereas the isomerisation of the dienes under the experimental conditions is unlikely.

It has been recently reported[168] that the diene condensation of 1-acetoxybuta-1,3-diene and its homologues with derivatives of acrylic and fumaric acids results in the formation of acetoxycyclohexene-carboxylic or dicarboxylic acids, which can be converted into the corresponding cyclohexa-1,3-dienes in 69–87% yield as a result of the elimination of

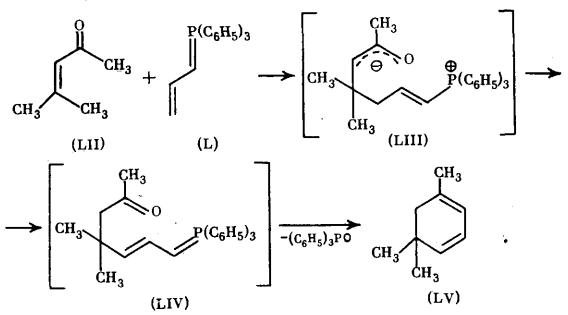
acetic acid and decarboxylation:

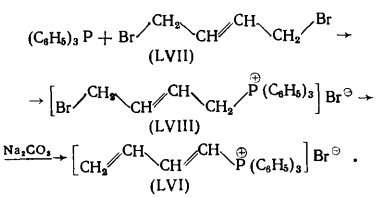


Unfortunately specific methods are not described in the above communication[168]: nor are there any data concerning the positions of the double bonds in the dienes formed.

(b) *Intramolecular Wittig reaction.* It has been observed [169] that, instead of the expected product of the Wittig condensation, the interaction of allylidenetriphenylphosphorane (L) with the ketoester (XLIX) gives rise to a 60% yield of compound (LI) with a cyclohexadiene ring:

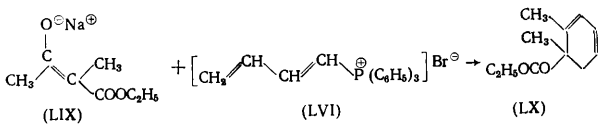
(XLIX) (L) (LI)

This method is general for the synthesis of substituted cyclohexa-1,3-dienes[169,170]:



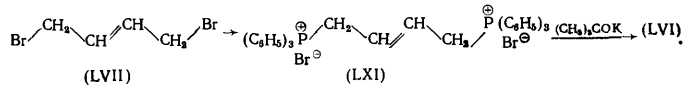
(LII) (L) (LIII) (LIV) (LV)

This reaction[170] involves the addition of the ylide (L) to the β-position of the unsaturated ketone (LII) with formation of a structure of type (LIII). Proton transfer leads to the ylide (LIV), which is capable of undergoing the intramolecular Wittig condensation. The reaction proceeds under mild conditions and makes it possible to obtain dienes in 30–60% yield. The initial ylide of type (L) is synthesised by the reduction of the corresponding phosphonium bromide with n-butyl-lithium:



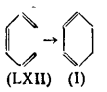
According to Büchi and Wüest[169] and Dauben et al.[170], the reaction is not accompanied by any side processes and makes it possible to obtain homogeneous preparations of cyclohexa-1,3-dienes. Examples of the application of this reaction are presented in Table 7.

The condensation of *trans*-1-butadienylphenylphosphonium bromide (LVI) with the enolates of carbonyl compounds is a convenient method of synthesis of cyclohexadienes[171–173]. The salt (LVI) can be obtained in a high yield (92%) on interaction of triphenylphosphine with *trans*-1,4-dibromobut-2-ene (LVII) in benzene with subsequent dehydrobromination of the resulting *trans*-4-bromobut-2-enyltriphenylphosphonium bromide (LVIII) by anhydrous sodium carbonate in chloroform:



(LVII) (LVIII) (LVI)

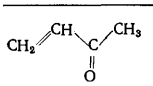
When the salt (LVI) is refluxed with carbonyl compounds in the form of enolates (LIX) in tetrahydrofuran, cyclohexa-1,3-dienes (LX) are formed:

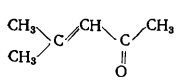


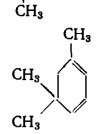
(LIX) (LVI) (LX)

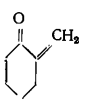
Examples of the use of this reaction are presented in Table 8. The method under discussion leads to highly pure dienes. The interaction of the diphosphonium salt (LXI) with potassium t-butoxide in ether also leads to the salt (LVI), which condenses with carbonyl compounds under the experimental conditions giving rise to cyclohexadienes in high yields[171]:

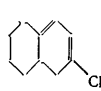
(LVII) (LXI)

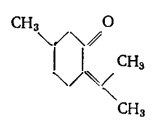


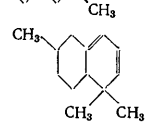


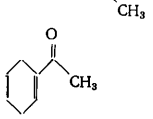


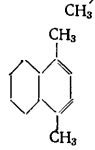


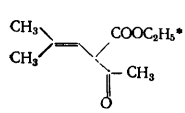


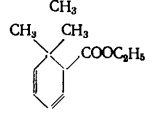


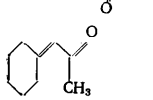


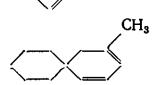












(c) *Electrocyclisation of hexa-1, 3, 5-trienes.* It is known that the thermal cyclisation of 3-*cis*-hexa-1,3,5-trienes leads to compounds of the cyclohexadiene series:

(LXII) (I)

The literature data for this reaction are compiled in Table 9. The reaction is typical electrocyclisation which proceeds strictly stereoselectively[185–187] via a disrotatory pathway. Only the 3-*cis*-trienes undergo the cyclisation reaction below 230 °C; their 3-*trans*-isomers are thermally stable below this temperature[184–188]. The potential barrier to the conversion of 3-*trans*-trienes into the *cis*-isomers is 41–51 kcal mol^{-1}.[188,189]

Table 7. Synthesis of cyclohexadienes by the condensation of α, β-unsaturated ketones with allylidenephosphoranes[170].

	A		THF, 25°, 16 h	41
	B		THF, refluxing, 30 h	25
	A		ether, 25°, 14 h	60
	A		ether, 25°, 12 h	32

* A = $CH_2=CH-CH=P(C_6H_5)_3$; B = $CH_3-CH=CH-CH=P(C_6H_5)_3$.

** See Büchi and Wüest[169].

Under mild conditions (100–170 °C), the reaction is not accompanied by the formation of side products. However, despite the simplicity with which it can be carried out, the cyclisation of *cis*-hexa-1,3,5-trienes has no preparative value at the present time because of the low availability of the pure 3-*cis*-trienes, whose synthesis usually leads to their mixtures with the *trans*-isomers. The employment of such mixtures precludes the preparation of homogeneous cyclohexa-1,3-dienes.

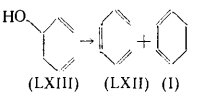

Table 8. Synthesis of cyclohexadienes by the reaction of the enolates of carbonyl compounds with *trans*-1-butadienyltriphenylphosphine bromide[171].

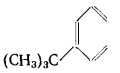
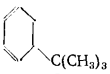
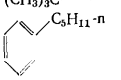
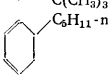
* See Büchi and Pawlak[172].

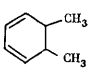
It has been reported[190,191] that the cyclisation reaction of hexa-1,3,5-trienes is catalysed by alumina, but the use of this catalyst cannot be regarded as desirable, since the reaction products are inevitably contaminated by aromatic compounds.

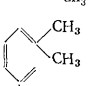


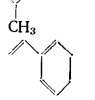


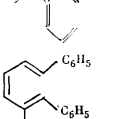


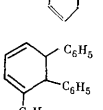


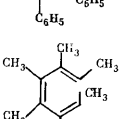


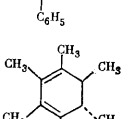












Many synthetic methods designed to obtain hexa-1,3,5-trienes lead directly to cyclohexadienes. Thus the dehydration of hexa-1,5-dien-3-ol (LXII) with phthalic anhydride results in the formation of the diene (I) (30%) together with the hexatriene (LXII) (70%):

(LXIII) (LXII) (I)

The cyclodehydration of substituted hexa-3,5-dien-2-ols also takes place under the influence of alumina at 200–500 °C. However, the cyclohexadienes obtained under such conditions[9,179,180,192,193] undergo aromatisation to a large extent (up to 80%)[179].

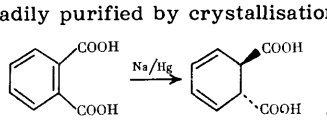
Table 9. Thermal cyclisation of hexa-1,3,5-trienes.

Initial triene	*t*, °C	Product	Yield, %	Thermodynamic parameters $\Delta H^{\neq}$, kcal mol^{-1}	Thermodynamic parameters $\Delta S^{\neq}$, e.u.	Refs.
	120—190		100	29.3	—7.3	[174—178]
	100—150		—	28.9	—4.9	[179—181]
	100—150		—	26.1	—12.4	[179—181]
	100—150		100	27.0	—6.2	[181]
	100—150		100	26.0	—11.3	[181]
	75—125		100	26.7	—11.3	[181]
	110—150		100	27.8	—7.9	[182]
	132		100	29.4	—7.0	[183]
	120—170		100	31.8	—13.8	[184]
	84—122		100	22.0	—13.8	[96]
	150		65	—	—	[84]
	210		98	27.4	—19.0	[185]

Thus, among the numerous condensation and cyclisation reactions leading to compounds of the cyclohexa-1,3-diene series, the synthesis via organophosphorus compounds and

the diene condensation of acyclic compounds with subsequent elimination of a substituent may be of preparative value. The latter reaction cannot, however, be regarded as a general method of synthesis of cyclohexa-1,3-dienes.

5. Other Methods

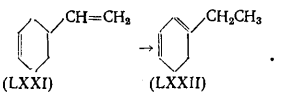


Among the numerous other reactions whose products are cyclohexa-1,3-dienes, only a few are of preparative importance. The isomerisation of cyclohexa-1,4-dienes, the synthesis of acids of the cyclohexadiene series, and also the transformation of substituents in the complete cyclohexa-1,3-diene ring can be included among them.

(a) *Isomerisation of cyclohexa-1,4-dienes.* Cyclohexa-1,4-dienes are obtained by the reduction of aromatic compounds with an alkali metal (usually sodium) and alcohol in liquid ammonia; despite the large bibliography on this reaction, we shall confine ourselves to mentioning only the first communication[194] and two reviews[195,196]. The most convenient recipe for the preparation of cyclohexa-1,4-diene itself was given by Wibaut and Hoak[197]. Cyclohexa-1,4-dienes containing electron-accepting groups (for example, the carbonyl or carboxy-groups) are available as a result of the diene condensation of buta-1,3-dienes with acetylenic dienophiles (see, for example, Onishchenko[198]).

It has been reported that the transformation of cyclohexa-1,4-diene into the 1,3-isomer (I) is possible on treatment with alkali metal alkoxides (in liquid ammonia[199,200] or in dimethylformamide[201]) or with potassium amide[202]. However, one should bear in mind that this transformation is reversible and that the ratio of the dienes in the resulting mixture depends significantly on the nature of the base and the solvent as well as other reaction conditions (see, for example, Mironov et al.[8]). One cannot rule out the possibility that the isomerisation of cyclohexa-1,4-diene in the presence of sodium ethoxide in liquid ammonia (in the absence of a proton donor from the reaction mixture) can serve as the basis of the industrial manufacture of the diene (I), provided that the admixture of the 1,4-isomer and benzene do not interfere with its subsequent employment.

The reduction of aromatic compounds with subsequent isomerisation of the resulting cyclohexa-1,4-diene has been described as a method of synthesis of substituted cyclohexa-1,3-dienes in relation to toluene[202,203], *p*-xylene[203], anisole [204–206], 1-methoxy-3,4-dimethylbenzene[205], 1-dimethylamino-4-methylbenzene[207], and biphenyl[208]. The isomerisation reaction has been carried out mainly under the influence of sodium amide in liquid ammonia and the yield has been as a rule high, but in some instances[206] the reversibility of the reaction has been noted.

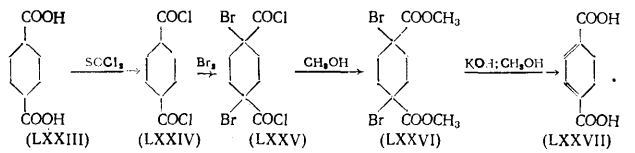


(b) *The Baeyer method.* Among the transformations of aromatic compounds into cyclohexa-1,3-dienes, one of the most convenient involves the reduction of phthalic acid (LXIX) (more precisely its sodium salt) with 3% sodium amalgam by the Baeyer method, which leads to a 60% yield of *trans*-cyclohexa-3,5-diene-1,2-dicarboxylic acid (LXX), which can be readily purified by crystallisation:

(LXIX) (LXX)

It has been reported[209] that the transformation of compound (LXIX) into compound (LXX) can be achieved by electrochemical reduction at a lead cathode in 99% yield. One should bear in mind that, on being refluxed in aqueous solution, the acid (LXX) isomerises quantitatively to cyclohexa-2,4-diene-1,2-dicarboxylic acid[210,211].

(c) *Isomerisation of 4-vinylcyclohexene.* The isomerisation of the readily available 4-vinylcyclohex-1-ene (LXXI) (dimer of buta-1,3-diene) has been used as a method of synthesis of 1-ethylcyclohexa-1,3-diene (LXXII):



(LXXI) (LXXII)

When the diene (LXXI) is passed over alumina at 350 °C, the yield of the diene (LXXII) is 60% [212,213]; according to GLC data, the substance contains a large number of small amounts of side products. However, it is extremely unlikely that the diene (LXXII) obtained under these conditions did not contain considerable admixtures of ethylbenzene and the 2-isomer.

Cobaltocene has been used as the catalyst of this reaction [214] (15 h at 185 °C). Presumably, under these fairly mild conditions, the substance obtained is more homogeneous, but its yield is low (23%).

(d) *Synthesis of cyclohexa-1,5-diene-1,4-dicarboxylic acid.* The following scheme has been widely used to synthesise cyclohexa-1,3-diene-1,4-dicarboxylic acid (LXXVII)[210, 215–217]:

(LXXIII) (LXXIV) (LXXV) (LXXVI) (LXXVII)

The interaction of the acid (LXXIII) with thionyl chloride at its boiling point leads to the acid dichloride ((LXXIV). Bromination of the latter (without isolation in a pure form) at room temperature and subsequent refluxing with methanol give rise to a mixture of the *cis*- and *trans*-isomers of the dibromoester (LXXVI). Crystallisation makes it possible to isolate in 44% yield the homogeneous *trans*-isomer of compound (LXXVI)#.[217] The dehydrobromination of the *trans*-dibromoester (LXXVI) by refluxing it with a solution of potassium hydroxide in methanol leads to an almost quantitative yield of the acid (LXXVII), which can be readily purified by crystallisation. Despite the large number of stages, the required product can be obtained in a satisfactory yield.

(e) *Transformation of substituents in the cyclohexa-1,3-diene ring.* The transformation of substituents in the complete cyclohexa-1,3-diene ring is represented by a limited number of examples and standard synthetic methods are used as a rule: esterification of carboxylic acids[210,215,217,218] (yield 70–80%), hydrolysis of the acid esters[219], conversion of cyclohexa-3,5-diene-1,2-dicarboxylic acid into the corresponding anhydride[163], and the reduction of esters of substituted cyclohexa-1,3,5-diene-1,2-dicarboxylic acid with lithium tetrahydroaluminate to the corresponding diols (yield 70 to 80%); [220,221] by reduction with lithium tetrahydroaluminate, the diols were re-reduced with lithium tetrahydroaluminate

---

The isolation of the residual reaction products[215] is apparently undesirable, since the resulting mixture contains dimethyl terephthalate.

via their toluene-p-sulphonates or methanesulphonates into hydrocarbons with two methyl groups in yields up to 80% [220, 221]. Thus the majority of the reactive groups in cyclohexa-1,3-dienes can be transformed without affecting the diene ring.

IV. CONCLUSION

Inspection of the synthetic methods described above for cyclohexa-1,3-dienes reveals the following features.

The method involving the bromination-dehydrobromination of cyclohexene is most convenient for the laboratory synthesis of cyclohexa-1,3-diene itself. The Hofmann–Damm method makes it possible to obtain a fairly homogeneous preparation. The much simpler method involving the dehydrobromination of dibromocyclohexane with quinoline or alkoxides can be recommended in those cases where the presence of cyclohexene and benzene in the resulting preparation does not interfere with subsequent reactions.

The majority of the methods of synthesis of substituted cyclohexadienes described in the literature must be regarded as satisfactory. Thus the commonest schemes in which the starting materials are cyclohexenes, cyclohexanediones, cyclohexenones, and cyclohexanediols as a rule give rise to complex mixtures of hydrocarbons where the diene which should be formally the product of the given reaction may be present in only insignificant amounts.

Among the general methods of preparative synthesis of pure substituted cyclohexadienes, the most important are as follows:

(a) Interaction of cyclohexenone tosylhydrazones with lithium alkyls.

(b) The coupled dehydration-carboxylation of 1-hydroxycyclohex-2-ene-4-carboxylic acids.

(c) The condensation of organophosphorus compounds with unsaturated ketones or the enolates of saturated ketones.

Cyclohexadienes containing electron-accepting groups can be most readily obtained by the diene condensation of acyclic dienes followed by the elimination of the functional group present in the diene or the dienophile. Many of the other methods described make it possible to obtain in specific individual instances substituted cyclohexa-1,3-dienes in satisfactory yields and with a high purity, but such instances constitute an exception rather than the rule for the schemes considered.

The method involving the oxidation of cyclohexene by atmospheric oxygen and the dehydration of the resulting cyclohexenol is at present most completely prepared for industrial application. Despite the relatively low yield of the oxidation product in a single cycle (15–30%), the possibility of the ready regeneration of the unreacted cyclohexene permits the attainment of its conversion into cyclohexenol up to 70%. The conditions for the dehydration of the latter have been fairly thoroughly determined. This and the other stage can serve as the basis of a continuous process. One cannot rule out the possibility that the chlorination of cyclohexene and the subsequent dehydrochlorination of dichlorocyclohexene or 3-chlorohexene may prove economically more effective but this method has been less thoroughly investigated compared with that described above.

Complementation Interactions of Oligonucleotides

N.G.Dolinnaya and E.S.Gromova

The results of studies by NMR, ultraviolet spectroscopy, circular dichroism, and X-ray diffraction of complexes of complementary oligonucleotides containing between two and fifteen monomeric units are surveyed. The review deals with the structures of the complexes in solution and in the crystalline state and the thermodynamics (using different theoretical models) and kinetics of their formation. The influence of the nucleotide composition and of the sequence and length of the oligomers on the structure and properties of the complexes as well as the biological importance of these systems are discussed. Attention has been devoted to the question of the stability of individual pairs of nucleotide complexes as a function of their nature and position in the oligomer chain.
The bibliography includes 124 references.

I. INTRODUCTION

The complementary complexes of synthetic poly(oligo)nucleotides are widely used as models of fragments of nucleic acids (NA) for the solution of many problems in molecular biology. The thermodynamic and kinetic aspects of the formation of complementary pairs, necessary for the understanding of any processes involving the breakdown and formation of double helices, are investigated with their aid. The role of nucleotide complexes has been increasing in the study of the protein–nucleic acid interactions, of the mechanism of the action of enzymes in nucleic acid metabolism, etc. The complexes of oligodeoxyribonucleotides, containing sequences which are split by restriction enzymes, recently found a new application—for the construction of recombinant DNA molecules. They serve as linkers in the addition of a natural or synthetic DNA molecule to the cloning vector or as adaptors with the aid of which additional restriction sites as well as DNA fragments, for example the initiating and terminating codons, the Shine–Delgarno sequence, etc. are built into the recombinant molecules.

Previously homopolynucleotides and polymers with repeating di(tri)nucleotide sequences mainly served as models of nucleic acids. Recently, in connection with considerable advances in synthetic nucleotide chemistry and development of methods of genetic engineering, complexes of oligo(poly)nucleotides with heterogeneous sequences have become available. Complexes of short nucleotides are used on a particularly wide scale. They make it possible to alter specifically the length of double helix sections and to vary the nucleotide sequence. Since short oligonucleotide complexes readily dissociate in aqueous buffer solutions at moderate temperatures, it is convenient to investigate with their aid any properties associated with the breakdown of double helix structures and the thermodynamic description of such systems can be based on simpler models. Oligomeric systems make it possible to investigate the influence of the length of the double helix section and of the nucleotide sequence on the thermodynamic and kinetic parameters of the complex formation as well as the optical properties of the double helices. Oligomeric systems are the most convenient objects for the elucidation of the kinetics of the formation of complementary complexes and of the influence of "error" bases on the stability and structure of the double helices.

Several reviews, constituting chapters of monographs and textbooks in English, have been devoted to the problems of the interaction of complementary oligonucleotides[1–4]. Riesner and Römer[1] discuss mainly theoretical aspects of the complex formation and the theory of the formation of "hairpin" structures. Ts'o's review[2] (1974) is devoted mainly to the consideration of complexes with non-canonical pairs of bases—the self-associated species oligo(A) [U, C, or G]. The review of Cantor and Schimmel[3] deals with the statistical thermodynamics and kinetics of the formation of duplexes by oligoribonucleotides (including mainly the hairpin and loop structures) and the employment of such data for the prediction of the secondary structure RNA as well as the kinetics of the denaturation and renaturation of DNA. The results of the crystallographic study of short oligomeric duplexes are discussed in Seeman's review[4]. In addition, the complexes of oligonucleotides are mentioned in reviews and other topics: on the interaction of mono(oligo)nucleotides with polynucleotides[5]; on the structure of RNA[6]; on the study of polynucleotides[7] and single-stranded oligonucleotides by NMR[8]. The present review embraces virtually all the aspects of the complex formation by oligonucleotides containing from 2 to 15 monomeric units (including studies up to 1981). Particular attention has been devoted to the results obtained in recent years in the study of the interaction of oligonucleotides by NMR and data on the structure of the oligomeric duplexes. The review does not discuss in detail studies dealing with the formation of "hairpin" structures and complexes of oligonucleotides containing non-complementary bases.

II. TYPES OF OLIGOMERIC COMPLEXES INVESTIGATED

The oligomeric complexes can be formed by oligonucleotides of identical or different lengths with complementary sequences or by self-complementary oligonucleotides. Depending on the nucleotide sequence and the chain length in these systems, the formation of several types of complexes has been noted.

Complexes of the readily available synthetic oligoribonucleotides with a homogeneous composition have been investigated most completely: oligo(A).oligo(U)[9–11] [the complexes oligo(G).oligo(C) have not been investigated hitherto]. Oligomers with a homogeneous sequence tend to form triple-stranded helices capable of coalescing into aggregates of the "concatameric" type with a higher molecular weight (see below)[9,11]. When the short oligomers of adenylic and uridylic acids interact, the stoichiometry of the complexes remains 1A:2U regardless of the chosen conditions[9]. It has been demonstrated[11] that the chain length of the oligomers, i.e. the number of monomeric units involved in the complementation interactions (N) above which there is a possibility of the formation of double helices, is seven. Systems incorporating oligodeoxyribonucleotides form as a rule double-stranded helices[12]. Thus the hybrid oligomeric complex $d(pT)_8.r[A(pA)_7]$ has the stoichiometry 1T:1A in a neutral buffer containing 1 M NaCl.[13] A double helix structure is also characteristic of a complex of oligodeoxyribonucleotides of different lengths: $d(pT)_{12}.d(pA)_6$.[14]

Oligomers with an alternating self-complementary nucleotide sequence usually form either intermolecular double helical complexes, such as, for example, oligo [d(pGG–C)] with a chain length ranging from 4 to 7 monomeric units[15], or intramolecular complexes as a result of the folding of the oligomer chain: $d(A–T)_n$ ($n > 7$).[16] The particular structure of the complex is apparently determined by the length of the oligomer. In the formation of complexes by oligonucleotides of different lengths with alternating non-complementary bases, namely oligo[d(C–A)].oligo[d(T–G)],[17] as well as trinucleotides and oligomers containing repeating trinucleotide sequences, namely d(pG–G–T).$d(pA–C–C)_{2-4}$, etc.,[18] the formation of double helix structures with continuous filling of the matrix by shorter oligomers is favoured.

Detailed study of the structural characteristics of the complexes of self-complementary block copolymers $(Ap)_mApU(pU)_n$[19] revealed a dependence of the structure of the complexes on the A/U ratio in the oligomer chain. A double-stranded helix is formed for $m \geq n$, while larger aggregates containing triple-stranded sections are produced for $m < n$.

The interaction of oligonucleotides with a heterogeneous nucleotide sequence leads to the formation of short double helix duplexes with a fixed position of one nucleotide chain relative to the other[21–26], provided that such interaction is not complicated by the self-aggregation of the components, as in the case of the complex G–G–C.G–C–C.[20] It has been observed recently that the hybrid ribo-deoxyriboduplex $r(C–U_5–G).d(C–A_5–C)$ has a triple helix (2:1) structure[27].

If the primary structures of the heterogeneous oligomers permit the formation of duplexes with "sticky" ends, for example, d(G–A–T–C–C–G–A–A–T–T–C–G)[28], d(T–G–C–A–C–A–T–G)[29], d(T–G–G–C–C–A–A–G–C–Tp)[30,31], and $d(A–T)_3(C–G)_3$,[32] etc.,[33] then the self-association of such oligomers results in the formation of double helices of the "concatameric" type. Concatamers are double helix complexes containing repeating nucleotide sequences. The structure of the concatamers formed by the above oligonucleotides resembles that of the polymeric complexes but differs from it by the presence of non-coincident breaks in the complementary chains.

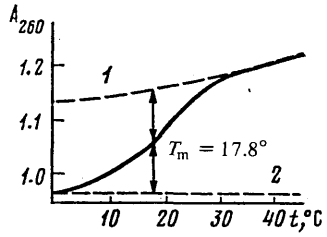
III. THERMODYNAMIC DESCRIPTION OF THE COMPLEX FORMATION BY COMPLEMENTARY OLIGONUCLEOTIDES

1. General Principles of the Cooperative Interaction of the Oligomers

According to modern ideas, the characteristics of the behaviour of double (triple) helix nucleotide structures in solution are determined by the interaction between the heterocyclic bases, the influence of the solvent, and the electrostatic effects of the phosphate groups. The forces involved in the complex formation have been considered theoretically in a monograph[34]. The change in the state of each covalently bound monomeric unit in the complementary complex does not take place independently of the neighbouring units, which is the reason for the cooperative character of the formation and dissociation of the double (triple) helix systems. The compact packing of the heterocyclic bases of the double helix is drastically impaired in the dissociation of the complex, which is reflected in the cooperative alteration of many physicochemical characteristics of the system[5]—the absorption ultraviolet and infrared spectra, the circular dichroism (CD) and optical rotatory dispersion (ORD) parameters, NMR signals, and also hydrodynamic parameters, etc. The curves for the temperature variation of these parameters are referred to as the melting curves and make it possible to estimate the fraction of paired bases (f) at a given temperature. For example[19]:

$$f(T) = \frac{A_s(T) - A(T)}{A_s(T) - A_d(T)},$$

where $A_S(T)$ and $A_d(T)$ are the ultraviolet absorbances of the denatured and native complexes respectively at the given temperature, $A(T)$ is the ultraviolet absorbance of the solution observed at the given temperature (a point on the melting curve—Fig.1). T_m is defined as the temperature at which $f = 1/2$.



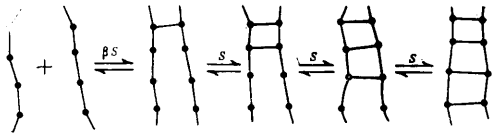


Figure 1. Temperature variation of the optical density of the intermolecular complex formed by $(Ap)_4ApU(pU)_4$ (1 M NaCl, pH 7.4): 1) $A_S(T)$; 2) $A_d(T)$.[19]

The statistical theory of the helix–coil transition, based on a modified monomeric Ising model[35], has now been fairly thoroughly developed[36] and is used to obtain the thermodynamic parameters of the complex formation process from the analysis of the experimental melting curves. Within the framework of this theory, the cooperative properties of the complementary oligomeric complexes, incorporating a single type of base pairs, can be described by a simple model with three parameters: the nucleation parameter β of the double helix ($\beta \ll 1$); the equilibrium constant S of the formation of the nucleotide pair next to a double helix sequence already

formed ($S > 1$); the number N of base pairs in the duplex. According to Applequist and Damle[37], the formation of the helix can be represented schematically as follows for the tetramer:

where βS is the formation constant of the isolated base pair (it determines the helix initiation process). The essential feature of the theory consists in the fact that the base pairs within the structure are much more stable than the terminal pairs and the initiation of the double helix therefore leads to the rapid complementary pairing of the bases of the entire nucleotide chain. However, the free energy gain for fairly long nucleotide sequences, which determines the increase in the length of the double helix, is compensated by the favourable entropy characteristics of the incompletely bound structures. The statistical weight of such structures increases sharply with increasing chain length. Indeed, whereas the formation of a complete double helical complex or a fully dissociated coil can occur in only one way, one can imagine a multiplicity of intermediate structures containing half of the theoretically possible nucleotide pairs. The competition between the above two factors leads to a finite average length L of the helical segments, in the region of the helix–coil transition, alternating with the melted sections; $L \cong 20$–100 nucleotide residues[1]. In the case of fairly short oligomeric sequences, with $N \ll L$, the complex formation process can be described with the aid of the "all or nothing" model (the two-state model), neglecting the number of oligonucleotides in which not all the bases are linked within the complex.

2. The Two State Model

Complex formation in accordance with the "all or nothing" principle takes place for fairly large helix propagation constants $S > 10$ (Pörschke[11]) ($\beta \ll 1$). Within the framework of this model, it is assumed that in the range of the helix–coil transition short or even nucleotides exist in only two states—in the fully double helix state or in the free state. The equilibrium constant K for the complex formation by the oligonucleotides containing N monomeric units can be formulated as the product of the constants for the individual stages of the reaction[15]:

$$K = \beta S^N \ .$$

The equilibrium constant can also be expressed in terms of f (Borer et al.[23]):

$K = f/2(1-f)^2c$ (interaction of self-complementary chains);

$K = 2f/(1-f)^2c$ (interaction of non-identical complementary sequences of the same length),

where c is the overall nucleotide concentration of the oligomeric components.

The equilibrium constant of the interaction of trinucleotides with complementary oligomeric matrices, containing repeating trinucleotide sequences[18], as well as the equilibrium constant of the formation reaction of concatamers with symmetrically overlapping blocks[29] were derived recently. The fraction of paired bases can be determined directly with the aid of osmometric experiments. A more convenient method of determination of f consists in the analysis of fusion curves.

The thermodynamic description of the complex formation process usually involves the calculation of $\Delta H°$, $\Delta S°$, β, and S.

Within the framework of the two-state model, the enthalpy of reaction can be determined as follows.

1. From the temperature variation of the equilibrium constant (by the van't Hoff method):

$$\ln K = -\Delta H°/RT + \Delta S°/R \ .$$

2. From the concentration variation of T_m[15,19]:

$$1/T'_{пл} = 1/T''_{пл} + R/\Delta H° \cdot \ln c'/c'' \ .$$

We may note that this method is applicable only to the description of intermolecular interaction, because intramolecular complex formation is independent of concentration.

3. From the slope of the melting curve at the point corresponding to T_m (Podder[21]):

$$(\partial f/\partial T)_m = \Delta H°/6RT_m^2 \ .$$

If the melting curve is expressed in a differential form, the formula relating the enthalpy of reaction to the half-width of the transition (T_1–T_2) can be written as follows[38]:

$$\Delta H° = -5.106 R T_1 T_2/(T_2 - T_1),$$

where T_1 and T_2 are the temperatures (K) at which $(\partial f/\partial T^{-1}) = 0.5(\partial f/\partial T^{-1})_{max}$. The enthalpy of complex formation determined by the second method agrees well with $\Delta H°$ obtained by direct calorimetric measurements [this has been demonstrated for the duplexes $d(G-C)_3$[39] (Table 1, system 9) and A_7U_7[40]].

The determination of the heat of formation of oligomeric duplexes with different numbers of base pairs makes it possible to estimate the enthalpy change per nucleotide pair[15]:

$$\Delta H° = \Delta H°_{\beta S} + (N-1)\Delta H°_S \ ,$$

where the indices βS and S denote respectively the thermodynamic parameters of the formation of the first and subsequent nucleotide pairs. If it is assumed that the stability of the oligomeric duplex is proportional to the number of monomeric units, then $\Delta H° = N\Delta H°_1$ and $\Delta S° = N\Delta S°_1$, where $\Delta H°_1$ and $\Delta S°_1$ are the thermodynamic parameters of the formation of the nucleotide pair on the assumption that all the base pairs are identical[19].

Since T_m for the duplex is usually measured more accurately than $\Delta H°$ and $\Delta S°$, it is useful to examine the dependence of T_m on the length of the oligomeric duplex. The direct proportionality between $1/T_m$ and $1/N$ has been predicted[37]:

$$1/T_m = 1/T_m^\infty + R \cdot \ln(\beta c)/N\Delta H°_1 \ ,$$

where T_m^∞ is the melting point of the corresponding polymeric complex and c the concentration of the oligomeric components. The slope of the $1/T_m - 1/N$ straight line and the intercept on the ordinate axis make it possible to determine the nucleation parameter and T_m respectively subject to the condition that $\Delta H°_1$ is known. Here it is assumed that $\Delta H°_1$ and β are constant. In real nucleotide systems the dependence of $1/T_m$ on $1/N$ frequently deviates from linearity[13,15], which indicates a temperature variation of β. If this is true, the enthalpies of the initiation ($\Delta H°_{\beta S}$) and propagation ($\Delta H°_S$) of the helix should differ. The temperature dependence of β is taken into account by introducing the stacking factor χ, which determines the relative contribution of the interplanar interactions to the enthalpy of propagation of the double helix[41]: $\Delta H°_\beta = -\chi\Delta H°_S$. The modified equation of Applequist and Damle has the following form[1]:

$$1/T_m = 1/T_m^\infty + 1/N - \chi R \ln(\beta S^\chi c)/\Delta H°_\beta \ .$$

The equation includes two limiting cases: the enthalpy of initiation is equal to the enthalpy of propagation of the helix ($\chi = 0$) and the enthalpy of initiation is zero ($\chi = 1$). The

best agreement with experimental data for the complexes oligo(A).oligo(U) is obtained when $\chi = 0.7$,[11] for $d(pG-C)_n$[15] and the hybrid complexes $d(pT)_8.rA(pA)_7$[13] when $\chi = 1$, and for the oligo(A) double helices in an acid medium when $\chi = 0$.[41]

The two-state model constitutes a good approximation for the calculation of the thermodynamic parameters of the complex formation by short oligomers. However, in each specific case it is useful to estimate the validity of the applicability of this model. The conditions governing the validity of the two-state model have been described in a review[1].

3. The Model Taking into Account the Set of States (the "Staggered Zipper Model")

In the calculation of the thermodynamic parameters of the complex formation by fairly long oligomers ($N \cong L$), it is no longer permissible to neglect the concentration of the oligonucleotides where not all the bases are linked in the complex. In order to describe the thermodynamics of such systems, Applequist and Damle[37] proposed a model taking into account the set of partially bound structures. Taking into account the equilibrium constants for each state βS^z (z is the number of paired bases), it is possible to derive the overall equilibrium constant of the complex formation reaction:

$$K_z = \beta\chi(z, N)S^z \ ,$$

where $\chi(z,N)$ is the number of possible states of the complex with z nucleotide pairs. The proposed model makes it possible to estimate quantitatively the populations of different states (for further details of the theory, see Applequist and Damle[37]). The formation of the oligo(A) double helix in an acid medium[41] as well as the complex formation by $d(A-T)_n$[16], oligo(A) + oligo(U)[11], and a large set of heterogeneous oligoribonucleotides[22] have been described thermodynamically with the aid of this model (Table 1). For comparatively short oligomeric complexes (up to 10 monomeric units), the experimental fusion curves are described satisfactorily, as stated above, by the simpler two state model and the thermodynamic parameters of the reaction obtained with the aid of the two models are very similar[22]. Since the direct application of the "staggered zipper model" is fairly complex in the interpretation of experimental data, the "all or nothing" model is usually employed as a first approximation in the determination of thermodynamic parameters. Subsequently the results are corrected on the basis of the analysis of the populations of the intermediate states.

4. The Introduction of Corrections in the Calculation of Thermodynamic Parameters

Evidently in the temperature range corresponding to the melting of oligomeric duplexes (usually at comparatively low temperatures) there is equilibrium between the double helix complex and the single stranded components in which the interplanar interactions are only partly affected. The intrinsic secondary structure of the oligomeric strands is determined by the stacking interactions of the bases, which weaken with increase of temperature[42,43]. Thus the non-cooperative process involving the breakdown of the stacking conformations of the single-stranded components is superimposed on the helix–coil transition in the oligomeric systems. In order to compare the thermodynamic parameters of the complex formation reactions in different systems, it is necessary to eliminate the stacking interactions of the oligomers, i.e. to begin the reckoning from the fully destructured state.

The contribution to the free energy of the helix–coil transition due to the breakdown of the stacking conformations of the single-stranded oligonucleotides can be represented as follows[11,22]:

$$\Delta G^0_{\text{stacking}} = RT \ln (1 + e^{\Delta G^0_A/RT})(1 + e^{\Delta G^0_B/RT}) \ ,$$

where ΔG°_A and ΔG°_B are the free energies of the stacking interaction between neighbouring bases in the complementary oligomeric chains (A and B). It is fairly difficult to calculate ΔG°_A and ΔG°_B. For this purpose, it is necessary to examine the transition of each interacting oligomer from the ordered to the disordered state and to calculate the enthalpy and entropy of this process. A simpler approach involves the use of the thermodynamic parameters of the stacking interaction of dinucleotide phosphates[13,22] This type of correction of thermodynamic data has been made for a series of oligoribonucleotide systems[11,13,22] (Table 1). It follows from the tabulated data that the enthalpies and entropies of complex formation of oligoribonucleotides calculated with and without allowance for the breakdown of the stacking conformations of the single-stranded components differ appreciably. This shows that at the melting point of the complex the intrinsic secondary structure of the oligoribonucleotide chains is only slightly affected. Since the thermal stability of the stacking conformations in oligodeoxyribonucleotides is much lower than in oligoribonucleotides[44,45], the corresponding energy contribution is not significant in the calculation of the thermodynamic parameters of the complex formation by the DNA oligomers[15]. It is of interest to note that the fraction of the stacking conformations of the single-stranded components diminishes after the addition of up to 10% of alcohols, urea, etc. to aqueous solutions[46].

The statistical theory developed by Warshaw and Cantor[47] predicts that the stacking conformations of the single-stranded oligomers are the most important of the three factors which determine the difference in the behaviour of short double helices and polymer systems. The two other factors are the influence of the terminal nucleotide pairs and the effects of the neighbouring base pairs, which are characteristic of heterogeneous oligomeric duplexes.

Electrostatic interactions also influence the free energy of complex formation. Theoretical examination of the interaction of the negative charge of the phosphate groups of the complementary nucleotide chains with the counterions predicts a linear increase of T_m with increase of the logarithm of the concentration of univalent ions in polymer systems[38,48]. For oligomeric complexes, some deviation is observed from the linear relation [for example, in the oligo(rA).oligo(dT) system[13]]. The influence of the length of the chain of the oligomeric complex on the relation between T_m and $\lg I$ (I is the ionic strength of the solution) has also been noted[14,15].

The contribution of electrostatic interactions to the free energy of the helix–coil transition is usually described by the equation[11,13,48]

$$\Delta G^0_{\text{electr}} = RT(C_1 - C_2 \lg I) \ ,$$

where C_1 and C_2 are empirical constants. According to the data of Hogget and Maass[13], the constant C_2 for oligomeric complexes can be estimated from the dependence of the stability constant of the double helix on the ionic strength of the solution.

Thus the change in free energy as a result of the increase in the length of the double helix by one nucleotide pair (ΔG°_S) can be expressed as follows taking into account the stacking interactions in the single-stranded oligomers and the electrostatic interactions[11,13]:

$$\Delta G^0_S = \Delta G^0_{12} + \Delta G^0_{\text{stacking}} + \Delta G^0_{\text{electr}} \ ,$$

Note. The thermodynamic parameters of systems 1, 2, and 8 were calculated taking into account the breakdown of the stacking conformation of the single-stranded components. The two-state model (systems 2–6 and 8–15), the model taking into account the set of states (system 1), or both models (system 7) were used in the calculation (the values of $\Delta H°_S$ calculated on the basis of the two-state model are given in brackets); the abbreviations for the oligonucleotides were taken from the original communications.

* The values of $\Delta H°$ and $\Delta H°_S$ calculated in different ways are quoted.

** The values of $S°$, $\Delta H°_S$, and $\Delta S°_S$ refer to the formation of the G:C pairs.

*** The values of T_m, $\Delta H°$, and $\Delta S°$ calculated from the temperature variation of the CD parameters are quoted; the values evaluated from the temperature variation of the ultraviolet absorption are given in brackets.

**** The values of $\Delta H°$ and $\Delta S°$ for $n = 3$ (n is the number of octanucleotide molecules involved in the formation of the concatamer) are quoted.

where $\Delta G°_{12}$ is the energy of formation of the additional nucleotide pair from the statistical coil with uncharged phosphate groups.

The chain propagation constant $S = e^{\Delta G°_S/RT}$. The breakdown of the stacking conformations of the single-stranded oligomers and electrostatic interactions also influence the initiation of the double helix[11].

The thermodynamic parameters of the formation of oligomeric complexes of different composition and length, calculated resorting to different models, are summarised in Table 1. The first detailed thermodynamic studies of the complex formation by oligoribonucleotides were undertaken by Pörschke[11] [oligo(A).oligo(U)] and in the studies of Martin et al.[19] and Uhlenbeck et al.[49] [$(Ap)_nApU(pU)_n$ and $(Ap)_nCpG(pU)_n$]. Subsequently oligomeric duplexes with a greater variety of compositions and nucleotide sequences were investigated. The thermodynamic parameters of 19 RNA duplexes containing between 6 and 14 nucleotide pairs have been reported[23]. The thermodynamics of the formation of DNA duplexes have also been investigated: self-complementary oligomers with the repeating dinucleotide sequences $d(A-T)_n$[16] and $d(pG-C)_n$[15], with the heterogeneous sequences d(A—T—G—C—A—T)[51], d(G—G—A—A—T—T—C—C)[52], etc. (Table 1). A thermodynamic description of the formation of double helical oligodeoxyribonucleotide complexes with breaks in the chain of phosphodiester bonds, including complexes of the concatameric type, has been achieved recently[18,29,30].

IV. CHARACTERISTIC FEATURES OF THE THERMODYNAMICS OF COMPLEX FORMATION BY HETEROGENEOUS OLIGONUCLEOTIDES

1. The Stability of the A:U(T) and G:C Pairs

The increase of the thermal stability of natural DNA and synthetic double helix polynucleotides with increase of the relative content of the G:C pairs is a well known experimental fact[54]. The correlation between the content of the G:C pairs and the stability of the helices has been demonstrated also at the level of oligomeric complexes. Thus, in a study[49] on the stability of the complexes of the block copolymers $(Ap)_nApU(pU)_n$, $(Ap)_nCpG(pU)_n$, and $(Ap)_nG(pU_n)(Ap)_n\cdot C(pU)_n$, it was shown that T_m of the double helices increases in direct proportion to the percentage content of the G:C pairs; with increase of the content of such pairs by 1%, T_m of the complexes increases on average by 0.9°. For natural DNA and RNA, the corresponding increments are 0.5° and 0.75° respectively. The enhanced stability of the G:C pairs in the oligomeric duplexes is believed[49] to be caused by the fact that the nucleotide sequence of the base pairs in the duplexes is far from the quasi-statistical distribution characteristic of the natural nucleic acids. The enthalpy of complex formation by $(Ap)_nCpG(pU)_n$ is significantly higher than the enthalpy of complex formation by $(Ap)_nApU(pU)_n$: −65 and −54 kcal mol^{-1} respectively (for $N = 8$). According to the authors' estimate[49], $\Delta H°_{G:C}$ is higher by ~ 3–4 kcal mol^{-1} than $\Delta H°_{A:U}$.

The study of duplexes containing complementary pairs of one type permitted the calculation of the thermodynamic parameters of the formation of the A:U(T) or G:C pairs. The value of $\Delta H°_{G:C}$ obtained from the study of the complex formation by $d(pG:C)_n$[15], which is −11.1 kcal mol^{-1}, greatly exceeds $\Delta H°_{A:U}$, which has been estimated as −8 kcal mol^{-1},[16] while the free energy of a single G:C pair at 37 °C corresponds to the free energy of two A:T pairs. Fig.2 presents the dependence of the thermodynamic parameters of the formation of nucleotide pairs on the composition of the deoxyribonucleotide duplexes.

The enthalpies of formation of the G:C and A:U pairs obtained with and without allowance for the stacking interactions in the oligomers have been compared[22]. In a study of the complex formation by a large set of oligoribonucleotide with a heterogeneous composition, it was established[22] that the enthalpy of formation of the G:C pair from a fully destructured coil (−15 kcal mol^{-1}) is higher than the corresponding value for the A:U pair (−10.7 kcal mol^{-1}). If a correction taking into account the temperature dependence of the stacking conformation of the single-stranded oligomers

is applied in the calculation of the enthalpy, then the difference between $\Delta H^{\circ}_{G:C}$ (−5 − −6 kcal mol^{-1}) and $\Delta H^{\circ}_{A:U}$ (−5 − −6 kcal mol^{-1}) virtually disappears, because the two bases in the G:C pairs interact with the neighbouring bases, whereas the stacking interactions in the A:U pair with participation of uracil are insignificant.

The stability constants S of the G:C and A:U(T) pairs have been calculated for a series of ribo- and deoxy-ribonucleotide complexes (Table 1). Comparison of $S_{G:C}$ (100–200) with $S_{A:U}$ (~ 10) shows that the G:C pair is on average 15 times more stable than the A:U(T) pair.

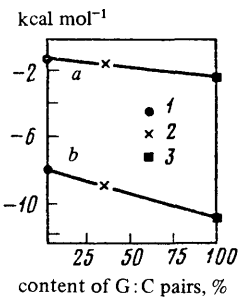

Figure 2. ΔG°_{S} (*a*) and ΔH°_{S} (*b*) for the formation of nucleotide pairs in DNA of different composition at 37 °C (1 M NaCl, pH 7.0): 1) poly d(A–T); 2) T-2:phage DNA; 3) oligo [d(pG–C)].[15]

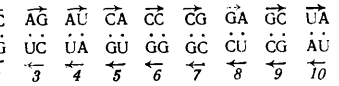
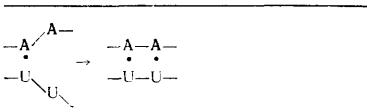
2. The Influence of the Nucleotide Sequence and Other Factors on the Stability of the Duplexes

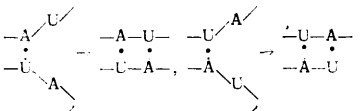
It follows from the analysis of the data in Table 1 (system 7) that $S_{G:C}$ depends on the nucleotide sequence of the oligomeric components, i.e. the stability of the oligomeric complexes is influenced not only by the length of the helix and the nucleotide composition but also by the sequence of the base pairs in the chain (nucleotide environment). The dependence of the thermal stability of nucleotide complexes on the base pair sequence was observed for the first time for synthetic polymer systems with a repeating di(tri)nucleotide sequence[55,56].

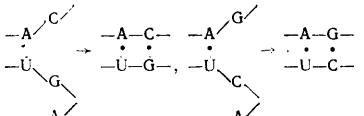
According to modern ideas[23], the difference between the stabilities of the isomeric complexes is due to the different geometries of the "stacking" of neighbouring base pairs in the helical structures. Theoretical calculations predict that the contribution of each base pair to the stability of the complex depends mainly on the nearest neighbouring base pairs, although in real systems it is frequently impossible to neglect the contribution of long-range interactions. Evidently the influence of the nucleotide sequence should be manifested most strikingly in the properties of short oligomeric complexes. Indeed, when five isomeric helices containing two G:C and four A:U pairs are compared, the T_m of these complexes under the conditions of identical nucleotide concentrations vary from −1.3° to 28.3 °C.[23] An increase in the length of the nucleotide chain leads to a gradual averaging of the thermodynamic parameters and in the limit this effect is not manifested for polymeric structures with a statistical distribution of bases along the chain.

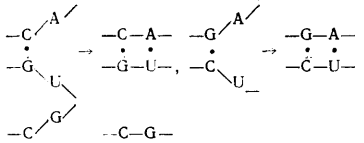
By considering only the Watson–Crick A:U(T) and G:C interactions, it is possible to formulate 10 different combinations of two nucleotide pairs, i.e. 10 different ways in which the interplanar interactions between two base pairs in the double helix can take place:

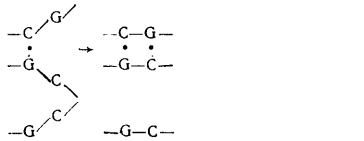












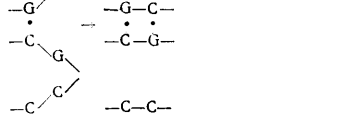


Table 2. Thermodynamic parameters of the formation of the nucleotide pair next to a base pair already formed (for all possible combinations of two Watson–Crick pairs)*[23].

Reaction	ΔH°_{S}, kcal mol^{-1}	ΔS°_{S}, e.u.	ΔG°_{S}, kcal mol^{-1} 25 °C
	−8.2	−23.5	−1.2
	−6.5	−16.4	−1.6
	−5.9	−12.7	−2.1
	−13.0	−33.5	−3.0
	−14.7	−34.9	−4.3
	−13.7	−29.8	−4.8

* The calculation was based on the thermodynamic data presented in Table 1 for these systems[23].

Gralla and Crothers[57] isolated three combinations of two pairs of bases—two neighbouring A:U pairs in any order, two neighbouring G:C pairs in any order, and two neighbouring A:U and G:C pairs in any order, and obtained three equilibrium constants for the description of the helix–coil equilibrium on the basis of the interaction of the neighbouring pairs. The study of the thermodynamics of the series of oligomeric duplexes of different compositions and with different nucleotide sequences permitted[23] the calculation of the thermodynamic contributions of six combinations of nucleotide

pairs. Table 2 presents the ΔH_S°, ΔS_S°, and ΔG_S° for the formation of a specific nucleotide pair next to one already formed. It is seen from the tabulated data that the $\begin{matrix}\rightarrow\\ CC\\ \cdot\cdot\\ GG\\ \leftarrow\end{matrix}$ doublet is more stable than $\begin{matrix}\rightarrow\\ GC\\ \cdot\cdot\\ CG\\ \leftarrow\end{matrix}$, which is in its turn more stable than $\begin{matrix}\rightarrow\\ CG\\ \cdot\cdot\\ GC\\ \leftarrow\end{matrix}$, while the complex consisting of a block of G:C pairs followed by a block of A:U pairs is more stable than the double helix containing repeating A:U and G:C pairs. We may note that it has recently been possible to determine the equilibrium constants for the dimerisation of dideoxyribonucleotides with different sequences by NMR[58]. The sequence of the stabilities of the corresponding minihelices is fully consistent with that predicted by Borer et al.[23]: d(pG–G).d(pC–C) ≥ d(pG–C).d(pG–C) > d(pC–G).d(pC–G). The stabilities of short double helix complexes can be predicted fairly accurately with the aid of the calculated thermodynamic chain propagation parameters and the T_m of polymeric structures with known sequences can be estimated approximately).

It has been observed[59] that the T_m of the double-stranded tetranucleotides C–A–U–G, U–G–C–A, and A–G–C–U, containing equal numbers of the G:C and A:U pairs, are different (25°, 33°, and 34° respectively), i.e. the duplexes with A:U pairs at the ends are more stable than those which terminate in G:C pairs. It has been suggested[59] that a central core of G:C pairs leads to an increase of stability.

One of the factors which increase the stability of the duplexes is the flanking of the double helix by an unpaired (looped) nucleotide residue[19,59], purine nucleotides leading to a greater stabilisation (by ~ 11°) than pyrimidine nucleotides (by ~ 5°).[59] The location of the additional nucleotide residues (the 3′- or 5′-end) is not very important[59]. The cause of the increased stability of the duplex is not completely clear. One of the explanations[6] consists in the fact that the additional "stacking" with the looped bases stabilises the terminal pairs of the duplex, which would otherwise frequently become uncoupled at temperatures below T_m (see below). If the length of the non-complementary shoulders amounts to several nucleotide residues, then the stability of the oligomeric duplexes actually diminishes. For example, a mixture of two icosanucleotides, capable of forming 10 nucleotide pairs, altogether fails to exhibit a cooperative melting profile[60].

Comparison of the stabilities of a series of seven-unit duplexes (system 13, Table 1) of the deoxyribo-series, the ribo-series, and hybrids with similar compositions and sequences (in oligoribonucleotides T is replaced by U) showed that the duplex $dC(pA)_5pG.rC(pU)_5pG$ with the oligo(dA.rU) sequence is extremely unstable, in contrast to the remaining duplexes[3]. The dA clusters with a length corresponding to ~ 5 pairs apparently assume preferentially the B-DNA conformation as a result of which they cannot form stable DNA–RNA hybrids. According to Martin and Tinoco[53], this facilitates the termination of transcription. The influence of the solvent on the thermodynamics of the $d(G–C)_3$ complex formation has been examined[46]. The addition of primary alcohols, formamide, dimethylformamide, or urea to an aqueous buffer solution of $d(G–C)_3$ destabilises the double helix.

V. KINETICS OF THE FORMATION AND DISSOCIATION OF THE OLIGOMERIC COMPLEXES

The kinetic parameters of the formation or dissociation of nucleotide complexes are usually obtained with the aid of the temperature jump method, which is based on the measurement of the time variation of various physicochemical parameters of the system, for example, ultraviolet absorption, after an abrupt increase of temperature. One then obtains the so-called relaxation curve. A characteristic feature of these curves is the relaxation time τ. In all the intermolecular oligomeric complexes investigated the reaction involving the formation of the complementary pairs is of second order and is characterised by a unique relaxation time (from 10^{-3} to 1 s)[22,61] and the temperature at which the maximum amplitude of the relaxation curve is attained is close to the T_m of the duplex[21].

The relaxation time, characterising the complex formation reaction of the oligomers, is related directly to the rate constants for the formation (k_r) and dissociation (k_d) of the double helix and the equilibrium concentrations of the complementary chains (c_A and c_B)[13,22]:

$1/\tau = 4k_r c_A + k_d$ (complex formation by self-complementary oligonucleotides: $A \underset{k_d}{\overset{k_r}{\rightleftharpoons}} AA$);

$1/\tau = k_r(c_A + c_B) + k_d$ (complex formation by non-identical oligomers: $A + B \underset{k_d}{\overset{k_r}{\rightleftharpoons}} AB$).

The rate constants for the forward and reverse reactions can be estimated by plotting $1/\tau$ against the concentration of the free chains.

The complex formation by oligonucleotides can be regarded as a process involving the successive formation of complementary pairs. Since the formation of the nuclei of a nucleotide pair (or several pairs) is a second-order reaction, this stage is a more complex and slower process than the subsequent growth of the double helix[62]. If the formation of the first nucleotide pair is the rate-limiting stage in the complex formation process, then the enthalpy of activation for the latter (ΔH_r^*) should be identical with that of the elementary reaction whose rate is limited by the diffusion of the components: +2 – 6 kcal mol^{-1}.[22] However, the ΔH_r^* for oligo(A) in an acid medium[41], for oligo(A).oligo(U)[61], and oligo(rA).oligo(dT)[13] are negative. In order to resolve this contradiction, Eigen and Pörschke[41] suggested that the stage limiting the rate of the recombination process is the formation of a stable core made up of several nucleotide pairs. The formation of a stable nucleus of the helix is preceded by a stage involving pre-equilibrium between the rapidly formed and decomposed unstable nucleotide pairs. Further growth of the double helix is very rapid. The overall recombination rate constant is then independent of the length of the oligomer chain[13]. On the basis of the analysis of the ΔH_r^*, it was established that, for the complexes containing only the A:U(T) pairs, the core of the helix incorporates ~ 3 pairs of bases[13,41,61,62].

Since the association constant of the G:C pairs is ~ 15 times greater than for the A:U(T) pairs, the recombination of oligonucleotides of mixed composition begins with the formation of the G:C pairs[22]. In these systems k_r changes from 10^5 to 10^7 litre mol^{-1} s^{-1}.[21,22,25,51]. For the $(A)_n.(U)_n.[(T)_n]$ helices, k_r is of the same order of magnitude (10^6 litre mol^{-1} s^{-1}).[61] Having investigated the kinetics of complex formation in heterogeneous systems, Pörschke et al.[22] isolated three characteristic kinetic features: (1) in the given series of oligomers the rate of recombination diminishes rapidly with increase of chain length; (2) the rate of recombination diminishes rapidly with increase of chain length; (2) the rate of recombination of oligomers with identical chain lengths is 6 times faster when the G:C pairs are at the end of the helix and not in its centre; (3) the enthalpy of activation for the formation of oligomeric duplexes containing G:C pairs is positive.

According to the authors[22], the first two features can be explained by the different accessibility of the G:C pairs initiating recombination in oligomeric systems with different nucleotide sequences and lengths. The positive enthalpy of activation for the complex formation by heterogeneous oligomers[21,22] is associated with the fact that the rate-limiting stage in the recombination process is the formation of one or possibly two G:C pairs. In this case there is no need to employ a model incorporating a stage with pre-equilibrium between several pairs of bases.

The dissociation of oligomeric duplexes is much slower than their formation[21,22,25,51,61]. In contrast to k_r, the rate constant for the dissociation of the duplex depends greatly on the length of the helix, i.e. on the number of nucleotide pairs which must be ruptured before the critical intermediate helix is attained[13,22]. The activation enthalpy for the dissociation process ΔH_d^* increases with increasing chain length[13,62].

VI. COMPLEMENTATION INTERACTIONS OF DINUCLEOTIDES

A characteristic property of double helical oligonucleotides is the dependence of the stability of the complex on the chain length and the nucleotide concentration. The relation between T_m, N, and c is given by the equation of Applequist and Damle (see above). The shorter the oligomers, the higher must be their concentration in order to observe the formation of the complementary complex. Thus, at an overall nucleotide concentration of 10^{-4} M, the oligomers capable of complementation interactions must comprise at least several mononucleotide units[10,14]. An increase of nucleotide concentration by a factor of 10 promotes the formation of complexes of tetramers[10]. In connection with the development of the high-resolution NMR technique, in recent years it has proved possible to observe in an aqueous medium the interactions between complementary dinucleotides constituting the smallest structural units containing the 3′ → 5′ phosphodiester linkages. It has been shown[58,63,64] that, in aqueous solutions at high nucleotide concentrations (up to 0.1 M), the self-complementary dinucleoside monophosphates of the ribo-series, namely CpG and GpC[63], and their deoxyanalogues[58], as well as the dinucleotides d(pC–G) and d(pG–C)[58,64] form hydrogen bond–stabilised dimers at low temperatures. The formation of complementary pairs was also observed in concentrated solutions of the CpU + ApC,[53] d(pG–G) + d(pC–C), and d(pG–T) + d(pA–C)[58] mixtures. It is noteworthy that, even at the level of dinucleotide complexes, the dependence of the thermal stability of the miniature double helices on the content of G:C pairs is manifested. Thus a less stable complex is formed in the GpU + ApC mixture than the complex arising in concentrated GpC (CpG) solutions as a result of the self association of the dinucleoside monophosphates, while in the UpA solution and also in the crystalline state (see below) complex formation is not observed at all[63].

VII. THE STRUCTURE OF THE OLIGOMERIC COMPLEXES

1. X-Ray Diffraction Analysis

The most exhaustive information about the steric structure of the double helix oligonucleotides can be obtained by their crystallographic investigation. Single crystals of the following self-complementary oligonucleotides have now been investigated by high-resolution (< 2 Å) X-ray diffraction analysis, which makes it possible to trace individual atoms: UpA[65,66], ApU[67], GpC[68,69], d(pA–T–A–T)[70], and d(C–G–C–G–C–G)[71]. The d(C–G–C–G)[72,73], d(C–G–C–G–A–A–T–T–C–G–C–G)[74,75], and d(G–G–T–A–T–A–C–C)[76] single crystals have been studied with a somewhat smaller resolution (2.25–2.7 Å). In addition, the X-ray diffraction patterns of yet another dimer, namely TpdA, were obtained in 1976.[77] However, instead of single crystals, "oriented" specimens of TpdA, in which the TpdA molecules were built into helical structures (the limit of the resolution in the X-ray diffraction of fibres usually does not exceed 3–4 Å), were investigated.

Among the self-complementary dimers enumerated, only ApU and GpC form Watson–Crick pairs in the crystalline state. The crystal structure of UpA models the loop-like sections of RNA as a result of the specific conformation of the phosphodiester linkage, while TpdA forms unique left-handed helical structures in which the adenine and thymine residues of neighbouring molecules are linked by hydrogen bonds in the "Hoogsteen" manner. We shall dwell in greater detail on the description by Rich and coworkers[67,69] of the crystal structures of ApU and GpC, because theirs were the first data on the Watson–Crick pairs with atomic resolution. Two ApU (or GpC) molecules form in the crystal a segment of the right-handed RNA double helix with the antiparallel directions of their chains. The complementary bases do not lie precisely in a single plane but are slightly tilted. In each chain the bases are arranged in a stack, overlapping to the maximum extent. Such complete "stacking" is a consequence of the purine–pyrimidine sequence of dinucleoside phosphates. The distance between the C(1′) atom of the ribose residues in the A:U pairs is somewhat shorter than the analogous distance in the G:C pairs. This means that the double-helical skeleton is not a completely regular structure but one with systematic "variations", which depend on the nature of the bases. Finally the sites where the counterions are bound depend on the composition and sequence of the bases. The binding of Na^+ ions alters the steric and electrostatic characteristics of the double helix in the sections containing the ApU sequence.

d(pA–T–A–T)[70] in the crystalline state forms a segment of a right-handed double helix with the antiparallel directions of the chains and two pairs of bases stabilised by hydrogen bonds between the first A and the second T in one molecule and the fourth T and the third A in another. The mononucleotide units not involved in the complementation interaction are remote from one another in space. A characteristic feature of the steric structure of d(pA–T–A–T) is different conformations of deoxyribose [C(3′)-*endo* for A and C(2′)-*endo* for T] and different angles of rotation about the glycosidic linkages for the thymidine and adenine residues. The conformations of the phosphodiester linkage in the ...ApT... and ...TpA... fragments also differ. These data served as the starting point for the description of the unusual conformation and hence the special biological role of the poly[d(A–T)].poly[d(A–T)] sections of DNA. Klug et al.[78] suggested that in solution poly[d(A–T)].poly[d(A–T)] assumes the so-called alternating *B* form. In contrast to the classical *B* form of DNA, the repeating structural motif in this double helix consists of two nucleotide pairs.

The most striking results, leading to the discovery of the left-handed double helix of DNA, were obtained by Rich's group in an X-ray diffraction study of d(C–G–C–G–C–G) crystals (resolution 0.9 Å; crystallisation under the conditions of a high ionic strength)[71]. The repeating structural element in this helix, containing 12 G:C pairs per turn, consists of two nucleotide pairs. The alternating guanosine and cytidine residues have different conformations of the glycosidic linkage and of the furanose ring: *syn*- and C(3′)-*endo* for G and *anti*- and C(2′)-*endo* for C. The configuration of

the carbon–phosphate skeleton is very unusual: the phosphate groups are arranged in a zig-zag. This led the authors[71] to call the new structure the *Z*-DNA. Soon the left-handed *Z*-form was discovered also in d(C–G–C–G) on crystallisation at a high ionic strength)[72] and in the poly[d(G–C)].poly[d(G–C)] fibres[79,80]. In their study of the conformational variability of d(C–G–C–G) in the crystalline state, Drew and Dickerson[73] concluded that the *Z*-DNA has a greater conformational flexibility than the *B* form. They described the structural transition from *Z* to *Z'*, associated with a change in the conformation of the furanose ring of guanosine [C(3')-*endo* → C(1')-*exo*] and also the $Z_I \rightarrow Z_{II}$ transition characterising the change in the orientation of the phosphodiester linkage in the ...GpC... unit. The authors conclude that *Z'*, Z_I, and Z_{II} are conformational variants within the limits of the *Z* form. It is of interest that the dodecamer d(C–G–C–G–A–A–T–T–C–G–C–G) exists in the crystalline state as the *B* form with 10.1 bases per turn of the helix, i.e. the terminal C–G–C–G sections are not twisted into the *Z* helix[74].

In 1981 Dickerson and Drew[75] made a detailed X-ray diffraction study with a nearly atomic resolution of the dodecanucleotide d(C–G–C–G–A–A–T–T–C–G–C–G), which forms in the crystalline state a complete coil of the double helix in the *B* form. As a result of the crystal packing effect, the axis of the helix of this duplex is somewhat bent and deviates from the vertical by 19°. It was demonstrated rigorously for the first time that the local parameters of the double helix depend on the sequence of bases, deviating from the classical *B* form, the influence of the nucleotide sequence on the structure of the duplex being much more significant than the influence of the crystal packing and other external factors. Although the local changes in the conformation of the duplex take place within the limits of the *B* form, sections of the double helix whose geometry is more characteristic of the *A* or *D* forms of DNA have been observed. It has been found that purine–pyrimidine steps open their base planes toward the major groove [of the double helix], pyrimidine–purine steps open toward the minor groove"; the bases in the complementary pairs are twisted like the propeller blades and to a greater extent in the A:T pairs. The authors[75,81] reached the important conclusion on the basis of the correlation between the degree of exposure of the sections of the carbohydrate–phosphate skeleton and the rate of cleavage of these sections by the enzyme DNase I, namely that the structure of the dodecanucleotide duplex is identical in both the crystalline state and in solution.

In the next communication of this series[82] the hydrate shell of d(C–G–C–G–A–A–T–T–C–G–C–G) in the crystal was described. It was found that 72 water molecules are arranged around each molecule of the duplex, 50 of which are within the grooves of the helix or in the first coordination shell of the phosphate groups. An attempt was made to estimate the contribution of this factor to the stability of the double helix. The electrostatic potential and the steric accessibility of the reactive sites of the self-complementary dodecamer were calculated from X-ray diffraction data[83]. It was found that a higher negative potential than at the ends is concentrated in the centre of the oligonucleotide duplex. This may be a common feature of such short helices, which is independent of their nucleotide sequence.

The possibility of a wide variety of conformations of the oligonucleotide duplexes of the deoxy-series has been demonstrated[76] in a crystallographic study of d(G–G–T–A–T–A–C–C) containing the fragment of the promoter region of the eukaryotes. It was found that this octamer forms a right-handed double helix in the *A* form. This unusual fact was observed for the first time for deoxyribonucleotide duplexes containing the G:C and A:T pairs. The existence of an oligomer with this sequence in the stable *A* form can be logically related to the functions of the promoter region.

The advances in the X-ray diffraction study of single crystals of self-complementary oligonucleotides open a new page in the study of the fine structure and conformational possibilities of nucleic acids. There is no doubt that the number of complexes investigated by this method will continuously grow, because information about the structural characteristics of nucleic acids is extremely important at the present stage for the elucidation at the molecular level of the mechanism of the protein–nucleic acid recognition and the regulation of gene activity, and mutagenesis.

2. Ultraviolet Spectroscopy and CD(ORD)

Optical methods, namely ultraviolet spectroscopy and CD(ORD), have found extensive applications in the study of the complementation interactions of oligonucleotides in solution. The stoichiometry of the bonding in oligomeric systems is determined with the aid of these methods[10,20]. The formation of a duplex is inferred from the change in the form of the CD spectra of the complementary (self-complementary) oligonucleotides[18,29,84]. Sometimes, in order to achieve more appreciable changes in CD, a ligand which interacts selectively with a double-helical structure, for example distamycin A, is added[84]. The study of the temperature variation of the ultraviolet absorption and the CD(ORD) parameters make it possible to determine T_m and to calculate the thermodynamic parameters of the formation of complementary pairs (Table 1). The change in the ultraviolet absorption of oligonucleotides during the formation (dissociation) of the double helix constitutes the basis of the determination of the kinetic characteristics of the complex formation[13,21]. Furthermore, the ultraviolet spectroscopic and CD(ORD) methods yield useful information about the secondary structure of oligomeric duplexes.

The structural aspects have been traced in a study by Pohl[85] of the dependence of the hypochromicity of the complexes formed by $d(pG–C)_n$ on the number of base pairs in the double helix. Analysis of this relation enabled the author to conclude that the geometrical parameters of the oligomeric duplexes and natural DNA are similar.

More complete information about the structure of the oligomeric complexes can be obtained with the aid of CD. As a consequence of the high sensitivity of the CD to the relative positions of the heterocyclic residues and the conformation of the monomeric units, the similarity of the CD spectra indicates the similarity of the geometrical parameters of the structures being compared. Thus the structural analogy of the triple-stranded $(Ap)_5A.2(Up)_5U$ and oligo(A).2poly(U) helices has been demonstrated with the aid of this method[9].

Comparison of the CD of the oligomeric complexes and natural nucleic acids of known structure is of particular interest. It was found that the CD spectra of complexes of oligoribonucleotides with one another or with oligodeoxyribonucleotides are of the non-conservative type characteristic of the *A* form of RNA in aqueous medium[10,53,86], while the CD spectra of the oligodeoxyribonucleotide complexes are similar to those of native DNA in the *B* form[53,87]. The CD spectra of the complexes formed by $d(pG–C)_n$ in solutions at a low ionic strength[69] and $d(pG–G–T).d(pA–C–C)_{2-4}$[18,89] are similar to those of DNA in the *B* form with a high content of the G:C pairs, while the CD spectrum of $d(pA)_3.d(pT)_{12}$[89] resembles that of DNA containing ~ 30% of G:C pairs. The CD method makes it possible to distinguish readily the different forms of oligomeric double helices in solution. The CD

spectrum of $d(C-G)_3$ in aqueous solution with a low NaCl concentration[32] resembles the spectrum of poly[d(C–G)]. .poly[d(C–G)] recorded under the same conditions and corresponding to the *B* form[90]. The addition of NaCl (up to 5 M) inverts the sign of the long-wavelength Cotton effect, which is associated with the transition of the oligonucleotide duplex to the left-handed *Z* form[32] [the existence of this form for $d(C-G)_n$ under the conditions of high ionic strength has been demonstrated by X-ray diffraction]. According to CD data, the *Z* form of $d(C-G)_2$ is unstable[32]. In the case of $d(A-T)_3(C-G)_3$, which forms a concatameric complex in which the $d(C-G)_n$ block is flanked by an alternating A–T sequence, the transition to the Z form is not observed according to CD data[32] [cf. the self-complementary d(C–G–C–G–A–A–T–T–C–G–C–G), which has been investigated by X-ray diffraction—see above].

The CD spectra have been calculated recently for numerous possible conformations of d(T–G–G–C–G–T–A–T–T–C–T). .d(A–G–A–A–T–A–C–G–C–C–A) and it has been shown that the CD amplitude at 275 nm varies linearly with the helix winding angle and the base pair twist[91]. The establishment of this correlation is important for the study of the dependence of the CD of nucleic acids on structural parameters.

According to modern ideas, the CD spectra of nucleic acids depend not only on the secondary molecular structure but also on the nucleotide sequence. Gray and Tinoco[92] developed a theory, according to which the form of the CD spectrum of DNA is determined by the interaction of mainly the neighbouring nucleotide pairs. Evidently the dependence of CD on the base sequence should be manifested particularly clearly at the level of oligomeric duplexes, because, in contrast to DNA, in the latter the frequencies of the encounters of specific combinations of two nucleotide pairs are not averaged out. Fig. 3 presents as an example the CD spectra of isomeric ribonucleotide duplexes[86]. The oligomeric duplexes with known sequences have been used in two investigations[86,93] to test the possibility of the determination of the nucleotide sequence of nucleic acids with the aid of CD. The contributions of all 10 combinations of two Watson–Crick nucleotide pairs have been isolated[86] on the basis of the analysis of the CD spectra of a series of oligonucleotide duplexes. The spectra obtained for the isomeric dinucleotide dimers differ sharply both in form and in amplitude. The CD spectra of the polymeric helices, constructed taking into account the spectroscopic contributions isolated, are in poor agreement with experimental curves. Hillen et al.[93] attempted to calculate the CD spectra of 12 restriction fragments of DNA with lengths ranging from 12 to 360 nucleotide pairs. For this purpose, use was made of a set of spectroscopic contributions of specific combinations of two nucleotide pairs taken from the spectra of synthetic double-helical polynucleotide (homogeneous or with repeating di- and trinucleotide sequences). The calculated and experimental spectra agree satisfactorily, with the exception of the positive CD band at 270 nm, which is particularly sensitive to conformational changes. The discrepancy is particularly notable for duplexes containing less than 43 nucleotide pairs apparently as a result of end effects.

3. Nuclear Magnetic Resonance

Together with the optical methods examined, NMR has been widely used recently in the study of the oligomeric complexes[24–27,39,46,52,58,59,87,94–106]. This method permits a detailed description of the steric organisation of the complexes in solution, the elucidation of the dynamics of the dissociation of the double-helical structures, and the estimation of the degree of structural analogy between the oligomeric duplexes and natural DNA and RNA. The overall effects accompanying the helix–coil transition are recorded with the aid of optical methods, while NMR makes it possible to trace the behaviour of individual base pairs.

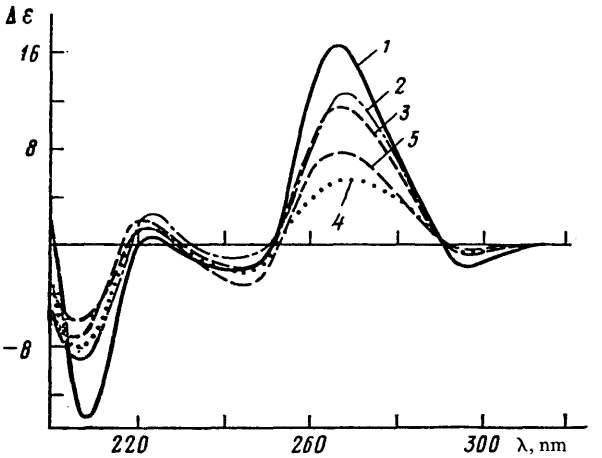

Figure 3. CD spectra of five double helical isomeric complexes containing four A:U and two G:C base pairs (1 M NaCl, pH 7.0, $c = 10^{-2}$ M per monomer unit): 1) A_2GCU_2; 2) A_2CGU_2; 3) U_2CGA_2; 4) $A_4G_2 + C_2U_4$; 5) $A_4CG + CGU_4$.[86]

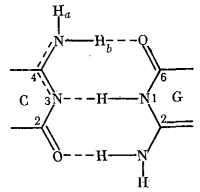
It has now become possible to resolve and assign on high-class instruments (270, 300, 360, 500 and 600 MHz) the majority of the resonance signals of the protons of the bases and the sugar rings in double-helical oligonucleotides containing up to 12 pairs of bases and to reach a conclusion concerning the local environment of each proton. This made it possible to observe independently the changes in the character of the environment of each nucleotide pair of the duplex as the concentration, temperature, pH, etc. are varied. In the case of long nucleotide duplexes, the broadening of the resonance lines is associated with the rigidity of the polymeric nucleic acids, which prevents the rapid movement of the segments of the nucleotide chains in solution. The ^1H NMR spectra of a series of such duplexes, namely $A_{25}.U_{25}$,[107] $d(C_{15}A_{15}).d(T_{15}G_{25})$,[108] $dG_n.rC_{22}$, $dG_n.rC_{11}dC_{16}$, and $dG_n.dC_{22}$ ($n > 70$)[109], as well as two restriction fragments of DNA containing 43 and 69 base pairs[102], have been obtained, but the proton signals of the individual bases have not been assigned.



The ^{31}P NMR (145.7 MHz) spectra of oligonucleotide duplexes have been obtained recently[52,98]. They contain data concerning the conformation of the carbohydrate–phosphate skeleton of the oligomers forming the double helix. The breakdown of the "stacking" of the bases at temperatures exceeding the T_m of the duplex has been detected with their aid. In 1980 Cohen[103] analysed the ^{31}P NMR spectra of oligo d(G–C) obtained previously and suggested that the presence of two well resolved ^{31}P signals in 4 M LiCl and of a single signal at a low concentration of the salt indicate a left-handed *Z* form of the helix in these oligomers in a concentrated salt solution.

Two different groups of proton signals are investigated in order to obtain information about the structure of the oligomeric complexes.

(1) The signals of the non-exchanging protons linked to the carbon atoms of the heterocyclic bases or the sugar—the doublets of the H(5) and H(6) protons of the pyrimidine bases [the H(6) singlet in the case of thymine], the singlets of the H(2) and H(8) protons of the purine bases, the singlet of the CH_3 protons of thymine, and the signals of the protons in the sugar ring, mainly H(1'). They are all located in the range 4–9 p.p.m. relative to sodium 4,4-dimethyl-4-silapentanesulphonate (DSS). The spectra are investigated in D_2O or in buffer solutions containing D_2O. The positions of the oligonucleotide signals are determined as a rule by the standard "incremental assignment" method[26,27,110,111] by measuring the δ for the dimers, trimers, and other fragments of the given oligomer and assuming that the values of δ do not in the main change on passing to the intact oligomer. The chemical shift δ of the signal of each proton is subjected to the shielding influence of the neighbouring bases and also the bases in the complementary chain. Furthermore, the position of the signal is determined by the conformation of the furanose ring, the rotation of the base around the glycosidic linkage, the anisotropy of the phosphate group, and the interchain hydrogen bonds. Consequently δ depends on the structure of the double helix. On thermal dissociation of the complex, the signals of the non-exchanging protons of the bases shift both downfield and upfield[27]. Curves for the temperature dependence of the chemical shifts of the signals of the non-exchanging protons permit a direct determination of the thermodynamic characteristics of the helix–coil transition. Here one can trace the dissociation of each nucleotide pair of the duplex, although the assignment and measurement of the changes in the signals as a function of temperature remain a difficult problem.

(2) The signals of slowly exchanging ring protons of the imino-groups N(1)–H of guanine and N(3)–H of uracil (thymine), which are directly involved in the formation of hydrogen bonds between the bases (Watson–Crick pairs). The spectra are recorded in H_2O or in aqueous buffer solutions. The N(1)–H resonance signal of guanine characterises the G:C pair and the N(3)–H signal of U (T) characterises the A:U(T) pair. We may note that the resonances of the imino-group protons of the free oligomers are not observed in water owing to the rapid exchange between the protons with the solvent. The formation of a hydrogen bond leads to a slower exchange of the protons with water and to the appearance of resonance signals in the region of weak fields (12–15 p.p.m. relative to DSS). The presence of such signals in the ^{1}H NMR spectrum of short oligonucleotides is convincing evidence for the formation of a duplex. With increase of temperature, an upfield shift and a broadening and disappearance of the signals, associated with the increase of the relative content of the open-chain forms and the rapid exchange of the imino-group protons in the open-chain form with water, are as a rule observed. The temperature of the disappearance of the signal is not related to the thermodynamic stability of the double helix and yields only comparative characteristics of the stabilities of different nucleotide pairs of the duplex, because the resonance signals of the N(1)–H protons of G and the N(3)–H protons of T (U) are markedly broadened even at a concentration of the open-chain forms of ~ 10% and cannot be traced further. The observation of the behaviour of the individual signals on gradual increase of temperature helps in their assignment[27,52,99,112]. Here account is taken of the fact that the resonance of the proton of the imino-group of the "isolated" G:C pair is observed in a stronger field (13.6 p.p.m.) than the corresponding resonance of the A:T pair (14.6 p.p.m.).[96] A procedure involving chemical modification is sometimes used in the assignment[99] or the calculated and experimental chemical shifts are compared[27]. When triply-stranded oligomeric complexes are formed, the signals of the imino-group protons corresponding to the formation of "reverse" Hoogsteen A:U pairs are observed[27,104] in addition to the signals of the exchanging protons of the Watson–Crick pairs in the range 14.6–15 p.p.m.

The signals of the exchanging protons of the imino-groups of the C(4)–NH_2 base of cytosine and the C(2)–NH_2 base of guanine, located in the range 6–9 p.p.m. relative to DSS, are considered together with the protons of the imino-group. The exchange of the amino-group protons with the solvent is slower than that of the imino-group protons[98]. The partial double bond character of the C–NH_2 linkage in cytosine restricts the rotation of the amino-group and therefore at low temperatures individual broad signals are observed for each of the protons of the NH_2 groups of cytosine. In complementation interactions the signal of the proton involved in the formation of a hydrogen bond (H_h in the scheme below) shifts downfield, whereas the signal of the proton accessible to the solvent (H_a) undergoes an upfield shift. For guanine, a single resonance signal due to the two protons of the amino-group is observed, which is explained by the rapid rotation of the latter about the C–NH_2 bond.

On formation of the complementary pair, the average signal of the NH_2 protons of guanine shifts downfield. The dependence of the chemical shift of this signal on the nucleotide concentration can be used to estimate the equilibrium complex formation constant for the dinucleotides[58,63]. Furthermore, by analysing the temperature dependence of the width of the proton signals of the amino-groups in cytosine and guanine, it is possible to discover if the rotation of the amino-group about the C–NH_2 bond in the oligomeric duplexes is rapid or slow[98]. It is noteworthy that these signals are more often used to detect the formation of complementary complexes between dinucleoside phosphates (dinucleotides)[58,63,64].

Detailed ^{1}H NMR study of the structural characteristics of a number of oligomeric systems showed that complexes containing the d(A–T–G–C–A–T)[96,113], d(pG–C)$_4$, d(pT–A)$_{3,4}$, d(pA–G)$_4$.d(pC–T)$_4$,[112] d(A–A–A–G–C–T–T–T)[114], d(C–C–G–G), d(G–G–C–C)[98], d(G–G–A–A–T–T–C–C)[52], d(A–T–C–C–T–A–T–A–G–G–A–T)[99], d(C–T$_5$–G).d(C–A$_5$–G)[27], and d(A–A–T–T–G–C–A–A–T–T)[106] deoxyribonucleotide units assume in solution a conformation close to that of the *B* form of DNA, while the geometry of the *A*(*A'*) form of RNA is characteristic of the complexes of the ribo-derivatives A–A–G–C–U–U[26,97], C–C–G–G[96], and A–G–C–U[105] as well as the d(C–T$_5$–G).r(C–A$_5$–G) hybrid derivatives[27]. This conclusion was reached as a result of a comparison of the calculated and experimental chemical shifts for the exchanging and non-exchanging protons of the bases of a given nucleotide pair of the oligomeric complex. In the calculation of the chemical shift, the influence of the magnetic fields of the ring currents on the signals of the corresponding protons was determined (without taking into account the influence of

other factors) for all possible combinations of the neighbouring base pairs, taking into account the known geometrical parameters of the *A*, *B*, and *D* forms of DNA[112,113,115]. One should bear in mind that agreement between the calculated and experimental chemical shifts of the signals of the exchanging protons is by no means always observed[27] and frequently only for the inner pairs of bases in the duplexes[95,96,98,112,114]. Signals of the protons of the end pairs are in a stronger field than required by the calculation. According to a number of investigators[95,112,114], equilibrium between the hydrogen-bonded and open forms are characteristic of the end nucleotide pairs of the duplexes (the signals of the open form were manifested in a stronger field) and the chemical shift of the signals of the imino-group protons is determined by the ratio of the populations of the two forms. An alternative explanation of the upfield shift of the signals of the exchanging protons in the terminal nucleotide pairs is the formation of intermolecular structures as a result of the "stacking" of the ends of the oligomeric duplexes[98]. A discrepancy between the calculated and experimental values of δ has been noted also for the non-exchanging protons of the terminal pairs and has been attributed to the stacking interaction of the ends of the duplexes[52,98]. In a study of the double helical A–G–C–U and A–C–G–U, the δ for the non-exchanging protons of the bases were calculated much more rigorously[105]. The calculated and experimental δ for the majority of the non-exchanging base protons of A–C–G–U did not agree, in contrast to its isomer. The authors concluded that the double helix in A–C–G–U is a non-standard form, and emphasised the importance of this conclusion for the estimation of the conformational possibilities in the RNA duplexes.

The conformation of the furanose rings in the nucleotide units of the complex, which determines the form of the double helix, has also been established with the aid of ^{1}H NMR data. For this purpose, measurements were made of the spin–spin vicinal coupling constants of the protons at C(1′) and C(2′) and were compared with the values predicted for different conformations of furanose. It was found that, for all the carbohydrate residues in d(A–T–G–C–A–T)[113], d(C–C–G–G), and d(G–G–C–C)[98], under complex formation conditions, the C(3′)-*exo*-conformation is characteristic of DNA in the *B* form. The two deoxyribose residue in the d(C–T_5–G).d(C–A_5–G) duplex, belonging to d(C–A_5–G), are 90% in the C(2′)-*endo*-conformation and the double helix therefore has the geometry of the *B* form[27]. In contrast to these systems, the furanose rings of all the monomeric units of the complex formed by A–A–G–C–U–U[26] or all the monomeric units of the ribo-chain of the d(C–T_5–G).r(C–A_5–G) complex[27] are in the C(3′)-*endo*-conformation characteristic of RNA in the *A*(*A*′) form[26]. Analysis of the temperature variation of $J_{1',2'}$ led to the conclusion that the C(3′)-*endo*-conformation of the furanose rings predominates, so that the helices in the duplexes formed by C–A–U–G[111] and A–G–C–U[105] and also in G–A–G–C.G–C–U–C[110] have the *A*(*A*′) form.

Additional information about the secondary structure of the oligomeric complexes was obtained in the study of the interaction with the antibiotic actinomycin D of the double helices enriched in G:C pairs. A characteristic property of this antibiotic is its specific binding to DNA in the *B* form and its lack of affinity for RNA and hybrid helices[116]. It was shown by ^{1}H NMR that the phenoxazinone ring of actinomycin D is inserted between the G:C pairs of the double helical oligodeoxyribonucleotides[96,112,117,118], which indicates a DNA-like conformation of such complexes in aqueous solution.

The formation of the A–G–C–U or A–C–G–U duplexes[105] entails a change (by 20° and more) of the glycosidic angle of twist in the adenosine and cytidine residues. This was demonstrated by analysing the δ for the anomeric H(1′) protons.

at 0 °C in water. The calculated positions of the resonance signals, subject to the condition that the structure of the double helical CpCpGpG corresponds to the structure of RNA-11, are indicated by lines[95].

The study of the temperature variation of the chemical shifts and the signal widths of the exchanging protons of the oligomeric duplexes led Patel and coworkers[52,94,117] to the conclusion that, under the conditions of the thermodynamic stability of the helix, there is a probability of the incomplete bonding of the terminal nucleotide pairs in such systems (regardless of the nucleotide composition and sequence). In other words, the rapid formation and rupture of the hydrogen bonds between the bases of the terminal nucleotide is postulated, the equilibrium shifting towards an increase of the relative content of the open forms with increase of temperature. The rapid formation and dissociation of nucleotide pairs at the ends of the double helix ("fraying") is much faster and occurs at a lower temperature than the thermodynamic fusion–separation of the strands of the duplex, and leads to an average resonance signal whose chemical shift and width are determined by the ratio of the open forms and the forms stabilised by hydrogen bonds. Fig. 4 presents the ^{1}H NMR spectrum of the duplex formed by C–C–G–G at 0 °C. The calculated positions of the proton signals of the terminal and inner G:C pairs are indicated by lines. If it is assumed that the upfield shift and the broadening of the signals due to the protons of the terminal G:C pairs are due to the increase of the relative content of the open forms, it is found that at 0 °C the terminal base pairs C–C–G–G.C–C–G–G are "fused" to the extent of 8%.[95] The analogous analysis of the ^{1}H NMR spectrum of the duplex formed by d(A–T–G–C–A–T) leads to the conclusion that, under the conditions of the stability of the double helix, the bases of the A:T end pairs are in the open form to the extent of 15%.[96] With decrease of temperature, the signals of the imino-group protons of the A:T and T:A pairs of the double helical d(A–T–G–C–A–T) undergo a downfield shift; the displacement of the signals of the protons of the terminal A:T pairs of the duplex is observed down to −30 °C (in aqueous methanol) and that of the signals of the inner T:A pairs is observed down to −20 °C. Patel and Hilbers[94] interpreted this as an increase of the fraction of the hydrogen-bonded forms with decrease

of temperature. According to their calculations, at 3 °C the fraction of the open forms is 22.5% for the terminal A:T pairs and 1.1% for the inner T:A pairs, being absent for the central G:C pairs. With increase of temperature, the reverse process, namely a successive increase of the relative content of the open forms (initially the terminal and then the inner nucleotide pairs undergo ring opening) is observed for oligonucleotide complexes of any composition and with any sequence[27,94,95,99,112]. Fig. 5 presents the ^{1}H NMR spectra of the complex formed by A–A–G–C–U–U in the region of a weak field at different temperatures. At 1 °C the absorption lines of the imino-group protons are observed at 13.2, 13.5, and 14.2 p.p.m. (each signal corresponds to two identical resonances of the imino-group protons of equivalent nucleotide pairs). With increase of temperature, all three signals are broadened and disappear in the following sequence: initially the signal at 13.2 p.p.m., to which correspond the terminal A:U pairs, then the signal at 14.2 p.p.m. associated with the inner A:U pairs, and finally the signal at 13.5 p.p.m. associated with the central G:C pairs[97]. Thus the signals of the less stable (owing to the incomplete pairing) terminal A:U pairs are broadened and disappear faster than the signals of the inner A:U and G:C pairs shielded from the effect of the solvent. In the d(A–T–C–C–T–A–T–A–G–G–A–T) duplex fusion also begins from the ends of the double helix. There is no preliminary fusion of the central A–T fragment, i.e. the sequence of four A:T pairs, protected by the G:C pairs, is too short for the local destabilisation of the duplex[99].

at different temperatures in H_2O (1 M NaCl, pH 7.6).[97]

In the study of the temperature variation of δ of the non-exchanging protons, the T_m of individual nucleotide pairs of duplexes were determined and it was shown that they depend on the composition and sequence of the bases. On dissociation of the double helical oligonucleotides without terminal G:C pairs, namely d(A–T–G–C–A–T)[51] and A–A–G–C–U–U,[26] the stability of the nucleotide pairs increases in the following sequence: terminal A:U(T) pairs < inner A:U(T) pairs < central G:C pairs. The tendency of the terminal pairs to undergo "differential" melting (i.e. before the melting of the remainder of the duplex) is greatly reduced for the duplexes in which the A:U pairs are internal and the more stable G:C pairs are terminal. Thus stepwise dissociation is not observed (the helix–coil transition takes place in accordance with the "all or nothing" principle[27]) for the C–A–U–G[111], G–A–G–C.G–C–U–C[110], d(G–G–A–A–T–T–C–C),[52] and d(C–A_5–G).d(C–T_5–G)[27] duplexes, as well as C–C–G–G which is made up exclusively of G:C pairs[95] and the T_m of the individual nucleotide pairs, determined with the aid of ^{1}H NMR (of the non-exchanging protons), corresponds to the T_m of the helix obtained by optical methods. On the other hand, the above tendency increases sharply for the d(pT–A)$_3$ duplex: at 5 °C the nucleotide chains are retained mainly via two central A:T pairs[100]. The result of studies of the A–G–G–A.U–C–C–U and U–G–C–A duplexes whose terminal A:U pairs melted at the same temperature as the inner G:C pairs[59], are in some conflict with these data. For the same nucleotide composition and the same number of inner G:C pairs in the A–G–C–U and U–G–C–A duplexes, the terminal residues are dissociated in the former but not in the latter[59]. Finally, the dissociation of the terminal pairs diminishes in the presence of unpaired (looped) bases[59] (see above). This information is useful for the understanding of the nature of the RNA–RNA interactions in the cell. In the study of the duplexes formed by the self-complementary d(G–G–C–C) and d(C–C–G–G), Patel observed a difference between the temperature variations of δ of the non-exchanging protons of the inner and outer G:C pairs[98]. He believes that these differences are due to "end to end" aggregation of the duplexes resulting from the stacking interactions of the end pairs and leading to a greater shielding of the protons of these pairs. As a result, the signals of the protons of the terminal G:C pairs are observed in stronger fields. With decrease of temperature, they continue to shift upfield (without reaching a plateau) and the T_m determined with their aid is smaller than the T_m for the inner pairs. It is noteworthy that the quantitative aspects of the analysis of the temperature variations must be approached with caution, since the T_m determined from the temperature variations of the signals of different non-exchanging protons within the limits of the same nucleotide residue sometimes differ appreciably[7]. The error in the determination of T_m is smaller for the duplexes formed by non-self-complementary oligonucleotides, since in this case one can take into account the temperature variation of the protons of each chain[27]. In the description of the "differential" fusion of the terminal nucleotide pairs of oligomeric duplexes, some workers unjustifiably used the term "fraying" of the ends[59,100,110], which reflects a kinetic effect (see above) and is in no way related to the equilibrium concentration of the open and hydrogen-bonded forms[27]. For example "fraying" of the ends occurs in d(C–T_5–G).d(C–A_5–G), but the duplex does not decompose and the content of the partly fused forms is very low[27].

A study[99] of the duplex d(A–T–C–C–T–A–T–T–A–G–G–A–T), containing one non-complementary T:T pair, provides a good illustration of the possibilities of the NMR method. It was shown that the tridecanucleotide forms a regular structure similar to DNA in the *B* form and that the non-canonical T:T pair does not emerge from the helix. However, it is of interest that the incorporation of the T:T pair diminishes appreciably the overall stability of the double helix as a result of the formation of an additional unstable region where fusion begins as well as in the terminal sections, as can be seen from the disappearance of the signals of the exchanging protons.

The NMR study of the relaxation behaviour of the resonances of the exchanging protons of the bases of an oligomeric duplex, namely the 12-unit restriction fragment d(C–C–G–C–A–C–T–G–A–T–G–G).d(C–C–A–T–C–A–G–T–G–C–G–G), was carried out recently for the first time[101]. Analysis of the rates of relaxation and of their temperature variation made it possible to examine a completely new aspect of the behaviour of the duplexes—the conformational fluctuations of the helix. The absence of internal dynamics in the 12-unit DNA fragment, at least on the 10–100 ns time scale, was observed[101]. It was shown that there is no reorientation of the bases (relative to the axis of the helix) and that this fragment can be regarded as a rigid rod. Furthermore, a remarkable observation was made concerning the mechanism of the opening of the individual base pairs. It was found that the exchange of the imino-group protons of the thymine residues with the solvent at 30–40 °C is not accompanied by the opening of the neighbouring G:C pairs. On this basis, the authors[101] concluded that the rates of the random opening of the A:T pairs in any DNA are independent of the nucleotide sequence and length and are therefore identical for all types of DNA. This conclusion has been confirmed experimentally in the study of the restriction fragments of DNA consisting of 43 and 69 units[102].

In a number of ^{1}H NMR studies of the complex formation by oligomers, detailed investigations were made of the kinetic aspects of the exchange of the imino-group protons with water[24,25,97]. These data made it possible to estimate the lifetime of the base pairs in the helical complex and to obtain independently the kinetic parameters of the initiation and propagation of the oligomeric double helix[25]. The calculated activation energies and rate constants for nucleation and dissociation agree well with the corresponding data obtained for ribo-oligonucleotides with the aid of the temperature jump method (Section V). The exchange process responsible for the broadening of the resonance lines can be described as follows in general terms[24,114]:

$$NH_h \underset{k_{ch}}{\overset{k_{hc}}{\rightleftarrows}} NH_c \xrightarrow{k_{H_2O}} H_2O \ .$$

According to this scheme, the imino-group protons can exist in one of three states: within the double helical structure (NH_h), in the open form (NH_c), and as part of the H_2O molecule. The equilibrium constant of the transition from the hydrogen-bonded (h) to the free (c) state is $K_{eq} = k_{hc}/k_{ch}$. The characteristics of these exchange processes are now well known[119]. Equations describing the relations between the widths and positions of the resonance lines of the double-stranded complex and the rates of the exchange reactions have been derived[52,97,119]. Further details of the mechanism of the exchange of the imino-group protons with water have been reported[24,119].

4. Column Chromatography

Oligonucleotides immobilised on a carrier can form complexes with complementary homogeneous[120–122] and heterogeneous[121,123] oligonucleotides (including the formation of hybrid ribodeoxyribonucleotide complexes[120,121]). Cellulose[120,121,123], hexamethylenediamine-Sepharose[123] to which the oligonucleotide was linked covalently, and DEAE-cellulose, in which the irreversible sorption of the oligonucleotide linked covalently to a soluble polymer [poly(vinyl alcohol)] has taken place[122], are used as carriers. Under temperature gradient conditions, the complementary oligonucleotide is desorbed and the stability of the complex can be estimated approximately from the temperature at which the peak emerges. It has been shown that all the bases of the immobilised oligomer participate in the formation of hydrogen bonds[120,121] and that this process is highly specific: a single non-complementary pair is sufficient to prevent the sorption of the oligonucleotide[124]. Chromatography on carriers with oligonucleotides is discussed in the literature mainly as a method for the separation of oligonucleotide mixtures[120–123].

The Structure of Simple Liquids

V.P.Skripov and A.E.Galashev

Theories of the structure of simple liquids, and the present state of the problem, have been examined. Attention has been paid to the unity of the static and dynamic characteristics of the structure. New results obtained by molecular-dynamic computer modelling, including the use of the ideas of statistical geometry, have been presented. The lack of justification for the quasi-crystalline approach to the structure of short-range order, and the fruitfulness of Bernal's ideas, have been pointed out.

The bibliography contains 89 references.

I. INTRODUCTION

A large amount of information on the properties of different liquids has been obtained in the last ten years. The number of liquids is very large, and is increasing continuously as a result of the synthesis of new compounds. The selection of substances for practical application requires their physico-chemical "classification", and this is becoming more difficult. A reasonable approach involves the use of sufficiently general regular features relating molecular structure to the properties of matter. Considerable progress has been made in reducing the amount of primary information needed by the use of the theory of physical similarity (the generalised law of corresponding states)[1,2].

A liquid, unlike a gas, is a collection of strongly interacting particles. It is distinguished from a crystal by the irregularity of its structure. Since it has not been possible to select a suitable simple model of a liquid, attempts have been made to bring it so "close" to either a gas or a solid crystal that the results based on the corresponding ideal model can be applied to a significant extent.

II. THE SEARCH FOR SIMPLE MODELS

In 1869, the detailed experimental work of Andrews[3] finally established the existence of the critical point (CP) of the liquid–vapour equilibrium as a universal property of matter. Andrews formulated the principal physical consequences of this fact: the possibility of a continuous change from a gas to a liquid in the region of the critical point; the existence of intermediate states above the critical point, which cannot be confidently assigned to any of the states of aggregation, and the unique character of transitions beyond the critical point. Van der Waals' thesis, which appeared four years after the publication of Andrews' work[3], contained

the elementary theory of the gas–liquid state in a very lucid form. Qualitatively, it showed satisfactory consistency with Andrews' discovery.

Boltzmann, in his review "Vorlesungen über Gastheorie"[4], discussed in detail the physical significance of van der Waals' equation and its many consequences. He pointed out the existence of intermediate states of matter in a continuous change from a gas to a liquid. Boltzmann's achievements in the development of the kinetic theory of gases stimulated studies in which the description of liquids was approached "from the direction of the gas".

These achievements provided a basis for bringing a liquid "closer" to the gaseous state (dense fluid states, and not an analogy between a liquid and a rarefied gas, were of course assumed). The range of applicability of the model of a weakly interacting gas was extended to an unjustifiable degree, however, and this led to the concept of the unstructured state of liquid. Experiments on the observation of the scattering of X-rays at small angles[5] (Stuart, Danilov, and their successors) demonstrated convincingly the existence of local ordering of the molecules of a liquid. For an arbitrarily chosen molecule, the neighbours in the first and second layers lie on the average at definite distances; the average number of neighbours in these layers can also serve as a characteristic of the short-range order in a liquid (the coordination number).

The breakdown of the view that liquids are unstructured was used, together with other arguments, to strengthen the position of the "solid" (quasicrystalline) model. This approach was developed most fully by Frenkel in 1945 in a monograph[6] which established an epoch in the physics of liquids. Many experimental facts received a simple explanation. It became possible to carry out elementary estimates of kinetic phenomena in liquids, and this stimulated studies in various branches of physical chemistry. This approach also has significant unsatisfactory features, however, particularly in the study of the structure of liquids, which is often interpreted as quasicrystalline. There is no satisfactory definition of quasi-crystallinity. The term combines a broad spectrum of concepts, from regularity in the arrangement of the atoms, disturbed by thermal motion, to a microcrystalline heterogeneous structure (the microcrystallinity is "softened", and the indefinite concepts of cybotaxes and clusters are introduced).

The adherence of many research workers to quasicrystalline models of liquids is strengthened by the established traditions of the processing and interpretation of the results of diffraction experiments. On the basis of an approximate form of the radial distribution function (RDF), conclusions are reached about the degree of correspondence between the structures of the liquid and the crystal. Although information about the average number of neighbours in the first coordination spheres and about the position of these spheres (layers) is reliably established from the processing of the X-ray diffraction patterns, the investigation of the finer details of the structure comes up against the indeterminate nature of the method. The RDF transforms the three-dimensional distribution of the atoms into a smoothed one-dimensional function. This imposes a fundamental restriction on the possibility of using the method to interpret the structure of the short-range order in a liquid: practically identical RDF can correspond to quite different configurations.

The concept of the quasicrystallinity of liquids does not follow from experimental data, but is rather related to an *a priori* underestimation of the unique character of the dense irregular structure. The existence of long-range order presupposes a quite definite type of short-range order. In the absence of the requirement of regularity (and when there is a certain free volume), the system has access to a new and extensive region of configuration space, and the system spends almost all its time in this region.

Quasicrystallinity is apparently a concept which is just as unacceptable as the unstructured dense liquid picture. Bernal was the first, in the late nineteen-fifties, to begin the battle against these concepts. He concluded that "this short-range order" is "quite different from what might be expected from an analogy with the crystalline state"[7]. Using "natural" (mechanical) models, Bernal demonstrated the existence (and even predominance), in a close-packed random structure, of elements of local ordering which are known to exclude the possibility of the appearance of a regular structure. Bernal's work will be examined in more detail below.

The next major achievement in the study of the structure and properties of simple liquids was associated with the use of the hard sphere model as an object of study by the methods of statistical physics and computer simulation. In this model, the forces of attraction between the particles is neglected, and the repulsion is described by the pair potential of inter-particle interaction $\Phi(r)$, which has the form of a rectangular wall

$$\Phi(r) = \begin{cases} \infty & \text{for } r < \sigma \\ 0 & \text{for } r \geqslant \sigma \end{cases} \qquad (1)$$

Here, σ is the diameter of the sphere, $v_0 = 1/6\pi\sigma^3$ its volume, $\rho/\rho_0 = Nv_0/V$ the proportion of the volume of the system occupied by the spheres (the density of packing), and V the total volume of the system. Allowance for thermal motion in the hard-sphere model leads to a linear temperature dependence; the RDF depends only on the density. The average potential energy of a system of N hard spheres is equal to zero, and the internal energy U is independent of the volume and can be written as for an ideal gas in the form

$$U = 3/2Nk_BT$$

It should not be thought that the theoretical description of the equation of state and the structure of this model is simple. The complexity of the problem is due to the fact that for dense states, the total volume of the spheres makes up a significant proportion of the total volume of the system. The simplicity of the model is sufficient, however, to permit the effective use of the Percus–Yevick approximation and the hyperchain approximation in the theory of correlative functions[8] and to bring the calculations to numerical values. Fig. 1 shows the RDF for "dense" argon, obtained experimentally[9] and calculated by the Monte Carlo method for the hard sphere model[10].

The RDF in the hard sphere model reproduces qualitatively the RDF of a real simple liquid. The dependence of the structural characteristics of the model on the curvature of a Lennard-Jones type potential in the range of small distances has been studied[10]. The splitting of the second peak of the RDF, which is observed for a system of hard spheres (see Fig. 1), takes place at values of the exponent of the repulsive part of the potential $n \geqslant 75$, whereas the average number of nearest geometric neighbours in the hard sphere model differs by less than 0.1% from the corresponding characteristic of systems with $n \geqslant 25$. This may indicate that the "geometric" factor has a decisive role in the formation of the irregular compact structure.

Before continuing the examination, it is appropriate to investigate how clearly and completely it is possible to formulate the actual concept of "the structure of liquids". This concept is much broader and deeper than any static

geometric representation. The structure of a molecular system is related to and forms a unity with the thermal motion. An "instantaneous photograph" of a single crystal at a high temperature, fixing the position of its particles, shows little similarity to the structure of the ideal lattice. An approximation to this structure is achieved by increasing the exposure time and averaging the configurational picture. The case of a liquid is even more complicated, because of the constant drift of particles from their immediate environment, and individual motion. Direct photography will give a picture which will become increasingly blurred with increase in the exposure. There arises the question of how to determine the characteristic geometric representation of the liquid in this case. It can be constructed by analysing the dynamic set of configurations formed by the particles of the system in thermal motion. Thus in the examination of the structure of a liquid, the treatment cannot be restricted to the geometric aspect. It is necessary to take into account the dynamic properties of the liquid. Its structure is revealed in different ways in time intervals of different scale.

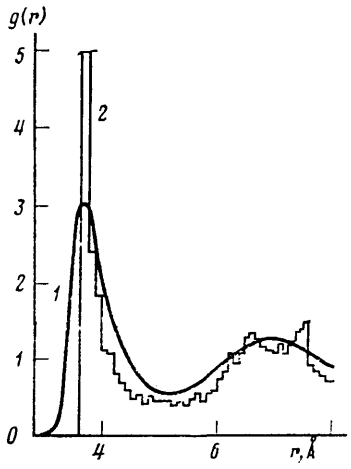

Figure 1. Radial distribution function of liquid argon: *1*) experimental, from elastic neutron scattering at 85 K,[9] *2*) histogram giving the result of a calculation by the Monte Carlo method for the hard sphere model[10].

III. THE STRUCTURE AND DYNAMIC PROPERTIES OF A LIQUID

1. Structure-sensitive Properties

In physicochemical analysis, the concept of "structure-sensitive" properties is often used, but attention is not always paid to which structural aspect is being revealed in the change in the given property. For example, the electrical conductivity of crystalline copper at room temperature is "sensitive" chiefly to constant defects of the structure and the difference between the instantaneous configuration of the ions and their regular average arrangement. With decrease in temperature, the positional "blurring" decreases, and the electrical conductivity σ_e increases. At 5 K it is ~1.5×10^4 times that at 300 K, and ~8.4×10^4 times that close to the melting point (1356 K). Compared with this difference, the change in σ_e on fusion is slight ($\sigma_e^l/\sigma_e^{cr} \cong 2.04$), and indicates a certain similarity between the instantaneous configurations of the liquid and the crystal at a high temperature. The electrical conductivity is a macroscopic characteristic, and represents a certain average value of microscopic variables of the crystal system, but from the structural viewpoint this averaging reflects the degree of irregularity in the "series" of successive configurations. For a macroscopic equilibrium specimen, the averaging of any local characteristic with time is equivalent to averaging with respect to the volume, since in the volume the system contains a vast number of independent sub-systems (microvolumes with linear dimensions greater than the de Broglie wavelength).

An example of a physicochemical property determined by positional and orientational ordering of the particles is the anisotropy. It is characteristic of crystals of low symmetry, and is not shown by ordinary liquids.

The heat capacity is another structure-sensitive property. In compact condensed systems, the heat capacity is determined by the spectrum of the frequencies of the elastic vibrations of the atoms; the main contribution is made by high-frequency modes. The influence of structure on the properties is due to a change in the spectrum of the vibrations in structural rearrangements, and also to a change in the contribution of individual motions to the energy characteristics† of the system. There is no simple relationship between them.

The dynamic structure of a liquid[11] (in momentum space) is related to the configurational structure. Experimental methods exist for the study of the dynamic structure, for example from scattering of neutrons by matter. By determining the elastic (without change in wavelength and energy) and inelastic coherent scattering on the one hand, and the inelastic noncoherent scattering on the other, it is possible to separate the contributions made to the scattering by the collective and individual motions of the particles.

2. The Fluctuational Aspect of Structure

The RDF is the most widely used primary characteristic of the structure of liquids. It is usually found from experiments on the low-angle scattering of X-rays. The scattering power of a liquid as a function of the angle of scattering θ is proportional to the static structure factor ($S(k)$, which carries the necessary information on the averaged configurations of the particles in the volume:

$$I/I_0Nf^2 = S(k)$$

Here, I_0 and I are the intensities of the exciting and scattered radiation respectively; N the number of atoms in the scattering volume V; f the atomic scattering coefficient, which depends on the electron density; $k = (4\pi/\Lambda) \times \sin(\theta/2)$ the modulus of the wave vector of the scattering; and Λ the wavelength of the X-rays.

The expression for the RDF is obtained from $S(k)$ by means of a Fourier transformation:

$$g(r) = 1 + \frac{1}{8\pi^3\rho}\int [S(\mathbf{k}) - 1]\exp(-i\mathbf{kr})\,d\mathbf{k}$$

Here, $\rho = N/V$ is the average numerical density.

†On the fusion of polyatomic (molecular) crystals, the heat capacity may also increase as a result of the removal of the degeneracy from rotational and librational degrees of freedom.

As noted earlier, the RDF gives extremely crude (contracted) information on the structure of a liquid. The important feature for scattering is the non-uniformity of the distribution of the scattering centres (molecules) with respect to the elementary volumes ΔV_i, the linear dimensions of which are of the order of the wavelength of the radiation; N_i is the number of molecules in the volume ΔV. The total effect of scattering with allowance for interference depends on the average value of the non-uniformity $\langle (N_i - \bar{N}_i)^2 \rangle^{1/2}$ in these volumes#. By changing the wavelength of the radiation or the angle of scattering (that is **k**), it is possible to "probe" non-uniformities of different scale. Essentially, the fluctuations in the density and their correlation in the thermal motion are being revealed here. Thus the structure factor, and hence the RDF, carry chiefly the information on the structure of the liquid which is contained in its description in the language of fluctuations. In the long-wave limit, the following relationship exists between the average value of the fluctuations $\langle (\rho - \bar{\rho})^2 \rangle / \bar{\rho}$ and the structure factor of RDF:[12]

$$\lim_{k \to 0} S(k) = 1 + \rho \int [g(r) - 1] \, dV = V \langle (\rho - \bar{\rho})^2 \rangle / \bar{\rho} \qquad (2)$$

On the other hand, statistical thermodynamics makes it possible to express the density fluctuations (naturally, long-wave compared with the internuclear distance) in terms of the isothermal compressibility of the substance $\beta_T = V^{-1} \cdot (\partial V / \partial p)_T$:

$$\langle (\rho - \bar{\rho})^2 \rangle / \bar{\rho}^2 = k_B T \beta_T / V \qquad (3)$$

The quantity β_T can be regarded as a function of the response to a small static perturbation of the system by pressure. It is clear from Eqn.(3) that the response function becomes large where the fluctuations are large, for example close to the critical point of the liquid–vapour equilibrium. Eqns.(2) and (3) can be generalised to the case of short-wave perturbations§ with wavenumber k:[12]

$$S(k) = \rho k_B T \beta_T(k) \qquad (4)$$

Here, $\beta_T(k)$ is the isothermal response function, which depends on k and which characterises the isothermal compressibility for short-wave perturbations.

Liquid argon or sodium are regarded as typical simple liquids. Close to the melting point, the structure factor of liquid argon does not differ greatly from $S(k)$ for liquid sodium (see Fig.2). The structural similarity between the liquid inert gases and the alkali metals was unexpected, since their forces of interaction are quite different. The existence in metals of a sub-system of almost free electrons alters the situation in many respects, for example by leading to the appearance of a long-range oscillating component in the effective potential of the paired interaction $\bar{\phi}(r)$.[12,13] Without going into details, it is found that the structure of the short-range order in a dense liquid is not appreciably sensitive to the form of the function $\phi(r)$. Its similarity to the structure of a system of hard spheres indicates the important role of the "geometric" factor (short-range repulsion forces) in the production of the short-range order of simple liquids. This is also indicated by the one-parameter thermodynamic similarity in the fusion curves of the inert gases and typical metals[14].

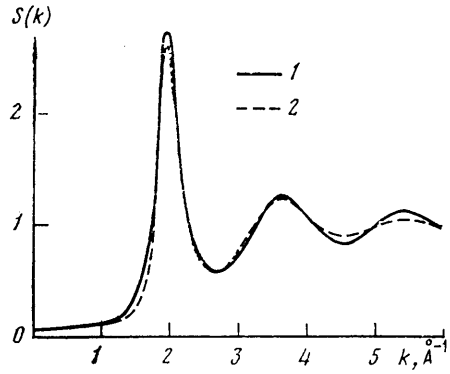

Figure 2. Structure factor for liquid argon at ~85 K [9] (*1*) and for liquid sodium at ~383 K [15] (*2*), close to the melting point.

It is not possible in the present review to carry out a detailed examination of the fluctuations and correlation functions. It is necessary, however, to distinguish the "fluctuational aspect" of the structural description of liquids. It is reflected in condensed form by Eqns.(2)–(4), from which it follows that the spectrum of the density fluctuations contains important information on the supermolecular structure. The dynamics of the fluctuations, the characteristic time of their dissipation, self-diffusion, and collective modes are all related to the structure of the liquid in the broad sense. The positions of two close molecules are statistically correlated not only in space but also in time. The Van't Hoff function $G(\mathbf{r}, t)$ is introduced as the average numerical density of the particles¶; close to the point **r** at moment of time t with the condition that the origin of coordinates coincides with one of the particles at $t = 0$. This function can be used to describe the space–time correlations. To change from $G(\mathbf{r}, t)$ to the RDF, it is necessary to fix the time and put $g(r) = G_d(r, 0)$; $G_d(r, t) = G(r, t) - G_s(r, t)$, where $G_s(r, t)$ is the auto-correlation part of the Van't Hoff function.

Just as the spatial fluctuation of the density represents a superposition of harmonic vibrations of different wavelength, the time "portrait" of the correlation can be expressed by a definite frequency spectrum (ω), using the Fourier transformation of the function $G(r, t)$ relative to the time t. This introduces the dynamic structure factor $S(k, \omega)$:

$$S(k, \omega) = \rho \iint \exp[-i(\mathbf{kr} - \omega t)] \, G(\mathbf{r}, t) \, d\mathbf{r} dt$$

#The angle brackets or the bar above the letter denote averaging with respect to the ensemble.

§In the present work, the letter k is used to denote both the wave vector of scattering and the Fourier components in the representation of the spatial density distribution by the set of harmonic functions $\rho(\mathbf{k})$ with different wavelength λ, $k = 2\pi/\lambda$. The condition of the first interference maximum when scattering is observed relates the quantities λ and Λ as follows: $\lambda = (\Lambda/2) \sin(\theta/2)$.

¶The terms "molecule" and "particle" are used as synonyms. Simple liquids are primarily monatomic. In this sense it might be possible to give preference to the word "atom", but it is not completely appropriate in the case of metallic liquids.

If the scattering is coherent, then for a given **k**, integration of $S(\mathbf{k}, \omega)$ with respect to all frequencies gives an expression for the static structure factor:

$$S(\mathbf{k}) = \int_{-\infty}^{\infty} S(\mathbf{k}, \omega)\, d\omega$$

The scattering function $S(k, \omega)$ can be calculated using model representations. A particularly important feature, however, is that $S(k, \omega)$ can be found from neutron scattering experiments.

The dynamic structure factors of liquid argon close to the melting point, 83.8 K, and of sodium at 506 K (m.p. = 370.9 K), are given in Fig.3. In spite of the differences in the nature of the interaction between the particles in sodium and argon, the dynamic characteristics of their structures are of the same type. The spectrum of the density fluctuations of sodium has many more high-frequency modes, however, and the spectrum of argon many more low-frequency modes. It may be noted that with decrease in temperature there is a decrease in the width of the range of values of $S(k, \omega)$ with respect to the variable ω. Thus the dynamic structure factors of liquid sodium and argon approach even closer in the region of the melting point.

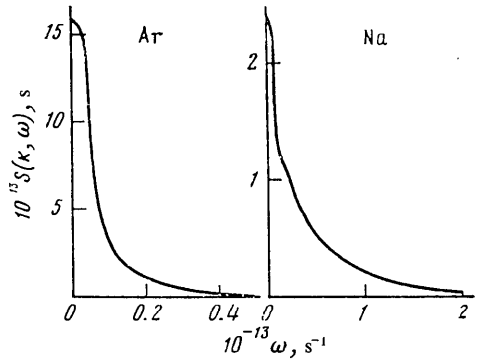

Figure 3. Dynamic structure factor for liquid argon (85.2 K) [16] and for liquid sodium (506 K) [17] with wavenumber $k_1 = 2$ Å^{-1}, corresponding to the position of the first $S(k)$ maximum.

3. The Nature of Thermal Motion in a Liquid

Attention has been drawn to the complexity of the concept of the structure of a simple liquid. To create the correct geometric representation of a structure (this is usually the problem posed), it is necessary to find a method for separating the characteristic indications of the structure from the large number of "transient" configurations arising in the process of thermal motion. This motion has collective and individual components. Ideas about the nature of the thermal motion of individual molecules in a dense liquid have changed with the passage of time. Van der Waals' approach led to the following picture. A particle undergoes hard elastic collisions with the particles of its environment. Between collisions, it moves freely, that is the average field does not change its rate vector significantly; there is no collective component. Some authors also attach importance to "soft" collisions, which are due to the forces of attraction between the particles and which should lead to convolutions in the path of the molecule between two successive hard collisions.

The Frenkel model of a dense liquid[6] assumes another basic mechanism of individual thermal motion: the molecule vibrates about a temporary equilibrium position, and then jumps abruptly to another position, at the foot of the potential well formed by the particles of the new environment. The magnitude of the jumps is close to the average distance between nearest neighbours d. The period of the vibrations τ_0 and the average settled time τ_s are the characteristic time scales in this model of a liquid. Their use together with the parameter d makes it possible to estimate the kinetic coefficients.

The use of molecular-dynamic computer modelling[18-20] has helped to answer questions about the real picture of the thermal motion of the individual particles of a liquid of the argon type close to the triple point, and about the method of study that will make it possible to establish it.

The modelling of simple liquids of the argon type is usually carried out assuming a pairwise central interaction between the particles. The computer is used to calculate numerically the trajectories of the particles with a time step Δt. The results obtained close to the triple point for a model of argon containing in the basic cell 108 interacting (Lennard-Jones potential) particles[21] are given below. The step size in the integration of the equations of motion Δt was 10^{-14} s.

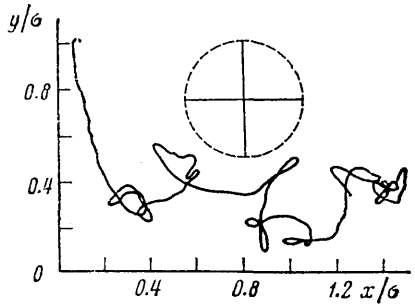

Figure 4. Projection of the trajectory of the motion of a particle on a plane in the molecular-dynamic model of liquid argon[21], 84 K; time interval 10^{-11} s; σ is the effective diameter of the particle (the parameter of the Lennard-Jones potential).

The motion of each particle resembles the Brownian drift in the field of the changing environment (Fig.4). This motion includes a high-frequency component (Fig.5), but it is difficult to distinguish it in the train of approximately monochromatic vibrations about the temporary equilibrium position and in the jump to a new fixed position. The time interval in Fig.4 contains 10^3 steps in the integration of the equations of motion, so that the picture of the individual motion is obtained with a high resolution. The two sections in the circle, intersecting at right angles (Fig.4) show the magnitude of the displacement of the argon atom in a time of 7×10^{-13} s for motion with an average thermal velocity. For a crystal near the triple point, the motion of the particle is concentrated in the region bounded by the broken circle in Fig.4. The maximum of the spectral density $f(\omega)$ of the

auto-correlation function of the velocity of the particle is observed at $\omega' = 2 \times 10^{12}$ s^{-1}, which corresponds to the most probable frequency of the individual vibrations of the atoms in the liquid. If the gas-dynamic approximation is used, a value close to ω' is obtained for the average number of collisions of the particle. Examination of a selected particle together with its environment, and the dynamic structure factor[20,22], shows, however, that the molecular motion in a dense liquid is essentially collective in character.

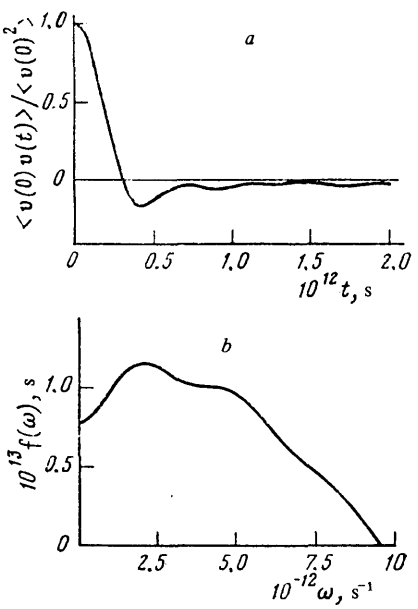

Figure 5. Self-correlation rate function (*a*) and its time Fourier transform (spectral density) (*b*) for the MD model of liquid argon (84 K).[21]

Table 1 gives the characteristic values of quantities related to the static and dynamic structures for two simple liquids, argon and sodium, close to the triple point. Table 1 was compiled using data from Refs.9, 11, 15–17, 21, 22. The average distance between the particles d was obtained as $v^{1/3} = (V/N)^{1/3}$. The positions of the first and second maxima of the RDF give the radii of the first and second coordination spheres r_1 and r_2. The average coordination numbers are determined by the integrals

$$\bar{z}_1 = \int_0^{r_{m1}} d z, \quad \bar{z}_2 = \int_{r_{m1}}^{r_{m2}} d z,$$

where r_{mj} is the position of the jth minimum of the RDF. The local coordination number $\delta z = dz$ is the average number of neighbours in a spherical layer of thickness δr at a distance r from the central particle:

$$\delta z = \frac{4\pi}{v} g(r) r^2 \delta r, \quad \delta r = (r_{i+1} - r_{i-1})/2;$$

the subscript $i = 1, 2, \ldots$ denotes the points of division of the interval in which the RDF was obtained from the experiment. The blurring of the coordination layers is characterised by the second moments of δz_1, δz_2, that is

$$\tilde{\Delta} z = \langle (\delta z - \bar{\delta z})^2 \rangle^{1/2} / \bar{\delta z}$$

The position of the first maximum of $S(k)$ is denoted by k. The average rate of thermal motion $u = (k_B T/m)^{1/2}$, and D is the self-diffusion coefficient. The characteristic frequency of the individual vibrations of the atoms (the position of the principal maximum of the frequency spectrum of the auto-correlation function of the velocity) is denoted ω'. In liquid alkali metals, propagating collective vibrations (modes) with fairly short wavelengths λ are observed (as far as $\lambda \cong 1.5\lambda_1$, where $\lambda_1 = 2\pi/k_1$ is the characteristic wavelength of the order of the interatomic distances). In liquid argon, only modes with $\lambda \geq (5-7)\lambda_1$ can be propagated, but as in liquid sodium, a mode of the relaxation type exists in argon. The characteristic frequency of this excitation ω_c is determined via the half-width of $S(k_1, \omega)$; ω_D is the Debye frequency (it depends on the temperature of the solid for which it is determined), and $\tau_R = \eta/G$ is the Maxwell relaxation time (η is the shear viscosity of the liquid, and the value of the shear modulus G is taken for the solid substance).

Table 1. Space–time characteristics of the structure of liquid argon (m.p. = 83.8 K) and sodium (m.p. = 370.9 K) close to the melting point.

Characteristic	Ar	Na	Characteristic	Ar	Na
T, K	85	373	k_1, Å^{-1}	2.0	2.0
d, Å	4.05	3.76	u, m s^{-1}	133	367
r_1, Å	3.67	3.82	$10^5 D$, cm^2 s^{-1}	1.9	5.8
r_2, Å	6.94	6.9	$10^{-13}\omega'$, s^{-1}	0.2	2.0
$\bar{z}_1$	12.2	13.9	$10^{-13}\omega_c$, s^{-1}	0.06	0.13 (T=506 K)
$\tilde{\Delta} z_1$	0.50	0.54	$10^{-13}\omega_D$, s^{-1}	1.0±0.2	1.5±0.3
$\bar{z}_2$	42.6	45.8	$10^{-13}\tau_R$, s^{-1}	0.3	0.8
$\tilde{\Delta} z_2$	0.40	0.39			

Table 1 shows that the greatest difference is between the principal frequencies of the individual vibrations of the atoms. This is due chiefly to the difference in the strengths of the interactions between the particles in liquid argon and sodium. The Na ions are in a stronger surrounding field than the Ar atoms. Thus the vibrations of the Na ions in this field also take place with a higher frequency than those of the Ar atoms. The characteristics of the static structure of liquid argon and sodium do not differ so markedly.

IV. THE RESULTS OF THE USE OF SIMPLE MODELS

1. Bernal's Model Representations

In the late nineteen-fifties, Bernal[23] stated that the structures of the short-range order in a liquid and in a crystal are essentially different. Bernal pointed out the inadequacy of the quasi-crystalline concept in the theory of simple liquids. He later pointed out[24] the symmetry-related source of this difference: "A necessary geometric property of any lattice or any structure constructed in a lattice, no matter how small its dimensions, is the presence of a definite form of axial symmetry, of second, third, fourth, or sixth order. Symmetry of fifth order is impossible in a crystal lattice, however". In the irregular structure of a liquid, however,

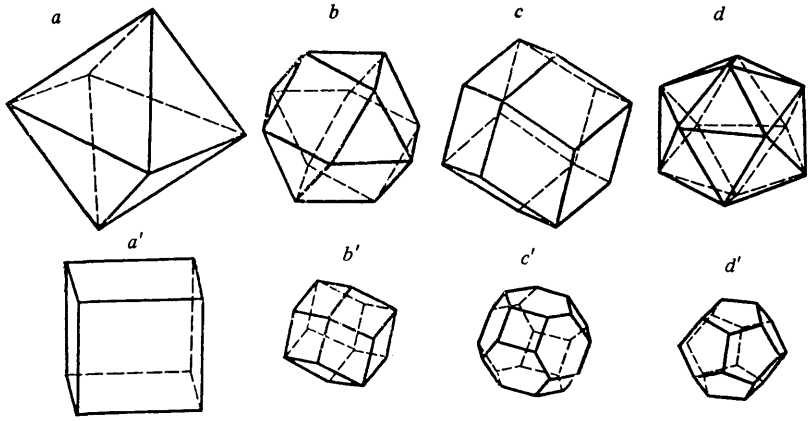

Figure 6. Polyhedra for the nearest neighbours (particles situated at the centre and apices of the polyhedra) in the ideal simple cubic (*a*), face-centred cubic (*b*), and body-centred cubic (*c*) lattices and for icosahedral coordination (*d*). The corresponding Voronoi polyhedra are: cube (*a'*), rhomboidal dodecahedron (*b'*), cubo-octahedron (*c'*), and dodecahedron (*d'*).[21]

other types of symmetry may be found. For example, elements with symmetry of fifth order are characteristic of dense random packing.

Since Bernal was interested in problems of the geometric structure of liquids, he turned to mechanical models, believing that random dense packing is closest to the typical molecular configurations of a simple liquid. Models of different types were used: 1) ball and spoke, 2) wax and plasticine spheres, and 3) steel (non-deformable) spheres. In the first type of model, a random distribution was approached by the successive addition of spokes whose length was selected in accordance with the RDF of argon, or by specifying the coordinates of the centres of the spheres by means of a computer using an established program ensuring a random distribution. The second type of model was subjected to compression, and the spheres were converted into polyhedra (analogues of the Wigner–Seitz cells), whose shape reflected directly the relative arrangement of neighbours. To make the corresponding construction without resorting to deformation of the spheres and replacing them altogether by points, the following procedure was used. Through the centres of the sections connecting the selected point (the centre of the sphere) to the points surrounding it, planes normal to the sections are constructed. The intersection of the planes gives a set of polyhedra round the given point. The convex internal polyhedron, which is not intersected by other planes, is called the Voronoi polyhedron (VP). It reflects the arrangement in space of the points nearest the selected point. The VP is a cube for a simple cubic lattice, a cubo-octahedron for a body-centred cubic lattice, and a rhomboidal dodecahedron for a face-centred cubic lattice. This correspondence between the cell and the VP is shown in Fig.6; to it is added another example—the Voronoi polyhedron for an element of an irregular arrangement of atoms—which can be represented by an icosahedron or by twelve deformed tetrahedra.

Bernal analysed the set of polyhedra obtained in the deformed model. it was found that the average number of faces of the Voronoi polyhedron $\bar{n} = 13.3$ (in the ball and spoke model, $\bar{n} = 13.6$), and of all types of face $3 \leq m \leq 7$ (m is the number of sides of the face), the quadrilateral was encountered most frequently; averaging over all the polyhedra gave $\bar{m} = 4.3$. The existence of five-particle configurations in the model of the liquid (the proportion of pentagonal faces was 27%, whereas the proportion of quadrilateral faces was 48%) is known to exclude the possibility of a regular structure. This characteristic, according to Bernal, reflects a fundamental structural property of a liquid.

The mathematical study of three-dimensional irregular networks[25] gives a higher value $\bar{m} = 5.115$ and a similar value $\bar{n} = 13.56$.

When polyhedra are obtained in close packing by compressing a model, fairly small faces and edges of the polyhedra are revealed ineffectively or not at all. Thus Bernal's analysis does not correspond rigorously to the actual configuration. As shown below, however, the smallest faces apparently should not be taken into account, since they reflect that element of random character which should disappear on appropriate averaging. In the molecular system they arise as the background produced by thermal motion.

Modelling showed that a random close-packed structure is characterised by a certain coordination number distribution function. This was clearly revealed in experiments with steel balls in a balloon[7]. After shaking and compressing the system, paint was poured into the balloon; the paint flowed freely, leaving thicker traces in the form of rings or points at those places on the surface of the spheres where they were in contact or almost in contact with one another. This detected neighbours for which the relative distance between the centres r/σ lay in the range $1 \leq r/\sigma \leq 1.05$.

The next method of studying models of steel balls ($N = 3000$, $\sigma = 6$ mm) was based on the determination of the Cartesian coordinates of each ball using a special measuring device[7]. Similar experiments were carried out by Scott[26] in Toronto. Spheres in a random close-packed structure occupy ~0.64 of the total volume. For a regular close-packed structure, $v_0 N/V = 1/6\pi\sigma^3 N/V = 0.7405$. This corresponds to a ratio of the densities of regular and irregular packing of 1.16. The number obtained is close to the ratio of the densities of crystalline and liquid argon (1.15) close to the triple point. The coordinates of the steel balls measured in

the packing were fed into a computer[27] for the construction and analysis of the Voronoi polyhedra. This gave the values $\bar{n} = 14.28$ and $\bar{m} = 5.16$, which are greater by 5% and 1% respectively than the values of $\bar{n}$ and $\bar{m}$ obtained in Coxeter's theoretical model[25].

The exact construction of the Voronoi polyhedra (with allowance for the small faces and edges) for the model of a simple liquid showed that pentagonal configurations predominate over other arrangements of the spheres. For the steel-ball models, the RDF was constructed and found to show satisfactory agreement with the RDF for liquefied inert gases and alkali metals. The independent determination of the RDF by Bernal and by Scott gave identical results. Thus the model of irregular close packing reflects essential features of the geometric structure of simple liquids. The theoretical study of the hard sphere model (the calculation of the RDF, mentioned above), and also computer modelling[28], lead to the same conclusion. Another conclusion is as follows. The form of the RDF of liquid argon or sodium close to the triple point is not determined by the need for a quasi-crystalline structure of the short-range order. Models show that the RDF arises from a large number of configurations, where there is a predominance of elements of short-range order excluded from the small set of coordinations allowed by the construction of a regular close packed structure.

Bernal also used other geometric methods of studying models. For example, he examined the shapes of the cavities between the spheres, which are clearly revealed in a system constructed from balls and spokes. The cavities (holes), bounded by planes passing (in contrast to the Voronoi polyhedra) through sections connecting nearest neighbours, form a certain set of polyhedra. Their variety is not particularly large, if the examination is restricted to the case where cavities into which a sphere can enter freely are not formed. The random close-packed model is characterised by a much larger number of types of polyhedra than the regular structure, however. In both cases, the predominant form of cavity is the tetrahedron. This reflects a high density of packing, since the tetrahedral coordination of four atoms corresponds to the highest local density (0.7795). A very compact formation is obtained by the connection of several tetrahedra. Bernal called these formations pseudo-nuclei. The prefix "pseudo" is related to the fact that a regular structure cannot be constructed from tetrahedra, but slightly curved chain formations of tetrahedra are possible.

The study of the angular distribution of neighbours in the models revealed the existence of groups of 4–6 atoms arranged almost in straight lines. These randomly oriented "collinear formations", according to Bernal, are a characteristic sign of irregular close packing.

Thus the use of mechanical models has proved extremely valuable in the investigation of a dense irregular structure. The absence of restrictions associated with regularity permits a large number of additional coordinations not characteristic of the crystal, and these configurations predominate. In this approach (for which there is justification) the structure of the short-range order of simple liquids is contrasted with the crystal structure.

2. Clusters with Minimum Energy

In the purely geometric approach to the determination of the structure of liquids, the role of inter-particle interaction and thermal motion is underestimated. In hard sphere models, the impenetrability of the spheres is equivalent to the introduction of repulsive forces (1), but forces of attraction are ignored. The more realistic Lennard-Jones and Morse potentials have been used to determine the optimum structure of clusters from a small number of interacting atoms. The configuration with the minimum potential energy U_{min} was found. For $N = 2$ there is one configuration. With increase in N there is an increase in not only the total number of configurations but also the number of relatively stable forms. Even for $N > 4$, the search for the spatial arrangement of the particles corresponding to the absolute minimum energy becomes difficult. Fig.7 shows the sequence of optimum figures for clusters containing up to 13 atoms[29].

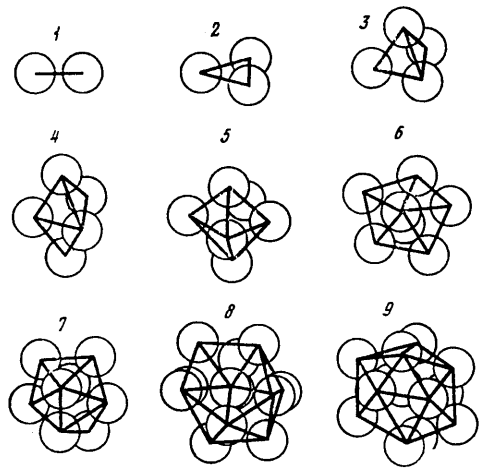

Figure 7. Sequence of small clusters with optimum shape: *1*) dimer (*2*), *2*) equilateral triangle (*3*), *3*) tetrahedron (*4*), *4*) twinned tetrahedra (*5*), *5*) octahedron (*6*), *6*) pentagonal bipyramid (*7*), *7*) bipyramid *6* brought up to eight atoms (*8*), *8*) bipyramid *6* brought up to 12 atoms (*12*), *9*) icosahedron (*13*); the number of atoms in the sequence is given in parentheses.

Most stable configurations are of the non-crystalline type, that is they cannot be elements of a regular lattice; they may, however, be present in an irregular structure of the liquid type. In this sense, the study of clusters with a free surface is also of interest for the investigation of the structure of liquids.

The use of modern fast computers makes it possible to increase the number of optimum figures to values $N > 13$. The examination of a given sequence of configurations is partly replaced by restricted or even free relaxation of the system. For example, a published algorithm[30] provides for the motion of each atom in the direction of the acting force in steps whose length is proportional to the magnitude of the force.

The initial configuration of the model of a cluster containing several tens of particles can be selected in accordance with the packing of tetrahedra[31], which determines the variety of forms of a cluster and its symmetry. In spite of the fact that the tetrahedron is an element of a regular (face-centred cubic) structure (together with the octahedron), it is impossible to fill an appreciable proportion of space by tetrahedra alone in compact form (without cavities). Twenty tetrahedra, combined in a convex compact figure (the centre of the figure is a common apex of the tetrahedra) form a

minimum of eleven pairs of non-contacting planes, giving gaps of different volume. If these gaps did not exist, that is if all the faces of the tetrahedra touched, an icosahedron would be obtained. For this to happen, however, it is necessary to deform the tetrahedra by reducing all the distances from the centre of the figure to its apices by a factor of ~1.048, leaving the distances between adjacent external angles unchanged.

It is assumed that atoms are situated at the centre of the figure and the apices (existing and assumed) through which a five-fold axis of symmetry passes. If this 13-atom cluster is allowed to change its configuration ($U \to U_{min}$), the result of relaxation will be an arrangement of atoms corresponding to an icosahedron. Seventeen tetrahedra, combined in definite fashion[31], after structural relaxation form a cluster of fourteen atoms with the symmetry of the tetrahedron (four three-fold axes of rotation). The same symmetry is shown by 26- and 38-atom clusters. A cluster formed by the packing of tetrahedra can also have the complete (33 atoms) and partial (45 atoms) symmetry of the dodecahedron, that is twelve five-fold axes of symmetry. High symmetry, however, does not guarantee an increased stability of the cluster. In a cluster containing $N < 50$ atoms, an arrangement of particles obtained from the packing of tetrahedra is more favourable than face-centred cubic or hexagonal close packing. The stability of clusters of large dimensions depends markedly on the form of the interaction potential responsible for the structural relaxation. The estimation of the equilibrium form of the cluster is made difficult by the fact that for short-range potentials (of the Lennard-Jones type), the main contribution to the energy is made by the first two layers of neighbours, and the difference in the contributions between the third and higher-lying layers is small.

The icosahedron is a structural formation with minimum energy among clusters of the same size (N). A cluster with icosahedral packing may have not only 13 atoms but also 55, 147, 309, 561, ... particles.. When the struture is optimised using a computer, icosahedral symmetry is apparently preserved in subsequent ($N > 561$) clusters for a long-range potential (of the Morse type). In the case of the Lennard-Jones potential, this symmetry may disappear. The symmetry of the icosahedron does not allow it to be the unit cell in a periodic lattice. The icosahedron is used as the basic structural unit in models of dense irregular extended phases such as amorphous metals[32].

In the construction of large clusters, the method of combination is sometimes used[33]. An example of a cluster constructed in this way is the 485-atom dodecahedron obtained by the structural relaxation of a 55-atom icosahedron surrounded by twenty 26-atom clusters with tetrahedral packing. Subsequent "additions" to the cluster brings its "size" up to 4000 atoms.

Increase in the size of the cluster is accompanied by a definite structural rearrangement, which wipes out the differences between its physical properties and those of an extended phase, determined by the high value of the ratio of the surface energies for the cluster and the volume. These differences concern chiefly the nature of the close packing of small groups (clusters) and the changes in their thermophysical properties. The particles of noble metals (dimensions 30–150 Å, that is $N \sim 10^4$–10^6) have been studied by electron microscopy and electron diffraction[34]. The clusters on nucleation had icosahedral packing, but subsequently their structure changed so that the electron diffraction pattern showed a similarity to the face-centred cubic structure. Metallic particles with shapes close to both icosahedral and dodecahedral were observed, possibly due to repeated twinning. The melting point and the Debye temperature for the small particles were lower than for the massive material[35]. The vibrations of the surface atoms in the cluster take place with a larger amplitude and a lower frequency than the vibrations of the atoms in the bulk. This is responsible for the change in the vibrational spectrum and the increase (relative to the massive specimen) in the heat capacity of the cluster.

Molecular-dynamic modelling of the structure of clusters of Ar, Kr, and Xe,[36] formed by 4, 7, and 16 layers of neighbours round a central atom (face-centred cubic lattice) established that in the smallest of these clusters (55 atoms), even at $T \cong 0.16$ m.p.* (m.p.* is the melting point of the cluster), a structural phase transformation takes place, leading to the structure of an icosahedron. Larger clusters (135 and 429 atoms), however, retained the face-centred structure as far as the melting point. The limiting size of a cluster with a structure having stable pentagonal symmetry is not yet known even for the simplest potentials, since this requires the determination of the free energy of a very large number of isomers.

3. Phase Transformations of the Fusion Type in the Hard Sphere Model

In the theory of the liquid state, the view has developed that the hard sphere model reflects the most important features of a dense irregular structure[37]. The chief advantage of the model is its simplicity: the spherical symmetry of the molecules, hard collisions, and free motion between collisions. In a system of hard spheres, the pressure p and the temperature T are proportional to the sum of the squares of the velocities of the spheres, averaged with respect to time or with respect to the ensemble, that is for a given density of packing, the ratio p/T remains constant for any finite values of the velocities. In other words, for the hard sphere model, all the isotherms on coordinates $p/T-V$ are equivalent.

The hard sphere model is widely used in the solution of the integral equations of statistical theory. Here, however, it either does not describe the phase transformation or predicts a disordering transition at densities not corresponding to the real densities. A phase transformation of the fusion type for the hard sphere model was detected in a computer experiment[38]. Computer calculations[39,40] showed that this transformation also exists for a two-dimensional model, that is for a hard disc model. Calculations for a cellular model of the crystal were carried out by the Monte Carlo method[41]. Identical cells filled compactly the space occupied by the particles. The centres of the cells coincided with the sites of the ideal crystal lattice. The cell represented a rhomboidal dodecahedron in the three-dimensional model, and an equilateral hexagon in the planar case. The condition of constant occupancy of the cells was used, that is it was assumed that in the motion of each particle, its centre did not go beyond the limit of the cell assigned to it. A break on the isotherm, indicating a phase transformation, is observed only when the region of the transformation is approached from the direction of the solid (see Fig.8). In the compression of a liquid consisting of hard spheres, a phase transformation was not observed either in computer calculations or when Pade's approximation[41] or Woodcock's equation[42] were used.

In a Monte Carlo experiment, Hoover and Ree[43] located a transition, which they interpreted as fusion, in a system of hard spheres by equating the chemical potentials of the liquid and crystalline phases (the line ab in Fig.8). The

sections of the isotherm *af* and *bc* correspond to metastable states: the supercompressed liquid and the stretched crystal. Table 2 gives the densities found in this way for the liquid and crystalline phases (their ratios to the density of close packing), the values of the pressure and the entropy changes on fusion, and also the corresponding values obtained in the self-consistent cellular model using a cluster expansion[44], and the experimental parameters of the fusion of argon[45] at $p = 1324$ MPa and $T = 295.7$ K. It is assumed that for these values of p and T, the Ar atoms can be described by hard spheres with diameter $\sigma = 3.405$ Å, that is compression leads to changes only in the distances between the atoms, and the size of the atoms themselves remains constant. Soft interaction between the atoms is replaced by hard interaction, and forces of attraction are neglected. It can be seen that the experimental values of $\Delta\rho$ and ΔS for Ar show much better agreement with those calculated by the Monte Carlo method than with those calculated using the self-consistent cellular model. The exponent of the repulsive potential[46] has a strong influence on the change in entropy, free energy (ΔF), and internal energy (ΔU) on fusion, but has little influence on the Lindemann fusion parameter. Thus with change in the exponent of the potential from 4 to ∞ (hard spheres), the values of ΔF increased by a factor of 2.5, whereas the value of $\langle[r(t) - r(0)]^2\rangle^{1/2}$ decreased by not more than 20%.

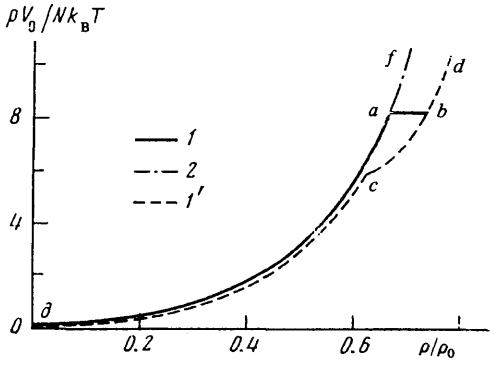

Figure 8. Isotherms for the liquid *ef* (*ec*) and the crystal *cd* in the hard sphere model: *1*) calculation by the Monte Carlo method[41] and using the Pade approximation[41]; *2'*) calculation using the equation of Ref. 42; *1'*) MC calculation in the cellular model[41], the line *ab* corresponds to equality of the chemical potentials of the liquid and solid phases; $V_0 = N\sigma^3\sqrt{2}/2$ is the volume of the close packing.

Table 2. Fusion parameters of hard sphere models and experimental fusion data for crystalline argon at a pressure of 1324 MPa.

Parameter	Monte Carlo method (Refs. 43, 46)	Self-consistent cellular model (Ref. 44)	Experiment (Ref. 45)
ρ_{cr}/ρ_0	0.736±0.003	0.747	0.851
ρ_l/ρ_0	0.667±0.003	0.650	0.805
$\Delta\rho/\rho_0$	0.069	0.097	0.046
pV_0/Nk_BT	8.27±0.13	8.84	9.05
$\Delta S/Nk_B$	1.16	1.77	1.05

The absence of attractive forces and soft interaction makes it possible to regard the disordering transformation in a system of hard spheres (or discs) from purely geometric viewpoints. This can be done most simply for the planar model (in the one-dimensional case, a transition of type I is not observed). In the computer modelling of a system of hard discs, a transformation of the fusion type takes place at the same density of packing as in the static model, when fusion is related[47] to the slipping of a number of discs relative to one another. The same mechanism of fusion is proposed for the three-dimensional model.

V. THE STUDY OF THE STRUCTURE OF A LIQUID BY MOLECULAR-DYNAMIC MODELLING

1. Molecular-Dynamic Modelling Using the Computer

Computer experiments by Monte Carlo (MC) and molecular dynamics (MD) methods have an important place in the study of condensed states of matter. The MC method is generally used to calculate the equilibrium (with averaging with respect to the assembly) properties of a substance, whereas the MD method (averaging carried out with respect to time) can also be used to determine kinetic characteristics (coefficient of self-diffusion, viscosity, thermal conductivity, etc.). Moreover, in the detailed study of the structure of a substance, the MD method has an undoubted advantage over the MC method, in that the configurations of the particles obtained with time are closer to the real values than those obtained by random rearranging of the particles. In this section, particular attention will be paid to the problem of a dense liquid and the crystal⇌liquid phase transformation, that is the range of states for which a theoretical description is difficult.

The MD method is based on the determination of the trajectories of the motion of the particles in the model by numerical integration of the equations of motion. The most widely encountered numerical methods for solving the equations of motion using a computer is the method of prediction and correction[18]. To obtain sufficient accuracy and a satisfactory speed of calculation, two iterations are usually carried out for the accelerations, momenta, and coordinates of the particles. The reliability of the results obtained is controlled from the value of the internal energy U, which should remain constant (in practice, a change in U by ~1% after 10000 time steps is permissible). The principal cell of the three-dimensional model is generally cubic, and contains from several tens to several hundreds (sometimes thousands) of particles. In the study of the properties of a liquid close to the crystallisation range, the number of particles N in the basic cell is selected in accordance with the number of sites of the lattice included in it, which reflects the average positions of the particles in the crystal. For the face-centred cubic lattice, it is assumed that $N = 4n^3$, where $n = 2, 3, 4, 5, 6, \ldots$, that is $N = 32, 108, 256, 500, 864$, etc. In the case of the body-centred cubic lattice, $N = 2n^3$. For the initial arrangement of the particles in the cell when modelling a liquid, either their random distribution or their arrangement at the sites of a given lattice is selected. The direction and magnitude of the initial velocity of the particles is given by a set of random numbers. The absolute values of the velocities for all the particles are corrected in accordance with the selected temperature.

The properties of the macroscopic phase are calculated by applying to the cell periodic boundary conditions to decrease the surface effects due to the small size of the system. By means of the periodic boundary conditions, the main cell is

surrounded by translationally symmetric images (at least 26 of the same cells). The constancy of the particles in the cell is preserved by the periodic boundary conditions; when a particle goes beyond the limits of the cell through one face, an anlogous particle appears in the cell through the opposite face. The interaction of the particles in the model of liquefied inert gases is more frequently described by an effective paired potential $\Phi(r)$ of the Lennard-Jones type. To keep the energy constant, the mutual penetration of the particles is restricted. Usually, the shortest distance r_{min} to which the particles can approach is selected from the condition: $\Phi(r_{min}) \cong 40 k_B T_T$, where T_T is the temperature of the triple point. This gave the value $r_{min} \cong 0.822\sigma$ for argon[18].

At distances greater than ~2.5σ, the interaction between the particles becomes very weak, $\Phi(r)$ amounts to less than 2% of the depth of the potential well, and the direct calculation of the interaction energy is replaced by the introduction of a constant correction determined by the static environment. The correction for a liquid is calculated in the approximation of a uniform distribution of the particles of the periphery, and for a crystal the arrangement of the particles at the sites of an ideal lattice is adopted. The main inaccuracy in the modelling is due[18] to the lack of correspondence between the potential of the interaction between the particles, used in the calculations, and the potential describing the interaction in a real substance. For the Lennard-Jones potential, a time step $\Delta t = 10^{-14}$ s ensures the required accuracy of the calculation of the trajectories for the motion of the particles. For high values of Δt, strong overlap of the volumes of the particles is possible, leading to a change in energy in the system.

The evolution of a system takes place according to the laws of motion of classical mechanics. Usually, in a time interval corresponding to several hundred time steps, a distribution of the particle velocities close to the Maxwellian is established, and the internal energy of the system remains constant with time, that is, the system reaches internal equilibrium. From this moment it is possible to proceed to the calculation of the thermodynamic, structural, and also kinetic properties of the substance being modelled.

Fusion in the three-dimensional model of Lennard-Jones particles has been studied in considerable detail by many authors (see, for example, Refs.20, 48, 49). Similar melting points were established[20] for the MD model and in actual crystalline argon (m.p. $\cong$ 84 K, $p \cong 0.1$ MPa). The complex mechanism of fusion is still not fully understood, however. Analysis of the results of MD calculations from any single viewpoint not only does not clarify but sometimes on the contrary confuses the picture of the real phenomenon.

Cotterill and co-workers[48] studied the mechanism of disordering on the basis of the assumption that spontaneous formation of extended defect-dislocations takes place in the crystal. Although considerable progress has been made in this field (for example, the change in volume on fusion for Ar and Kr crystals was ~15%, in good agreement with the experimental data), nevertheless the dislocation interpretation of fusion must be approached with some care. The description of fusion in this approach is based exclusively on the properties of the ordered phase; the unique nature of the structure of the liquid is ignored. Melikhov and co-workers[49] studied the breakdown of a crystal† within the framework of the cluster model of a liquid. The clusters in the MD model were determined via a correlation function of the distances, which can be calculated in the approximation of the Frenkel mechanism of the motion of the atoms[6] in the solid and liquid phases. The mechanism, convenient for theoretical models, of the motion of the atoms in a liquid as vibrations about equilibrium positions and jumps into new equilibrium positions was not confirmed by MD modelling[20]. The conclusions reached[49] appear doubtful, however. Thus it is assumed[49] that fusion is due to the production of the nuclei of an irregular structure, and that the critical nucleus should contain one or two particles. The concept of "structure" (in its geometric sense) clearly has no meaning for such small "formations".

It has been shown[50,51] that the breakdown of the lattice of a face-centred cubic crystal is due primarily to displacements of the particles in a close-packed plane; a body-centred cubic crystal with a Lennard-Jones interaction of the particles is also unstable with respect to displacements in the most highly pupulated plane, which is the (110) plane (in contrast to the (111) plane for the face-centred cubic crystal).

2. The Crystallisation and Stability of a Supercooled Liquid

In recent years, considerable effort has been directed to the study of the crystallisation of a supercooled liquid by MD modelling. Rahman and co-workers[52-55] studied processes of vitrification and crystallisation in Lennard-Jones systems. The vitreous state of argon was obtained[52] in a system of 500 particles, and the transition to the glass was studied in more detail for a system of 108 particles. The radial distribution function $g(r)$ of vitreous argon (see Fig.9) has a clearly defined double peak with maxima at $r/\sigma \cong \sqrt{3}$ and 2, indicating random close packing of the particles in the system. A simple explanation has been proposed[56] for the production of these peaks, using the concepts of contacts between hard spheres. Thus the peak at $r/\sigma \cong 2$ is due to contacts between spheres with a gap which does not allow them to approach more closely. The peak at $r/\sigma \cong \sqrt{3}$ is observed for the contacts of four hard spheres when the two equilateral triangles which they form have a common edge, around which they are able to rotate through an angle which defines the blurring of the peak. Close to the triple point for a face-centred cubic crystal or argon, the maxima of the second and third peaks of $g(r)$ correspond to values $r/\sigma \cong 1.6$ and 2, and for the liquid, $g(r)$ has a second peak which is not split, with a maximum at $r/\sigma \cong 2$. The splitting of the second peak of $g(r)$ on the vitrification of argon (broken line in Fig.9) begins at $T \cong 50$ K ($p = 8.6$ MPa).

In spite of the satisfactory approximation of the RDF of vitreous argon within two coordination spheres by the function $g(r)$ for a body-centred cubic crystal with Lennard-Jones interaction of the particles, the microstructures of these states are different[57]. The shear viscosity of vitreous argon[52], determined from the Einstein–Stokes relationship (via the calculated coefficient of self-diffusion $D = 10^{-9}$ cm^2 s^{-1}) is ~100 Pa.s. This value is ~37 times the viscosity of liquid argon close to the triple point.

The crystallisation process has been studied[53-55] for systems of 108, 256, and 500 Lennard-Jones particles. From the value of $S(k)$ at different points in the space occupied by the particles, it was found that the critical nucleus should contain ~40–70 particles. The type of nucleating strongly-defect crystal structure depends on the nature of the interaction between the particles. In a model of 500 particles of supercooled rubidium (shielding by electrons was taken into account in the potential), the transition to a body-centred cubic crystal was detected[55]. After crystallisation, the

†In fact, Melikhov and co-workers[49] studied not the fusion but the spinodal breakdown of an argon crystal superheated by a factor of 2.86 relative to the melting point ($p \cong 105$ MPa).

potential for rubidium was replaced by a short-range potential (only the repulsive branch of the potential for rubidium, the Lennard-Jones potential, and its repulsive part were used), as a result of which the structure relaxed into the face-centred cubic lattice.

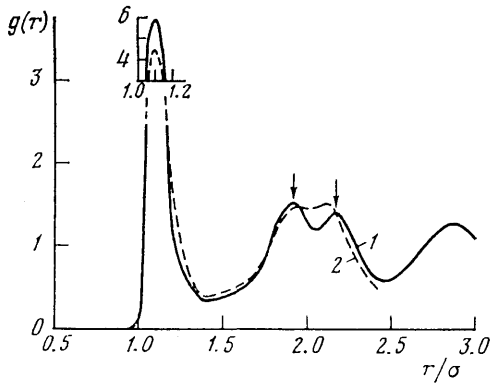

Figure 9. Radial distribution function of vitreous argon, obtained in the MD model: *1*) $T = 12.9$ K, $\rho = 1.596$ g cm^{-3},[52] the arrows indicate the positions of the two maxima of the split peak at $r/\sigma = 1.93$ and 2.16; *2*) $T = 48.8$ K, $\rho = 1.667$ g cm^{-3}.[57]

The actual identification of the crystalline nucleus presents considerable difficulty in the MD experiment. It has been suggested[58] that in MD modelling, the following factors have a decisive influence on the production of a regular structure: 1) the error of the method of integrating the equations of motion; 2) the rounding-off error of the computer calculation; and 3) the periodic boundary conditions. In the MD models, however, crystallisation was observed for different (including short-range) potentials of intermolecular interaction, so that the errors in the integration and the application of the periodic boundary conditions can hardly play a decisive role, since these errors have a smaller order of smallness than the perturbations associated with a change in the potential.

The computer experiments[53–55] may have detected not genuine crystallisation but a preceding stage of heterogeneous fluctuations in the supercooled system in which an ensemble of prenucleation formations is produced and relaxes to the stationary state.

Schneider and co-workers[59] proposed to study the possibility of another mechanism of crystallisation. It is assumed that a supercooled liquid may be unstable with respect to perturbations of the density, taking place throughout the volume of the liquid and having a wavelength of the order of the interatomic distances. Schneider's hypothesis was verified[60,61] in a study of a Lennard-Jones liquid with respect to external time-independent perturbations. In both the planar[60] and the three-dimensional[61] cases, when a periodic perturbing potential was applied, ordering of the particles in the model was obtained. As soon as the potential was removed, however, the system returned to the internal-equilibrium liquid state.

The response of a system to an external perturbation is closely related to the fluctuations in the density, taking place in the system itself (fluctuation–dissociation theorem). Thus the reaction of a system to external perturbations can be found via the calculated spectrum of the density fluctuations. A criterion of the thermodynamic stability of the isotropic phase (in the long-wave limit) is the fulfilment of the inequality[62,63]:

$$T/C_p > 0, \quad -(\partial p/\partial V)_T = (V\beta_T)^{-1} > 0$$

According to Schneider[59], in the static case the system will be stable with respect to perturbations of arbitrary wavelength with the condition

$$\beta_T^{-1}(\mathbf{k}) = \rho k_B T/S(\mathbf{k}) > 0 \qquad (5)$$

Here, $\beta_T(\mathbf{k})$ is the isothermal response function for a time-independent perturbation.

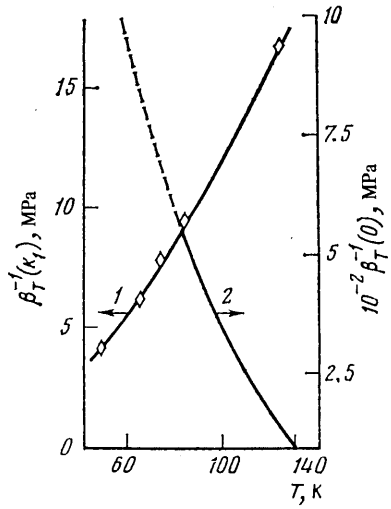

Figure 10. Elasticity of the liquid with respect to long-wave ($\beta_T^{-1}(0) \equiv \beta_T^{-1}$) and short-wave [$\beta_T^{-1}(k_1)$] perturbations: *1*) result of molecular-dynamic calculation[22], *2*) experiment[64]; the broken line corresponds to the extrapolation of the experimental data.

The elasticity of a simple liquid towards short-wave perturbations decreases with decrease in temperature, whereas the thermodynamic (long-wave) elasticity increases (see Fig. 10).[22] In the temperature range studied (with a deep descent into the metastable range), condition (5) is fulfilled both for $k = 0$ and for $k = k_1$. The increase in the mechanical stability to long-wave perturbations ($\beta_T^{-1}(0)$ increases), together with the fulfilment of the thermal stability condition $T/C_p > 0$,[21] indicates the absence of a boundary of appreciable instability (spinodal for the supercooled liquid). Attention was first drawn to this fact by Skripov and Baidakov[65]. The essential feature of this statement is that if the treatment is restricted to an examination of small (continuous) perturbations of the type of fluctuations in the density and energy, the liquid retains its internal stability to as low a temperature as desired. In a real experiment, breakdown of stability may take place as a result of the spontaneous production of a crystalline nucleus (a perturbation of special form) or as a consequence of dynamic instability.

To detect the dynamic (phonon) instability of a liquid, it is necessary to determine the temperature dependence of the dynamic structure factor $S(k, \omega)$ in the deep descent to the range of metastable states. If with change in the thermodynamic state of a system the complex frequency of any collective vibration decreases to zero (soft mode), the system approaches the limit of stability[66]. The frequency of the collective mode Γ_c [half-width $S(k, \omega)$], determined in the MD model of argon[22], decreases more rapidly with temperature than Γ_c calculated in the central field approximation[67] or the generalised Pathak–Singwi approximation[68] (Fig.11). The explicit form of the $\Gamma_c(T)$ relationship was obtained in the form of a polynomial of second degree on treatment of the results of the MD calculation by the least-squares method

$$\Gamma_c(T) = -2.36 + 0.045T - 0.00012T^2 \qquad (6)$$

(in units of 10^{12} s^{-1}). The $\Gamma_c(T)$ relationship in the form of Eqn.(6) is given by the broken line in Fig.11. At $T \cong 64$ K, the polynomial in Eqn.(6) becomes zero. This result, however, apparently cannot be interpreted as the attainment of the limit of dynamic stability of the simple liquid ($k \cong k_1$). At low temperatures ($T < 65$ K for Ar), vitrification of the supercooled liquid takes place, accompanied by a marked increase in the relaxation time. This leads to a no less marked decrease in the half-width of the first (quasi-elastic) peak for $S(k, \omega)$, compared with that for the change to crystalline order. The instability of the liquid can be judged from the decrease in Γ_c when it is certain that the decrease in Γ_c is not due to some other factor.

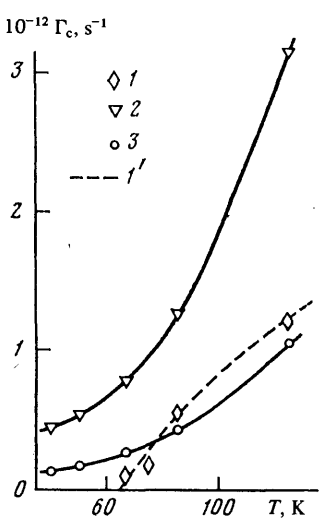

Figure 11. Temperature dependence of the frequency of the collective mode Γ_c: *1*) data from a computer experiment[22], *1'*) result of the approximation of $\Gamma_c(T)$ by the polynomial *6*; *2*) central field approximation[67]; *3*) Pathak–Singwi approximation[68].

The above examination was restricted to simple liquids. For substances with complex molecules, in the description of the structure of the condensed phases, it is necessary to take into account the orientational effects and internal degrees of freedom. The latter influence the "external" dynamics of the system as a consequence of the exchange of energy between different degrees of freedom[69].

3. The Method of Statistical Geometry (Developed for the Computer)

Statistical geometry involves the analysis of the geometric elements characterising the packing of the atoms, based on the construction of Voronoi polyhedra (the Dirichlet region) or Delaunay tetrahedra. The definition and method of construction of the Voronoi polyhedra (VP) were given above in the description of Bernal's mechanical models. Another method of breaking down the space occupied by the particles is associated with the name of Delaunay and is based on the construction of irregular tetrahedra (IT) or, more accurately, triangular pyramids. The method used by Bernal to study the structure of simple liquids by examining the shapes of the cavities formed by the particles reduces to the Delaunay-tetrahedra method. The apices of the IT coincide with the centres of four closely situated particles. For the case of the packing of hard spheres, the IT combines both spheres in direct contact with one another and spheres separated by a small gap (see Fig.12). The section connecting the centres of two spheres in contact is called an edge of the IT,[70] and the section connecting spheres not in contact is called a diagonal of the IT. Each additional particle placed inside the IT leads to the appearance of four smaller IT. For an ensemble of randomly close-packed hard spheres of equal size, the probability of the appearance of a new edge of the IT is 3/4, and that for a diagonal is 1/4. Any IT can be represented by a Delaunay diagram, which describes the nature of the contact between the particles forming it. For a random arrangement of the particles, it is possible to calculate the frequency of the appearance of a given type of IT.

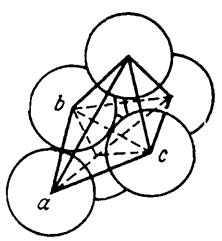

Figure 12. Delaunay tetrahedra for the packing of hard spheres: *ab*—edge of the IT, *ac*—diagonal of the IT.

This method of examination is convenient for the description of the packing of particles of different size, since the distance between the particles is itself an object of statistical analysis. For the study of the regular features of the packing of particles of equal size, however, the method based on the construction of the VP has been more widely used. The methods of describing the structure of the packing of particles on the basis of the VP and the IT are closely related. Thus the number of faces of the VP is determined by the sum of all edges and diagonals passing through an apex "common" to a group of IT (with allowance for all

acceptable versions of the breakdown of space into IT). In a structural analysis using the computer, the VP method is more convenient than the IT method, in that it relates to one definite particle and characterises its environment; the VP carries information on the number and relative arrangement of the nearest geometric neighbours.

Various exact and approximate methods for the computer construction of the VP exist[71-75]. The method proposed by Galashev[75] can be described as follows. The configuration of the system of particles, obtained in the MD experiment for a given step, was known; VP were constructed around the centres of individual particles in the model. Intersecting planes were constructed for the particle environment selected round the centre being considered. From the centre O, a sphere of radius OM was drawn at half the distance to the nearest neighbour; ~200 points were arranged uniformly over the sphere. The points M_c at which the rays, starting at the centre, which had passed through the points arranged on the sphere, meet the set of intersecting planes were then found (see Fig.13). The planes nearest the centre formed the VP. The number of points used ensured that account was taken of all the faces and edges of the VP with area $s > 0.01\bar{s}$ and length $l > 0.1\bar{l}$ respectively, where $\bar{s}$ is the average area of a face, and $\bar{l}$ the average length of an edge of the VP. The accuracy of the construction of the VP can be made as high as desired, by increasing the number of reference points (nodes of the net).

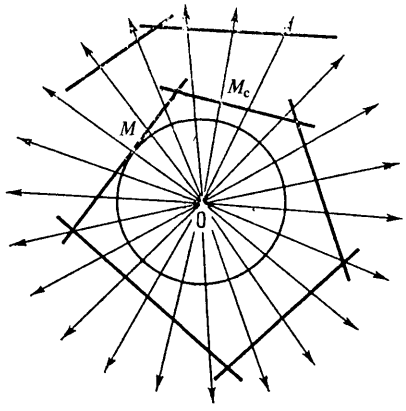

Figure 13. Construction of the VP and its faces by an approximate method[75] (projection of three-dimensional specimens on a plane): *OM* is the radius of a sphere equal to half the distance to the nearest neighbour; the straight lines represent planes passing at right angles through the centres of sections joining the central particle *O* to its neighbours; the arrows leaving the point *O* are the rays; M_c represents the points where the rays meet the planes. The construction used to determine the faces of the VP has a similar form.

The study of the structure of a simple liquid by the method of statistical geometry using a computer led to the discovery of a number of interesting regular features. Thus Rahman[19] established that the average number of geometric neighbours (or the number of faces in the polyhedra) in a simple liquid increases according to a linear law with change in the order of the layer of neighbours from one to five. The magnitude of the calculated average displacement vector, determined as the sum of the vectors drawn from the centre to the apices of the VP, coincides with that of the displacement of the central particle in a time of $\sim 5 \times 10^{-13}$ s. Finney[76] studied the types of VP encountered for a simple liquid in the mechanical hard sphere model and for modelling by the MC method[10]. The predominant VP in the liquid had a relatively simple form, containing, for example, only four-, five-, and six-sided faces.

Statistical geometry was recently used to study the nucleation of a crystalline phase. The states were identified beforehand from the topological characteristics of the VP. The configurations of 108 and 500 particles, averaged over a time interval of 5×10^{-13} s, were analysed[77]. For the model of a liquid with only repulsive interaction (exponent 12), the number of VP having a set of four-, five-, and six-sided faces for a total number of faces of 13 or 14 reached ~5% of the total number of VP (see Fig.14). Fig.14 also shows that for a supercooled liquid the picture is almost identical, although the number of definite groups of 13- or 14-faced VP having only four-, five-, and six-sided faces is close to 10%. In a face-centred cubic crystal, the fraction of characteristic types of VP amounted to up to 20%. For the body-centred cubic crystal, more than 90% of all the VP belong to the class of the cubo-octahedron. The difference in the number of VP of characteristic type for regular packing is due to the fact that the cubo-octahedron (see Fig.6*c'*) is stable with respect to thermal vibrations of the particles, whereas the rhomboidal dodecahedron (Fig.6*b'*) is completely unstable to these displacements[55].

The initial stage of crystallisation has been studied. In a supercooled liquid, discrete "nuclei" combining several particles were detected; the VP of these groups belonged to the class of the cubo-octahedron. With the passage of time, the nuclei grew to form a large particle of irregular shape, containing several tens of atoms with a distorted body-centred cubic structure. When uniform compression of the system was applied along a definite axis[78] (the degree of compression was varied from 0.90 to 0.71), structural relaxation to the face-centred cubic structure took place in it after ~2000 time steps. Hsu and Rahman[55,79] consider, on the basis of the MD experiment carried out, that the crystallisation of liquid argon begins with the simultaneous formation of face-centred cubic and hexagonal close-packed structures, whereas for rubidium the body-centred cubic lattice is formed.

Up to the present, only the positive features of the method of structural analysis based on the VP have been noted. This method, however, has a serious disadvantage. The statistics (frequencies of appearance) of the faces and edges of the VP are essentially topological, and not metric characteristics. It is therefore sometimes difficult to interpret the results of the analysis of the VP. Thus the distortions of the VP brought about by the thermal vibrations of the particles do not make it possible to identify the face-centred cubic structure reliably. Finney and Wallace[80] studied the structure of non-crystalline close packing using a characteristic which is very sensitive to both topological and metric changes—the correlation function for the cavities formed by the particles. They examined two types of cavity[80], a distorted tetrahedron and a distorted octahedron, and concluded that other types of Bernal cavity are rarely encountered in systems with soft interaction, because of the existence of a relatively large (compared with the packing of hard spheres) free volume corresponding to one particle.

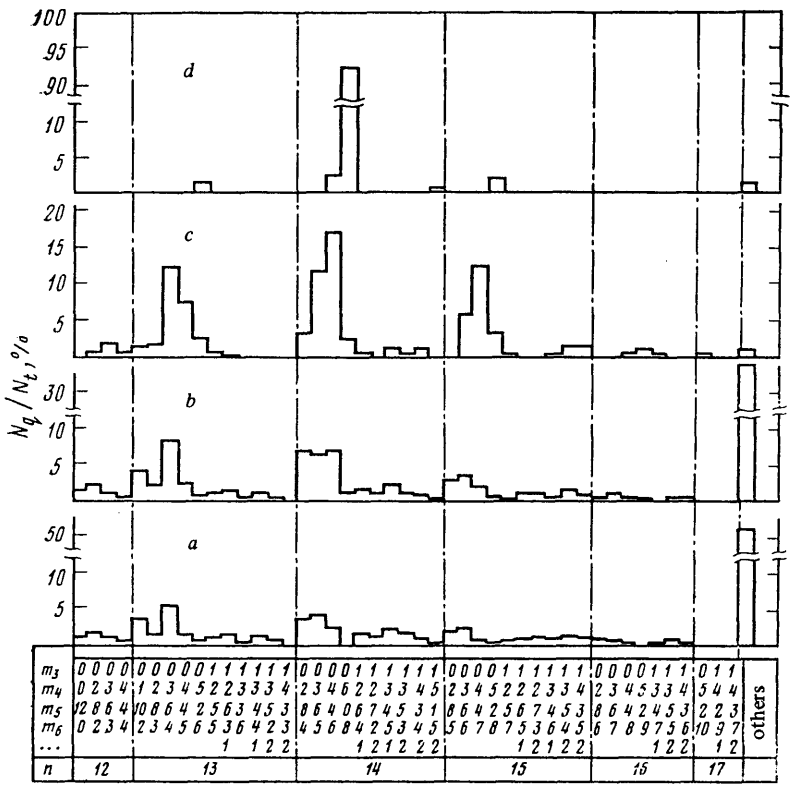

Figure 14. Distribution of the types of VP encountered in the MD models of systems with purely repulsion interaction of the particles[77]; $\Sigma m_i = n$, m_i is the number of i-sided faces in the VP with n faces; N_q/N_t is the relative number of VP containing n faces with i sides; *a*) equilibrium liquid (T = 96.2 K, ρ = 1.511 g cm^{-3}); *b*) supercooled liquid (T = 52.9 K, ρ = 1.847 g cm^{-3}); *c*) face-centred cubic crystal (T = 57.7 K, ρ = 2.099 g cm^{-3}); *d*) body-centred cubic crystal (T = 56.2 K, ρ = 2.099 g cm^{-3}); the values of T and ρ, given in brackets, were calculated for the parameters of the interaction potential σ and ε corresponding to argon.

4. The Structures of the Short-Range Order of the Crystal and the Liquid (the Argon Model)

The short-range coordination of atoms in a liquid has been established from experiments on the diffraction of electrons, neutrons, and X-rays. This coordination does not reduce to crystalline coordination, and is produced by a much larger set of configurations of neighbours. The studies of Bernal, devoted to the investigation of the variety of structures in simple liquids, were discussed above. At the present time, in addition to the alternative approach[7,24], ordering in a liquid is still being interpreted as quasi-crystalline. Use is made, for example, of the models of blurred lattices[81] and floating microcrystallites[82], cluster models in the form of sets of body-centred cubic and face-centred cubic structures[83], etc. The view[84], based on the concept of the quasi-crystallinity of a liquid, that polymorphism exists in liquid metals, is widely encountered. These views are based on an *a priori* under-estimation of the difference between the liquid and the crystal.

From a geometric analysis of mechanical models of irregular packing, Bernal concluded that the most important characteristic of the structure of a simple liquid, distinguishing it from a crystal, is related to the existence of a five-fold rotational axis of symmetry. In fact, pentagonal faces are frequently encountered in the VP of irregular random packing. To confirm this important characteristic of the structure for more reliable models, it is necessary to find for them the distribution of the faces of the VP with respect to the number of sides. Calculations carried out by the MC [10] and MD [19] methods in fact detected a predominance of pentagonal faces in the Voronoi polyhedra for a liquid. It would appear that an essential feature of the structure of a liquid had been reliably determined, but computer calculations[10] raised some doubt about this. The fact is that pentagonal faces are most frequently encountered in the VP not only for instantaneous configurations of the liquid, but also for the crystal. The factor leading to the predominance of five-fold symmetry in both disordered and regular structures has still to be determined. It is natural to relate it to the thermal motion of the atoms. Five-fold symmetry, inadequate for the crystal, can be avoided by changing from an analysis of instantaneous configurations of the particles to an examination of configurations averaged with respect to time.

This method of averaging for a crystal with a large atom settling time is quite acceptable, and gives a positive result. The elements of five-fold symmetry disappear for an averaging time $\tau \gg \tau_0$, where τ_0 is the period of the vibrational motion of the atoms. In a liquid, however, in contrast to a crystal, there are no equilibrium positions of vibrational

motion of the atoms. With developed translational motion of the atoms, averaging over a large time interval may lead to an unnatural configuration with marked overlap of the particles#. This can be avoided by decreasing the averaging time interval, but there is no guarantee that this procedure corresponds to the desired goal.

Averaging with respect to a short time interval was also carried out for the configurations of particles obtained in the MD model of a liquid[77]. The averaging time[77] was 5×10^{-13} s for a time step $\Delta t = 10^{-14}$ s. Displacement of the particles of the immediate environment in a liquid cannot take place in this short time interval. The particles are displaced on the average a distance $r \leqslant 0.1\sigma$. The time of 5×10^{-13} s is close to the average period of the vibrational motion of the atom in a liquid, so that the configurations of the particles, averaged over this time interval, should not differ greatly from the instantaneous configuration§.

Thus in the study of the structure of an equilibrium liquid, direct averaging with respect to time is not effective. To obtain structural characteristics which show little sensitivity to thermal fluctuations, another method of analysis using VP was proposed independently[55,96]. In a study of the crystallisation of supercooled argon, to record the face-centred cubic structure more accurately, small edges ($l \leqslant 0.3\sigma$) in the VP were excluded[55].

To establish the differences in the arrangement of the nearest neighbours in a simple liquid and a crystal, the small faces and edges in the VP were excluded[86]. The application of this procedure to the VP for crystalline argon brings the n- and m-distributions closer to the results obtained by averaging with respect to time. This indicates the physical justification (acceptability) of the procedure involving the rejection of the small edges and faces. The n- and m-spectra of liquid and crystalline argon, constructed after excluding the small geometric elements (see Figs.15 and 16), differ considerably. Thus the difference between the dispersions of the n- and m-distributions of the liquid and the crystal increased by average factors of 2.5 and 3.5 respectively. The proportion of pentagonal faces in the VP for the liquid remained high, whereas for the crystal it decreased considerably. After excluding the faces with $s \leq 0.2\bar{s}$ and the edges with $l \leq 0.4\bar{l}$, four-sided faces predominate in both the crystal and the liquid. The ratio of the numbers of five- and four-sided faces was 0.81 in the liquid, however, whereas for the crystal it was 0.14.

#In the case of liquid argon, the averaging time should be shorter than the time $\tau_\sigma = 1 \times 10^{-11}$ s, after which the particle is displaced on the average through a distance σ.

§The results of an analysis of VP constructed for the instantaneous configurations of the particles of the MD model of liquid Al at the melting point and with superheating by ~200 K have been interpreted[85] as confirming the possibility of structural transformations in the melt, analogous to the transformations in the solid phase. The face-centred cubic and body-centred cubic phases were detected in the melt[85] only from the topological characteristics of the VP, but the dimensional (metric) characteristics of the VP were not examined. This method of identifying the structure is not unambiguous[55]. Even if it is assumed that the proportions of VP of the face-centred cubic and body-centred cubic types have been determined correctly, it can still hardly be concluded that a structural transformation takes place in the melt, since the number of VP of these types is small (reaching ~5%).

If the system is compressed and cooled rapidly, the vitreous state of the element is produced in the MD model[52,57]. In this case the particles undergo only vibrational motion about the irregular equilibrium positions, and in the structural analysis it is possible to study the configurations of the particles averaged with respect to time. A comparison of the configurations, averaged with respect to time, of regular and irregular face-centred cubic and body-centred cubic structures has been carried out[57]. The n- and m-distributions for these configurations, shown in Fig.17, were obtained with an averaging time $\tau \cong 8 \times 10^{-11}$ s and 3×10^{-11} s for vitreous argon and the ordered structures respectively. The differences in the spectra are obvious. The dispersion of the n-distribution for the irregular structure is 6.5 times that for the face-centred cubic structure. Pentagonal faces predominate in the m-distribution of vitreous argon. Four-sided faces predominate in the face-centred cubic crystal, and hexagonal faces in the body-centred cubic crystal. The structure of vitreous argon was found to be non-uniform. Its spatial non-uniformity is reflected by the VP, shown in Fig.18. The shape and size of the Voronoi polyhedron characterising the intermediate "structural granule" (Fig.18*b*) are close to those of the most probable VP for an equilibrium liquid at the melting point; the differences between their volumes and surface areas are very small (~0.7% and 2.2% respectively). The intermediate configuration has a distorted structure, and its dimensions are smaller than those of the critical crystalline nucleus, which contains ~50 particles[53].

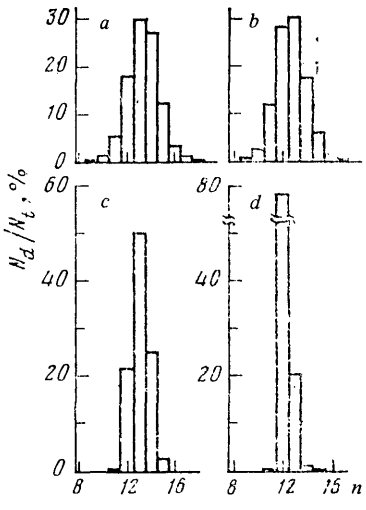

Figure 15. Distribution of VP with respect to the number of faces before (left) and after exclusion of the faces with area $s \leqslant 0.2\bar{s}$ [86] (*a*, *b*—spectra of liquid argon at 83.7 K; *c*, *d*—crystalline argon at 81.1 K); N_d/N_t is the relative number of VP with a definite number of faces.

Yet another method for determining the structural differences in the short-range order of a liquid and a crystal has been proposed[87]. This version of the structural analysis involves not the direct comparison of the packing

of particles in a liquid and a crystal, but an intermediary—an ideal crystal lattice corresponding to an average density $\rho = N/V$. The essential feature of the method is the mapping of the particles in the model on to the sites of this lattice. The number of sites is greater than the number of particles mapped on to them. The lattice penetrates the sphere distinguished in the basic MD cell. The sphere is drawn around one of the particles selected randomly in the calculation. For the liquid, this procedure is repeated after every 50 time steps ($\Delta t = 10^{-14}$ s); the total calculation time is 5×10^{-12} s. In the case of the crystal, one configuration of the particles was analysed. The volume of the sphere contained the particles of the first two coordination spheres in the liquid (an average of 57 particles), and three in the crystal (43 particles). The central particle was superimposed on a site of the lattice; for the other particles present in the sphere, the distances to the nearest sites of the lattice were determined. With this correspondence between the particles and the lattice sites, two or even three particles of the liquid were assigned to some of the sites.

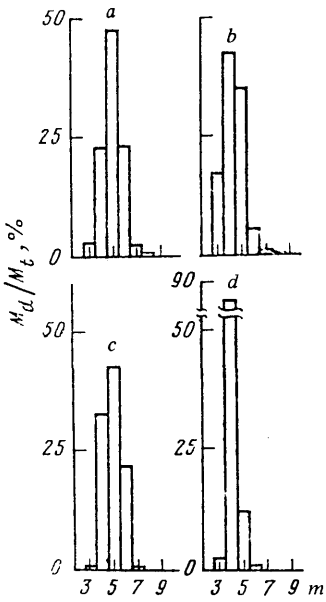

Figure 16. Distribution of the faces of the VP with respect to the number of faces without restriction on l and s (left) and with the exclusion of edges with $l \leq 0.4\bar{l}$ and rejection of faces with $s \leq 0.2\bar{s}$;[86] *a–d*) see Fig. 15; M_d/M_t is the relative number of faces with a definite number of sides.

Another method of mapping involves searching for the nearest unoccupied site for each particle. In this case a one-to-one correspondence was achieved between the particles and the lattice sites. The configurations of the particles averaged over time intervals of 5×10^{-13} s for the liquid and 10^{-11} s for the crystal were analysed. The results of the mapping of the particles on to the sites of a face-centred cubic lattice are shown in Fig. 19 (N_r/N_t denotes the relative number of particles situated at a distance Δr from the lattice sites, and d the distance between nearest neighbours in the ideal face-centred cubic lattice). For a liquid, two distributions with respect to the distances from the lattice sites are obtained, depending on the method of mapping. For a crystal there is only one distribution, independent of the method of mapping. The distribution for the liquid, corresponding to one-to-one mapping, extends as far as distances greater than d. The proportion of particles which for the transformation to a regular structure must be moved through distances greater than d is ~0.7%. This means that it is impossible to obtain the crystal from the liquid only by local displacements of the atoms. In exactly the same way it is impossible to obtain the liquid from the crystal by random small displacements of the particles from the lattice sites (blurred lattices). An appreciable proportion of the atoms in these transitions are displaced through a distance of the order of the interatomic distance.

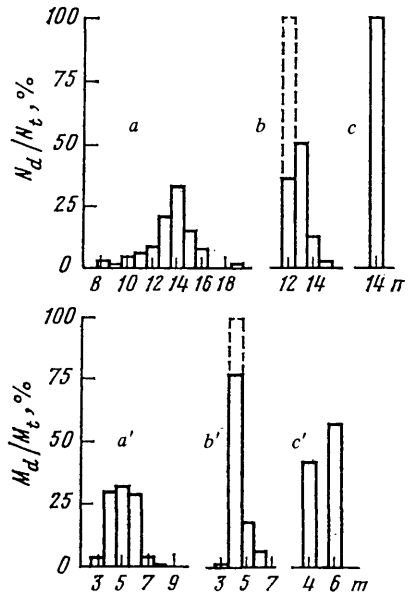

Figure 17. Distribution with respect to the number of faces of the VP and of faces with respect to the number of edges[57]: *a,a'*) vitreous argon at 48.8 K; *b,b'*) face-centred cubic crystal at 41.4 K; *c,c'*) body-centred cubic crystal at 48.4 K; Broken line—ideal face-centred cubic lattice.

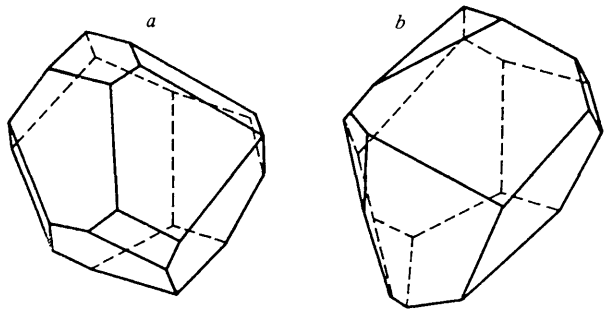

Figure 18. Voronoi polyhedra for the averaged configuration of vitreous argon[57]: *a*) for one of the particles of the uniform part of the volume; *b*) for a particle in the region of the "structural granule".

The results[57,86,87] obtained by the MD method do not confirm the quasi-crystallinity concept in the theory of the liquid state. This is also indicated by the experimentally observed avalanche-like character of the phenomenon of crystallisation and the extensive supercooling of liquids. The structure of the short-range order is different for a liquid and for a crystal. For the production of a crystal-like nucleus in a liquid, "continuous" local rearrangement of the atoms of the immediate environment of the uniform deformation type is insufficient. The conclusion from the study of random packing that five-fold symmetry plays a significant role is confirmed. When this symmetry is present, a regular crystal cannot be constructed.

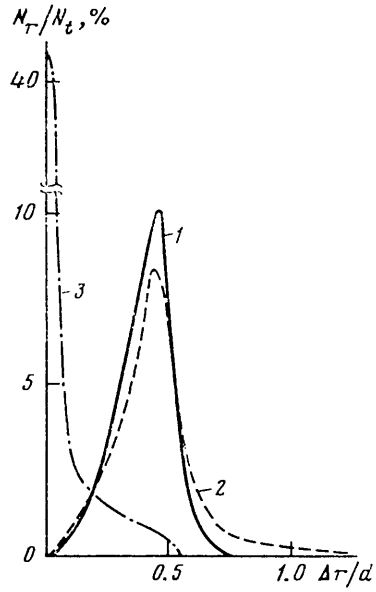

Figure 19. Radial distributions of the particles of a liquid (*1*, *2*) and a crystal (*3*) relative to the ideal face-centred cubic lattice[87]: *1*) with the possibility of repeated action of the lattice sites; *2*) for one-to-one correspondence between the particles and the lattice sites.

VI. SUMMARY

There is as yet no exhaustive answer to the question of how a liquid is constructed. The efforts of research workers are revealing new knowledge, refining old ideas, and developing an overall picture.

A liquid, as a dense irregular structure, is more unique than assumed by quasi-crystalline representations. It is characterised by more numerous and "free" local configurations than an ordered regular structure. The high mobility of the particles and the presence of small groups of particles (with a local density exceeding the crystalline density) create favourable conditions for the exchange of energy and molecular rearrangements.

Attention has been drawn[88] to the structural aspect of chemical transformations in a condensed phase. The principal restriction on the reaction rate is seen in the deficit of free volume for the reacting atoms, and their low mobility. The value of the activation energy in this sense can be regarded as "generalised" and it is not always an exact indicator of the structural-dynamic restrictions in chemical kinetics. The variety of packings of the particles in a liquid is revealed in the excess entropy of the state compared with the crystal. An adequate theory of the elementary chemical act must be constructed with allowance for the local structural-dynamic characteristics of the liquid.

New and interesting facts have been observed in the study of the kinetics of chemical transformations at low temperatures[89]. The reaction rate in the liquid phase decreases with decrease in temperature. When the solution is frozen, however, in some cases it begins to increase very strongly, reaches a maximum, and decreases again on further cooling of the system. This behaviour is not exceptional; it is observed for many reactions involving substitution, decomposition, oxidation, and polymerisation[89]. A significant role in the kinetics of a transformation is apparently played by the phase non-uniformity of multi-component systems. Because of this, conditions are created for the high mobility of groups of particles. The high mobility has been related[89] to the existence of local liquid-like regions ("liquid microphase") in the heterogeneous frozen system. The new facts necessitate a detailed analysis of the structural-dynamic causes of the "anomalous" chemical behaviour of solutions in the region of the heterogeneity and the phase transformation. The state of the supercooled liquid permits a large number of local rearrangements of the particles in a large number of configurations of the non-crystalline type. Decrease in temperature most frequently leads of the production of very compact formations of several molecules, facilitating chemical reaction.

The structure of simple liquids exhibits a certain universality. This is reflected in the existence of thermodynamic similarity in the properties of substances in the liquid state. The marked difference in various properties of metallic and non-metallic liquids is due chiefly to the influence of the electronic sub-system.

Palladium(I) Complexes in Coordination Chemistry and Catalysis

O.N.Temkin and L.G.Bruk

The state of a rapidly developing branch of the coordination chemistry of platinum metals, namely the chemistry of palladium(I) complexes, is examined. The fundamental properties, chemical reactions, and methods of synthesis of palladium(I) complexes are described. The role of palladium(I) compounds in the mechanisms of catalytic and stoichiometric reactions is discussed.
The bibliography includes 163 references.

I. INTRODUCTION

Complexes of metals with the d^9 electronic configuration are known for the metals at the ends of the transition series in the Periodic System. Until recently, the family of these compounds was limited mainly to copper(II) and zerovalent cobalt complexes[1]. Although the first representatives of the coordination compounds of the nickel triad in the +1 oxidation state have been known for a fairly long time [nickel(I)—1913 [2] and palladium(I)—1942 [3]], the early studies concerning palladium(I) complexes have been treated with much scepticism. For example, there is not even a mention of palladium(I) in the monograph of Cotton and Wilkinson[1] (1965), while Livingstone's book[4] (1973) describes three complexes and notes that "the existence of univalent palladium still cannot be regarded as proved". Only Maitlis's monograph[5] (1971) presents complete information about all the few compounds of formally univalent palladium known at the time.

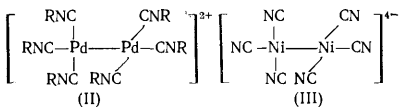
During the last ten years, numerous studies concerning nickel(I), palladium(I), and platinum(I) have been published, the early investigations have been re-examined, and it has become possible to speak of a new family of complexes of formally univalent nickel, palladium, and platinum. The interest in these compounds has been to a large extent stimulated by studies in the field of metal complex catalysis and in the chemistry of cluster compounds. It was found that the complexes of the metals M(I) of the nickel triad contain a wide variety of σ and π ligands and have a series of rarely encountered structural features. The present review is devoted to palladium(I) compounds whose structure and reactivity have been investigated most fully.

II. THE STRUCTURE AND PHYSICAL PROPERTIES OF PALLADIUM(I) COMPLEXES

By the beginning of 1981, more than 140 palladium(I) compounds with various σ and π ligands had been synthesised. In the vast majority of instances the palladium(I) complexes are dimeric as a result of the formation of Pd—Pd bonds and are diamagnetic in contrast to the numerous monomeric paramagnetic nickel(I) complexes[6,7]. Only one monomeric paramagnetic palladium(I) [and platinum(I)] complex (I) with a chelating thiolene ligand is known[8].

(I)

Furthermore, the formation of paramagnetic Pd^+ ions has been detected by EPR on the PdY zeolite under various conditions[9,10]. The most thoroughly investigated class of cluster complexes of palladium comprises dimers with the Pd_2^{2+} fragment, although complexes containing the following skeletons made up of palladium atoms are already known: Pd_2^{2+}, Pd_3^{2+},[11,12] Pd_3^{4+},[13-15] Pd_4^0,[16] Pd_4^{4+},[17-21] Pd_5^{4+},[22] Pd_{10}^0,[23] Pd_{10}^{8+},[24] and Pd_{12}^0.[25]



The formal oxidation state of the metal atom in the complex is defined, according to Nyholm[26], as the charge which remains on the group of metal atoms after the removal of the ligand and is referred to the number of metal atoms. It is assumed that in the leaving ligand atoms or groups of atoms (H^-, Cl^-, O^{2-}, OH^-, NH_2^-, PR_2^-, $SnCl_3^-$, CH_3^-) the electron cloud of the atom linked to the metal corresponds to the cloud of the nearest inert gas atom and that the ligands are removed in the form of neutral molecules (CO, NO, N_2, CO_2, C_2H_2, C_4H_4). Certain π-bonded organic groups (C_3H_5, C_5H_5) are believed to be anions like the σ-bonded groups ($C_3H_5^-$, $C_5H_5^-$). From this standpoint, the oxidation state of palladium in the compounds C_3H_5PdCl, $(C_3H_5)_2Pd$, and C_5H_5PdCl is +2, while in the compounds $C_3H_5Pd_2Cl$, $(C_3H_5)_2.Pd_2$, and $C_5H_5Pd_2C_3H_3$ it is +1. In view of the foregoing, compounds containing Pd^+, Pd_2^{2+}, and Pd_4^{4+} belong to the class of complexes of formally univalent palladium (+1 oxidation state). These complexes will be considered in the present review.

1. Palladium(I) Complexes with σ-Ligands

In this subsection we shall deal with palladium(I) complexes containing ligands which supply to the metal unshared σ (or *n*) electron pairs and are linked to the metal via a single centre (atom)†.

†In contrast to the π-ligands which form π-complexes, ligands of this kind can be usefully referred to as σ-ligands regardless of the predominant direction of electron transfer in the M—L bond and its multiplicity. Ligands containing π-electron pairs as well as σ-electron pairs can naturally be coordinated as π-ligands or as both σ- and π-ligands simultaneously (RCN, RNC, N_2, CO, CS_2).

Palladium(I) complexes with isonitriles (Table 1) are the most stable among the palladium(I) compounds with σ-ligands. This factor as well as the possibility of growing their single crystals made it possible in 1974 to carry out the first X-ray diffraction study on the palladium(I) complex with a σ-ligand: $[Pd_2(CH_3NC)_6](PF_6)_2 \cdot \frac{1}{2}(CH_3)_2CO$.[27,28] A characteristic feature of the structure of the complexes $Pd_2(RNC)_6^{2+}$ (II) as well as the analogous nickel(I) complex $Ni_2(CN)_6^{4-}$ (III) [29] is a square planar environment of the metal atom:

(II) (III)

This structure is apparently characteristic of all dimeric palladium(I) complexes with σ-ligands.

*C.H.Lindsay, L.S.Benner, and A.L.Balch, Inorg.Chem., 1980, 19, 3503.

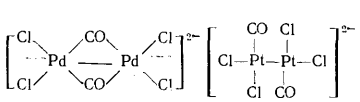
A typical feature of the complexes of isonitriles is the absence of bridge ligands, which, together with the diamagnetism and the short Pd–Pd distance (2.53 Å) makes it possible to infer with confidence the presence of a metal–metal bond. Thus the complexes are dsp^2 hybridised and the fourth coordination site at each palladium atom is occupied by a neighbouring palladium atom. The angle between the planes in which the PdL_3 groups are located is 86.2° for L = CH_3NC.[27,28]

Certain bidentate σ-ligands#, namely CH_3COO^-, $CH_2[As(C_6H_5)_2]_2$, and $CH_2[P(C_6H_5)_2]_2$, are bridge ligands in complexes with Pd–Pd bond (Table 2). In the case of bridge phosphine the angle between the planes of the PdL_3 groups is 39° (38.5° in the platinum analogue). However, the virtually square planar coordination around each palladium atom is retained[49]. The Pd–Pd distance in the complex $Pd_2Br_2dpm_2$ (IV) is 2.699 Å.[49]

(IV)

#Henceforth $CH_2[As(C_6H_5)_2]_2$ and $CH_2[P(C_6H_5)_2]_2$ will be designated by *dam* and *dpm* respectively.

We shall consider in greater detail the carbonyl complexes of palladium(I).[52] During the time since the publication of the first study[53], a large set of carbonyl halide complexes of palladium have been obtained under similar conditions from CO and PdX_2 with an average degree of oxidation from +0.5 to +2, which was calculated from the determinations of the contents of the elements[35–41,53–57]. According to the majority of investigators, these compounds are coordination monomers of the type $Pd_m(CO)_lX_n$. The insoluble polymeric complexes have been synthesised by various investigators and had similar spectroscopic characteristics but differed significantly in composition. It has been established[38,39] that the composition and properties of the coordination polymers are determined to a large extent by the amount of water in the reaction medium during their synthesis. The influence of the water concentration on the composition of the complexes and hence on the average degree of oxidation of palladium is apparently related to the involvement of water in the stages involving the reduction of palladium(II) and palladium(I) to zerovalent palladium via reaction (1). The interaction of the carbonyl complexes of palladium(I) with PdX_2 and Pd(0), whose ratio in the reaction system depends on the concentration of water, proceeds via Scheme (2) and leads to coordination polymers with different degrees of oxidation of palladium:



$$PdX_2 \xrightarrow{CO,H_2O} Pd^0 \xrightarrow{PdX_2} Pd_2X_2(CO)_n \xrightarrow{CO,H_2O} 2Pd^0 \quad (1)$$

$$m\,Pd_2X_2(CO)_n \begin{cases} \xrightarrow{n PdX_2} Pd_{(2m+n)}X_{2(m+n)}(CO)_n \\ \xrightarrow{p Pd^0} Pd_{(2m+p)}X_{2m}(CO)_n \end{cases} \quad (2)$$

When certain conditions are maintained, it is possible to obtain polymeric complexes having the composition $(PdCOX)_n$ (Table 2, Nos.1–9).

Together with these compounds, numerous dimeric diamagnetic compounds have been synthesised, the first representatives having been obtained as early as 1942 [3] (Table 2, Nos.31–33).

A detailed study of the structures of palladium carbonyl halides by infrared and Raman spectroscopy threw some light on the question, which had been under discussion for a long time, whether the halide or the carbon monoxide functions as the bridge in the palladium(I) carbonyl halide complexes[41]. According to Goggin and Mink[41], the carbonyl groups constitute the bridges in the dimeric palladium carbonyl halides $[Pd_2(CO)_2X_4]^{2-}$ [structure (V)], while the polymeric complexes consist of dimers linked by halide bridges. It is of interest to note that the dimeric platinum(I) carbonyl halide complexes have the non-bridge structure (VI),[58,59] characteristic of palladium(I) isocyanides, in contrast to the analogous palladium(I) complexes.

(V) (VI)

The first palladium(I) carbonyl acetate cluster of the type $[Pd(CO)(OOCCH_3)]_4 \cdot 2CH_3COOH$ was obtained in a number of studies[17–19] (Table 2, Nos.10 and 14). The crystal of this compound is made up of planar tetranuclear complexes (VII) and acetic acid dimers located at the centres of symmetry. The complex (VII) contains two dimeric complex species $Pd_2(CO)_2^{2+}$ with Pd–Pd bonds (l = 2.663 Å) and carbonyl bridges linked via four acetate groups[42]. Moiseev et al.[19] and Kuz'mina and Struchkov[42] carried out the first X-ray diffraction studies on palladium(I) carbonyl complexes.

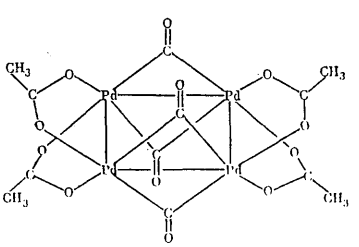


Table 2. Palladium(I) complexes with CO and other σ-ligands.

*C.H.Lindsay, L.S.Benner, and A.L.Balch, Inorg.Chem., 1980, **19**, 3503.

The same workers obtained a tetranuclear cluster (Table 2, No.17) with a tetrahedral Pd_4^{4+} skeleton[20,21]. X-Ray diffraction analysis of the complex $Pd_4(CO)_2(phen)_4(OOCCH_3)_4$ (VIII) showed that all four palladium atoms are equivalent and form an almost regular tetrahedron. The two Pd–Pd bonds having carbonyl bridges (the Pd–C–Pd angle is 105°) are somewhat longer (l_{Pd-Pd} = 2.890 Å) than the four Pd–Pd bonds without such bridges (2.718 Å). *o*-Phenanthroline behaves as a bidentate terminal ligand; the acetate ions are in the inner sphere of the complex[20,21].

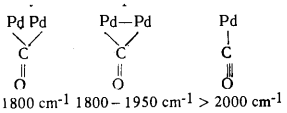
(VII)

(VIII)

Solutions of palladium(I) carbonyl halide complexes in concentrated hydrochloric acid, obtained by the method of Colton et al.[40] and Goggin and Mink[41], were used[45,46] to synthesise the complexes $[(PdLX)_2CO]$ (Table 2, Nos.19–30). After being dried in an atmosphere of argon, these complexes are entirely stable but in solution in benzene, acetone, and ethanol they slowly disproportionate (the formation of colloidal, metallic palladium is observed). They contain only one carbonyl group for two palladium atoms and have a large dipole moment (μ = 7–9 D) and reduced stretching vibration frequencies ν(CO) of the carbonyl group (Table 2). Furthermore, their ^{31}P NMR spectra contain two bands with the chemical shifts δ_1 = −22 – −24 p.p.m. and δ_2 = −19 to −21 p.p.m., which apparently indicates different types of coordination of the two phosphine ligands[46].

In conclusion we shall consider briefly the possibility of using the parameters of the infrared spectra, in particular the frequencies ν(CO), for the analysis of the structure of the complex and the determination of the oxidation state of the metal. The range of variation of ν(CO) for the palladium and platinum complexes is very large, reaching ~500 cm^{-1}.[60,61] The main factors influencing ν(CO) are (a) the nature of the coordination of the CO group (terminal or bridge groups), (b) the type of bridge, (c) the degree of oxidation of the metal (metals), and (d) the nature of the other ligands. The influence of the degree of oxidation of platinum and palladium on ν(CO) can be traced from the following examples. The change in the stretching vibration frequency of the terminal CO group $\Delta\nu$(CO) on passing from platinum(II) to platinum(0) is ~30 cm^{-1} and that on passing from platinum(II) to platinum(I) is 52–71 cm^{-1} (Table 3). Similarly in the case of the Pd(II) → Pd(0) transition the value of $\Delta\nu$(CO) is low (~70 cm^{-1}). The change in the type of coordination (transition from the terminal to the bridge CO group) leads to a considerable decrease of ν(CO).

Table 3. The influence of the degree of oxidation of the metal and of the type of coordination of carbon monoxide on ν(CO).



Metal (degree of oxidation)	Complex	ν(CO), cm^{-1}	References
Pt(II)	$PtCl_3(CO)^-$	2098	[61]
Pt(I)	$Pt_2(CO)_2Cl_4^{2-}$	2047, 2027	[58]
Pt(0)	$[Pt(CO)_2]_n$	2068	[58]
Pd(II)	$PdCl_3(CO)^-$	2132	[61]
Pd(I)	$Pd_2(CO)_2Cl_4^{2-}$	1922, 1973	[41]
Pd(0)	$Pd(CO)_4$	2060	[62]

Thus ν(CO) for the dimer $[Pd_2(CO)_2Cl_4]^{2-}$ is reduced compared with ν(CO) for $[PdCl_3CO]^-$ by 210–160 cm^{-1}, while the decrease of ν(CO) as a consequence of the change in the oxidation state of palladium [Pd(II) → Pd(I)] should not exceed 70 cm^{-1}. The vibration frequencies of the CO group coordinated as a bridge at the Pd–Pd bond in palladium(I) complexes are in the range 1800–1980 cm^{-1}.[16–21,23,41] This wide range of ν(CO) is apparently associated with the number of CO groups (strong π-acceptors), coordinated to the Pd_2 group, and with the characteristics of the Pd_2CO fragment (the Pd–C–Pd angle and the Pd–Pd bond length) rather than with the influence of other ligands. Thus ν(CO) for the complexes $[Pd(CO)(OOCCH_3)]_4$, $[Pd(CO)Cl]_n$, and $[Pd_2(CO)_2Cl_4]^{2-}$ are in the range 1900 to 1980 cm^{-1}, while those for the complexes $(PdLX)_2CO$ or $[Pd_4(CO)_2Phen_4]^{4+}$ are in the range 1800–1890 cm^{-1}. The vibration frequencies of the CO groups coordinated in the form of bridges in the zerovalent palladium clusters are in the same range[16,23]. There is no doubt that there is a correlation between ν(CO) and the characteristics of the Pd_2CO fragment—the Pd–C–Pd angle of the Pd–Pd bond length (Table 4). In the limiting case (Table 4, No.5) CO is inserted in the Pd–Pd bond, the Pd–C–Pd angle is ~120°, and ν(CO) has the usual values characteristic of the carbonyl group in organic compounds (see Section III, subsection 4).

Table 4. Relation between ν(CO) and the characteristics of the Pd_2CO fragment.

No.	Complex	ν(CO), cm^{-1}	l_{Pd-Pd}, Å	$\alpha_{Pd-C-Pd}$, °	l_{Pd-C}, Å	Refs.
1	$[Pd(CO)CH_3COO]_4$	1940, 1975	2.663	84.5	1.99	[18,19,42]
2	$Pd_4[P(C_6H_5)_2CH_3]_4(CO)_4$	1840, 1820	2.75	82.5	2.085	[16]
3	$Pd_{10}(CO)_{12}[P(n\text{-}C_4H_9)_3]_6$	1800, 1853, 1890	2.70; 2.82	83	2.05	[23]
4	$[Pd_4(CO)_2phen_4]^{4+}$	1800	2.890	105	—	[20, 21]
5	$[Pd(dam)Cl]_2CO\cdot 3C_6H_{14}$	1720	3.274	119	1.9	[63]

Thus the following limiting frequencies ν(CO) can be used for a preliminary assessment of the nature of the coordination of the CO group in palladium compounds on the basis of infrared spectroscopic data:

Palladium(I) complexes with terminal CO groups and palladium(II) complexes with CO groups coordinated in the form of bridges are hitherto unknown, but the frequencies ν(CO) for such compounds should apparently be within the limits indicated.

The first binary palladium(I) complex of the type $M_2Pd_2I_4 \cdot 2H_2O$, where M = Li or Cs, has been synthesised[51] from the complex $H_2Pd_2(CO)_2Cl_4$ obtained by the method of Colton et al.[40] and Goggin and Mink[41]. These compounds are diamagnetic and are apparently coordination polymers, because they dissolve in alcohols, acetone, dimethylformamide (DMF), and tetrahydrofuran only in the presence of an excess of I^- ions. When the complex $Li_2Pd_2I_4 \cdot 2H_2O$ is treated repeatedly with deaerated concentrated hydrochloric acid in an inert atmosphere, a compound is obtained whose elemental analysis leads to the formula $(PdI \cdot H_2O)_n$.

The complex $(LPdOOCCH_3)_2$ has been obtained[52] in the study of the mechanism of the formation of the active forms of hydrogenation catalysts in the $L_2Pd(OOCCH_3)_2$–H_2 system. The complex $\boxed{Si}$–P_2–$Pd_2(OOCCH_3)_2$ with a similar composition has been synthesised by the reduction of palladium acetate immobilised on a phosphinated silica gel surface[64].

The first palladium(I) nitrosyl complex was synthesised in 1960.[47] Several other nitrosyl complexes, tentatively of palladium(I) (Table 2, Nos.43–45), were described later but their structure was not established[48,65]. It has been suggested that they are coordination polymers with Pd–Pd bonds like the complexes $[Pd(CO)Cl]_n$.

A comparatively high thermal stability of palladium(I) complexes has been noted in a number of studies (Table 5). Some of the data on the thermal stability of palladium(I) compounds (Table 5, Nos.1–9a) have been obtained as a result of visual observations and are approximate. The stability of the complexes $[Pd(CO)Cl]_n$ (Table 5, No.9b),

$Li_2Pd_2I_4.2H_2O$, and $(PdLX)_2CO$ has been investigated by the thermographic method. The degradation of the complex $Li_2Pd_2I_4.2H_2O$ is preceded by the elimination of water (120–320 °C), which is followed by the liberation of I_2 (one mole per mole of the initial compound in the temperature range 320–600 °C).[51] The first stage in the thermal transformations of the complexes $(PdLX)_2CO$ is isomerisation, carbon monoxide being split off on raising the temperature. At 300–400 °C the final decomposition of these compounds takes place[46,66]. The above data indicate the possibility of the existence of palladium(I) compounds under fairly severe conditions.

Note. For compounds Nos.11–17, the isomerisation temperature is indicated first and the second figure denotes the temperature at which the elimination of CO groups begins.

2. Palladium(I) Complexes with π-Ligands

The π-complex of palladium(I) was synthesised in 1965 [67] by Fischer's method ($PdCl_2 + AlCl_3 + Al + C_6H_6$) (Table 6, No.1). X-Ray diffraction studies[67,68] established that complexes Nos.1 and 2 contain a Pd–Pd fragment [see structures (IX) and (X)].

Both compounds consist of centrosymmetric molecules containing benzene rings with virtually identical C–C bond lengths. Complexes Nos.1 and 2 differ in the position of the benzene rings relative to the Pd–Pd bond. In complex No.1 the two benzene rings located in parallel planes have at least two different orientations relative to the Pd–Pd bond [structure (IX)], differing from the orientation in the rings in complex No.2 [structure (X)] (Fig.1). The centres of the rings are displaced from the projection of the centre of symmetry of the complexes by 0.18 Å in structure (IX) and by 0.43 Å in structure (X).

Table 6. π-Complexes of palladium(I).

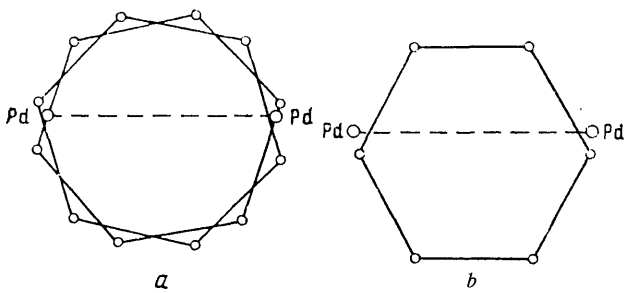

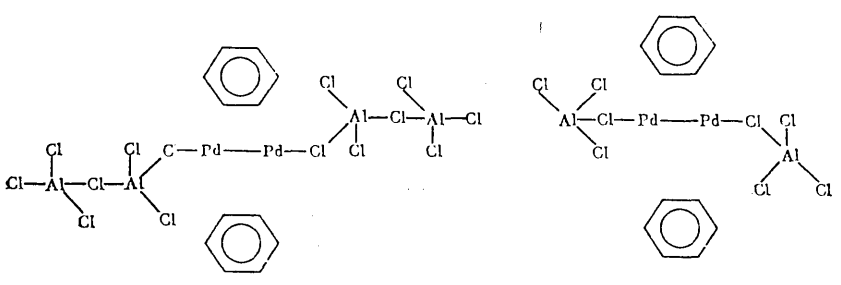

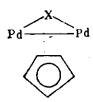

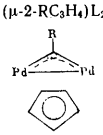

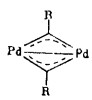

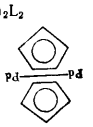

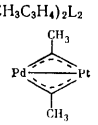

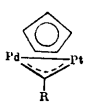

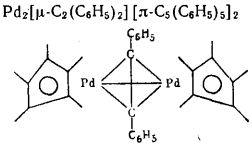

Figure 1. The disposition of the carbon atoms of the benzene rings relative to the Pd–Pd fragment in bis-π-arene complexes: *a*) complex (IX); *b*) complex (X).

The π-complexes of palladium(I) with benzene apparently have structures similar to those of complexes Nos.1 and 2 described by Davidson and Triggs[70] (Table 6, No.5) and Rudakov and co-workers[71,72] (Table 6, No.6). The studies of Rudakov and co-workers[71,72] showed that complex No.5 is diamagnetic, despite the view of Davidson and Triggs[70], and has a singlet due to benzene protons in the ^{1}H NMR spectrum, displaced upfield by 0.76 p.p.m. relative to benzene. The π-complex No.6 (Table 6) has been obtained[71,72] by the oxidation of cyclohexane or cyclohexene with palladium

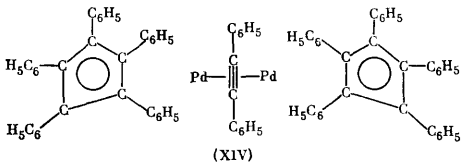
*l_{Pd-Pd} = 2.686 Å, **l_{Pd-Pd} = 2.609 Å, ***l_{Pd-Pd} = 2.679 Å, ****l_{Pd-Pd} = 2.689 Å.

sulphate and also from benzene and H_2 in 90% of sulphuric acid. Complexes Nos.5 and 6 disproportionate following the addition of Cl^- or dilution of the solutions with water.



The reaction of $Pd(OOCCF_3)_2$ in CF_3COOH with benzene or naphthalene results in the formation of complexes with an involved composition[75] which the authors regard as π-arene complexes on the basis of infrared spectroscopic and NMR data as well as chemical reactions. It has been suggested that $Pd_2(OOCCF_3)_2$, formed on reduction of palladium(II), coordinates aryl groups to form $ArPdOOCF_3$.

Two π-complexes, tentatively of palladium(I) (Table 6, Nos.7 and 8), have been obtained under the conditions of the oxidation of cyclohexa-1,4-diene in acetic acid[73] and of ethylene in sulphuric acid[74] in the presence of palladium(II) salts. According to Postnikov[76], the compounds of palladium and graphite (Pd_2Cl_2-graphite) which he synthesised are π-complexes of the type of compounds Nos.1–6 in Table 6.

The palladium(I) compounds containing π-allyl and π-cyclopentadienyl ligands are also believed[32,77,78] to constitute a large group of very interesting π-complexes (Table 7). The first examples of compounds containing π-allyl and π-cyclopentadienyl ligands coordinated at an M–M bond [compounds (XI), (XII), and (XIII)] and the first examples of symmetrical bis-π-allyl and bis-π-cyclopentadienyl sandwich compounds with an M–M fragment are encountered within this group. The bond lengths l_{Pd-Pd} in these complexes are similar, exceeding slightly l_{Pd-Pd} in the bis-π-arene complex of palladium(I).

The C_5H_5 group can be regarded as one non-coordinated double bond (l = 1.331 Å) and an allyl fragment (1.48 and 1.52 Å) linked mainly to two palladium atoms (Table 7, No.2).[84] Mixed complexes with a Pd–Pt bond have been obtained as a result of the interaction of $(C_5H_5)Pt(2\text{-}CH_3C_3H_4)$ and $Pt(2\text{-}CH_3C_3H_4)_2$ with PdL_2 (Table 7, Nos.6 and 7). The interesting π-complex of palladium(I) with $(C_6H_5)_2C_2$ (XIV)

is a structural analogue of the complex $[\mu\text{-}(C_6H_5)_2C_2].Ni_2(\pi\text{-}C_5H_5)_2$.[91]

3. X-Ray Photoelectron Spectra of Palladium(I) Complexes

Relatively extensive data have now accumulated on the X-ray photoelectron (XPE) spectra of palladium(I) complexes, which permit the estimation of the range of variation of the binding energies of the palladium(I) electrons and the influence of the ligand on $E(3d_{5/2})$.[92–100] Table 8 and Fig.2 show that the ranges of variation of $E(3d_{5/2})$ for complexes containing palladium in different oxidation states (0, +1, or +2) have no distinct limits and partially overlap.

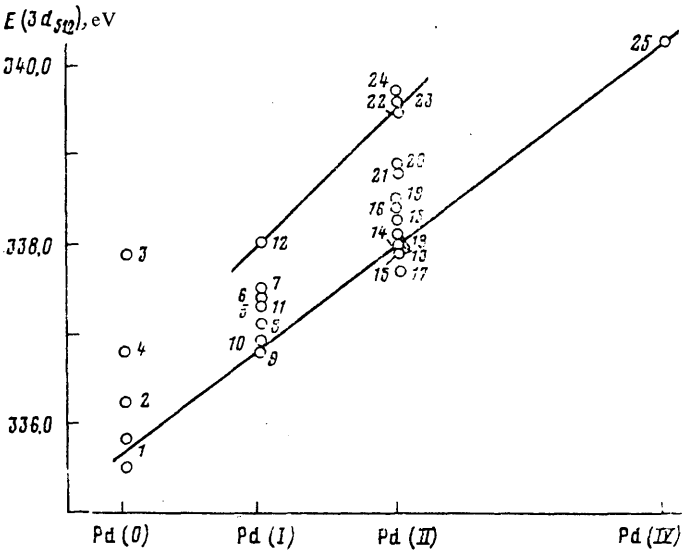

Figure 2. XPE spectra of metallic palladium and palladium compounds; the numbers against the points correspond to the numbers of the compounds in Table 8.

The influence of the ligands on the position of the $E(3d_{5/2})$ level is very strong, for the oxidation states 0 and +1 the range of variation of E as a function of the ligand is on average ~1.5 eV, and for palladium(II) it is as much as 2 eV. The binding energies in complexes with ligands having pronounced π-acceptor properties (Table 8, Nos.12, 22, and 23) increase to a particularly marked extent also in the case of $Pd(OOCCF_3)_2$. The high values of $E(3d_{5/2})$ for complexes Nos.3 and 4 give rise to some doubts—this may be a possible consequence of the oxidation of zerovalent palladium.

The spectrum of PdI_2, obtained by Kumar et al.[98], also deviates from the general pattern of the XPE spectra presented in Fig.2, the value $E(3d_{5/2}) = 336.6 \pm 0.1$ eV for PdI_2 actually lying below the values obtained for palladium(I). A probable explanation is the possible reduction of the surfaces of the PdI_2 specimens on irradiation in the course of the recording of the spectra.

If a line is drawn in Fig.2 through points *1*, *13*, and *25* corresponding to Pd(0), $PdCl_2$ and K_2PdCl_6, then the value of $E(3d_{5/2})$ for the Pd_2Cl_2-graphite complex lies on this line (Table 8, No.9). The values of $E(3d_{5/2})$ for all the remaining compounds lie above this line and below the line drawn through points *12* and *22*, corresponding to $Pd(CNR)_4^{2+}$ and $Pd_2(CNR)_6^{2+}$. Points *2*, *5*, and *15*, which correspond to phosphine-containing zerovalent palladium, palladium(I), and palladium(II) complexes, lie somewhat above the line drawn through points *1*, *9*, *13*, and *25*. We are aware of two studies of palladium carbonyl complexes by XPE spectroscopy. The binding energies $E(3d_{5/2})$ for PdL_3CO [94] and $[Pd(CO)(OOCCH_3)]_4.2CH_3COOH$ [17] are 337.9 and 338.7 eV respectively. The replacement of $P(C_6H_5)_3$ by CO in the complexes PdL_4 (Table 8, No.2) and $Pd_2L_2(OOCCH_3)_2$ (Table 8, No.8) should increase the binding energy $E(3d_{5/2})$ owing to the pronounced π-acceptor properties of the CO group; however, the observed increase of $E(3d_{5/2})$ by 1.6–1.7 eV appears to be very surprising.

Thus the interpretation of the XPE spectroscopic data for the purpose of the identification of palladium(I) complexes should be approached with caution. It is desirable to compare the spectra of complexes with similar sets of ligands or with ligands which have only a slight influence on the electron density of the central atom (Cl, Br, PR_3, CH_3COO, AsR_3).

III. SYNTHESIS AND REACTIONS OF PALLADIUM(I) COMPLEXES

We shall consider the principal methods of synthesis of palladium(I) complexes, their oxidation-reduction properties, and their oxidation-reduction reactions. These problems are mostly inter-related, because the principal difficulties in the synthesis of compounds of palladium in the intermediate +1 oxidation state are due to the capacity of palladium(I) for oxidation, reduction, and disproportionation.

The first palladium(I) complexes were obtained by the reduction of palladium(II) compounds, but at the present time numerous palladium(I) complexes have been synthesised [directly] and information has been obtained about their chemical properties. Ligand substitution reactions are therefore widely used for the synthesis of new palladium(I) compounds.

1. Ligand Substitution Reactions Involving Palladium(I) Complexes

The polymeric carbonyl halides $[Pd(CO)X]_n$ or the dimer $H_2Pd_2(CO)_nCl_4$ in hydrochloric acid solutions are frequently used as the starting compounds. Thus the complexes $Pd_2L_2X_2$ have been synthesised[40] by treating $[Pd(CO)X]_n$ (X = Cl or Br, L = dpm or dam) with the ligand in methylene chloride. The addition of lithium or caesium iodide to the hydrochloric acid solution of $H_2Pd_2(CO)_nCl_4$ leads to the evolution of CO and the formation of the complex $M_2Pd_2I_4.2H_2O$ (M = Li or Cs) [51] (Table 2).

The complexes $[Pd_2X_2L_2]CO$ [45] (Table 2), in which one CO group corresponds to two Pd atoms, have been isolated as a result of the reaction of a hydrochloric acid solution of $P(C_6H_5)_3$ with $H_2Pd_2(CO)_nCl$ using the proportions [L] : [Pd] = 1.5. The ligand substitution reactions involving palladium(I) carbonyl halide complexes may be accompanied by extremely complicated processes. Thus the reaction of $[Pd(CO)Cl]_n$ with dam involve the insertion of CO in the Pd–Pd bond[63] (see below) and the interaction of $H_2Pd_2(CO)_nCl_4$ with MI results in the evolution of small amounts of CO_2 and H_2 together with CO.[51]

The mode of the substitution reaction and the product composition depend on the nature of the substituting ligand, the [L] : [Pd] ratio, and other factors. Thus, when the carbonyl acetate complex $[Pd_2(CO)_2(CH_3COO)_2]_2$ [17–19] was used as the starting material for the synthesis of palladium(I) complexes with other ligands, it was established[44] that unstable complexes are formed for the initial reactant ratio [L] : [Pd] = 0.25, where L = $(C_6H_5)_3$, C_5H_5N, ½ bipy, or ½ phen. For [L] : [Pd] = 0.5, the state of palladium(I) is stabilised by triphenylphosphine 2,2-bipyridyl, and o-phenanthroline. Treatment with pyridine and its alkyl derivatives leads to the evolution of the entire carbon monoxide bound in the initial carbonyl acetate and the precipitation of metallic palladium; palladium(II) complexes are detected in solution.

The substitution reactions are different for different palladium(I)-stabilising ligands. Treatment with $P(C_6H_5)_3$ also leads to the complete evolution of carbon monoxide and the formation of the complex $Pd_2[P(C_6H_5)_3]_2.(CH_3COO)_2$ [44] (Table 2). The composition of the ligand substitution reaction products when o-phenanthroline and bipyridyl are employed is determined by the initial concentrations of these ligands and palladium(I) carbonyl acetate for [L] : [Pd] = 0.5. In bipyridyl solutions at concentrations ≥0.5 M the entire carbon monoxide is evolved:

$$[Pd_2(CO)_2(OOCCH_3)_2]_2 + 2bipy \rightarrow 2Pd_2bipy(CH_3COO)_2 + 4CO.$$

For [bipy] ≤ 0.5 M, half of the carbon monoxide remains in the coordinated form:

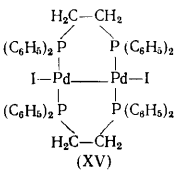
$$[Pd_2(CO)_2(OOCCH_3)_2]_2 + 2bipy \rightarrow 2Pd_2(CO)bipy(CH_3COO)_2 + 2CO.$$

Whatever its concentration, phenanthroline displaces half of the CO molecules present in the carbonyl acetate complex:

$$[Pd_2(CO)_2(OOCCH_3)_2]_2 \xrightarrow{[phen]<10^{-2}\ M} 2Pd_2(CO)\,phen\,(CH_3COO)_2 + 2CO;$$
$$[Pd_2(CO)_2(OOCCH_3)_2]_2 \xrightarrow{[phen]\geq 0.5\ M} 2Pd_2(CO)\,phen_2\,(CH_3COO)_2 + 2CO.$$

In the carbonyl complexes with bipyridyl and phenanthroline as ligands, the acetate is reversibly substituted by the anion X (X = ClO_4^-, Cl^-, CCl_3COO^-, CF_3COO^-, or CNS^-).[44]

The ligand and outer anion substitution reactions involving the isonitrile complexes of palladium(I) have been investigated[31,33]. The methylisocyanide groups in the cationic complexes $[(CH_3NC)_6Pd_2]^{2+}$ are exchanged at a high rate with free methyl isocyanide in acetone solution in the temperature range +40– –50 °C. On treatment with an excess of $t\text{-}C_4H_9NC$ or C_6H_5NC under conditions ensuring the removal



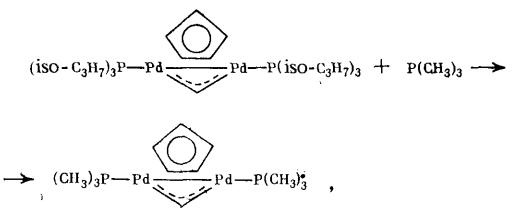
of the methyl isocyanide molecules to be substituted, it is possible to replace completely the methyl isocyanide groups and to isolate the complexes $[(t\text{-}C_4H_9NC)_6Pd_2](PF_6)_2$ and $[(C_6H_5NC)_6Pd_2](PF_6)_2$.[31,33] The same workers obtained complexes containing one or two triphenylphosphine groups (Table 1) in the axial coordination positions. It is not possible to substitute more than two methylisocyanide groups by triphenylphosphine[31,33].

Complexes of the type $[Pd_2(\text{diphosphine})_2(CH_3NC)_2](PF_6)_2$ have been obtained recently§ by the substitution of isonitrile ligands in the complex $[Pd_2(CH_3NC)_6](PF_6)_2$ by the diphosphines $(C_6H_5)_2P(CH_2)_nP(C_6H_5)_2$ (n = 2–4) or *cis*-$(C_6H_5)_2PCH=CHP(C_6H_5)_2$. According to NMR data, these complexes have a symmetrical non-bridged structure in which the diphosphine ligand is bound to one palladium atom. When the triphosphine $(C_6H_5)_2P(CH_2)_2P(C_6H_5)(CH_2)_2P(C_6H_5)_2$ is used in an analogous reaction, the isonitrile ligands are fully substituted and crystals of the complex $\{Pd_2[(C_6H_5)_2P(CH_2)_2P(C_6H_5)(CH_2)_2P(C_6H_5)]_2\}(PF_6)_2$ are formed. The absence of reactions of the isonitrile complexes with CO, pyridine, 2,2′-bipyridyl, cyclo-octa-1,5-diene, and tetrachloroethylene has been noted[31-34].

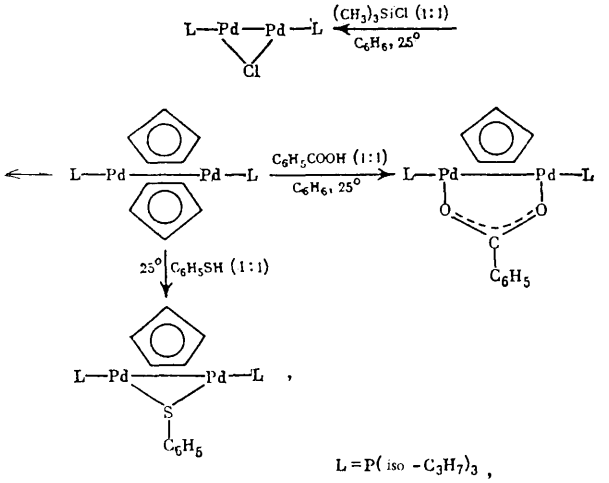
The complexes $Pd_2X_2(CNR)_4$ have been obtained by the substitution of some of the isonitrile groups by the corresponding ligands (X = I or SCN; R = CH_3, t-C_4H_9, or C_6H_5) in the complexes $[Pd_2(RNC)_6](PF_6)_2$.[31,33] The complex $Pd_2I_2(t\text{-}C_4H_9NC)_4$ has been used[30] to synthesise palladium(I) complexes with phosphorus-containing ligands:

$$Pd_2I_2(t\text{-}C_4H_9NC)_4 \xrightarrow{2P(C_6H_5)_3} Pd_2I_2(t\text{-}C_4H_9NC)_2[P(C_6H_5)_3]_2;$$
$$Pd_2I_2(t\text{-}C_4H_9NC)_4 \xrightarrow{[P(C_6H_5)_2CH_2]_2} Pd_2I_2[(C_6H_5)_2PCH_2CH_2P(C_6H_5)_2]_2.$$

Presumably the complex with the diphosphine ligand has structure (XV), analogous to the structure of the complexes with bis(diphenylphosphino)methane[49].



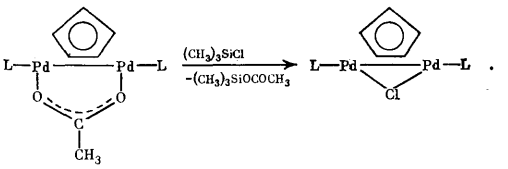
(XV)



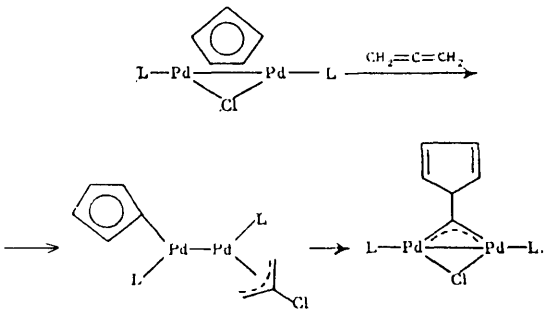
There is virtually no information about substitution reactions involving π-complexes of palladium(I). The possibility of the substitution of the ClO_4^- anion in Davidson's complex has been demonstrated[71]:

$$[Pd(ClO_4)(H_2O)(C_6H_6)]_2 \xrightarrow{H_2SO_4} [Pd_2(C_6H_6)_2](HSO_4)_2.$$

The substituion of a neutral ligand[88],



and of a single cyclopentadienyl ligand by Cl^-, $C_6H_5COO^-$, or $C_6H_5S^-$,[85]



L = P(iso-C_3H_7)$_3$,

has been reported. The acetate ligand in the analogous complex can be substituted by Cl^-:[83]

The only reaction of the π-ligands without change in the oxidation state of palladium(I) has apparently been described by Kühn and Werner[88]:

L = iso-C_3H_7

It follows from the substitution reactions described above that this method of synthesis of palladium(I) complexes is fairly convenient and extremely effective.

2. Synthesis of Palladium(I) Complexes by the Reduction of Palladium(II) Compounds

The reduction of palladium(II) compounds constitutes the most general method of synthesis of palladium(I) complexes. When this reaction is carried out, it is necessary to employ ligands which stabilise the intermediate palladium(I) oxidation state and prevent the disproportionation reaction

$$Pd_2^I \rightarrow Pd^{II} + Pd^0. \qquad (3)$$

In some cases the same substance can fulfill the functions of the reductant and the ligand:

$$Pd^{II} + L(\text{Red}) \rightarrow Pd^IL + L'(\text{Ox}).$$

§C.H.Lindsay, L.S.Benner, and A.L.Balch, Inorg.Chem., 1980, 19, 3503.

CO,[3,40,41] C_6H_6,[70] C_6H_8,[73] and RNC [27,32,34] have been used as such bifunctional reagents. However, this type of combination of functions is not always possible and palladium(I) complexes are therefore usually synthesised in accordance with the equation

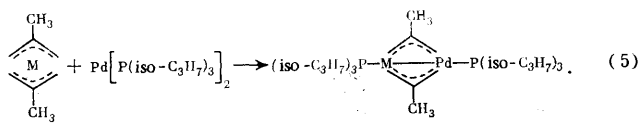
$$Pd^{II} + Red + L \rightarrow Pd^{I}L + Ox .$$

The following combinations of reductants and ligands, in which the reductant fulfilled in many instances also the function of an additional ligand, have been used to synthesise π- and σ-complexes: Na/Hg–CN^-,[101] CO–CH_3COO^-,[17–19] Al–C_6H_6,[67,68] CO–phen, CO–bipy,[43,44] H_2–C_6H_6,[71,72] C_6H_{12}–C_6H_6,[71,72] H_2–$P(C_6H_5)_3$,[50] and C_2H_2–I^-, $CrCl_2$–I^-,[51,102] and C_2H_4–*p*-benzoquinone[74]. For example, the bis-π-arene complex of palladium(I) was obtained for the first time by the reaction[67]:

$$2PdCl_2 + 4AlCl_3 + \tfrac{2}{3}Al + 2C_6H_6 \rightarrow Pd_2(C_6H_6)_2(Al_2Cl_7)_2 + \tfrac{2}{3}AlCl_3 .$$

The series of reductants Mg, Na/Hg, LiAlH $(t\text{-}C_4H_9O)_3$, $LiAlH_4$, $NaBH_4$, and $n\text{-}C_4H_9MgBr$ [80,84] have been used to synthesise the complexes $[(\mu\text{-}C_5H_5)(\mu\text{-}X)Pd_2(PR_3)_2]$ (X = Br, R = iso-C_3H_7, C_6H_5, or C_6H_{11}; X = Cl or I, R = iso-C_3H_7). A paramagnetic palladium(I) complex with thiolene ligands is synthesised by the electrochemical reduction of the corresponding palladium(II) compound[8].

One of the possible mechanisms of the formation of palladium(I) complexes with a Pd–Pd bond in the instances enumerated consists in the reaction of the zerovalent palladium complex formed initially with palladium(II), i.e. involves a reaction which is the opposite of the disproportionation reaction (3), for example:



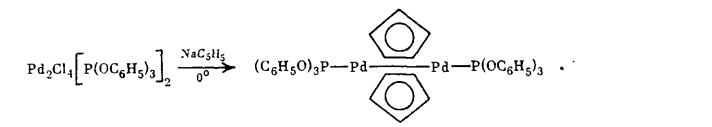
$$\begin{gathered}\tfrac{1}{2}(C_3H_5PdI)_2 + 3P(C_6H_5)_3 \rightarrow [C_3H_5P(C_6H_5)_3]^+I^- + Pd[P(C_6H_5)_3]_2 ;\\ \tfrac{1}{2}(C_3H_5PdI)_2 + Pd[P(C_6H_5)_3]_2 \rightarrow [C_3H_5Pd_2IL_2] ;\\ 2(\pi\text{-}C_6H_5)Pd(2\text{-}CH_3C_3H_4) + 2PR_3 \rightarrow (C_6H_5)Pd_2(2\text{-}CH_3C_3H_4)(PR_3)_2 + C_6H_5C_3H_4CH_3 ;\\ L = P(C_6H_5)_3 .\end{gathered} \quad (4)$$

The compound $[C_3H_5P(C_6H_5)_3]^+I^-$ has been isolated[79].

The possibility of reactions of this type has been demonstrated by direct synthesis of palladium(I) complexes from palladium(II) and zerovalent palladium complexes. Thus the isonitrile complexes of palladium(I) of the type $Pd_2X_2(t\text{-}C_4H_9NC)_4$ have been obtained by the reaction of $Pd(t\text{-}C_4H_9NC)_2$ with $PdX_2(t\text{-}C_4H_9NC)_2$ (X = Cl, Br or I) at −30 °C in chlorobenzene[30]. Analogous complexes have been prepared from $PdCl_2(C_6H_5NC)_2$ and $Pd(dba)_n$¶ (*n* = 2 or 3) in the presence of an excess of the isonitrile[32]. The reaction of platinum(II) and zerovalent palladium complexes results in the formation of compounds containing the Pt–Pd fragment[26,29]:

$$2[(CH_3NC)_4Pt][PF_6]_2 + Pd_2(dba)_3\cdot CHCl_3 \xrightarrow[CH_3NC]{CH_3CN} 2[(CH_3NC)_6PdPt][PF_6]_2 .$$

The complex $Pd_2[P(C_6H_5)_3]_2(CH_3COO)_2$ has been synthesised by the reaction of $Pd_2[P(C_6H_5)_3]_2$ with $[(C_6H_5)_3PPd\cdot(CH_3COO)_2]_2$.[50] Numerous π-complexes with cyclopentadienyl and allyl ligands have been obtained in accordance with the same scheme (Table 7), for example:



(5)

The coordination-unsaturated zerovalent palladium complex of the type PdL_2 or the zerovalent palladium complex $Pd_m(dba)_n$ which readily loses ligands is involved in reactions via Scheme (5). It is therefore extremely important to follow the ratio L/Pd in the syntheses of complexes with π-allyl and π-cyclopentadienyl ligands. Thus, when L/Pd > 4, the complex PdL_4 is formed instead of the palladium(I) complexes [reaction (4)].

Owing to the absence of the complex $Pd(C_5H_5)_2$, the bis-cyclopentadienylpalladium(I) complex has to be synthesised by a more complicated procedure[85]:

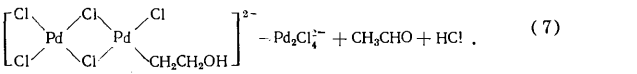
$$\begin{gathered}Pd_2Cl_2L_2(\mu\text{-}OOCCH_3)_2 \xrightarrow{TlC_5H_5} 2C_6H_5PdL(OOCCH_3) \rightarrow\\ \xrightarrow[C_6H_6]{NaK_{2.8}} Pd_2(\mu\text{-}C_5H_5)_2L_2 ;\\ L = P(iso\text{-}C_3H_7)_3 .\end{gathered}$$

An analogous complex has also been obtained via the reaction[89]

The reactions of zerovalent palladium and palladium(II) complexes have been used to synthesise palladium(I) dimers fixed on the surface of silica gel[64]:

$$\boxed{Si}-P_2Pd(OOCCH_3)_2 \xrightarrow{Red} \boxed{Si}-P_2Pd \xrightarrow{Pd(CH_3COO)_2} \boxed{Si}-P_2Pd_2(OOCCH_3)_2$$

where $\boxed{Si}-P_2$ is silica gel with grafted groups containing tertiary phosphines and Red is formic acid.



Other mechanisms of the formation of palladium(I), involving the reactions of hydride and σ-organopalladium intermediates, are also possible[102]:

$$HPdX + PdX_2 \rightarrow HX + Pd_2X_2 .$$

This mechanism probably operates in the reduction of palladium(II) with carbon monoxide, acetylene, and alcohol[103], as well as hydrogen[71], and in other reactions leading to the appearance of hydride complexes:

$$RPdX + PdX_2 \rightarrow \begin{cases} \rightarrow RX + Pd_2X_2 \\ \rightarrow R_{-H} + Pd_2X_2 + HX . \end{cases} \quad (6)$$

This mechanism, involving the oxidative demetallation of RPdX, does not include a stage in which zerovalent palladium is formed. The demetallation of a dimeric σ-organopalladium compound and the formation of palladium(I) in the oxidation of olefins by palladium(II) chloride probably take place in precisely this manner[104]:

(7)

3. The Oxidation-Reduction Properties and Reactions of Palladium(I) Complexes

As already mentioned above, palladium(I) complexes exhibit in their reactions the properties of both reductants and oxidants, which is reflected primarily in the disproportionation reaction (3), which is very characteristic of palladium(I). The ligand coordinated to palladium(I) or a nucleophile interacting with the coordinated ligand (CH_3COO^-, RO^-, H_2O, ROH) can play the role of the reductant. Thus on heating to 70 °C *in vacuo*, the complex $Pd_2(C_6H_8)(OOCCH_3)_2$ undergoes the reaction[73]

$$Pd_2(C_6H_8)(OOCCH_3)_2 \rightarrow 2Pd_{met} + C_6H_6 + 2CH_3COOH .$$

¶ Here and henceforth dba = dibenzylideneacetone.

The reaction of the complex $[Pd_2(CO)_2(OOCCH_3)_2]_2$ in the presence of CH_3COONa in acetic acid at 90 °C is of interest[105]:

$$Pd_2(CO)_2(OOCCH_3)_2 \xrightarrow{CH_3COONa} 2Pd_{met} + CO_2 + (CH_3CO)_2O \,. \qquad (8)$$

The probable mechanism of reaction (8) involves attack by the acetate ion on the coordinated carbon monoxide[105]:

$$Pd_2(CO)_2(OOCCH_3)_2 + CH_3COO^- \rightarrow Pd_2(CO)(OOCCH_3)_2(\overset{\overset{O}{\|}}{COOCCH_3})^- \rightarrow$$

$$\xrightarrow{-CO_2} Pd_2(CO)(OOCCH_3)_2(\overset{\overset{O}{\|}}{CCH_3})^- \rightarrow 2Pd_{met} + CO + CH_3COO^- + (CH_3CO)_2O \,.$$

As already mentioned above, palladium(I) carbonyl halides are readily reduced by H_2O. Thus treatment of $[Pd(CO)Cl]_n$ [$\nu(CO)$ = 1975, 1930 cm^{-1}] with water leads to the slow formation of CO_2 and metallic palladium[106]. The rate of formation of CO_2 increases sharply following the addition of $Cr_2O_7^{2-}$ or *p*-benzoquinone in an acid medium[106]. The same palladium(I) carbonyl in methanol or in methanol containing CH_3ONa gives rise to $ClCOOCH_3$, i.e. the product of the reductive elimination reaction[107]:

$$ClPd{-}PdCOOCH_3 \rightarrow 2Pd_{met} + ClCOOCH_3 \,.$$

This mechanism has been confirmed by the following reaction[107]:

$$\frac{2}{n}[Pd(CO)Cl]_n + CH_3COOHgCOOCH_3 \rightarrow [Pd_2(COOCH_3)Cl(CO)_2] \rightarrow$$

$$\rightarrow ClCOOCH_3 + 2Pd_{met} + 2CO + Cl^- \,.$$

In the decomposition of $[Pd(CO)Cl]_n$ in alcohol in the presence of *p*-benzoquinone, the reaction pathway changes and dimethyl oxalate is mainly formed[107]. Treatment of $[Pd_2(CO)_2(OOCCH_3)_2]_2$ with water and ethanol also leads to the formation of CO_2 and the product of the oxidative carbonylation of methanol, namely dimethyl carbonate[105].

The behaviour of palladium(I) complexes with respect to a reductant such as H_2 depends greatly on the nature of the ligands. For example, the reduction of the palladium(I) acetate complex[50] leads to the formation of the diamagnetic cluster Pd_2L_2:

$$Pd_2(OOCCH_3)_2L_2 + H_2 \rightarrow Pd_2L_2 + 2CH_3COOH \,,$$

while the compounds $Pd_2(C_6H_6)_2(HSO_4)_2$ and $Pd_2(CH_3NC)_6 \cdot (PF_6)_2$ are not reduced by hydrogen.

Palladium(I) in complexes is oxidised by various oxidants (O_2, I_2, Br_2, MnO_4^-, $Cr_2O_7^{2-}$, *p* benzoquinone, etc.), including coordinated ligands, for example NO:[47]

$$2Pd(NO)Cl + 8CN^- + H_2O \rightarrow 2Pd(CN)_4^{2-} + N_2O + 2Cl^- + 2OH^- \,.$$

The quantitative characteristics of the oxidation-reduction properties have so far been obtained only for several palladium(I) complexes, but extensive experimental data have been accumulated on reactions of the oxidation-reduction type which it would be useful to analyse and to estimate at least approximately the oxidation-reduction properties of palladium(I). For this purpose, we shall consider in greater detail the disproportionation reaction

$$Pd_2^I \rightleftarrows Pd^0 + Pd^{II} \,.$$

The complexes $Pd_2(C_6H_6)_2^{2+}$ do not disproportionate in acetic and sulphuric acid solutions and only the addition of Cl^- leads to a rapid oxidation-reduction process. This finding is in good agreement with the hypothesis[108,109] that $Pd_2Cl_4^{2-}$, formed via reaction (7), tends to disproportionate in accordance with the mechanism

$$Pd_2Cl_4^{2-} \rightleftarrows Pd_{met} + PdCl_4^{2-} \,. \qquad (9)$$

It can be easily shown that the free energy ΔG° of reaction (9) is negative if the standard oxidation-reduction potentials ε_2^0 and ε_1^0 in the scheme below

$$PdCl_4^{2-} \xrightarrow{\varepsilon_1^0} \tfrac{1}{2}Pd_2Cl_4^{2-} \xrightarrow{\varepsilon_2^0} Pd_{met} \qquad (10)$$

$$\varepsilon_3$$

satisfy the inequality $\varepsilon_2^0 > \varepsilon_1^0$. In this case $\varepsilon_1^0 < 0.62$ V and $\varepsilon_2^0 > 0.62$ V when $\varepsilon_3^0 = 0.62$ V.[110] Since according to some data[108,109] *p*-benzoquinone (Q) oxidises $Pd_2Cl_4^{2-}$ in acid media and the potential of benzoquinone ε_Q varies from 0.7 to 0.6 V in the pH range 0–2, one may conclude that ε_1^0 is indeed smaller than 0.6 V. If it is assumed that the reaction of the palladium(I) complex with an oxidant (Ox) reaches equilibrium[11],

$$Pd_2^I + Ox \rightleftarrows 2Pd^{II} + Red \,, \qquad (11)$$

it is possible to achieve a further refinement of the values of ε_1^0 and ε_2^0. Since the expression for ε_1^0 corresponding to reaction (11) assumes the form (in terms of the concentration approximation)

$$\varepsilon_1^0 = \varepsilon_{Ox/Red}^0 - \frac{RT}{2F}\ln\frac{[Red][Pd^{II}]^2}{[Ox][Pd_2^I]} \,, \qquad (12)$$

it is possible to estimate Δ in Eqns.(12) and (13) by specifying different degrees of conversion of $Pd_2(I)$ and using the real concentrations of all the components:

$$\varepsilon_1^0 = \varepsilon_{Ox/Red}^0 - \Delta \,. \qquad (13)$$

In the calculation of Δ it is of course necessary to take into account the concentration of H^+ ions and the ligands involved in the reaction (11). When account is taken of Δ (estimated from the data of Moiseev and Pestrikov[108]), the potential ε_1^0 for $Pd_2Cl_4^{2-}$ can be $\varepsilon_1^0 \leqslant 0.5$ V; then $\varepsilon_2^0 \geqslant 0.74$ V.

The complex $Pd_2SO_4 \cdot Q$ [74] is formed in an acid medium with $[H^+] = 0.1$–0.2 M. Since metallic palladium cannot be oxidised by *p*-benzoquinone to $PdSO_4$ in sulphuric acid solutions[110], one may assume that metallic palladium is oxidised to Pd_2SO_4, which is additionally stabilised by *p*-benzoquinone:

$$2Pd_{met} + 2Q + H_2SO_4 \rightarrow Pd_2SO_4 \cdot Q + QH_2 \,.$$

Hence, without taking into account the complex formation reaction of Q with Pd_2SO_4, we obtain $\varepsilon_2 \leqslant 0.7$ V [the designation of the potentials is analogous to that in scheme (10)]. If it is assumed that ε_3^0 for $PdSO_4/Pd_{met}$ does not differ greatly from $\varepsilon^0_{Pd^{2+}/Pd_{met}} = 0.987$ V,[110] we obtain $\varepsilon_1^0 \geqslant 1.1$ V (for $HgSO_4$, $\varepsilon_1^0 = 0.92$ V and $\varepsilon_2^0 = 0.789$ V). The complex $Pd_2SO_4 \cdot Q$ does not disproportionate precisely because in this case $\varepsilon_2^0 < \varepsilon_1^0$ and in addition there is a possibility of some stabilisation of palladium(I) on treatment with *p*-benzoquinone. The addition of concentrated hydrochloric acid to $Pd_2SO_4 \cdot Q$ leads immediately to the oxidation of palladium(I) and the formation of hydroquinone and $PdCl_4^{2-}$ (because Cl^- displaces Q and SO_4^{2-} from the coordination sphere of palladium and lowers ε_1^0).[74]

The complex $Pd_2(C_6H_6)_2(ClO_4)_2$ [70] is oxidised by O_2, Br_2, and $KMnO_4$. However, $Cr_2O_7^{2-}$ and $Pb(OCOCH_3)_4$ in acetic acid oxidise this complex only in the presence of Cl^-. The high potential of $Cr_2O_7^{2-}$ in the six-electron reduction ($\varepsilon^0_{Ox/Red} = 1.33$ V) in a weakly acid medium is probably low in the first stages of the oxidation [Cr(VI) → Cr(V) → Cr(IV)] and for this reason $Cr_2O_7^{2-}$ does not oxidise the stabilised cation $Pd_2(C_6H_6)_2^{2+}$ in the absence of Cl^-; only in concentrated 90% H_2SO_4 is that cation oxidised by dichromate[74].

The complex $Li_2Pd_2I_4 \cdot 2H_2O$ in butanol is oxidised by I_2.[51] In the presence of an excess of LiI, at a concentration of 0.5 M for $[Pd_2^I] = 0.01$ M, the complex probably exists in

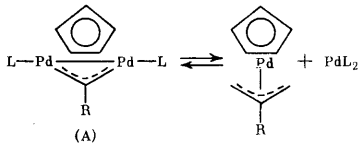
the form $Pd_2I_6^{4-}$. In this case the oxidation reaction can be formulated as the equilibrium

$$Pd_2I_6^{4-} + I_2 \rightleftarrows 2PdI_4^{2-}. \qquad (14)$$

The standard potentials of the I_2/I^- and I_3^-/I^- pairs in water are 0.62 and 0.55 V [$\varepsilon^0_{Ox/Red}$ in Eqns.(12) and (13)]. Judging from potentiometric data[97], equilibrium (14) is almost completely displaced to the right. For a degree of conversion of PdI_2 of 0.99 and at the real concentrations of the reactants, $\Delta = 0.15$ V in Eqn.(13). If it is assumed that in butanol $\varepsilon^0_{Ox/Red}$ for I_2 does not differ greatly from the value in aqueous solutions and amounts to ~0.6 V, then ε_1^0 in scheme (15) is $\varepsilon_1^0 \leqslant 0.45$ V†:

$$\begin{array}{ccccc} PdI_4^{2-} & \xrightarrow{\varepsilon_1^0} & \tfrac{1}{2}Pd_2I_6^{4-} & \xrightarrow{\varepsilon_2^0} & Pd^0_{met} \\ & \searrow^{\varepsilon_3^0} & & \nearrow & \end{array} \qquad (15)$$

According to Fasman[111], the overall instability constant of the complex PdI_4^{2-} in water at $I = 1$ is close to 10^{-24}. Then (on the same assumptions) $\varepsilon_3^0 \cong 0.3$ V and $\varepsilon_2^0 \geqslant 0.15$ V. The above estimate makes it possible to explain the stability of the palladium(I) iodide complex with respect to the disproportionation reaction ($\varepsilon_2^0 < \varepsilon_1^0$). The potentials of system (15) are probably very similar to those of the system $HgBr_4^{2-} \rightarrow \frac{1}{2}Hg_2Br_2 \rightarrow Hg^0$ [110] ($K_{inst} = 2.3 \times 10^{-22}$, $\varepsilon_1^0 = 0.31$ V, $\varepsilon_2^0 = 0.14$ V, and $\varepsilon_3^0 = 0.227$ V).



The complex $Pd_2(CH_3NC)_6^{2+}$ proved to be very stable with respect to oxidants. It is not oxidised by O_2 and chloranil[34], but is oxidised by iodine (and bromine) via the reaction

$$Pd_2L_6^{2+} + I_2 \rightarrow PdL_4^{2+} + PdI_2L_2.$$

Here I_2 in essence displaces the disproportionation equilibrium to the right:

$$PdL_2^0 + I_2 \rightleftarrows PdI_2L_2.$$

The disproportionation reaction proceeds also in the case of π-cyclopentadienyl-π-allyl complexes[88]. Thus the equilibrium in the reaction

(A)

is usually strongly displaced to the left (see Section III, subsection 2 above), but is displaced to the right in the presence of substituents giving rise to an appreciable steric hindrance (R = t-C_4H_9 and L = PR_3). The complexes (A) are readily oxidised by I_2, CH_3I, and even HCl, but in this instance the primary reaction products are those resulting from the oxidative addition of I_2 and CH_3I (as well as HCl) to PdL_2^0:[80]

$$(A) + I_2 \rightarrow [(C_6H_5)Pd(R - C_3H_4) + L_2PdI_2] \rightarrow (C_6H_5)PdLI + (R - C_3H_4)PdLI.$$

In conclusion of this Section, we shall consider the results of polarographic studies of palladium(II) and palladium(I) complexes. The number of studies devoted to the polarography of palladium(II) is small. At a mercury electrode, polarographic waves can be detected for complexes whose oxidation potential ε^0 is in excess of 0.25 V [i.e. above the potential of the saturated calomel electrode (s.c.e.)].[112] The measured values of $E_{\frac{1}{2}}$ for palladium(II) are therefore in the range between −0.3 and −1.96 V (relative to s.c.e.) or in the range −0.05– −1.65 V (relative to the hydrogen electrode). Thus the $E_{\frac{1}{2}}$ refer to complexes in which the state of palladium(II) is much more stable than the zerovalent palladium and palladium(I) states [C_5H_5N, NH_3, $P(OR)_3$, dpe, CN^-, acac$^-$, $S_2C_2(CN)_2^{2-}$].[8,112–116]#

Polarographic studies of palladium(II) cyanide complexes[113] yielded for the first time the electrochemical characteristics of the palladium(I) cyanide complex. The value of $E_{\frac{1}{2}}$ (relative to s.c.e.) for the reaction $Pd(CN)_4^{2-} + 2e \rightarrow Pd(CN)_4^{4-}$ is −1.6 V (reversible reaction). The product of the dimerisation of $Pd(CN)_4^{3-}$, namely $Pd_2(CN)_6^{4-}$, does not give rise to a cathodic wave. The anodic half-wave potential of this intermediate (−0.85 V) is close to the anodic half-wave potential of the product of the reduction of $Pd(CN)_4^{2-}$ by sodium amalgam (−0.93 V). In order to estimate ε_1^0 for the transition $Pd(CN)_4^{2-} \rightarrow \frac{1}{2}Pd_2(CN)_6^{4-}$ from the potential of the anodic wave, we shall assume that the transition is reversible. Then $\varepsilon_1^0 = -0.65$ V (relative to the hydrogen electrode). Using the value $K_{inst} = 10^{-51}$ for $Pd(CN)_4^{2-}$,[111] we obtain $\varepsilon_3^0 = -0.51$ V and $\varepsilon_2^0 = -0.38$ V. It follows from these estimates that CN^- stabilises palladium(II) to a much greater extent than zerovalent palladium and palladium(I) and the postulated complex $Pd_2(CN)_6^{4-}$ is therefore a very powerful reductant. The half-wave potential of the reversible cathodic Pd(II)/Pd(I) transition was first measured with a dithiolenepalladium(II) complex[8]. The reaction

$$Pd(mnt)_2^{2-} + e \rightleftarrows Pd(mnt)_2^{3-} \qquad (16)$$

where mnt = $(NC)_2C_2S_2^{2-}$, in acetonitrile leads to the formation of the only known paramagnetic palladium(I) (d^9) complex. The complex is stable in acetonitrile and dimethoxyethane and is not reduced further up to a potential of −2.8 V. The value of $E_{\frac{1}{2}}$ for reaction (16) is −1.9 V relative to the aqueous saturated calomel electrode. After a number of assumptions have been made, $\varepsilon^0_{Pd(II)/Pd(I)}$ for this complex is in the range between −1.6 and −1.65 V. Thus the above palladium(I) complex is an exceptionally powerful reductant.

The formation of univalent palladium has been detected also in the polarographic reduction of palladium(II) oxinate and acetylacetonate complexes in DMF.[115] The complexes $Pd(oxine)_2$§ and $Pd(acac)_2$ are reduced in two one-electron stages. In the case of $Pd(oxine)_2$, the potential $E_{\frac{1}{2}}$[Pd(II)/. .Pd(I)] (relative to s.c.e.) corresponds to a reversible reaction and amounts to −1.46 V. The lifetime of palladium(I) is ~0.18 s, the first stage in the reduction of $Pd(acac)_2$ is not fully reversible ($E_{\frac{1}{2}} = -1.29$ V), and the palladium(I) complex decomposes faster (lifetime ~0.02 s).

The first oscillopolarographic characteristics of palladium(I) complexes have been obtained recently in a saturated solution of KCl in 98% acetic acid[46,117]. The complex $K_2Pd_2(CO)_2Cl_4$ has a cathodic reduction potential $E_1 = -0.576$ V (relative to s.c.e.). The complexes $(PdXL)_2CO$ in acetic acid have similar potentials[46,117]. Their electrochemical behaviour has been studied by cyclic voltamperometry[46,117] in DMF and acetonitrile. The reduction potentials of the complexes $(PdXL)_2CO$, reversible in DMF, are in the range −0.56 to −0.63 V (relative to the aqueous hydrogen electrode).

Table 9 presents the values of ε_1^0 and ε_2^0 which we estimated (see above) from indirect or polarographic data or they were measured polarographically. Evidently the oxidation-reduction properties of palladium(I) vary within very wide limits as a function of the nature of the ligands.

†Presumably the equilibrium constant of $PdI_3^- + I^- \rightleftharpoons PdI_4^{2-}$ is small and does not alter ε_1^0 appreciably.

#Here and henceforth acac$^-$ = acetylacetonate anion.

§Oxine = 8-hydroxyquinolinate anion.

4. Reactions Involving the Insertion of Various Molecules in a Pd–Pd Bond

The first complex containing a CO molecule inserted in a Pd–Pd bond was synthesised in 1973,[40] but its structure was interpreted erroneously. The diamagnetic complex $Pd_2dam_2.Cl_2(CO)$ was obtained by the reaction[40,63]

$$\frac{2}{n}(PdCOCl)_n + 2\,dam \rightarrow Pd_2(dam)_2Cl_2(CO) + CO\ .$$

Table 9. Estimated standard potentials for palladium(I) complexes [the notation is based on Scheme (10)].

Complex	Solvent	ε^0_1, V	ε^0_2, V
$Pd_2SO_4 \cdot Q$	water	$\geqslant 1.1$	$\leqslant 0.7$
$Pd_2Cl_4^{2-}$	water	$\leqslant 0.5$	$\geqslant 0.74$
$Pd_2I_6^{4-}$	n-butyl alcohol	$\leqslant 0.45$	$\geqslant 0.15$
$[PdX(PR_3)]_2CO$ *	CH_3CN, DMF	−0.56 – −0.63	—
$Pd(CN)_6^{4-}$ *	water	−0.65 **	−0.38
$Pd(oxine)_2^-$ *	DMF	−1.21	—
$Pd[S_2C_2(CN)_2]_2^{3-}$ *	CH_3CN	−1.6 – −1.65	—

*The potentials relative to the aqueous hydrogen electrode are quoted.

**$\varepsilon^0_1 \cong \varepsilon_{1/2}$.

The surprisingly low vibration frequency of the carbonyl group [$\nu(CO) = 1720\ cm^{-1}$] was explained with the aid of X-ray diffraction analysis[63]. Thus the parameters of a fragment of complex No.1 (Table 10 and Fig.3) indicate the absence of a metal–metal bond. The Pd–C–Pd angle appreciably exceeds the angles in metal carbonyls having the M–C–O–M bridge (<88°) and even in aldehydes and ketones (108–113°).

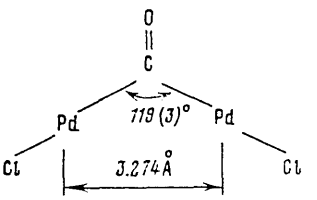


Figure 3. Fragment of the complex $Pd_2(dam)_2Cl_2(\mu\text{-}CO)$.[63]

If the complex $Pd_2dpm_2X_2$ is kept in methylene chloride at p_{CO} = 1 atm, a red crystalline product $(Pd_2dpm_2X_2)CO$ (X = Cl or Br), for which $\nu(CO) = 1704\ cm^{-1}$ when X = Cl, is formed[118]. The RNC molecule behaves similarly to carbon monoxide[118,119] (Table 10), being inserted in the Pd–Pd bond in the following reactions:

$$Pd_2(dpm)_2X_2 + RNC \rightarrow Pd_2(dpm)_2X_2(\mu\text{-}RNC);$$
$$Pd_2(RNC)_6(PF_6)_2 + 2\,dpm \xrightarrow{-3RNC} [Pd_2(dpm)_2(RNC)_2(\mu\text{-}RNC)](PF_6)_2\ .$$
(XVI)

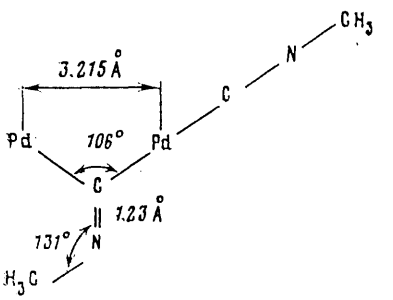

Figure 4. Fragment of the complex $Pd_2(dpm)_2(\mu\text{-}CH_3NC).(CH_3NC)_2(PF_6)_2$.[118]

The stretching vibration frequency of the CN bridge group (μ-RNC) (1640–1680 cm^{-1}) is appreciably reduced compared with that of the terminal ligand (2183–2231 cm^{-1}). The fragment of complex (XVI) (Fig.4) has parameters analogous to those of the fragment of the complex with an inserted CO group, although the Pd–C–Pd angle is appreciably smaller. The products of insertion in a Pd–Pd bond have also been isolated in the case of SO_2 molecules[120], ArN_2^+,[121] alkynes[122], and atomic sulphur[123] (Table 10).

Table 10. Products of the insertion of molecules in a Pd–Pd bond.

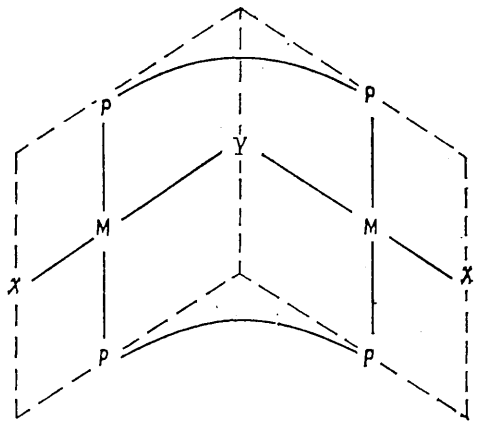
CO and SO_2 molecules are inserted reversibly while RNC, S, and RN_2^+ are inserted irreversibly. A somewhat idealised structure of all the complexes with an iserted group Y is illustrated in Fig.5. The environment of the Pd atom is planar and almost square. Only in the case of $C_2(CF_3)_2$ does the C–Pd–C angle (~165°) differ appreciably from 180°.

The marked reduction of the ν(CO) and ν(NC) frequencies, the absence of the Pd–Pd interaction, the change in the hybridisation of the carbon atom in the CO, RNC, and C_2R_2 complexes (for example, the C–C=C angles[122] are 122.8° and 124.7°), and the increase in the length of the N=C bonds in RNC and of the C=C bonds in C_2R_2 are all facts indicating that the oxidative addition of various molecules and atoms to palladium(I) complexes takes place via the dissociation of the Pd–Pd bond. Thus the formation of a disubstituted palladium(II) sulphide takes place in essence in the reaction

$$(dpm)_2Pd_2Cl_2 + {}^1/_8S_8 \rightarrow S(PdCl)_2(dpm)_2\ .$$

In the reaction involving CO the characteristics of the inserted carbon monoxide approach those of the carbonyl group in ketones and it is therefore entirely appropriate to regard these complexes as derivatives of dimetallated formaldehyde[124]. Naturally the insertion of C_2R_2 molecules as well as those of $C_2(CN)_4$ and CS_2 [122] in the Pd–Pd bond is an oxidative addition reaction. The reaction involving the insertion of alkenes in an M–M bond is known for nickel(I), cobalt(II), zerovalent cobalt, and molybdenum(I) complexes.



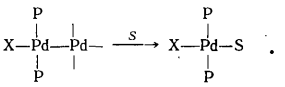


Figure 5. Idealised structure of complexes containing the M–Y–M fragment.

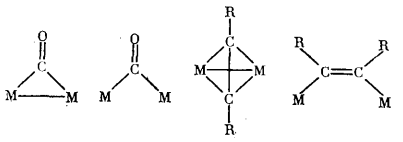
However, studies of the XPE spectra of palladium(I) complexes and the products of the insertion of various molecules have shown[96] that it is impossible to detect appreciable charge transfer and changes in the degree of oxidation of the palladium atoms. This factor led Balch et al.[122] to the conclusion that the question of the degree of oxidation of palladium and of the type of insertion reaction is to a large extent semantic. We shall consider this problem in greater detail. In all cases where it has been possible to measure the binding energy of the electrons at the atom linked directly to two palladium atoms, there is an entirely appreciable decrease of the binding energy on passing from a free to an inserted species. Thus $E(2p_{3/2}) = 161.6$ eV for the S atom in the complex $S(PdCl)_2(dpm)_2$ is lower by 2.4 eV than $E(2p_{3/2})$ for S_8. The transition from free SO_2 to μ-SO_2 decreases the $2p_{3/2}$ binding energy for sulphur by 1.4 to 1.5 eV. Thus there is partial charge transfer to the sulphur atoms. The slight change in $E(3d_{5/2})$ for palladium atoms is also entirely explicable:

(a) electron density is transferred to the inserted species (μ-Y) from two palladium atoms, which decreases the absolute magnitude of the effect;

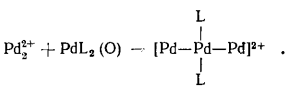
(b) apart from the two palladium atoms, four (!) powerful σ-donor ligands (P and As) atoms are involved in the charge transfer;



(c) the $3d_{5/2}$ binding energy for palladium (see Section II, subsection 3) depends greatly on the ligand environment (within the limits of 1 eV and more for a constant degree of oxidation). There is therefore a possibility of the mutual cancelling of two effects—the increase of E on transition to palladium(II) and its decrease on transition from the palladium atom as the ligand to, for example, a sulphur atom or CO and SO_2 molecules:

The solution of this problem still requires further study.

The achievement of extremely interesting reactions involving the insertion of various molecules in a Pd–Pd bond expands our ideas concerning the nature of the possible intermediates in catalytic and stoichiometric reactions.



On the basis of the data described above, the types of coordination of CO and acetylenes at the two metal atoms in palladium and platinum complexes can be represented by structures (B), (C), (D), and (E):

(B) (C) (D) (E)

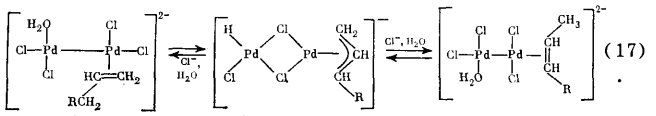
In the case of platinum, a type (C) complex is formed from $Pt_2Cl_2(dpm)_2$ and CO in dichloromethane [ν(CO) = 1638 cm^{-1}] [125–127] and also from the complex $Pt_2(CO)_2Cl_4^{2-}$ and dpm.[125–127]

Within the framework of this Section, which is devoted to reactions involving insertion in a Pd–Pd bond, mention should be made also of the insertion of the PdL_2 complex[11], which can be called a "reductive" addition reaction:

The formal degree of oxidation of palladium approaches +2/3 in this instance.

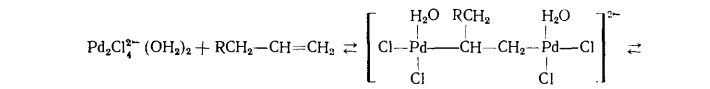
Thus the Pd–Pd bond in palladium(I) complexes is able to react with both electron acceptors (oxidants—for example, sulphur) and with electron donors (reductants—for example, zerovalent palladium).

IV. THE ROLE OF PALLADIUM(I) COMPOUNDS IN STOICHIOMETRIC AND CATALYTIC REACTIONS



As already mentioned above, the increase of interest in palladium(I) complexes is associated to a large extent with the acquisition of information concerning the involvement of palladium(I) compounds in stoichiometric and catalytic reactions as catalysts and intermediates or about the formation of reaction products containing palladium(I). In this Section we shall consider the available data on the functions of palladium(I) complexes in various reactions. We believe it is useful to mention also the studies in which the postulates of the involvement of palladium(I) are merely working hypotheses and have not yet been sufficiently convincingly demonstrated.

1. The Positional Isomerisation of Olefins



The isomerisation of olefins was apparently the first reaction the results of the study of which were quite convincingly interpreted within the framework of the mechanism of an unbranched chain reaction with a palladium(I) complex as the chain carrier (the catalyst of the isomerisation stages).[104,108,109]. This reaction has been recently discussed in detail[128,129] and we shall therefore mention only its principal features. As a result of the oxidation of an olefin (butenes) with

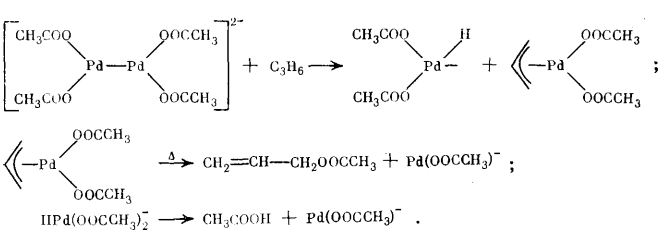
palladium(II) chloride, a palladium complex is formed [tentatively $Pd_2Cl_4^{2-}$: reaction of type (7)] and catalyses the isomerisation of butenes (α-$C_4H_8 \rightarrow \beta$-C_4H_8). As a consequence of its instability, the complex $Pd_2Cl_4^{2-}$ disproportionates (Section III, subsection 3), which terminates the kinetic chain. The chain termination occurs also after the addition of *p*-benzoquinone (Q), which oxidises palladium(I).[108] Within the framework of this mechanism, it was possible to explain the surprising proportionality of the rate of isomerisation of α-C_4H_8 to its concentration and the concentration of the total olefins $[C_4H_8]_\Sigma$. These results constitute kinetic proof that the isomerisation of olefins is catalysed by a palladium(I) compound. It has been shown[39] that the insoluble palladium carbonyl chloride $[Pd(CO)Cl]_n$ catalyses the isomerisation of liquid hept-1-ene to *cis,trans*-hept-2-enes. These experiments were repeated under homogeneous conditions[51]. The complex $[Pd(CO)Cl]_n$ was synthesised by the method of Kushnikov et al.[38] and was dissolved in DMF saturated with LiCl. The isomerisation of but-1-ene takes place at 20 °C without an inductive period, comes to a complete stop after the addition of *p*-benzoquinone in amounts comparable to those of palladium(I), and is resumed after the reduction of *p*-benzoquinone. It has been shown quite recently[69] that aromatic π-complexes of palladium(I) catalyse the isomerisation of butenes, pentenes, and hexenes at a high rate at room temperature without an inductive period and the hypothesis put forward by Moiseev and co-workers[108,109] has been thereby confirmed.

The mechanism of the isomerisation in the presence of palladium(I) complexes is based on the hypothesis of the transformation of the π-allyl complex, formed as a result of the oxidative addition of $H_2C = CH-CH_2R$ to the complex $Pd_2Cl_4^{2-}$ with dissociation of a C–H bond[104,109]:

(17)

The existence of the dimeric allylpalladium(II) hydride complex has not so far been confirmed. Presumably allylpalladium chloride interacts with the complex $HPdCl_2^-$ and is converted into $Pd_2Cl_4^{2-}$ and $CH_3CH = CHR$. In the light of new data concerning the possibility of the insertion of various molecules in the Pd–Pd bond in palladium(I) complexes, another version of the C–H bond dissociation mechanism can be suggested:

The highly reactive σ-allylpalladium chloride can interact directly with $HPdCl_2^-$ or can be first converted into a π-allyl complex as in scheme (17).



2. The Oxidation of Organic Compounds

As we have seen above, palladium(I) complexes were regarded as the final reaction products in olefin oxidation reactions. This hypothesis was confirmed chemically by Davidson and Triggs[70]. A benzenepalladium(I) complex is formed (Table 6, No.5) on reduction of palladium(II) acetate with hex-1-ene in perchloric acid-containing acetic acid in the presence of 25% of benzene. An analogous complex is formed also in the oxidative dimerisation of benzene. Under the conditions of the oxidation of cyclohexa-1,4-diene catalysed by $Pd(OOCCH_3)_2$, a palladium(I) complex was also isolated[73] (Table 6, No.7). The reduction of $PdSO_4$ by ethylene in the presence of *p*-benzoquinone (Q) results in the formation of the complex $Pd_2SO_4.Q$.[74] As mentioned above, the formation of palladium(I) in the reactions considered may be a consequence of two processes—the decomposition of intermediate organometallic σ-compounds [reaction (6)] or the reduction of palladium(II) by a zerovalent palladium complex stabilised by some kind of π ligand:

$$PdSO_4 + C_2H_4 + H_2O + Q \rightarrow Pd^0 \cdot Q + H_2SO_4 + CH_3CHO\ ;$$
$$Pd^0 \cdot Q + PdSO_4 \rightarrow Pd_2SO_4 \cdot Q\ .$$

The palladium(I) formed in the oxidative dehydrogenation of cyclohexane to benzene[71,72] exhibits an interesting "protecting" function—the benzene bound in a complex with palladium(I) is not sulphonated in 98% H_2SO_4. When oxidants capable of oxidising palladium(I) are added, only benzene sulphonation products are formed.

It is believed[130–135] that the palladium(I) complexes $[Pd_2(OOCCH_3)]_2$ (or clusters with a large number of atoms) are involved in the heterogeneous catalytic oxidative acetoxylation of olefins. The study of the XPE spectra of the catalyst $[Pd(OOCCH_3)_2 - CH_3COOK]/Al_2O_3$, prepared in different ways before and after tests for catalytic activity, showed that the specimens which have the 336.2 ± 0.1 eV band $[E(3d_{5/2})]$ in the XPE spectrum are active in the acetoxylation of propene. Politanskii et al.[135] assigned this band to the $CH_3COOPd-PdOOCCH_3$ fragment located on the catalyst surface. The specimens whose XPE spectra contain only the 335.3 or 336.8 eV bands, which the authors assigned to Pd(0) and PdO/Al_2O_3 respectively, have no catalytic activity in the process investigated[135]. A mechanism, close to the mechanism of the isomerisation of olefins, which does not specify in detail the possible modes of coordination of acetate groups, was proposed[131]:

The interaction of zerovalent palladium or of the hydride and allyl complexes with oxygen leads to the regeneration of the catalytically active form of palladium(I).

As mentioned above, the formation of paramagnetic palladium(I) centres has been established by EPR in a study of the interaction of the PdY zeolite with H_2 and CO.[9,10] Treatment of this specimen with oxygen at 500 °C with subsequent evacuation converts ~1% of palladium to the +3 state. If the same specimen is then treated with hydrogen at 25 °C, the zeolite blackens, the EPR signal corresponding to palladium(III) disappears, and the signals of two different palladium(I) states appear (8% of the total amount of palladium). The palladium(I) signals vanish when the specimen is treated with oxygen at 300 °C. The action of carbon monoxide on the specimens treated beforehand with oxygen or hydrogen leads to the disappearance of the EPR signals detected previously and to the appearance of a triplet signal, which the authors attributed to palladium(I) carbonyl[9]. Analogous results were obtained later in a different study[10]. When the zeolite specimen was treated in succession with hydrogen, carbon monoxide, and oxygen, the formation of carbon dioxide was observed. The involvement of palladium(I) carbonyl in this reaction is extremely probable[9].

Taking into account the comparatively high thermal stability of the palladium(I) complexes with isonitrile, carbonyl, and other ligands, one must bear in mind the possibility of the involvement of palladium(I) compounds as intermediates or catalysts in heterogeneous processes catalysed by palladium.

3. Oxidation of Carbon Monoxide

The oxidation of CO in solutions of palladium(I) complexes has been known since 1894 [136] and has been studied in fair detail[102,137,138]. Nevertheless, the role of the palladium(I) complexes in this reaction has started to become clear comparatively recently. It is known that CO reduces palladium(II) to palladium(I) (this is a method of synthesis of carbonyl complexes[38-41]), while $[Pd(CO)Cl]_n$ or $Pd_2(CO)_2Cl_4^{2-}$ decompose in aqueous solutions to CO_2 and zerovalent palladium[36]:

$$Pd^{II} \xrightarrow[-CO_2]{CO,\ H_2O} Pd^{I}CO \xrightarrow[-CO_2]{H_2O} Pd^0 .$$

The rate of decomposition of $[Pd(CO)Cl]_n$ increases greatly in the presence of an oxidant (Q, $Cr_2O_7^{2-}$). However, the characteristic features of the transformation of $[Pd(CO)Cl]_n$, investigated by Zhir-Lebed' and Golodov[106], left open the question of the role of palladium(I) in the CO oxidation process. Autocatalytic phenomena and a stepwise character of the reduction of palladium(II) have been observed in studies[139-141] of the reaction of $PdCl_2$ with CO without an oxidant. The inductive period was abolished after the introduction of the complex $[Pd(CO)Cl]_n$ into the initial solution ($PdBr_2$–H_2O–dioxan), and the rate of oxidation of CO increased. It follows from these findings that not only are palladium(I) complexes formed in the course of the reduction of palladium(II) but (in the absence of an oxidant) they also play the role of a catalyst of the oxidation of CO. The catalytic cycle (the chain propagation stages) in this process can be represented schematically as follows[102]:

$$[Pd_2(CO)_2X_4]^{2-} \xrightarrow{H_2O} Pd_2(COOH)(CO)X_3^{2-};$$

$$Pd_2(COOH)(CO)X_3^{2-} + PdX_2 + CO \rightarrow Pd_2(CO)_2X_4^{2-} + Pd^0 + CO_2 + HX .$$

In the presence of oxidants, the role of palladium(I) can change, but the stages involving the formation of palladium(I) complexes and their conversion into CO_2 can take place[141-143]. Studies of the kinetics of this reaction in the $PdCl_2$–$FeCl_3$–HCl–H_2O system led Brailovskii and co-workers[142,143] to the conclusion that zerovalent palladium complexes (carriers of the kinetic chain) play an important role in this system, while palladium(I) complexes are formed as a result of chain termination [Pd(0) + Pd(II)], which lowers the rate of formation of CO_2.

According to current information, there is a possibility of the direct transfer of an oxygen atom to CO from O_2 under homogeneous conditions. Thus the oxidation of CO by oxygen takes place selectively in the $Pd_4(phen)_2(CO)\cdot(OOCCH_3)_4$ cluster in acetic acid solution:[99]

$$Pd_4(phen)_2(CO)(OOCCH_3)_4 + \tfrac{1}{2}O_2 \rightarrow Pd_4(phen)_2(OOCCH_3)_4 + CO_2 .$$

4. Oxidative Carbonylation of Alcohols and Certain Other Oxidation-Reduction Reactions of Carbon Monoxide

A study of the kinetics of the catalytic carbonylation of methanol in the presence of $PdCl_2$,[102,107,144]

$$2CO + 2CH_3OH + Q \xrightarrow{PdCl_2} (COOCH_3)_2 + QH_2 , \qquad (18)$$

established that, under conditions where the rate of formation of dimethyl oxalate r_{DMO} is independent of p_{CO}, the dicarbonyl complex $PdCl_2(CO)_2$ is involved in the reaction. The rate of reaction is then described by the equation

$$r_{DMO} = \frac{k[PdCl_2(CO)_2]_\Sigma \cdot [Q]}{1 + k_1[PdCl_2(CO)_2]_\Sigma^n} ,$$

where $n = 1-2$, depending on the range of variation of $[PdCl_2]_\Sigma$. One of the hypotheses which explained the variable and fractional order of the reaction with respect to $[PdCl_2]_\Sigma$ is the possibility of the formation of palladium(I) carbonyl chloride clusters. We already noted above (Section III, subsection 3) that $[Pd(CO)Cl]_n$ is converted into the chloride carbonate in alcoholic solutions, while in the presence of p-benzoquinone it is converted into dimethyl oxalate. The carbonylation of phenol to diphenyl carbonate and salicylate also takes place in the presence of palladium(I) carbonyl halides[145,146]. However, a study[107] of the kinetics of the reaction (18) catalysed by $[Pd(CO)Cl]_n$ showed that the rate of reaction in this system under steady-state conditions (under conditions of independence of p_{CO}) is described by another equation:

$$r_{DMO} = k_2[Pd_2(CO)_2Cl_4^{2-}]_\Sigma \cdot [Q] .$$

In the region of first order of the reaction with respect to the catalyst, the constant k_2 is greater than k by a factor of 1.6. For $[Pd]_\Sigma = 0.06$ M, the rate of reaction in palladium(I) solutions is 4.5 times higher than r_{DMO} in palladium(II) solutions, other conditions being equal.

In $[Pd(CO)Cl]_n$ solutions in the presence of an excess of LiCl [when account is taken of the CO content in the initial palladium(I) carbonyl halide], one mole of CO is absorbed per gram-atom of palladium, i.e. dimeric dicarbonyl complexes, probably $Pd_2(CO)_2Cl_4^{2-}$, are formed in these solutions. Thus the results of the above investigations lead to a remarkable consequence: in a CO atmosphere in alcoholic solutions of p-benzoquinone, palladium(II) and palladium(I) form two different catalytic systems which are not interconverted to an appreciable extent. This conclusion has been confirmed in a study of the kinetics of the model reaction

$$2CH_3COOHgCOOCH_3 + Q + 2HX \rightarrow (COOCH_3)_2 + QH_2 + Hg(OOCCH_3)_2 + HgX_2$$

catalysed by $PdCl_2$ and $[Pd(CO)Cl]_n$. Different dependences of the rates of reaction on [Q] were obtained in this instance, and, for identical reactant concentrations under the conditions of first order of the reaction with respect to both Q and the catalyst, the second-order rate constant is higher by a factor of 4.2 for $PdCl_2$ than in $Pd_2(CO)_2Cl_4^{2-}$ solutions. The mechanism of the synthesis of dimethyl oxalate in palladium(I) solutions is described by the scheme[107]

$$Pd_2(CO)_2Cl_4^{2-} + Q \overset{K}{\rightleftarrows} \underset{(XVII)}{QPd_2(CO)_2Cl_3^-} + Cl^- ;$$

$$(XVII) \begin{cases} \xrightarrow[H^+,\ Cl^-]{ROH} QPd_2(COOR)(CO)Cl_2^- + Cl^- \ (XVIII) ; \\ \xrightarrow[k_2']{CH_3COOHgCOOR} (XVIII) ; \end{cases}$$

$$(XVIII) \begin{cases} \xrightarrow[H^+]{ROH} QPd_2(COOR)_2Cl_2^{2-} \ (XIX) ; \\ \xrightarrow[k_3',\ -CO]{CH_3COOHgCOOR} (XIX) ; \end{cases}$$

$$(XIX) + 2HCl \rightarrow Pd_2Cl_4^{2-} + QH_2 + (COOR)_2 ;$$

$$Pd_2Cl_4^{2-} + 2CO \rightarrow Pd_2(CO)_2Cl_4^{2-} .$$

It has been reported that the carbonyl chloride $[Pd(CO)Cl]_n$ [147] and the carbonyl acetate $[Pd(CO).(OOCCH_3)]_4$ [148] are involved in the oxidative carbonylation of olefins:

$$CH_2{=}CHR + ArOH + [Pd(CO)Cl] \xrightarrow[CH_2Cl_2;\ CO\ (1\ atm)]{R_3N;\ 20^\circ} \begin{cases} \longrightarrow ArOOCCH(OAr)CH_2R \\ \longrightarrow ArOOCCH{=}CHR \end{cases} + Pd_{met};$$

$$C_6H_5CH{=}CH_2 + CH_3OH + [Pd(CO)(OOCCH_3)]_4 \xrightarrow[28^\circ]{CO\ (1\ atm)} C_6H_5CH{=}CHCOOCH_3 + Pd_{met}.$$

The same reactions occur in catalytic systems based on palladium(II) in the presence of oxidants[102,149]. The elucidation of the role of palladium(I) compounds in the oxidative carbonylation of olefins requires further study.

The oxidative carbonylation of amines resembles closely the reactions considered in this Section[150-152]. The short inductive period in the $PdCl_2$–$CuCl_2$ system in the synthesis of dibutylurea

$$4RNH_2 + CO + CuCl_2 \xrightarrow{PdCl_2} RNHCONHR + 2CuCl + 2\overset{+}{R}NH_3Cl^-,$$

and the fractional order of the reaction with respect to $PdCl_2$ (~0.5) is treated[151,152] as a consequence of the catalysis of this reaction by palladium(I) complexes. This hypothesis cannot yet be regarded as sufficiently well founded.

Palladium complexes catalyse an interesting reaction involving the reductive carbonylation of nitro-compounds[153]:

$$RNO_2 + 3CO \rightarrow RNCO + 2CO_2.$$

It has been suggested that palladium(I) carbonyl halide complexes can participate in this reaction. Its mechanism is apparently close to that of the stoichiometric reduction of ArNO by carbon monoxide coordinated to palladium(I).[154] When equimolar amounts of ArNO and Pd(CO)Cl interact in dichlorobenzene at 90 °C, ArN–NAr and CO_2 are formed via the reaction

$$2Pd(CO)Cl + 2ArNO \rightarrow ArN{=}NAr + 2CO_2 + [Pd_2Cl_2]$$
$$[Pd_2Cl_2] \rightarrow PdCl_2 + Pd_{met}.$$

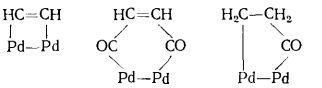
In the case of C_6H_5NO the products are ~90% of azoxybenzene and 10% of azobenzene relative to the initial C_6H_5NO.[154]

The oxidative dehydration of acetic acid is a very interesting reaction[155]:

$$2CH_3COOH + CO + \tfrac{1}{2}O_2 \xrightarrow{Pd(CH_3COO)_2} (CH_3CO)_2O + CO_2 + H_2O.$$

It is a coupled process. There is reason to regard palladium(I) complexes as intermediates in this reaction. It has been suggested that the reaction proceeds via the formation and transformation of the carbonyl acetate cluster [see reaction (8)]:

$$Pd(OOCCH_3)_2 \xrightarrow{CO} Pd_2(CO)_2(OOCCH_3)_2 \xrightarrow{NaOOCCH_3} (CH_3CO)_2O + CO_2 + 2Pd^0.$$



There is also a possibility of the formation of the anhydride and CO_2 in the stage leading to palladium(I). The oxidation of zerovalent palladium by oxygen or another oxidant makes the process catalytic.

5. Alkoxycarbonylation of Acetylene

The first hypothesis of the involvement of palladium(I) complexes in the oxidative alkoxycarbonylation of acetylene was put forward in a study[156] of the synthesis of maleic and fumaric diesters in the $PdCl_2$–$SC(NH_2)_2$–ROH system. The first evidence for the catalysis by palladium(I) complexes of the reactions of acetylene with RO and ROH was obtained in a study of the coupled reaction involving the synthesis of acrylic, propionic, maleic, fumaric, and succinic acid esters in the Li_2PdI_4–ROH–HCl system[51,97,102]. The potentiometric study of the active catalyst formation stage and the study of the influence of oxidants and reductants on this stage and on the rate of reaction under steady-state conditions led to the conclusion that the alkoxycarbonylation of acetylene is catalysed by palladium(I) complexes. Tests of the activities of a number of palladium(I) compounds, namely $[Pd(CO)Cl]_n$, $Cs_2Pd_2(CO)_2Cl_4$, and $Li_2Pd_2I_4.2H_2O$,[51,97] in this reaction in the LiI–C_4H_9OH system showed that palladium(I) complexes catalyse the synthesis of the acid mono- and di-esters and that the catalytic properties of $Li_2Pd_2I_4.2H_2O$ and its potentiometric characteristics are very close to the properties and characteristics of the catalytic system formed from Li_2PdI_4 after the attainment of the steady state. A study of the kinetics of this complex coupled reaction showed that the experimental dependences of the rate of formation of all the products (and their ratio) on p_{CO} and $[H^+]$ are not described by the mechanisms proposed previously[97] and not even by their combination. In order to account for the set of experimental findings, it proved essential to resort to the information about specific properties of the palladium(I) complexes and about the reactions involving the Pd–Pd bond; the products of the insertion of C_2H_2 and CO in the Pd–Pd bond (IPd–CO–CH=CH–PdI, IPd–CO–CH=CH–CO–PdI) as well as the polynuclear organometallic σ-compounds[157]

and metal-containing cyclic compounds

formed in the system were regarded as intermediates.

The study of the $PdBr_2$–$P(C_6H_5)_3$–C_4H_9OH–DMF system in the same acetylene alkoxycarbonylation reactions showed that oxidants and reductants influence the process parameters in the same way as in the Li_2PdI_4–C_4H_9OH system[158]. This influence is particularly strong in the stage involving the formation of the active complex. The hypothesis of the involvement of low-valence forms of palladium [palladium(I)] in this system does not conflict with recent data, according to which the complex $[PdClP(C_6H_5)_3]_2CO$ [$\nu(CO)$ = 1860, 1890 cm^{-1}] proved to be catalytically active in the DMF–C_4H_9OH system; the overall rate of reaction and the rates of formation of individual esters are comparable to the rates of alkoxycarbonylation in the $PdBr_2$–$P(C_6H_5)_3$–DMF–C_4H_9OH system[159].

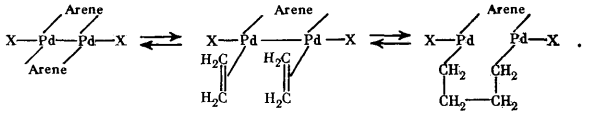
6. The Hydrogenation, Dimerisation, and Cyclo-oligomerisation of Unsaturated Molecules

The important role of palladium(I) compounds in the mechanism of the formation of catalytically active complexes—catalysts of the hydrogenation of dienes and alkynes in the $[(C_6H_5)_3PPd(CH_3COO)_2]_2$–$H_2$ system in various solvents—has been established[50,160]. It has been shown convincingly that the interaction of the complex $[(C_6H_5)_3PPd(CH_3COO)_2]_2$ with H_2 constitutes an autocatalytic process whose mechanism has been accounted for by the formation of the zerovalent palladium complex Pd_2L_2 [$L = P(C_6H_5)_3$] catalysing the reduction of $[LPd(CH_3COO)_2]_2$ via the intermediate palladium(I) complex $Pd_2(OOCCH_3)_2L_2$, which undergoes hydrogenolysis faster than $[LPd(CH_3COO)_2]_2$ with formation of Pd_2L_2:[160]

$$[LPd(OOCCH_3)_2]_2 + H_2 \rightarrow L_2Pd_2(OOCCH_3)_3H + CH_3COOH;$$
$$L_2Pd_2(OOCCH_3)_3H \rightarrow Pd_2(CH_3COO)_2L_2 + CH_3COOH;$$
$$Pd_2(CH_3COO)_2L_2 + H_2 \rightarrow Pd_2L_2 + 2CH_3COOH.$$

On interaction with $[LPd(CH_3COO)_2]_2$, the Pd_2L_2 formed leads to $Pd_2(CH_3COO)_2L_2$:

$$Pd_2L_2 + [LPd(CH_3COO)_2]_2 \rightarrow 2Pd_2(CH_3COO)_2L_2 ;$$
$$2Pd_2(CH_3COO)_2L_2 + 2H_2 \rightarrow 2Pd_2L_2 + 4CH_3COOH .$$



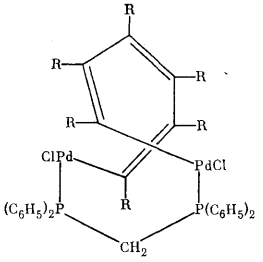
It has been established recently that the palladium cluster $Pd_5L'_2$ [$L' = P(C_6H_5)$], active in hydrogenation, is formed from Pd_2L_2 and palladium(II) [22] via the scheme

$$Pd^{II} \rightarrow Pd^{I} \rightarrow Pd_2L_2 \xrightarrow{Pd^{II}} Pd_5L'_2 .$$

Palladium clusters having the composition $\boxed{Si}\begin{matrix}P\\ \diagdown\\ \diagup\\ P\end{matrix}Pd_n$.

$.(OOCCH_3)_2$ (where n = 2, 3, 4, or 5) and immobilised on the surface have been obtained by the reaction of $Pd(CH_3COO)_2$ with zerovalent palladium on a silica gel surface modified by the diphosphine ligand $\boxed{Si}-P_2$ and also from the complex $[Pd_2(CO)_2(OOCCH_3)_2]_2$ and $\boxed{Si}P_2$.[64] The complex with n = 2 [formally of palladium(I)] resembles closely palladium(I) complexes according to XPE spectroscopy and is converted by triphenylphosphine into the complex $Pd_2(OOCCH_3)_2L_2$ described by Berenblyum et al.[50¶] The immobilised complex with n = 2 catalyses the hydrogenation of cyclopentadiene; the ratio of the rates of hydrogenation of cyclopentadiene and cyclopentene is in the range 0.2–1.[161]

The first information about the catalytic dimerisation of ethylene in solutions of palladium(I) complexes has appeared recently[69]. The aromatic π-complexes $(ArH)_2Pd_2(Al_2Cl_7)_2$ and $(ArH)_2Pd_2(AlCl_4)_2$ in benzene and toluene (ArH = benzene, toluene, or p-xylene) form a mixture of *trans*-but-2-ene (80%) and *cis*-but-2-ene (14–20%) at room temperature at a rate greatly exceeding the rate of dimerisation in palladium(II) solutions (~25 moles of butene per hour per gram-atom of palladium). The catalytic system is stable only in aromatic solvents. A mechanism incorporating a stage involving the oxidative addition of two ethylene molecules to the Pd-Pd bond has been proposed:



(XX) (XXI) (XXII)

According to Pertici and Vitulli[69], the reaction of compound (XXII) takes place synchronously because palladium atoms promote the transfer of two hydrogen atoms with formation of the primary product—*trans*-but-2-ene.

The possible involvement of palladium(I) complexes also in the polymerisation of propene to polyethylene, catalysed by palladium(II) cyanide, has been suggested[104]. The transfer of hydrogen from one propene molecule to another can take place via a mechanism similar to that of the isomerisation of butene [reaction (17)] on the fragment containing NCPd–PdCN. The available information about the existence of the complex $Pd_2(CN)_6^{4-}$ even in aqueous solutions (see Section III, subsection 3) makes this hypothesis entirely probable.

In connection with the synthesis of the products of the insertion of acetylenes and olefins in a Pd–Pd bond[122], the activity of the complex $Pd_2(dpm)_2Cl_2$ in the cyclotrimerisation of dimethyl acetylenedicarboxylate was tested. The complex proved to the active, like the complex $Pd_2(dpm)_2$. $.[\mu\text{-}C_2(COOR)_2]Cl_2$, formed under reaction conditions and capable of being an intermediate in the synthesis of hexamethyl mellitate. The reaction takes place at room temperature with formation of 10–13 moles of the product per hour per mole of the complex. The subsequent insertion of three alkyne molecules in the Pd–Pd and Pd–C bonds can lead to the intermediate (XXIII) in which the Pd atoms linked to the bisphosphine ligand are in a position convenient for the reductive elimination reaction with ring closure [like the complex $(RC_2R')_3Co_2(CO)_4$] [163] and the formation of benzene derivatives.

(XXIII)

In conclusion of this Section, we may note that, for the understanding of the mechanisms of a large number of catalytic processes, it is useful to resort to the hypothesis of the involvement of the Pd–Pd cluster bond of palladium(I) complexes in the formation of intermediates compounds in catalytic reactions. The presence of the Pd–Pd fragment in the catalytically active complexes may promote the formation of metal-containing rings with a metal–metal bond and can lead to partial reduction of a number of substrates (CO, RNC, C_2R_2) as a result of their oxidative addition to Pd_2, to the formation of Pd–C bonds as a consequence of the rupture of the Pd–Pd bonds, and to the homolytic rupture of C–H bonds at two centres. Judging from all the considerations, palladium(I) complexes are in general convenient models for the study of catalysis by metal clusters.

* * *

Thus compounds of palladium in the +1 oxidation state constitute a fairly numerous family with a number of structural features associated with the presence of a metal–metal bond. The possibility of the extensive variation of the oxidation-reduction properties of palladium(I) by varying the nature of the ligands is extremely important for catalysis by palladium(I) complexes because the range of variation of the standard electrode potential of the Pd(II)/Pd(I) pair is very large, amounting to ~2.7 V.

The data presented above show that palladium(I) compounds can exist in aqueous, non-aqueous, and non-polar media under different conditions, including high temperatures and in the presence of oxidants (oxygen, *p*-benzoquinone). The appearance of palladium(I) compounds under the conditions of catalytic processes can lead to the operation of unusual mechanisms due to the presence of the Pd–Pd bond.

The Mechanism of the Oxidative Coupling of Unsaturated Hydrocarbons Under the Influence of Palladium(II) Complexes

I.V.Kozhevnikov

The results of studies on the mechanism of liquid-phase reactions involving the oxidative coupling of arenes to biaryls, of arenes and olefins to arylolefins, and of olefins to 1,3-dienes under the influence of palladium(II) complexes are surveyed. The bibliography includes 161 references.

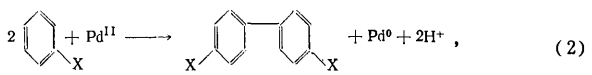
IV. The oxidative coupling of olefins 147

I. INTRODUCTION

The liquid-phase reactions involving the oxidative coupling of unsaturated hydrocarbon to biaryls, arylolefins, and 1,3-dienes under the influence of palladium(II) complexes have been discovered and widely investigated in the course of the last twenty years[1-3]. In a general form, they can be represented by the equation

$$RH + R'H + Pd^{II} \rightarrow R{-}R' + Pd^{0} + 2H^{+}, \quad (1)$$

where R, R′ = aryl or alkenyl. These reactions involve the formation of a new C–C bond and as a rule give rise to products with a conjugated system of π-bonds. The oxidative coupling of hydrocarbons has come to be widely used synthetically because of its many advantages over traditional methods. These include simplicity, universality, and the possibility of carrying out catalytic reactions by oxidising zerovalent palladium to palladium(II) *in situ*. The importance of these reactions is indicated by the abundance of publications devoted to them[4-18].

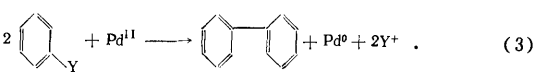


Qualitative hypotheses concerning the mechanism of the oxidative coupling of hydrocarbons and based on the fundamental reactions of organometallic chemistry were put forward a long time ago[4-18]. The formation of a new C–C bond is treated as a result of a sequence of π–σ transformations of the substrate in the coordination sphere of palladium(II). Here the key stage is the formation of the reactive intermediate RPdX with a C–Pd σ-bond. The hypothesis of the π–σ rearrangements proved useful in metal complex catalysis[19]. However, it does not provide a detailed picture of the reaction mechanism. The questions of the rate-limiting stage, the active form of palladium(II) compounds, the role of π-complexes of RH with palladium(II), and others remain obscure. An answer to these questions has been obtained only recently as a result of detailed kinetic studies of reaction (1) and also the synthesis of organopalladium compounds and the study of their reactions.

The aim of the present review is to survey the results of studies on the mechanism of the oxidative coupling of unsaturated hydrocarbons under the influence of palladium(II) complexes.

II. THE COUPLING OF ARENES

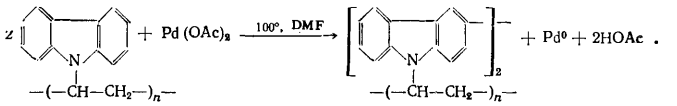
1. General Considerations



The coupling of arenes takes place under the influence of palladium(II) salts in organic and more rarely aqueous solutions at a temperature which does not usually exceed 120 °C:[1,16,20,21]

(2)

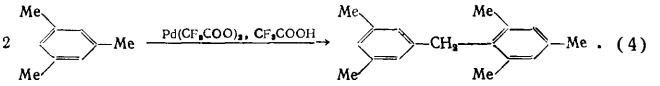
where X = H, alkyl, halogen, aryl, OR, CO_2R, OCOR,[1] NO_2,[22] OH,[23] etc. In the general case a mixture of all the theoretically possible biaryl isomers is formed (six isomers for PhX), their proportions being determined by the nature of the substituents in ArH.[1,21,24]



The coupling of organoelemental compounds takes place much more readily and selectively:

(3)

These include the aryl derivatives of mercury(II),[25-27] magnesium(II),[28] thallium(III),[29,30] tin(IV), lead(IV),[25] and boric[21] and sulphinic[31] acids. The mercury(II) compounds are most frequently used.



The coupling of arenes takes place in a large series of aromatic systems[16]. Derivatives of benzene[23-32] and napthalene[33,34], heterocyclic compounds[14,35-42], metallocenes[43,44], etc. undergo this reaction. The aromatic groups of polymers undergo intermolecular coupling[42]:

In the presence of oxidants capable of oxidising zerovalent palladium to palladium(II), catalytic coupling takes place[16]. Copper(II),[25,33,37-39] thallium(III),[29,30] and iron(III)[39,45]

salts, V_2O_5,[39] vanadium(V)-containing heteropolyacids[41,46,47], nitrogen oxides[48], and molecular oxygen[34,49-54] have been used as oxidants in homogeneous systems. Heterogeneous catalysts of the coupling of arenes are also known[16,55]. The yields of biaryls in the catalytic process reach hundreds of moles per mole of palladium(II).[52]

The pathway followed in the reactions of arenes depends on the nature of the ligands in the palladium(II) complexes. Inorganic acids, for example, $HClO_4$, catalyse the coupling of arenes[20,21,26,56]. The reaction of benzene and $Pd(ClO_4)_2$ in acetic acid takes place with a quantative yield of biphenyl[56]. In the presence of $Pd(OAc)_2$ in acetic acid, ArH undergoes acetoxylation in the ring and in the side chain as a side reaction[20,21,50,57-59]. In the presence of $Pd(CF_3COO)_2$, the contribution of these reactions is smaller[60]. Acetate ions promote the acetoxylation[20,57], while inorganic acids and oxygen suppress it[20,21,50]. The ring acetoxylation of ArH has been widely investigated as a potential method of synthesis of phenols[36,51,61-64]. There is reason to believe that the acetoxylation of methylbenzenes in the side chain is catalysed by palladium clusters[65,66]. When $Pd(NO_3)_2$ is used, the coupling is accompanied by the nitration of arenes[48,67,68]. In acid media the reaction of palladium(II) with methylbenzenes gives rise to diarylmethanes together with biaryls[21,22]:

. (4)

Among promising reactions mention may be made of the coupling of polymethylbenzenes as a method of synthesis of biphenylpolycarboxylic acids, which are valuable monomers for polycondensation[18]. The coupling of phthalic acid esters is of interest from this standpoint. The coupling of furan derivatives can be used to synthesise long-chain α,ω-bifunctional compounds, for example, dicarboxylic acids. Thus, in the presence of $Pd(OAc)_2$ and $CuCl_2$, furfural and pyromucic acid esters are smoothly converted into 2,2'-bifuryl derivatives[38], from which sebacic acid can be obtained by the cleavage of the furan ring[69].

2. The Mechanism of the Coupling of Arenes

(a) *Palladium(II) acetate complexes.* Reaction (1) proceeds with different palladium(II) compounds, but preference is usually given to palladium(II) acetate. The latter is trimeric in the crystalline state[70]. In benzene at 37 °C and in acetic acid at 25 °C it is also trimerised, but depolymerises on heating[70-73]. At 80 °C in benzene, palladium(II) acetate is monomeric[70].

Palladium(II) salts of strong acids show a smaller tendency towards association. Thus $Pd(CF_3COO)_2$ is monomeric in benzene at 37° and 80 °C.[70]

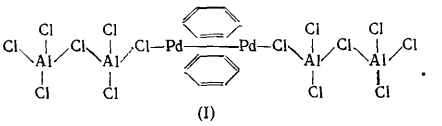
On heating in acetic acid solution, the $Pd_3(OAc)_6$ trimer slowly dissociates to the monomer:

$$Pd_3(OAc)_6 \overset{K_{3,1}}{\rightleftarrows} 3Pd(OAc)_2 .$$

$K_{3,1} = 2.7 \times 10^{-10}$ mol^2 litre^{-2} at 75 °C.[71] In the presence of sodium or lithium acetate, palladium(II) acetate depolymerises even at 25 °C and the following equilibria are established:

$$2Pd_3(OAc)_6 + 6NaOAc \overset{K_{3,2}}{\rightleftarrows} 3Na_2Pd_2(OAc)_6 , \quad (5)$$

$$Na_2Pd_2(OAc)_6 + 2NaOAc \overset{K_{2,1}}{\rightleftarrows} 2Na_2Pd(OAc)_4 , \quad (6)$$



where $K_{3,2} = 7.77 \times 10^4$ litre^5 mol^{-5} and $K_{2,1} = 7.6 \times 10^{-4}$ litre mol^{-1} at 25 °C in acetic acid. In the presence of 0.2 M sodium acetate, the trimer is fully converted into the dimer $Na_2Pd_2(OAc)_6$.[72]

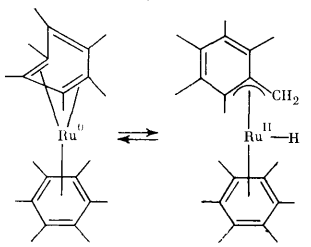
Palladium(II) acetate polymers readily decompose on treatment with ligands L such as pyridine, bipyridyl, Me_2SO, PPh_3, and $AsPh_3$ with formation of the complexes *trans*-$Pd(OAc)_2L_2$,[70] which undergo the *cis–trans* isomerisation in solution[74,75]. The slow interaction of $Na_2Pd_2(OAc)_6$ with olefins takes place similarly[76].

Palladium(II) acetate and chloride complexes have similar stability constants in aqueous solution[77] and for this reason palladium(II) chloride is converted into the acetate in the presence of an excess of sodium acetate.

The palladium(II) acetate monomer, dimer, trimer can have different reactivities[78,79]. If reactions (5) and (6) are used for their synthesis, then account must be taken of the possibility of base catalysis by the acetate ion in the determination of the relative reactivities of these species.

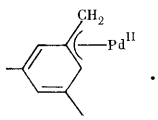
(b) *Arenes as ligands.* There is sufficient reason to assume that π-arene complexes of palladium(II) are intermediates in the oxidative coupling of arenes. π-Arene complexes are known for many metals, including palladium[80]. The diamagnetic complex $[Pd(C_6H_6)Al_2Cl_7]_2$, containing palladium in the formal +1 oxidation state, has been obtained by the Friedel–Crafts reduction. The complex has the structure

(I)



The lengths of the Pd–Pd and Pd–Cl bonds are 2.58 and 2.46 Å respectively and the Cl–Pd–Pd–Cl atoms are located virtually on a straight line[81].

When benzene was coupled under the influence of palladium(II) acetate in acetic acid in the presence of 0.5 M $HClO_4$ at 50 °C, the palladium(I) complex $[Pd(C_6H_6)(H_2O)ClO_4]_n$ where apparently $n = 2$ (Rudakov et al.[82]), was isolated[21], but its role in the reaction was not established. An analogous complex has been detected by NMR in the interaction of benzene with $PdSO_4$ in 90% sulphuric acid[82]. The complex Pd_2SO_4.(quinone).$3H_2O$ was isolated[83] in the oxidation of olefins to carbonyl compounds in an acid aqueous solution in the presence of quinone and $PdSO_4$. Virtually all the known palladium(I) complexes are diamagnetic and contain an even number of palladium atoms[84].



The less stable arene complexes of palladium(II) have not been isolated, but their formation in reaction (1) has been detected by kinetic methods. The coupling of thiophen to bithienyl under the influence of $Pd_3(OAc)_6$ in acetic acid obeys the Michaelis equation; the stability constant of the thiophen complex of palladium(II) $K = 0.2$ litre mol^{-1} at 70 °C.[40] The arylation of styrene on treatment with $Pd_3(OAc)_6$ in acetic acid at 70 °C was similarly found to have $K = 0.11$ and 4.6 litre mol^{-1} for benzene and naphthalene; in both cases ΔH is close to zero[85]. In the oxidative coupling of benzene in 90% sulphuric acid under the influence of $PdSO_4$, the π-complex $(C_6H_6)Pd(II)$ with $K = 17$ litre mol^{-1} at 23 °C was detected by NMR.[82]

Both all the π-electrons of ArH and only some of them can participate in the formation of the bond between the metal ion and the arene[18]. Thus, in the complex $(Me_6C_6)_2Ru(0)$ one ring is involved in complex formation symmetrically (η^6), while the other is involved with participation of two double

bond (η^4) and the free C–C bond is located to one side of Ru(0) and has the usual length of 1.33 Å.[86] It is assumed that in solution there is equilibrium with the π-benzyl hydrido-complex of ruthenium(II):[87]

It has been suggested[22] that the formation of diarylmethanes in the oxidative coupling of methylbenzenes [reaction (4)] proceeds via π-benzyl complexes:

(c) *Stoichiometric mechanism.* It is generally accepted that the oxidative coupling of arenes proceeds via electrophilic substitution as the rate-limiting stage[4,5,10,11,16,88,89],

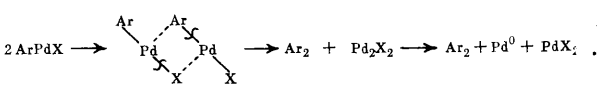
$$ArH + PdX_2 \rightleftarrows \pi\text{-}ArH \cdot PdX_2 \rightarrow ArPdX + HX\,, \qquad (7)$$

which constitutes a π–σ reaction of ArH in the coordination sphere of palladium(II). The coupling of arenes is in fact accelerated by electron-donating and retarded by electron-accepting substituents in ArH; the isomeric composition of the biaryls is characteristic of electrophilic substitution reactions, at any rate for coupling in acid media[1,21,22,24,47]. The reaction proceeds in accordance with the kinetic equation[1,21,40,56]

$$W = k[Pd^{II}][ArH]\,, \qquad (8)$$

is catalysed by bases[40], and exhibits a powerful isotope effect: $k_H/k_D = 5.0$.[21,24] Certain azo-coupling reactions, which are typical examples of electrophilic aromatic substitution, possess analogous properties[90]:

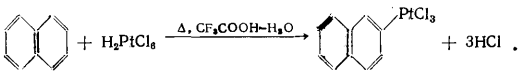
$$ArN_2^+ + Ar'H \rightarrow ArN{=}NAr' + H^+\,.$$



Reaction (7) is confirmed also by the finding that the coupling of arenes proceeds much more readily when one uses aromatic organoelemental compounds in which the element can be substituted by palladium(II), for example ArHgX (Eqn.(3)).[26]

Several pathways have been suggested for subsequent rapid reactions of ArPdX.[1,10,14,16,21,22,89,91] The mechanism involving the symmetrisation of ArPdX with formation of Ar_2Pd and subsequent reductive elimination of biaryl from Ar_2Pd is best supported by evidence[16]:

$$2ArPdX \rightarrow Ar_2Pd + PdX_2\,, \qquad (9)$$

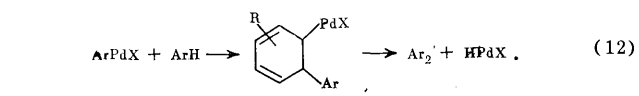


$$Ar_2Pd \rightarrow Ar_2 + Pd^0\,. \qquad (10)$$

One cannot rule out the synchronous formation of biaryl in a dinuclear complex:

The possibility of reactions (9) and (10) has been demonstrated by the occurrence of similar reactions when aryl and alkyl derivatives of palladium(II), stabilised by phosphine ligands, are used[92–95].

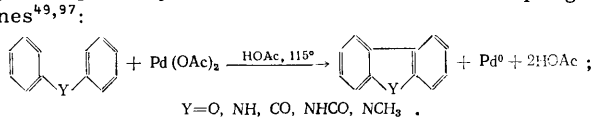
Aryl derivatives of platinum(IV) without phosphine ligands and functioning as intermediates in the oxidative coupling of arene under the influence of platinum(IV) have been obtained recently[96]:



The structure of β-naphthylplatinum(IV) has been determined.

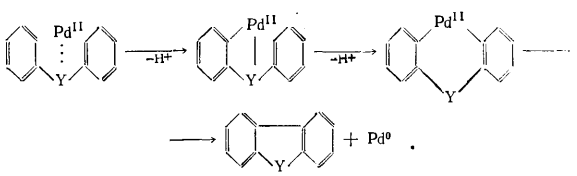
Repeated electrophilic substitution, which proceeds via an aryl-arene complex with palladium(II), has been considered as another pathway leading to the formation of biaryls[13,18,26,54]:

$$ArPdX + ArH \rightarrow [ArPd \cdot ArH] \rightarrow Ar_2 + Pd^0 + H^+\,. \qquad (11)$$



Stage (11) is possible in individual instances, for example, in the coupling of organoelemental compounds, but it is not apparently a stage in the general mechanism of the coupling of arene[16].

It is believed[22] that the coupling of arenes can proceed via the arylpalladisation of ArH and the β-elimination of palladium hydride:



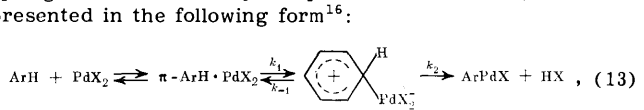
The choice between stage (9), on the one hand, and stages (11) and (12) on the other, can be made on the basis of the relative rates k/k_0 (relative to benzene) and the isotope effects k_H/k_D in the coupling of arenes[24]. It has been found that the values of k/k_0 for the coupling of toluene, measured in separate and competing reactions of benzene and toluene, agree. The isotope effects in the rates and products of the coupling of C_6H_6 and C_6D_6 have also proved to be equal. This confirms the mechanism involving stages (7), (9), and (10) but disagrees with the involvement of stages (11) and (12), because in the separate reactions the ratios k/k_0 and k_H/k_D depend on the rate-limiting stage (7), while in the competing reactions they depend on all the stages in which ArH participates and the dissociation of a C–H bond takes place.

Stage (11) probably occurs in the intramolecular coupling of arenes[49,97]:

Y=O, NH, CO, NHCO, NCH_3 .

The reaction takes place with a high yield of 2,2′-coupling products (60–90%) and apparently involves the *ortho*-palladisation of the arene by a palladium(II) complex with an *n*-donor group Y. The structure of ArPdX is favourable for the repeated intramolecular electrophilic substitution:

The *ortho*-metallation of aryl derivatives of nitrogen and phosphorus by Group VIII metal salts and complexes is well known[98].

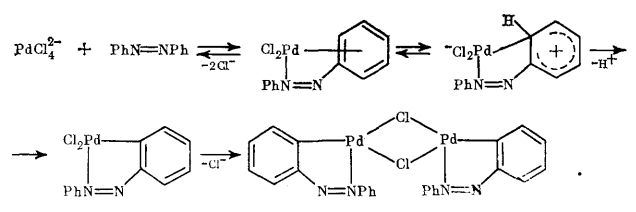


In the coupling of arenes the formation of free radicals is ruled out because phenol has not been found in the products of the coupling of benzene in an atmosphere of O_2,[1] the inhibitors of free radicals have no effect[49], and there is no H–D exchange between the arene and the solvent[21].

The detection of palladium(I) compounds in the coupling products[21] raises the question of the possible involvement of the reduced forms of palladium as intermediates in this reaction[21,82,99]. Many instances of catalysis by palladium(I) complexes and palladium clusters of liquid-phase oxidation reactions have been discovered recently[65,66,100–104]. In such reactions the initial compounds may be palladium(II) derivatives. The active reduced forms of palladium are formed in the course of the reaction, which leads in certain instances to the appearance of an inductive period[100,101]. In contrast to palladium(II) compounds, palladium clusters do not usually play the role of stoichiometric oxidants but act as catalysts in the presence of O_2.[100,104]

The question of the role of palladium(I) in oxidative coupling reactions has been investigated inadequately. However, a number of data show that palladium(I) compounds have only an indirect bearing on such reactions, at least under the most typical conditions—in aqueous acetic acid media. Indeed, the coupling of arenes can proceed both stoichiometrically and catalytically—in the presence of oxidants capable of oxidising the reduced forms of palladium [Pd(0), Pd(I), and Pd(II)].[37–39,47]. The stoichiometric reaction takes place without an inductive period, obeying the kinetic equation (8) up to the complete conversion of palladium(II),[1,40] which shows that palladium(II) is responsible for the coupling of arenes. Palladium(I) compounds are probably formed in a side reaction of zerovalent palladium with palladium(II) and are stabilised as a result of the coordination of the arene. This applies equally to other oxidative coupling reactions of unsaturated hydrocarbons considered here.

The mechanism of reactions (7), (9), and (10) is examined in detail below.



(d) *Palladisation of arenes.* The rate-limiting stage in the coupling of arenes, namely the palladisation of ArH, can be represented in the following form[16]:

(13)

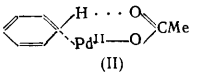
where the cyclohexadienylpalladium(II) derivative is the usual intermediate in electrophilic aromatic substitution[90]. The palladisation of ArH is probably a common stage in many oxidation reactions of arenes catalysed by palladium(II), such as the arylation of olefins, the acetoxylation and nitration of ArH, etc. The mechanism of reaction (13) is therefore of considerable interest.

Direct data on reaction (13) have been obtained for the *ortho*-palladisation of azobenzenes, which leads to the formation of stable cyclic metal-containing compounds. The following mechanism has been proposed for this reaction[98]:

Metallation in the *ortho*-position has been confirmed by X-ray diffraction, the synthesis of deutero-derivatives of arenes in the reduction of palladisation products by $LiAlD_4$, and the analysis of the products of the insertion of CO in the Ar–Pd bond[98]. That *ortho*-palladisation is a kind of electrophilic substitution is indicated by the influence of the substituents in the aromatic ring on the rate of reaction[98].

ortho-Palladisation is catalysed by bases (amines, carboxylate ions, and OH^-), which facilitate the elimination of a proton[98,105]. The dependence of the rate of this reaction on the concentration of the base B is of the type $W = a[B]/\{[B] + c\}$, where a and c are constants[105]. Certain azo-coupling reactions are characterised by a similar relation[90].

The majority of data on the mechanism of the palladisation of arenes, which are discussed below, have been obtained indirectly in the study of the oxidative coupling of arenes[24,88]. In stages (9) and (10) the initial location of palladium(II) in the aromatic ring is retained, which is confirmed by numerous data concerning reaction (3). Thus in the coupling of both 4-tolylmercuroacetate and 4,4′-ditolylmercury(II) under the influence of palladium(II) and under conditions which rule out the isomerisation of the substrate, only 4,4′-bitolyl is formed[26]. Thus the rate of coupling of arenes and the isomeric composition of the biaryls correspond unambiguously to the rate and selectivity of reaction (13).[24,88]



The palladisation of ArH proceeds in conformity with the kinetic equation (8) and is catalysed by strong acids ($HClO_4$)[21,26,56,88] and bases[40]. Eqn.(8) holds for both monomeric palladium(II) complexes[1,21,56] and under the conditions corresponding to the existence of palladium acetate dimers and trimers[40].

Reaction (13) with palladium(II) acetate in acetic acid has a strong primary isotope effect $k_H/k_D = 5.0$ (at 50 °C),[21] which does not change when the concentration of perchloric acid in the reaction mixture is varied from 0 to 0.86 M.[24] It has been noted that there is no isotope exchange between ArH and the solvent[21,106]. Hence it follows that the rate of palladisation of arenes is limited by the irreversible stage (k_2) involving the elimination of a proton from the cyclohexadienyl intermediate; the stage governed by the constants k_1 and k_{-1} involved rapid equilibration. It is noteworthy that mercuration of benzene by mercury acetate in acetic acid is to some extent limited by the stage with k_1 and k_{-1}. This is indicated by the increase of k_H/k_D from 3.2 to 6.0 with increase of perchloric acid concentration from 0 to 0.32 M.[107]

The catalysis by $HClO_4$ can be explained by the increase of k_1 as a result of the formation of more reactive palladium(II) perchlorate complexes[26] and also by the increase of k_2 as a consequence of the increase of the inductive effect of palladium(II) in the cyclohexadienyl intermediate on substitution of $X = OAc^-$ by ClO_4^-.

In the reaction of benzene with palladium(II) acetate in 94% acetic acid at 50 °C, the solvent was found to have the isotope effect $k_{DOAc}/k_{HOAc} = 2.7$; in the presence of 0.43 M perchloric acid, it is smaller (1.3).[24] These data apparently show that, in aqueous acetic acid in the absence of perchloric acid, the active form of palladium(II) acetate is the monomer PdOAc(OH), formed on dissociation of the trimer: $Pd_3(OAc)_6 + H_2O \rightleftharpoons PdOAc(OH) + Pd_2(OAc)_4 + HOAc$. Since the acid DOAc in D_2O is weaker than HOAc in H_2O ($K_H/K_D = 3.2$ at 25 °C [108]), the dissociation equilibrium of $Pd_3(OAc)_6$ in DOAc–D_2O is more displaced to the right compared with the equilibrium in HOAc–H_2O. In the presence of perchloric acid, palladium(II) exists predominantly in the form of monomeric perchlorate complexes and for this reason a weak isotope effect is observed.

It has been suggested that the palladisation of arenes proceeds in a single stage via the transition state

(II)

in which there is simultaneous formation of the C–Pd bond and proton transfer to the acetate ligand[56]. However, in reality there is no grounds for ruling out the generally accepted two-stage electrophilic substitution mechanism involving a cyclohexadienyl intermediate[90].

The possibility of proton transfer to the ligand in the cyclohexadienyl intermediate had been suggested previously in the mercuration of arenes[107,109]. This mechanism probably operates in the palladisation of arenes in weakly basic media, for example, in the arylation of arenes in benzene. In aqueous and aqueous organic solutions in the presence of strong inorganic acids, the solvent is more likely to be the proton acceptor, because its basicity is higher than that of the ligand. The linear dependence of the rate of coupling of benzene under the influence of $Pd(ClO_4)_2$ in 70% acetic acid on the perchlorate acid concentration is consistent with this postulate[56]. When a proton is transferred to the ligand, a linear dependence of the rate of coupling on the Hammett function h_0 would be expected[110].

Table 1 presents data on the site of substitution, the relative rates k/k_0, and the partial rate factors f_o, f_m, and f_p for the palladisation of arenes in acetic acid. They were obtained by analysing the products of the competitive coupling of arenes[24]. In acid media, in the presence of $HClO_4$ or other strong acids, the site of substitution is characteristic of electrophilic substitution, although the positional selectivity (the selectivity of attack on different positions in the ring) is much lower than for other reactions of this class[24,88]. The Hammett equation $\lg f_p = \rho\sigma^+$ holds (Fig. 1).[24] The values $\rho = -0.7 - -2.2$ [24,88] are significantly higher than for typical electrophilic aromatic substitution reactions: $\rho = -5 - -11$, [111] i.e. palladisation has a low substrate selectivity.

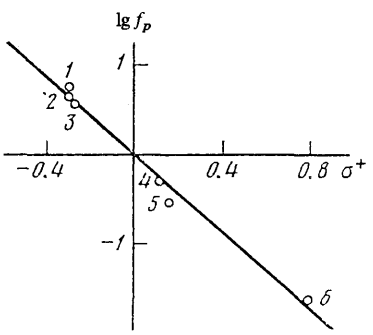


Figure 1. Dependence of $\lg f_p$ on σ^+ for the palladisation of arenes by palladium(II) acetate in acetic acid in the presence of 0.25 M $HClO_4$ at 20 °C; $\rho = -2.22$: *1*) PhMe; *2*) PhEt; *3*) iso-PrPh; *4*) PhCl; *5*) PhBr; *6*) $PhNO_2$.[24]

The selectivity in palladisation decreases with decrease of perchloric acid concentration, although its mechanism does not change under these conditions, since k_H/k_D is independent of the perchloric acid concentration[24]. An unexpected result was obtained for the reaction of toluene with palladium acetate in the absence of added strong acids: the relative contents of the *o*-, *m*-, and *p*-isomers are 5.8, 62, and 32%, i.e. the usual mode of electrophilic substitution is reversed. The yields of the *m*- and *p*-isomers are nearly statistical[24,88]. This anomaly is discussed below (see also Refs. 1, 14, and 22).

The palladisation in the *ortho*-position in a monosubstituted arene is controlled to a greater extent by the steric influence of the substituent than by its electronic influence. This can be seen from the decrease of f_o in the sequence PhMe > PhEt > iso-PrPh (Table 1). The bulk of the attacking species is also important in the *ortho*-attack. Thus in the palladisation of toluene in acetic acid, the yield of *o*- and *p*-isomers decreases with decrease of the perchloric acid concentration from 0.86 M to zero. However, f_p decreases only by a factor of 3, while f_o decreases by a factor of 8. The state of palladium(II) in solution changes under these conditions: the monomer $Pd(ClO_4)_2$ is converted into the trimer $Pd_3(OAc)_6$. The latter is evidently subjected to a stronger steric hindrance in attack on the *ortho*-position of toluene[24].

Table 1. The mode of substitution and the partial rate factors *f* for the palladisation of arenes in acetic acid {[ArH] = 2.5 M, $[Pd(OAc)_2]$ = 0.050 M, $[H_2O]$ = 0.95 M, 20 °C}.[24]

The increase of f_p in the sequence iso-PrPh < EtPh < MePh is remarkable, illustrating the influence of hyperconjugation in the palladisation of arenes[24].

The palladisation reaction is compared in Fig. 2 with other aromatic substitution reactions in relation to the reactions of toluene in terms of the Brown selectivity ratios $\lg f_p = a \lg (f_p/f_m)$ (for toluene, $a = 1.31$).[111] The selectivity ratio characterises the relation between the substrate selectivity f_p and the positional selectivity f_p/f_m of the substitution in the ring of ArH. Evidently, palladisation is the least selective reaction in the series of electrophilic aromatic substitution processes, its selectivity approaching that of radical substitution, which is nearly statistical with respect to *m*- and *p*-isomers.[88]

The low selectivity in the palladisation of arenes indicates the compensation of the polar (electronic) effects of the substituents in the ArH ring[88]. Such compensation is possible as a result of the $d\pi$–$p\pi$ binding in the π-arene complex of palladium(II). The π-ArH.PdX_2 linkage is achieved as a result of the transfer of electron density from the occupied $p\pi$ orbitals of arene to the unoccupied *s*, *p*, and *d* orbitals of palladium(II) and in the reverse direction from the occupied *d* orbitals of palladium(II) to the vacant antibonding π orbital of ArH (dative bond). The operation of two mechanisms of the transfer of electron density creates conditions for the compensation of the polar influence of the substituent on the reaction centre[88]. With increase of the

"rigidity" of the ligand environment of palladium(II), for example, following the introduction of the electron-accepting ligand ClO_4^-, the efficiency of the compensation diminishes as a consequence of the weakening of the dative bond. Both the selectivity of the palladisation and its rate then increase. These qualitative ideas make it possible to explain the anomalous mode of substitution in the palladisation of arenes. However, they require a more rigorous quantum-chemical justification.

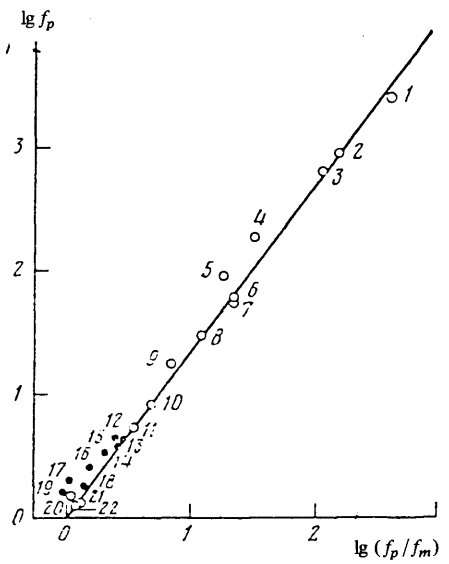

Figure 2. The ratio of selectivities for substitution in the toluene ring[88]; filled circles—reactions with palladium(II): *1*) bromination (Br_2 in 85% acetic acid, 25 °C);[111] *2*) chlorination (Cl_2 in acetic acid, 25 °C);[111] *3*) benzoylation (PhCOCl in nitrobenzene, 25 °C);[111] *4*) thallation [$Tl(CF_3COO)_3$ in trifluoroacetic acid, 10 °C];[112] *5*) ditto, 73 °C;[112] *6*) nitration (HNO_3 in 90% acetic acid, 45 °C);[111] *7*) thallation [$Tl(OAc)_3$ + H_2SO_4 in acetic acid, 70 °C];[114] *8*) mercuration [$Hg(OAc)_2$ + $HClO_4$ in acetic acid, 50 °C];[111] *9*) ditto [$Hg(OAc)_2$ in acetic acid, 50 °C];[111] *10*) sulphonation ($MeSO_2Cl$ + $AlCl_3$, 100 °C);[111] *11*) iso-propylation (iso-PrBr + Ga_2Br_6, 25 °C);[111] *12*) palladisation [$Pd(OAc)_2$ + H_2SO_4 in acetic acid, 95 °C];[88] *13*) ditto [$Pd(OAc)_2$ + $HClO_4$ in acetic acid, 55 °C];[88] *14*) ditto, 95 °C;[88] *15*) ditto ($PdCl_2$ + NaOAc in acetic acid, 90 °C;[88] *16*) ditto [$Pd(OAc)_2$ + CF_3COOH in acetic acid, 95 °C];[88] *17*) ditto [$Pd(OAc)_2$ + NaOAc in acetic acid, 95 °C];[88] *18*) catalytic coupling [$Pd(OAc)_2$ in ArH, 25 atm O_2, 150 °C];[53] *19*) palladisation [$Pd(OAc)_2$ in acetic acid, 95 °C];[88] *20*) radical arylation (attacking radical *p*-$NO_2C_6H_4$, 20 °C);[113] *21*) ditto (*p*-$MeC_6H_4^{\cdot}$);[113] *22*) ditto ($Ph^{\cdot}$).[113]

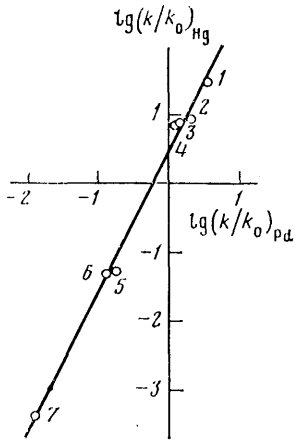
It is of interest to compare the palladisation of arenes with their mercuration. It is generally accepted that the mercuration of ArH, at least in polar media, is a type of electrophilic substitution[90]. The palladisation and mercuration of arenes are characterised by a profound similarity of the mechanisms, which is confirmed by the clear-cut correlation between their rates (Fig.3).[24] Both reactions proceed in conformity with the kinetic equation (8) and have a powerful primary isotope effect[107,109,115]. The rate and selectivity of mercuration increase following the addition of $HClO_4$,[109,115] which indicates the compensation of the polar influence of the substituents. The effect of compensation is weaker than in the palladisation of arenes, because it does not lead to the reversal of the mode of substitution. This is apparently due to a weaker $d\pi-p\pi$ bonding in the π-$ArH.HgX_2$ complex as a consequence of the lower energy of the *d* electrons of mercury(II) compared with palladium(II).



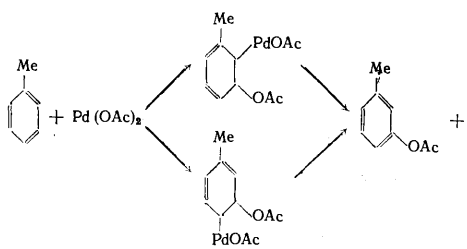


Figure 3. Relation between the rates of palladisation and mercuration of arenes in acetic acid in the presence of $HClO_4$: *1*) *o*-xylene; *2*) PhMe; *3*) PhEt; *4*) iso-PrPh; *5*) PhCl; *6*) PhBr; *7*) $PhNO_2$.[24]

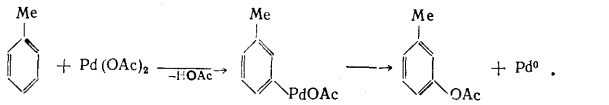
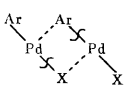
The thallation of arenes probably has a similar mechanism[112,114,116]. The ratio k_H/k_D = 3.7 has been found for the reaction of $Tl(CF_3COO)_3$ with C_6H_6 and C_6D_6 in CF_3.$COOH$.[112] The electrophilic character of the metallation of arenes increases in the sequence Pd(II) < Hg(II) < Tl(III) (the corresponding values of *p* are −2.2,[24] −5.3,[115] and −7.5 [112]).



An anomalous selectivity has also been observed in the acetoxylation[51,64,89] and nitration[48,68] of arenes in the ring under the influence of palladium(II), but this phenomenon has not been attributed to electrophilic substitution in ArH. The reaction of arenes with $Pd(NO_3)_2$ in acetic acid at 90 °C involves simultaneous acetoxylation (ρ = −1.2) and nitration (ρ = −1.4). MeC_6H_4OAc and $MeC_6H_4NO_2$ with the relative proportions of isomers *meta* > *para* have been obtained from toluene. In the presence of a strong acid (Cl_3CCOOH) the acetoxylation is suppressed and the normal relative isomeric composition (*para* > *meta*) is restored for nitration, as in the oxidative coupling of arenes[68].

In order to account for the anomalous selectivity in the acetoxylation reaction, a mechanism involving the acetoxypalladisation of ArH has been proposed[51,64,89]:

(14)



However, from the above considerations, the mechanism involving electrophilic substitution and reductive elimination is more probable for these reactions. For example, we have for *meta*-acetoxylation:

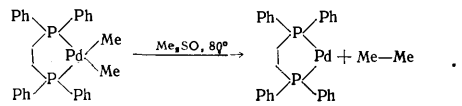
This mechanism provides a good explanation of the acceleration of the ring acetoxylation of arenes in the presence of strong oxidants[14], since they facilitate the reductive elimination from ArPdOAc as a result of the increase of the effective positive charge on the palladium atom.

It is remarkable that the hypothesis of the influence of the $d\pi-p\pi$ bonding in the arene complexes of palladium(II) on the selectivity in the coupling of arenes was already put forward in a pioneer investigation[1]. Similar ideas have received wide currency for the reactions of olefins catalysed by metal complexes[117,118]. However, the picture for the reactions of olefins is complicated as a result of the superposition on the compensation effect of the steric influence of substituents acting in the same direction. In the palladisation of arenes, the steric effects play no role for *meta*- and *para*-substitution. The conclusion that the polar influence is compensated therefore appears more justified. The unusual nature of this phenomenon from the standpoint of the general treatment of electrophilic aromatic substitution must be emphasised[90]. The use of the compensation effect to control the selectivity in the palladisation of arenes is of practical interest.

(e) *The symmetrisation of ArPdX.* The symmetrisation of ArPdX [Eqn.(9)] probably proceeds via a mechanism involving the synchronous dissociation of old bonds and the formation of new bonds in the transition state[16]

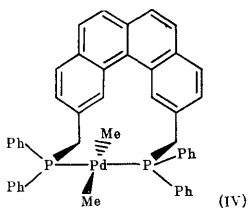
(III)

This mechanism has been proposed for the symmetrisation of stable aryl and alkyl derivatives of metals, for example ArHgX.[119]



Information about reaction (9) has been obtained by analysing the distribution of aryl groups in the arene coupling products[16,88]. By analogy with the symmetrisation of ArHgX, the preferential formation of the asymmetric biaryls Ar–Ar' as a result of the synergistic effect of the Ar groups of different polarity in the transition state (III) is to be expected in the interaction of ArPdX and Ar'PdX.[119] In reality the distribution of the Ar groups in biaryls is usually close to the statistical distribution. Only in the case of very powerful directing groups ($ArNO_2$, the 2- and 3-positions in thiophen) are asymmetric biaryls formed preferentially[16,88]. This can be explained by the compensation of the polar influence of the substituents in the transition state (III) as a result of the $d\pi-p\pi$ interaction of palladium(II) with the Ar groups[88].

The distribution of the aryl groups in biaryls has been put forward as a justification of reaction (12).[22] However, in reality the available data[22] indicate a statistical distribution of the Ar groups with the exception of the coupling of nitrobenzene, for which the synergistic effect indicated above takes place[88].

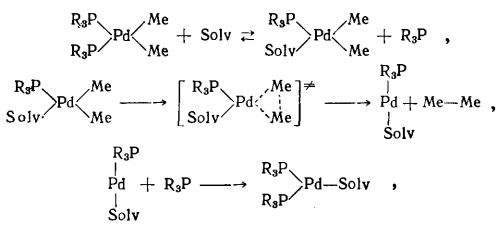


(f) *Reductive elimination.* Considerable advances have been made recently in the understanding of the mechanism of the reductive elimination of hydrocarbons from σ-diorganopalladium(II) in reactions of dialkyl and diaryl compounds of palladium(II), stabilised by phosphine ligands, taking place at a measureable rate[92–95]. These compounds are usually obtained by the oxidative addition of organic halogeno-derivatives to zerovalent palladium or by an exchange reaction:

$$ArX + Pd(PPh_3)_4 \rightarrow ArPdX(PPh_3)_2 + 2PPh_3 ,$$
$$PdCl_2(PPh_3)_2 + 2MeLi \rightarrow Me_2Pd(PPh_3)_2 + 2LiCl .$$

It has been established that palladium(II) complexes containing organic groups in the *cis*-position undergo reductive elimination[95]:

The complexes *trans*-$Me_2Pd(PPh_3)_2$ and *trans*-$Me_2Pd.(PPh_2Me)_2$ undergo the reductive elimination of ethane only after isomerisation to the *cis*-derivatives, which can be clearly observed by ^1H and ^{31}P NMR.[95] On the other hand, the complex (IV), which cannot isomerise, is stable as regards the elimination reaction.



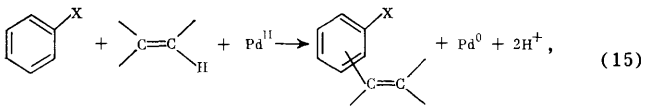
(IV)

Polar solvents [dimethyl sulphoxide (DMSO), dimethylformamide (DMF), and tetrahydrofuran (THF)] promote the elimination reaction in contrast to non-polar solvents (benzene and tetrachloroethane). The same may be said about the oxidative coupling of arenes under the influence of palladium(II). A polar solvent facilitates both *cis–trans* isomerisation of diorganopalladium(II) and the reductive elimination from *cis*-complexes [the latter via the substitution of σ-donor phosphine ligands in the coordination sphere of palladium(II), which results in an increase of the effective positive charge on the palladium ion].

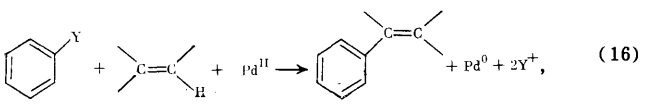
The reductive elimination proceeds as an intramolecular process. This is clearly indicated by the absence of a redistribution of deuterium in the competing reaction

and by the first order of the elimination reaction with respect to diorganopalladium(II). The addition of phosphine ligands inhibits the reaction, which indicates its dissociative mechanism[95]:

where Solv is a solvent molecule.



The reductive elimination is greatly accelerated in the presence of organic halogeno-derivatives capable of undergoing the oxidative addition reaction ($PhCH_2Br$, MeI, etc.). It has been suggested that in this case the elimination proceeds via palladium(IV) compounds[93–95].

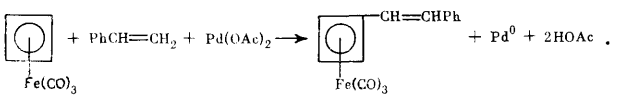


The absence of free radicals in the reductive elimination is confirmed by the retention of optical activity in α-deuteroethylbenzene obtained by the reaction of the optically active α-deuterobenzyl bromide with *cis*-$Me_2Pd(PPh_3)_2$.[93]

III. THE ARYLATION OF OLEFINS

1. General Considerations

The reaction involving the coupling of arenes with olefins, also referred to as the arylation of olefins, can be represented by the equations



(15)

(16)

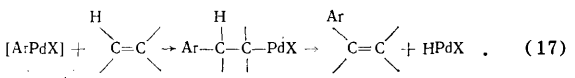
which are analogous to Eqns.(2) and (3). Here X and Y are in the main the same substituents as in reactions (2) and (3).[8,9,25,120] Reaction (15) is much faster than reaction (2) and reaction (16) is much faster than reaction (3). In the presence of olefins, biaryls are apparently hardly formed. The arylation reaction (15) is usually carried out in the presence of $Pd(OAc)_2$ in solution in acetic acid or in an arene at about 100 °C, ArH being introduced in excess relative to the olefin and palladium(II).[9] As in the coupling of arenes, reaction (16) takes place under milder conditions and more selectively than reaction (15).[25] Very effective methods have been developed using aryl derivatives of mercury(II).[25,121-123] The arylation of olefins by organosilicon compounds is promising[7].

Soluble copper(II) [25,121-124] and silver(I) [2] salts, heteropolyacids,[125] and O_2 [126] are used as oxidants in the catalytic coupling. Platinum metals on carbon are known as heterogeneous catalysts of the gas-phase arylation of ethylene[127].

The arylation of olefins is characterised by a high yield of products and a notable universality with respect to arenes and olefins. The coupling reaction takes place with aromatic carbocyclic[8,9,25] and heterocyclic[9,124,128] compounds, metallocenes[44], etc. Coordinated cyclobutadiene reacts[129,130]:

Olefins from C_2 upwards[9], cyclo-olefins[131], butadiene[123,132], alkenyl derivatives with the substituents Ar, Cl, Br, OAc, CN,[9] NO_2,[133] OR, OCOR,[122] and CH_2OH,[121] styrene, and norbornadiene in their complexes with palladium(II) [9,134], and other compounds[135,136] undergo the reaction. Acetylenes enter into an analogous reaction with formation of arylacetylenes[137].

Substituents at the double bond lower the reactivity of the olefin. In arylation by arylmercury(II) in the presence of $PdCl_2$ and $CuCl_2$ at 20 °C, the reactivity of the olefins decreases in the following sequence: ethylene (14000) > methyl acrylate (970) > propene (220) > styrene (42) > 1-methylstyrene (1).[25] The reaction is accompanied by the isomerisation with respect to the position of the double bond[25,131]. The arylation of methylolefins takes place both at the double bond of the olefin and in the allyl position[15,136].

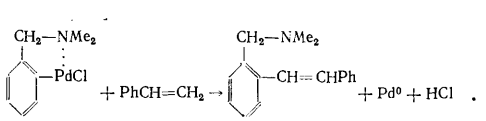


In the arylation of olefins containing an electronegative substituent (for example, a halogen) in the allyl position, aromatic allyl-substituted compounds are formed and the reaction proceeds catalytically with respect to palladium(II).[121] The arylation of olefins has a high stereoselectivity[138].

The phenylation of ethylene by benzene has been investigated as a possible method of synthesis of styrene[126,139-141]. The reaction takes place catalytically in the presence of $Pd(OAc)_2$ in benzene at 80 °C and an O_2 pressure of 10 atm.[126] However, owing to its low selectivity, it has no advantages over the traditional method of synthesis of styrene.

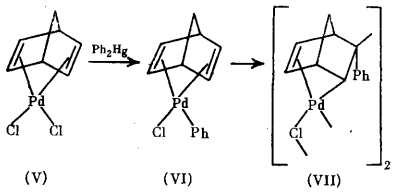
The selectivity in the coupling of arenes with olefins is determined by the competition with side reactions involving the oxidation, acetoxylation, and oxidative dimerisation (coupling) of olefins[126,141]. Reaction (16) of the aryl derivatives of mercury(II), tin(IV), and lead(IV) in the presence of $CuCl_2$ is accompanied by the formation of organochlorine compounds[142].

2. The Mechanism of the Coupling of Arenes with Olefins



The coupling of arenes with olefins proceeds via the π–σ rearrangement of the arene and olefin π-complexes of palladium(II). Several mechanisms of the arylation of olefins have been proposed[9,10,85]. The mechanism involving the arylpalladisation of olefins and the subsequent β-elimination of palladium hydride is most thoroughly justified[10,130,134,143-149]:

(17)



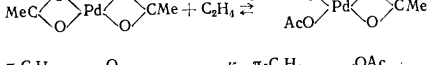
As in the coupling of arenes, the active intermediate ArPdX is formed via the electrophilic substitution in ArH, which is the rate-limiting stage of the reaction.

The arylation of olefins is accelerated by electron-donating and retarded by electron-accepting substituents in ArH. Like the coupling of arenes, the reaction has a low substrate and positional selectivity with respect to the arene as a consequence of the compensation of the electronic influence of the substituents. Thus $\lg f_p = 0.48$, $\lg (f_p/f_m) = 0.33$,[141] and $\rho = -1.4$ [130] for the reaction of toluene with styrene under the influence of palladium(II) acetate. This is consistent with the arylation of olefins via palladised ArH. At the same time the activation of palladium(II) by the olefin plays a major role in the arylation of olefins because the rate of arylation is higher by several orders of magnitude than the rate of coupling of arenes to give biaryls[85].

The involvement of ArPdX as an intermediate has been confirmed by the arylation of styrene by the palladium(II) complex of benzyldimethylamine, which has a C–Pd σ-bond:[146]

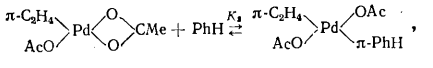
Stereochemical studies have shown that the arylpalladisation is in fact *cis*-addition[134,147]. Thus the phenylation of dichloro-η^4-norbornadienepalladium(II) by Ph_2Hg and $NaBPh_4$ in solution in CH_2Cl_2 or acetone at 20 °C gives rise to the *endo*-addition product (VII) in 79% yield:

(V) (VI) (VII)



The structure of compound (VII) has been established by ^{1}H NMR and X-ray diffraction. It is suggested that the complex (VI) is an intermediate in the phenylation of compound (V); it has been possible to isolate its stable platinum analogue[134].

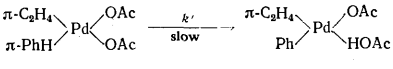
The *cis*-addition of ArPdX to the double bond of the olefin is controlled to a greater extent by steric factors than electronic factors[143]. The compensation of the electronic effects of the substituents in the olefin in its π-complex with ArPdX prior to the arylpalladisation reaction (17) probably plays an appreciable role in this process. A large organic group usually adds contrary to the Markovnikov rule, to the least substituted carbon atom involved in the double bond, while palladium(II) adds to the most substituted carbon atom. Thus the phenylation of propene by PhHgOAc in the presence of palladium(II) acetate in acetic acid yields 70% of 1-phenylprop-1-ene, 14% of allylbenzene, and 16% of 1-methylstyrene, i.e. the ratio of the yields of the products of the addition of PhPdOAc to the terminal and inner carbon atoms of propene is 5.3.[143] A similar result was obtained in the phenylation of propene by benzene[141].



The phenylation of olefins (Ol) under the influence of the monomeric $Pd(OAc)_2$ complexes in benzene proceeds in accordance with the kinetic equation

$$W = k\,[Pd(OAc)_2]\,[Ol]\,[PhH]\ . \qquad (18)$$

For the reactions of ethylene and styrene, the values of $k[PhH] \times 10^3$ are respectively 2.2 and 0.196 $mol^{-1}\ s^{-1}$ at 95 °C. For the reaction of ethylene, E = 68.7 kJ mol^{-1}.[141,145] The phenylation of styrene and ethylene by benzene and deuterobenzene-d_6 is characterised by the kinetic isotope effect k_H/k_D = 5.0; for the reaction of C_2D_4 and styrene-β,β-d_2 with benzene, k_H/k_D = 1.2. The isotope effects in the reaction rates and products are the same[141,144,145]. Taking into account these data, the mechanism of the arylation of olefins by the monomeric $Pd(OAc)_2$ in benzene has been represented as follows[144,145]:



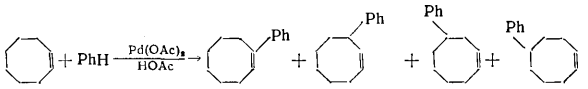
(19)

(20)

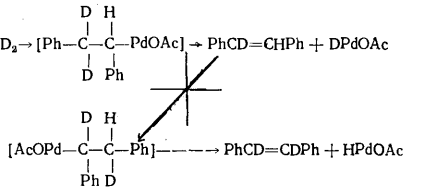
(21)

(22)

(23)



(24)



(25)

Stages (19)–(21) involve rapid equilibration. The coordination of the olefin facilitates the partial substitution of the bidentate acetate ion in the *trans*-position by an arene molecule as a consequence of the strong *trans*-effect of the olefin. The isomerisation [reaction (21)] to the favourable *cis*-configuration can proceed via the five-coordinated intermediate as a result of the addition of a second phH molecule[74,75] or with participation of the bidentate acetate ion. The rate-limiting stage (22), analogous to reaction (13), involves the π–σ rearrangement of the arene in the coordination sphere of palladium(II). It is irreversible because there is no H–D exchange between ArH and the solvent in the arylation of olefins[144]. There is a probability of proton transfer to the ligand in the reaction in benzene; in more basic media, the solvent may be the proton acceptor (see above). Since the introduction of additional π ligands into the coordination sphere of the metal ion promotes the π–σ rearrangement as a result of the destabilisation of the existing π ligands[19], the higher rate of arylation of olefins compared with the coupling of arenes to biaryls becomes understandable[141]. The *cis*-arylpalladisation stage (23) is apparently rapid and irreversible. In the general case the β-elimination reaction (24) is fast and reversible[131,143], as shown by the isomerisation of the products of the arylation of cyclo-olefins via the repeated addition-elimination of palladium hydride[131]:

However, in the arylation of styrene stage (24) is almost irreversible, which is confirmed by the absence of a hydride shift in the reaction of styrene-β,β-d_2:[128,148]

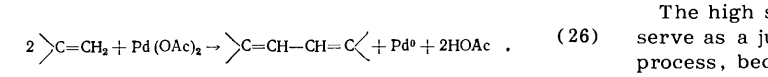
The kinetic equation

$$W = \frac{k'K_1K_2K_3\,[Pd(OAc)_2]\,[Ol]\,[PhH]}{1 + K_1[Ol]\,\{1 + K_2[PhH]\,(1 + K_3)\}}\ ,$$

which is the same as Eqn.(18) for $K_1[Ol]\{1 + K_2[PhH].(1 + K_3)\} \ll 1$, where $k = k'K_1K_2K_3$, follows from reactions (19)–(25).[141,145] The olefin activity series obtained C_2H_4 > $PhCH=CH_2$ [141,145] is consistent with the sequence of the stabilities of the π-complexes of olefins with palladium(II) acetate[76].

The trimer $Pd_3(OAc)_6$ and the dimer $Na_2Pd_2(OAc)_6$ are active in the arylation of olefins in acetic acid[85]. The kinetics of the arylation of olefins in acetic acid under the conditions of the association of palladium(II) acetate are more complex than the kinetics of the reaction with monomeric $Pd(OAc)_2$ in benzene and depend significantly on the nature of the arylating agent. The phenylation of styrene by benzene in acetic acid is of zero order with respect to the olefin and of first and 0.5 order with respect to the palladium(II) acetate dimer and trimer respectively. The dependence of the rate on the concentration of PhH is consistent with the Michaelis equation, which indicates the formation of π-arene complexes of palladium(II). The arylation of styrene by naphthalene and PhHgOAc proceeds via two parallel pathways of zero and first order with respect to the olefin. In order to account for these data, a mechanism involving the oxidative addition of ArH to palladium(II) has been proposed at the rate-limiting stage[85,150]. However, one cannot rule out the possibility that the process may be limited by the dissociation of polymeric palladium(II) species under the influence of ArH to give more active monomeric palladium(II) complexes.

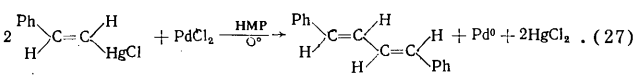
It is of interest that the arylation of olefins can be carried out with participation of σ-vinyl complexes of palladium(II):[9]



However, this mechanism has no general importance. This is demonstrated by data concerning the oxidative dimerisation of α-olefins to 1,3-dienes which proceeds via σ-vinyl derivatives of palladium(II) (see below). Since ethylene and linear olefins do not enter into this reaction, there is no reason to assume that their arylation proceeds via σ-vinylpalladium(II) compounds. Furthermore, the stage involving the substitution of the vinyl hydrogen atom by palladium(II) should be partily reversible, since it precedes the rate-limiting stage in which ArH is palladised. However, this is inconsistent with the absence of H–D exchange between olefins and the solvent under the conditions of the arylation reaction[128,148].

IV. THE OXIDATIVE COUPLING OF OLEFINS

1. Conditions and Products of the Reaction

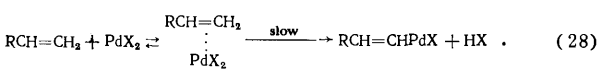


The coupling of olefins (another commonly used term is oxidative dimerisation) takes place in solutions of palladium(II) salts, usually $Pd(OAc)_2$, with formation of derivatives of 1,3-dienes:[3,151,152]

(26)

Olefins substituted at the double bond, for example, styrene, 1-methylstyrene, 1,1-diphenylethylene, vinyl acetate, etc., undergo this reaction[151,152]. Ethylene, the β-unbranched olefins $R-CH_2-CH=CH_2$, and β-chloroolefins are inactive. The coupling is exclusively of the "head to head" type, i.e. a C–C bond involving the least substituted carbon atoms of the double bonds is formed[152].

Alkenylmercury(II) derivatives, obtained by the addition of mercury(II) salts to acetylenes, undergo stereospecific coupling under the influence of $PdCl_2$:[153]



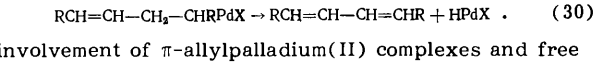
(27)

In the presence of copper(II) and iron(III) salts[154] or oxygen[126], reaction (26) takes place catalytically. Both homogeneous[126] and heterogeneous[155,156] catalysts based on palladium compounds are known.

The oxidation and acetoxylation of olefins[3,126,141] as well as their non-oxidative dimerisation[5] compete with the coupling of olefins. In the presence of arenes, olefins are arylated[141].

2. The Mechanism of the Coupling of Olefins

The available experimental data can be generalised within the framework of the hypothesis that the oxidative coupling of olefins proceeds via a slow π–σ transformation stage with formation of vinylpalladium(II) derivatives[5,10,14,157]:



(28)

Next, as in the non-oxidative dimerisation of olefins[117,158], rapid insertion of the olefin in the C–Pd bond and β-elimination of palladium hydride take place[5,10,157]:

(29)

(30)

The involvement of π-allylpalladium(II) complexes and free radicals is ruled out in view of the high selectivity of the "head to head" coupling and the retention of deuterium in the products of the coupling of 1-methyl-d_3-styrene:[152]

A disproportionation reaction, analogous to the sum of reactions (9) and (10) for the coupling of arenes, has been proposed as a second pathway leading to the formation of the C–C bond[10,14,157]:

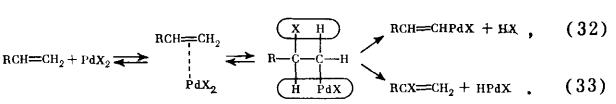
(31)

Reaction (27) of vinylmercury(II) derivatives confirms the possibility of such a pathway. However, stage (29) is more probable in the coupling of olefins. It should be fairly rapid, because it is an analogue of the chain propagation stage in the Ziegler–Natta polymerisation[117,158]. The occurrence of reaction (29) is promoted by the condition $[RCH=CHPdX] \ll [RCH=CH_2]$. An example of the faster insertion of an olefin in the C–Pd bond compared with the disproportionation of the σ-organopalladium(II) may be provided by the arylation of olefins, since biaryls are hardly formed in this reaction. The involvement of stage (29) in the coupling of olefins is also confirmed by the formation of non-oxidative dimerisation side products[5,141].

The high selectivity of the "head to head" coupling cannot serve as a justification of the involvement of stage (31) in the process, because, as mentioned above, the insertion of olefins in the C–Pd bond is subject to rigid steric control[138,143]. Furthermore, examples are known of non-oxidative "head to head" dimerisation of olefins catalysed by palladium(II) complexes with nearly 100% selectivity[158].

The mechanism (28)–(30) has been confirmed by kinetic data. Polymeric forms of palladium(II) acetate are active in the oxidative dimerisation of styrene in acetic acid: $Pd_3(OAc)_6 > Na_2Pd_2(OAc)_6 \gg Na_2Pd(OAc)_4$. The reaction is of first order with respect to the palladium(II) acetate dimer and trimer and in the latter case also of first order with respect to the olefin[157]. The formation of fairly stable π-complexes $Na_2Pd_2(OAc)_5(Ol)$ in a system containing $Na_2Pd_2(OAc)_6$ has been demonstrated by kinetic and spectroscopic methods[76,157].

The detailed mechanism of the π–σ reaction (28) has not been elucidated. The reaction is irreversible, because the products of the oxidative dimerisation of olefins in DOAc do not contain deuterium[152]. It has been suggested that the vinylpalladium(II) derivative is formed via the acetoxylation of the olefin and subsequent oxidative addition of alkenyl acetate to zerovalent palladium[5]:



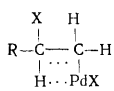
A scheme has been proposed for the direct electrophilic substitution of vinyl hydrogen by palladium(II), by analogy with the palladisation of arenes[14,157]:

However, such a reaction is uncharacteristic of olefins.

The electrophilic substitution of vinyl hydrogen via an addition–elimination mechanism is more probable[141]:

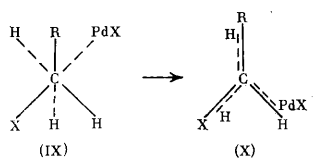
(32)

(33)



(VIII)

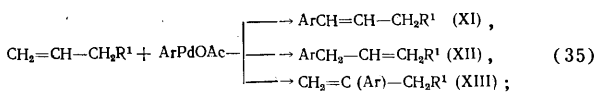
This mechanism agrees well both with oxidative dimerisation data and with the general ideas concerning the reactivity of olefins. The addition of PdX_2 in accordance with the Markovnikov rule leads to the coupling of olefins; otherwise, acetoxylation takes place. The probability of the latter is evidently smaller for β-disubstituted olefins as a consequence of the concerted steric and electronic influence of substituents in the olefin. β-Unbranched olefins are inactive in oxidative dimerisation, probably as a consequence of their acetoxylation in the allyl position and the formation of inert π-allyl-palladium(II) complexes. β-Chloro-olefins are apparently preferentially acetoxylated via the elimination of palladium chloride.



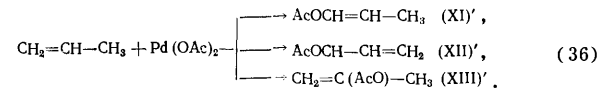
The addition of palladium(II) to olefins is reversible. This is indicated by the catalysis by palladium(II) compounds of reactions such as the transesterification of vinyl esters of carboxylic acids[159], the isotope exchange of chloride ions between $Li^{36}Cl$ and vinyl chloride[160], the isomerisation of *trans*-ethylene-1,2-d_2,[161] etc. The acetoxypalladisation of olefins in acetic acid solution proceeds via the *trans*-attack on the olefin by a solvent molecule[14].

The elimination from the intermediate (VIII) takes place via the two competing reactions (32) and (33). Reaction (32), which leads to the formation of vinyl-palladium(II), belongs to the class of the well known olefin 1,2-elimination processes in which the mode of substitution and the effects of substituents have been investigated in detail[90]. For X = OAc, the 1,2-elimination of olefins usually proceeds via a bimolecular E2 mechanism involving the synchronous removal of X^- and proton transfer to a base, which may be a nucleophilic solvent[90]. The influence of the substituent R on the rate of reaction (32) is determined by its inductive and mesomeric effects; steric effects do not usually play a significant role. The introduction of alkyl substituents in the α-position relative to X accelerates reaction (32). The effect of α-aryl substituents is much stronger; they promote reaction (32) as a result of conjugation with the double bond formed in the transition state[90].

The β-elimination of palladium hydride [reaction (33)] probably takes place intramolecularly via a cyclic transition state[117]:



The activation process apparently involves the transition of the system from a more stable inhibited conformation, for example, of type (IX), to the eclipsed conformation (X):



(34)

(IX) (X)

The mode of substitution and the effect of substituents in the β-elimination of palladium(II) hydride have been hardly investigated although they are undoubtedly of great interest. Certain conclusions can be reached from data concerning the products of the reactions involving the arylation and acetoxylation of olefins considered below, which have been studied in detail under conditions which rule out the migration of the double bond[78,138,143]:

(35)

(36)

The ratio of the products (XI) and (XII) [and correspondingly (XI)′ and (XII)′] yields information about the influence of the nature of the substituents in the β-position relative to palladium(II) on the mode of β-elimination of HPdOAc:

(XI) (XII)

These data are presented in Table 2. In the first place it is seen that the polar influence of the substituents on the β-elimination of HPdX agrees with the fact that in this reaction hydrogen is split off from the carbon atom in the form of the hydride ion and palladium is split off in the form of XPd^+. Thus electron-accepting substituents hinder the abstraction of an α-hydrogen atom, while electron-donating substituents facilitate it [cf. R^1 = OAc or CN and R^2 = Ph, R^1 = H and R^2 = *p*-$MeOC_6H_4$, Ph, or *p*-$AcOC_6H_4$, and R^1 = H or n-Pr and R^2 = Ph in reaction (35)]. In these series the steric effects of the substituents R^1 and R^2 are either of the same order of magnitude or do not change when the substituents are varied. The data for reaction (36) permit the same conclusion, although here the role of the steric factors may prove to be more significant. This is indicated by the dependence of the yields of the products (XI)′ and (XII)′ on the sodium acetate concentration, which determines the degree of association of palladium(II) acetate (see Section II, Subsection 2). The mode of elimination of palladium hydride is influenced by both the inductive and mesomeric effects of the substituent. The aryl group promotes the formation of a double bond which is conjugated with it. The directing effect of the aryl group is much stronger than that of the alkyl group (see R^1 = n-Pr, R^2 = Ph).

Table 2. The mode of β-elimination of palladium hydride in olefin arylation and acetoxylation reactions under the influence of palladium(II) acetate.

Reaction*	R^1	R^2	Relative contents, %		
			XI, (XI),	XII, (XII),	XIII, (XIII),
(35)	H	*p*-$MeOC_6H_4$	53	4	43
(35)	H	Ph	62	12	26
(35)	H	*p*-$AcOC_6H_4$	58	18	24
(35)	n-Pr	Ph	47	7	18
(35)	CN	Ph	45	0	0
(35)	OAc	Ph	94	0	5
(36)	H	OAc	2	2	96
(36) **	H	OAc	0.5	13	86.5
(36) ***	H	OAc	3	71	26
(36) ****	H	OAc	<0.5	94	2

*Reaction (35)—in acetonitrile at 20–30 °C;[138] reaction (36)—in acetic acid at 25 °C.[78] The reactions were carried out in the absence of chloride ions; there is then no migration of the double bond.

**[NaOAc] = 0.098 M.

***[NaOAc] = 0.49 M.

****[NaOAc] = 0.90 M.

It follows from the foregoing that the electronic effect of the substituent R acts in the same direction on reactions (32) and (33) and apparently does not affect their competition.

However, the steric effect of R differentiates these reactions. As already mentioned, the steric factor usually does not play a significant role in reaction (32). On the other hand, in the β-elimination of HPdX the rate of the activated process (34) depends greatly on the bulk of the substituent R. For bulky substituents, for example Ar, the formation of the eclipsed conformation (X) is difficult and reaction (32), leading ultimately to the olefin coupling products, therefore take place preferentially. For β-disubstituted olefins, reaction (33) is altogether ruled out. Thus the addition–elimination mechanism (32) and (33) is fully consistent with the experimental data on the coupling of olefins.

In conclusion one should note that the oxidative coupling reactions of unsaturated hydrocarbons under the influence of palladium(II) compounds have common fundamental elements in their mechanisms. They all proceed via a sequence of $\pi-\sigma$ reactions in the coordination sphere of palladium(II) and include the electrophilic substitution of hydrogen by palladium(II) at a trigonal carbon atom as the rate-limiting stage. The intermediate $d\pi-p\pi$ binding of palladium(II) as a "soft" acid to "soft" bases (arenes of olefins) plays an important role in these reactions. As a result of this, the mode of palladisation of the substrate is inconsistent in many instances with the traditional ideas concerning the ratio of the electronic and steric factors in reactions of unsaturated hydrocarbons with electrophiles. This phenomenon is of significant interest for metal complex catalysis as a method of controlling the selectivity of reactions and merits detailed study.

Steric Aspects of the Formation of Metal Chelate Complexes

V.G.Dashevskii, A.P.Baranov, and M.I.Kabachnik

The geometrical and thermodynamic aspects of the formation of complexes between metal cations and organic ligands are examined theoretically from the standpoint of conformational analysis. Particular attention has been devoted to the problem of the selectivity of the complex formation, which is of practical importance. It is shown that the selectivity of complex formation is largely determined by the steric factor. The advantages and disadvantages of the available methods for the quantitative allowance for the steric factor as well as methods of calculation of the structure of coordination compounds are analysed.
The bibliography includes 105 references.

I. INTRODUCTION

The problems of the stability of metal complexes and the selectivity of complex formation are of central importance in coordination chemistry, particularly in the chemistry of complexones and extractants. Universal complexones, which are capable of binding effectively to the majority of cations in solution (in a specific pH range), have been synthesised on the basis of iminodiacetic, ethylenediaminetetra-acetic, and a number of other acids[1-3]. By virtue of their flexibility and multidentate nature, the molecules of these acids can form complexes with cations of different size. However, much more attention has been devoted recently to the synthesis of highly selective reagents capable of the selective chelation of specific cations. Numerous applications are associated with the synthesis of such reagents: in atomic industry and hydrometallurgy (extraction and separation of rare metals and radioactive isotopes), in medicine and pharmacology (the elimination from the organism of harmful metals, particularly radioactive metals, and the introduction into the organism of the essential metals—for example, iron in iron-deficiency anaemia), and in chemical industry and catalysis (the formation of complexes with a specified steric structure and with a specified stability in a particular medium).

The free energy of the binding of the metal to the ligand under specified external conditions (solvent, temperature, etc.) depends both on the metal–donor centre bond energy and on the steric structure of the ligand. In many instances of practical importance the variations in the metal–ligand donor centre bond energy are either small or are comparatively easy to take into account quantitatively. The most important factor determining the selectivity of the ligand therefore becomes its steric structure (conformation).

This review is devoted to the consideration of the influence of the ligand conformation on the selectivity of the complex formation and also of the methods for the theoretical study of the conformational possibilities and the steric structure of metal complexes. Its aim consists in summarising the hitherto few investigations in this field and in assessing the likely usefulness of the theoretical approaches to the prediction of the structures of ligands exhibiting a specified selectivity with respect to particular metal cations.

II. THE STERIC FACTOR IN COMPLEX FORMATION

1. Thermodynamic and Geometrical Conditions Governing Complex Formation in Solution

We shall consider initially certain questions of the thermodynamics of complex formation[4]. Bearing in mind that the reactions take place in solution, we can write

$$M_s^+ + L_s \rightleftarrows (ML')_s \qquad (1)$$

where M^+ is the metal cation, L the ligand, and (ML') the complex formed; the prime denotes that, as a result of its interaction with the cation, the ligand can undergo a change in its conformation, while the subscript s denotes the solvated state. In the general case L can have an integral coefficient; in addition, one cannot rule out the possibility of the addition of several different ligands to the cation.

Eqn.(1) can be given the following simple significance: the formation of the complex is equivalent to the replacement of the solvation shell and the new shell of the cation consists of the ligand molecules, which are in their turn solvated. When the free energy ΔF of the forward process in reaction (1) is negative, the equilibrium is displaced to the right, i.e. the formation of the complex is favoured by free energy factors; on the other hand, if $\Delta F > 0$, the equilibrium is displaced to the left.

In order to consider reaction (1) further, we shall divide it into several hypothetical elementary processes whose thermodynamics can be investigated in principle:

$$M_s^+ \rightleftarrows M^+, \qquad (I)$$

$$L_s \rightleftarrows L, \qquad (II)$$

$$L \rightleftarrows L', \qquad (III)$$

$$M^+ + L' \rightleftarrows (ML'), \qquad (IV)$$

$$(ML') \rightleftarrows (ML')_s. \qquad (V)$$

Processes (I) and (II) correspond to the desolvation of the cation and the ligand and are accompanied by a considerable increase of the free energy of the system ($\Delta F_1 > 0$ and $\Delta F_2 > 0$; here and henceforth we speak of the free energies of the forward processes). Process (III) is also

energetically unfavourable, because generally speaking the ligand molecule must undergo a change in its conformation on approaching an ion having a particular radius†. The free energy gain in the first three stages is compensated by energy factors favouring the formation of coordinate bonds [process (IV)] and the solvation of the complex [process (V)]. Ultimately we have for the overall process

$$\Delta F = \sum_{i=1}^{5} \Delta F_i$$

and

$$K_M^{ML} = [ML]/[M]\cdot[L] = \exp(-\Delta F/RT) \quad .$$

If equilibrium (1) is displaced to the right, one can write

$$|\Delta F_4 + \Delta F_5| > |\Delta F_1 + \Delta F_2 + \Delta F_3| \quad .$$

It is significant that the hypothetical processes (III) and (IV) are gas-phase reactions. In the calculation of ΔF_3, one can therefore use the classical methods of conformational analysis based on the model of atom–atom potential functions[5] and the influence of the solvent can be disregarded. The greatest and approximately equal in absolute magnitude are the contributions ΔF_1 and ΔF_4, which amount to $\sim 10^2$–10^3 kJ mol^{-1} and have the opposite signs. Complex formation therefore resembles a replacement of the solvation shell of the cation when it is transferred from one solvent to another with a greater solvating capacity (for example, from alcohol to dimethylformamide).

A rigorous estimation of all the contributions to ΔF requires the knowledge of the potential surfaces of the interactions of the cations, ligands, and complexes with the solvent molecules and also of the cations and ligands with one another. However, even if one imagines that such surfaces have been obtained with the aid of non-empirical calculations, the extremely complex problem of the statistical-mechanical averaging of thermodynamic functions with respect to the microstates of the system still remains. Various approximate approaches, postulating certain relations between the contributions to ΔF for specific series of ligands and cations, are therefore of interest[4]. One can imagine a situation where such relations permit the calculation of the stability constants of the complexes K_M^{ML} solely on the basis of the calculated ΔF_3 (naturally a particular model of the solvation shell must be selected for this purpose[6]).

In considering the geometrical aspects of complex formation, one may isolate three different levels of theoretical studies, each of which yields useful information about the structure and energetics of coordination compounds.

1. The study of the geometrical stabilities of isolated ligands, i.e. their theoretical conformational analysis.
2. The search for the possible distribution of the ligand donor atoms on the sphere of the central ion.
3. The study of the interaction of atoms in the complex not linked by valence bonds: (a) in chelate rings; (b) between different rings (for example, in the case of two or three bidentate ligands); (c) between chelate rings and solvent molecules (with partial retention of the solvation shell).

†Complex formation is not always accompanied by an appreciable alteration of the ligand conformation; for example, there is a possibility of the capture of a metal cation on rupture of intermolecular hydrogen bonds without significant changes in various geometrical parameters of the ligand. However, even then, by taking into account the energy of hydrogen bonding, one may speak of a contribution ΔF_3.

We shall consider each of the levels enumerated. Theoretical conformational analysis of the ligand makes it possible to discover, in principle, whether the given ligand forms a ring with the metal ion and which ions are preferable in this sense. In a macrocyclic complex one can investigate the question of the minimum and maximum sizes of the cavity. Ligands whose potential surfaces are characterised by a deep minimum corresponding to the conformer capable of binding ions with a specific radius are evidently highly selective. The selectivity of such systems is associated with the rigidity of the ligand.

If the rigidity of a bidentate ligand is defined in terms of the distance between the donor atoms, then the shorter the range within which this distance varies, the more effective the "approach" or "its failure" to the "claws" by an ion having the specified radius. This is illustrated in Fig.1, where $R_{L\ldots L}$ denotes the distance between the donor atom and the ligand calculated theoretically, l the length of the coordinate bond, and θ the LML angle. For alkali metal ions, the bond length l has been shown by experimental data to be approximately equal to the sum of the van der Waals radius of the donor atom and the crystal-chemical radius of the ion; for other metals, particularly transition metals, this bond is in general somewhat shorter (to a first approximation, its length can be assumed equal to the sum of the covalent radii of the metal and the donor atom) and can be obtained from crystal-chemical data.

It is readily seen that

$$R_{L\ldots L} = 2l\sin(\theta/2) \qquad (2)$$

or, if it is assumed that $l = R_0 + R_M$ (where R_0 and R_M are the van der Waals and crystal-chemical radii), which is usually the case for ionic bonds, we obtain

$$R_M = R_{L\ldots L}/2\ \sin(\theta/2) - R_0 \ . \qquad (3)$$

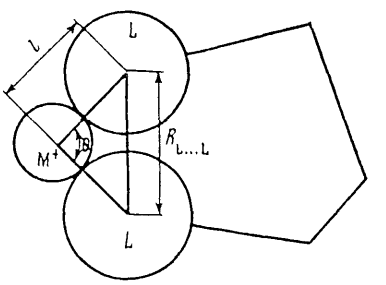

Figure 1. Schematic illustration of the formation of a chelate ring.

Eqn.(3) shows that even an absolutely rigid ligand does not determine the radius of the metal ion unambiguously; the angle θ is also significant. For octahedral or square coordination, the values of θ are close to 90°. However, it is also necessary to take into account the possibility of the deformation of θ (according to X-ray diffraction data for metal complexes, the experimental θ are in the range from 75° to 95°). If only one bidentate ligand is involved in the complex formation and the remaining sites in the octahedron (which is generally speaking distorted) are occupied by the

donor atoms of the solvent molecules, then θ should approach 90°. This happens also in the square coordination; in tetrahedral coordination the angle θ is known to be close to 109°.

In the analysis of complex formation between polydentate (in particularly macrocyclic) ligands and metal cations, the scheme in Fig.1 is unsuitable and a more detailed approach is necessary. In this instance it is apparently essential to find the optimum position of the cation by minimising the sum $\sum_i (l_i - l_0)^2$ (where l_i are the calculated cation–donor atom distances and l_0 is the "ideal" length of the coordinate bond). If the sum remains fairly large after minimisation, then the formation of a complex is not favoured. Naturally, the optimisation procedure must be carried out for each conformation of the macroring corresponding to a fairly low energy.

The approach to the analysis of the complex formation geometry examined above is not of course the only one possible. Thus, in the chemistry of metal complexes having monodentate phosphorus ligands, the "steric parameter" θ, equal to the solid angle formed by the van der Waals spheres of different substituents at the phosphorus atom, is widely used[7]. If the Stewart–Briegleb models of ligands such as $P(OCH_2)_3CMe$, PMe_3, $P(OPh)_3$, PPH_3, P(cyclohexyl)$_3$, and P(t-Bu)$_3$ are assembled, it becomes clear that the solid angle diminishes in this series (in the case of the asymmetric ligand $PX_1X_2X_3$ the parameter θ is defined as the sum of the contributions θ_i of each X_i). Consequently the ability of phosphorus-containing ligands to form complexes with metals must fall within the above series, which is in fact observed experimentally. However, it is difficult to assess the energetics of the complex formation on the basis of the steric parameter θ.

In the next level of theoretical studies of the steric structure of coordination compounds, one can consider the interaction of the donor atoms of ligands on the sphere of the central ion (see Section IV). For this purpose, one may employ the approach, developed by Kepert[8,9], which resembles the familiar Gillespie–Nyholm "points on a sphere" theory[10] and in our case the points are not electron pairs as in Gillespie's book[10] but the donor atoms of the ligands, whose positions on the sphere of the central ion are optimised. The optimum structure of the complex and the relative stabilities of the different coordination polyhedra must evidently depend on the radius of the ion, the size of the donor atoms (or the adjacent polyatomic groups), and the number of binding sites of the ligand. Calculations within the framework of the models for the interaction of donor atoms considered below permit, firstly, the prediction of the type of polyhedron for the given coordination compound and, secondly, the selection of the starting point for the minimisation of the energy of the complex.

In the third level of investigations, as in the first, the calculations are performed within the framework of the model of the atom–atom potential functions, but here one takes into account not only the interactions within the chelate rings but also the "intermolecular" interactions between them and the interactions with the solvent molecules involved in the coordination. Conformational studies on complexes of certain transition metals with alkylenediamines and some aminoacids, which belong to the third level within the framework of the scheme considered here, have been frequently carried out by different investigators (see, in particular, the careful review by Hawkins[11]). However, the problem of the logical analysis of the steric effects with determination of the principal factors governing the stability of the complexes in solution was apparently formulated only a few years ago[4].

2. Methods for the Calculation of the Conformational Energy and Entropy of Ligands

We shall consider the problem of the conformational analysis of isolated ligands. The task is to calculate the energy as a function of independent geometrical parameters, i.e. to obtain the potential surface and to find on the latter the energy minima corresponding to stable conformers. Such information can be provided, in principle, by quantum-chemical methods—both non-empirical and semi-empirical. Taking into account the fact that the potential surfaces of metal complexes with organic ligands as well as the surfaces of the ligands themselves are multidimensional and "have many extrema", one of the requirements which must be met by the method for their investigation is a not unduly long time for machine computation of the energy. This requirement is satisfied most effectively by the method of atom–atom potential functions (AAPF) and it is not surprising that this is in fact used in the vast majority of calculations. According to the AAPF method, the energy of the molecule is represented by the sum of the contributions of non-valence, torsional, and electrostatic interactions as well as the energy of the deformation of the valence bonds and angles:

$$U_{\text{non-}\sigma} + U_{\text{tors}} + U_{\text{el}} + U_{\text{bond}} + U_{\text{angle}} \ .$$

The parameters of the potential functions have been discussed in a series of reviews[5,12–15], in particular the parametrisation for the calculations of the conformations of metal complexes has been examined[11,15]. We shall therefore consider only certain features associated with the application of the AAPF method to the conformational analysis of complexes and ligands.

As regards the parameters of the potentials of the non-valence interactions (the Lennard-Jones or Buckingham potential), the spectra of their values used by different workers are so broad that, within the framework of this review, we are unable to discuss this question in any detail. Thus modified Hill potentials[19] (p.529) have been used in the pioneer studies of Gollogly and Hawkins[16–18], who were the first to estimate the conformational energies of chelate rings. De Hayes and Busch[20,21], who calculated the conformations of five- and six-membered rings in compounds of the type M(L)Cl$_4$, where M is the metal atom [cobalt(III)] and L is ethylenediamine, trimethylenediamine, etc., using Allinger's parametrisation[22,23]. Niketić and Woldbye[24,25], who investigated trisdiamine complexes of cobalt(III), used two sets of constants for the Buckingham (6-exp) potential—those of Liquori and coworkers[26,27] and Ramachandran et al.[28]—and showed that both sets lead to approximately identical results. Finally the potentials of Scott and Scheraga[29] or Dashevskii[30,31] are most often used in the conformational analysis of peptide and depsipeptide macrocyclic complexes. We may note that all the sets of parameters of the atom–atom potentials are concerted (with the possible exception of the Liquori potential) and give rise to a good accuracy of the calculation of the conformational energies. The only important feature is that these potentials should be applied together with the corresponding sets of angular and torsional constants, since otherwise the calculation can lead to serious errors (for example, the use of the Allinger potentials requires the neglect of the 1...3 interactions and the use of spectroscopic constants for the valence angles).

The choice of the energy barrier U_0 in the expressions for the torsional potentials involves certain difficulties. Whereas the majority of investigators agree on the value $U_0 \cong 10$–12 kJ mol^{-1} for saturated C–C bonds, the values

of U_0 adopted by different investigators for bonds with a nitrogen atom and in particular for the Co–N bond in classical ethylenediamine complexes diverge significantly. It is therefore necessary to investigate the question of the influence of the uncertainty in the form of the torsional potential and in the value of U_0 on the principal calculated results, for example, on the calculated relative stabilities of the conformers. This is also true of the electrostatic component of the potential energy function (although the majority of workers who have calculated the conformations of the classical complexes were able to disregard it). The errors introduced by this component are associated with the uncertainty in the choice of parameters (the charges and the value of ε, present in the denominator of the expression for Coulomb's law and defined as the effective dielectric constant of the medium).

In the conformational analysis of ligands, the deformation energies of the valence angles and bonds can be neglected in most cases. However, when chelate rings are considered, these terms of the potential function are significant. Without taking into account the deformations of the valence angles, it is hardly possible to predict correctly the geometries and relative stabilities of different spatial isomers of involved complexes with two or three chelate rings. An important variable is also the length of the coordinate bond l. The analysis of the results of the X-ray diffraction of numerous octahedral complexes leads to the conclusion that the lengths l are minimum when $\theta = 90°$ (see Fig.1); on the other hand, when the angles θ are distorted, the increase in the length of the coordinate bond can actually exceed 0.01 nm.

The search for the optimum (or simply the stable) conformation of the complex involves the minimisation of the potential energy with respect to independent geometrical parameters, which is carried out for a specified zeroth approximation. Buckingham and coworkers[15], Busch[20], and certain other investigators have used in their calculations Boyd's program[32] based on the Newton–Raphson method and requiring the calculation of second derivatives. The advantage of this program consists in the fact that, simultaneously with the choice of direction of the one-dimensional descent, the computer yields information also about the normal vibration frequencies. In a number of other studies[24,25] the potential energy minimisation procedure was based on Wiberg's algorithm[33], the idea of which consists in selecting the direction of descent on the basis of first derivatives; the independent geometrical parameters are then the cartesian coordinates of the atoms. From our point of view, neither algorithm is entirely successful: the first requires a large amount of calculations in order to obtain the second derivatives of the conformational energy with respect to independent parameters and the second converges much too slowly near the potential minimum (furthermore, when the cartesian coordinates of the atoms are chosen as the independent variables, the function is found to be relatively insensitive to the angles of rotation). The Fletcher–Powell and parallel tangent methods as well as certain others are more successful (they are discussed by Dashevskii[5]); they do not require the calculation of second derivatives but exhibit second order convergence.

The minimisation of the potential energy with respect to independent geometrical parameters leads to the optimum geometry of the isolated ligand and yields the energy E_0 corresponding to this geometry. On the other hand, if the minimisation is carried out for a fixed value of $R_{L\ldots L}$, it is possible to estimate the energy E' of the deformed ligand (the deformation is associated with the formation of a chelate ring) and to calculate $\Delta E_3 = E' - E_0$, i.e. the contribution of the potential energy to process (III). However, this is still insufficient to estimate the contribution ΔF_3, because the calculations based on the minimisation of the conformational energy do not take into account the entropy factor.

It is noteworthy that chelation is generally speaking unfavourable on entropic grounds (naturally if no account is taken of translational entropy), since it inevitably involves the loss of one or several degrees of freedom by the ligand. The magnitude of this effect naturally depends on the conformational freedom of the isolated ligand: if the formation of coordinate bonds leads to the generation of one of a multiplicity of the possible conformers which in addition has a wide probability distribution (the potential surface of the ligand has several minima and/or these minima are fairly broad), then the free energy gain on chelation may be so large that the entropy factor is in fact the main one in determining the stability of the given complex in a certain series; on the other hand, if the ligand is fairly rigid in the isolated state, then complex formation does not alter the entropy of the system seriously.

This factor has been noted by many workers[34–38], but the methods for taking into account the entropy remained for a long time far from perfection. The first semi-quantitative estimates of the entropy of chelation were made by Westheimer and Ingraham[39], who calculated the translational entropy on substitution of two monodentate ligands by a single bidentate ligand and also the entropy of cyclisation due to the "freezing out" of internal rotations. Their main result[39] reduces to the fact that the increase of translational entropy as a result of the liberation of two solvent molecules on binding only one ligand molecule is compensated by the decrease of entropy associated with the freezing out of the internal rotations in five- and six-membered rings. However, this compensation is not always complete.

Schwarzenbach[40,41] suggested that the entropy contribution is independent of the nature of the metal ion and of the binding ligand and found that the smallest free energy gain occurs on formation of small chelate rings—a five-membered ring for a saturated bidentate ligand and a six-membered ring for an unsaturated ligand. Hawkins[11] pointed out that elementary calculation of the entropy is possible within the framework of the simple model of a one-dimensional harmonic oscillator by the formula

$$S_\xi = \Delta E/T\,[\exp(-\Delta E/RT) - 1] - R\ln[1 - \exp(-\Delta E/RT)]\ ; \quad (4)$$

where $\Delta E = (2\pi c)^{-1}(K_\xi/\mu)^{1/2}$ is the spacing of the vibrational levels, K_ξ the force constant, μ the effective mass of the oscillator, and c the velocity of light.

A much more effective calculation of the entropy of chelate complexes has been carried out by De Hayes and Busch[20], who also used the harmonic approximation but took into account the entire set of interacting oscillators, having first estimated the frequencies and modes of the normal vibrations of the complex. [We may note that the above workers[20] did not calculate the entropy of the isolated ligands, because they were interested in the contributions of the entropy factor only to the relative stabilities of different spatial isomers of cobalt(III) complexes and not to the stabilities of the complexes themselves]. In the approximation adopted, the following relation is valid for the vibrational entropy of an N-atomic complex:

$$S_{vibr} = R\sum_{i=1}^{3N-6}\{(h\nu_i/kT)/[\exp(h\nu_i/kT) - 1] - \ln[1 - \exp(-h\nu_i/kT)]\}\ , \quad (5)$$

where ν_i are the frequencies of the normal vibrations, h is the Planck constant, and kT the Boltzmann factor.

The translational and rotational entropies can be readily calculated from the formulae[42]

$$S_t = R\left[\frac{3}{2}\ln M + \frac{5}{2}\ln T - \ln p - 3.664 + {}^5/_2\right], \quad (6)$$

$$S_{rot} = R\ln[8\pi^2(8\pi^2 ABC)^{1/2}(kT)^{3/2}/\sigma h^3] + {}^3/_2 R, \quad (7)$$

where M is the molecular weight, p the pressure, ABC the product of the moments of inertia, and σ the rotational symmetry number.

Eqns.(6) and (7) do not give rise to any uncertainties because with their aid the translational and rotational entropies can be calculated exactly. However, we believe that the use of Eqn.(5) is not entirely justified, since, firstly, the configuration entropy can differ very markedly from the vibrational entropy (for example, when there are several minima on the potential energy surface) and, secondly, the vibrations may be significantly anharmonic (the form of the potential well may be far from parabolic). The attempts at a more exact calculation of the contribution of configuration entropy to ΔF_3 are therefore of interest.

It is useful to employ for the estimation of the configuration entropy of the ligands the procedures which had been used previously in the conformational analysis of dipeptides and regular polypeptides[43,45]. We shall assume that the potential energy surface of the ligand is two-dimensional and that it can be represented by a conformational map. For the configuration integral, we can then write

$$Z = \frac{1}{4\pi^2}\int_0^{2\pi}\int_0^{2\pi}\exp(-U/RT)\,d\varphi_1 d\varphi_2, \quad (8)$$

where ϕ_1 and ϕ_2 are the angles of rotation, U is the conformational energy, which is a function of these angles, R the gas constant, and T the temperature.

Having at one's disposal a procedure for the calculation of the configuration integral Z, it is possible to determine the free energy:

$$F = -RT\ln Z \quad (9)$$

(we may note that, when the configuration integral is used, no account is taken of the contribution of the kinetic energy to the free energy of the system[45,46], although to a first approximation this contribution can be neglected), the average energy

$$\langle U\rangle = Z^{-1}\int_0^{2\pi}\int_0^{2\pi} U\exp(-U/RT)\,d\varphi_1 d\varphi_2, \quad (10)$$

and the entropy

$$S = \langle U\rangle/T - R\ln Z. \quad (11)$$

Practical calculations can be carried out by replacing integration by summation over a grid. For example, we have for the free energy

$$F = -RT\ln\sum_{\varphi_1}\sum_{\varphi_2}\exp[-U(\varphi_1,\varphi_2)/RT]\,s_0, \quad (12)$$

where s_0 is the area of the elementary square ($\Delta\phi_1$, $\Delta\phi_2$). Clearly the denser the grid of the values of ϕ_1 and ϕ_2, the greater the accuracy of the calculation of the thermodynamic functions. A completely adequate accuracy is as a rule attained using intervals of 5–10° in ϕ_1 and ϕ_2 (summation outside the limits of 20 kJ mol^{-1} contours is pointless, since the contribution of such energetically unfavourable conformers to F is extremely small).

Eqns.(8)–(12) do not take into account the influence of other degrees of freedom—valence angles and bonds. However, this influence is insignificant, since the main contribution to the configuration integral comes from the torsional degrees of freedom (in exactly the same way as the low-frequency vibrations determine almost completely the vibrational partition function).

The situation is more complex when the potential surface of the ligand (or the complex) is significantly multidimensional. In this case the calculation of a multidimensional integral of type (8) is best performed by the Monte Carlo method using one of the variants of the existing selection[47]. On the other hand, if the treatment is restricted to the harmonic approximation, equations of type (5) are valid for thermodynamic functions.

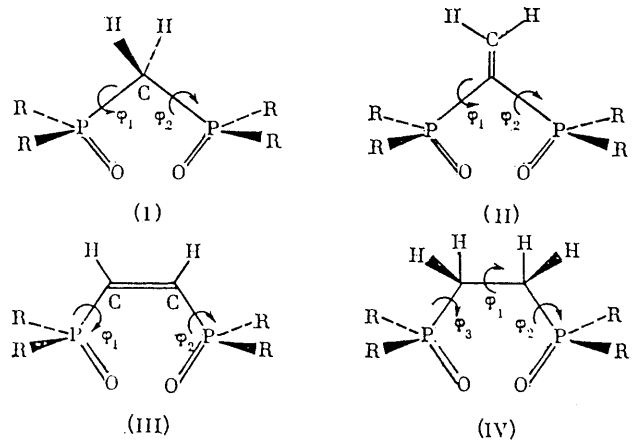

Figure 2. The valence angles and bond lengths in tetramethylmethylenediphosphine (I), tetramethylvinylidenediphosphine (II), tetramethylvinylenediphosphine (III), and tetramethylethylenediphosphine (IV) dioxides. The conformational angles are indicated by curved arrows.

The conformational entropy plays an important role in the determination of the stability of complexes of not only simple bidentate ligands but also complex polydentate ligands. The high complex-forming capacity of macrorings relative to the analogous linear systems is associated with this entropy. Thus the stability of the complex of the cyclic 18-crown-6 polyether with the K^+ ion is ~10^4 times higher than that of the analogous complex of pentaglyme $CH_3O(CH_2CH_2O)_5CH_3$, whose molecule also contains six ligand oxygen atoms[48,49]. This is in fact not surprising because the binding of the pentaglyme molecule to the ion requires the freezing out of several rotational degrees of freedom, whereas in the cyclic system certain degrees of freedom are frozen out (as a result of the ring closure conditions) even before complex formation (in the general case of an asymmetric ring the number of degrees of freedom frozen out, subject to the condition that the valence bonds and angles are fixed, is exactly six; it has been shown[50] that allowance for the ring symmetry decreases this number).

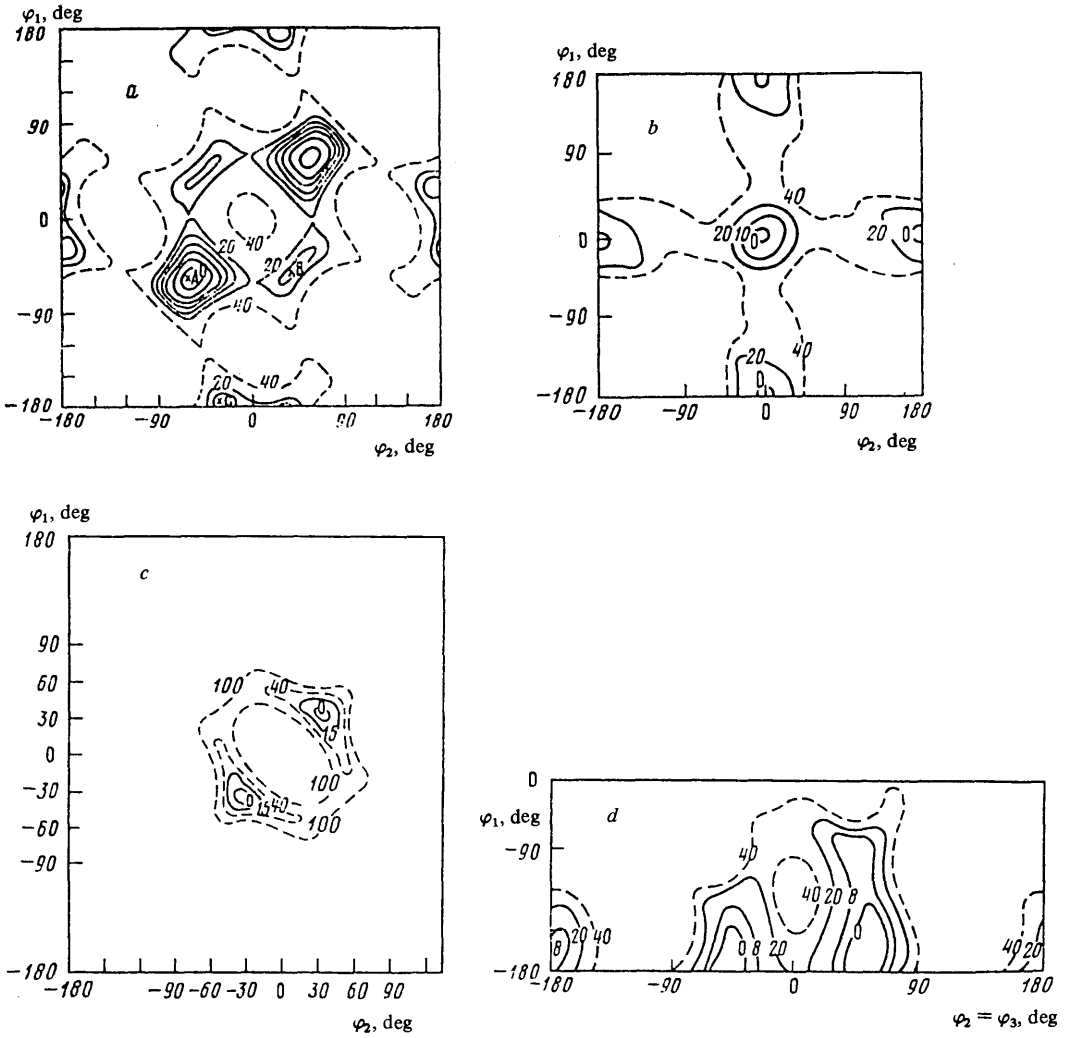

Figure 3. Maps of the conformational energies of ligands (I)–(IV) (*a*–*d* respectively) as a function of the angles of rotation ϕ_1 and ϕ_2. The numerals represent the energies in kJ mol^{-1}.

III. THEORETICAL CONFORMATIONAL ANALYSIS OF THE LIGANDS

1. Chelating Ligands

The considerations described in the previous Section show that the conformational analysis of the isolated ligands permits an approach to the estimation of the selectivity of the complex formation. In fact, if the regions of the conformational map of a rigid ligand corresponding to the required distance $R_{L\ldots L}$ are prohibited, then complex formation is impossible. Furthermore, if the ligand is not sufficiently rigid and the complex formation involves the loss of internal degrees of freedom, then the complex cannot be stable. The complexes formed by rigid ligands subject to the condition that the distance $R_{L\ldots L}$ corresponds to the energy minimum (it is best when this is a global minimum) of the isolated ligand are the most stable.

Taking into account the foregoing, we shall consider the conformational analysis and the estimation of the complex-forming capacities of several *cis*-diphosphine dioxides[51]— compounds which are believed to be highly selective extractants (the methods of synthesis of compounds of this series as well as the procedures used to study some of their properties have been described[52–55]). Although the most complete experimental data are available for the complex formation reactions of phosphine dioxides with various transition metals (many investigators[56–58] pointed out the major role of steric effects), we shall consider their interactions with alkali metal cations, which are characterised by large changes in the crystal-chemical ionic radii and hence in the steric requirements. Fig. 2 presents ligands whose conformations have been calculated within the framework of the model of atom–atom potential function[51,59]. Their choice is not fortuitous because, other conditions being equal, they contain alkylene bridges having different lengths and mobilities and connecting two functional groups. The

geometry of the molecules of compounds (I), (II), and (III) is determined by the internal rotation about the P–C bonds and only in the molecule of compound (IV) is there a possibility of additional rotation about the C–C bond.

Fig.3 presents the conformational maps of ligands (I)–(III) (*a*–*c*) plotted as a function of the angles of rotation ϕ_1 and ϕ_2 for fixed bond lengths and valence angles and also the cross-section of the potential surface of ligand (IV) at $\phi_1 = \phi_3$ (*d*). Fig.3*a* shows that there are three non-equivalent minima on the potential surface of ligand (I) corresponding to forms A, B and C (the first two of these have the C_2 and C_S symmetries respectively). Form A corresponds to the global energy minimum and form B represents an energy loss relative to the former of 15 kJ mol^{-1}. Form C has the open-chain (transoid) structure and is incapable of forming a chelate ring.

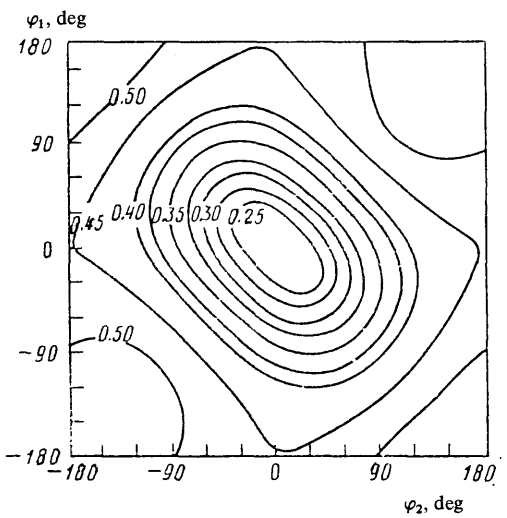

Figure 4. Dependence of the distance $R_{O...O}$ in tetramethylmethylenediphosphine dioxide on the angles of rotation ϕ_1 and ϕ_2 ("distances map"). The numerals opposite the isolines denote the distance in nm.[51]

In order to investigate the possibility of chelation, it is necessary to analyse the possible distances between the donor atoms of the ligand in order to reach conclusions on the basis of the scheme in Fig.1 concerning a suitable radius of the cation. The "distances map" of ligand (I) as a function of the same angles of rotation ϕ_1 and ϕ_2 is presented in Fig.4. If it is superimposed on the conformational map in Fig.3*a*, one can discover immediately which O...O distances correspond to regions with a low energy. It is found that in conformation A the functional groups rotate in such a way that the oxygen atoms are separated by a distance of ~0.45 nm, while in conformation B they approach one another to $R_{O...O} \cong 0.3$ nm. If we now estimate the radii of the alkali metal cations by Eqn.(3) (on the assumption that θ can vary from 75° to 95° and $R_O = 0.15$ nm), we obtain $R_M = 0.12–0.18$ nm and $R_M = 0.05–0.12$ nm for conformations A and B respectively. Thus ligand (I) can form chelate rings with all alkali metal cations and in the complex with Li^+ and Na^+ it must be in the B conformation, while in the complex with K^+, Rb^+, and Cs^+ it must be in the A conformation.

The considerations described show that ligand (I) does not exhibit a high selectivity. However, this does not imply that the constants for its binding to all the cations must be the same or similar. Firstly, there exist "natural" stability series which are independent of the steric factor. Thus it is believed[3] that, in terms of the strength of binding to specific ligands, the cations of alkali and alkaline earth metals as well as the elements of the first transition period can be arranged in the series $Li^+ > Na^+ \geq K^+ > Rb^+ > Cs^+$, $Mg^{2+} > Ca^{2+} > Sr^{2+} > Ba^{2+}$, and $Zn^{2+} > Cu^{2+} > Ni^{2+} \cong Co^{2+} > Fe^{2+} > Mn^{2+}$. Secondly, the appreciable deformations of the angle θ (up to 75–80° in the complex with Li^+, for example) are energetically unfavourable and lead to a lower stability of the complex. This factor is taken into account in the quasi-elastic model of the solvation shell whereby one can estimate roughly the stability constants of the complexes[6].

We shall now consider the conformational map of ligand (II) (Fig.3*b*). In contrast to the preceding case, here there are deep and narrow potential wells, i.e. the ligand is rigid and hence also selective. One of the minima at the centre of the map corresponds to the cisoid arrangement of the P=O bonds and an O...O distance of 0.28 nm [having carried out the same calculations as for (I), it is easy to show that ligand(II) should bind preferentially to the Li^+ and Na^+ ions]. The other minima are of no interest, since they correspond to the transoid disposition of the P=O bonds which precludes the formation of a chelate ring. We may note that the selectivity of ligand (II) can be significantly increased if the hydrogen atoms of the olefinic group are replaced by bulky groups or halogen atoms. The minimum at the centre of the map then begins to resemble a deep well and the rotations of the phosphoryl groups about the equilibrium positions are extremely limited.

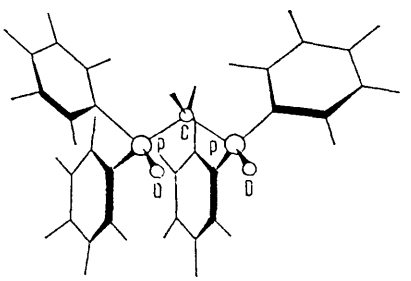

Figure 5. The optimum conformation of tetraphenylmethylenediphosphine dioxide with stacking interaction between the benzene rings[59].

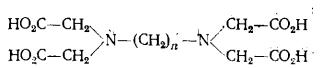
The map in Fig.3*c* shows that ligand (III) must be more selective than (I). It is significant that for this ligand only one conformation, with the C_2 symmetry, is stable while the conformation with a symmetry plane becomes unfavourable owing to the mutual approach of the oxygen atoms. As regards ligand (IV), its conformational map (Fig.3*d*) is very "free" and the ligand cannot therefore be selective. Furthermore, one should bear in mind that the formation of the chelate ring with participation of ligand (IV) must involve the freezing out of three degrees of freedom, which is clearly unfavourable from the standpoint of entropy. Therefore, if ligand (IV) binds an alkali metal cation, only one phosphoryl group is most likely to be involved in such binding.

The conformational calculations described show that, in terms of their selectivities, ligands (I)–(IV) can be arranged in the sequence (II*) > (III) > (II) > (I) > (IV), where (II*) is a halogeno-derivative of (II). Furthermore, having analysed the positions of the energy minima and the $R_{O...O}$ distances maps, one can indicate to which cations particular ligands can be bound.

Analogous conclusions can be reached also for diphosphine dioxides of types (I)–(IV) in which the substituents in the phosphoryl group are phenyl rings and not CH_3 groups[60]. The effective volume of the phenyl rings is not only not greater but actually somewhat smaller than the volume of the CH_3 groups, since they can become readily "adjusted" to the conformation of the main chain as a result of rotations about the P–C bonds. The conformational maps of the phenyl derivatives of compounds (I)–(IV) therefore differ little from the maps discussed above. The difference consists only in the fact that the energy minima are as a rule broader and the barriers are not quite so high. It has been noted[54, 61] that the phenyl-substituted compound with a methylene bridge [compound (I)] forms much more stable complexes with certain cations than the corresponding alkyl-substituted complexes and exhibits an enhanced extractability. Calculation showed that the reason for this "anomalous" behaviour of the compounds consist in the increased stability of the conformations with parallel benzene rings (Fig.5). Such conformation is stabilised by the dispersion interaction of the rings, to which corresponds an energy of ~5–10 kJ mol^{-1} (in the gas phase). The solvent, particularly if it is non-polar, naturally can decrease significantly the above quantity, because the interaction of the benzene rings with solvent molecules can compete with the stacking interaction between the rings; furthermore, a rigid conformation is entropically more favourable than the "mixed" conformation because it causes a lower degree of "structure formation" in the solvent. Nevertheless, in many instances the conformation with parallel benzene rings (the average distance between which is 0.34 nm) is preferred.

We shall now turn to experimental data for the stability constants of the complexes of phenyl-substituted ligands (I)–(IV) with alkali metal cations[62]. These data refer to ethanol–chloroform mixtures with equal proportions of the two components and, strictly speaking, correspond to the equilibrium constants K_{MA}^{ML}, where MA is the metal acetate, and not to K_{M}^{ML}. However, the latter factor is insignificant because the free energy of formation of compounds of type MA from the metal and acetate has been shown by measurements to be the same in all cases and the values of K_{MA}^{ML} presented below therefore differ from the relevant K_{M}^{ML} by the same constant amount. The stability constants of complexes of ligands (I)–(IV) with alkali metal ions are listed below:



Ion	Li^+	Na^+	K^+	Cs^+
(I)	56	42	20	12
(II)	400	300	—	—
(III)	400	100	40	25
(IV)	10	8	6	7

It is easily seen that the variation of selectivity in the sequence (I)–(IV) deduced by conformational calculations agrees with the experimental trend. Ligand (II), which forms stable complexes with cations of small radius and does not form complexes with large cations, exhibits the greatest selectivity. The least stable complexes are formed, in full agreement with calculated data, by ligand (IV) and it has been established experimentally that only one phosphoryl group participates in complex formation.

Naturally geometrical analysis permits only a qualitative estimation of the relative stabilities of complexes of a series of ligands and cations. In order to obtain quantitative estimates, it is necessary to resort to additional models. In particular, if certain assumptions are made concerning the contributions ΔF_i to the free energy of formation, it is assumed that the energy of deformation of the angle θ (Fig.1) is described by Hooke's law and, after adding together the Boltzmann exponential functions, calculations of the entropy change are made on the basis of conformational maps [see Eqns.(11) and (12)], it is possible to achieve a reasonable agreement between the calculated and experimental stability constants of the complexes[6].

The same principles of the analysis of the steric structure are apparently applicable to hundreds of other ligands synthesised, which are of completely different types, ranging from bidentate to hexadentate, and whose donor atoms may be not only oxygen but also nitrogen, sulphur, phosphorus, and arsenic (we deliberately do not consider in this review complexes containing carbon–metal π- and σ-bonds, because their formation is determined primarily by electronic effects which are usually treated on the basis of the molecular orbital theory). The experimental studies in this field have reached the state where it is possible to speak of the "construction" of ligands which are bound to specific metal ions (this has been specially emphasised in an excellent review[63]) and the task of conformational analysis should be to predict the structures of the ligands.

Conformational analysis, which makes it possible to estimate not only the internal energy but also the entropy of complex formation, can explain the decrease of the stability constants of metal complexes of tetracarboxylic acids of the type

when n varies from 2 to 5 (Schwarzenbach[40]) (the entropy factor associated with the freezing out of certain degrees of freedom on formation of the complex is of primary importance here), and can also account for the topological structure[63] of polydentate chelating agents, the detailed geometry and stability of their complexes with metals, and a whole series of other facts known in coordination chemistry. Since the theory lags far behind the requirements of the experiment in this instance, the sharp increase of the number of theoretical investigations in this field and the appearance of new ideas are to be expected in the foreseeable future.

2. Macrocyclic Complexones

Among macrocyclic complexones the following have become best known: (1) tetradentate chelating agents with strong conjugation throughout the ring and an exceptionally rigid structure in the free state (porphyrins, phthalocyanines, vitamin B_{12}, corrins, and as well as their derivatives and analogues); (2) membrano-active complexones of the peptide and pepsipeptide nature, whose important characteristic is a change in the conformation of the ligand when it is bound to the metal; (3) cyclic polyethers.

The selectivity of the rigid complexones of the first class is actually determined solely by the size of the cavity within the macroring[64]. As regards the relative stabilities of the complexes of a series of ligands with different substituents,

the latter are determined by electronic factors, since the substituents exert a strong influence on the conjugation in the ring.

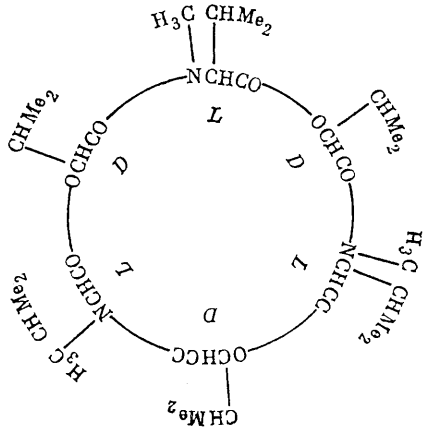


Figure 6. The structural formula of enniatin B.

Among compounds of the second class, there are membrano-active depsipeptide antibiotics such as valinomycin, enniatins, nonactin, antamanide, etc.[65]. The stability constants of the 1 : 1 complexes of three natural macrorings with the Na^+ and K^+ cations (in solution in ethanol) presented below show that the ligands exhibit an appreciable selectivity: two of these bind preferentially to the K^+ ions and one (antamanide) binds preferentially to Na^+ ions. Valinomycin exhibits a unique K/Na selectivity: in its presence the ratio of the K^+ and Na^+ fluxes through mitochondrial membranes is 10000 : 1:

Macroring	Enniatin B	Antamanide	Valinomycin
Na^+	1300	2800	50
K^+	3700	220	$26 \cdot 10^5$
References	[126–129]	[126, 130, 131]	[126, 129]

We shall consider the conformational analysis of the above compounds, which explains their high selectivity. It has been established experimentally that the molecule of enniatin B can assume two conformations depending on the polarity of the medium—the "non-polar" N and "polar" P conformations. Calculations of the conformations within the framework of the model of atom–atom potential functions[66] unambiguously predict these two structures and explain the extensive experimental data on enniatin B (infrared and Raman spectra, etc.).

The fragments of *N*-acetyl-*N*-methyl-L-valine and the dimethylamide of *O*-acetyl-*D*-hydroxyisovaleric acid, whose conformations are described by the angles of rotation ϕ and ψ about the $N-C^{\alpha}$ and $C^{\alpha}-C'$ bonds respectively, can be isolated as the structural units in the enniatin B molecule (Fig.6). Assuming that the ring has the C_{3v} symmetry and that the combination of two pairs of angles ϕ and ψ should lead to cyclic structures, it is possible to find two conformers corresponding to the energy minimum for the entire molecule: the conformer N, in which all the ester and carbonyl oxygen atoms are directed into the interior of the ring, and the conformer P in which they are all directed "outwards". Analysis of spatial models shows that the N conformer can readily bind to the K^+ ion and that a distorted octahedron made up of donor oxygen atoms is formed on the sphere of the central ion. The cavity in the N conformer is too large for the Na^+ ion, which leads to serious deformations of the macroring on binding. On the other hand, if the ions are too large compared with the cavity (Rb^+ or Cs^+), then it has been shown experimentally[65] (p.155) that sandwich structures with the 2 : 1 composition as well as 3 : 1 complexes are the most favourable.

Valinomycin is a 12-membered depsipeptide ring with 36 bonds in the main chain and an alternation of configurations of the type LLDDLLDD... There are in all 24 angles of rotation ϕ and ψ in valinomycin and it would seem, on the ground of general considerations, that less stable complexes are to be expected for this compound than for enniatin B. However, the stability constants quoted above show that this is by no means the case. The question arises of the reason for the anomalously high stability of valinomycin complexes with large cations.

An answer is provided to this question by the results of conformational calculations and the experimental data for both free valinomycin and its complexes. The search for stable conformations of valinomycin without any limitations is naturally associated with serious computational difficulties, because the potential surface has numerous extrema and simple sorting through the possible zeroth approximations would require far too long a machine computation time. Mayers and Urry[67], who carried out calculations within the framework of the model of atom–atom potential functions, therefore used the available experimental infrared and ultraviolet spectroscopic, NMR, optical rotary dispersion, and circular dichroism data for valinomycin and its complexes. They showed that valinomycin has an extremely limited set of low-energy conformations and that in non-polar solvents the "bracelet" form, stabilised by six intramolecular hydrogen bonds, is most favoured. In this form all the oxygen atoms which could, in principle, participate in complex formation are turned "outwards". Another form, also stabilised by siz hydrogen bonds but with the oxygen atoms directed "inwards" into the cavity, is less favourable according to the theoretical calculation (by 250 kJ mol^{-1}). All the remaining conformations correspond to the much more [part of Russian text missing (Ed.of Translation)].

The values presented are naturally too high because the authors[67] did not minimise the potential energy with respect to independent geometrical parameters. In fact, if the other forms possessed such a high energy, they could not have been detected experimentally. Furthermore, spectroscopic data demonstrate the existence of a whole series of forms of valinomycin stabilised by only three hydrogen bonds and also forms in which three oxygen atoms are directed "outwards" and three are directed "inwards", etc. (For a detailed discussion of the conformations of valinomycin and its analogues, see the monograph of Ovchinnikov et al.[65], pp.127–151).

Thus the exceptionally high stability of the complexes of valinomycin with large cations is apparently due to the conformational rigidity of the ligand. Despite the much smaller size of the enniatin B ring, the conformational freedom of its isolated molecule is much greater and its complexes are less stable owing to the decrease of the entropy of the system on complex formation. The selectivity of valinomycin as a complexone is determined by the consumption of the energy required for a deformation of the macroring which ensures a size of the cavity suitable for the given cation. Mayers and Urry[67] calculated the conformational energy of valinomycin as a function of the oxygen–metal distance and showed that the optimum binding should occur for K^+. Binding to a large cation (for example,

Cs^+) requires appreciable opening of the macroring, which entails an increase of the conformational energy. It is not therefore surprising that the stability constant of the valinomycin complex of Cs^+ (in solution in ethanol) is only 6.5×10^5 (compared with 2.6×10^6 for the complex with K^+).

Calculations of the geometry and energetics of certain other natural macrorings have been carried out at a higher level than in the study of Mayers and Urry[67]. The conformational calculation for nonactin[68], whose molecules selectively transfer K^+ ions through phospholipid layers and which contain 32 bonds in the main chain, is instructive. The first stage of the calculation consisted in the selection of the allowed regions of the conformational space by the hard sphere method. It was assumed that the molecule has the same symmetry S_4 as the corresponding chemical formula. Next the potential function was scanned with respect to five symmetrically independent conformational angles; for this purpose, 2×10^6 conformations, i.e. $(360/20)^5$, were examined overall, since the scanning for each angle was carried out at 20° intervals. After the minimisation of the potential function, only 7 conformations had energies within the limits of 21 kJ mol^{-1} and 39 had energies within the limits of 42 kJ mol^{-1} (if the energy of the global minimum is adopted as the zero point). It is noteworthy that all the energetically favourable conformers constitute a single family, i.e. they occupy a fairly narrow region of conformational space. The shape of the molecule then resembles a tennis ball in which there is an aperture compatible with the size of the K^+ ion. The detailed geometry of nonactin and its complex with K^+, found by Lee and Hamori[68], agrees extremely well with the results of X-ray diffraction analysis.

Another approach has been used to investigate the conformations of antamanide[69]—a macroring of approximately the same size as nonactin. Initially the antamanide molecule was subdivided[69] into fragments and low-energy conformers of the latter were selected, rejecting those which are clearly unfavourable; after this, the complete calculation was carried out taking into account all the degrees of freedom.

Synthetic polyethers of the type $(-CH_2-CH_2-O)_n$, for whose complexes with alkali metal cations numerous experimental stability constants, steric structures of the molecules, etc. are available [see, for example, Ovchinnikov et al.[65] (pp.64–78) and Refs.193–204], give rise to an interesting class of macrocyclic complexes. Theoretical studies of the conformations of these compounds and of the selectivity of their complex formation reactions so far lag behind the experimental investigations and our knowledge is limited to estimates of the dimensions of the cavities (carried out[48,70,71] by studying spatial models) and some quantum-chemical calculations[72–78]. The diameters of alkali metal cations are compared below with the dimensions of the cavity in the macroring D (the lowest value corresponds to the Corey–Pauling–Coltun model and the highest to the Fisher–Hirschfelder–Taylor model):

Cation	Li^+	Na^+	K^+	Cs^+
d, nm	0.136	0.194	0.266	0.334
Macroring	12-crown-4	15-crown-5	18-crown-6	21-crown-7
D, nm	0.12–0.15	0.17–0.22	0.26–0.32	0.34–0.43

(in the trivial names of the compounds the first numeral corresponds to the number of bonds in the macroring and the second to the number of oxygen atoms). On the basis of the data presented, the molecule of 12-crown-4 should bind more strongly to the Na^+ cation than to K^+; the following stability series should hold for the different polyethers: $Na^+ \cong K^+ > Cs^+$ for the 15-crown-5 polyether; $K^+ > Cs^+ > Na^+$ for the 18-crown-6 polyether; $Cs^+ > K^+$ for the 21-crown-7 polyether. These predictions are satisfactorily correlated with the experimental data for the stabilities of the complexes in solutions. However, in many instances certain deviations are observed, associated with the formation of sandwich structures (if the cation cannot be accommodated in the cavity, it is "clamped" between two macrorings, which results in a 2:1 "sandwich").

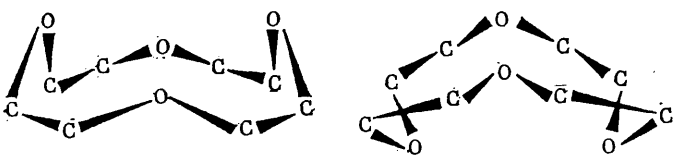

Figure 7. Schematic representation of the maxidentate (*a*) and alternate (*b*) conformations of the 12-crown-4 polyether.

We shall now consider quantum-chemical calculations of the conformations and on the energetics of the complex formation reactions of the crown ethers[72]. The conformational energies of the molecule of 12-crown-4 and the potential surfaces of the interaction of this molecule with the Li^+ ion have been calculated by the non-empirical self-consistent field LCAO-MO method in terms of the STO-3G basis. For an isolated molecule, the calculation was performed on the assumption that the C_4 symmetry (form M, maxidentate) or C_2 symmetry (form A, alternate) is retained with the standard bond lengths and valence angles (Fig.7). Subject to the limitations indicated, the only independent parameter determining the conformation of the macroring is the angle of rotation about the O–C bond χ; the remaining angles of rotation can be calculated from the symmetry and ring closure conditions.

The calculations made it possible to find the optimum value of χ for each conformer and showed that form A is more stable than form M (the energy of form A is lower by 16 kJ mol^{-1}). However, as a result of the interaction with the Li^+ ion, the maxidentate form is naturally preferable; here the equilibrium value of the angle χ in the Li^+ complex becomes different and depends on the distance d between the Li^+ ion and the centre of the molecule. Fig.8, which presents the dependence of the total energy of the system on the angle χ for three values of d, shows that the "expulsion" of the Li^+ ion to a certain distance from the plane of the macroring constitutes the optimum configuration and is apparently best when $d = 0.04$ nm. This factor as well as the deformation of the macroring on its interaction with the ion was not taken into account by Pedersen and Frensdorff[71] in their explanation of the selectivity of macrocyclic polyethers which they based on the analysis of spatial models. Nevertheless it can play a major role in complex formation (this is indicated also by data for the structure of the crystalline complex of 18-crown-6 with the Na^+ ion obtained by X-ray diffraction[79]).

It is noteworthy that the relative stabilities of the different conformers of macrocyclic polyethers predicted by calculation depend both on the method of calculation and on the parametrisation. For example, in contrast to the *ab initio* calculation examined, the CNDO/2 method predicts that form M of 12-crown-4 is favourable[76,78] and, according to Guzikevich et al.[78], the difference between energies of

forms A and M for this ether exceeds 100 kJ mol^{-1} (!). However, the CNDO/BW (Boyd–Whitehead) parametrisation leads to the conclusion that the stability of form A is higher[77]. One cannot rule out the possibility that calculations within the framework of the model of atom–atom potential functions will throw light on the problem of the relative stabilities of the conformers of crown ethers.

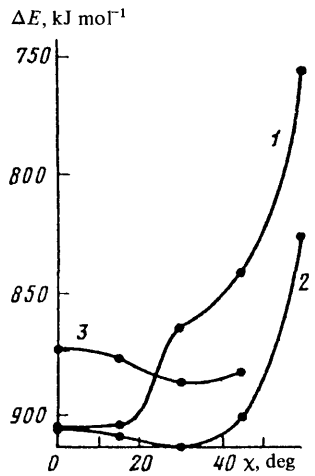

Figure 8. The energy of the interaction ΔE of the Li^+ ion with a molecule of 12-crown-4 in the conformation M as a function of χ for different values of d: *1*) 0; *2*) 0.4; *3*) 0.8.[73]

The examples examined show that both the structure of the spatial models and theoretical calculations of the conformations make it possible to explain the selectivity of natural and synthetic macrocycles with respect to specific alkali metal cations. However, for a quantitative prediction of the stabilities of the complexes, more detailed calculations are needed which take account not only of ΔE_3 corresponding to the change in the potential energy of the ligand, but also of the entropy of complex formation and of the influence of the solvent#.

IV. INTERLIGAND INTERACTIONS AND THE STERIC STRUCTURE OF COORDINATION COMPOUNDS

The steric structure of coordination compounds containing chelate rings and/or monodentate ligands is to a large extent determined by the interactions between the ligand atoms. Even if one considers simple cation–bidentate ligand complexes, these interactions also occur, because the vertices of the coordination polyhedron are occupied by the donor atoms of the solvent molecules.

The first attempt to analyse the disposition of the donor atoms on the sphere of the central ions was undertaken by Zemann[81], who examined the interaction of five point charges of the same sign on the basis of Coulomb's law.

#For the analysis of certain thermodynamic problems of chelation and macrocyclisation in solution, see Yatsimirskii[80].

Kepert[82–85] developed an approach based on allowing for the mutual repulsion of the donor atoms in the form $U_{ij} = ar_{ij}^{-n}$, where r_{ij} is the distance between atoms i and j, a a constant, and n the power exponent, which can assume values of 1 (Coulomb's law), 12 (repulsive component of the Lennard-Jones potential), or some other intermediate value (for example, 6). The energy of the complex is calculated from the formula $U = \Sigma U_{ij}$.

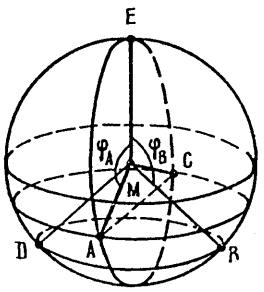

Figure 9. Schematic representation of a complex with five monodentate ligands. The metal cation M is in the centre of the sphere. The planes of the two cross-sections shown under the large circle are parallel by virtue of the pair equivalence of the ligands A, C and B, D.

We shall consider as an example the calculation of the geometry of a pentacoordinate compound with five monodentate ligands. If ligands A and C and also B and D are equivalent in pairs, the stereochemical structure of the complex can be expressed as a function of the two independent angles ϕ_A and ϕ_B (Fig.9). For $\phi_A = \phi_B$, the configuration of a tetragonal pyramid obtains; on the other hand, if $\phi_A = 90°$ and $\phi_B = 120°$ (or conversely), the configuration of a trigonal bipyramid arises.

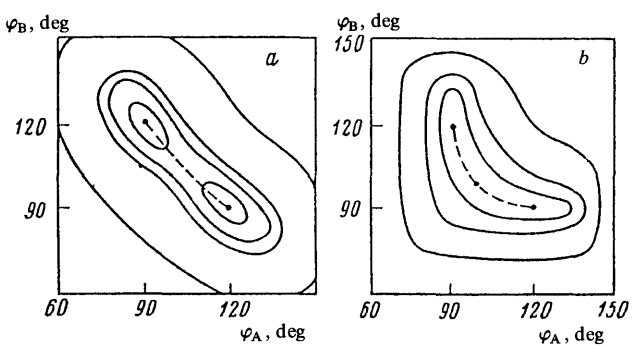

Figure 10. Contours on the potential surface (energies in relative units) of a compound M(monodentate)$_5$: *a*) for $n = 1$ in the formula of the potential $U = \sum_{i>j} \sum a r_{ij}^{-n}$; *b*) for $n = 12$.[87]

Fig.10 presents the potential surface of the coordination compound in terms of the parameters ϕ_A and ϕ_B. It is easily seen that, for $n = 1$ (i.e. when the Coulombic

repulsion of the donor atoms predominates), the trigonal bipyramid is energetically favourable, while the configuration of the tetragonal pyramid corresponds to the saddle point (Fig.10*a*). For $n = 12$ (when the repulsion of the electron shells of the atoms predominates), the last configuration becomes optimal. This calculation permits the conclusion that bulky ligands promote the appearance of the tetragonal pyramid, while ligands with residual charges on the donor atoms promote the trigonal bipyramid. However, Kepert did not reach this conclusion[82-85]. Instead he adopted the value $n = 6$, which ensured the best agreement with numerous and also extremely varied experimental data.

The value $n = 6$ found by Kepert lacks physical significance, since it corresponds to dispersion attraction with, however, the sign reversed. Examination of the interaction potentials of the donor atoms or ligands as a whole in the form of the sum of the terms with r^{-1} and r^{-12} is more realistic: if the coefficient of r^{-1} is much greater than the coefficient of r^{-12}, then Coulombic repulsion predominates; in the opposite case the geometry of the complex is determined mainly by the repulsion of the electron shells. Incidentally, there is altogether no need to employ terms with r^{-12}; the treatment can be based also on Kitaigorodskii's universal atom–atom potential[86], which depends only on the single parameter r_0. Then all calculations of this kind can be usefully performed for different values of the normalised bite of the donor atom r_0/l, (where l is the length of the coordinate bond) and for different charges on the donor atoms. In this case one other theoretical parameter has to be added (because a term of the type ar_{ij}^{-n} "is split" into two terms), but this formulation of the problem makes it possible to understand to what extent the geometry of coordination compounds is determined by electrostatic interactions and to what extent by steric hindrance.

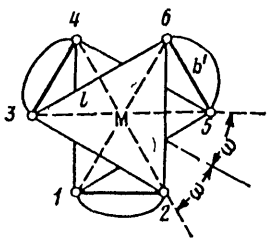

Figure 11. The view of a regular octahedron "from above". It can be represented as a prism whose upper and lower bases are rotated in opposite directions by the angle ω. The numerals denote the numbers of the donor atoms; b' is the distance between the donor atoms of one ligand.

It has been suggested[87] that a generalised dispersion-Coulombic potential, which is the sum of Kitaigorodskii's potential and the energy of the Coulombic interaction of point charges equal in magnitude, be used for the calculation of the relative stabilities of different polyhedra. The interligand interaction energy calculated with the aid of this potential is minimised on the basis of several zeroth approximations corresponding to the proposed steric structure. The possible equilibrium structures, which in the general case can differ from the ideal configuration (prism, octahedron, etc.) and determine the difference between the energies of different configurations, are then found.

The approach described has been applied to the study of the M(monodentate)$_5$, M(monodentate)$_6$, and tris(bidentate)M systems. We shall consider some results obtained[88] for the tris(bidentate)M system, which is represented conventionally in Fig.11 (the metal M is in the centre of a sphere on which the donor atoms of the ligands are distributed). It is easily seen that the configuration of the complex depends on the trigonal distortion angle ω: when $\omega = 30°$, the configuration of a regular octahedron arises and for $\omega = 0°$ that of a trigonal prism is produced; for intermediate values of the angle, the configuration is not highly symmetrical and it is usually classified as a distorted prism (it is assumed that, on distortion of the trigonal prism, both triangles shown in Fig.11 rotate by the angle ω in opposite directions relative to the "ideal" configuration with D_{3h} symmetry).

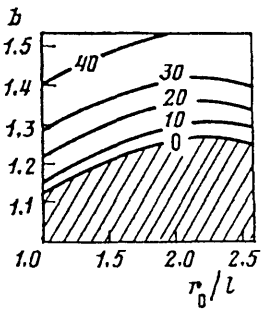

Figure 12. The equilibrium values of the trigonal distortion angle ω for different values of b and r_0/l ($q = 0.4\ e$). The isolines denote the values of the angle in degrees. The shaded regions correspond to the trigonal prism configuration[88].

The equilibrium structure of the complex must evidently be determined by purely geometrical factors (l and b', where b' is the distance between the donor atoms of a single ligand) and also by the potentials of the interaction of donor atoms (in principle, these should be the effective potentials of the interligand interaction). Calculations of the equilibrium structure were carried out for different values of the normalised bite of the ligand $b = b'/l$ and for different charges on the donor atoms ($q = 0.0\ e$, $0.1\ e$, $0.4\ e$, and $1.0\ e$) on the assumption that r_0(O...O) is 0.30 nm. Fig.12 presents a diagram indicating the equilibrium value of the trigonal distortion angle ω for different values of b and r_0/l and for $q = 0.4\ e$ (analogous diagrams were also constructed for other charges). The trigonal prism configuration corresponds to the shaded region. On the other hand, a considerable proportion of the diagram corresponds to distorted configurations—intermediate between the prism and the octahedron, a comparatively small region corresponding to the ideal octahedron ($\omega = 30°$) [in contrast to compounds of the type M(monodentate)$_6$ for which the octahedral configuration is preferred for all values of r_0/l except very low ones]. Analysis of various diagrams of this kind shows that, with increase of the charge q, the region of the stability of the trigonal prism diminishes.

On the basis of the data in Fig.12 (for $q = 0.4\ e$), we shall examine the results of the calculation of the trigonal distortion angle ω in relation to several fairly arbitrarily selected compounds (see Table). The Table shows that, despite a whole series of assumptions made in the model (for example, the assumption that all the donor atoms are distributed on

the sphere of the central ion), the agreement between the calculation and experiment is entirely satisfactory and not only for alkali and alkaline earth metal cations, whose binding is ionic, but also for transition metals, for which preferred directions of binding are frequently postulated. The points on a sphere model arises from the idea that in the ion itself there are no preferred directions and that, when they arise, this is solely due to the interaction of the ligands and their donor atoms. Whether or not this model conflicts with quantum-chemical results should be revealed by future investigations.

V. CONFORMATIONAL ANALYSIS OF CHELATE RINGS AND COMPLEXES

Calculations of the conformations of isolated ligands, whereby conclusions concerning the selectivity of the complex formation can be reached, were considered in Section III. Here we shall deal with analogous calculations for ligands bound to the metal cation by coordinate bonds. For classical ethylenediamine complexes (the $H_2NCH_2CH_2NH_2$ ligand), in which the chelate rings contain five bonds (of these two are coordinate bonds), conformational studies within the framework of the model of atom–atom potential functions were carried out by Gollogly and Hawkins[16–18,89,90]. The ideal angle θ (Fig.1) was assumed to be 90° and its deformation was described by the harmonic law with the elastic constant determined from spectroscopic data. As a result, it was shown that the five-membered ring can have two stable conformations (half-chair and envelope) and that whether or not a particular form is favourable is dictated by geometrical limitations: if the metal–donor atom bond length is less than 0.175 nm, the envelope form is preferred; for longer bonds, the half-chair form is usually realised.

The problem of the relative stabilities of the five- and six-membered chelate rings has been recently investigated[91,92], the authors having calculated the conformations of nickel(II) complexes with eight different ligands within the framework of the method of atom–atom potential functions. Among the ligands, ethylenediamine and diethylenetetramine could form five-membered rings, while 1,3-propylenediamine and dipropylenetriamine could give rise to the corresponding six-membered rings. It was found that the experimentally observed reduced stability of the six-membered rings may be fully attributed to steric strain and that the main contribution to the difference between the enthalpies of the five- and six-membered rings comes from the deformation of the valence angles and non-valence interactions.

Depending on the position of the substituent at the asymmetric carbon atom, *C*-substituted ethylenediamines can have two configurations—*R* and *S*. For each structural isomer, there is equilibrium between the λ- and δ-conformers (as shown for 1,2-diaminopropane in the *R*-configuration), in one of which (λ) the methyl group occupies the equatorial position and in the other (δ) the axial position. These conformers can be interconverted after overcoming a potential barrier whose magnitude is ~40 kJ mol^{-1} according to the measurements of the temperature dependence of the ^{13}C NMR spectra of complexes of diamines with cobalt, molybdenum, and tungsten[93].

However, not only the barrier but also the difference between the energies of the conformers is significant for complex formation. In an early pioneer study, Corey and Bailar[94] found that the λ-conformer is more stable by ~4 kJ mol^{-1}. Calculations by other workers[11], based on the minimisation of the potential energy, showed that this difference should be even smaller. According to estimates[20,21], the difference between the free energies ΔF of the axial and equatorial conformers (δ and λ for the *R*-isomer) depends mostly on the entropy contribution, which the authors[20,21] took into account within the framework of the harmonic approximation for interacting oscillators (see Section I). As a result, they obtained $\Delta F = 10$ kJ mol^{-1} and noted that allowance for the entropy leads in almost all cases to an increase of the free energy difference compared with the value of ΔE calculated by minimising the potential energy. Thus the potential well corresponding to the more "strained" δ-conformer is narrower.

Conformational analysis of the different *C*- and *N*-methyl- and dimethyl-substituted ethylenediamines as well as numerous six-membered chelate rings has been described in detail in a monograph[11]. The chair conformation of six-membered rings is the most stable; the twist-form is less favourable in almost all cases, but the presence of particular substituents can influence the difference between the energies of these forms. The problem of the stability of the axial and equatorial conformers of six-membered rings is in many respects similar to the analogous problem for substituted cyclohexanes and, since it has been thoroughly investigated, we shall not consider it.

However, we believe that the problem of parametrisation requires further study. All the workers who investigated the conformations of chelate rings assumed that the ideal value of α_0 (or the angle θ_0 if the scheme in Fig.1 is resorted to) should be 90°. Furthermore, from both the standpoint of quantum mechanics and general considerations, the presence of any preferred directions of binding at the metal atom appears doubtful. It is most likely that the angle α_0 (or θ_0) is dictated by the conditions of the environment of the metal atom (octahedral or square configuration of the metal cation) and the most direct method of taking into account the environment consists in the complete analysis of the interligand interactions on the basis of the model of atom–atom potentials. There is then no need to make any assumptions about the values of α_0 (θ_0) and the corresponding elastic constant *C*. On the other hand, in calculations on isolated chelate rings, α_0 and the constant *C* take into account implicitly the interaction of the ligand atoms with the solvent molecules, but in this approach *C* may vary on passing from compound to compound and from solvent to solvent.

In classical bistridentate complexes of cobalt(III) with ethylenediamine ligands, their derivatives, and aminoacids, the stabilities of different conformations of the chelate rings are determined in many respects by the interaction between the rings. The combination of λλλ conformations

is therefore not always energetically the most favourable. Calculations of the conformations of such complexes have been analysed in a review[15] (see also later publications[95-101]) and certain improvements to the method of calculation, consisting, in particular, in allowance for the symmetry of the complex and the conformational entropy of the ligands, have been described[102]. As a result of these improvements and also of the more accurate specification of the force field for certain fairly involved complexes, the theoretical structural parameters are almost exactly identical with X-ray diffraction data.

However, one should note that the calculation does not always yield unambiguous information about the most favourable structure. Niketič and Woldbye[24,25], who carried out exceptionally troublesome and laborious computer experiments in order to discover the possible conformers of trisdiamine complexes of cobalt(III) with three six-membered chelate rings and also similar complexes with dimethyl-substituted ligands, concluded that the situations where the potential surface contains several wells of comparable depth are typical. In solution there should therefore be equilibrium between several conformers and in the crystal (by virtue of the influence of intermolecular interactions) the most favourable conformer need not necessarily obtain. The predictions of the theory are fully unambiguous concerning the relative stabilities of the axial and equatorial conformers of different methyl-substituted derivatives and agree with experimental data.

Calculation of the relative stabilities of the conformers of involved complexes is most closely related to the problem of stereoselectivity[103]. Stereoselective reactions are understood to be those which result in the formation of two or several isomers of different chirality and one of these is present in the equilibrium mixture in a greater relative amount than the others, so that it becomes possible to isolate it by means of a series of technical procedures (in contrast to stereospecific reactions which lead to the formation of only one isomer).

The problem of stereoselectivity is too wide to be considered in the present review in any detail. We shall attempt to answer the question whether it is possible to predict theoretically the relative energies of isomeric complexes and to outline the procedures for the most effective stereoselective synthesis. In the first place one should note that the differences between the energies of the chelate rings formed by DD- and LD-ligands, for example, aminoacids, are extremely small, which is shown particularly by the results of calculations carried out by Hawkins[11] (the greatest energy difference is reached for the diastereoisomers of proline). Furthermore, the interaction with the solvent, which is usually disregarded in conformational calculations, plays a major role in determining the stability of the diastereoisomeric complexes. Finally, one must bear in mind that the intermediates formed in the reaction are not true transition states and that their energies can be regarded as proportional to the energies of the transition states only with some approximation.

Hawkins therefore viewed very pessimistically the possibility of a theoretical prediction of stereoselectivity. However, accurate conformational calculations carried out in recent years apparently have disproved this view. We may point out, in particular, studies[104,105] devoted to the conformational analysis of involved isomeric cobalt(III) complexes of glycine and alanine (the predicted[104,105] differences between the energies of the diastereoisomers were ~3–5 kJ mol^{-1}, which corresponded to a 60–80% yield of one of the isomeric forms); a satisfactory agreement with the available experimental data was achieved.

* * *

Summarising, we may note that the method of theoretical conformational analysis makes it possible to interpret and predict, on the basis of calculation of ΔF_3, the relative stabilities of metal complexes and the selectivities of the complex formation and that in many instances it is important to take into account the solvation shell, which can be done both in the continuum model and in an explicit form. In the latter case it is useful to make the calculation gradually more complex by considering in succession the conformations of the chelate ring and the interactions between the solvent molecules and/or the chelate rings. Since this problem involves many extrema when it is formulated in terms of the atom–atom approximation, the optimisation of the positions of the donor atoms on the sphere of the central ion constitutes an important auxiliary stage whereby one can find the possible zeroth approximation and predict the stereochemical configuration of the complex.

However, the calculation need not of course be carried out in this sequence in all cases. For example, the model of interacting points on a sphere has no direct bearing on complexes with macrocyclic ligands. Furthermore, in the general case certain aspects of the selectivity of complex formation can be understood simply on the basis of the conformational analysis of isolated ligands.

Theoretical studies of the stability of metal complexes and of the selectivity of complex formation are only just beginning and it must be supposed that in the near future new interesting results will be obtained in this field.

Heterometallic Ferrocene-based Transition Metal Compounds

P.N.Gaponik, A.I.Lesnikovich, and Yu.G.Orlik

The literature data on the synthesis, properties, and applications of ferrocene derivatives containing a *d* element or its inorganic and organic derivatives in the molecule are described systematically and surveyed.
The bibliography includes 293 references.

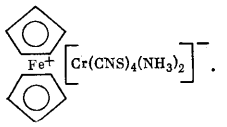
IV. Applications of heterometallic derivatives of ferrocene 177

I. INTRODUCTION

The practical applications of ferrocene and its derivatives have greatly expanded in recent times[1-4] primarily due to the successful development of synthetic studies on this extremely interesting class of compounds.

Among the wide variety of ferrocene derivatives, compounds containing in the molecule another transition metal, namely dinuclear and polynuclear heterometallic derivatives of ferrocene (HMF), occupy a special place. They have been investigated extremely vigorously in recent years. More than 300 compounds have been synthesised and extensive experimental data on their properties and practical applications have accumulated. It is noteworthy that the principal results for HMF have been obtained in the last ten years and as yet have not been adequately surveyed in the literature. The majority of the studies published up to 1970 are discussed in monographs[5-7]. Individual scattered data on HMF have also been published in annual reviews on ferrocene[8-19] and in Gmelin's handbooks[20-25]. A review devoted to ferrocene-containing metal complexes, in which these compounds have been formally classified on the basis of the nature of the heterometal, was published[26] in 1981. It covers up approximately one-third of the published literature but little attention is devoted to the chemistry of HMF, in particular its synthetic aspects.



The aim of the present review is to give a systematic account of the literature data, mainly on the synthesis and also on the properties and applications of HMF, and to classify the existing compounds. The generalisations made concerning the methods of synthesis of HMF can be used to develop procedures for the preparation of polynuclear compounds based on other organometallic compounds of transition metals. The literature up to 1980 inclusive and the majority of the publications in 1981 are covered.

II. TYPES OF HETEROMETALLIC DERIVATIVES OF FERROCENE AND METHODS OF THEIR SYNTHESIS

HMF can be most rationally classified taking into account the characteristics of the chemical bond whereby the ferrocene fragment is coupled to a derivative of another metal in the course of the formation of the HMF. This approach takes into account not only the specific features of the bond but also its genesis, reflecting thereby to some extent also the method of synthesis of the compound. The proposed classification of HMF is used in this review and in its subdivision into sections.

1. Salts of the Ferrocenium Cation

One of the most unusual reactions in the chemistry of ferrocene is its oxidation to the ferrocenium cation, which takes place readily in an acid medium[20]. In order to obtain the HMF, the ferrocenium cation may be combined with an anion incorporating the transition metal atom. The first bimetallic salt obtained in this way has been ferrocenium reineckate[20]:

This salt precipitates when an acid solution of ferrocenium sulphate is mixed with a solution of the Reinecke salt. The infrared spectra[27] and thermal decomposition[28] of this compound have been investigated. Ferrocenium molybdate, tungstosilicate[27], metatungstate, and tetravanadate[29,30], which are solid powders insoluble in organic solvents, were obtained similarly to the reineckate. The formula $[FcH]MoO_4$ was attributed[27] to the molybdate†. There is a possibility of the formation of $[FcH]Mo_8O_{26}.2H_2O$, which is associated with the polymerisation of the molybdate ions in an acid medium and the tendency of ferrocenium cations to form precipitates with bulky anions[30]. The reineckates of substituted ferrocenes have also been isolated[21,31].

A series of compounds of the ferrocenium cation with noble metal anions have been obtained: ferrocenium hexachloroplatinate $[FcH]PtCl_6$ [from ferrocenium chloroferrate(III) and chloroplatinic acid][32] and salts with gold-containing anions[33]: $[(FcX)^+(AuCl_4)^-]_3Au$, where X = H, Cl, Br, I, Et, Ph, CN, NO_2, COMe, COPh, or COOMe. These compounds are almost quantitatively precipitated on interaction of ferrocene derivatives with chloroauric acid. In a number of instances (X = H, Cl, CN, COOMe) gold was washed out with aqua regia and the compounds $[FcX]AuCl_4$ were isolated.

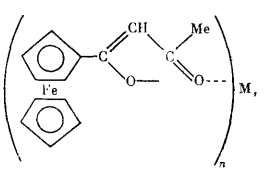
Similar complexes of palladium $\{[FcH]PdCl_3\}$,[34] iridium $\{[FcH][IrCl_4(PMe_2Ph)_2]\}$,[35] vanadium $\{[FcH]VOX_3(X = Cl \text{ or } Br)\}$,[36-39] and titanium $\{[FcH]TiCl_4\}$[38,39] were obtained by the reaction of ferrocene with the corresponding salt in a hydrocarbon medium in the absence of oxidants. The ionic nature of the compounds was confirmed by Mössbauer[34], ultraviolet, and infrared spectroscopy[36,37]. Thermochemical

† Here and henceforth Fc = ferrocenyl ($C_5H_5FeC_5H_4$) and correspondingly FcH = ferrocene.

study of the formation of complexes of ferrocene with Lewis acids[38] showed that an ionic complex is formed if the energy of the donor–acceptor bond exceeds the ionisation energy of ferrocene. There exists also information about the synthesis of a ferrocenium salt with a complex nickel-containing anion: $[FcH][Ni(S_2C_4F_6)_2]$.[20] Single crystals of this compound exhibit a high conductivity.

2. Salts of Ferrocene-containing Acids

Compounds of this type are obtained by the reaction of the corresponding acid with transition metal salts. The copper salts of ferrocenecarboxylic[22,40], ferrocenedicarboxylic[5], and ferrocenylcyanoacrylic acids[24], as well as the uranyl salts of ferrocenemonocarboxylic and ferrocenedicarboxylic acids[41] have bee described. Such salts, which are coloured powders insoluble (with some exceptions[42]) in organic solvents, have been described also for other ferrocene acids; ferrocenemonosulphonic acid $[(Fc{-}SO_3)_2M.4H_2O$, M = Cu or Mn], [43] ferrocenedithiocarboxylic acid $[(Fe{-}CSS)_2M$, M = Cu,[40] Co, Ni, Mn, Cu, Pd,[42] or MoO_2 [44]], ferrocenehydroxamic acid $[(Fc{-}CONHO)_2Cu]$, and ferrocenylacetylhydroxamic acid $[(Fc{-}CH_2CONHO)_2Cu]$.[45,46]



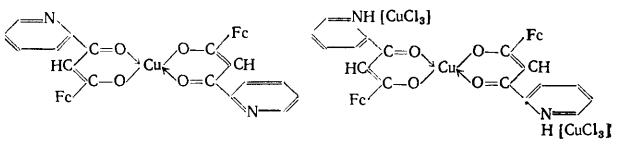
The fairly stable gold-containing derivatives of thioferrocene, which is dimeric in solution and is obtained by the exchange reaction[47]

$$Fc{-}SNa + ClAuPPh_3 \rightarrow Fc{-}SAuPPh_3 ,$$

may be assigned to the same type of HMF. Its interaction with fluoroboric acid results in the formation of the cationic complexes $[Fc{-}S(AuPPh_3)_2]^+BF_4^-$ and $[Fc{-}S(AuPPh_3)_2PPh_3]^+ . BF_4^-$.

3. Chelate Compounds

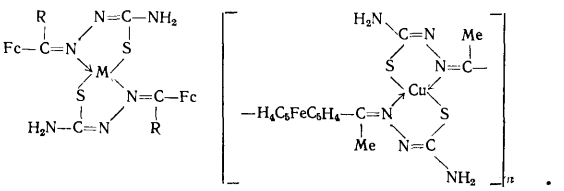
One of the ways of synthesising HMF involves the use of ferrocene-containing β-diketones as chelating ligands. Stable compounds soluble in organic solvents have been obtained from acetoacetyl ferrocene in 70–90% yield:[22,48–57]



M = Ni, Co, Cu, Mn, Cr, VO, Ru; $n = 2, 3$.

Like metal acetylacetonates, they are capable of forming adducts with electron-donating molecules (pyridine and water)[49–51,56]. Nickel ferrocenoylpivaloylmethanate[58], copper ferrocenoylbenzoylmethanate[53], copper, palladium[53], allylpalladium[59,60], and ruthenium[57] ferrocenoyltrifluoroacetonates, a series of copper[61] and uranyl[41,62] complexes of 1,1′-bis-(acetoacetyl)ferrocene and 1,1′-bis(benzoylacetyl)ferrocene, the ethylenediaminenickel complex of 1,1′-bis(acetoacetyl)-ferrocene[63] and the cyclopentadienylnickel complex of ferrocenoyltrifluoroacetone (NFTA) [64] have also been described. The metal : iron ratio in these compounds varies with the oxidation state of the metal ion and the number of β-diketone substituents in ferrocene. In contrast to its fluorine-free analogue, in reactions with dichlorometallocenes under mild conditions, NFTA substitutes a chlorine atom and a cyclopentadienyl group with formation of metallocene bis-β-diketonates[60,64]:

$$Cp_2MCl_2 + 2NFTA \rightarrow CpM(FTA)_2Cl,\ M = Ti,\ Zr,\ Hf,\ Nb .$$

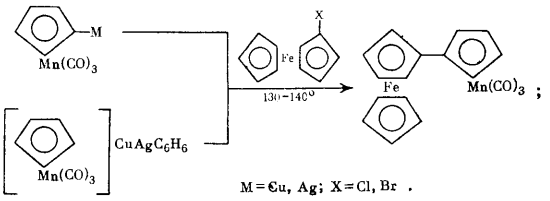


Metallocenes β-diketonates are brightly coloured crystalline substances which are readily soluble in organic solvents, are stable in air, and have relatively high decomposition temperatures.

The isomeric pyridoylferrocenoylmethanates behave unusually in their reactions with copper salts[65]. By virtue of the presence of the pyridine nitrogen atom they form chelates with the ratio Fe : Cu = 1 : 0.6–1 : 3.5 depending on the ratio of the reactants and their concentrations. Several compounds of the type

have been isolated and characterised.

There is also a possibility of the formation of chelates from ferrocene thiosemicarbazones. Copper, nickel, and cobalt chelates based on formylferrocene thiosemicarbazones[66–68], acetylferrocene thiosemicarbazones, and 1,1′-diacetylferrocene bis(thiosemicarbazones) [69] have been obtained:



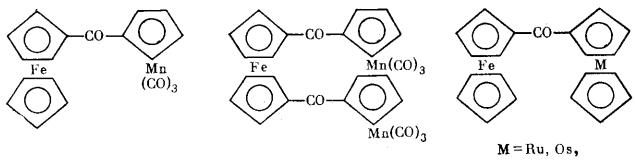
The displacement of the absorption band of the ferrocene fragment in the electronic spectra of these compounds takes place as a consequence of the appreciable mutual influence of the ferrocenyl system and the central metal atom in the complex[57]. Measurements of the magnetic moments have shown that the cobalt complex is a dimer with a Co–Co bond. It has been noted that the coordination of such ligands to metal atoms can occur in the thiol and imine forms[68,70].

Polymeric, infusible, and insoluble in organic solvents chelates of copper, manganese, cobalt, and chromium based on ferrocene-containing β-ketoimines[71–73] and also silver and copper chelate complexes of salicylferrocene[5] have been described. The instability constants of certain organometallic compounds (OMC) of this type have been determined[22].

4. Compounds of the Type Fc–OMC and Fc–R–OMC with σ-Linked Fragments

Various reactions involving the coupling of a cyclopentadienyl ring of ferrocene to groups containing a transition metal entail wide possibilities for the synthesis of HMF. Cymantrenylferrocene—a compound which incorporates the fragments of two of the most thoroughly investigated cyclopentadiene complexes (ferrocene and cymantrene)—has been obtained[74–77]:

M = Cu, Ag; X = Cl, Br .



The cymantrenyl substituents can be introduced also into both rings of ferrocene. Cymantrenylferrocene can be obtained by the pyrolysis of diferrocenyl- and dicymantrenylmercury in the presence of silver powder[78]. It has been recently reported[79] that the most convenient method involves the interaction of copper(II) halides with lithiometallocenes. These procedures are also applicable to the synthesis of substituted cymantrenylferrocenes. The yield of the HMF is 30–70%. Cymantrenylferrocene is a stable crystalline substance which is readily soluble in organic solvents and enters into various reactions.

Various HMF can be synthesised similarly from lithio-, sodio-, or other metal-substituted derivatives of one organometallic compound and halogeno-derivatives of another. The synthesis for this procedure of a derivative of tervalent gold, namely dibutylgold thioferrocenolate Fc–SAu–$(n\text{-Bu})_2$, having a trimeric structure, has been described[47]. Diferrocenyldicymantrenyltin has been obtained by the reaction of cymantrenyl-lithium and dichlorodiferrocenyltin. The reaction between ferrocenyl-lithium and dichlorocymantrenyltin also leads to this compound but with a lower yield[80,81]. Under mild conditions, it was possible to obtain ferrocenylmethyl compounds of molybdenum[82] and tungsten[82,83] according to the scheme

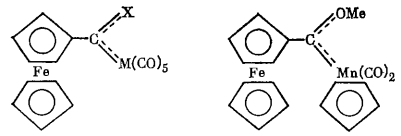
$$Fc{-}COCH_2Cl + NaM(CO)_3Cp \rightarrow Fc{-}COCH_2M(CO)_3Cp .$$

The tungsten-containing ketone is stable on storage and in solution in contrast to molybdenum-containing ketone, which decomposes even in the solid state to the extent of one-third in 24 h. Similar HMF and $Fc{-}CH_2Mn(CO)_5$ have been obtained from chloromethyl- and chlorocarbonyl-ferrocene[84,85]. On heating, the carbonyl derivatives are decarbonylated with formation of $Fc{-}M(CO)_3Cp$.

The Friedel–Crafts alkylation and acylation constitute a convenient method of coupling to organometallic fragments[5,7,20,86–89]. A series of HMF of the type

M = Ru, Os,

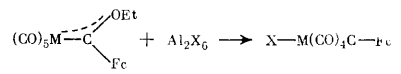
have been obtained and characterised. The carbonyl groups of these compounds are readily reduced to CH_2 groups with retention of the HMF structure.



The condensation reactions of aldehyde and ketone derivatives of ferrocene, benzenechromium tricarbonyl, and cymantrene result in almost quantitative yields of the corresponding HMF [90–92] of two types:

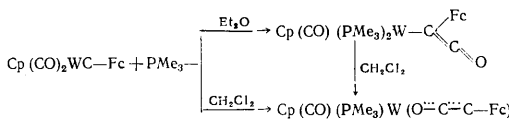
RCH=CHCOR′ and RCOCH=CHR′;
R = Fc; R′ = $PhCr(CO)_3$, $C_5H_4Mn(CO)_3$.

Such condensation of ferrocene derivatives has also been achieved with cymantrenylamine and dinuclear ketimines were obtained as a result[22]. The condensation products are crystalline high-melting substances which are soluble in various organic solvents. The manganese derivatives are somewhat less stable in solutions.



Ferrocenylacetylene can be used to synthesise HMF. Like the synthesis of copper acetylides, the interaction of CuI in aqueous ammonia with ferrocenylacetylene in alcohol[20] leads to copper ferrocenylacetylide (Fe–C≡CCu) in 73–80% yield. Its derivatives dideuterated[93], brominated, and iodinated[94] in the ring have been obtained. Such acetylides can be used successfully in a wide variety of syntheses[13,20,95] including the synthesis of HMF. The exchange reaction of copper ruthenocenylacetylide with iodoferrocene in pyridine gave rise to ferrocenylruthenocenylacetylene[96]: $Fc{-}C{\equiv}CC_5H_4RuC_5H_5$. This compound sublimes *in vacuo* (1 mmHg) at 180 °C without change in its melting point. The reactions of ferrocenylacetylene with *cis*-$PtCl_2(PMe_2Ph)_2$ and $(PPh_3)_2IrCl(CO)$, leading respectively to *trans*-$PtCl(C{\equiv}CFc)(PMe_2Ph)_2$ [97] and a hexacoordinate iridium complex, decomposing on recrystallisation into the initial components, have been described[98].

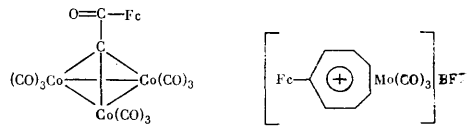
A series of reactions involving addition to the carbonyl ligand in metal carbonyl have been achieved. The reactions of metal carbonyls with organolithium compounds lead to the conversion of the carbonyl ligand into a carbene ligand. A series of bimetallic ferrocenylcarbene complexes were obtained in the course of studies of a series of ferrocene derivatives[99–101]:



X = OMe, OEt, NH_2, NMe_2, NC_4H_8, $ONMe_4$; M = Cr, W .

These compounds are crystalline, stable in air (with the exception of the manganese complex), and soluble in inorganic solvents. It was not possible to synthesise the analogous cobalt and vanadium complexes. The chromium, molybdenum, and tungsten complexes based on 1,1′-dimethylferrocene were obtained recently[102]. The carbene complexes are the starting materials for the synthesis of new HMF. They react with boron and aluminium halides with elimination of an electron-donating group (one CO ligand), forming carbyne complexes[103,104]:

M = Cr, Mo, W; X = Cl, Br .



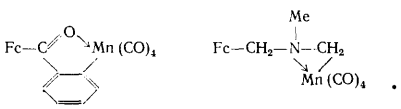
The iodo-homologues have been obtained by the exchange reaction of the above complexes with LiI. The thermal stability of these compounds decreases in the sequence W > Cr > Mo and I > Br > Cl; the chemical stability ranges from that of the iodotungsten derivative, which is stable on storage in air, to the chlorochromium compound, which ignites spontaneously. It has been shown for the tungsten derivative[105] that these complexes react with cyclopentadienylsodium to form dicarbonyl(π-cyclopentadienyl)carbyne complexes, which are readily soluble in organic solvents and whose reactions with phosphines give rise to metal-substituted ketens, which are stable in the solid state[106]:

In CH_2Cl_2 these ketens combine almost quantitatively with CO at 30 atm over a period of 24 h [107] with the formation of $Cp(CO)_2(PMe_3)W{-}C(Fc){=}C{=}O$.

The electrophilic substitution of hydrogen in ferrocene by new acylating agents—carbotricobalt decacarbonyl hexa-

fluorophosphate[108] and the complex $[C_7H_7Mo(CO)_3]BF_4$—has been achieved[7,20], which led to the following HMF:

Other ferrocene cluster compounds have also been obtained: $Fc-CCo_3(CO)_9$ [20,109] and $Fc-CH_2CO_2CCo_3(CO)_9$.[110]

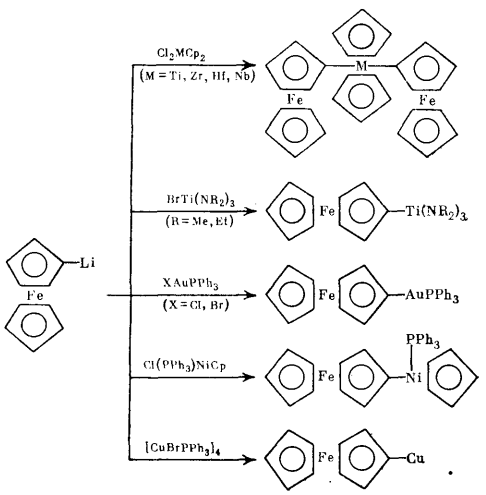


A simple method of synthesis of HMF consists in the addition of organometallic compounds to carbonyl derivatives of ferrocene[21,22,111,112], for example:

$$Fc-CHO \xrightarrow{LiR} Fc-CH(R)OLi \xrightarrow{H_2O} Fc-CH(R)OH,\quad R=C_6H_4Mn(CO)_3;$$
$$Fc-COMe + Cp_2Zr(Cl)H \rightarrow Cp_2Zr(Cl)OCH(Me)-Fc.$$

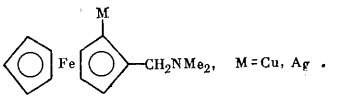
These compounds are soluble in hydrocarbons but hydrolyse at the metal–oxygen bond with liberation of ferrocene-containing alcohols.

There are literature data concerning polymeric HMF obtained by the copolymerisation of vinyl derivatives of cymantrene and ferrocene[113], (benzyl acrylate)chromium tricarbonyl, and 2-ferrocenylethyl acrylate[114,115]. Polymers of other metal-containing monomers are also known[117–122].



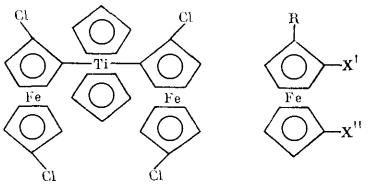
The possibility of the synthesis of HMF by the cyclometallation of substituents in ferrocene derivatives is also noteworthy[127]. Various dinuclear heterometallic derivatives can be obtained by this procedure, but in the case of ferrocene the reaction is known only in a few instances. These involve the metallation of benzoylferrocene and dimethylaminomethylferrocene with methylmanganese pentacarbonyl in the benzene ring and in the methyl group respectively[128]:

Pyrazolines containing the ferrocenyl and cymantrenyl substituents have been described[116,129]. Catalytic thermolysis of such pyrazolines in the presence of KOH and platinum on charcoal leads to the corresponding cyclopropane HMF.[116]



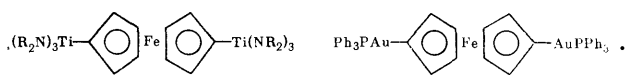
5. Compounds With a Cyclopentadienyl–Metal Bond

HMF of this kind are usually obtained by the exchange reaction between lithioferrocenes and transition metal halides[130–137]:



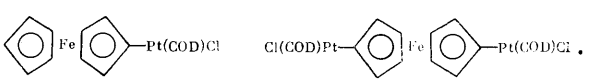
The reaction with $AuCl_3$ terminates with the formation of HMF in satisfactory yield only for the ratio Li : Au = 2 : 1.[133] Only the compound $Fc_2AuClPPh_3$ has been obtained under these conditions.

The thermal stability of HMF of this type varies within wide limits—from the nickel compound which is unstable in a pure form[135,136] to the cyclopentadienyl derivatives of Group IV metals which sublime *in vacuo* at high temperatures[130,131]. However, the latter are unstable in air. Ferrocenylcopper, which in unstable in an inert atmosphere up to 120 °C, also decomposes in air. It is noteworthy that the presence of halogen atoms and of the dimethylaminomethyl group in the cyclopentadienyl rings of ferrocene stabilises the carbon–metal bond and the HMF is also much more stable. Thus the HMF obtained from 1-(dimethylaminomethyl)-2-lithioferrocene and copper and silver iodides (yield more than 60%) are stable in air up to 150–170 °C:[138,139]



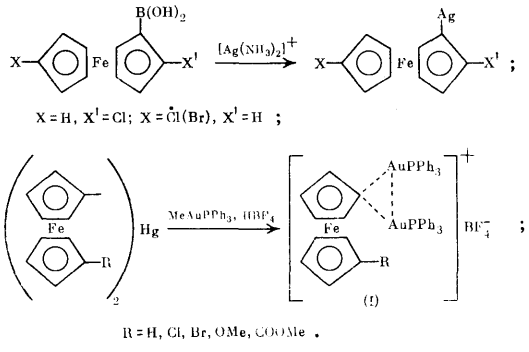
Similar methoxy-substituted HMF are somewhat less stable[140].

Copper and silver derivatives without stabilising substituents were obtained only recently[137,141]. The silver derivative is more stable and persists in air for several hours. A series of derivatives of other metals have been obtained from lithioferrocenes containing stabilising substituents:[142,143]

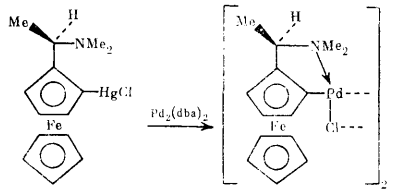


$X^I = X^{II} = Cl$, $R = Mn(CO)_5$, $AuPPh_3$, $Ir(CO)PPh_3$;
$X^I = Cl$, $X^{II} = H$, $R = AuPPh_3$.

If 1,1′-dilithioferrocene is used in the synthesis, HMF substituted in both rings are obtained[132,142,144,145], for example:

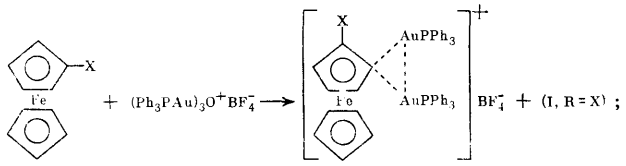


The same results were obtained on incomplete ferrocenylation of the platinum salt $Pt(COD)Cl_2$ (COD = cyclo-octa-1,5-diene) with trimethylstannylferrocene and 1,1′-bis(trimethylstannyl)ferrocene[146]:

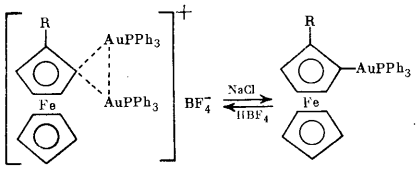


The reaction of 1,1′-dilithioferrocene with cobalt chloride leads to the formation of polyferrocenylenes[147].

Apart from the organolithium and organotin compounds, ferrocene derivatives of boron[148–151] and mercury[152–156] are used for the synthesis of HMF of this type:

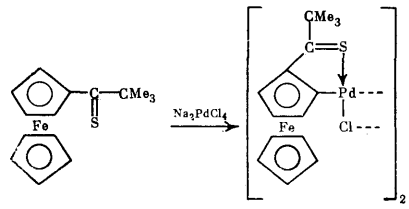


These reactions involving organomercury compounds proceed over a period of several minutes at room temperature with yields of compounds (I) up to 80–90%. The use of the optically pure 2-chloromercuri-derivative of 1-dimethylaminoethylferrocene for the synthesis of an optically active complex with a palladium atom in the ring has been described[157–159]:



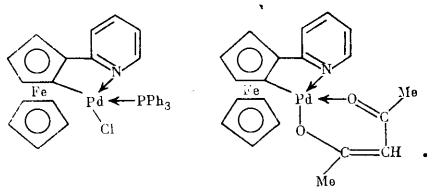
where dba = dibenzylideneacetone.

Other methods of adding a transition metal directly to a cyclopentadienyl ring of ferrocene are also known. Nesmeyanov and coworkers[160–163] were the first to metallate ferrocene and its derivatives by an aurating agent—a gold-containing oxonium salt. Ferrocene is aurated at 20 °C in the presence of HBF_4, giving a 60% yield of a cationic digold complex (I, R = H). Ferrocene derivatives form mixtures of homoannular and heteroannular isomers:



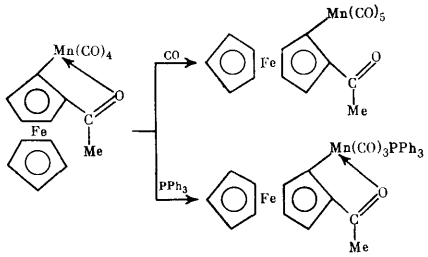
X = Me, Ph, $C_6H_4NO_2$, COMe, Cl .

In all cases, except when X = Ph, homoannular 1,2-isomers are formed preferentially. Methoxy- and nitro-ferrocenes give rise to 1,2-disubstituted ferrocenes only. Under the influence of nucleophiles (Cl^-, CN^-, PPh_3), the cationic complexes are converted quantitatively into organomonogold compounds, whose reaction with tetrafluoroboric acid readily reconverts them into ionic complexes[164]:



The reaction proceeds from right to left also under the influence of dinuclear organogold complexes $[R(AuPPh_3)_2]BF_4$.[165] In view of the ease of such reactions, it is assumed that it is most convenient to synthesise gold-containing HMF of the type $Fc–AuPPh_3$ from organomercury compounds via the cationic complexes[155]. It is of interest that acetylferrocene is aurated by tris(triphenylphosphinegold)oxonium permanganate not in the cyclopentadienyl ring but in the acetyl group, forming $Fc–COCH_2AuPPh_3$, albeit in a low yield (5%).[161,162]

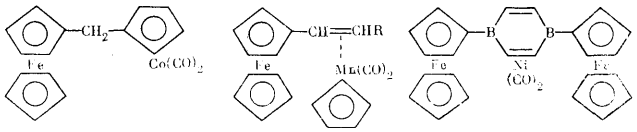
The first example of the intramolecular orthopalladisation of metallocenes was published in 1974:[166]

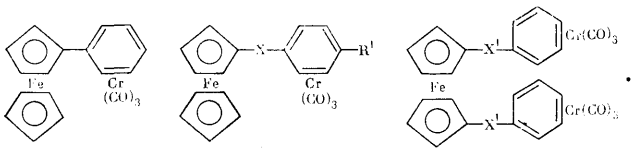


Subsequently this reaction was achieved also for other ferrocene derivatives—dimethylaminomethylferrocene[167], 2-pyridylferrocene[168], acetylferrocene *N,N*-dimethylhydrazone[169], acetylferrocene acetylhydrazones[170], and 1,1′-diacetylferrocene bis(acetylhydrazone).[171] Li_2PdX_4 (X = Cl or Br) are also used as palladising agents. The reaction is carried out in the presence of sodium acetate. The dimeric complexes obtained in a yield exceeding 90% react with electron-donating molecules or metal acetylacetonates to form the corresponding monomeric HMF, for example;

If the palladisation is carried out in the presence of a salt of an optically active acid or an optically active derivative of ferrocene is used, then optically active HMF are obtained. The asymmetric cyclopalladisation of dimethylaminomethylferrocene [172,173] and the optically active *N,N*-dimethylamino-1D-methylferrocene [174] and 1-dimethylaminoethylferrocene[157,158] has been achieved.

The metallation of acetyl- and dimethylaminomethyl-ferrocenes by methylmanganese and methylrhenium pentacarbonyls has also been described[128,175]. In all cases homoannular *ortho*-metallated ferrocenes are formed in 32–50%, yield except in the reaction of dimethylaminomethylferrocene with the manganese compound described in the previous section. The reaction of the manganese derivative with CO is accompanied by ring rupture, which indicates the lability of the Mn ← O bond; however, the reaction with triphenylphosphine proceeds differently—with substitution of one carbonyl group:



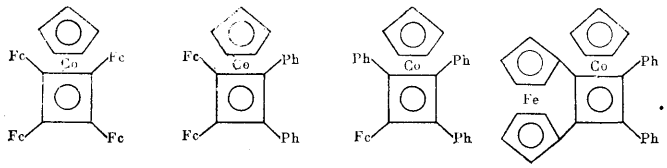


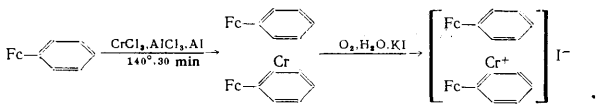
6. π-Complexes of Unsaturated Ferrocene Compounds

Heterometallic derivatives of ferrocene can be obtained from metal carbonyls using the ability of the latter to substitute their CO groups by π-donor ferrocene-containing ligands. Several compounds of this type have been described. Ferrocenylacetylenes readily react with cobalt carbonyl[26,98]:

$$Fc{-}C{\equiv}CR + Co_2(CO)_8 \xrightarrow{C_6H_6,\,25^\circ} Fc{-}C{\equiv}CR\,[Co_2(CO)_6]\ ;$$
$$R=H,\ Fc\ .$$

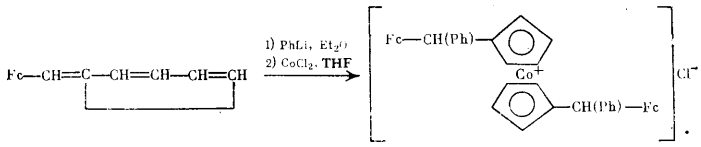
The following cobalt-, manganese, nickel-, and chromium-containing HMF have been obtained similarly (sometimes with ultraviolet irradiation): [20,85,176–180]





(a) R = H, Me; (b) R' = H, X = CH_2, CO, CH_2CH_2, $COCH_2$, CH(OH)CH_2, CH=CH, CH(OH); (c) R' = Me, X = CO, CH(OH); (d) X' = $COCH_2$, CH(OH)CH_2 .

Cobalt- and manganese-containing HMF of this type are relatively readily fusible compounds (or liquids); the chromium-containing HMF and the nickel complex melt (sometimes with decomposition) in the range 135–230 °C.



The interaction of the ethynylferrocenes Fc–C≡CPh, Fe–C≡C–Fc, and Fe($C_5H_4C{\equiv}CPh)_2$ with the cyclopentadienylcobalt complexes $CpCo(CO)_2$, $CpCo(PPh_3)_2$, and CpCo(RC≡CR)PPh_3 have been studied by two groups of investigators[181,182]. Mixed cyclobutadiene complexes with different Fe : Co ratios, soluble in hydrocarbons, were isolated:

The group of compounds which are synthesised using arene- or cyclopentadienyl-containing metallocenes, usually ferrocenes, while the other metal is introduced, by the method for the synthesis of metallocene and arene compounds, should be assigned to this type of HMF. Thus, 1,1'-diferrocenyldibenzenechromium, identified as the iodide, has been synthesised under the conditions of the Fischer reaction in 17% yield[123]:

Since the synthesis is complicated by side reactions, an attempt was made to synthesise this compound and its *p*-tolylferrocenyl analogue by the reaction of chromium vapour with phenyl- and *p*-tolylferrocene in a high vacuum (10^{-5} mmHg, 77 K); the yield was approximately 1% relative to the evaporated chromium, which entered the reaction zone[124]. A similar cobaltocenium derivative was obtained from α-ferrocenylfulvene[20]:

The manganese[125] and tungsten[126] derivatives have been obtained analogously.

Dimeric 1-ferrocenyl-π-allylpalladium chloride complexes have been synthesised by the reaction of conjugated dienes (butadiene, isoprene, and 2,3-dimethylbutadiene) with ferrocenylpalladium chloride, obtained *in situ* from chloromercuriferrocene and Li_2PdCl_4.[183] A complex of vinylferrocene and palladium(II) chloride has also been obtained[33].

7. Transition Metal Complexes with Ferrocene Ligands Containing Group V and VI Elements as Donor Atoms

The complex formation reactions of ferrocene derivatives containing electron-donating nitrogen, phosphorus, arsenic, etc. atoms with transition metal compounds constitute a convenient method of synthesis of HMF. Thus, when dimethylaminomethylferrocence is mixed with nickel and cobalt halides and thiocyanates[184] and also with palladium chloride[185], solid coloured adducts are formed:

$$[FcCH_2NMe_2]_2MX_2 \quad M=Co,\ Ni,\quad X=Cl,\ Br,\ I,\ CNS;\quad M=Pd,\ X=Cl\ .$$

The reaction with titanium and zirconium halides gives rise to 1 : 1 complexes[186]. Dimethylaminomethylferrocene hydrochloride reacts with K_2MCl_4 and $Na_2M(CN)_4$, yielding compounds with a different structure[185]: $[FcCH_2NHMe_2]_2MX_4$, where M = Pt or Pd. Nickel, platinum, palladium, ruthenium [187], and rhodium[188] complexes of 1,1'-bis(dimethylarsino)ferrocene[187,188] and 1,1'-bis(diphenylarsino)ferrocene[187], the palladium complex of 2-ferrocenylpyridine[168], the nickel[189], cobalt[190], gold[191], and palladium[192] complexes of ferrocenylphenylphosphines, the cobalt, nickel, and copper complexes of 1,1'-bis(diphenylphosphino)ferrocene [193], the rhodium complexes of ferrocenylphosphinamines[194], the cobalt complex of 1-(dimethylaminomethylmethyl)-2-pyridylferrocene[26], the titanium and zirconium complexes of ferrocenylacetonitrile[186], the silver[39], titanium, and vanadium[39,195] complexes of 1,1'-dicyano-ferrocenes[7,22], and the ruthenium complexes of cyanoferrocene and ferrocenylacrylonitrile[196] have been synthesised and investigated.

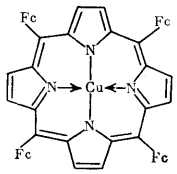
Ferrocenylphosphinegold halide complexes are converted into organogold HMF under the influence of organolithium and organomagnesium compounds[197]

$$BrAuL + MeMgI \rightarrow MeAuL\ ;$$
$$L = PFc_3,\ FcPPh_2\ .$$

Oxidants react with these complexes in a way which depends on the nature of the reagent[191], oxidising either gold or the ferrocene system:

$$BrAuFcPPh_2 \xrightarrow{Br_2} Br_3AuFcPPh_2$$
$$BrAuFcPPh_2 \xrightarrow{HAuCl_4} [(BrAuFcPPh_2)^+(AuCl_4)^-]_3Au\ .$$

Triferrocenylphosphine complexes of arylgold compounds are obtained by displacing triphenylphosphine with triferrocenylphosphine, the latter being a stronger electron donor[197]:

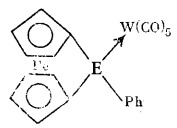


$$ArAuPPh_3 \xrightarrow{Fc_3P} ArAuPFc_3\ ;$$
$$Ar = p\text{-}MeC_6H_4,\ m\text{-}FC_6H_4\ .$$

HMF of this type are also known to include cationic digold complexes[165,197,198], which are formed, like the compounds

aurated in the ferrocene nucleus, via the following mechanisms:

$$R_2Hg + MeAuPFc_3 \xrightarrow{HBF_4} R(AuPFc_3)_2BF_4,$$
$$R=PhCH=CH,\ PhCH=C(COOMe),\ o\text{-}IC_6H_4,\ \alpha\text{-thienyl};$$
$$p\text{-}MeC_6H_4AuPFc_3 \underset{Fc_3P}{\overset{HBF_4}{\rightleftarrows}} p\text{-}MeC_6H_4(AuPFc_3)_2BF_4.$$



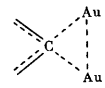
The first heterometallic derivative of ferrocene of the porphyrin series has also been obtained from *meso*-tetraferrocenylporphyrin and copper acetate in dimethylformamide and has been isolated after recrystallisation from chloroform in the form of an adduct with dimethylformamide and $CHCl_3$:[199]

According to Mössbauer spectroscopic data, oxidation of this compound results in the formation of several ferrocenium centres.

A series of HMF have been obtained by the reactions of metal carbonyls with ferrocenylphosphine ligands: $CpMn(CO)_2L$ (L = PFc_3, PFc_2Ph, or $PFcPh_2$), $RC_5H_4Mn(CO)_2PFc_3$ (R = Et, C_5H_{11}, MeCO, or C_4H_9CO), $C_6H_6Cr(CO)_2L$ and $(CO)_5ML$ (M = Cr, Mo, or W), $(CO)_4ML_2$ (M = Mo or W), $Fc_3PMn_2(CO)_9$, $[(FcPPh_2)_2Co(CO)_3]^+BPh_4^-$,[190,200–203] and $Fc_3PMn(CO)_4Me$.[128] Similar complexes of chromium, molybdenum, tungsten, vanadium, cobalt, and nickel carbonyls with bifunctional nitrogen-, phosphorus-, and arsenic-containing ferrocene ligands have been described[193,194,204,205].

It is known that coordination to transition metals appreciably stabilises ligands which are relatively unstable under the usual conditions. It is therefore possible to employ in the synthesis of stable HMF of this type even ferrocene compounds which are unstable in air. For example, crystalline complexes stable in air have been obtained from thioketones which readily polymerise and oxidise under the usual conditions and from ferrocenophanes, which are unstable in air[206–208]:

$Fc{-}CS{-}CMe_3Cp_2Mo_2(CO)_4$
$Fc{-}C(R){=}S \rightarrow M(CO)_5$;
R=Ph, M=Cr, Mo, W; R=Me, M=W;
E=P, As.



The possibility of synthesising HMF of this type by displacing amine ligands from the Reinecke salt by aminoferrocenes (L) has also been demonstrated[209]. With a 1 : 1 component ratio, the outer-sphere ammonia is displaced with formation of the solid crystalline complex $LH[Cr(SCN)_4(NH_3)_2]$. With increase of the aminoferrocene : Reinecke salt ratio, the inner-sphere ammonia is displaced.

III. STRUCTURE AND PROPERTIES

1. Structure

The structural analysis of crystalline HMF has been carried out for certain compounds, which made it possible to discover their structural characteristics. When a metal forms σ-bonds directly with a carbon atom of a cyclopentadienyl ring of ferrocene, there is a possibility of a redistribution of electron density with participation, in particular, of the metal *f* orbitals, which alters the interatomic distances in the Fc fragment[138]. On the other hand, in the case of diferrocenyltitanocene Cp_2TiFc_2, a shortening of the σ-bond between titanium and a carbon atom of the cyclopentadienyl ring of ferrocene and constancy of the bond lengths in the sandwich fragments were observed[210]. The molecular structure of $(Et_2N)_3TiC_5H_4FeC_5H_4Ti(NEt_2)_3$ has been described[211].

There is also a possibility of a more complex bonding of the metal atom to the cyclopentadienyl ring with formation of the structural fragment

in which the two gold atoms linked to one another form a three-centre two-electron bond with one of the carbon atoms with the ferrocene-containing group[154,164]. The presence of the above fragment has been most clearly confirmed by X-ray diffraction data for the compound $[(\pi\text{-}C_5H_5)Fe(\pi\text{-}C_5H_4)Au_2.(PPh_3)_2]BF_4$.[212,213]

The Au–Au bond (2.77 Å) in such compounds is shorter than in metallic gold (2.88 Å). As a consequence of the presence of the Fe–Au bond (2.82 Å), the planes of the cyclopentadienyl rings are not parallel (the dihedral angle is 16°) and the bridging ring has the envelope configuration. Ultraviolet spectroscopic and ^1H NMR data show that the bridge structure of the compounds is maintained also in solutions[153,214]. The related compound 2-copper(dimethylaminomethyl)ferrocene and its silver analogue have the cluster structure[215,216]. In these substances it is also possible to isolate the fragment

but the distortion of the Fc is smaller probably due to the weaker interaction between M and Fe. A weak interaction between the silver atom and the nitrogen atom of the aminogroup has been noted for the silver derivative.

Direct bonding of the metal to a carbon atom of a cyclopentadienyl ring of ferrocene is not always accompanied by the M–Fe interaction. Apart from the nature of the atom M, the character of the bonds which it forms with the atoms in the immediate environment is of decisive importance. For example, in cyclo-1-(1′-dimethylaminoethylferrocene)-2-(acetylacetonato)palladium the metal is involved in the square planar coordination fairly characteristic of palladium with formation of acetylacetonate and PdC_3N metal-containing rings. The ferrocene fragment has a configuration intermediate between crossed and eclipsed with the usual average bond lengths[159].

In the absence of a direct bond between M and a cyclopentadienyl ring of ferrocene, the mutual influence of the M and Fe atoms on the structural characteristics of their environment is also weakened. However, it is still fairly pronounced, for example, in halogenotetracarbonyl complexes of transition metals bound to the ferrocenyl residue by a linkage of the type $M{\equiv}C{-}Fc$.[104] In these compounds, as in the carbene derivatives which resemble them[102], there is a significant decrease of electron density in the cyclopentadienyl rings of ferrocene as a result of the stronger conjugation than in the usual substituted ferrocenes, caused by the overlap of the π orbitals of the substituted ring by the p_z orbital of the acetylenic carbon. The HMF considered are oxidised more readily than ferrocene; their oxidation-reduction properties are appreciably influenced by the nature of the metal and to a lesser extent the halogen.

The compound of nickel iodide carbonyl with ferrocene-1,1'-bis(dimethylarsine) [217] is of interest because in it the cyclopentadienyl rings of ferrocene form part of a bidentate ligand. The nickel atom has a trigonal bipyramidal coordination with the equatorial and axial dispositions of As. The $FeAs_2$ and $NiAs_2$ planes form an angle of 46.6° and the cyclopentadienyl rings are rotated by 8.8° compared with the eclipsed conformation and are inclined to one another at an angle of ~3°. The Ni–As distances are within the usual limits for nickel complexes with arsenic derivatives, but the equatorial bond is somewhat longer than the axial bond. The interatomic distances in the ferrocene fragment have the usual values. The C–O bond is shorter than in the carbonyl complexes. The bidentate ligand may include also one cyclopentadienyl ring of ferrocene. It has been established by NMR and infrared spectroscopy[204] that 1-(dimethylamino)-methyl-2-(diphenylphosphino)ferrocene behaves as a bidentate ligand in reactions with Group VI metal (Cr, Mo, and W) carbonyls and gives rise to a complex of the type $[CpFeC_5H_3.(PPh_2)CH_2NMe_2]W(CO)_4$.

Polydentate ligands can also be linked with the aid of the ferrocene fragment. This can entail the formation of strained structures. Comparison of the EPR spectra of copper chelate complexes of acetylacetone, ferrocenylacetone, and 1,1'-bis-acetoacetylferrocene showed that only in the latter case does the symmetry of the environment of the copper ion deviate from the acetylacetonate symmetry[50,51]. When the ferrocene nucleus is separated from the M atom by two and more atoms, the mutual influence of the metal-containing fragments on their structure is not observed. In such complexes ferrocene frequently has the eclipsed conformation[182,218]; however, as in the cases discussed above, the conformation may be influenced decisively by the packing in the crystal and not by the electronic structure and geometry of the molecule. Estimation of the mixing coefficients in the molecular orbital of the unpaired electron showed that these coefficients of the $d_{x^2-y^2}$ orbitals of the copper atoms are identical to within 0.04 for the acetylacetonate and ferrocenoylacetonate. This indicates identical distibution of spin density in a type b_1 orbital in both chelates and the absence of an appreciable influence of the ferrocenyl substituent on this orbital[51]. The ferrocenyl residue also does not have a significant influence on the metal atom in the tetraferrocenylporphyrin complex; the EPR spectrum corresponds to the spectra of other copper complexes of porphyrins[199]. The usual structure of the chelate unit has been found also in other metal ferrocenoylacetonates[51,56]. However, a redistribution of electron density can occur in orbitals without unpaired electrons[219,220].

The nature of the localisation of the charge in the ferrocene component is most significant in ionic compounds. If the ferrocene component consists of a ferrocenium type cation, then the Fe–Cp bonds in it are weakened (compared with the corresponding ferrocene derivative) and the absorption bands in the infrared spectrum corresponding to these bonds undergo a bathochromic shift[27,30]. Allowance for this and also for the bathochromic shift of the d–d transition band in the optical spectrum led to an ionic structure for complexes of ferrocene with metal halides[36,37].

2. Solubility

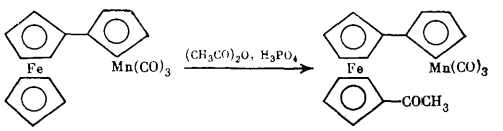
There are no quantitative literature data on the solubilities of HMF (with a rare exception[56]). Only qualitative data are usually quoted, from which it follows that many HMF are appreciably soluble in organic solvents. In order to increase the solubility of compounds based on β-diketones in hydrocarbons, the oleic acid residue is introduced into the molecules of the β-diketonates[221]. The low solubility of salts of nitrogen-containing ferrocene chelates[65,69] and acids[45,46] is apparently associated with intermolecular association in the solid state via the electron-donating nitrogen atoms or with the polymeric structure of the compounds. HMF of other types are apparently also insoluble due to their polymeric structure[5,47,63].

3. Thermal Stability

Polymerisation in the solid state influences appreciably the thermal behaviour of HMF. For example, polymeric chelates of ferrocene thiosemicarbazones and β-ketoimines[66–69,71] do not melt up to 250–300 °C, decomposing in the solid state on further heating. The unusually high stability of ferrocene-silver compared with alkyl- and aryl-silver can also be accounted for by the formation of intermolecular bonds[151].

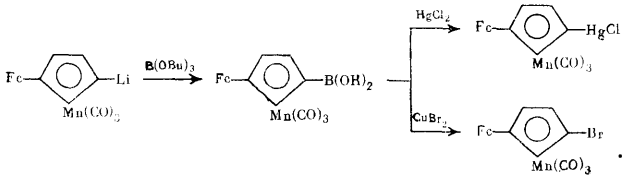
The thermal decomposition of HMF has been investigated for a few compounds. Thermolysis of ferrocenium salts has been investigated for the reineckate and salts with isopoly-acids[28–30,49]. A characteristic feature of the process is the formation of ferrocene. The thermal stability of salts of ferrocenemonosulphonic acid has been characterised by thermogravimetric and differential thermographic methods[43]. The compounds are unstable in air in the anhydrous state, the copper salt decomposing even before the loss of the entire water of crystallisation.

The thermal decomposition of the copper chelate of ferrocenylacetone has been investigated by derivatographic, mass-spectrometric, and gas-chromatographic methods[49,51]. It has been established that cyclopentadiene, methane, and hydrogen are evolved at 200–260 °C together with a keto-derivative of ferrocene (identified by the infrared spectra); the residue contains metallic copper and iron(II) and iron(III) oxides. The chelates of ferrocene-containing β-ketoimines decompose in the same temperature range (>200–250 °C),[73] their thermal stability being lower than that of the initial β-ketoimines, which the authors attribute to the presence of the unstable ferrocenium form in the polychelates.



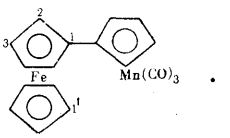
There exist data on the thermal stabilities and decomposition of other compounds, in particular the copper salt of ferrocenecarboxylic acid[22], allylpalladium ferrocenyltrifluoro-acetonate[59,60], 2-copper-1-(dimethylaminomethyl)ferrocene[215], a series of ferrocenesilver compounds[148–150], diferrocenyl-dicyclopentadienyl derivatives of titanium, zirconium, hafnium[130], and niobium[131], and also ferrocenephosphinegold cationic complexes[197]. The majority of HMF lose the ability to sublime on heating which is characteristic of ferrocenes. One of the few exceptions to this rule is ferrocenylruthenocenylacetylene[96] and the dicyclopentadienyldiferrocenyl derivative of zirconium, hafnium, and titanium[130] (the heat capacity of the last compound was measured and its thermodynamic functions were calculated[222]).

4. Chemical Properties



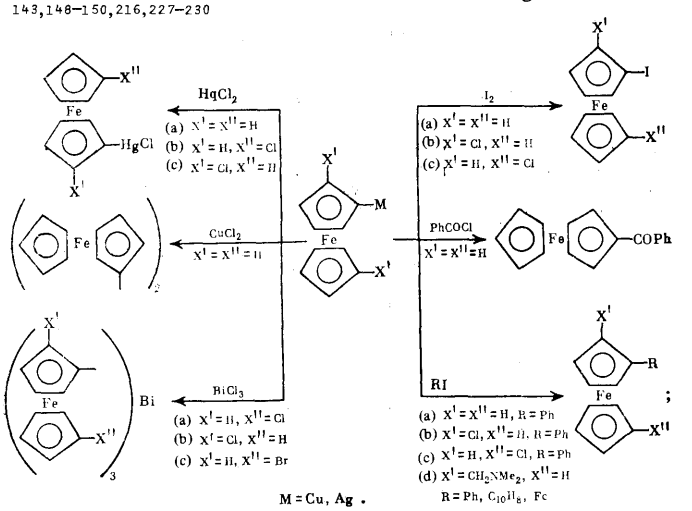
The majority of HMF are resistant to oxygen and atmospheric moisture, except for the compounds mentioned in the appropriate parts of the review. The instability of individual HMF in organic solvents has also been pointed out[33,60,64,102,105,133,161,205].

Many HMF exhibit an important chemical property of ferrocene—the ability to be oxidised to the cation[87–90,178,180,223], which may serve as one of the ways of synthesising trimetallic compounds[128,129]. Both organometallic fragments of HMF are chemically reactive. For example, depending on



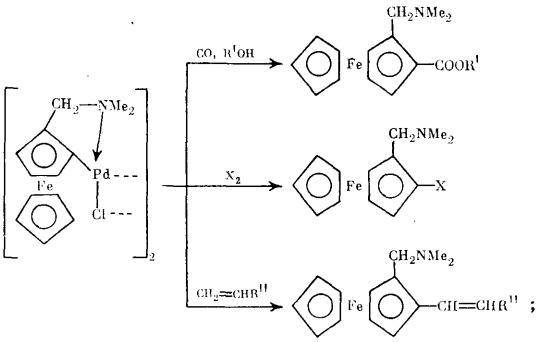
the type of reagents employed, the substitution of a hydrogen atom in cymantrenylferrocene can take place in a cyclopentadienyl ring of either ferrocene or cymantrene. Acylation by acetic anhydride proceeds in accordance with the mechanism[76,77]

In contrast to this, metallation by n-butyl-lithium occurs in the cyclopentadienyl ring of cymantrene. The organolithium derivative obtained is a convenient reagent for the synthesis of various derivatives of ferrocenylcymantrene containing substituents in the cymantrene ring:



The bromo-derivative of this HMF, containing bromine in a cyclopentadienyl ring of ferrocene, can be obtained from 1,1'-dibromoferrocene and cymantrenylcopper or cymantrenylsilver via the reactions described above (in Section II). Bromine can be substituted by other groups on treatment with bivalent copper salts (acetate and phthalimide)[75,77]. Thus the properties of the σ-linked cymantrenyl and ferrocenyl residues in cymantrenylferrocene differ from those of cymantrene and ferrocene. The difficulty of the exchange of the bromine in 1-bromo-1'-cymantrenylferrocene for different groups, the ease of reduction of the ferrocene derivative to cymantrenylferrocene, the smaller tendency of the latter (compared with ferrocene) to undergo oxidation to the ferrocenium cation, the reduced basicity of 1-amino-1'-cymantrenylferrocene (compared with ferrocenylamine), and also its oxidation to the corresponding azoferrocene, which takes place with difficulty, are associated with the electron-accepting influence of the cymantrenyl group. This has been confirmed by the formal oxidation-reduction potentials[223,254] and data for the isotope exchange of the hydrogen in cymantrenylferrocene with acids[225], from which it follows that the cymantrenyl substituent decreases the rate of the isotope exchange involving the ferrocene nucleus by a whole order of magnitude and that the most reactive positions for electrophilic substitution are 1' and 3:

It was established that the 1'-, 3-, and 2-positions are respectively 8 times, 11 times, and 20 times less active than in ferrocene. It is significant that, under the conditions of the hydrogen isotope exchange, the cymantrenyl fragment does not react. The result of the study of the isotope exchange involving benzenedicarbonyldiferrocenylphosphinechromium[226] is unexpected—the hydrogen atoms of the π-benzene and cyclopentadienyl rings are exchanged at almost the same rates, indicating the equalisation of the electron density in the given complex. The hydrogen atoms of the cyclopentadienyl rings in Ph_2PFc, coordinated to the chromium atom, undergo isotope exchange faster almost by three orders of magnitude than the hydrogen atoms of the non-coordinated ferrocenylphosphine.

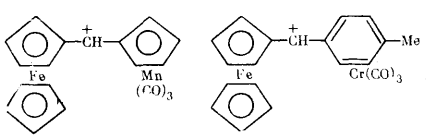


Many HMF with a metal–carbon σ-bond readily react with various reagents, which can be used for the synthesis of ferrocene otherwise difficult to obtain, including HMF:[137,140,143,148–150,216,227–230]

M = Cu, Ag .

The reactions of the organonickel σ-complexes $CpFeC_5H_3$.(Cl)$Ni(PPh_3)Cp$ with acids, acetyl chloride, and mercury(II) chloride also take place under mild conditions and with high yields[135,136]. The nickel–π-cyclopentadienyl ring and nickel–triphenylphosphine bonds are not involved in this process. The organogold derivatives $Fc-AuPPh_3$ react with halogens also with formation of halogenoferrocenes and triphenylphosphinegold halides[231,232]. However, reactions involving the electrophilic substitution of the gold atom could not be carried out[233]. The high reactivity of the gold–carbon bond has been used to synthesis the substituted vinylferrocenes Fc–C(CN) = C(CN)R, where R = CN or $AuPPh_3$.[234] Hydrogen sulphide and the acids HX (X = Cl or Br) readily decompose many similar HMF.[42,130,131,141,148–150] Stabilised ferrocenylsilver and ferrocenylcopper condense with cymantrenylcopper and chloroferrocenylsilver above 120 °C, forming dinuclear metallocenes[216].

It has been shown for various aminoferrocenes with a Pd atom in the ring that extensive synthetic possibilities are associated with HMF of this type. The reaction conditions depend greatly on the nature of the reagent; the products of the synthesis are 1,2-substituted ferrocenes[168,235,236]:

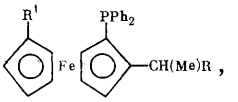


R'=H, Me; X=Br, I; R''=Me, Ph, CN, COOMe, etc.

Such reactions have also been achieved for similar enantiomeric HMF.[172,235,237–239] The latter are planar-chiral compounds and substitution of the metal by some other group takes place with retention of not only the stereochemical configuration but also of the enantiomeric purity. The presence in these HMF of the dimethylamino-group, which tends to

undergo nucleophilic substitution in the form of a quaternary ammonium base, makes it possible to vary within wide limits the nature of the substituents and to obtain a wide variety of 1,2-disubstituted ferrocenes.

The marked influence of the organometallic fragment linked to the ferrocene fragment on the properties of the latter is also illustrated by the behaviour of the α-metallated ketones $Fc-COCH_2M(CO)_3Cp$ (M = Mo or W) in relation to nucleophiles[83,240]. In contrast to acetylferrocene, such HMF do not form derivatives involving the keto-group. This is associated with the low electrophilic activity of the carbon atom of the keto-group, caused by the marked electron-donating properties of the cyclopentadienylmetal carbonyl fragments, and also with the dissociation of the metal–carbon σ-bond in reactions with nucleophiles. Triethyloxonium tetrafluoroborate converts these ketones into the corresponding salts $[Fc-C(OEt)CH_2M(CO)_3Cp]BF_4$, which are convenient reagents for the synthesis of derivatives of α-metallated ketones. α,β-Unsaturated ketones, for example, ferrocenylideneacetylcymantrene, react with methylmagnesium iodide via the 1,2-addition mechanism to form the corresponding ketone and tertiary alcohol[92]. The latter is converted under the influence of HBF_4 in acetic anhydride into a salt of the allyl cation, which alkylates dimethylaniline in the *para*-position with an almost quantitative yield of the derivative $Fc-CH.(C_6H_4NH_2)CH=C(CH_3)C_5H_4Mn(CO)_3$. Secondary and tertiary carbinols of this type readily ionise on treatment with acids, forming intensely coloured carbenium ions[179,241,242]:



Such cations are extremely stable owing to the delocalisation of the positive charge over both metallocenyl residues.

Finally, the high reactivity of the carbene complexes $(CO)_5CrC(Fc)X$, where X = OMe or NC_4H_8,[218,243] and of ferrocenylpalladium chloride obtained *in situ*,[244,245] which produce various linear and cyclic ferrocene derivatives in reactions with unsaturated compounds, is noteworthy. The reactions involving other types of HMF have been little studied. In contrast to palladium chloride, ferrocenium trichloropalladate reacts with allyl chloride, forming the complex $(C_3H_5)_2Pd_3Cl_4$.[246] Reactions involving the addition of neutral molecules (CO, SO_2, MeSCN) to the rhodium complexes of 1,1′-bis(dimethylarsino)ferrocene (AF) of the type $[Rh(AF)_2]PF_6$ to form the complexes $[Rh(L)(AF)]PF_6$, which in their turn combine with various molecules X (X = H_2, O_2, Br_2, I_2, HCl, HBr, HI, MeI, $MeSO_2Cl$, $F_3CC{\equiv}CCF_3$, or MeSSMe), forming the compounds $[RhX(AF)]PF_6$, have been described[188]. The compound $[Rh(S_2)(AF)_2]PF_6$ has been obtained by the reaction with sulphur, while the reaction of $[Rh(O_2)(AF)_2]PF_6$ with SO_2 yields $[Rh(SO_4)(AF)_2]PF_6$.

IV. APPLICATIONS OF HETEROMETALLIC DERIVATIVES OF FERROCENE

In contrast to ferrocene and benzenechromium tricarbonyl, the ferrocenylcarbene complexes of chromium are catalysts of the hydrogenation of nitriles and amides to amines[100]. The hydrogenation of olefins does not occur under these conditions. The hydrogenation of various unsaturated compounds in the presence of chiral ferrocenylphosphinerhodium complexes is used to obtain optically active compounds[247–251].

Derivatives of the type

R = H, OH, NMe_2; R′ = H, PPh_2

are used as a rule of the chiral ligand.

The hydrogenation of α-acetamidoacrylic acids takes place with a yield of 86–94%.[194,248,252] The process takes place in various solvents with a high stereoselectivity (the optical yield is 89–93%). Acetophenone is hydrogenated rapidly and quantitatively to (*R*)-1-phenylethanol with an optical purity of 40%,[253] which is much higher than in the presence of other known rhodium catalysts of this process. The biologically active 2-amino-1-arylethanols are obtained by the hydrogenation of aryl aminomethyl ketones with 100% conversion and an enantioselectivity up to 95%.[249] Phosphine complexes of rhodium without ferrocenyl substituents exhibit a lower activity (80% conversion) and a lower optical yield (12%).

Dichloro[1,1′-bis(dimethylphosphine)ferrocene]nickel(II) catalyses the hydrosilylation of olefins and acetylenes[254,255]; in some cases this entails the substitution of hydrogen by chlorine. The hydrosilylation reaction is catalysed also by a platinum complex of this type. The asymmetric hydrosilylation of olefins, catalysed by chiral ferrocenylphoephine-palladium complexes[256], is used for the synthesis of optically active alcohols and alkyl bromides. A series of chiral phosphineferrocenerhodium complexes have been used successfully for the asymmetric hydrosilylation of ketones[257]. These HMF can give rise to hydrosilylation products with a higher optical yield than the phosphinerhodium complexes without ferrocene. Ferrocenylphosphinerhodium complexes are also effective catalysts of the hydroformylation of unsaturated compounds[258,259]. For example, the hydroformylation of hex-1-ene to n-hexanol takes place with 100% conversion and 93.2% selectivity.

The complex $(Ph_2PC_5H_4)_2FePdCl_2$ is the most active of the nickel and palladium complexes of phosphines in reactions of s-alkyl Grignard reagents with organic halides[260] and allyl alcohols[261]. The corresponding secondary derivatives are obtained as a result in a high yield (up to 97%). The reactions are not complicated by the isomerisation of the secondary alkyl groups to the primary groups, which is characteristic of other palladium and nickel complexes of phosphine. When chiral aminoalkylferrocenylphosphinenickel complexes are made to undergo this reaction, the corresponding optically active compounds are formed with a high stereoselectivity[262]. The same procedure has been used successfully for the asymmetric synthesis of terpenes[263]. It has also been shown recently that $(Ph_2PC_5H_4)_2FeNiCl_2$ is an effective catalyst of the reactions of t-alkyl Grignard reagents with bromostyrene[264], which results in the selective formation of $PhCH=CHCMe_3$. The application of nickel and cobalt compounds with polyfunctional aminophosphineferrocene ligands as catalysts of the isomerisation of alkyl groups[265] and prochiral allylamines[266] has been described. The initiating effect of the chelate complexes of ferrocenoylacetone in the polymerisation reactions of styrene and methyl methacrylate has also been described[267,268]. There are data concerning the catalytic activity of HMF in the thermolysis of $KClO_4$ [269] and as regulators of the combustion of rocket fuels[270]. The advantages of the application of salts of ferrocenesulphonic acid in rocket fuels compared with ferrocene have been noted[270]. It has been suggested that chromium complexes of ferrocenoylacetone be used as antistatic additives to petroleum products[4,48,221]. The application of the Fc–Li + Cp_2TiCl_2 mixture for the fixation of nitrogen[271], of the $TiCl_4$

complex of ferrocene in the photopolymerisation of epichlorohydrin[272], and of the salt $FeCp_2[Ni(S_2C_4F_6)_2]$ in dactyloscopy[20] has also been noted. The effectiveness of HMF in the synthesis of various ferrocene derivatives has been described in previous Sections.

The possibility of oxidising ferrocene to the cationic form and of carrying out the classical reactions of organic chemistry with the latter and the relatively ready availability of ferrocene derivatives permitted a successful development of synthetic studies designed to produce various heterometallic derivatives of ferrocene. A multiplicity of compounds of this type, containing virtually all transition metals, have been obtained. The data described in the review indicate the main pathways leading to the specific synthesis of HMF with specified structures and properties. The specific synthesis is facilitated when the classification of HMF proposed in this review and based on the characteristic features of the bond between the heterometal or its derivative and the ferrocene fragment is used, since such features determine the specific characteristics of the synthetic reactions of HMF of different classes. Because of this, definite possibilities arise in the planned synthesis of new HMF.

The successful development of synthetic studies created a basis for the practical application of HMF but hitherto only a few of them have found such applications. This is apparently because the majority of the compounds have been obtained in recent years and their properties have been inadequately investigated. The available data on HMF suggest that they will exhibit specific properties, particularly in catalysis, in various chemical reactions, and especially in the synthesis of ferrocene derivatives and optically active compounds which are otherwise difficult to obtain. However, at present it is still by no means always clear which characteristics of HMF determine the manifestation of particular useful practical properties of these compounds.

During the preparation of the review for the press, new studies on the synthesis, properties[273–287] and applications[288–293] of HMF were published.

Bivalent Tin Analogues of Carbenes

V.I.Shiryaev and Y.F.Mironov

The structure and certain chemical and physiocochemical properties of bivalent tin compounds (stannylenes) are examined and the electronic, structural and chemical similarity between these compounds and carbenes and their analogues—bivalent compounds of Group IVB elements—is demonstrated. The possibilities of stannylenes in the synthesis of organotin (IV) compounds as well as complexes in which stannylenes are electron-donating ligands, like carbenes, are analysed. The bibliography includes 457 references.

I. INTRODUCTION

During the last 15–20 years, the chemistry of bivalent tin compounds has developed rapidly; their structural and chemical similarity to compounds of other Group IVB elements in their lowest oxidation state—the bivalent compounds of carbon (carbenes)[1-5] and their closest analogues in the subgroup (silylenes, germylenes, and plumbylenes)[6-24]—is becoming increasingly evident.

Certain questions of the chemistry of tin(II) compounds have been reflected in monographs and reviews devoted mainly to the chemistry of quadrivalent tin[25-33]. The review by Donaldson[34], in which the structure and chemical properties of tin(II) compounds (mainly inorganic) were considered for the first time fairly fully (on the basis of the literature data up to 1966) as well as a series of reviews devoted to individual aspects of the chemistry of these compounds[9,18,35-38] merit special attention. For further information concerning the review literature and various problems of the synthesis, properties, and structure of tin(II) compounds, the reader is recommended to consult the Bibliographic Guide[39].

Numerous data indicating the chemical and structural similarity of carbenes and their analogues were first considered thoroughly in the review of Nefedov and Manakov[6] and later also other reviews[40-42], but they describe the chemistry of tin(II) compounds very briefly and incompletely. With the exception of relatively inaccessible publications in 1977 and 1978,[43,44] there has been hitherto no review analogous to those on silylenes and germylenes which would provide an adequate survey of studies demonstrating the structural and chemical similarity of tin(II) compounds to carbenes and their analogues. This review, which surveys studies published up to 1980, aims to fill this gap to some extent.

II. THE STRUCTURE AND PROPERTIES OF BIVALENT TIN COMPOUNDS

As a Group IVB element, tin has the outer electronic configuration ns^2np^2 in the ground state and, like its nearest neighbours in the subgroup (germanium and lead), can form stable compounds not only in the quadrivalent but also in the bivalent state. The formation of covalent inorganic and organic tin(II) compounds as well as organotin(II) compounds† can take place as a result of the employment of two unpaired p electrons (Fig.1).

Like carbenes and their analogues, in this case tin(II) compounds have the structure in the gas phase which can correspond in the one-electron approximation (i.e. when the fully occupied low-lying and vacant high-lying molecular orbitals are excluded from consideration) to the σ^2, σp, and p^2 configurations (Fig.2). The σp configuration can then be both singlet ($^1\sigma p$) and triplet ($^3\sigma p$), while the σ^2 and p^2 configurations are singlet.

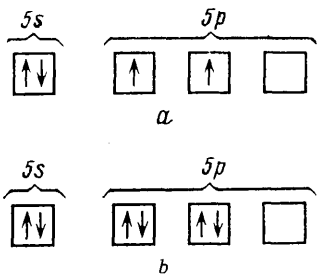

Figure 1. The distribution of electrons in the ground state: *a*) tin atom; *b*) SnX_2 molecule.

In the gas state at high temperatures, tin(II) dihalides are monomeric[45] and the study of their emission spectra under such conditions has shown that the SnX_2 molecules are non-linear[46]. The chemiluminescence emission spectra of SnX_2 in a flame[47] as well as the Raman spectra of the vapours of $SnCl_2$ [48,49] and other compounds of the type SnX_2 [50] at temperatures above 630 °C confirm the non-linearity of the structure of tin(II) dihalides under these conditions. Electron diffraction studies of the vapours of tin(II) dihalides established that the valence angle in their molecules is close to 95°.[50]

The results obtained agree with one another and also with infrared spectroscopic[51,52] and Mössbauer spectroscopic[53] data for tin(II) dihalides fixed in low-temperature inert matrices and make it possible to refine the values of the valence angles in the SnX_2 molecules (90–94°). Comparison of the bond angles and lengths in tin(II) dihalides and the dihalides of other Group IVB elements[9,40,41,50] shows that they are all isostructural and the closeness of the bond angles to 90° suggests that, like other carbene analogues,

† In contrast to organotin(II) compounds having at least one Sn–C bond, there is no direct bond between tin and carbon in organic compounds of tin(II).

stannylenes have a singlet ground state ($^1A_1$).[40,41] The singlet state of dihalogenostannylenes is confirmed by the fact that the energies of their orbitals (between −10 and −11.5 eV), determined from the ionisation potentials[54,55], are close to the energies of the σ orbitals of dihalogeno-derivatives of carbenes, silylenes, germylenes, and plumbylenes[40,41].

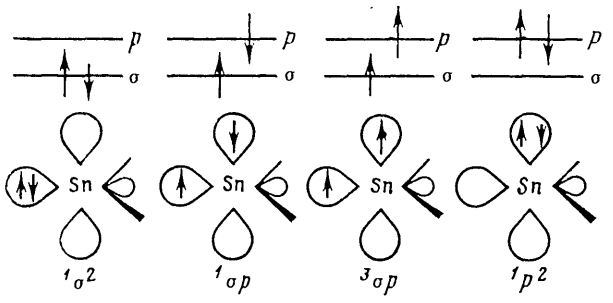

Figure 2. The structure of tin(II) compounds.

The direct determination of the energies of the *p* orbitals of stannylenes is impossible, but they can be estimated from the differences between the energies of the σ and *p* orbitals, which can be determined from the energy of the transition from the ground to the excited state ($^1A_1 \rightarrow {}^1B_1$). It was found that the energies of the *p* orbitals of dihalogeno-stannylenes (−6– −7 eV) are somewhat higher than the energies of *p* orbitals of carbenes but are very close to those of silylenes, germylenes, and plumbylenes. Thus the σ^2 configuration with a vacant *p* orbital makes the dominant contribution to the ground state of dihalogenostannylenes.

As in dihalogenostannylenes, in certain free stannylenes of other types in the gas phase and in the low-temperature matrices the tin orbitals are in a state close to sp^2. Thus spectroscopic investigations support a singlet ground state in a few diorganostannylenes[56] and stannylenes of the type $Sn(NR^1R^2)_2$.[57–59]

In a study of the phosphorescence observed in the GeO, GeS, SnO, and SnS molecules[60] isolated in low-temperature matrices, their lifetimes in the excited triplet states were calculated (3–100 μs).

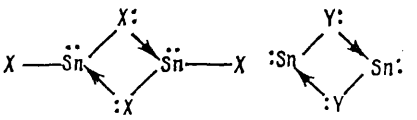

Figure 3. The structure of the dimers $(SnX_2)_2$ and $(SnY)_2$.

Mass-spectrometric studies of tin(II) halides and tin(II) monoxide[61,62] in the vapour phase revealed the presence, together with monomers, of the corresponding dimers, which consist, according to the spectroscopic studies of $(SnX_2)_2$ and $(SnO)_2$ molecules[52,53,63–66] as well as $(SnY)_2$ (Y = S or Se) [67] isolated in matrices at a low temperature, of four-membered rings formed as a result of the coordination interaction of the free electron pair of halogen, oxygen, sulphur or selenium with the vacant p orbital of the tin atom (Fig.3).

Structural and other physicochemical studies have shown that in the condensed (liquid or solid) phase many tin(II) compounds with electronegative substituents incorporating heteroatoms having unshared electron pairs are coordination polymers where the tin atoms employ in the hybridisation their own free *p* and *d* orbitals. Thus the X–Sn–X bond angles are somewhat less than 90° in crystalline anhydrous SnF_2,[68] $SnCl_2$,[69,70] $SnBr_2$,[71] and SnI_2 [72] and also in the mixed tin(II) halides[73,74], while their molecules form a coordination polycarbenoid layer structure (Fig.4), in which the free electron pair of the tin atom is involved in the hybridisation of the orbitals. The tetragonal tin monoxide $(SnO)_n$ [75] and tin(II) sulphide[69], selenide, and telluride[76] have similar structures.

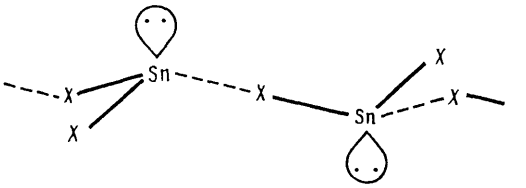

Figure 4. The layer structure of crystalline $(SnX_2)_n$.

The study of the Raman[77] and absorption[78] spectra of a melt of tin dichloride over a wide temperature range showed a gradual breakdown of the $(SnCl_2)_n$ chains with increase of the temperature of the melt. The weaker axial coordinate bonds begin to dissociate first and at a high temperature *in vacuo* free stannylenes can be formed in the gas phase[45,46,48–50]. The coordinate bonds in the polycarbenoid chains $(SnX_2)_n$ can break down also under the influence of electron-donating solvents (Solv) which results in the formation of discrete carbenoid complexes $Solv.SnX_2$, in which the tin atom is an acceptor of the electron pair of the solvent. The synthesis and properties of numerous complexes of this kind have been described in reviews[32,34]. It is of interest to note that the geometry of carbene-like molecules in such complexes differs little from the geometry of the free stannylenes, as shown by the similarity by the geometries of dichlorostannylenes and its complex with dioxan[79].

Organic compounds of tin(II) consists of a large group of compounds in which the organic moieties are linked to the tin atom via a heteroatom (oxygen, nitrogen, sulphur, phosphorus, and others). It has been established mass-spectrometrically that some of these [for example, $Sn(OCOAr)_2$,[80] bis(diketonato)tin(II),[81] and tin(II) amides[57,58]] are monomeric in the gas phase and also in solution. The majority of organic compounds of tin(II) having electron-donating heteroatoms are coordination intra- or inter-molecular complexes in the liquid and crystalline state. The most common types of compounds of this kind are cyclic[82–85] and linear[86–90] tin(II) alkoxides as well as acyloxy-derivatives of tin(II).[91–94]

Chelates with Sn–O bonds, such as bis(1,3-diketonato)-tin(II),[81,95–97] tin tropolonates[98], and many other tin(II) chelates[97,99–101] constitute a large group of organic compounds of tin(II). Their crystal structures have not been established in most cases, but the available X-ray diffraction data for solid bis(benzoylacetonato)tin(II) [101] and bis(1,3-diphenylpropane-1,3-dionato)tin(II) [102] suggest that their

ligands are bidentate and that the tin atom is an sp^3d hybrid (Fig.5*a*). It is believed[95,103] that the tin atom in 1,3-diketonatotin(II) halides is in the sp^3 configuration (Fig.5*b*). The tin atom in the monomeric product $Sn(OCH_2CH_2)_2NCH_3$ is evidently in the same state (Fig.5*c*).[104]

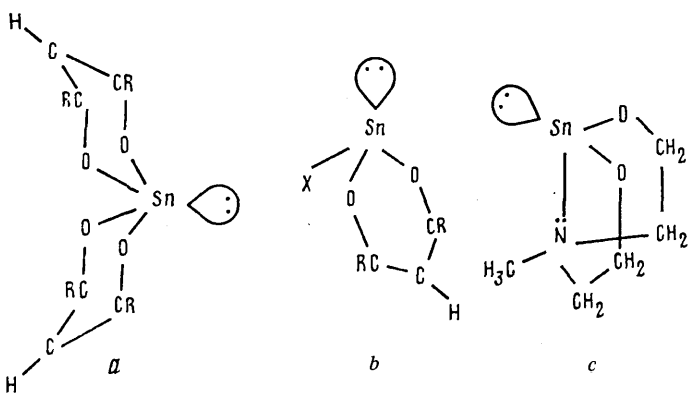

Figure 5. The structures of certain organic compounds of tin(II): *a*) bis (1,3-diketonato)tin(II); *b*) 1,3-diketonatotin(II) halides; *c*) $Sn(OCH_2CH_2)_2NCH_3$.

The crystal structure of bis(*O*-methyl dithiocarbonato)-tin(II),[105] bis(diethyldithiocarbamato)tin(II),[106] and diazasilastannetidines[107] are in principle analogous to the structures presented above. The structures of other organic compounds of tin(II), containing the Sn–N,[104,108-111] Sn–P,[112] Sn–As,[113] and certain other bonds[100,103,114] have not been established exactly although it has been suggested that the dimers of some of them, which exist in solutions, have structures analogous to those of the tin(II) dihalide dimers (Fig.3).

Little is so far known about the structures of organotin(II) compounds. The reason for this is in the first place that only few compounds of the type R_2Sn: (the first was obtained as early as 1852 [115]) can retain the tin atom in the bivalent state for a long time. In the vast majority of cases, regardless of the methods of their synthesis, diorganostannylenes polymerise very readily (see Section III). Certain organotin(II) compounds containing specific groups, which prevent the polymerisation of diorganostannylenes to the corresponding polystannanes, constitute an exception. Such compounds include dicyclopentadienyltin(II) [116] and bis-(methylcyclopentadienyl)tin(II),[117] which contain the cyclopentadienyl groups (Cp)—carriers of a closed π-electron system. Gas-phase electron diffraction studies established that the Cp^2Sn molecule has an angular sandwich structure[118] (Fig.6*a*).

Although dicyclopentadienyltin(II) is monomeric in the gas phase and in benzene solution, in the solid state it is a coordination polymer in which the cyclopentadienyl rings form a kind of bridges between the tin atoms (Fig.6*b*). In solid cyclopentadienyltin(II) chloride the coordination polymer is formed as a result of Cl...Sn coordinate bonds (Fig.6*c*). Other more exotic examples of organostannylenes are presented in Fig.7.[119-122]

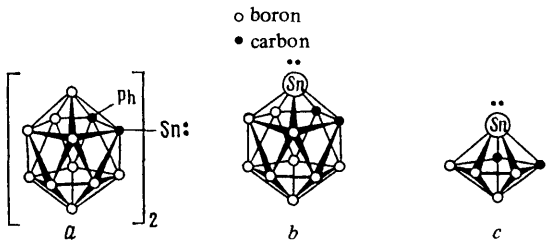

Figure 7. Some examples of organostannylenes: *a*) bis[2-phenyl-1,2-dicarba-*closo*-dodecaboran(12)-1-yl tin(II); *b*) 3-stanna-1,2-dicarba-*closo*-dodecaborane(11); *c*) small tin(II)-containing metallocarbaboranes.

The synthesis of the first stable dialkylstannylene containing two bis(trimethylsilyl)methyl groups, namely $[(Me_3Si_2)CH]_2Sn$:, was reported in 1973.[123] Its structure in the gas phase was not investigated but it was shown mass-spectrometrically that it exists in a free state: it is monomeric in solution and spectroscopic data indicate a singlet

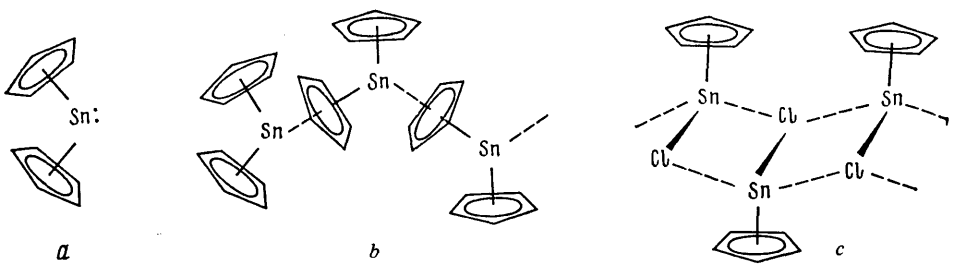

Figure 6. The structure of cyclopentadienyl derivatives of tin(II): *a*) Cp_2Sn in the gas phase; *b*) Cp_2Sn in the solid state; *c*) CpSnCl in the solid state.

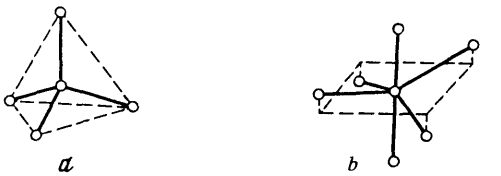

ground state of the molecule[56]. This has been confirmed by the study of the crystal structure of the complex $\{Cr(CO)_5 . Sn[CH(SiMe_3)_2]_2\}$ in which the valence angle of the diorganostannylene is close to 98°.[124] According to X-ray diffraction data[125], in the solid state $Sn[CH(SiMe_3)_2]_2$ is a dimer, whose curved bonds are formed as a result of the mutual overlap of the free electron pair of the tin atoms with their unoccupied *p* orbitals[56]. The angle between the C–Sn–C bonds then increase to 112°.

Numerous other compounds, which were believed for a long time to have been diorganostannylenes, proved to be polystannanes with a quadrivalent tin atom. Valuable information, which makes it possible to establish the valence state of the tin atom, is provided by Mössbauer or γ-resonance spectroscopy. The isomer shifts (*IS*) in the Mössbauer spectra of the majority of tin(II) compounds are in the range 3–4 mm s^{-1} (here and henceforth the values of *IS* are quoted relative to SnO_2), which indicates an appreciable *s*-electron density at the tin nuclei. This is a consequence of an appreciable *s* character of the orbital occupied by the free electron pair. When the environment of the resonating nuclei is non-spherical, usually two peaks are observed in the Mössbauer spectrum (quadrupole splitting); on the other hand, when the *s*-electron cloud is fully spherical, there is no quadrupole splitting. Information about the Mössbauer spectroscopy of tin(II) compounds can be found in a number of publications[53,126–129].

The diorganostannylene $[(Me_3Si)_2CH]_2Sn$ has a small isomer shift (*IS* = 2.16 mm s^{-1}) compared with other organotin(II) compounds[123,130], which is consistent with the difference between its structure and those of other diorganostannylenes—Cp_2Sn, CpSnCl, and CpSnBr (Fig.6)—in which the isomer shift (3.76 mm s^{-1},[131] 3.90 mm s^{-1}, and 3.69 mm s^{-1} [103,132] respectively) is only slightly smaller than for $SnCl_2$ (4.07 mm s^{-1}).[133] In solid $[(Me_3Si)_2CH]_2Sn$ the *s* electrons are involved in the formation of a dimer with weak Sn–Sn bonds (see Section III, subsection 1), while cyclopentadienyltin(II) compounds have no Sn–Sn bonds and are characteristic examples of tin(II) compounds with a non-bonding electron pair at each tin atom. Compounds of the type $(R_2Sn)_n$ (R = Bu, Ph, etc.) are polymeric or cyclic with a strong Sn–Sn interaction and their isomer shift (0.72 to 1.55 mm s^{-1}) [131,134] correspond to the quadrivalent state of the tin atom. Their structures have been demonstrated by chemical[25,26,135] and spectroscopic[136–138] methods and also by X-ray diffraction[139].

It is known that under certain conditions (in the vapour phase at the high temperature) carbon, silicon, and germanium form atomic species, which manifest carbene-like properties[4]. As will be shown below, tin in the vapour phase also exhibits similar properties. Metallic tin exists in two allotropic modifications: the α-form (grey tin) and the β-form (white tin). β-Tin is converted into the α-form fairly readily at +18 °C and below, particularly on contact with even very small amounts of α-tin. The shift *IS* in the Mössbauer spectrum is 2.56 mm s^{-1} for β-tin [140] (*IS* = 2.06 mm s^{-1} for α-tin [141]), i.e. it adjoins the region in which the values for tin(II) compounds are located.

In contrast to the tetrahedral configuration of α-tin (Fig.8*a*), in the β-form (Fig.8*b*) each tin atom is in a somewhat distorted octahedral environment characteristic of tin(II) compounds. Since the distance between the nearest tin atoms in the β-form is somewhat greater than in the α-form, the Sn–Sn bonds in β-tin should be weaker. The octahedral environment in β-tin probably entails the involvement of the free electron pair in hybridisation and the occurrence of donor–acceptors interactions (although these may be weak) between the tin atoms. Consequently Sn(II) binding evidently occurs in β-tin and the latter can be regarded as a carbene-like layer polymer with donor–acceptor bonds between the layers. Chemical confirmation of this is provided by the formation of tin(II) dihalides from β-tin and hydrogen halides (see Section III). Tin(IV) tetrahalides are formed from α-tin under analogous conditions[32]. It is noteworthy that atomic tin, fixed in a nitrogen matrix, has *IS* = 3.23 mm s^{-1} in the Mössbauer spectrum[142] and therefore consists of the free stannylene—more precisely the bistannylene $\dot{S}n$.

III. REACTIONS OF STANNYLENES LEADING TO THE FORMATION OF QUADRIVALENT TIN COMPOUNDS

A consequence of the electronic and structural similarity of stannylenes to other carbene-like molecules of Group IVB elements with covalence unsaturation is the ability to form new chemical bonds. The presence of the stereochemically active free electron pair enables stannylenes, like carbenes, silylenes, and germylenes, to polymerise, to become inserted in single bonds, to add to carbon–carbon double bonds, etc. and also to form carbenoid complexes in which stannylenes behave as donors of an electron pair. The high reactivity of carbene-like molecules is determined mainly by the electrophilicity of the vacant *p* orbital, which decreases appreciably from carbenes to silylenes, but changes little in the series of germylenes, stannylenes, and plumbylenes[40,41].

1. Dimerisation and Polymerisation of Stannylenes

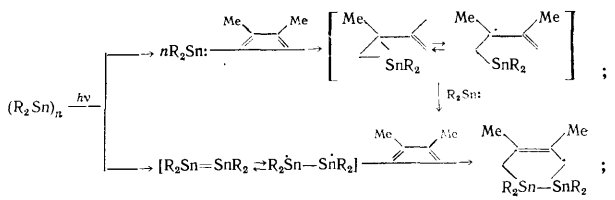
One of the main characteristic properties of carbenes, which follows from their covalence unsaturation, is the ability to form one (sp^2) or two (sp^3) new covalent bonds. The carbene-like compounds of Group IVB elements, including stannylenes, are not exceptional in this respect although the formation of a single new covalent sp^2 is energetically less favourable for these elements[40,41]. The possibility of the existence of the dimers of certain organic compounds of tin(II), namely $(R_2P)_2Sn{=}Sn(PR_2)_2$ and $(Me_2N)_2Sn{=}Sn(NMe_2)_2$, has been postulated by some workers[143,144], while the dimer $\{[(Me_3Si)_2CH]_2Sn\}_2$, which has been isolated and characterised in the crystalline state, has, as mentioned above, a weak Sn–Sn bond which readily dissociates on dissolution in benzene[125].

Presumably the absence in the vast majority of instances of "olefinic" stannylene dimers from the reaction products can be explained by their extremely high reactivity and especially their tendency to polymerise[25,26,28,30,31,33,145,146]:

$$n/2\,[R_2Sn{=}SnR_2] \rightarrow n/2\,[R_2\dot{S}n{-}\dot{S}nR_2] \rightarrow (R_2Sn)_n .$$

The reduced ability to polymerise of a few of the diorganostannylenes presented in Fig.7 can be accounted for primarily by steric factors due to the presence of bulky substituents. Steric factors are not the only cause of the decrease

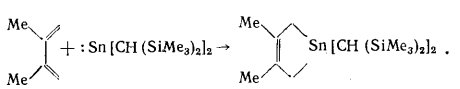
of the ability of stannylenes to dimerise and polymerise. Thus the reduced capacity for polymerisation of Cp_2Sn molecules agrees with the postulated filling of the unoccupied *p* orbital of the tin atom by the π electrons of the cyclopentadienyl ring (Fig. 6*b*). The polymerisation of Cp_2Sn becomes possible in the presence of dimethylformamide (DMF).[131] Similarly the "filling" of the unoccupied *p* orbital of the tin atom by the free electron pair of a halogen, oxygen, or sulphur atom or another donor of an electron pair in inorganic and organic compounds of tin(II) lowers their ability to polymerise with formation of Sn–Sn bonds. An instance of the copolymerisation of $SnCl_2$ with methylene, generated from CH_2N_2, is known[147]:



$$:SnCl_2 + :CH_2 \rightarrow [H_2C{=}SnCl_2] \rightarrow [-SnCl_2-CH_2-SnCl_2-CH_2-]_n \ .$$

2. The Reactions of Stannylenes with Unsaturated Compounds

The main and preparatively most interesting reaction of carbene is that with the multiple bonds of unsaturated compounds leading to the formation of cyclopropane or cyclopropene derivatives[1–6]. When carbene analogues, derivatives of Group IVB elements, react with olefins, the products of the further reactions of the corresponding heterocyclopropanes rather than the heterocyclopropanes themselves are isolated.

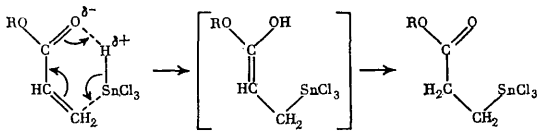


The polymer $(-CF_2-CF_2-SnPh_2-)_n$, the product of the formal addition of diphenylstannylene to the C=C bond, has been obtained in the photolysis of $(Ph_2Sn)_n$ in the presence of tetrafluoroethylene[148].

The photolysis of cyclic polystannanes $(R_2Sn)_n$ in the presence of 2,3-dimethylbutadiene yielded additional products containing two tin atoms in the ring[149]. The formation of these products can be represented as a result of the 1,4-addition of the biradical $R_2\dot{S}n-\dot{S}nR_2$ or the consecutive addition of the stannylenes R_2Sn: to the diene:

R = Me, n-Bu .

The 1,4-cycloaddition of $[(Me_3Si)_2CH]_2Sn$ to 2,3-dimethylbutadiene takes place readily (in hexane at room temperature) and this is perhaps the only example in which it has been shown unambiguously that free diorganostannylenes participate in the formation of the addition product[150]:



Conflicting data have been obtained in reactions of tin(II) dihalides[151,152], organic compounds of tin(II),[153] and organotin(II) compounds[146] with acetylenedicarboxylate esters: in some cases the formation of the corresponding addition products has been reported, while in others it is claimed that complexes are formed whose Mössbauer spectra contain a doublet in the region characteristic of bivalent tin, which corresponds to a structure with simple donor–acceptor interaction. Analogous complexes are probably formed in reactions of stannylenes with diethyl diazodicarboxylate[103,152] and with tetracyanoethylene[154–156].

It has been established recently that trichlorostannane etherate (see subsection 4 below), which has a structure analogous to trichlorogermane etherate[157–159], interacts with unsaturated compounds having a carbonyl group in the α-position relative to the carbon–carbon bond (acrylates, crotonates, acrylic and methacrylic acids, acryloyl chloride, phorone and others), giving rise to high yields of hydrostannylation products[159–163]:

$$RO-\overset{\overset{O}{\|}}{C}-CH{=}CH_2 + HSnCl_3 \cdot 2Et_2O \rightarrow RO-\overset{\overset{O}{\|}}{C}-CH_2CH_2SnCl_3 \ .$$

The etherates of $HSnX_3$ react similarly with the methyl esters of acetylenecarboxylic acids $RC{\equiv}CCO_2CH_3$ (R = H, Me, Ph, or $COOCH_3$), forming the corresponding 1,4-addition products $Cl_3SnCR{=}CHCO_2CH_3$ and the products of their further reactions[164].

The mechanism of these reactions is not altogether clear. The ionic 1,4-addition of $HSnCl_3$ is believed to be the most probable[159,161–163]:

The analogous reaction of the etherates of $HSnX_3$ with unsaturated compounds of the type of acrylonitrile[165], in which the carbon–carbon double bond is activated by conjugation with a C≡N bond, has also been described.

3. The Insertion of Stannylenes in Single Bonds

The insertion in single bonds is a general reaction of those carbenes[1–5] and their analogues[6–24,40,41] although the latter should exhibit a greater selectivity in this process than carbenes, whose electrophilicity is higher. Instances of the insertion of stannylenes in various single bonds are known: C–X, M–X, C–M, M–M, S–S, etc.

(a) The insertion of stannylenes in a carbon–halogen bond. This reaction discovered by Pfeiffer and Heller almost 100 years ago[166] is of great practical importance, since it makes it possible to obtain in a single stage compounds which are usually difficult to synthesise:

$$R-X + SnY_2 \rightarrow RSnY_2X \ .$$

The reactivity of alkyl halides in these reactions decreases appreciably in the sequence RI > RBr > RCl, so that different catalysts are used to achieve a successful reaction with bromides and even more so, chlorides: amines[167], phosphines[168] (and their onium salts), bivalent sulphur and selenium compounds[169], salts of various Group I–III metals[170–173], and tervalent antimony compounds[174,175]. In conformity with the influence of steric factors, the yield of reaction products decreases with increase of the number of carbon atoms in the alkyl group R.[175]

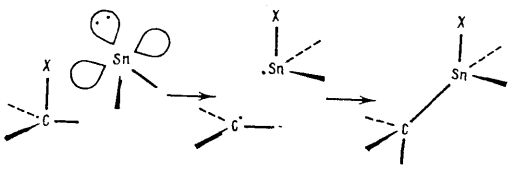
This reaction has been used successfully to develop an industrial method of synthesis of $MeSnCl_3$ [172,176] and also for the development of preparative methods of synthesis of carbofunctional trihalogenostannanes which are difficult to obtain, for example[175,177–179,180–182]:

$$X(CH_2)_nX + SnX_2 \rightarrow X(CH_2)_nSnX_3 \ ;$$

X = Cl, Br; n = 1, 3, 4, 5, 6 ;

$$Y_nMe_{3-n}SiCH_2Cl + SnCl_2 \rightarrow Y_nMe_{3-n}SiCH_2SnCl_3 \ ;$$

Y = alkyl, aryl, cyclopropyl, F, Cl, MeO, EtO, RCOO; n = 0–3 ;



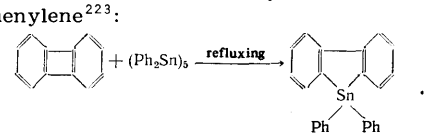
$$R_3SiCH_2Cl + SnO \rightarrow [R_3SiCH_2Sn(O)Cl]_4 + R_3SiCH_2SnCl_3 + (R_3SiCH_2)_2SnCl_2 \ .$$

Different diorganostannylenes R_2Sn, obtained by the thermal, photolytic, or some other method, are also inserted in the carbon–halogen bonds of organohalogen compounds[103,146,149,150,153,184–194] and their reactivity is so high that, for example, $[(Me_3Si)_2CH]_2Sn$ is inserted even in the C_{ar}–Cl bonds of chlorobenzene[184].

The reactivity of organic compounds of tin(II) without the C–Sn bond is somewhat lower than that of diorganostannylenes; nevertheless the products of the insertion of various tin(II) chelates[95,98,103,153,195,196] and also $[(Me_3Si)_2N]_2Sn$ [184,185] and $[(CO)_5M]_2Sn$ (M = Cr, Mo, or W) [197] in the C–I bond in alkyl iodides and in the activated C–halogen bonds of organobromine or organochlorine compounds have been obtained in high yields.

Finally, the reactions of the anions $:SnX_3^-$ and $:Sn(OH)_3^-$, having stereochemically active free electron pairs, with organic halides RX, leading to the formation of the product of the formal insertion in the C–X bond, have been described[198–201]. It has been suggested that the insertion of stannylenes in the C–X single bond in organic halides constitutes the basis of a direct synthesis of organotin halides[202–205]. It has been established that free (in the vapour phase) tin atoms readily react with alkyl halides to form the intermediate [RSnX] (R = Me, Et, or Bu; X = Br or I).[206] It has been shown for the intermediate [BuSnBr], isolated at a low temperature, that these alkylhalogenostannylenes are highly reactive with respect to various reagents and are particularly readily inserted in the C–halogen bonds in alkyl halides to form R_2SnX_2—the desired product of the direct synthesis.

The mechanism of the insertion of stannylenes in the C–halogen bond is not altogether clear[207–209]. Bearing in mind the fact that stannylenes are isostructural with singlet carbenes, silylenes, and germylenes, a common mechanism may be expected for the insertion of these species in single bonds[40,41,43], according to which the electrophilic unoccupied *p* orbital of the carbene or its analogue attacks the corresponding bond. Next the reactive molecules approach one another, which is accompanied by the migration of the halogen to the tin atom and the recombination of the resulting close radical pair.



It may be that in the catalytic reactions of SnX_2 or $(R_2Sn)_n$ with R'X the electron-donating catalyst molecules promote the dissociation of the polymer chain of the polystannylene and the formation in solution of discrete stannylene molecules. In some communications the insertion of stannylenes in C–halogen bonds is regarded as a radical-chain process[185,194].

(b) The insertion of stannylene in the C–M, C–C, M–M, and M–H bonds. Like carbenes, diorganostannylenes R_2Sn are readily inserted in the C–Li, C–Na,[210] and C–Mg[211] bonds with formation of compounds of the type R_3SnM (M = Li, Na, or MgX). The appearance of branches in the polymer chain of $(R_2Sn)_n$ [25,26,28,191] and the formation of $(R_3Sn)_3SnLi$ when an attempt is made to isolate R_3SnLi from solution[212,213] can probably be explained by the insertion of diorganostannylenes in the C–Sn bond. This is confirmed by the formation of $Me_3SnSnBu_2Me$ in the reaction of Bu_2Sn with Me_4Sn.[149] One cannot rule out the possibility that the familiar reaction involving the displacement of mercury from its dialkyl and particularly diaryl derivatives by tin(II) dihalides and diorganostannylenes also proceed via the initial insertion of stannylenes in the C–Hg bond:[214–218]

$$R{-}Hg{-}R + SnY_2 \rightarrow [R{-}Hg{-}SnY_2{-}R] \xrightarrow{-HgY_2} R_2SnY_2\ ;$$
Y = halogen, alkyl, or aryl.

Stannylenes are inserted just as readily in carbon–transition metal bonds. The insertion of $Sn(NR_2)_2$ [219] and SnX_2 (X = Cl or Br) [220–222] in the Fe–C bond and also of $[(Me_3Si)_2CH]_2Sn$ [150] in the Mo–C and Fe–C bonds has been described.

So far only one example of the insertion of stannylene in a carbon–carbon bond is known, namely in the strained C–C bond of biphenylene[223]:

Like the carbonoid molecules of other Group IVB elements, paricularly germylenes[20–22], stannylenes are readily inserted in metal–metal bonds. In particular, the insertion of diorganostannylenes in the Sn–Na [6,224,225] and Sn–Sn [149,188,192,226–228] bonds and also the insertion of $SnCl_2$ in the B–Hg bond[229] are known. However, this reaction is represented most widely by instances of the insertion of stannylenes in the M–M bonds of dinuclear compounds of transition metals [L is a ligand of the type CO, Cp, PR_3, $P(OR)_3$, etc.]:

$$L_xM{-}ML_x + SnY_2 \rightarrow L_xM{-}SnY_2{-}ML_x\ .$$

Examples of the insertion of stannylenes in the Fe–Fe,[230–232] Ni–Ni,[233] Co–Co,[118,233–239] Cr–Cr, Mo–Mo, W–W,[240] Mn–Mn, and Re–Re [241–243] bonds have been described. The synthesis by this method of tin-containing carbonyl complexes of iron, cobalt, rhenium, and rhodium fixed on a carrier has been reported[244]. Mössbauer spectroscopic data are available for certain products of insertion in M–M bonds, showing that the tin atom in such products is in the quadrivalent state of oxidation (*IS* = 1.27–1.99 mm s^{-1}).[231–237,245–247] It is believed [248] that the formation of $Sn[Co(CO)_4]_4$ from metallic tin and $Co_2(CO)_8$ also involves the insertion in the Co–Co bond initially of the Sn atom and then of the intermediate stannylene $[Co(CO)_4]_2Sn$:.

A few examples indicating the ability of stannylenes to be inserted in the Sn–H [6,149] and Mo–H [124,150,249] bonds are also known.

(c) Insertion of stannylenes in M–X bonds. There are very few examples of the insertion of stannylenes in a non-transition metal–halogen bond. In particular, reactions involving the insertion of diorganostannylenes in the Sn–Cl bond[226,228] and also of metallic tin[217], dihalogenostannylenes[250], and di(permethylcyclopentadienyl)tin(II) [251] in the Hg–X bond have been described. The reaction involving the insertion of stannylenes in a transition metal–halogen bond is more general. Examples of the insertion of dihalogenostannylenes in the Fe–Hal,[130,150,231,232,246,252–256] Cr–Hal, Mo–Hal, W–Hal,[40,257] Co–Hal,[258,259] Rh–Cl,[124,140] Pd–Cl,[260–262] Pt–Cl,[255,263–265] Ir–Cl,[140,255,266] Mn–Hal,[266] Ni–Cl,[267] and Ru–Hal [255,268,269] bonds and also of $[(Me_3Si)_2CH]_2Sn$ in the Pt–Cl,[130] Fe–Cl,[130,150] and Rh–Cl [124] bonds are now known.

The reactions are usually carried out in polar or non-polar solvents at room temperature or with slight heating; sometimes the process is initiated photolytically. The isomer shifts *IS* in the Mössbauer spectra of the products of the insertion of stannylenes in the M–X bonds are 1.54–2.02 mm s^{-1},[130,140,150,231,246,253,256,258,259,270] which corresponds to the quadrivalent oxidation state of the tin atoms. However,

in certain similar instances the isomeric shift for the formal products of the insertion of stannylenes in a transition metal–halogen bond are in the intermediate range or even in the range characteristic of bivalent tin. Such products, containing discrete SnX_3^- anions as electron-donating ligands, are formed via an ionic mechanism and are discussed below (in Section IV).

(d) The insertion of stannylenes in the S–S bonds of disulphides, the O–O bonds of peroxides, and certain other bonds. Different types of stannylenes are extremely readily inserted in the S–S bonds of diorganodisulphides:

$$Y_2Sn + RS{-}SR \rightarrow RS{-}SnY_2{-}SR ,$$

where Y = Me, Bu, Ph,[149,253] Cp, OMe, SPh, chelate[103,153], oxinate (Ox),[271] or halogen[152,272,273] and R = alkyl, phenyl, Br, Py, or (iso-Pro)$_2$P(S).

The insertion of tin(II) dihalides[152], diarylstannylenes[253], dialkylstannylenes[149,274,275], and tin(II) oxinates[271] in the O–O bonds of organic peroxides ROOR [R = alkyl or C(O)Ph] takes place just as readily, sometimes exothermically.

Examples of the insertion of dihalogenostannylenes in the P–O–P bond in diethylphosphoric and diphenylphosphinic acid anhydrides[276] and also in the N–Cl bond of *N,N*-dichloro- or *N*-chloro-*N*-methyldialkylphosphoramides[277] and the *N,N*-dichloramides of arenesulphonic acids[278] are known.

4. Reactions of Stannylenes with Oxygen, Sulphur, Phosphorus, Halogens, Hydrogen Halides, and Other Similar Compounds

One of the first reactions of diorganostannylenes discovered is their oxidation by atmospheric oxygen[25,26,31,33,150,225]:

$$R_2Sn + O_2 \rightarrow R_2SnO .$$

Organohalogenostannylenes RSnX [206] and organic compounds of tin(II) [81,97,279] are also readily oxidised in air. The capacities of inorganic tin(II) compounds for oxidation are different: tin(II) monoxide is oxidised in air only on heating[32]; tin(II) sulphate $SnSO_4$ is very resistant to oxidation[34]; solid tin(II) halides are slowly oxidised in air but in solutions the reaction is greatly accelerated[152]. In a study of the products of the reaction of atomic tin with oxygen in the vapour phase by the matrix isolation method, it was shown that the initial step in the formation of the main products (SnO_2, SnO, Sn_2O_2, Sn_3O_3, etc.) is the insertion of atomic tin in the O–O bond of the O_2 molecule[280].

Stannylenes react analogously with sulphur, forming the corresponding sulphides $(R_2SnS)_x$.[253,281–283] Diorganostannylenes react just as readily with white phosphorus[284,285] and tellurium[286] forming the corresponding insertion products $(Me_2Sn)_nE_m$ (E = P or Te; n = 3, 5, or 6; m = 2, 3, or 4).

When stannylenes react with halogens, a wide variety of halogenostannanes are formed very readily[6,98,99,103,150,153,186,206,251,271,281,287,288] (Y = halogen, alkyl, aryl, chelate, etc.):

$$Y_2Sn + X_2 \rightarrow Y_2SnX_2 .$$

Free diorganostannylenes react readily with hydrogen halides:

$$R_2Sn + HX \rightarrow R_2Sn(H)X .$$

where R = $(Me_3Si)_2CH$ [150] or t-Bu [289] and X = F or Cl.

On the other hand, protolytically unstable stannylenes undergo various reactions under the influence of hydrogen halides. Thus the cyclopentadienyl groups in Cp_2Sn are readily split off under the influence of HX to form CpSnX or SnX_2,[103,132] while the P–Sn bond in $(t\text{-Bu})_2P{-}Sn{-}Cl$ dissociates on treatment with HCl and $[(t\text{-Bu})_2\overset{+}{P}H_2]SnCl_3$ is formed[290].

In contrast to the analogous carbon, silicon, and germanium compounds, trihalogenostannanes $HSnX_3$, formed when SnX_2 reacts with dry hydrogen halides, are unstable[157]. However, in ethereal solution the $HSnX_3$ are stabilised as a result of the formation of relatively stable etherates $[Et_2O \rightarrow H...OEt_2]^+ . SnX_3^-$,[158] for which the more complex structure $H_nSnX_{2+n} . mEt_2O$ (m/n = 1.1–1.5) has been postulated[159]. The aminates of trihalogenostannanes $[R_3NH]^+SnX_3^-$ proved to be more stable[291,292].

Evidently the formation of SnX_3 from metallic β-tin and HX can also be regarded as a carbenoid reaction, although the formation of the extremely unstable intermediates [HSnX] and $[H_2SnX_2]$ still awaits confirmation:

$$\beta\text{-}Sn + HX \rightarrow [HSnX] \xrightarrow{HX} [H_2SnX_2] \xrightarrow{-H_2} SnX_2 .$$

IV. STANNYLENES AS ELECTRON-DONATING LIGANDS IN COMPLEXES

One of the characteristic properties of carbenes and their analogues is their ability to form complexes with various compounds of non-transition and transition metals[9,36,42,293–299]. By virtue of the presence of the σ orbital, which is a carrier of a nucleophilic free electron pair, stannylenes can also play the role of electron-donating ligands in complexes where the tin atom is in the lowest oxidation state. In connection with the increased interest in complexes of carbenes and their analogues, there has been a recent appreciable increase of the number of publications on the corresponding complexes of tin(II) compounds[18,33,34,36–38,42,44,300–308].

Treatment of tin(II) dihalides with an excess of organolithium, organosodium, organomagnesium, or organozinc compounds is known to result in the formation of the corresponding compounds of the type R_3SnM:[33]

$$Y_2Sn: + 2R{-}M \rightarrow R_2Sn: \xrightarrow{R-M} R_3SnM ;$$
$$M = Li, Na, MgX, ZnX .$$

As early as 1952, it was suggested that Rh_3SnLi is 20% dissociated in solution[309]:

$$Ph_3SnLi \rightleftarrows Ph_2Sn: + PhLi .$$

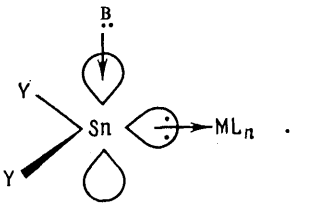
Later equilibrium between R_3SnLi, R_2Sn:, and RLi,[310,311] and also in the analogous reactions involving magnesium [312] and zinc [313,314] compounds, possibly with participation of stannylene–salt complexes of the type $R_2Sn.MR$, was frequently confirmed chemically, although Mössbauer spectroscopic data have shown that the values of *IS* in such cases correspond, with rare exceptions[315], to the quadrivalent state of the tin atom[211,313].

The possibility of the existence of such carbene-salt complexes has been postulated in the mechanism of Simmons–Smith reactions[315–318] and also in the explanation of numerous data concerning the appreciable influence of alkali metal salts present in the reaction medium on the properties of independently generated carbenes (the salt effect).[4,42,299,319,320]

In their reactions with stronger electron pair acceptors such as the trihalides of Group III elements, stannylenes form the stable complexes $Y_2Sn.MX_3$ [M = B or Al; Y = Cp, MeCp, $(Me_3Si)_2CH$, halogen, or chelate].[98,150,204,321–323] In a number of instances such complexes are formed as a result of the displacement of weaker ligands from their complexes with MX_3:[98,204,322,323]

$$Y_2Sn: + BX_3{\cdot}OEt_2 \rightarrow Y_2Sn{\cdot}BX_3 + Et_2O .$$

The Mössbauer parameters of these complexes (*IS* = 3.71 to 3.83 mm s^{-1}) [98,204,323] correspond to the bivalent state of the tin contained in them. The possibility of the formation



of the ionic complexes $[CpSn]^+MX_4^-$ or the bridged complexes $CpSn-X-MX_3$, in which there is no Sn–M σ-bond, has been discussed for organohalogenostannylenes of the type CpSnX in reactions with MX_3 (M = B or Al).[323–327]

As in carbene chemistry[42,293–299], complexes of stannylenes with various transition metal compounds are the most stable and have been investigated more than others. One of the main reactions involved in the synthesis of complexes of this kind is the displacement (photolytic or thermal) by stannylenes of other ligands, for example, carbon monoxide molecules, from transition metal carbonyls:

$$Y_2Sn: + LM(CO)_x \rightarrow CO + Y_2Sn\cdot M(CO)_{x-1}\cdot L \ ;$$
$$M = Fe, Cr, Mo, W, Mn;\ L = CO, Cp, MeCp, PhCN \ .$$

This reaction is common to different types of stannylenes—diorganostannylenes[38,123,124,150,328,329], organic compounds of tin(II) such as tin(II) chelates[330–332], $Sn(NMe_2)_2$,[144] $Sn[N(SiMe_3)_2]_2$,[37] $Me_2Si\begin{matrix}NR\\ \diagup\ \diagdown\\ NR\end{matrix}Sn$,[283] and 1,2,3-$SnC_2B_4H_4Me_2$,[122] as well as inorganic tin(II) compounds, in particular dihalogenostannylenes[331,333–336]. The more electrophilic ligand $[(Me_3Si)_2CH]_2Sn$ displaces norbornadiene ligands[124,150], Ph_3P,[124] and Et_3P [124,150] from transition metal complexes.

In some cases stannylene complexes are stabilised by the additional coordination interaction of the tin atom with the electron pair of a base B:[144,334,335]

Similar complexes are known also for silylenes and germylenes, where stabilisation as a result of coordination to a base B̈ evidently constitutes an essential condition for their stability[42,337–342]. An instance of a carbene complex with additional stabilisation by a base is also known, namely the complex $(CO)_5W.CPh_2.PMe_3$.[343]

Complexes of stannylenes stabilised by a base can also be obtained by the cleavage of complexes whose structure is based on the four-membered ring M_2Sn_2.[144,328,344–348] These complexes are readily cleaved by bases B̈ and the ability of the latter to split the Sn–M bond in the four-membered ring M_2Sn_2 decreases in the sequence[346,348] pyridine > dimethyl sulphoxide (DMSO) > acetone > tetrahydrofuran (THF) > diethyl ether. Weak bases in such complexes can be displaced by stronger bases:[349]

$$(CO)_5W\cdot SnCl_2\cdot THF + (Me_3C)_3P \rightarrow (CO)_5W\cdot SnCl_2\cdot P(CMe_3)_3 + THF \ .$$

The additional coordination interaction with the base B makes the stannylenes more nucleophilic and stabilises the stannylene complex to such an extent that various reactions involving the substitution of chlorine atoms in dichlorostannylene complexes become possible[197,350–352]:

$$(CO)_5M\cdot SnCl_2\cdot THF + Me_3Si{-}X \rightarrow (CO)_5M\cdot Sn\begin{matrix}X\\ \diagup\\ \diagdown\\ Cl\end{matrix} + Me_3SiCl + THF;$$
$$M = Cr, Mo, W;\ X = \ t\text{-}Bu_2E(E = P, As), \quad t\text{-}BuS \ .$$
$$(CO)_5M\cdot SnCl_2\cdot THF \xrightarrow{ROH} (CO)_5M\cdot Sn(OR)_2 \ ;$$
$$M = Cr, Mo, W;\ R = H, Et \ .$$
$$(CO)_5M\cdot SnCl_2\cdot THF + Me_3SnOH \rightarrow (CO)_5M\cdot Sn(OH)_2 + Me_3SnCl \ ;$$
$$(CO)_5M\cdot SnCl_2\cdot THF + NaM'(CO)_5 \rightarrow (CO)_5M\cdot Sn[M'(CO)_5]_2 + NaCl + THF \ ;$$
$$M, M' = Cr, Mo, W \ .$$

The stannylene complex evidently can be stabilised also by the coordination interaction of the stannylene with the free electron pair of a halogen atom which functions as the base B̈. Tin(II) dihalides and also certain other stannylenes with electronegative substituents X (electron pair donors) are known[32,34,129] to be capable of forming intermolecular coordinate bonds Sn–X–Sn (Figs. 3 and 4) and to be able to react with electron-donating solvents (Solv.) to form discrete complexes $SnX_2.Solv.$[32,34] The electron pair donor X can be abstracted also from other metal halides, which entails the formation of discrete stable complex anions X_3Sn^- (Fig. 9*a*). The ions X_3Sn^- have a trigonal-pyramidal structure in which all three atoms X and the free electron pair are involved in the sp^3 hybridisation of the tin(II) orbitals[322,323,353].

The high nucleophilicity of the stannylene stabilised by coordination to an anion X^- and the extremely high stereochemical activity of its free electron pair make it possible to obtain stable complexes of the type $M^{n+}(SnX_3)_n$ (Fig. 9*b*) from SnX_2 and alkaline earth metal salts $M^{n+}X_n$ (n = 1 or 2; X = halogen[354–361], acetate[94,353,362], or other anions[32,34,363,364]) and also quaternary oniom salts[133,361,363,365–368]. A characteristic feature of these complexes is the largely ionic character of the Sn–M bond and the high density of the *s* electrons at the tin nuclei and hence also high Mössbauer *IS* values (2.83–4.03 mm s^{-1}).[94,133,355,357–359,365,367–370]

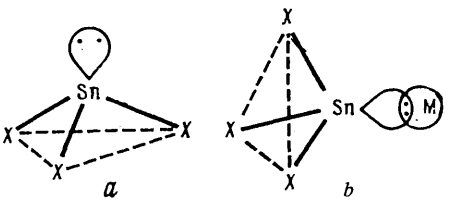


Figure 9. The structures of the anion X_3Sn^- (*a*) and the complex $M^+SnX_3^-$ (*b*).

Taking into account the stereochemical activity of the free electron pair in X_3Sn^-, an attempt was made to obtain its complex with BF_3,[371] but it was shown later that in this case a different process takes place[372]:

$$SnCl_3^- + BF_3 \rightarrow (BF_3Cl)^- + SnCl_2 \ .$$

As electron pair donors, the anions SnX_3^- form stable complexes with various transition metal compounds. One of the commonest and simplest methods of synthesis of complexes of the type $X_3Sn.M$ is the reaction of dihalogenostannylenes with transition metal halides, particularly those which contain electron-donating ligands L:

$$SnX_2 + MX\cdot L \rightarrow X_3Sn\cdot M\cdot L \ .$$

Such reactions, which involve the insertion of SnX_2 in a covalent bond M–X, were described above (Section III). When the M–X bond in metal halides is ionic, the interaction of the latter with SnX_2 is ionic, as happens for alkali and alkaline earth metal salts, and also in the reaction of $SnCl_2$ with $(Ph_3P)_3MCl$ (M = Cu, Ag, or Au) in organic solvents[255] or in water[373]. The interaction of tin(II) dihalides with MF_2 (M = Fe, Co, or Ni),[374] $CpNi(PPh_3Cl$,[375,376] $[RuI(CO)_3.(PPh_3)_2]I$,[268] $CpFe(dppe)X$,[377] $(R_3P)_2Pt(CL)H$,[263,378,379,380] and other halogeno-derivatives of transition metals[250,381,382] takes place similarly:

As in the case of stannylenes, one of the methods of synthesis of complexes of type $X_3Sn.M$ involves the displacement of other ligands by X_3Sn^- anions:

$$ML_n + SnX_3^- \rightarrow [ML_{n-1} \cdot SnX_3]^- + L\ ;$$
$$M = Cr, Mo, W, Fe, Co, Ni, Mn, V\ .$$

CO molecules,[257,383–389] π-arene ligands (mesitylene, cycloheptatriene, and benzene),[385,386] acetonitrile[386] and PF_3 [390, 391] molecules, and also halide anions[255,392–399] are displaced in this way. Solutions of mixtures of SnX_2 with R_4EX (E = N, P, or As) or with HX in water or organic solvents[255, 393–399], for example, in ether where the corresponding etherates are formed from SnX_2 and HX,[158,159] can serve in this instance as sources of the ligands X_3Sn^-. The etherates of $HSnX_3$, which are convenient sources of the X_3Sn^- anions, can be obtained successfully by reducing SnX_4 with lithium tetrahydrolaluminate[400]. Other methods of synthesis of complexes of the type $X_3Sn.M$ from quadrivalent tin compounds are also known[268,401–404].

The few available literature data indicate the similarity of the structures of a series of stannylene and carbene complexes[42]. Thus according to structural studies[38], the valence angle of stannylene in the complex $[(Me_3Si)_2CH]_2Sn.Cr(CO)_5$, which is 98°, differs little from the valence angles of free stannylenes, i.e. the tin(II) atom retains the sp^2 configuration. Mössbauer spectroscopic data confirm this conclusion; the isomer shifts *IS* of the free and complexed diorganostannylenes are similar and amount to 2.16 and 2.21 mm s^{-1} respectively[130]. The coplanarity of the stannylene fragment C–Sn–C with the transition metal atom in such complexes ensures the possibility of an additional π-interaction between the occupied 3*d* orbitals of the transition metal and the unoccupied *p* and *d* orbitals of the tin atom, as a result of which the Sn–M bond length is always smaller than the sum of the covalent radii of the atoms of these elements, as in the carbene complexes[42].

Unfortunately there are so far no structural data on complexes of inorganic and organic compounds of tin(II) of the type $SnX_2.ML_n$ (X = halogen or chelate; M = transition metal). Nevertheless it has been suggested on the basis of spectroscopic studies that they have analogous structures and that the anomalous *IS* values in the Mössbauer spectra of these complexes can be accounted for by the synergistic Sn → M σ-interaction and the M → Sn $(d-p)\pi$- or $(d-d)\pi$-interactions along the Sn–M axis (Fig.10).[328,330,405]

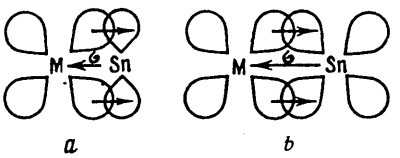

Figure 10. The $(d-p)\pi$-interaction (*a*) and the $(d-d)\pi$-interaction (*b*) of the *p* and *d* orbitals of the tin atom and a transition metal M.

This is confirmed by the absence of appreciable differences between the *IS* values for stannylenes (even dihalogenostannylenes) and their complexes with BX_3 or AlX_3,[98,204,323] which do not have occupied *d* orbitals. However, one cannot rule out the possibility that the appreciable decrease of *IS* in certain complexes of dihalogenostannylenes with transition metals can be accounted for by their ylide structure.

Analogous effects are probably observed in stannylene complexes stabilised by a base B. In the complex $Py(t\text{-}Bu)_2Sn.Cr(CO)_5$, the tin atom projects by only 0.44 Å from the plane passing through the carbon atoms and the chromium

**The values of *IS* are quoted for isostructural complexes with the phosphine ligand Ph_3P or $(MeO)_2PhP$.

atom linked to tin. The stabilisation of the complex by the base is accompanied by some alteration of the configuration of the tin(II) atom ($sp^2 \rightarrow sp^3$) and a corresponding increase of the C–Sn–C valence angle[406].

In the complexes $X_3Sn.M$, where the role of the base B is assumed by the anion X^-, analogous structural changes should be observed in the dihalogenostannylene fragment. The available data on the Mössbauer spectra, structures, and vibrational spectra of a series of complexes of the type $Cl_3Sn.M$ are compiled in the Table. The large differences between the Sn–M bond lengths in complexes of this type and also the available conductimetric data for solutions of some of them in CH_2Cl_2 or nitromethane[375,376,407] indicate different types of the Sn–M bond, which changes from ionic in complexes of the type $Cs^+[SnCl_3]^-$ to a σ-bond in many complexes with transition metals. In ionic complexes with discrete $SnCl_3^-$ anions, in which the tin(II) atom has a pyramidal sp^3 configuration (Fig. 9*a*), the high value of *IS* is determined by the high density of the *s* electrons at the tin atom, which are not involved in the formation of the Sn–M bond.

A satisfactory correlation between the *IS* values in the Mössbauer spectra, the stretching vibration frequency ν of the Sn–Cl bond in the infrared and Raman spectra, and the structural parameters is observed for the stannylene complexes $Cl_3Sn.M$, in which there is an Sn–M σ-bond. In conformity with the increase of *IS*, the Cl–Sn–Cl valence angle decreases and the Sn–Cl bond length increases in these complexes within the range of limiting values from 109.5° and 2.31 Å for the tetrahedral sp^3 configuration of $SnCl_4$ [418] to 95° ± 2° and 2.42 Å for the sp^2 configuration of free $SnCl_2$ in the vapour phase or in the argon matrix[50,53]. Similarly the shift of the absorption bands of the Sn–Cl bond from the region of lower frequencies characteristic of free $[SnCl_3]^-$ ions in solution[419] to higher frequencies indicates the approach of the SnX_3 configuration in the complexes to the tetrahedral configuration, which is possible with participation of the $5s^2$ orbitals of tin(II) in the formation of a σ-bond with the metal.

The majority of investigators believe that the tin atom in these complexes is in a bivalent state of oxidation; the observed low *IS* values can be explained (as in the complexes $X_2Sn.M$ unstabilised by a base) by the occurrence, apart from the relatively weak Sn → M σ-interaction, of a strong M → Sn $(d–d)\pi$-interaction (Fig. 10*b*). The overlapping of the *d* orbitals of the tin atom and the *d* orbitals of the transition metal leads to additional π-bonding and hence to a decrease of the Sn–M bond length (see Table).

Generalising the results of numerous investigations, one can probably conclude that the *s* character of the sp^x-hybridised orbitals of the tin atom in stannylenes and their complexes, both stabilised and unstabilised by a base, decreases in the sequence

$$sp^2\text{-Sn(II)} > sp^3\text{-Sn(II)} > sp^3d\text{-Sn(II)} > sp^3\text{-Sn(IV)} .$$

The Mössbauer isomer shift *IS* decreases and other spectroscopic and structural characteristics vary in the same sequence.

---o0o---

During the preparation of the manuscript for the press, numerous studies on the topic of this review were published. In the first place mention should be made of publications describing new sources of diorganostannylenes. This dimethylstannylene was obtained from $(Me_3Sn)_2S$ at 150° to 160 °C in the presence of copper[423].

Certain new monomeric organic compounds of tin(II) and organotin(II) compounds have been obtained and investigated. Free phenylstannylenes, stabilised by *ortho*- or 2,6-substitution (by CF_3, OMe, and t-Bu groups), have been obtained from $SnCl_2$ and the corresponding phenyl-lithium derivative[424]. A cyclic organostannylene has been obtained by the reaction of 1,1-dichloro-3,3,5,5-tetramethyl-1-stanna-3,5-disila-4-oxacyclohexane with magnesium or lithium in THF.[425,426] A series of organic compounds of tin(II), such as $Sn(OAr)_2$ (Ar = 2,6-t-Bu_2-4-MeC_6H_2 or 2,4,6-t-$Bu_2C_6H_2$), [427] $Sn[NCMe_2(CH_2)_3CMe_2]_2$,[428] $(CO)_5WP[P(O)(OEt)_2]_2SnCl$,[429] and $Sn[Al(OPr\text{-iso})_4]_2$ [430] have also been synthesised. Stannylenes forming part of the composition of various polycyclic systems have been obtained from cyclic diazastannylene[431–433].

The study of the synthetic possibilities of stannylenes has been continued. The insertion of $SnCl_2$ in the C–Br bond of allyl bromide under various conditions[434] and also the insertion of a cyclic organostannylene in the C–Cl bonds of alkyl and aryl chlorides and allyl chloride[425] have been described. The insertion of dihalogenostannylenes in the C–I bond of perfluoroalkyl iodides takes place extremely readily (in DMF at 20 °C).[435]

New examples of the insertion of stannylenes in the Hg–X and Hg–C bonds[436], of $SnCl_2$ in the Tl–Cl bonds of compounds of the type R_2TlCl (R = C_6F_5, C_6F_4H, or $C_6F_3H_2$),[437] of $(MeCp)_2Sn$: in the W–H bond of the complex $HW(CO)_3Cp$–Me,[438] of Me_2Sn: in the S–S bond of the complex [μ-dithio)-bis(tricarbonyl iron),[439] of $SnCl_2$ in the N–Cl bonds of the compounds p-$RC_6H_4SO_2NCl_2$ (R = Cl, H, or Me),[440] and of $[(Me_3Si)_2N]_2Sn$: in the N–Br bond of the compound $(Me_3Si)_2$.NBr [441] have been discovered.

As before, the reaction in which the dihalogenostannylenes are inserted in M–X bonds involving transition metals has continued to attract most attention. The interaction of SnX_2 with cobalt and iron complexes containing two M–X bonds has been studied[442]. It was established that the ligand SnX_2, formed when SnX_3 is inserted in the Co–X or Fe–X bond, deactivates the second M–X bond. The employment of modern research techniques makes it possible to solve in such cases the problem of the nature of the product of the reaction of the M–X bond with SnX_2. In some cases insertion products containing a quadrivalent tin atom are formed[443], while in the others the products are complexes with electron-donating ligands $:SnX_3^-$, in which the tin atom is bivalent[444–446]. The reaction in which $[Re(CO)_5]_2Sn$: [447] and a cyclic organostannylene[426] are inserted in the M–M bonds of bis-(metal pentacarbonyl) derivatives of transition metals proved to be extremely effective in the synthesis of mixed polynuclear metal carbonyls.

Numerous studies, in which stannylenes behaved as electron-donating ligands in complexes, have been published. Thus the complexes $Sn(NR_2)_2.nBF_3$ (n = 1, 2, or 3; R = Me or Et) have been described[448]. Stable complexes of SnX_2 with BF_3 have been obtained by stabilising them with electron-donating molecules of the type Me_3N, DMSO, tetramethylethylenediamine, etc. The high Mössbauer *IS* values confirm the bivalent state of the tin atoms in the complexes $F_3B \leftarrow :SnX_2 \leftarrow :Solv$ obtained[449].

A number of investigators have continued to study transition metal complexes of stannylenes both unstabilised[450] and stabilised[451,452] by a base B.

New examples of the substitution of chlorine atoms in dichlorostannylene complexes of transition metals $M(CO)_5$.$SnCl_2$.B, stabilised by a base B, have been reported[453,454].

Finally, it has been reported that organic compounds of tin(II) with benzil give rise to products of the formal 1,4-cycloaddition involving both carbonyl groups of benzil[455]. It has been shown that compounds of this type, 2,2-dialkyl-1,3,2-dioxastannols, are capable of forming dialkylstannylenes on thermolysis[456]. Analogous formal 1,4-cycloaddition reactions involving the carbonyl groups of *o*-benzoquinone are known for cyclohexadiene carbenes[457].

The Role of Free-radical Oxidation Reactions in the Molecular Mechanisms of the Ageing of Living Organisms

L.K.Obukhova and N.M.Emanuel'

The review describes the present state of knowledge about the free radical oxidation reaction of biomacromolecules as one of the ageing factors and considers the possible causes of the changes in the rate of ageing and of the prolongation of life in experiments involving exposure to chemical geroprotectants.
The bibliography includes 157 references.

I. INTRODUCTION

Regardless of the complexity and wide variety of theoretical ideas about the mechanisms of ageing, the majority of gerontologists are unanimous in their view that it can be a consequence of the accumulation of lesions and defects at all levels of the living organisms.

One can point to at least two fundamentally different sources of the breakdown of the functions and of the structural damage to macromolecules. Firstly, errors may arise in the course of the normal functioning of the cell, for example, in the copying of the DNA matrix or in the synthesis of protein as a consequence of the imperfection of the transmission of information from one macromolecule to another. The reliability of the replication of DNA and of the components of the protein synthesising mechanism depends on their molecular structure and is genetically determined.

In this review attention is concentrated mainly on the second source of the impairment of functions as a result of ageing, associated with the random changes in various components of the cell caused by processes involving the oxidative degradation of the macromolecule. The "free radical" hypothesis, which was initially based on the similarity of the radiation-induced and natural ageing processes, was at one time received with reserve by some gerontologists, but it nevertheless proved fruitful because it led to the possibility of influencing the rate of ageing by chemical agents. Radioprotectants and antioxidants are at the head of the list (fairly extensive nowadays) of chemical geroprotectants.

Chemical geroprotectants are widely used as instruments for the study of the mechanisms of the ageing of various objects of experimental gerontology: cell cultures, unicellular organisms, nematodes, insects, mammals, etc. Recognition of the usefulness of antioxidants was reflected, in

particular, in the fact that, during the last decade, the study of the so-called "membrane component" of the mechanism of ageing has become widely popular.

On the basis of an enormous amount of empirical data, the view has been established in the gerontological literature that there exist many independent ways in which age-induced changes accumulate even at the molecular level. This view is difficult to reconcile with the attempts to create a simple and universal theory of ageing and to suggest some way of altering the rate of ageing and the species dependent limits of the lifespan established in the course of evolution.

In the present review we attempted, using our own and literature data concerning the nature of the stochastic damage to biostructures, to justify the view that free-radical oxidation processes constitute a special and all-permeating background against which the metabolic activity of the cell takes place.

II. FREE-RADICAL SPECIES (O_2^-, OH·, $RO_2^·$) AS ENDOGENIC DAMAGING AGENTS

The free radical states of organic coenzymes, mainly semioxidised flavins and the semiquinone forms of ubiquinones localised in mitochondria, cytochrome P-450 functioning in the electron-transport chain of microsomes, as well as haemoproteins, copper-containing proteins, and manganese, molybdenum, etc. complexes, can be relatively readily detected in biological objects by radiospectroscopic methods. There is a direct quantitative relation between the metabolic activity of the tissue and the intensity of the EPR signals[1-3]. Attention has been devoted in a number of studies[4-6] to the changes in the concentrations of these metabolic free radicals during ageing. The involvement in the ageing mechanism of free radicals whose source is non-enzymatic reduction of oxygen, resulting in the formation of paramagnetic species such as the hydroxy-radical, the superoxide radical-ion, and the peroxy-radical (OH·, O_2^-, $RO_2^·$), appears to be more appreciable. The O_2 reduction reactions are presented below:

$$O_2 + e^- \rightarrow O_2^{\cdot-}$$
$$O_2 + 2e^- + 2H^+ \rightarrow H_2O_2$$
$$O_2 + 3e^- + 3H^+ \rightarrow H_2O + OH^·$$
$$O_2 + 4e^- + 4H^+ \rightarrow 2H_2O$$

The complete reduction of oxygen to water requires the participation of four electrons, while in the remaining cases partial reduction products are formed: hydrogen peroxide and the radical species O_2^- and OH·, whose high reactivity is the main cause of the toxic properties of pure oxygen.

Attention has been drawn to the fact[7] that the prebiotic atmosphere of the Earth did not contain free oxygen, which appeared in it as the product of the vital activity of photosynthesising blue-green algae. The origin, propagation, and certain initial stages of the development of life took place in an atmosphere lacking oxygen, whose appearance could not fail to influence evolution.

Oxygen accumulating in the atmosphere and the world ocean led to new possibilities for its utilisation by living organisms in biosynthetic processes and energetic reactions but at the same time it constituted a definite threat to the very existence of life. Obligatory anaerobes, which live in the absence of oxygen and have no means of protection against the free radical toxic products of its reduction, are destroyed in air[8]. For all respiring organisms, oxygen, which maintains their life, is at the same time toxic; they exist in its presence solely as a result of definite protecting systems which arose during evolution and function so effectively that the toxic properties of O_2 have attracted the serious attention of scientists only comparatively recently in view of the analogy between oxygen poisoning and radiation damage[9].

It is possible to formulate briefly the general postulates reflecting the fundamental features of the "free radical danger" in the following manner:

(1) Non-enzymatic O_2 reduction reactions constitute the background against which all processes involved in vital activity take place;

(2) oxygen-containing free radicals are the cause of the oxidative degradation of biological macromolecules;

(3) by virtue of their high reactivity (the rate constants for the interactions of the OH· radical are close to the diffusional values), the free radicals do not require a specific substrate for their reactions, the site which they attack is random, and they can damage any unit in the molecular structure of the cell;

(4) transition metals (Fe, Cu) play the role of catalysts of peroxide oxidation.

It can now be claimed that the "free radical" hypothesis of ageing proposed in the 1950's[10] refers to a small number of ideas in gerontology which have withstood experimental tests. Indeed, following self-evident logic, one may expect the acceleration of ageing with increase of the concentration of free radicals, which can be readily achieved by chronic irradiation or by an increase of O_2 pressure. Exposure to ionising radiation is one of the most effective methods for the experimental acceleration of ageing. On irradiation by sublethal doses, explicit signs of radiation damage do not arise in animals (with the exception of the early greying of hair) but their lifespan is shortened in proportion to the size of the dose. An example of the acceleration of ageing in Drosophila males irradiated at the age of one day by γ-ray doses of 80 and 40 krad has been quoted in a monograph[11]. Doubling of the dose shortens the average lifespan of the flies by a factor of two. Analogous data are available for laboratory mice and rats[12]. There is no complete identity between natural ageing and the reduction of the lifespan induced by radiation[13], but analysis of the causes of the death of the irradiated animals showed that they die due to the same illnesses as the non-irradiated animals, although the relative frequencies of the different illnesses may not be the same. Thus, presumably at least some of the damage due to radiation is similar to age-induced changes.

An increase of the O_2 concentration in air also leads to an appreciable decrease of the lifespan of Drosophila, which is accompanied by an intense accumulation of the "age pigment" (lipofuscin) in the tissues of the flies, which indicates the activation of the free-radical oxidation[14]. In this case the average lifespan of the flies fell from 78.1 to 34.6 days and their viability decreased much faster than in the control. The study of their tissues under light and electron microscopes revealed the presence of large accumulations of ceroid lipofuscin in the internal organs, consisting of dense lamellar bodies, and the breakdown of cytoplasmatic membranes in the nerve tissues.

The ageing process in cultured cells also proved sensitive to changes in the oxygen concentration. When human diploid fibroblasts were cultured under a high O_2 pressure up to 50 atm, a retardation of the rate of cell division and of capacity for the formation of colonies, particularly in later stages, was observed. On the other hand, if the same pressure was established with an excess of nitrogen, there was no effect on the viability of the cells, i.e. the observed decrease of the capacity for proliferation is a consequence of the toxicity of the O_2 and not the increased pressure[15].

Another method of accelerating free-radical oxidation, by enriching the diet in unsaturated readily oxidisable fats, was used in other studies. An increase in the amount and degree

of unsaturation of fats reduced the average lifespan of mice and increased the frequency of malignant tumours[16]. When two strains of Drosophila were maintained on a medium in which glucose was replaced by palmitic acid, vegetable oil, margarine, etc., keeping the calorific value of the feed at a constant level, a decrease of the average lifespan proportional to the amount of added fat was observed. If the flies were transferred from the fat-enriched diet to the standard diet, their mortality diminished but not all the changes induced by the introduction of excess fat into the diet were reversible[17].

On the other hand, a decrease of the intensity of the free-radical reactions in the organism retards ageing and increases the lifespan. The results of these studies will be presented in the concluding section of this review in connection with the discussion of the mechanism of the action of geroprotectants.

In a more careful examination of the reaction of oxygen-containing free radicals, account must be taken of specific features of their interaction with the cell components. The interaction of the superoxide radical-ion $O_2^{\cdot-}$ with hydrogen peroxide leads to the formation of the radicals OH· and singlet oxygen whose molecule carries excess energy[18]:

$$O_2^{\cdot-} + H_2O_2 + H^+ \rightarrow OH^{\cdot} + H_2O + O_2^*$$

$$O_2^{\cdot-} + H_2O_2 \rightarrow O_2 + OH^- + OH^{\cdot}$$

The spontaneous dismutation (disproportionation) of $O_2^{\cdot-}$ leads to the reformation of hydrogen peroxide[19]:

$$O_2^{\cdot-} + O_2^{\cdot-} + 2H^+ \rightarrow O_2 + H_2O_2$$

the rate constant for this reaction at pH 7.4 amounting to 10^5 s^{-1}.

Numerous spontaneous and enzymatic oxidation reactions, generating considerable amounts of $O_2^{\cdot-}$, are known: autoxidation of reduced flavins, hydroquinones, catecholamines, ferredoxins, and haemoproteins, enzymatic processes with participation of xanthine oxidase and many flavin hydrogenases, etc.[20,21] The superoxide radical-ion reacts as both a reductant and an oxidant. It participates in reactions involving the reduction of cytochrome c, Nitro Blue Tetrazolium, tetranitromethane, etc. and also oxidises sulphydryl compounds, sulphites, ascorbic acid, etc. The reduced NADH when linked to lactate dehydrogenase is readily oxidised by the $O_2^{\cdot-}$ radical-ion, while free NADH is oxidised more slowly[22].

The enzymatic dismutation of $O_2^{\cdot-}$ to hydrogen peroxide and oxygen is effected by the enzyme superoxide dismutase (SOD); the cytoplasm of the cells of eukaryotes contains SOD incorporating copper and zinc and its participation in the disproportionation reaction of the $O_2^{\cdot-}$ radical-ions makes the latter take place up to the theoretical diffusion limit, the rate of spontaneous dismutation being exceeded by a factor of approximately 20000. SOD protects the cell from the toxic action of the $O_2^{\cdot-}$ radical-ion and the OH· radical, which is even more reactive and arises on interaction of hydrogen peroxide with $O_2^{\cdot-}$ or bivalent iron salts[23,24].

The oxidative decomposition of the lysosomal membrane has been observed[25] and it has been established that the cause of the decomposition is free-radical reactions initiated by the superoxide radical-ion, formed on oxidation with reduced flavoprotein of liver microsomes. The authors showed that the $O_2^{\cdot-}$ radical-ion does not itself react with the membrane and that the direct participant in the chain oxidation reactions of the membrane lipids is OH· formed in the presence of ADP and Fe^{3+}. The presence of SOD prevents the breakdown of lysosomes.

Ascorbic acid can be used as a reductant for the ADP–Fe^{3+} complex which is more effective than superoxide, which apparently accounts for its role as the promoter of peroxide oxidation in those cases where vitamin C is used in doses known to be many times greater than the physiological dose[26].

Using the oxidation of xanthine by xanthine oxidase as the source of superoxide radical-ions, measurements were made of the rate of oxidation of vitamin E; the rate constant for the interaction of $O_2^{\cdot-}$ with α-tocopherol proved to be fairly large (1.7×10^{-4} mol^{-1} s^{-1}), which enabled the authors to postulate that the α-tocopherol built into the membrane can trap the $O_2^{\cdot-}$ radical-ions and prevent the initiation of the lipid oxidation[27]. The coefficient of the permeability of the two-layer lipid membrane to oxygen radical-anions is close to the coefficients of permeability to other ions[28]. On irradiation, stimulation of peroxide oxidation, and in inflammatory processes, the depolymerisation of the synovial liquid and of purified preparations of hyaluronic acid, occurring with participation of the $O_2^{\cdot-}$ and OH· radical species, was observed. SOD and catalase have a protecting effect[29,30].

Many aspects of the role of superoxide dismutase in the ageing process still remain obscure. Some information can be derived from data concerning the age-induced changes in the activity and properties of SOD. Much work in this field has been done by Reiss and Gershon[31], who were able to observe differences between the properties of the purified enzyme isolated from the livers of young and old rats. The "old" enzyme was 1.5 times less active than the "young" enzyme, although their kinetic properties were identical. The inhomogeneity of the "old" enzyme, which included a thermolabile fraction absent from the specimen of the "young" enzyme, was discovered in the study of thermal inactivation. Thus SOD supplemented the list of "inactive" enzymes (it includes enzymes such as aldolase, glucose-6-phosphate dehydrogenase, isocitrate lyase, etc.[32]).

Few data are available concerning the changes during ageing of the activity of SOD in the tissues of laboratory animals. Sometimes the age differences are quite distinct, but instances are known where they are absent. The activity of cytoplasmatic SOD in the hearts and livers of 34-month old mice was reduced by 50% compared with 3-month old mice. The same pattern was observed in 40-day old and 4-day old nematodes[33]; in the mouse brain tissues the activity of this enzyme decreases by 32–36% (relative to the protein or DNA content) in the range 50–900 days[34]. No changes were found[35] in the activity of SOD in 3-month and 2-year old rats, but an appreciable increase of the activity of catalase and glutathione peroxidase was noted.

The simultaneous decrease of the efficiency of the generation of $O_2^{\cdot-}$ and of the activity of SOD in the livers of old rats has been demonstrated[36], which enabled the authors to suggest the retention in the cells of a balance between free radical generation processes and the protecting reactions tending to inhibit the stochastic oxidation.

Opposed views have been expressed concerning the question whether or not superoxide dismutase can be regarded as an adaptive enzyme. An increase of the activity of this enzyme has been observed under the conditions of hyperoxia in human lung tissues[37] and also under the influence of the dye methylviologen, which is able to increase the intracellular concentration of the $O_2^{\cdot-}$ radical-ion[38]. After prolonged irradiation with moderate doses, no decrease in

the SOD activity in the tissues of Drosophila and rats was observed[39]. When more severe conditions reproducing the peroxidation syndrome were generated experimentally by maintaining rabbits on a diet lacking exogenic antioxidants, an increase in the activity of SOD was observed[40,41]. The latter study established a monotonic decrease of its activity with age; assuming that the SOD activity in the livers of sexually immature rats is 100%, the following data were obtained: 50% activity in 8-month old rats, 18% activity in 23-month old rats, and 15% activity in 30-month old rats.

In the course of the preimago development of Drosophila, the SOD activity increases by a factor of 3.5, but in the imago it hardly changes with age (in relation to the entire body weight)[42]. The activity of the mitochondrial enzyme reaches a maximum in 8-day old Drosophilas and then decreases by 21% in the course of the next 50 days. One cannot rule out the possibility of detecting age-induced changes in the SOD activity in various organs and tissues of the adult insect. In a mutant strain of Drosophila with an appreciably reduced lifespan the activity of cytoplasmic SOD was always lower than in the wild flies[43].

Interesting data were published in a communication[44] dealing with the study of the life cycle of a mutant of *Neurospora crassa* with a short lifespan. In the ageing stage an EPR signal due to the superoxide radical-anion with $g = 2.02$ was detected. In the presence of nordihydroguaiaretic acid as the antioxidant, the intensity of this signal diminished, but at the same time there was an increase in the intensity of the signal of high-spin Fe with $g = 5.45$. According to the author, the antioxidant accelerates the conversion of O_2^- into hydrogen peroxide, inducing the synthesis of catalase with which the $g = 5.45$ signal is associated.

In cultured strains of diploid human cells, which have only a limited lifespan and are usually regarded as a model for cell ageing[45], the observed changes in the SOD activity do not as yet permit an unambiguous interpretation. In cells whose source was embryonic lung tissue the SOD activity did not change in the course of the last 30 passages, the life of the culture[46]. According to other data[47], the greatest increase in the activity of superoxide dismutase occurs in the early stages of the growth of the culture, from the tenth to the twentieth passage. In the above study the specific activity of SOD was measured in the cells of diploid cultures obtained from adult donors; a significant increase of activity with increase of the number of times the population doubled was noted for strains derived from cells of embryos or the newborn but the maximum (and constant) activity of SOD proved to be characteristic of cells in cultures derived from the tissues of adult humans. Simultaneously with the increase of the SOD activity in the cells of the skin of the newborn, the rate of protein metabolism diminished and the fraction of thermolabile enzymes and the rate of reparative synthesis of DNA increased against the background of the accumulation of oxidation products. The authors are inclined to assume that the SOD activity in the old cells increases in response to the activation of the free radical oxidation processes.

Thus at the present time there are numerous facts showing that the enzymes superoxide dismutase, catalase, and glutathione peroxidase, which eliminate O_2^-, H_2O_2, and organic peroxides, play the role of the most important cell protecting systems together with natural antioxidants. The factors having a negative or positive influence on the lifespan of mammals have been arranged systematically[48]. Among the negative factors (there are 10 in all), the second place is taken by the accumulation of the age pigment lipofuscin, which is formed in the free radical oxidation of the lipid and protein components of biomembranes according to the majority of gerontologists. In the list of the positive factors (there are 18) the first place is occupied by DNA reparation processes and is followed in order of importance by the antiradical (enzymatic and antioxidant) protecting systems.

The possible role of SOD in determining the longevity of mammals has been investigated[49]. Its specific activity was measured in the cytoplasm of the liver, brain, and heart of two species of rodents, eleven species of primates, and man; the range of the changes in the maximum lifespan was from 3.5 to 95 years. The SOD activity in the tissues of animals of one species was the same but in different species its level differed by a factor greater than two and was a maximum in man. The age-induced changes in activity are not clearly expressed in all the species. The ratio of the SOD activity to the specific metabolic rate in a given tissue or the whole organism (the metabolic rate was determined from the absorption of O_2) increases with the maximum lifespan in all the species. This correlation suggests that in the long-lived species there is a more effective protection against the side products of the O_2 metabolism. Here it is appropriate to mention the results of a search for a relation between the lifespan and the anatomic-physiological parameters of the organism[50]. It has been shown by the method of multiple regression for 85 mammalian species that the lifespan is determined by only two independent parameters: the "cephalisation index", i.e. the ratio of the weight of the brain to the body weight, and the intensity of the metabolism (calculated from the absorption of O_2 at 37 °C). The equation obtained shows that the lifespan is longer the higher the cephalisation index and the lower the metabolic rate (the longer the period of development associated with it). According to Cutler[48], the increase of lifespan in the evolution of mammals occurred as a result of the selection and improvement of the protecting systems and "life support processes" (the opposite of ageing), which led, in particular, to the increase of the period of development in the long-lived species.

It is not possible to consider within the framework of this review another aspect of the biological role of H_2O_2 and O_2^-, whose high reactivity is used by the cells for protection against unfavourable factors. It is known, for example, that phagocyte-producing leukoctyes contain 2–4 times more H_2O_2 and generate O_2^- more actively than the non-phagocyte-producing polymorphic-nuclear cells[51]. We shall confine ourselves to listing the literature references on this question[20–22,24,52].

The enzymatic dismutation of O_2^- radical-ions results in the formation of water and oxygen in the triplet state. The spontaneous disproportionation reaction leads to the formation of a hydrogen peroxide molecule, which reacts in its turn with another O_2^- radical-ion, giving rise to singlet oxygen and the OH· radical. The molecule of singlet oxygen reacts with the biosubstrate by virtue of its excess energy and initiates new free radical oxidation centres. The damage to the DNA molecule by singlet O_2 has been investigated[53]; a review has been devoted to the role of singlet oxygen in the pathology of cell membranes[52]. The known producers of singlet oxygen, namely NaOCl and the 3-AT herbicide, the latter inactivating catalase with the consequent accumulation of excess H_2O_2 in the tissues, were added to the Drosophila feed. The average lifespan then decreased by 25–29%. The simultaneous addition of large doses of O_2^- quenching agents, namely β-carotene and 1,4-diazabicyclo[2.2.2]octane, had some protecting effect but it could not fully prevent the negative influence of the sources of O_2^-. The quenching agents did not exhibit the properties of geroprotectors, i.e. they did not retard the ageing of intact flies. On this basis, it has been concluded[54] that the role of singlet oxygen in natural ageing is insignificant and becomes appreciable only in those cases where its high concentrations are created artificially.

III. THE CONTRIBUTION OF PEROXIDE OXIDATION PROCESSES TO STOCHASTIC MECHANISMS OF AGEING

There exists an extensive literature on the relation between ageing processes and the peroxide oxidation of lipids, which also have a definite place in the normal vital activity of the cell[6,55-59]. In contrast to mitochondrial oxidation, which serves mainly as a source of energy, the role of peroxide oxidation is associated primarily with the formation of active metabolic products involved in the reactions of lipids—the main substrates of peroxide oxidation. The rate of peroxide oxidation is regulated by many factors, which can both initiate the process (pro-oxidants) and inhibit it. The structure of the protecting mechanisms, which protect the cell against the excess accumulation of toxic oxidation products, is usually believed to comprise two stages[60]. The first involves antioxidants, which react directly with free radicals and the second involves enzymes and non-enzymatic components, which reduce hydroperoxides and which were partly examined in the previous Section. In another study[61] an additional antioxygen protecting stage was introduced. The relevant function is fulfilled mainly by compounds of the type of carotenoids, which absorb the excess of free oxygen and maintain the O_2 pressure in the cell within the physiological limits.

The concentration of endogenic lipid peroxides in tissues is determined by the ratio of their formation and decomposition. In the cell membrane there is a constant content of lipid peroxides on the concentration of which the permeability of the membrane depends. In rat liver, for example, the normal concentration of lipid peroxides does not exceed 10^{-7} mole. The biosynthesis of hormones such as the prostaglandins proceeds via a stage involving the formation of unsaturated acid peroxides[62]; in the synthesis of cholesterol and steroid hormones, squalene oxide is formed as an intermediate[63].

Studies relating the lipid metabolism to the rate of cell division are of great interest. Analysis of extensive factual data led the authors of a book[64] to the conclusion that the decrease of the proliferative activity of cells is accompanied by a decrease of the amount of their natural antioxidants and an increase of the intensity of free radical reactions. The role of cell division inhibitors is usually attributed to lipid peroxides. These observations serve as a basis for the hypothesis of a free radical mechanism of the regulation of cell division which is very labile and sensitive to a wide variety of external influences which alter the concentration of natural antioxidants, the lipid composition, the rate of initiation of free radical reactions, etc. The presence of antioxidants in the lipid phase of the membrane is nowadays regarded as an obligatory condition for the maintenance of its structure, while peroxide oxidation reactions of lipids lead to its breakdown. One cannot rule out the possibility that vitamin E also plays a structural role[65-67].

An important place in the biochemistry of peroxides has been assigned[68] to their interaction with proteins, assuming that the NH_2 and sulphydryl groups (the latter are oxidised to disulphide groups) are the most vulnerable; not only peroxides but also the product of their further reactions, for example, epoxides, form insoluble complexes by combining with proteins. The above communication lists 15 enzymes whose activities are inhibited by lipid peroxides, including the enzymes involved in glycolysis, the tricarboxylic acid cycle, and the respiratory chain. Ribonuclease A, which contains no SH groups, is nevertheless inactivated by the products of the oxidation of unsaturated aliphatic acids, the inactivated enzyme containing high-molecular-weight polymers, whose fluorescence spectrum is identical with that of lipofuscin accumulating in senile heart muscle[69]. Interaction with lipid peroxides causes the degradation of catalase, γ-globulin, haemoglobin, egg and serum albumins, methionine, histidine, and other aminoacids[70].

Structures most vulnerable to oxidative breakdown are the microsomal and mitochondrial membranes in which are located enzymes such as monoamino-oxidase or microsomal cytochrome oxidase, whose normal function is catalysis of the oxidation by oxygen. The destabilisation of membranes as a result of the local interaction of lipids with metabolic or exogenic free radicals converts them into a substrate readily susceptible to oxidation. When suspensions of rat liver mitochondria were treated with a solution of bivalent iron salts, the activation of free-radical oxidation was observed, which resulted in the loss of approximately 65% of mitochondrial protein and of 40% of lipids. Induction of peroxide oxidation leads to the complete inactivation of isocitrate dehydrogenase, 3-hydroxybutyrate dehydrogenase is 80% inactivated, and malate and succinate dehydrogenases are 36 and 23% inactivated. Oxidative phosphorylation breaks down[71]. A secondary consequence of the partial oxidation of the unsaturated aliphatic acids of the membrane is their replacement by saturated lipids, which alters the permeability and functional properties of the membranes; the affinity of the membranes of microsomes for cholesterol diminishes and a deficiency of the latter arises[72,73].

The breakdown of the biological mechanism of the inhibition of free radical oxidation may be the factor initiating the development of pathological conditions such as radiation sickness, atherosclerosis, and tumours[2,4,74]. Ageing, regarded as the experimental syndrome of lipid peroxidation, is characterised, according to Voskresenskii's definition[75], by a "tetrad" of features—damage of the membranes, inactivation of the enzymes, breakdown of cell division, and the accumulation of ballast polymers. Experimentally recorded deviations at the physiological, cellular, and subcellular levels, whose origin is damage of the membrane during the ageing process, have been listed in a review[72]. The most significant of these are the breakdown of the permeability of the cell membranes, the appearance of microsomes and mitochondria with heterogeneous structures and properties, a decrease of the amount of cholesterol in the liver microsomes of old animals, a decrease of the efficiency in relation to endocrine effectors such as insulin and catecholamines, whose physiological activity depends on the stereospecificity of the interaction between the hormone and the receptor, and the accumulation of the transoxidation products in the cells and in the blood.

The search for a criterion of the ageing of human diploid fibroblasts, cultured routinely outside the organism, has led to the conclusion[76] that the "imprint of age" is most appreciably reflected in the properties of the cell membrane. By fractionating a normal cell population which has lived through 20 passages *in vitro*, the authors obtained several subcultures consisting of cells of identical size and traced their transition to the ageing phase. It was found that ageing parameters frequently employed such as cell size, the volume of the nucleus, the intensity of the incorporation of thymidine, the DNA content, etc. are poorly correlated with the age of the culture. As the cell ages, the adsorption properties of its surface change; concanavalin A, bound to erythrocytes, is weakly adsorbed by cells of young cultures; the adsorption intensity increases linearly with the number of passes and is independent of the cell cycle phase and the metabolic age.

Thus the main source of the structural and functional disorders arising in ageing may consist in the breakdown of the steric and cooperative interactions in the cytoplasm, in the matrix, in the membranes of organelles, and on the surfaces of cells. The activity of membrane enzymes, reception,

and permeability depend on these properties, which determine the specific organisation. If the properties undergo irreversible changes or are lost, then, even with a correct programme of synthesis, the functioning of the cell is difficult owing to the impaired efficiency of the endocrine receptors or modulators ensuring the reliability of the transport of metabolites.

The maintenance of the relative constancy of the internal medium within the organism is one of the obligatory conditions for existence. The constancy of the physiological level of free radical oxidation reactions is achieved mainly by antioxidants, among which the main role is played by vitamin E whose distribution and metabolism have been adequately studied mainly in connection with the E vitamin deficiency[64, 65,68,75,77-82]. The need for vitamin E and other antioxidants changes in the course of life. The content of vitamin E in the blood, livers, and skeletal muscles of sexually immature rabbits and rats progressively increases during growth, in the adult animals a relative stabilisation is observed, while in the old animals there is a decrease. The latter may be associated with the intense breakdown of antioxidants in oxidation reactions and their inadequate assimilation. Compared with 30-year old humans, in 60–70-year-old individuals the concentration of vitamin E in the blood plasma is reduced to 60%.[83] According to Leibovitz et al.,[84] during the ageing of stable strains of mice and New Zealand black mice with a hereditary defect of the immune system, a redistribution of ascorbic acid in the liver and spleen tissues is observed. In immunodeficient mice the level of vitamin C in the spleen tissue decreased during the period preceding the development of the autoimmune sickness. A steady decrease of the antioxidant activity of lipids with age has been recorded[85,86]; it is significant that the rate of decrease of this quantity was greater for short-lived mice. The change in the rate of formation of lipid peroxides in rat microsomes during ageing has been described[87]; in the presence of ascorbate the rate of oxidation increased non-uniformly with age: at the age of 600 days it was lower than at the age of 400 days but exceeded that in the young animals. The author explains this observation by the decrease of the efficiency of the monoxygenase microsomal system in old rats.

The data concerning the age-induced changes in the intensity of peroxide oxidation in the subcellular fractions of tissue homogenates are contradictory; a decrease of the accumulation of malonic dialdehyde under the conditions of the induced oxidation of the microsomal, mitochondrial, and postnuclear fractions of the livers of old rats has been reported recently[88,89]; oxidation was retarded with increase of the protein concentration.

Many facts indicate a functional relation between different units of the antioxidant protecting system in cells. The activity of the glutathione peroxidase of erythrocytes, which reduces lipid peroxides, depends on the vitamin E content of the blood[90]. The concentration of reduced glutathione in mouse erythrocytes decreases both on ageing of the red cells themselves and on ageing of the organism. In old mice (31 months) its amount in the liver, kidneys, and heart muscle is lower by 30, 34, and 24% than in the 17–23-month old animals. Involution of the thymus in mice is accompanied by a depletion of its tissues in coenzyme Q (ubiquinone), which is lost to the extent of 80% by the age of two years, and this leads in its turn to the almost complete inactivation of succinate dehydrogenase in this organ[91,92].

It has been concluded[75] that the biological inhibition of free radical reactions in the organisms, which takes place via a series of interacting oxidation-reduction reactions of tocopherols, glutathione, and ascorbate, is systemic in nature.

The SH-containing proteins, whose concentration in the human blood plasma decreases with age almost by 30%, belong to the class of natural antioxidants[93]. There is now no doubt that the status of vitamin E in the organism is associated with the biochemical function of selenium compounds; when there is a deficiency of selenium in food, the metabolism of tocopherols and the catabolism of the proteins in the liver microsomes are accelerated[94].

When there is a deficiency of vitamin E or after prolonged hyperoxia, distinct changes arise in the morphology of cells, particularly non-dividing cells. Lipofuscin is formed in the cytoplasm of the nerve and muscle cells and accumulates in the form of small yellow or brown granules with a characteristic weak fluorescence. Lipofuscin or the "age pigment" is regarded by many gerontologists as the best indicator of age; the linear relation between age and the content of lipofuscin in the human myocardium established by Strehler[95] is generally known. There is an extensive literature on the origin of the lipofuscin grains and their biochemical properties and biological role[96-98], which makes it unnecessary to describe the problem in detail. Numerous data on the structural and biochemical properties of lipofuscin have shown that free radical oxidation reactions of membrane lipids and proteins may be the source of its formation. It is known that on ageing and under unfavourable conditions (stress and poisoning), the membranes are depleted in natural antioxidants. On oxidation of the membranes of mitochondria, microsomes, and lysosomes under model conditions, phosphatidylethanolamine is "cross-linked" by malonic dialdehyde with formation of a fluorescent product; in animals fed a diet lacking vitamin E, lipofuscin accumulates in various organs faster by a factor of 1.5–6.[97] An increase in the number of lipofuscin grains towards the end of the life cycle of cultured normal cells has never been observed. Human diploid cells are in stage III of growth after 40–42 passages and contain approximately 80% of non-dividing cells; secondary lysosomes of the type of residual bodies accumulate in such cells; by analysing X-ray scattering, it has been found that the residual bodies contain large amounts of iron[99].

The way in which the accumulation of lipofuscin grains affects cell functions remains a controversial question. Large accumulations of lipofuscin can themselves hinder the functioning of the cell, particularly of neurones, in which the content of endogenic lysophosphoglycerides, exhibiting a detergent effect on the membranes, increases with age and also under the conditions of an incomplete diet or an irrational administration of drugs. Electron microscope studies on the tissues of various sections of the brains of patients suffering from neuronal ceroid lypofuscinosis who died at the age of 7.5–22 established a characteristic accumulation of large masses of lipofuscin in the nerve cells at a young age. The characteristics of premature ageing (loss of vision, extensive pigmentation of tissues, muscular atrophy) also accompany this hereditary disease[100]. Measurements have been made[101] of the average percentages of the volume of the large human neurone occupied by the nucleus, the cytoplasm, and lipofuscin at different ages. At the age of 40, these percentages are in the proportions 1:2:2, i.e. cytoplasm has already been half-absorbed by lipofuscin; at the age of 60 and 80 the volume of the nucleus does not change but the volume of the functioning cytoplasm decreases by factors of 1.3 and 2; in humans who have reached the age of 100 the volume of the nucleus diminishes by 60% (compared with 40-year old individuals) and lipofuscin occupies more than 80% of the overall cytoplasmic volume. The accumulation during ageing of lipofuscin and amyloid and the increase of the number of senile end-plates has been demonstrated by electron microscopy in 17 sections of human brain[102]. The authors of this study

believe that the nature of the age-induced changes and their consequences for the organism depend on the type of tissues and attribute the role of the main regulator of the rate of ageing—the "biological clock"— to the cells of the central nervous system. The non-uniform accumulation of lipofuscin in different sections of rat and mouse brains is indicated by the data of Reichel et al.[103] In the hippocampus of old rats and mice the accumulation of the pigment begins much sooner (from the age of 9–11 months) and is much faster than in the Purkinje cells and in the brain cortex. The pigment occupies less than 0.6% of the surface of the section in the layer of granular cells of the cerebellum in rats and mice of all age groups.

The ageing of insects is also accompanied by the accumulation of the ageing pigment. The low content of tocopherols and the absence of glutathione peroxidase are the cause of the relatively high rate of peroxide oxidation in the cells of the honey bee. The evolution of pentane, formed as a result of the cleavage of unsaturated aliphatic acid hydroperoxides and the age dependent increase of the concentration of lipofuscin in the cells of the thoracic segment in worker bees have been recorded[104]. Measurements have been made of the content of fluorescent substances in the tissues of house flies aged 1,4,11, and 15 days and an increase of their concentration with age was observed, the greatest amount being extracted from neurones. Analysis of the absorption and emission spectra of their complexes with europium made it possible to identify the fluorescent pigments as conjugated Schiff bases; their localisation in the lipofuscin grains was discovered by means of fluorescence microscopy[105]. New data, confirming the role of lipofuscin as the cellular marker of physiological age, have been obtained in studies where the rate of ageing was varied experimentally[106,107]. Flies belonging to a highly inbred strain were separated into two groups in one of which flying activity was restricted, which increased by a factor greater than two the average and maximum lifespans. The relative contents of lipofuscin in the giant neurones in the brains of flies of different ages were determined by electron microscopy and spectrofluorimetry. The rate of accumulation of the pigment in short-lived flies with a high flying activity was four times greater and its maximum content (the same for both groups) was attained sooner.

However, one cannot ignore studies whose authors adhere to the directly opposite point of view, regarding the accumulation of lipofuscin as adaptive and assuming that the age pigment is a normal structural component of the cell. There is a view[108] that the inclusions of lipofuscin are identical with the carotenoid-containing cytosomes in the neurones of molluscs, which function as an intracellular depot of oxygen in certain lower animals which exist permanently under the conditions of hypoxia. This view is shared by the authors of a book[109] who regard the accumulation of lipofuscin as an adaptive process partly balancing the hypoxic state of the cell on ageing. It is known that the oxygen tension in the tissues decreases in elderly and old individuals which is apparently associated with the age-dependent decrease of the level of energy metabolism. At the same time the activation of free radical oxidation reactions inhibits tissue respiration by damaging the mitochondria and the biological oxidation enzymes. The decrease of the consumption of oxygen in the late stages of ontogenesis by no means indicates a decrease of the need for O_2 and may represent the result of the breakdown of its utilisation. According to Voskresenskii and Levitskii[68], there exists an antagonistic interaction between the enzymatic oxidation and the peroxide oxidation involving a free radical mechanism. Under the optimum conditions of the functioning of the oxidative enzyme systems of the cell, the possibility of the formation of lipid peroxides diminishes and, conversely, on ageing the direct oxidation of lipids is enhanced as a result of the decrease of the utilisation of O_2 in energetic processes.

The possible protecting role of vitamin E in acute experimental hypoxia is indicated by a study[110] in which an increase of the concentration of tocopherols in the adrenal tissue was observed, which leads to release of the reserves of adrenalin, a decrease of the intensity of the stress response, and a decrease of the consumption of O_2 by the tissues.

Among the pathological states characteristic of elderly individuals, the most common is undoubtedly atherosclerosis, the development of which may be associated with a change in the antioxidant status of the organism. The results of studies employing experimental models of atherosclerosis are of interest. When animals are maintained for a long time on a fat-rich diet lacking antioxidants, a decrease of the parameters of the functional activity of the antioxidant system and the development of the biochemical and morphological signs of atherosclerosis are observed. As the severity of the disease increases there is a rise in the concentration of total lipids, lipid peroxides, and malonic dialdehyde in the blood, and the wall of the aorta is degraded. The employment of antioxidants makes it possible to regulate their supply to the organism and to retard the development of atherosclerosis. Tests on ionol, hexahydro-4-ubiquinol, quercetin, sodium selenite, and vitamins P, E, and C showed that the action of these compounds is associated with the inhibition of peroxide oxidation and protection against the oxidative degradation of the elastic fibres of the arteries[111–113].

IV. CHARACTERISTICS OF THE ACTION OF ANTIOXIDANT GEROPROTECTANTS

Several careful reviews[114–117] and also one of the chapters in Comfort's monograph[118] were devoted to the mechanisms of the action of chemical geroprotectants of different classes, which enables us to avoid a detailed description except for antioxidants which we believe to be the most promising geroprotectants. The compilation published in 1975[119] of the geroprotectants known at the time must be supplemented by several new compounds. Lactic and gluconic acids, which are inhibitors of the OH' radical, as well as sodium and magnesium salts of thiazolidinecarboxylic acid (antioxidants) retard the ageing of Drosophila and laboratory mice[120,121]. Succinic acid, which acts on the energy balance of the cell, proved to be active[122]. Diphenine (5,5-diphenylhydantoin-sodium), phenformin (1-phenylethylbiguanide hydrochloride), and the polypeptide extract from epiphysis are able to reduce the threshhold of the sensitivity of the hypothalamo-hypophyseal complex to regulating influences, to decrease the frequency of spontaneous tumours, and to increase the lifespan of the experimental animals[123,124]. Inhibitors of the biosynthesis of protein—olivomycin, actinomycin D, and morphocycline—constitute a new group of chemical geroprotectants with a specific mechanism of their action[125,126].

In most cases whether or not a substance is a geroprotectant is determined by the set of properties characterising its biological activity and not its chemical structure or some one property. In this respect antioxidants have been studied in greatest detail. The free-radical hypothesis involves the postulate that antioxidants retard the ageing process because they prevent the accumulation of lesions at the molecular level[127]. It is implied that the accumulation of lesions embraces all cell structures without exception, ranging from the genetic material to membrane lipids. Arguments in

support of this hypothesis are examined in detail in previous Sections of this review. It would appear that agreement with this thesis logically requires the recognition of the universality of the action of antioxidants, which, by reducing the background level of the free radical reactions in the cell, decrease the number of stochastic lesions in biostructures. However, this simple treatment conflicts with facts: not all the antioxidants tested experimentally proved to be geroprotectants and the latter are in their turn active only in relation to specific objects. Thus according to Harman[128], 2-mercaptoethylamine, which has been tested on four strains of mice, increased by 29% the average lifespan of LAF_1 mice, but was almost inactive in relation to the AKR, Swiss, and C3H strains. The antioxidant 2,6-di-t-butyl-4-methylphenol (ionol or BHT) showed no influence on the rate of ageing of C57BL mice, but greatly increased the average lifespan of the BALB/C strain of mice[129,130]; the authors of both studies emphasise that the animals were maintained under optimum conditions. The geroprotectant 2-ethyl-3-hydroxy-6-methylpyridine hydrochloride retarded the rate of ageing of SHK at C3HA mice by a factor of 1.5–1.8. SHK mice belong to a non-inbred population characterised by a high incidence (50–90%) of spontaneous cancer of the mammary gland; the administration of this compound to mice of the AKR strain affected by spontaneous leukaemia was unsuccessful[131]. No attention has been devoted to the specific causes of the non-reproducibility of the results in the gerontological literature, it being merely stated that the given compound is active or inactive. This reflects the predominantly empirical approach to the problem. As a rule, in communications dealing with the retardation of ageing by chemical agents no well-founded methods for the selection of the dose of the preparation used in chronic experiments on survival are described; at best a preliminary study is made of toxic properties. As regards the selection of the dose of synthetic antioxidants, account must be taken primarily of their interaction with natural antioxidants, which can lead to the inhibition of stochastic free radical processes and to an increase of the reliability of the protecting systems of the organism or, conversely, it can induce the activation of peroxide oxidation and rapid depletion of the tissues in antioxidants[64]. It has been shown[86] that the range of doses of 2-ethyl-3-hydroxy-6-methylpyridine suitable for chronic experiments on laboratory mice is from 75 to 300 mg per kilogram of live weight. The use of this synthetic antioxidant in such amounts during the life of the animal makes it possible to maintain the antioxidant activity of the lipids (it is proportional to the content of the antioxidants in the tissues) above the normal level and to compensate for the age-induced decrease in the amount of natural antioxidants. The effectiveness of 2-ethyl-3-hydroxy-6-methylpyridine as regards the retardation of the ageing of Drosophila depends not only on its concentration but also on the stage of development, the age of the imago, sex, and the particular strain of the insects. In particular, it has been found that males are more sensitive to the geroprotectant than females; in experiments with females an increase of only the average lifespan was observed, while in the experimental groups of males the maximum lifespan also increased. The effect of this geroprotectant on flies of the $R(1)2yv/y^+Y$ strain with a rearranged karyotype also differed significantly from its effect on the D-32 wild strain. The average and maximum lifespan of males of the $R(1)2yv/y^+Y$ strain increased by 20% at a concentration of the preparation of 0.1 wt.%, whereas for the males of the D-32 strain this concentration of the preparation had the opposite effect: the rate of ageing increased and the lifespan diminished by 30%.[132] The decrease of the lifespan of guinea pigs observed when vitamin C was used in doses exceeding severalfold the physiological dose can be accounted for by the activation of the free-radical oxidation of lipids[133].

It is known that constant addition of certain chemicals to the diet can influence the consumption of food. This important aspect of the action of geroprotectants has been very little investigated. The influence of the antioxidant ionol on the appetite and live weight of adult rats is ambiguous and depends both on the concentration of the additive and on the composition of the food. The weight of the animals increased with increase of the concentration of ionol in the food up to 0.5% and remained constant when its content was raised to 0.9%, after which its slow decrease was observed. If the food contained at least 13% of protein, then the permissible dose of the antioxidant was 300 mg per kilogram of live weight per day; an increase of the protein content by a factor of two correspondingly made it possible to increase the safe dose of ionol[134]. Thus the application of the same chemical agent in different doses and for a variable diet may lead to opposite results even in the same species of animals.

Biological systems of different degrees of complexity, ranging from cell cultures to mammals, have been used as models in experimental gerontology. The more complex the system, the more stringent the requirements imposed on the potential geroprotectants, which must not interfere grossly in the metabolism and must not affect the course of the normal physiological processes. Hydrocortisone, which is a cell division stimulator, maintains active proliferation in old cell cultures, i.e. is a geroprotectant of the ageing of cultured cells in the given instance[135]. The properties of stabilisers of biomembranes make it possible to employ corticosteroids to retard the ageing of insects[136], whose tissues consist mainly of populations of non-dividing cells, in which the specific activity of lysosomal enzymes increases by a factor of 4–23 with increase of age[137]. However, the results of Akif'ev et al.[138] justify the rejection of corticosteroids as geroprotectants for mammals. The authors showed that constant stimulation of liver cells by hydrocortisone has a negative effect and leads to the breakdown of genetic regulation. Only instances of substitutional therapy are exceptions when hormones are used: the lifespan of dwarf mice increases under the influence of the growth hormone[139]; the ageing of autoimmune mice is retarded by prednisolone and hydrocortisone[140].

Vitamin E has been used successfully to retard the ageing of cultured diploid human fibroblasts and also increased the lifespan of Drosophila and nematodes[141,142]; however, numerous attempts to retard the ageing of laboratory mice demonstrated either a very low effectiveness of tocopherol or the complete absence of its influence on the rate of ageing. Nevertheless, vitamin E has a set of properties similar to those of synthetic antioxidants, namely ionol and santoquin (there is also a structural similarity with the latter), which may determine the geroprotecting activity or may accompany it[119]. It is still unknown why synthetic antioxidants have a more effective influence on the ageing of mammals than natural antioxidants. Presumably, when the physiological level of tocopherol or ascorbate is exceeded, the equilibrium involving the vitamins in the organism is disturbed[143]. Furthermore, it has been suggested that the function of vitamin E does not reduce exclusively to the antiradical activity[144].

The results of a study which established a decrease of the age-induced mortality of mice of the Swiss strain born to mothers which received the following antioxidants in their diet are very interesting and difficult to explain[145]: 0.2% of santoquin; 0.5% of 2-mercaptoethylamine; 0.2% of vitamin

E; 1% of sodium hypophosphite; a mixture of 0.2% of santoquin and 1.0% of sodium hypophosphite. The offspring were maintained on a constant diet without extraneous additives. At the age of 26 months, the fraction of surviving males whose mothers consumed 2-mercaptoethylamine and hypophosphite exceeded the control by 26 and 8%; santoquin and 2-mercaptoethylamine decreased the mortality of males by 13 and 23%. Vitamin E was inactive. The interpretation of this result is difficult, because the communication gives no information concerning any physiological or biochemical peculiarities of the offspring. It may be that the phenomenon of enzymatic imprinting, in which the administration of xenobiotics or other gene inductors to newborn animals induces in the latter a stable (over a period of 8 months and more) enhancement of adaptive synthesis, may be reflected in this instance in an unusual manner. Thus there is a phenotype correction of the symptoms of certain hereditary diseases. In 1974 attention was drawn to the fact that effective geroprotectants are as a rule inductors of microsomal oxidases[116]. The induction of the enzyme detoxification system of microsomes constitutes the molecular mechanism of the mobilisation of the protecting forces of the organism against the harmful influence of the chemical components of the environment and is manifested particularly clearly in chemical carcinogenesis, in which antioxidant inductors decrease the number of tumours or prevent their formation[147,148].

The results of several studies of the influence of antioxidants on the ageing of Drosophila showed that the most important events determining the lifespan occur in early ontogenesis. Using 2-ethyl-3-hydroxy-6-methylpyridine hydrochloride as the geroprotectant, it has been established[132] that the retardation of the ageing of Drosophila observed in this instance is not a consequence of the increase in the period of development. In addition it was found that the greatest effect is attained on treatment in the preimago stage or of the young imago, i.e. during the period when the phenotype characteristics of ageing are still absent. The older the imago, the less effective the geroprotectant: treatment begun at the age of 20 days and later is virtually without results. It has been suggested that lesions leading subsequently to ageing accumulate in the tissues of the larva from which the organs of the adult flies are formed (nervous tissue, imaginal discs). By regulating the incidence of these lesions in the larval period by means of a geroprotectant or a mutagen, it is possible to influence the rate of ageing of the adult individuals. According to the authors, the ageing of Drosophila consists of two stages: the stage of the accumulation of lesions and the stage of their realisation; the onset of the second stage requires not only a definite threshhold level of lesions but also a period of time after the elapse of which phenotype signs of ageing appear. Once this time has elapsed, a further increase in the number of lesions no longer has an appreciable influence on the rate of ageing. Since these stages are separated in time, it has been suggested that only molecules capable of prolonged storage of information about the harmful influence can serve as the "ageing substrate", i.e. the most likely candidate for the role of the ageing substrate is the molecule of chromosomal DNA. Information about the injury to other chemical components of the cell cannot be directly transmitted from the larvae to the adult individuals, since all the remaining components are repeatedly renewed in the course of metamorphosis.

The existence of a critical age limit beyond which treatment ceases to be effective or has the opposite result has been noted in a number of studies. In the investigation of the influence of α-tocopherylquinone on the ageing of a nematode, it has been observed[49] that the antioxidant is active only in relation to young animals; at the age of 20 days it was not possible to retard ageing. It may be that in the presence of an antioxidant the number of errors in the synthesis of membranes, which occurs most actively during the first ten days of the life of the nematode, is reduced[150]. Similar results have been published recently. The addition of lactic and gluconic acids to the feed of Drosophila larvae increased the average lifespan by 22%, while treatment of the young imagos was less effective by a factor of 2. The authors suggest that the retardation of ageing is achieved by inhibiting the reactions of the $OH^{\cdot}$ radical[120].

The causes of the existence of threshhold phenomena in ageing apparently involve the ratio of the rates of accumulation and repair of lesions. A mathematical treatment of a generalised scheme for the ageing process, taking into account critical phenomena, has been described[127].

The protecting effect of antioxidants in the age-induced accumulation of lesions of the secondary DNA structure is indicated by the results of Khudolii et al.[151] They established that lesions, recognised by endonuclease S_1 as apparently single-stranded breaks, accumulate during ageing in the mouse liver nuclear DNA. The retardation of the ageing of mice receiving an antioxidant is accompanied by a decrease of the number of similar defects.

The action of the majority of geroprotectants lacks a distinct specificity and is varied. The non-specific activity of antioxidants can be partly accounted for by their involvement in the reactions of the general adaptation syndrome, whose development occurs against the background of decreasing antioxidant activity of the tissues. In the state of stress, peroxide oxidation processes are activated[64]. Antioxidants modify the rate of supply of corticosteroids to the blood and lower the overall stress response. The prophylactic administration of antioxidants promotes adaptation under the conditions of experimental stress[152].

Studies in recent years established that antioxidants belong to the category of immunoactive compounds. The maximum humoral response of mice whose diet was permanently treated with antioxidants (vitamin E, ionol, santoquin, 2-mercaptoethylamine, etc.) corresponded to the age of 50–65 weeks and exceeded the control values approximately by a factor of 2. The cell immune response was enhanced to a lesser extent. It is believed[153] that life is prolonged because the age-induced immune deficiency is made good with the aid of antioxidants. A more careful examination of the results of this study makes it impossible to agree with this conclusion, since stimulation is replaced by immunodepression, which actually occurs in the experimental groups before the age-induced decrease of the immune response. This group of long-lived mice, whose life is prolonged as a result of a decrease of their mortality rate, reach the normal lifespan when the immune status is reduced. The retardation by antioxidants of the development of amyloidosis, a typical senile disease of the autoimmune type, can be logically explained by immunodepression[154]. The decrease of the rate of migration and proliferation of blood-forming stem cells in mice has been noted in chronic treatment with a geroprotectant belonging to the class of 3-hydroxypyridines. An increase by a factor of 1.5 of the latent period in the formation of spontaneous tumours of the mammary gland has been observed against the background of the immunodepression induced by the preparation[155]. The same preparation normalised the level of adrenalin in the adrenal gland of tumour carriers, which is believed[156] to be extremely significant for the outcome of the relations between the tumour and the organism.

The experimental data presented throw some light on the question why the action of antioxidants lacks a distinct specificity, depends on the complexity of the object, and is

frequently manifested by effects which are not clearly interrelated at first sight. Indeed, it is difficult to explain by a single cause data obtained for the same antioxidant and showing a decrease of the fraction of "defective protein" in liver cells[157] and a change of the rate of migration of blood-forming stem cells[155]. Although the hypothesis that geroprotectants act in both cases on the "membrane component" of ageing may be regarded as likely, a more exact answer requires a pharmacokinetic study of the preparation. Interference with the free radical oxidation reactions, which we believe constitute a universal background for metabolic processes, can be realised in accordance with the "weak link" principle and can lead to changes in a wide variety of biochemical mechanisms responsible for age-induced deviations. The structure and functional inter-relations between cells, tissues, and organs ensure the similarity of the final results of the age-induced changes due to different causes.

Separation of Sulphur Isotopes by Physicochemical Methods

B.M.Andreev and A.S.Polevoi

Recent work on the separation of sulphur isotopes by distillation, chemical exchange, and isotope exchange methods is reviewed, and the characteristics of both laboratory and industrial apparatus for the separation of sulphur isotopes are tabulated. The direction of further developments is discussed with emphasis on a more rational organisation of the work and on the scientifically most promising approaches. 138 references.

CONTENTS

I. Introduction 213
II. Distillation 213
III. Chemical isotope exchange 215
IV. Ion exchange processes 225

Natural sulphur is a mixture of stable isotopes of mass numbers 32, 33, 34, and 36, present at relative concentrations of 95.006, 0.76, 4.22, and 0.014 at.% respectively[1]. This isotopic composition is not absolute, and depends on the source of the sulphur, suggesting fractionation of the isotopes in the course of biochemical and geochemical processes. Fluctuations in the $^{32}S/^{33}S$, $^{32}S/^{34}S$, and $^{32}S/^{36}S$ isotope ratios can be as high as 2.5%, 5%, and 10% respectively[2,3]. The sulphur of the troilite in the Canyon Diablo meteorite, with an $^{32}S/^{34}S$ ratio of 22.22, has been adopted as the international standard[4].

Sulphur isotopes are used in biology[5,6], medicine[7], geology[8-16], nuclear physics[17,18], agrochemistry[20], organic[20-23] and physical chemistry[19,20,24-26], astronomy[27,28], physiology[29], etc.

Stable sulphur isotopes (and their methods of analysis) have also been used in practice to solve problems in geological uranium prospecting[30], estimating the quality of petroleum deposits[31], monitoring the sulphur content of cast iron and steel[20], and controlling the emission of sulphur waste gases and their rate of circulation and neutralisation in the atmosphere[32]. Another important group of applications of stable sulphur isotopes includes the preparation (by nuclear processes) of new radioactive isotopes, including the very important isotopes[17,18] ^{33}P and ^{35}S. The radioactive phosphorus isotope ^{33}P, prepared by the $^{33}S(n; p)^{33}P$ reaction, has been used increasingly in medicine and biology in recent years. Another radioactive isotope of phosphorus is known (^{32}P), but it is less easy to use in biochemical, ecological, agrochemical, and medical studies because its emission energy (E_{max} = 1.71 MeV) is higher than that of ^{33}P (E_{max} = 0.25 MeV).

It is clear, from recent publications, that the use of stable sulphur isotopes is increasing not only in the traditional branches of science and technology but also in new (and unexpected) directions. This explains the decision to create reserve stocks of these isotopes in many countries.

An analysis of the literature suggests that the three most important limiting factors to the still wider exploitation of stable sulphur isotopes are:

1) the high cost of these isotopes, due to the complexity of existing methods of production;

2) the complexity and high cost of the methods of isotopic analysis;

3) the lack of cheap, simple, and effective methods of synthesising the sulphur-labelled compounds needed in science and technology.

The most serious of these problems is the first. For example, the cost of one gramme of the ^{34}S isotope with an enrichment of 40–60 at.%, prepared by electromagnetic mass separation, is 4200 roubles, and the cost of one gramme of ^{36}S with an enrichment of 1.5–2 at.% is 50000 roubles[33]. The first paper dealing specifically with the technology of the separation of sulphur isotopes was published more than 40 years ago[34], and a great deal of work, both theoretical and practical, has been devoted to the separation problem throughout this period in many countries[25,29,35,36]. The development of new methods of separation stimulated the development of new or improved methods of analysis of sulphur isotopes[16,37-39], new methods of producing pure and specially pure sulphur, and new developments in the chemistry of labelled compounds[20-23].

The fact that according to papers published between 1937 and 1980 approximately 89 sulphur isotope separation processes were investigated in 46 scientific establishments of 13 countries gives an indication of the scale of this work. These developments have created a need for a systematic analysis of the different trends in the theory and practice of sulphur isotope separation, including an assessment of the factors which determine the cost of the isotopes, aimed at identifying promising directions in the search for cheaper isotopes. This review is devoted to these problems.

II. DISTILLATION

Processes based on the distillation of hydrogen sulphide, sulphur dioxide, and sulphur trioxide have been proposed for the separation of the sulphur isotopes. The choice of these compounds was dictated not only by general considerations of ease of distillation (simple apparatus design, easy and cheap flow reversal arrangements at the ends of the cascade, absence of side-processes leading to "parasitic" take-off), but also by the wide use of these compounds in the chemical industry. The latter circumstance offers a routine basis for the production of isotopes as well as the possibility of exploiting "transit" schemes, in which an existing industrial production flow of sulphur compound is used for the extraction of the heavy sulphur isotopes. The waste flow, with a decreased content of heavy sulphur isotopes, is returned to the chemical production cycle from which it had been diverted. In this way the intrinsic cost of the product can be lowered very substantially, and the problems of environmental protection can be greatly simplified, since the waste from the isotope production process is fully utilised elsewhere. We should stress that "transit" schemes are economically attractive not only in the extraction of isotopes by distillation but in any large-scale method of isotope production[40].

The results of a study of isotope equilibria in liquid–vapour systems are summarised in Table 1. We note that the use of SO_2 or SO_3 is unattractive because the separation coefficients (α) are extremely low: these coefficients effectively determine both the capital costs and the running costs of the process [since the size of the apparatus is specified by the expression $V \propto 1/(\alpha - 1)^2$, and the energy needed for phase reversal is $E \propto 1/(\alpha - 1)$], and they also control the length of the start-up time [$\tau \propto 1/(\alpha - 1)^2$].

Symbols: methods of determining α: 1) simple distillation and calculation by the Rayleigh integral equation; 2) recalculation from the experimental values of $\alpha(^{32}S/^{35}S)$ obtained by method 1; 3) from the separation (K^∞) obtained in a column of height H_K having a known number of separation steps (n); 4) calculated by the equation

$$\varepsilon=(\alpha-1)=0.2\left(\frac{\Delta V}{\Delta T d}\right)^2\cdot\left\{1-\left[0.2\left(\frac{\Delta V}{\Delta T d}\right)^2\right]^2\right\}\cdot\left(\frac{T_{cr}}{T_{nbp}}-1\right)\cdot\varepsilon_K\Delta m,$$

where $\varepsilon_K = \frac{3}{2}\cdot\frac{1}{M}$ for mono-atomic molecules and

$$\varepsilon_K=\frac{3}{2}\cdot\frac{1}{M}+\frac{\mu}{m^3};$$

for polyatomic molecules, M is the molecular weight, μ is the reduced mass, $\Delta V/\Delta T = (V_{cr} - V_l)/(T_{cr} - T_{nbp})$, V_{cr} is the critical volume, V_l is the volume of the liquid at the normal boiling point, T_{cr} is the critical temperature, T_{nbp} is the normal boiling point, d is the density of the liquid, and Δm is the difference in mass between the isotopic molecules.

*H_K = 1 m; n = 96 ($^{10}BF_3$ – $^{11}BF_3$).
**H_K = 0.74 m; K^∞ = 1.022.

However, we should also note that though the data in Table 1 on the temperature dependence of α during the distillation of H_2S suggest relatively high values of the separation coefficient they include some inconsistencies, and a critical reappraisal of these results is essential. The simple distillation method[41,50] followed by calculation of α by the Rayleigh integral equation assumes that the initial hydrogen sulphide is free from involatile impurities, and that equilibrium conditions are maintained throughout the evaporation of the liquid phase[42–46]. Neither of these assumptions is invariably obeyed[42,44]. Results obtained from the distillation of H_2S in a column with a known number of theoretical plates (n) are also not entirely reliable, because the n values (determined for the distillation of BF_3) may not be exactly applicable to the distillation of H_2S. The determination of $\alpha(^{32}S/^{34}S)$ by calculation from experimental values of $\alpha(^{32}S/^{35}S)$ is also inexact, since it assumes that the separation coefficient is proportional to the relative difference in mass of the isotopic molecules.

In spite of these shortcomings of the methods the α values for low temperatures agree tolerably well (but not those for high temperatures). For example, the parameter $\varepsilon = (\alpha - 1)$ determined[51] at 208 K differs by a factor of 1.76 from the value obtained[41] by simple distillation followed by application of the Rayleigh integral equation, whereas the values of ε obtained[47,53] at 213 and 298 K respectively are 3–7 times lower than the values expected from the temperature dependence of α given in Ref. 41. We should also stress that the experimental results[41] are inconsistent with a quantum-statistical calculation[48] based on spectroscopic data. The latter discrepancy probably arises from failure to allow, in the calculation, for the complex composition of the liquid phase [including associated groups of the $(H_2S)_n$ type[49,50]].

*The separation reported in Ref. 51 was in a column of height H_K = 1.02 m and diameter D_K = 12 mm, packed with Nichrome spirals (1.5 × 1.5 × 0.2 mm). The separation reported in Ref. 53 was for a column having H_K = 1.0 m and D_K = 7.6 mm and packed with Constantan rings (1.2 × 0.25 mm).
**Estimated for the distillation of BF_3 from the degree of separation of $^{10}BF_3$ and $^{11}BF_3$.
***No separation detectable within experimental error.

The characteristics of the experimental assemblies used to study the separation of sulphur isotopes by distillation are listed in Table 2: the most favourable are those for the distillation of hydrogen sulphide, offering low values of the HETP (height of the equivalent theoretical plate) as well as the possibility of achieving high specific loadings. By using the criterion W to characterise the effectiveness of unit length of the column ($W = \ln K^\infty \cdot \tau/L$, where K^∞ is the stationary separation obtained in the column, τ is the transfer of the desired isotope along the column, and L is the flow circulating in the column) Devyatykh and co-workers[51] compared the effectiveness of various sulphur isotope separation processes. The conclusion was that hydrogen sulphide is

the best working substance for the separation of sulphur isotopes by distillation ($W_{H_2S} = 1.00$, $W_{SO_2} = 0.33$†), since its molecular weight is close to the atomic weight of sulphur, and it is a naturally occurring compound as well as being in industry on a large scale (for example, in the production of heavy water by the two-temperature hydrogen sulphide method[52]). The distillation of hydrogen sulphide could be of practical interest not only as a method of separation of sulphur isotopes but also in the production of very pure sulphur and sulphides[56], the demand for which has increased sharply in recent years.

An important contributory factor to the wide use of the hydrogen sulphide distillation process for the production of heavy sulphur isotopes is the amount of information already available on this process[41,51,55]. In addition to the above data on the isotope exchange equilibrium, wide-ranging results on the hydrodynamics of the distillation of hydrogen sulphide in glass columns under vacuum can be found in the published literature. This work has established that for the column packing used in the measurements [(2 × 2 × 0.3) × 10^{-3} m elements made of stainless steel wire and etched with a mixture of nitric and hydrochloric acid to improve the wetting] the maximum load L^* (kg m^{-2} h^{-1}) in the temperature range 189–210.6 K is described by the equation

$$L^* = -460 + 1870(d_e\gamma_v\gamma_l)^{0.5} \quad (1)$$

where d_e is the equivalent diameter of the packing (m), and γ_v and γ_l are the density of the vapour and of the liquid respectively (kg m^{-3}).

Experimental data on the retention capacity of the packing (ΔH) under the above conditions are described by the equation

$$\Delta H = 0.11\mathrm{Re}_l^{1/3}\left(a\frac{\mu_l}{\gamma_l}\right)^{2/3} \quad (2)$$

where μ_l is the viscosity of liquid H_2S, a is the specific surface area of the packing (in the present case, 3350 $m^2 m^{-3}$), and Re_l is the Reynolds number for the liquid phase.

The measurements of the hydraulic resistance of the packing are described by the equation

$$\frac{\Delta p}{l} = \lambda\left(\frac{W_v + W_l}{2g}\right)^2 \gamma_v \frac{a}{(V_{free} - \Delta H)^3} \quad (3)$$

where W_V and W_l are the linear velocities of the flows of vapour and liquid (m s^{-1}), λ is the coefficient of friction ($\lambda = 1600/\mathrm{Re}_V$), and V_{free} is the fractional free volume.

In conclusion we note that according to the reported[41] anomalous temperature dependence of α it should be possible to carry out the distillation of hydrogen sulphide without cooling: however, in view of the doubts mentioned above, this prediction requires experimental confirmation. We should also stress that because of the high toxicity of hydrogen sulphide the cost advantage of distillation under pressure may be offset by the more stringent requirements of completely leak-free operation.

To conclude this survey of distillation processes for the separation of sulphur isotopes we should not that the technological advantages of the distillation of H_2S mentioned above may rule out the use of any other compounds, in view of the steep increase in the demand for the heavy isotope ^{34}S (now more than 10 kg per annum) in a highly enriched state (≥90%).

†At the normal boiling point of the sulphur compound.

III. CHEMICAL ISOTOPE EXCHANGE

Chemical isotope exchange processes offer values of α much greater than those found in distillation, and are widely used in the production of isotopes of the lighter elements[40,57–60]. They also play a key role in the production of the heavy sulphur isotopes[35]. A large fund of experimental information on the equilibrium and kinetics of the isotope exchange of sulphur in chemical isotope exchange processes has accumulated during the past 40 years, and furthermore the technological value of the methods has been fully characterised.

The term technological value denotes the combination of factors not directly related to the isotope exchange process in the two-phase system and yet relevant to the technology and the economics of the separation process. The latter aspects can be predominant in determining the industrial importance of a process. These factors include the availability, compatibility, toxicity, and corrosion activity of the working substances, the problems arising in organising a continuous countercurrent process, the simplicity of the phase reversal arrangements, the cost of the processes involved, the possibility of combining the isotope separation process with other industrial operations, etc.

***H_K = 1.8 m.
****Separation observed, but α not measured.
*****For this system the total concentration of sulphur in solution is given (calculated as SO_2).
******No separation.

The ratios of partition functions (β-factors) have been calculated[61,62,85] by inserting spectroscopic data into a model for many isotopically substituted sulphur-containing molecules and ions, and the equilibrium constants of the isotope exchange reactions of inorganic sulphur compounds have been obtained. By combining these results with experimental studies of sulphur isotope exchange equilibria (see Tables 3 and 4) and with phase equilibrium data we can identify and characterise a number of special features of the parameter α. The recognition of correlations in isotope effects in different systems can be useful not only in a rational search for the most effective working substances but also in optimising existing separation processes. However, we should note that many of the working systems listed in Refs.61 and 85 and in Tables 3 and 4 cannot be used in controlled sulphur isotope separation processes for a number of reasons (low rate of isotope exchange (see Table 5), low single-pass isotope effect, or difficulty in arranging the phase reversal at the ends of the separation cascade).

1. Hydrogen Sulphite Process

The hydrogen sulphite process, which relies on isotope exchange between gaseous SO_2 and the hydrogen sulphite ion HSO_3^-, satisfies most of the above requirements[35,60,75,78]. The slight discrepancies in the experimental values of α (Table 3) may be due to inadequacies in the methods employed or, in some cases, to failure to allow for the presence of other ions (e.g. SO_3^{2-} and $S_2O_5^{2-}$) in an aqueous solution of hydrogen sulphites containing dissolved SO_2.[72,73,80] The relative contribution of these spurious reactions to the overall separation effect is determined by the factors which influence the equilibrium between the various ions in the liquid phase: temperature, pressure, concentration of hydrogen sulphite, and pH.

Table 4. Data on the isotopic equilibrium of sulphur in chemical isotope exchange processes between SO_2 and its complexes (p = 0.1 MPa).

Solutions of sodium or ammonium hydrogen sulphite were found to be prone to "ageing" effects[65,71,75] associated with oxidation by dissolved atmospheric oxygen in the presence of ultraviolet light. It was noted[89] that the "ageing" of hydrogen sulphites takes place in two steps: in the first, sulphate, thiosulphate, and polythionates are formed, and in the second the thiosulphate and polythionates are converted into sulphate and free sulphur (generating small quantities of sulphate). The solution develops a colour, due to colloidal sulphur. The formation of colloidal sulphur takes place mainly by the reaction

$$S_2O_3^{2-} + 2H^+ \rightleftarrows H_2S_2O_3 \rightleftarrows H_2O + SO_2 + S$$

in the reactor of the lower flow reversal unit, in parallel with the decomposition of the hydrogen sulphite by sulphuric acid at $T \cong 373$ K. All these side-reactions in the solution of hydrogen sulphite should, in principle, disturb the technological regime and cause a loss of enriched product, since the exchange between HSO_3^-, SO_3^{2-}, and SO_4^{2-} ions is negligible both in acid and in alkaline solutions (as is also the exchange between thiosulphates, polythionates, and colloidal sulphur).

Many attempts to "moderate" the ageing of hydrogen sulphite solutions by various means have been reported, including additions of oxidation inhibitors, degassing of the solutions, improved designs of the lower flow reversal unit, and a search for an oxidation-resistant source of hydrogen sulphite ions. It was found that small amounts of hydroquinone[68] or *N*,*N*-dimethylformamide[80] can be used as oxidation inhibitors in solutions of ammonium hydrogen sulphite. Auto-oxidation was also shown to be avoidable[65] by degassing the initial solutions and by displacing the air in the column with an inert gas.

Many workers have found that the oxidation of hydrogen sulphite depends on the method of preparation of the solutions[75] and on their purity[71]. Thus the formation of colloidal sulphur can be largely suppressed by using freshly prepared solutions of sodium hydrogen sulphite[75]. A comparative study of different sources of hydrogen sulphite ions ($NaHSO_3$, $KHSO_3$, NH_4HSO_3, $Na_2S_2O_5$) showed that industrially the best results are obtained with sodium pyrosulphite[90] supplied in a crystalline form, which allows solutions of $Na_2S_2O_5$ to be

****Concentrations of 45% ^{34}S, 2.7% ^{33}S, and 0.9% ^{36}S reached.

prepared immediately before the separation process. Furthermore, by using a reactor incorporating three separately heated sections[75] and carrying out the lower phase reversal operation at successively higher temperatures (50, 75, 95, and 100–105 °C) the precipitation of colloidal sulphur was suppressed to a large extent and quantitative evolution of the SO_2 was obtained though its concentration in the effluent solution was very low (5 × 10^{-3} kg m^{-3}). Small amounts of colloidal sulphur were precipitated after lengthy boiling of the solutions, but they were easily entrained by the liquid and did not interfere with the separation.

An isotopic analysis of the colloidal sulphur precipitated during the separation was carried out[75] in order to determine whether the precipitation causes a loss of enriched product. Though the laboratory apparatus produced a concentration of ^{34}S of 6.2% at the lower end of the column in a stationary regime, the isotopic composition of the sulphur was identical to that of the initial solution, showing that the precipitation of colloidal sulphur had not caused a loss of enriched product. This conclusion is of the utmost importance in determining the possibility of obtaining sulphur isotopes at high concentrations by the hydrogen sulphite process, and it requires experimental confirmation by the same method but at higher levels of enrichment of ^{34}S in the column.

Another important series of studies on the hydrogen sulphite process was aimed at developing improved apparatus designs and lowering the unit cost of the process. Perhaps the most significant of these were the search for a more effective type of column packing[66,71,88] and the work on minimising the cost of flow reversal. The need for these improvements was dictated by the very high values of the HETP (from 0.25 to 1.1 m) reported in the early publications[65, 71,77] (see Table 6) and by the excessive consumption of relatively expensive high-purity reagents in the flow reversal process.

One of the earliest attempts[71] to increase the efficiency of the packing (by improving its wetting by the working solution) relied on the addition of small amounts of technical octanol, but the performance of the packing (glass saddles or Fenske helices) was not measurably improved. Nevertheless the use of additives to improve the wetting of the packing and to increase the rate of diffusion processes in the liquid phase should not be dismissed, especially if the additives also act as oxidation inhibitors for the hydrogen sulphite ions, if they assist the flow reversal or protect the apparatus from corrosion, or if they favour the mutual solubility of the phases participating in the separation. An alternative method of increasing the effectiveness of the

packing relies on etching the surface with acid solutions (in the case of stainless steel packings). This method is interesting, and its effectiveness has been noted in a number of studies of different isotopic mixtures using different packings[54,91,93].

The most systematic investigation of possible ways of improving the effectiveness of column packings for the hydrogen sulphite process was reported by Stiehl and coworkers[88]. By studying five types of stainless steel packing of different geometrical form they showed that the best packing consists of extended triangular spirals, which offer a large free volume and a low retention for aqueous solutions of hydrogen sulphites. These workers calculated that by using this type of packing for the separation of sulphur isotopes in the NH_4HSO_3–SO_2 system an apparatus not exceeding 35.4 m in height can give a fractional take-off of 90%-enriched ^{34}S equal to 0.2677×10^{-3} of the flow (L) circulating in the column. The calculations apply to an aqueous solution of NH_4HSO_3 with a total concentration of SO_2 of 9 mole litre^{-1}, assuming a working temperature of 353 K and a specific loading (with liquid) of 1.765×10^{-4} m^3 m^{-2} s^{-1}.

At the current level of production of sulphur isotopes (up to 2 kg of 50–90% ^{34}S per annum[90]) the most important item in the overall cost of manufacture is that of the flow reversal arrangements (in addition to the labour costs)[35].

One of the most promising methods of minimising this cost in the hydrogen sulphite process is to combine this separation with the separation of nitrogen isotopes in the NO–HNO_3 chemical exchange system[76] (see Fig.1)#, which can itself easily be combined with the low-temperature distillation of NO to yield oxygen isotopes[96]. A combination of these processes by the scheme shown in Fig.1 minimises the flow reversal costs of both the hydrogen sulphite and the HNO_3–NO process as well as solving the problem of by-product utilisation. Any practical embodiment of this scheme should include provisions for removing dissolved SO_2 from the sulphuric acid emerging from the lower flow reversal unit of the "nitric acid" assembly: otherwise, the acid will cause a serious dilution of the enriched sulphur isotopes when admitted to the lower flow reversal unit of the "hydrogen sulphite" assembly.

The problem of removing dissolved SO_2 from the sulphuric acid is made much simpler by organising the flow reversal in the NO–HNO_3 process as shown in Fig.2. This allows the concentration of the H_2SO_4 issuing from the flow reversal unit to reach 70–75% [100] (since the solubility of SO_2 in H_2SO_4 goes through a minimum as the concentration increases to 80% [99]). The concentration of SO_2 in the sulphuric acid is lowered also by heating the acid, since the solubility varies inversely with temperature. For example, according to standard Tables[98] the solubility of SO_2 in 95% H_2SO_4, which is 25 m^3 SO_2 m^{-3} H_2SO_4 at 298 K, falls to 4 m^3 SO_2 m^{-3} H_2SO_4 at 363 K. This suggests that failure to control the SO_2 content of the sulphuric acid used for flow reversal in "hydrogen sulphite" plants may be responsible for the reported[76,83] discrepancies in the HETP obtained for isotope exchange between the hydrogen sulphite ion and SO_2 in counter-current packed columns and in ion exchangers[17,101] (see also Tables 6 and 9). In the latter case the motion of the Spedding zone was achieved by using hydrochloric rather than sulphuric acid (thus avoiding the presence of dissolved SO_2). We also note from the results in Table 6 that substantially different values of the HETP were obtained by different workers using H_2SO_4 for flow reversal in counter-current columns under similar conditions (identical temperature, pressure, concentration of hydrogen sulphite ion, load (and shape and size) of the packing, and similar column diameters).

#The production of a kg of ^{15}N by the NO–HNO_3 process requires a supply of more than 50000 kg of sulphur dioxide for flow reversal[97]. This gas is a waste product in the hydrogen sulphite process, and at the same time the waste product of the NO–HNO_3 process (sulphuric acid) can be utilised (after suitable treatment) to induce flow reversal in the hydrogen sulphite process.

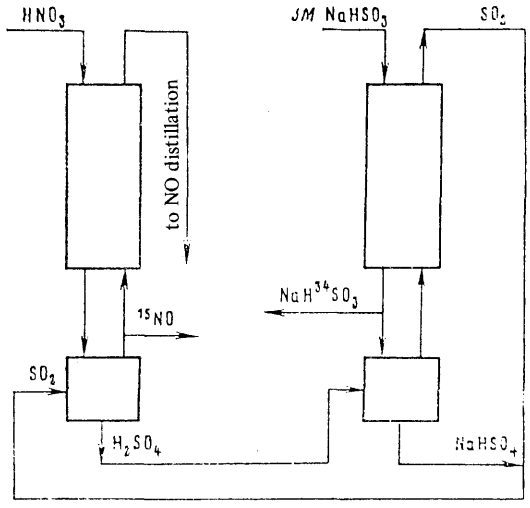

Figure 1. Combination of the hydrogen sulphite sulphur isotope separation and the NO–HNO_3 nitrogen isotope separation process.

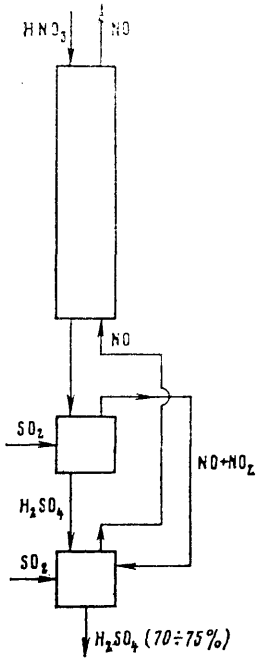

Figure 2. Flow reversal scheme suggested[100] for the lower unit in the nitrogen isotope separation process.

Knowing the maximum solubility of SO_2 in sulphuric acid[98] we can calculate the possible isotopic dilution of the product caused by the SO_2 of natural isotopic composition contained in the sulphuric acid added to the flow reversal unit. For a concentration of ^{34}S of 4.2 at.%, and a separation coefficient of the ^{32}S and ^{34}S of $\alpha = 1.008$ (at 20 °C), the production of 1 kg of ^{34}S in an apparatus without take-off requires the treatment of a flow of raw materials containing $L = p/x_0\Gamma \cong$ 3000 kg of sulphur, as well as an input of 9000 kg of H_2SO_4 for flow reversal. At 293 K the solubility of SO_2 is 0.0365 kg SO_2 kg^{-1} H_2SO_4, and as a result of isotopic dilution the ^{34}S content of the product may fall from $x_K = 100\%$ to $x_K = 4.79\%$. At higher temperatures the solubility of SO_2 decreases, but not to a negligibly low value. For example, at 90 °C the solubility is 0.00475 kg SO_2 kg^{-1} H_2SO_4, which can also lead to marked isotopic dilution ($x_K = 8.5\%$). Evidently, failure to allow for these effects may have been responsible for serious errors in the determination of the HETP from experimental values of the degree of separation obtained, and hence it may explain the large discrepancies between HETP values reported from different laboratories.

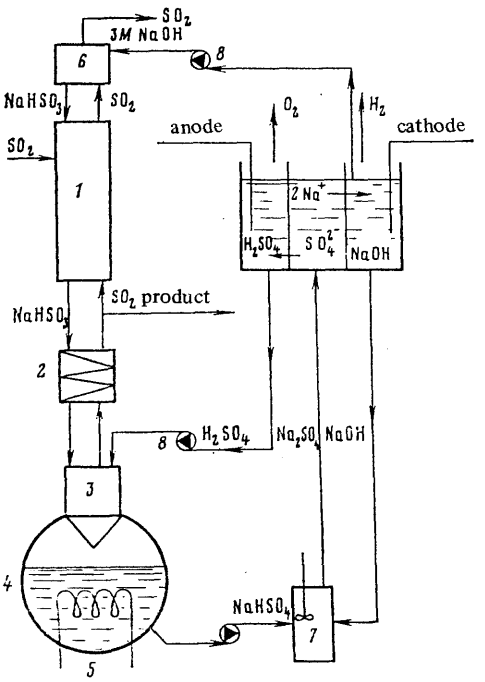

Figure 3. Flow reversal using an electro-dialysis system in the hydrogen sulphite process: *1*) exchange column, *2*) condenser, *3*) hydrogen sulphite decomposition column, *4*) boiler, *5*) heater, *6*) reactor of upper flow reversal unit, *7*) hydrogen sulphite converter, *8*) pump.

In order to reduce the cost of the reagents used for flow reversal (sulphuric acid in the lower unit and sodium hydroxide in the upper unit for flow reversal in a "hydrogen sulphite" apparatus with take-off) an electro-dialysis system has been used[19,25,35,36] to regenerate NaOH and H_2SO_4 from the $NaHSO_4$ formed in the lower flow reversal unit (Fig.3). The additional consumption of electrical energy in this case is 3500 kJ per mole of $NaHSO_4$.[35]

The advantages of the electro-dialysis scheme include inducing flow reversal by using electrical energy, and the possibility of using a gas as feed-stock (thus allowing the process to be combined with the "nitric acid" process, or, using the "transit" scheme, with the sulphuric acid process based on SO_2). Furthermore this scheme avoids the difficulties arising from the need to use freshly prepared solutions of hydrogen sulphite, and minimises "ageing" effects.

The problem of using HETP data obtained for small-diameter columns in the design of large industrial isotope separation plant is still unsolved. However, for the hydrogen sulphite process this problem is easily solved by using the abundant experimental information on HETP values available for columns of widely different diameter (up to 0.07 m [71]) and using packing of different shape and size (see Table 6).

We shall conclude this discussion of the hydrogen sulphite process with a brief review of the characteristics of industrial assemblies and of the results of experiments in large laboratory apparatus and in pilot plant. The first separation of sulphur isotopes by the hydrogen sulphite process was achieved in a fairly large laboratory cascade assembly[67,70,71] whose main parameters are listed in Table 6. Because of the low flow rate of gaseous SO_2 the pressure drop in the columns was also low, and therefore the cascade could be operated without intermediate gas compressors. A stationary distibution of ^{34}S concentration was reached after 21 days' operation of the cascade. It was found that 3.0×10^{-5} m^3 of enriched $NaHSO_3$ solution (3.2×10^{-3} kg of sulphur) could be taken daily from the last column of the cascade with a concentration of ^{34}S not less than 25%. Having determined experimentally the hold-up of ^{34}S in the column, Thode and co-workers[70] calculated the average rate of transfer (1.272×10^{-8} kg ^{34}S s^{-1}).

It was subsequently found[69] that the heavy sulphur isotopes could be concentrated to the level of 10 at.% ^{34}S and 1.5 at.% ^{33}S in the $NaHSO_3$–SO_2 system by using an apparatus with columns 20 m high. In the early 1970's a cascade consisting of two columns 8 and 12 m high was built in the Soviet Union, and this gave an enrichment of 45 at.% for ^{34}S, 2.7 at.% for ^{33}S, and 0.9 at.% for ^{36}S in 20 days. From these results a design was produced for a three-column cascade apparatus capable of producing 0.5 kg $year^{-1}$ of sulphur containing 90 at.% of ^{34}S or 0.1 kg $year^{-1}$ of sulphur containing 3 at.% of ^{36}S. The estimated cost[90] was 117000 roubles per kilogramme of ^{34}S and 580000 roubles per kilogramme of ^{36}S.

A group of French workers[29] described a series of tests on a large-scale apparatus consisting of a column 5.5 m long and 0.04 m in diameter filled with Helipak 316 packing. By using the NH_4HSO_3 system these workers studied the effect of load and temperature on the HETP at atmospheric pressure and 3 M concentration of the aqueous hydrogen sulphite solution. Their results are given in Table 6. A comparison of these results with those obtained[75] under otherwise similar conditions for the $NaHSO_3$–SO_2 system in a column 0.02 m in diameter confirms the report[76,102] that the HETP for the NH_4HSO_3–SO_2 system is lower than the corresponding value for the $NaHSO_3$–SO_2 system. These pilot experiments established that the apparatus can produce 0.1 m^3 day^{-1} of SO_2 containing 50% of ^{34}S.

The development of a large-scale apparatus for separating sulphur isotopes at the Mound laboratory (USA) has recently been described[25,35,36]. It is based on the laboratory's five-step cascade process for the production of carbon-13 by the amine–carbamate method[36,103]. The consumption of reagents for flow reversal is minimised by adopting an electro-dialysis system in conjunction with the $NaHSO_3$–SO_2 working system.

The separation is carried out at 343 K with a 3 M concentration of sodium hydrogen sulphite in water. For a feed rate of $(1.157–3.48) \times 10^{-5}$ kg SO_2 per day this plant is expected to produce 5×10^{-8} kg of ^{34}S with a concentration of 90 at.% per day at a cost between 100000 and 200000 dollars per kilogramme. It is also proposed[36] to use some of the product in the Mound laboratory's thermo-diffusion apparatus[25,36] to produce ^{33}S at high concentration.

In addition to the hydrogen sulphite process, the exchange of isotopes between potassium xanthate $S{=}C(OR)(SK)$ and carbon disulphide CS_2 has also been studied as a means of separating sulphur and carbon isotopes simultaneously[104,105]. The lower flow reversal in this process uses the reaction

$$RO{-}C(SK){=}S + HCl \rightarrow ROH + KCl + CS_2$$

and the upper flow reversal uses the reaction

$$CS_2 + KOH + ROH \rightarrow RO{-}C(SK){=}S + H_2O\ .$$

This process is not very attractive for the separation of sulphur isotopes, because sulphur isotope exchange is very slow in the C–S and O–S bonds[20]. Furthermore, the practical value of the method is very doubtful in view of its reliance on expensive chemical flow reversal arrangements.

2. Systems Using Thermal Flow Reversal

The possibility of using complexes of SO_2 with various organic compounds has been studied in several laboratories (see Tables 4 and 7). The systems examined include xylidene and dimethylaniline[55,81,82,87], pyridine[55] and its mixtures with water and phosphoric acid[94,95], and also diethyl and dimethyl ether, anisole, and phenetole[75,84,106], trimethoxyborane and acetonitrile[83], and aniline, triethylaniline, ethylene oxide, phenol, and tetrahydropyran[55]. Other sulphur-containing complexes have also been studied, including those formed by the reaction of H_2S, $(CH_3)_2S$, CS_2, COS, $SOCl_2$, SCl_2, and S_2Cl_2 with complexing agents such as diborane, boran trifluoride, boron triaryls and trialkyls, and also aluminium trialkyls (in particular, $(CH_3)_3Al$ and $(C_2H_5)_3Al$).[107] The largest isotope effect was obtained for a mixture of SO_2 and the complex of SO_2 with the pyridine–water azeotropic mixture: on a column 1.85 m long this gave a separation of the ^{32}S and ^{34}S isotopes of $K^\infty = 1.15$.[95]

Though these systems offer the great advantage of thermal flow reversal, they are not serious competitors of the hydrogen sulphite system for the separation of sulphur isotopes. In most cases their α values are extremely low (see Table 4), and the low stability of the complexing agent towards atmospheric oxygen and water vapour can create serious practical problems. As a result, the separation has to be carried out in an inert atmosphere, and provisions for continuous (or periodic) drying have to be made, together with provisions for removing the decomposition products of the complexing agent. We should also note that the complexing agents and the sulphur-containing compounds listed above are, in most cases, highly toxic and corrosive.

However, these difficulties should not be used as an argument to stop the research in these areas, because analogous systems have long been used with success in industrial plant for the separation of boron isotopes[108].

The most important outcome of these investigations is the establishment of clear correlations between the parameter α and the physicochemical of structural properties of the complexes. However, before examining these correlations we should briefly consider the reliability of the α values listed in Table 4 for the SO_2 complexes. These values were obtained either by repeated equilibration or by separating a mixture of isotopes on a column. The weakness of the latter method has already been stressed in this review. The main weakness of the repeated equilibration method is its reliance on a strict preservation of the material balance[109–112], which cannot always be ensured owing to mechanical losses or to the volatility of the gaseous sulphur compounds. The results may be distorted also by kinetic isotope effects in the evolution of the gaseous sulphur compound from the complex former (or its absorption). Furthermore, errors in the determination of α may arise from fluctuations (from step to step) in the amount of flow contraction assumed for the calculation[109,110,117].

These factors may be responsible for the large discrepancies in the α value for the SO_2–SO_2·dimethylaniline system (see Table 4) and for the good agreement of the α values in the SO_2–SO_2·xylidene system for the ^{34}S–^{32}S and ^{33}S–^{32}S isotope mixtures. Another possible reason for the poor reproducibility of experimental data is the dependence of the separation coefficient α on the composition of the complex (or, more exactly, on the parameter r, which is the ratio of the number of moles of the sulphur-containing compound in the complex, D, to the number of moles of complexing agent, R). This dependence is due to the presence in the liquid phase of free molecules of the sulphur-containing compound, leading to inter-phase isotope exchange (in addition to ordinary isotope exchange) between the sulphur compound in the gas phase and in the liquid complex former respectively. Therefore the observed effective separation coefficient α depends on the fractional amount m of free sulphur compound in the liquid phase according to the equation

$$\alpha = mK_{ph} + (1-m)K$$

where K is the equilibrium constant of the isotope exchange reaction between the sulphur compound in the gas phase and its complex in the liquid phase, and K_{ph} is the separation

coefficient for the inter-phase isotope exchange between the free sulphur compound in the gas phase and in the liquid phase respectively.

A rational search for efficient working systems by quantum-statistical calculations can be based on the ratio of the partition functions (β-factors) of the isotopic forms of the sulphur compounds[61,113]. In addition to an estimate of the equilibrium constants for different sulphur compounds this calculation gives an indication of the trends in the dependence of the β-factor on various characteristics of the compounds, as in the earlier work on boron compounds[113–116]. However, the calculation assumes that the vibration frequencies and the anharmonicity factors for both the normal and the isotopic molecules are experimentally known, and in the case of the more complex molecules these measurements are extremely difficult[115]. Reported calculations[61,85] suggest that the SO_3 and SO_2 molecules should have the highest β-factor of all gaseous sulphur compounds. At the same time these calculations point to the advantages of using a thermally unstable complex (e.g. a complex of H_2S) for the separation of sulphur isotopes.

A relationship has been reported[118,119] between the parameter α for sulphur isotopes and the ionisation potential J of the complexing agent. These calculations were based on the wave function

$$\varphi_N = a\varphi_0(RD) + b\varphi_1(R^+ + D^-)$$

which describes the ground state of the complex molecules ($R + D \rightleftharpoons RD \rightleftharpoons R^+ + D^+$), and assumed a linear dependence of the separation coefficient α on the ionisation potential J of the donor: $\alpha = m - nJ$, where m and n are constant coefficients, equal to 1.0109 and 9.8×10^{-4} respectively for the separation of the sulphur isotopes ^{32}S and ^{34}S in SO_2–SO_2(complex) systems at 293 K.

The above equation is not acceptably consistent with experiment[118], and it assumes that the isotope effect is negligible for $J = 11.1$ eV. Since the potential J usually decreases as the size of the molecule increases, we can expect[118] α to increase with the molecular weight of the donor. As Table 4 shows, this expectation is not borne out in general: for different homologous series the parameter α tends to increase with the molecular weight of the complexing agent, but within any one homologous series no such tendency is observed.

It has also been pointed out[118] that the choice of a linear correlation between α and J is purely empirical, and there may be exceptions arising from steric hindrance to the formation of additive compounds, from orientation effects, or from the screening effect of free electrons. Furthermore, the assumed correlation between the ionisation potential and the properties of the resulting donor–acceptor complex has been shown[120] to be valid only if the complex forming power and the ionisation potential are referred to the same system of electrons in the donor molecule. In aliphatic or in saturated cyclic ethers, sulphides, or amines both these quantities refer to the properties of the unshared pair of electrons on the hetero-atom, but in aromatic or unsaturated compounds containing a hetero-atom the ionisation potential may relate to the excitation of a π-electron whereas the formation of the complex takes place through an n-electron of the hetero-atom. Furthermore, the use of the ionisation potential of the donor molecule to characterise the donor–acceptor interaction fails to take account of the overlap of the orbitals involved in the formation of the intermolecular bond and of "spatial" factors.

It has therefore been suggested[120] that the donor–acceptor interaction (and therefore also the parameter α) could be more accurately characterised by using the overlap integrals of the atomic orbitals of the donor and the acceptor. The possibility was demonstrated[120] for the complexes of BF_3 with a class of amines, ethers, and thio-ethers in which α varies in the order $\alpha_S > \alpha_O > \alpha_N$ whereas the overlap integrals calculated by using the Slater functions for the B–O, B–N, and B–S bonds vary in the opposite order (B–S < B–O < B–N). It is interesting to note that in these classes of compounds the ionisation potential decreases in the sequence $J_O > J_S > J_N$.[121] This tends to support the correlation proposed in Ref.118.

A dependence of α (or of the equilibrium constant K of the isotope exchange reaction) for a series of compounds of a given type has been noted[108] as a function of the nature of the electron-donor atom in the complex former R, of the nature and position of the complex former in the homologous series, of the presence of polar or easily polarisable groups in the molecule, and of the structure of R. The effects were ascribed to the factors listed above and their influence on the stability of the complexes, and in particular to the heat of formation of the complex ΔH_{form}. The relationship between α and the heat of formation of the complex was specially stressed[108]. In the case of boron complexes of a single type the parameter α was found to increase as the stability of the complex decreases, i.e. as ΔH_{form} decreases. In such a series of complexes the stability decreases as the atomic number of the donor atom increases, due not only to the larger size of the atom but also to the screening of the inner electrons from the electrons in the outer sphere of the donor atom. These considerations led to the suggestion[107] that the α values for a series of sulphur complexes of a given type including B, Al, Ga, In, or Tl as the electron-donor atom should decrease in the sequence Tl > In > Ga > Al > B. At the same time, the data on the boron complexes indicate that in the case of sulphur complexes the α values should decrease in the sequence Se > S > O > N.

Clearly, in the sulphur complexes (as in the BF_3 complexes) the maximum value of α is found in the second member of the homologous series of complex formers. This was confirmed experimentally[55,75] in a study of the separation of sulphur isotopes by using the complexes of SO_2 with phenol[55] and with anisole and phenetole[75]. Whereas by using phenol no separation was obtained in a column 0.84 m long, by using anisole in a column 1 m long with a packing of particle size ($1.6 \times 2.0 \times 0.2$) $\times 10^{-3}$ m a stationary distribution of ^{32}S and ^{32}S corresponding to a separation of $K^{\infty} = 1.06$ was obtained, and this was greater than the separation obtained in the same column by using phenetole. The maximum in the α values for the second member of the homologous series of complex formers has been ascribed[108], in the case of the separation of boron isotopes, to the influence of the geometry of the R molecule on the energy of the bond between the donor atom and the boron atom, and hence on the parameter α. This explanation can be extended to the complexes formed by sulphur-containing compounds, since the influence of the structure of the complex former on α is unmistakable in the results (Table 4) for the complexes of SO_2 with aniline ($\alpha = 1.002$)[55] and with dimethylaniline ($\alpha = 1.013$)[81]. The presence of two methyl groups on the donor (nitrogen) atom of dimethylaniline causes steric hindrance to the formation of a donor–acceptor bond between the sulphur and the nitrogen atom, thus lowering the stability of the complex and as a result raising α.

In the case of the BF_3 complexes the introduction of polar or easily polarisable groups into the complex-forming molecule lowers the stability of the complex: conversely, the stability is increased by the introduction of electron-donor substituents[108]. Thus the parameter α can be varied by inserting appropriate groups into the complex-forming molecule. However, we should not that the tendency of α to

increase in response to a decrease in the stability of the complex (by the introduction of polar or easily polarisable groups) also leads to a decrease in r. We also note that because of the scarcity and unreliability of the published data on the heat of formation of the complexes of sulphur-containing compounds it may be necessary to use the composition r (at saturation) as a measure of the stability of these complexes.

Some data on the phase equilibria in systems including sulphur complexes are given in Table 4. The properties of complexes of the $(CH_3)_2O\cdot SO_2$ and $(C_2H_5)_2O\cdot SO_2$ type have also been studied[84,106]: for $(C_2H_5)_2O\cdot SO_2$ the dependence of the vapour pressure p on the composition r was determined for 258 K and a partial pressure of SO_2 of 0.1 MPa (see Table 8), whereas for $(CH_3)_2O\cdot SO_2$ an azeotrope containing 58% SO_2 and 42% $(CH_3)_2O$ was observed at 273 K. The degree of dissociation of the latter complex in the vapour phase at 273 K was found to be 0.93. The melting point and boiling point of the $(CH_3)_2O\cdot SO_2$ complex are given[84] as 177.5 and 263 K respectively, and its heat of formation as ~15.5 kJ mole^{-1} (the composition of the saturated complex r = 1 mole SO_2 mole^{-1} $(CH_3)_2O$ is reached at 263 K and 0.1 MPa). The boiling point of $(C_2H_5)_2O\cdot SO_2$ is given[106] as 258 K, and its heat of formation as ~29.4 kJ mole^{-1}.

Attempts to relate the separation coefficient to the polarisability and dipole moment of the complex former have been described[122,124]. The more readily polarisable the complex former, and the larger the dipole moment of the complex, the weaker is the bond formed in the complex. Therefore we can expect α to increase with the dipole moment of the complex. This expectation has been confirmed experimentally for the complexes of BF_3 with the lower olefins, and is probably equally valid for the complexes of sulphur-containing systems. The dipole moments of some selenium, sulphur, and phosphorus compounds and their complexes are listed in Ref.125.

The importance of establishing the correlation between α and the parameters which describe the electronic and structural properties of the donor molecules and their substituents has been stressed[126,127]. By classifying the effect of substituents on the properties of the donor molecule as inductive, steric, mesomeric, etc. we can write the following expression for α in terms of the Hammett–Taft equation

$$\lg \alpha/\alpha_0 = \rho\Sigma\sigma + \Delta n \cdot h + \delta E_S + \psi$$

where α_0 and α are the separation coefficients of the sulphur isotopes for the initial and the substituted compound respectively, σ is the inductive constant (a measure of the effective electronegativity of the substituents), E_S is the steric constant of the substituent, Δn is the difference in the numbers of hydrogen atoms involved in hyperconjugation in the initial and the substituted compound, ρ, δ, and h are the parameters of the reaction series (a measure of the sensitivity of the reaction to the inductive, steric, and hyperconjugation effects respectively), and ψ is the coefficient which reflects the contribution from the conjugation of any π system to the reaction centre. Values of σ, E_S, and Δn are available for almost any substituent[128]. Often some of the effects can be ignored, and the equation becomes simpler.

In conclusion we note that all the complexes of SO_2 and of other sulphur compounds can be arbitrarily divided into two large groups. The first group includes complexes whose vapour pressure is lower than that of the complex former (for example, $(CH_3)_2O\cdot SO_2$ and $(C_2H_5)_2O\cdot SO_2$). These are only partially dissociated in the vapour phase, and as a result the gaseous sulphur compound included in the complex cannot be separated from the complex former. This group of compounds can be used in the separation of sulphur isotopes by chemical isotope exchange combined with distillation, involving isotope exchange between the liquid and the partially dissociated vapour of the complex. The lower flow reversal is achieved by evaporation of the liquid complex.

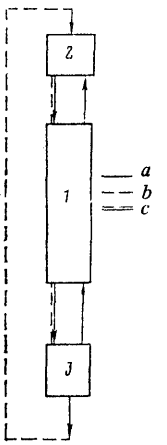

Figure 4. Process for the separation of sulphur isotopes by chemical isotope exchange with thermal phase reversal: *1*) exchange column, *2*) adsorber, *3*) desorber; *a*) gas flow, *b*) flow of complex former, *c*) flow of complex.

The second group of complexes includes those whose vapour pressure is greater than that of the complex former (for example, $C_6H_5OCH_3\cdot SO_2$, $C_6H_5OC_2H_5\cdot SO_2$). These complexes are almost fully dissociated in the vapour phase. By heating them to the boiling point of the complex former it is possible to strip the sulphur-containing gas almost quantitatively from the complex, since the vapour pressure of the complex former is relatively low. This makes possible the separation of sulphur isotopes by counter-current exchange between a gaseous sulphur-containing compound and its liquid complex, i.e. by "clean" chemical isotope exchange (Fig.4). Flow reversal at the ends of the separation cascade is achieved by thermally dissociating the complex in the desorber to the sulphur-containing gas and the complex former. The complex former is cooled and re-used to absorb the gas emerging from the separating column in the upper flow reversal unit, which is also an apparatus of the column type[108].

We should stress that the possibility of exploiting this group of compounds for separating sulphur isotopes was first demonstrated by Soviet workers[81]. Evidently, solid complexes of sulphur-containing gases could also be used, as in the gas–solid hypersorption processes proposed for the separation of hydrogen, nitrogen, and oxygen isotopes[129–131]. High values of r and α can be expected with these complexes. Furthermore, solid complexes of gaseous sulphur compounds can be used in separation processes as liquid solutions in solvents inert towards both the compounds and their complexes. However, the use of a solvent may have an unfavourable effect on the economics of the process because of the energy cost of heating, cooling, and transporting the solvent, and also because of the decreased throughput of the column. Nevertheless the use of a solvent could improve the rate of isotope exchange in the columns.

IV. ION EXCHANGE PROCESSES

Extensive work carried out during the 1960's in Sweden[17], East Germany[83,101,132,133], and France[60] demonstrated the possibility in principle of using ion exchange processes in the separation of sulphur isotopes (see Tables 9 and 10), and resulted in the production of gramme quantities of the isotopes[17]. Separation in columns was achieved by using Spedding's method[134] of organising a counter-current process on ion exchangers without motion of the solid phase. However, the low HETP values thus obtained are insufficient compensation for the disadvantages of ion-exchange separation, including the high consumption of reagents for flow reversal and regeneration of the resin (thus, the production of 1 mole of ^{33}S in the NH_4HSO_3–Dowex resin system requires[17] the expenditure of 4×10^4 mole of HCl and $\sim 5 \times 10^4$ mole of NH_4HSO_4), and also the complexity of the apparatus, due to the difficulty of arranging a continuous counter-current process in this type of system[135–137]. Similar problems are encountered in processes using liquid anion exchangers. Isotopic mixtures of ^{32}S and ^{34}S have been separated in an experimental column at 298 K by using the following working systems: CCl_4/tri-n-octylamine $H{\cdot}HSO_3/H_2SO_3$, C_6H_6/tri-n-octylamine $H{\cdot}HSO_3/H_2SO_3$, n-octanol/tri-n-octylamine $H{\cdot}HSO_3/H_2SO_3$, toluene/tri-n-octylamine $H{\cdot}HSO_3/H_2SO_3$, cyclohexane/tri-n-octylamine $H{\cdot}HSO_3/H_2SO_3$, tetralin/tri-n-octylamine $H{\cdot}HSO_3/H_2SO_3$, nitrobenzene/tri-n-octylamine $H{\cdot}HSO_3/H_2SO_3$, pentane/tri-n-octylamine $H{\cdot}HSO_3/H_2SO_3$, and hexane/tri-n-octylamine $H{\cdot}HSO_3/H_2SO_3$. Separation was observed in every case, but the α and HETP values were not determined[83]. In spite of the almost two-fold saving in materials achieved by combining the ion-exchange separation of sulphur isotopes with the separation of carbon isotopes[83, 132,133], the disadvantages of the method still make it unacceptable in practice. A possible combined scheme, relying on the use of acids of different strength for the separation, is shown in Fig.5.

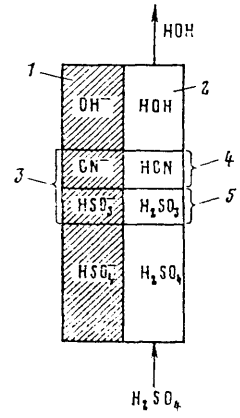

Figure 5. Combined ion-exchange separation process for sulphur and carbon isotopes: *1*) solid phase, *2*) liquid phase, *3*) separation part of the column, *4*) carbon isotope separation zone, *5*) sulphur isotope separation zone.

A far more promising method is based on continuous counter-current adsorption processes, analogous to those previously used to separate nitrogen or oxygen isotopes[130,138],

since these offer α values usually much greater than those obtained in ion exchange or in distillation as well as the possibility of thermal flow reversal.

---o0o---

Thus we may conclude that studies of equilibrium two-phase counter-current processes for the separation of sulphur isotopes have not yet led to the development of a really efficient process, combining low cost with other desirable attributes, in spite of the pressing need for such a process in both scientific and industrial practice. The most promising directions for future development work include: a search for new and more effective working systems, optimisation of the technological parameters of the separation processes, the development of rational technological schemes for combining the separation of sulphur isotopes with other chemical or isotopic production processes, and a search for means of using cheaper energy sources for phase reversal, and for means of utilising the waste products.

The main aim of the work should be to establish relationships between the physicochemical properties of the working systems and their separation coefficients, rate of isotope exchange, and other characteristics of the separation process.

From the industrial point of view it would be desirable to investigate new systems compatible with thermal flow reversal. The most promising of these are the various adsorption processes, and also the chemical isotope exchange between SO_2 and its thermally unstable complexes in the solid form, or dissolved in an inert solvent.

Prediction and Analysis of Heterogeneous Catalysis Mechanisms by Pattern Recognition Methods with a Computer

I.I.Ioffe, A.M.Dobrotvorskii, and V.A.Belozerskikh

The basic aspects of the prediction of catalytic activity in one-component and multi-component heterogeneous catalysts and of the analysis of the mechanism of heterogeneous catalytic reactions by using pattern recognition theory with a computer are discussed. The present state of development is reviewed, and examples of the use of this method in choosing catalysts for different types of reaction are given. 53 references.

VI. Prospects of future developments 237

I. INTRODUCTION

Catalyst prediction should be clearly distinguished from the search for entirely new types of catalyst, or for catalysts for new and unexplored classes of reactions†. Catalyst prediction denotes the *a priori* search for suitable catalysts for known types of reaction on the basis of existing information on a range of potential catalysts and of a general understanding of the mechanism of their action. As well as having the right chemical composition, an effective industrial catalyst should have the required permeability (or porosity) parameters, including strength and geometric size. In this review we shall be concerned exclusively with the problem of predicting the chemical composition of the catalyst, though the pattern recognition algorithms are equally applicable to the prediction of the physical parameters of the catalysts.

By using the existing level of scientific understanding of catalytic reactions, and the vast fund of empirical information (extending over more than a century), we can often select suitable catalysts for various reactions, including new reactions, if they fall within one of the main classes of chemical transformation (e.g. hydrogenation, oxidation, condensation, etc.). However, this type of prediction offers no information on the productivity or selectivity of the catalyst, parameters of the utmost importance in industrial applications. We should note that in large-scale industrial production even a small improvement in performance could be very important economically.

Modern ideas on catalysis, such as the relationship between catalytic action and the acid–base properties of the surface[1,2], the energetics of the interatomic bonds of the lattice[3,4], the stabilisation energy of the crystal field[5], the geometric parameters of the lattice, etc. can be used to construct an acceptably rational scheme for the selection of catalysts for stated reactions[6–8]. However, in spite of its attractiveness and of its usefulness in research this scheme cannot predict quantitatively the main practical characteristics (activity, selectivity, etc.) of the proposed catalysts.

† Throughout this review the term catalyst will be used to denote heterogeneous catalysts.

In the present state of knowledge we can distinguish three possible paths for catalyst prediction: 1) the theoretical approach, based on the theory of the structure of chemical compounds and on quantum chemistry, 2) the semi-empirical approach, based on correlation methods, and 3) the mathematical (heuristic) approach, which relies on the methods and algorithms of the mathematical pattern recognition theory.

In spite of the important advances recently made in the quantum chemistry of heterogeneous catalysis[9–11] the first approach is still far from the state of development which would justify quantitative predictions of the output parameters of the catalysts. Nevertheless, as we shall show below, theoretical (and especially quantum-chemical) considerations play an important role in computer methods of catalyst prediction.

The second approach is equivalent, in practice, to using one of the many variants of the principle of linear free energy relationships (LFER), such as Balandin's principle of energy correspondence, or the Brønsted, Hammett–Taft, or Voevodskii–Semenov equation. Numerical calculations by these equations are possible only for empirical coefficients, and are only valid for catalysts of a single type used in one particular reaction of (in the case of a group of homologues) for one catalyst in one reaction. These methods are unsuitable for predicting multi-component catalysts and they do not reveal extrema in the quantities being correlated (except the Balandin method, which is not accurate enough, however). Nevertheless investigations in this direction are continuing. Empirical correlation equations have been obtained for the hydrogenolysis of ethane and of alcohols[12,13] and for the dehydrochlorination of chloro-ethanes on sulphates[14]. These problems are discussed in depth in Ref.9.

Unlike the LFER methods, the pattern recognition methods do not need to be confined to catalyst (or reaction) analogues: though the mathematical recognition methods when applied to structure–property problems are effectively methods of detecting multi-dimensional or multi-level correlations they differ from the classical correlation analysis methods in their ability to reveal the inter-relationship of ten or more properties used as indicators of the quality of the samples by taking the combination of criteria into account. This feature of the pattern recognition methods has already led

to their successful application in chemical problems such as the determination of molecular structure from spectral data, the *a priori* calculation of the properties of inorganic compounds, and the prediction of biological activity in organic compounds[15–17].

The most important aspect of the pattern recognition methods as applied to catalysis problems is their ability to exploit the very large fund of experimental information on catalysts in standard handbooks[18] or in original publications as a predictive basis. The published data differ widely in precision and reliability: they include misleading information introduced for patent reasons, and they are only valid in statistical, computer-aided information processing methods such as the pattern recognition methods.

The use of these methods for the prediction of catalyst behaviour is made easier by the level of reliability required, which can be very high in some applications but not in catalyst prediction. Thus in radar, medicine, and geological prospecting the probability of the prediction must be 99.5% or more. In the case of catalyst selection an economically effective forecast is achieved simply by short-circuiting a laborious empirical search, and increasing the probability of finding the optimum catalyst. Since in any case the prognosis must be tested experimentally, there is no danger of making a "catastrophic" mistake. As compared to catalyst selection by the conventional semi-empirical methods, a quantitative prediction with a probability of ~80–85% would be economically effective.

The potential value of pattern recognition methods in the search for optimum catalysts is confirmed by calculations of their effectiveness[19,20]. In recent years pattern recognition methods and related methods of mathematical statistics have been used by many workers. Thus in Refs. 21–24, discussed below in detail, pattern recognition algorithms are used to identify catalysts for the hydrogenation and synthesis of thiophen. The factor analysis method has been used[25,26] to predict catalysts for electrochemical processes. Some results obtained by the present writers since the publication of their monograph[9] and only partially reported[27–29] will also be discussed in this review.

Essentially all recognition methods consist in establishing step-by-step relationships between the parameters of the solid responsible for its catalytic properties and its other physicochemical properties. These parameters include (depending on technological and cost considerations) either the productivity of the catalyst in terms of the desired product (i.e. its activity) or the selectivity of the reaction (or process) when catalysed by this material. The latter quantity is defined as the yield of desired product expressed as a percentage of the theoretically possible yield (or of the potential yield in petroleum chemistry), and it corresponds to the selectivity of the anion of the catalyst itself. In special cases other selection criteria are possible; for example, the operational life of the catalyst, its thermal stability, etc.

Since the recognition algorithms allow the ranking of the properties with respect to their effect on the useful parameters of the catalyst we can also solve the inverse recognition problem, i.e. identify the most "influential" physicochemical properties of the catalysts and reactants from the point of view of ensuring a fast and selective reaction. The results obtained give a basis for proposing the mechanism of the catalytic action. The main value of this method of analysing the mechanism of catalysis lies (as in the case of catalyst prediction) in the ability to exploit the extensive but not always very accurate experimental information, and to obtain reliable results by virtue of the statistical treatment implicit in the pattern recognition algorithms.

II. FUNDAMENTALS OF PATTERN RECOGNITION METHODS

Pattern recognition theory is a branch of cybernetics. The mathematical foundations of the methods used in pattern recognition are fully discussed in textbooks[30–32]. In this Section we shall merely give a short description of the methods which have been used in chemistry to predict the properties of substances.

The solution of the recognition problem is based on empirical input data, called the "training sample". In our case the "training" consists in "tuning" the specially developed algorithms in a way which enables the computer to determine the property of interest to the experimenter from the structure of the materials. The term structure denotes the set of primary properties of the material which can be used as criteria. The training process includes separating the materials into classes according to the value of the property being predicted. The assignment to one of these classes of a material not included in the training sample is the solution of the pattern recognition problem.

Existing recognition algorithms are either "deterministic" or "statistical". The former include the algorithms based on geometric considerations, and the perceptron algorithms, developed as a model of the perception of patterns by human beings[33]. The latter class includes the algorithms of the stochastic approximation and those based on the principles of statistical decision making. A special group, only recently recognised, consists of algorithms which have been called syntactic[34]. So far only algorithms from the deterministic group have been used in chemical problems. The desirability of using other types of algorithm to solve these problems will be considered below.

Let us examine more closely the geometrical treatment of the recognition problem. In this treatment the set of criteria of the objects to be recognised is treated as a hyper-space with one coordinate axis for each criterion. In such a space each object is represented by a point whose coordinates give the numerical values of the criteria. Coordinates corresponding to qualitative criteria can also be used: this is done by numbering the possible realisations of the qualitative criterion and equating the numbers to the values of the coordinate on the axis for that criterion. Since the limits and the ranges of the characteristics used as criteria are always known it is convenient to adopt a system of dimensionless units such that all possible objects lie within a unit cube of the criterion space.

In property forecasting it is a natural assumption (and one consistent with our chemical intuition) that substances whose Euclidean distance apart in the criterion space is small will have similar properties. This hypothesis underlies the application to the chemical problem of algorithms based on geometrical considerations. The geometric treatment includes algorithms which have been used successfully in catalyst prediction problems (potential functions, and binary or segmented linear classifiers).

The simplest of these algorithms is the binary linear classifier. Its action consists in finding a hyper-plane which divides the objects into two classes: the "dichotomy" problems. It is convenient to make this plane pass through the origin of the coordinate system. This can be done by introducing an additional $(N + 1)$-th coordinate (where N is the number of criteria of interest) whose value is assumed to be the same for all the objects (Fig. 1). In this space any dividing plane is uniquely defined by the unit vector of the normal **W**, called the weight vector. The vector **W** is found by an iterative process, during which the positions of the objects in the training sample relative to an arbitrarily chosen initial plane are tested sequentially. If an object

(radius vector $\mathbf{R}_k$) is found to be incorrectly classified, the position of the plane is correlated accordingly, and its new vector is expressed as the linear combination

$$\mathbf{W}' = c_1\mathbf{W} + c_2\mathbf{R}_k$$

The coefficients c_1 and c_2 are determined from the normalising condition of the weight vector and from the expression

$$\mathbf{W}' \cdot \mathbf{R}_k = -\mathbf{W} \cdot \mathbf{R}_k$$

If this condition is satisfied the kth object is on the correct side of the new plane and at the same distance from it as from the initial plane. It can be shown[35] that if a dividing plane exists, i.e. if the classes are linearly separable, this iterative process always converges.

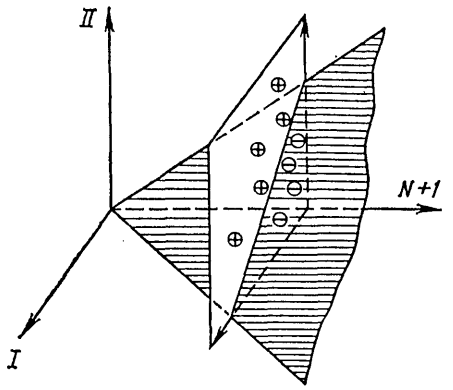

Figure 1. Dividing plane in criterion space, with an additional coordinate.

Unfortunately, linear separability into classes is seldom found. The boundaries of the classes usually have a more complex structure, and a simple linear classifier is inadequate. This weakness of the algorithm can be partly overcome by replacing the dividing plane by a plate of finite thickness and treating the objects lying within its thickness as unclassifiable. The thickness of the dividing plate is called the threshold, and the algorithm is called a linear classifier with non-zero threshold[15].

Even more flexible is the segmented linear classifier: a generalised form of the linear classifier in which the dividing surface is formed by a set of planes. In this algorithm a correction is applied to the position of the planes when the object is incorrectly classified with respect to the majority of the planes[35].

Linear classifiers have been widely used, and in spite of their simplicity they have been found to be effective in a wide range of recognition problems (including chemical ones)[15]. Many more complex binary classifiers, in which the dividing surfaces are not linear, can be reduced[35] to algorithms of this type. With any of the above algorithms the objects can be classified into three or more groups by sequential dichotomies, i.e. by repeating their application to the already classified populations.

Another geometric approach used in pattern recognition theory is the potential functions method, which relies on the concept of a potential for the kth object in the criterion space, $u(|\mathbf{R}-\mathbf{R}_k|)$, and a potential for the α class of objects,

$$U_\alpha(\mathbf{R}) = \frac{1}{N_\alpha} \sum_{k \equiv \alpha} u(|\mathbf{R} - \mathbf{R}_k|)$$

where N_α is the number of objects in the class. The boundary between the two classes (α and β) is taken to be the surface on which the potentials are equal:

$$U_\alpha(\mathbf{R}) = U_\beta(\mathbf{R})$$

It is convenient to choose for $u(x)$ a continuous, monotonically decreasing function having a finitie value at $x = 0$, for example

$$u(R) = 1\ (a + bR^2),\ a > 0$$

As in the case of binary classifiers, in the potential functions method objects are most easily classified into a large number of groups by successive dichotomies. At each step the assignment to one of two classes is determined by the sign of the difference between the potentials, $U_\alpha - U_\beta$. A more detailed discussion of the application of the potential functions algorithm can be found in textbooks[9,36].

Without attempting to examine in depth the principles of the perceptron theory (see, for example, Refs.30 and 33) we can define the method as the classification of a set of objects in terms of the sets of values of the criteria prescribed for each class. In catalysts prediction and similar problems the algorithms and programs based on logic functions[37] are more useful than the classical perceptron. The advantage of this approach lies in the possibility of defining classes forming an interpenetrating system of the "water in a sponge" type. The principle has been used for catalyst prediction in the "Prognoz-73" program[9], which relies on the following algorithm. Ranges of values are defined for all the properties of the catalysts. The number of criteria is assumed to be equal to the total number of ranges, and each criterion can take the values 1 or 0 depending on whether the property lies within or outside the range. Thus each catalyst is associated with a Boolean (logic) vector. We can now construct the discriminant conjunctions, i.e. the Boolean vectors whose termwise logic product with any vector from the class of effective catalysts is equal to the same vector and whose product with the vectors from any other class is equal to the zero vector. By using the discriminant conjunctions any catalyst can be assigned to one of the classes.

The recognition algorithms described in this Section are far from exhausting the enormous range of possible approaches to the solution of problems in this rapidly expanding field of applied mathematics. They do, however, give a clear illustration of one of the most important ways of "recognising": the assignement of an unknown object to a defined class. This includes preliminary training (in other words, tuning) of the algorithm by using an existing sample of already classified objects. As a rule, recognition algorithms are not "ideally" tunable. We must therefore introduce a new concept: the classifying power α_{cl} of the algorithm, defined as the ratio of the number of correctly classified objects to the total number of objects in the training sample#. The next step is to apply the trained algorithm to the unknown objects. The ratio of the number of objects which subsequent experience shows to have been correctly classified to the total number of objects investigated is called the predictive power of the algorithm α_{pr}.

The parameter α_{cl} is determined by carrying out a prediction for each object in the training sample with the recognition algorithm trained by using the remaining (N − 1) objects.

The coefficients α_{cl} and α_{pr} calculated in this way should be treated as arbitrary quantities, depending on the size and composition of the sample. Adequate estimates of the true classifying power and predictive power are obtained if sufficiently representative (or generally valid) samples are used. An important characteristic of the general validity of the sample is the ratio of its volume to the number of criteria used in the recognition, denoted by the symbol λ. It is usually assumed that successful prediction requires a fairly large value of the ratio λ, which we shall term the relative sample volume ($\lambda > 2$, say). However, there is evidence that satisfactory solutions of applied problems can be obtained also with much smaller values of λ.[38]

We should stress that problems requiring detailed statistical analysis of the pattern recognition results are only seldom included in current publications, and will not be considered in this review.

III. PREDICTION OF ONE-COMPONENT CATALYSTS OR PROMOTERS

The problem most simply solved by pattern recognition theory is the prediction of one-component catalysts. In this case the choice of a new catalyst (metal, oxide, etc.) can be made by comparing existing experimental data on the activity and selectivity of the proposed catalysts and on the physical and chemical characteristics (used as selection criteria) of all the substances involved. Promoters, or any other modifier or additive for the chosen catalyst, can be selected in a similar way.

Extensive information on the crystalline and electronic structure and on the physical and physicochemical properties of solids of stoichiometric composition is now available in standard handbooks. This allows us to choose as the selection criteria the most reliable data, determined by identical methods and under identical conditions, for the one-component catalysts. The most obvious choice of criteria includes the properties which are known (according to current theories of catalysis, or from experimental results) to be related to the ability of solids to accelerate chemical reactions. Some of these have already been discussed in Section II in relation to the use of simple correlation expressions for predicting catalyst behaviour. Some of the best known relationships between the catalytic activity and the physical characteristics of substances are discussed in Refs.6 and 18.

As well as experimental data, we can use as criteria the parameters of the electronic structure of solids, calculated by quantum mechanics or quantum chemistry methods, or various combinations of physical characteristics. Obviously, some of the properties of solids may be closely correlated, or even functionally related, if they have a common origin. The paramagnetism and the low-temperature specific heat of metals are typical examples; in the case of oxides the width of the forbidden energy gap is related to the colour and to other properties of the material. When choosing a system of criteria it is important to allow for these effects and to select characteristics which are as far as possible independent. The screening of superfluous (in this sense) properties can be made automatic by using the algorithms of mathematical statistics.

However, great care is needed in any preliminary statistical analysis of the system of criteria, because the exclusion of one or more members of a series of formally correlated properties may result in a serious lowering of the classifying and of the predictive power of the algorithm. This situation is illustrated in Fig.2, which shows a set of objects linearly separable in the space of two strongly correlated criteria (*A* and *B*). If one of these criteria is rejected the objects become unclassifiable by a simple binary classifier.

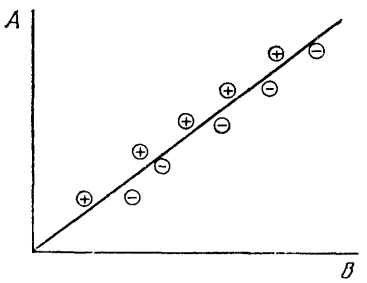

Figure 2. Examples of a linearly separable population in a space of correlated criteria *A* and *B*.

Even greater care is needed (for the same reason) in sifting the criteria on the grounds of weak correlation with the property of interest (catalytic activity, selectivity, etc.). It is intuitively obvious that some of the criteria may contribute only marginally to the catalytic activity towards certain reactions. These can be eliminated at the algorithm training stage, thus decreasing the number of dimensions of the recognition space. The "influence" of the criterion is a useful concept in this context. In the case of binary classifiers we can use as a measure of the influence the ratio

$$\beta_i = [\alpha_{cl} - \alpha_{cl}(i)]/\alpha_{cl}$$

where $\alpha_{cl}(i)$ is the classifying power of the algorithm in a space from which the *i*th criterion has been excluded. If the influence of the criterion is small, i.e. if its exclusion does not materially affect the classifying power, the criterion can legitimately be omitted.

The first reported use of recognition methods for catalyst prediction[39] dealt with the oxidation of CO on metal oxides, relying on the experimental information collected by Krylov[40]. The training sample consisted of 26 oxides: MoO_2, CoO, Co_3O_4, MnO, CdO, Ag_2O, NiO, CuO, SnO_2, Cu_2O, Co_2O_3, ZnO, TiO_2, Fe_2O_3, MgO, CeO_2, V_2O_5,, Cr_2O_3, ZrO_2, HgO, WO_3, ThO_2, BeO, GeO, Al_2O_3, and SiO_2. 20 physical properties of the catalysts, available in standard tabulations, were used as criteria. The catalysts were divided into three classes: good, moderately good, and poor, on the basis of their catalytic activity (listed in Ref.40). A success rate of 84% was achieved in the prediction for oxides taken out of the training sample by using successive dichotomies with a potential functions program[41]. By using methods to be discussed below it was shown that only 8 of the 20 criteria had any influence on the activity. Predictions of catalytic activity towards the oxidation of CO were made for a number of oxides not previously used in this reaction: in the case of HfO_2 the prediction was experimentally confirmed[42].

In the selection of a promoter for the catalytic formation of low-molecular aromatic hydrocarbons from alkanes of intermediate molecular weight (for example, dodecane) the training sample consisted of the oxides V_2O_5, MoO_3, CeO_2, Cr_2O_3, CaO, Bi_2O_3, and K_2O, which had been previously studied experimentally[29]. The objects for recognition included the oxides CoO, Mn_2O_3, CuO, Ag_2O, NiO, PdO, La_2O_3, ZrO_2, and WO_3.

Five "influential" properties were identified (Table 1) from the initial list of 12. Recognition was effected by the "Prognoz-73" program, using a two-category system. The validity of the prediction was tested experimentally, and the high activity which had been forecase for the oxides ZrO_2, Mn_2O_3, and WO_3 was confirmed.

Table 1. Physicochemical properties of oxide promoters[29].

Oxide	$Z(I+a)$	μ	r_M, (Å)	r_K, (Å)	n
V_2O_5	52.20	+128.00	0.91	0.80	0
MoO_3	51.72	+3.00	0.91	0.81	0
CeO_2	28.64	+26.00	0.94	0.99	0
K_2O	2.74	—29.00	1.39	1.08	0
CaO	9.60	—15.00	1.06	1.03	0
Bi_2O_3	23.88	—83.00	1.025	0.915	2
Cr_2O_3	28.59	+1 960.00	0.815	0.935	3
Ag_2O	8.23	—134.00	1.19	0.91	10
NiO	19.88	+660.00	0.875	0.95	6
CuO	20.00	+238.90	0.95	0.90	9
PbO	11.40	—42.00	1.11	0.935	2
Mn_2O_3	29.64	+14 100.00	0.81	0.945	4
La_2O_3	19.50	—78.00	1.04	0.99	0
ZrO_2	30.16	—13.80	0.88	0.94	0
WO_3	51.72	—15.80	0.91	0.82	0
CoO	18.58	+4 900.00	0.88	0.955	5

Symbols: Z is the valence of the metal, I is the ionisation potential (eV), a is the electron affinity (eV), μ is the magnetic susceptibility, r_M is the ionic radius of the metal, r_K is the ionic radius of the oxygen, n is the number of valence electrons not taking part in metal–oxygen bonds.

Table 2. Prediction of the promoting properties of elements added as oxides to vanadium–molybdenum catalysts[44].

Element	Δ_{exper}, %	Δ_{pred}, %	Element	Δ_{exper}, %	Δ_{pred}, %
Mg	35	32	Ce	—15	—11
Ti	5	11	Pr	10	6
Fe	—10	—8	Nd	5	10
Co	20	14	Gd	3	13
Ni	20	17	Tb	—3	2
Cu	—10	—8	Ho	10	14
Y	35	24	Er	20	10
Ag	—10	—7	Yb	35	13
Cd	3	4	Tl	—3	—4
La	3	13			

Symbols: experimental (Δ_{exper}) and predicted (Δ_{pred}) values of the change in the depth of oxidation of furfural caused by the addition of the promoter to the vanadium–molybdenum system.

A study[43] of the properties of the training sample of metallic promoters (consisting of metals from Groups VI and VII) has led to the prediction of a new, active promoter for nickel catalysts used in the hydrogenation of unsaturated compounds: niobium. The calculation was carried out with a potential functions program, using a three-category successive dichotomy scheme.

Promoters for multi-component vanadium–molybdenum catalysts used in the oxidation of furfural to maleic anhydride have been predicted[44]. The predictive experiments were organised as follows: out of 19 experimentally tested promoters, 17 were used to train the computer, and for the other 2 the selectivity of the reaction was predicted from the variation in the yield of side-products (resulting from full oxidation). An algorithm which forecasts the numerical value of the parameter of interest (in this case, the selectivity of the reaction) was used in this work. The algorithm, fully discussed in Ref. 44, consists in reproducing the shape of the function which describes the dependence of the selectivity on the physicochemical properties of the promoters. Effective criteria (and combinations of criteria) were chosen by an algorithm of the type used in Ref. 37. The results are shown in Table 2.

It is clear from Table 2 that the algorithm used in that work[44] had a high predictive power. Only four of the ten properties of the promoters arbitrarily selected were found to be effective: the distance between the metal atom and the oxygen atom, the electronegativity difference and the width of the energy gap in the oxide, and the colour of the oxide.

A factor analysis algorithm, based on the coefficients of the linear correlation between the output parameter Y (the logarithm of the exchange current) and a set of criteria chosen *a priori*, has been used[25] in the recognition and prediction of one-component metallic catalyst electrodes for electrolytic hydrogen evolution. The output parameter was defined by the expression

$$Y = \sum_{j=1}^{N} a_j \tilde{x}_j$$

where $\overline{x_j}$ are the average values of the normalised criterion, and a_j is a coefficient obtained by least squares. By using factor analysis for ranking the criteria[45] the initial set of seven criteria was reduced[25] to three: classifications based on these criteria (by the dichotomy method) agreed in 80% of the cases. The algorithm has also been used[26] to recalculate earlier results[39]: it gave a slightly worse agreement (80% instead of 84%), probably because the postulated linear dependence of the property of interest on each of the criteria is too rough an approximation. This work[25,26] shows that the factor analysis algorithms can be useful for catalyst recognition and prediction, though their power is lower than that of the "pure" recognition algorithms and their validity is more limited.

IV. PREDICTION OF MULTI-COMPONENT CATALYSTS

The most difficult (and yet, perhaps, the most important) problem of this type is the use of recognition methods in predicting multi-component catalysts at the component selection stage, i.e. when the true physicochemical properties of the working catalyst are still unknown. The only possible approach is to use the properties of the components used in the synthesis of the catalyst. Two paths are available: either to seek an effective method of calculating the physicochemical properties of multi-component solids, thus reducing the problem to the use of algorithms adequate for one-component catalysts, or to construct multi-level heuristic programs in which the recognition programs appear as sub-programs[46].

The simplest approach[21,22] to the prediction of multi-component catalysts relies exclusively on chemical composition data, using the following algorithm. The catalysts are classified into two opposite groups: one group catalyses the reaction for which a prediction is required, while the other group catalyses a reaction with the opposite mechanism. The identification (assigned to a class) problem is solved geometrically. The total set of initial data used as a training sample forms a matrix having $(M \cdot N)$ dimensions, where M is the number of objects and N is the number of criteria (in the

form of zeros and unities). In a row describing an object an entry of 1 denotes the presence in the object of a particular element. Standards are chosen for each class, and these act as "centres of gravity" for the class in N-dimensional criterion space. The object is considered to belong to one of the classes if its Euclidean distance from the standard for that class is less than the distance from the standard of the other class. The closer the unknown object is to the standard of the class of interest, and the further from the standard of the other class, the better are its prospects. A linear relationship between the activity of the catalyst and its geometric criterion (defined above) was demonstrated, as well as a high (>90%) probability of correct assessment of the activity or selectivity of catalysts.

An obvious disadvantage of this approach is that the search for possible new variants of catalysts is limited to elemental composition, since this is the only variable parameter in the training sample.

A more systematic approach to the prediction of multicomponent catalysts relies on a preliminary calculation of the physicochemical characteristics of the catalysts from data relating to the components. This type of problem is not uncommon in solid state chemistry, and it can be solved in a number of ways[47–49], all based on interpolation relationships in which the properties of the components are somehow averaged. Modern theories of the electronic structure of disordered solids also rely on this approach, though not always explicitly[50].

The use as criteria of quantities calculated by interpolation formulae offers two important advantages. One, already mentioned above, is the possibility of exploiting the extensive data available for one-component catalysts in predictions of multi-component catalysts. The other advantage is the very attractive possibility of predicting the properties of catalysts of complex composition from data on the catalytic properties of pure metals, oxides, etc.

The simplest way of averaging is with respect to mole fractions. In spite of its roughness this method is found experimentally to be useful for tentative predictions. It has been applied[29] in the prediction of the activity of mixed oxide catalysts for the aromatisation of the lower alkanes (the first step in the selection of a catalyst for the preparation of a "low aromatic" fraction from alkanes of moderately high molecular weight, described above). The correlations between the catalytic activity and the electronic and structural properties of the mixed oxide catalysts were established by the potential functions method. The catalytic activity was quantified (in terms of the selectivity s) from the total yield of aromatic compounds for the very large number of mixed dehydrocyclisation catalysts described in the literature, using the three-class system

class I ("good"): $67 < s < 100$
class II ("fairly good"): $33 < s < 67$
class III ("poor"): $0 < s < 33$

The effect of the energy of electron vacancies in the active centres and of the defect structure of the catalyst surface was calculated by the function

$$Q = \frac{\sum \nu_i [Z_i (I_1 + a)_i]}{1 + \bar{\mu}}$$

where ν_i is the mole fraction of the component in the mixture of oxides, Z_i is the valence of the metal in the ith oxide, and $(I_1 + a)$ is the sum of the first ionisation potential and of the electron affinity of the metal in the ith oxide. The numerator of the fraction is a measure of the acidity of the catalyst. The parameter $\bar{\mu}$ is the crystal-chemical similarity of the components of the oxide mixture, expressed on a point scale, which determines the defect structure of the surface. The averaged value of the magnetic susceptibility ($\bar{\chi}_\mu$) was used as the second criterion.

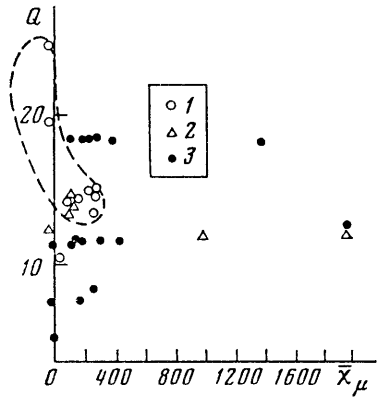

Figure 3. Distribution in criterion space of the catalysts for the aromatisation of the lower alkanes: *1*) good, *2*) average, *3*) poor catalysts.

It is clear from Fig.3 that in spite of the rough approximation of the initial assumptions the catalysts are well classified into three groups, even in two-dimensional space.

Other reactions have been studied on mixed oxide catalysts, including the hydrogenation of compounds with an ester group to alcohols and the gas-phase conversion of formaldehyde and isobutene into isoprene[27]. Owing to the lack of strict methods of calculating the characteristics of the electronic structure of mixed solid-phase systems there is no alternative to using an approximate additive scheme to obtain the properties of the mixed oxide catalyst: the property X is expressed as $X = \sum_i x_i \nu_i$, where x_i is the property for the pure component i and ν_i is its mole fraction. The following combinations of properties were identified as the most effective for catalysts used in these processes. For the hydrogenation of esters, $\sum_i (n_{d,f} + N_{d,f})_i \nu_i$ (where $n_{d,f}$ is the number of d and f valence electrons not taking part in bond formation with the oxygen, and $N_{d,f}$ is the number of fully occupied d and f shells in the metal atom) and $\sum_k J_k \nu_k$, an average value of the bond ionicity, and for the conversion of formaldehyde the average magnetic susceptibility $\sum \chi_i \nu_i$ and the parameter $\sum_k J_k$ (the sum of the bond ionicities in the active components).

Thus only two properties were found to be effective for each of these processes, and therefore the assignment to classes in property space can be displayed graphically (Fig.4). A separation is achieved, but we note some overlap of the classes (due to the lack of precision of the additive scheme used to calculate the properties).

Since many physical and chemical properties are not additive even in systems consisting of chemically similar components much care is needed in selecting the recognition criteria when averaging procedures are used. The most convenient and valid approach appears to be the use of microscopic characteristics, i.e. atomic parameters. Averaged

values of the atomic parameters, though physically meaningless, are often very accurately correlated to the properties of multi-component systems. Thus averaged values of the ionisation potential and of the electron affinity can be correlated with the work function of alloys, averaged radii with the molar volume, etc.

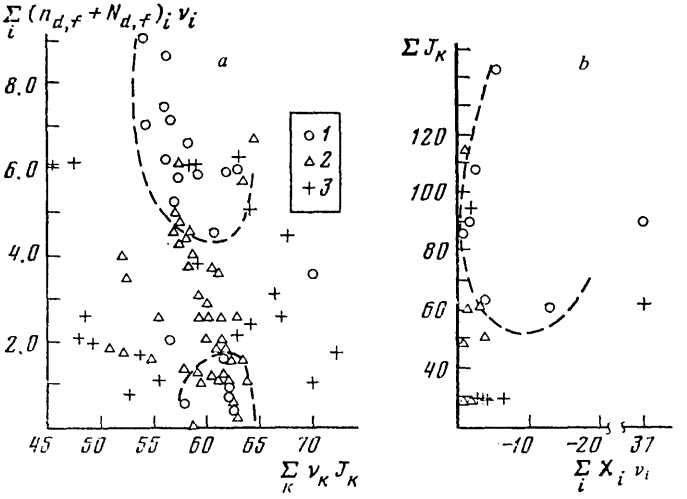

Figure 4. Distribution in criterion space of the catalysts for the hydrogenation of esters (*a*) and for the conversion of formaldehyde/isobutene into isoprene (*b*). Points *1–3* as in Fig. 3.

We have used averaged atomic parameters[28] as criteria for predicting hydrogen peroxide decomposition catalysts by a linear binary classifier with a non-zero threshold. The training sequence consisted of 93 alloys of silver or gold with Group VIII metals, for which catalytic activity data are given in a recent review[51]. The proportion of correctly classified catalysts was 85%, which appears to be the highest success rate which this algorithm can offer. Predictions were attempted for 38 catalysts. The predictive power of the algorithm was found to be slightly lower than the classifying power (80%).

The next improvement in the system of criteria is the replacement of atomic by averaged orbital characteristics, corresponding to the electrons in the valence sub-shells of the atoms. These include the quantum numbers, the orbital ionisation potentials, the average orbital radii, etc. Average values of whole classes of some of these characteristics can also be used as criteria. This allows us on the one hand to adopt a more flexible training program, since it can be shown[35] that the use of these characteristics is equivalent to changing from a linear classifier to one of a higher order. On the other hand the use of averages of a class of criteria (i.e. the moments of the criteria) justifies the departure from a purely additive scheme in the calculation of the parameters of multi-component catalysts.

The general formula for calculating the criteria thus becomes

$$X_{n\alpha} = \sum_i \nu_i \sum_j c_{ij\alpha} x_{ij}^n$$

where ν_i is the atom fraction of the *i*th component, *j* is the number of valence sub-shells, $c_{ij\alpha}$ is a weighting coefficient for averaging with respect to orbitals, and α is an index denoting the method of averaging used. This index is used because the orbital parameters for the atoms of each component can be averaged in different ways: over the number of orbitals in the valence sub-shells or over the number of valence electrons in the sub-shells (i.e. for the occupancy of the sub-shells, and hence also the number of unoccupied states ("holes")). All these methods of averaging give mutually independent results, with a different physical meaning.

Table 3. Classification, criteria, and level of influence of the criteria for bimetallic hydrogen peroxide decomposition catalysts.

[M], at.%	Activity, arbitrary units	Criteria				
		I (−0.387)	II (−0.375)	III (−0.349)	IV (−0.344)	V (+0.266)
		High activity

Symbols (criteria): I) square of the valance orbital ionisation potential (VOIP) of the neutral atom averaged over the unoccupied states of the valence sub-shells; II) VOIP of the neutral atom averaged over the unoccupied states of the valance sub-shells; III) square of the VOIP of the positively charged ion (+1) averaged over the number of atomic orbitals in the sub-shells; IV) square of the VOIP of the positively charged ion (+1) averaged over the number of valance electrons in the sub-shells; V) orbital quantum number averaged over the unoccupied states in the valence sub-shells. The level of influence of the criteria is shown in brackets.

*Au–M alloys; all the other alloys are Ag–M.

We have tested a system of 54 orbital criteria by producing a new set of predictions for the hydrogen peroxide decomposition catalysts mentioned above. Using the same algorithm, we raised its classifying power to 94.5% and its predictive power to 97.4%. Table 3 lists the most influential criteria for some of the compositions used in the classification, and Table 4 gives the corresponding values for the catalysts whose activity was predicted.

The use of orbital parameters as criteria in recognition algorithms brings the statistical approach closer to the methods of quantum mechanics and quantum chemistry, since those parameters are used in the calculation of the electronic structure of solids. Further progress in this direction can

be expected. Thus it should be possible to express the structure of multi-component catalysts by the procedures used in the cluster component method[48,49], i.e. to characterise the catalyst in terms of a set of lattice fragments (clusters) corresponding to different types of lattice site. In this representation the formula of an ideal binary crystal with an NaCl type lattice becomes $[AB_6]_{1/2}[BA_6]_{1/2}$, whereas an ideal substitutional solution with the same lattice and the same proportion of components is described by the formula

$$[AA_6]_{\nu_6^A}[AA_5B]_{\nu_5^A}[AA_4B_2]_{\nu_4^A}\ldots[BB_6]_{\nu_6^B}[BB_5A]_{\nu_5^B}\ldots$$

where ν_i^A and ν_i^B are calculated by assuming a random distribution of the two types of atom over the lattice sites. Averaged values of the parameters of the electronic structure of the clusters, calculated by quantum-chemical methods, can conveniently be used as criteria for the multi-component system. The averaging over the cluster components of a whole series of electronic structure characteristics (local densities of states, their moments, atomic contributions to the total energy, etc.) could have real physical significance, since these characteristics are strictly additive.

Table 4. Prediction of bimetallic hydrogen peroxide decomposition catalysts.

Note: the criteria and their influence are as defined in Table 3.

*Au–M alloys; all the other alloys are Ag–M.

So far in our discussion we have treated multi-component catalysts as fairly homogeneous solids (effectively single-phase systems). In fact, a large group of industrial catalysts has a more complex structure, and must be treated as multi-phase systems. The most important members of this group are the supported catalysts, consisting of an active metal phase and a carrier. In spite of their greater complexity, their catalytic properties can be predicted by the methods discussed here. The only new requirement is for a unified criterion space, including the properties of the carrier and of the support phase. The properties of each phase separately can be calculated by averaging.

As an alternative to averaging, we can approach the problem of multi-component catalyst prediction by constructing multi-level heuristic programs[46]. This possibility was tested[9,22] by applying the "Prognoz-76" program to the set of data on catalysts for the oxidation of 2,6-dimethylpyridine to 2,6-pyridinedialdehyde. The program was based on the following algorithm. The first stage consists in classifying the objects of the training sample according to the amount of components, using the "Prognoz-73" program. In the second stage the same program is used to identify the influential conjunctions of component properties which determine the assignment of the catalyst to class A. At this stage a distinction is made between the main components, present in all catalysts of classes A and B, and the promoters. In the third stage the substances possessing criteria similar to those of the components of class A catalysts are selected. In the last stage consisting of components with the required criteria in the optimum relative amounts (as determined in the first stage) is synthesised.

We should stress that methods of predicting multi-component catalysts are not yet fully developed. Further tests are needed before syntactic algorithms can be used to rationalise the combination of components with different properties into a single complex catalyst. The initial "words" for the grammar of syntactic algorithms of this type could be provided by the proposed[6] scheme of logic attributes of a good catalyst, such as activity of the components in side-reactions, type of adsorption, influence of promoters on the geometry of the crystal lattice of the catalyst, etc. However, in computer-aided recognition schemes the predictive power of this scheme is enhanced by the presence within each logic unit of quantitative information from the data banks, which facilitates the gearing of logic couplings.

V. ANALYSIS OF CATALYTIC ACTION MECHANISMS (THE INVERSE RECOGNITION PROBLEM)

Pattern recognition methods can be used not only in the prediction and classification of catalysts, but also as an effective means of analysing the mechanism of catalytic reactions. For this purpose we use the "inverse pattern recognition problem", whose goal is not the prediction of new catalysts but the study and the ranking of the properties of catalysts, reactants, and products (in so far as they affect the rate and the selectivity of the stated reaction). By identifying these products and relating them semi-quantitatively to the output parameters of the reaction the investigator can acquire a basis for a theoretical model of the catalytic reaction and of the relationships between its mechanism and the structure of the reactant and product molecules. Stricter functional dependences can be obtained from the sem-quantitative relationships. The data required for analysing catalytic action mechanisms follow directly from the method of solving the prediction problem, and can be considered to be incidental results. This is because all recognition algorithms contain some provision for minimising the number of dimensions of the problem, i.e. for "rejecting" unimportant criteria, so that the criteria are ranked in terms of their influence on the output parameters of the objects.

Several algorithms for ranking the criteria and minimising their number have been used in the solution of catalysis problems. In the potential functions methods a simple "sliding recognition" algorithm (involving repeated recognition) has been effective. Each criterion is omitted in turn from the initial sample: if the success rate of the recognition is unchanged (or increased) by this omission the criterion is excluded from all further calculations. The other criteria (or properties) are ranked according to their contribution to the success of the recognition.

The pattern recognition problem for CO oxidation catalysts was solved by taking an initial set of 26 properties[39]. However, by using the sliding recognition algorithm the number of criteria was decreased to eight. We note that only four of these could be related to the catalytic activity by correlation analysis methods with a probability greater than 95%. The other criteria, taken singly, showed practically no correlation with the catalytic activity: this shows the importance of combinations of properties in creating an effective solid catlyst, as well as underlining the limitations of the predictive power of correlation methods in one dimension (or in a few dimensions).

Table 5. Results of the computer recognition of the selectivity of oxidation reactions on a V_2O_5 catalyst[41].

No.	Initial compound	Final compound	Success of prediction
	Class A (selectivity greater than 50%)		
1	*o*-Xylene	Phthalic anhydride	+
2	Naphthalene	Phthalic anhydride	+
3	Anthracene	Anthraquinone	+
4	Toluene	Benzoic acid	+
	Class B (selectivity between 50 and 10%)		
1	*m*-Xylene	Maleic anhydride	+
2	Pent-1-ene	Acetaldehyde	–
3	Pent-2-ene	Acetaldehyde	–
4	Butadiene	Maleic anhydride	+
5	Naphthalene	1,4-Naphthylquinone	+
6	Anthracene	Phthalic anhydride	+
7	*p*-Xylene	Maleic anhydride	+
8	*p*-Xylene	*p*-Toluic anhydride	+
9	*p*-Xylene	Terephthalic anhydride	+
10	2-Methylbut-2-ene	Acetone	+
11	*m*-Xylene	*m*-Toluic aldehyde	+
12	Toluene	Benzaldehyde	+
13	2-Methylbut-2-ene	Acetaldehyde	+
14	2-Methylbut-1-ene	Acetone	+
15	2-Methylbut-2-ene	2,3-Epoxy-2-methylbutene	–
16	2-Methylbut-1-ene	Acetaldehyde	+
17	But-1-ene	Maleic anhydride	+
18	But-2-ene	Maleic anhydride	+
19	3-Methylbut-1-ene	Acetone	+
20	Pent-1-ene	Acetone	+
21	Pent-2-ene	Propionaldehyde	–
22	Pent-2-ene	Methanol	–
23	2-Methylbut-2-ene	3-Methylbutan-2-one	–
	Class C (selectivity less than 10%)		
1	Propene	Formaldehyde	–
2	Pent-1-ene	Butanol	+
3	2-Methylbut-1-ene	2,3-Epoxy-2-methylbutane	+
4	Pent-2-ene	2,3-Epoxypentane	+
5	2-Methylbut-1-ene	Butanol	+
6	3-Methylbut-2-ene	Acetaldehyde	+
7	Pent-1-ene	Propionaldehyde	+
8	Pent-1-ene	Butyraldehyde	+
9	Pent-2-ene	2,3-Epoxypentane	+
10	Pent-1-ene	Methanol	+
11	Pent-1-ene	Crotonaldehyde	+
12	3-Methylbut-1-ene	Butanol	+
13	Propene	Acetaldehyde	+
14	Pent-2-ene	Butanol	+
15	Pent-2-ene	Acetone	–
16	2-Methylbutene	2,3-Epoxy-2-methylbutane	+
17	*p*-Xylene	*p*-Toluic acid	–
18	Butadiene	Formaldehyde	–
19	3-Methylbutane	3-Methylbutan-2-one	+
20	Pent-2-ene	Butan-2-ol	+
21	2-Methylbut-2-ene	Butanol	+
22	Pent-2-ene	Ethanol	+

In the "Prognoz-73" program the level of influence of the criteria is measured by the frequency with which a criterion occurs in the conjunctions of criteria leading to recognition. By using this algorithm we were able to lower the number of influential properties of the reactant and product molecules from 46 to five or six in the prediction of the selectivity of the oxidation of hydrocarbons on vanadium pentoxide. The problem was specially formulated to clarify the mechanism of oxidative conversions. The training sample consisted of a set of data[52,53] on the selectivity of the partial oxidation on vanadium pentoxide of more than 50 hydrocarbons. The results of the recognition experiment (Table 5) show a high proportion of successes, and therefore they confirm the validity of conclusions on the influence of the properties of reactant and product molecules on the selectivity of the reaction.

The properties of the reactants, catalysts, and products which affect the rate and the selectivity of the oxidation of hydrocarbons most markedly can be listed as follows. For the hydrocarbons being oxidised the properties (in decreasing order of influence) include: 1) the ionisation potential, 2) the number of symmetry operations, 3) the free valency index, 4) the magnetic susceptibility, 5) the dipole moment, 6) the steric accessibility of the C–C bond with maximum structural correspondence. For the oxidation products we have: 1) the π-electron density, 2) the highest π-electron level, 3) the ionisation potential, 4) maximum structural correspondence between the C–C bond and the crystal lattice of the catalyst, 5) steric accessibility of the C–C bond with maximum structural correspondence.

The most influential properties of the catalysts for the oxidation of carbon monoxide can be arranged in the following sequence: 1) density, 2) colour, 3) melting point, 4) ratio of the volume of the crystallographic holes in the oxide to the volume of the metal atom, 5) width of the forbidden energy gap, 6) molar magnetic susceptibility, 7) number of *d* electrons not involved in bond formation between metal and oxygen, 8) ionisation potential of the metal atom (averaged for the valence of the metal in the catalyst). The effective properties of the promoters[44] for vanadium–molybdenum catalysts used in the oxidation of furfural can also be listed (though the relative magnitude of their influence has not yet been determined): 1) distance between metal and oxygen atoms in the oxide, 2) electronegativity difference in the oxide, 3) width of the forbidden energy gap, 4) colour. Similarly, for the oxidation of dimethylpyridine: 1) width of the forbidden gap, 2) ionisation potential of the metal atom, 3) ratio of the volume of the crystallographic holes in the oxide to the volume of the metal atom, and 4) coordination number of the metal atom in the crystal lattice of the oxide.

These results allow us to make some general conclusions on the mechanism of oxidation reactions on heterogeneous catalysts, and can be used as evidence for the general validity of the inverse recognition problem.

The properties of the catalysts, and those of the organic molecules, can be classified into two groups: electronic and geometric. The selectivity of the oxidation reactions (i.e. the ratio of the rates for different reaction paths on the given catalyst) is a function of a combination of properties of both the reactant and the product molecules.

Let us examine more closely the electronic properties group of the solid. They all affect the mobility of the electrons in the solid, which is ultimately determined by the excitation energy of the electrons. These properites can be treated as enthalpic properties of the catalyst, which determine the activation energy of the reaction. The factors which affect the mobility of the electrons can themselves be divided into two groups: individual (determined by the electronic configuration of the metal atom, i.e. the ionisation potential, number of free *d*-electrons, etc.), and collective (electron density, width of the energy gap, colour, magnetic susceptibility). The latter group of properties includes also the melting point, which varies in the same sense as the energy of the interatomic

bonds in the lattice and therefore characterises the ease of "unpairing" of electrons in these bonds (in particular, the metal–oxygen bonds), and also the probability of forming lattice defects.

Thus, in contrast to the narrow view that catalytic properties result either from the local or from the collective properties of solids our analysis shows that the formation of an effective catalyst requires a combination of both types of property.

In addition to the electronic properties, the group of influential properties of catalysts includes parameters which characterise the geometry of the lattice: the ratio of the volume of the holes to the volume of the metal atom, and the distance between the metal and the oxygen atoms in the oxide. The mechanism of action of these parameters can be related both to the structural correspondence between the lattice of the catalyst and the organic molecule and to the ease of diffusion of oxygen atoms from the bulk to the surface, which can be very important in the partial oxidation of organic compounds.

Let us now turn to the properties of the organic molecules (reactants and products). The properties which affect the selectivity of the reaction now include the ionisation potential, the π-electron density and the π-electron level, the magnetic susceptibility, and the free valency index. This is not surprising, since the rate and the selectivity of the oxidation reaction are ultimately determined by electron transfer processes in the reactant–catalyst–product system.

Consider now the geometric properties of the organic molecules which are found to be influential. On the whole, their correlation with the mechanism of the catalytic action is self-evident: steric accessibility of the bond and maximum structural correspondence between the C–C bond and the lattice of the catalyst The importance of the number of symmetry operations of the reacting molecule is not coincidental: the influence of this factor arises from the increased probability of interaction between the reacting molecule and the catalyst surface, since interaction occurs during any type of collision if the molecule is symmetrical. The presence of a dipole moment in the molecule also increases the probability of effective collision by orienting the incident molecule in the electrostatic field of the catalyst. It is interesting to note that this analysis fully confirms Balandin's principle of geometric correspondence in heterogeneous catalysis.

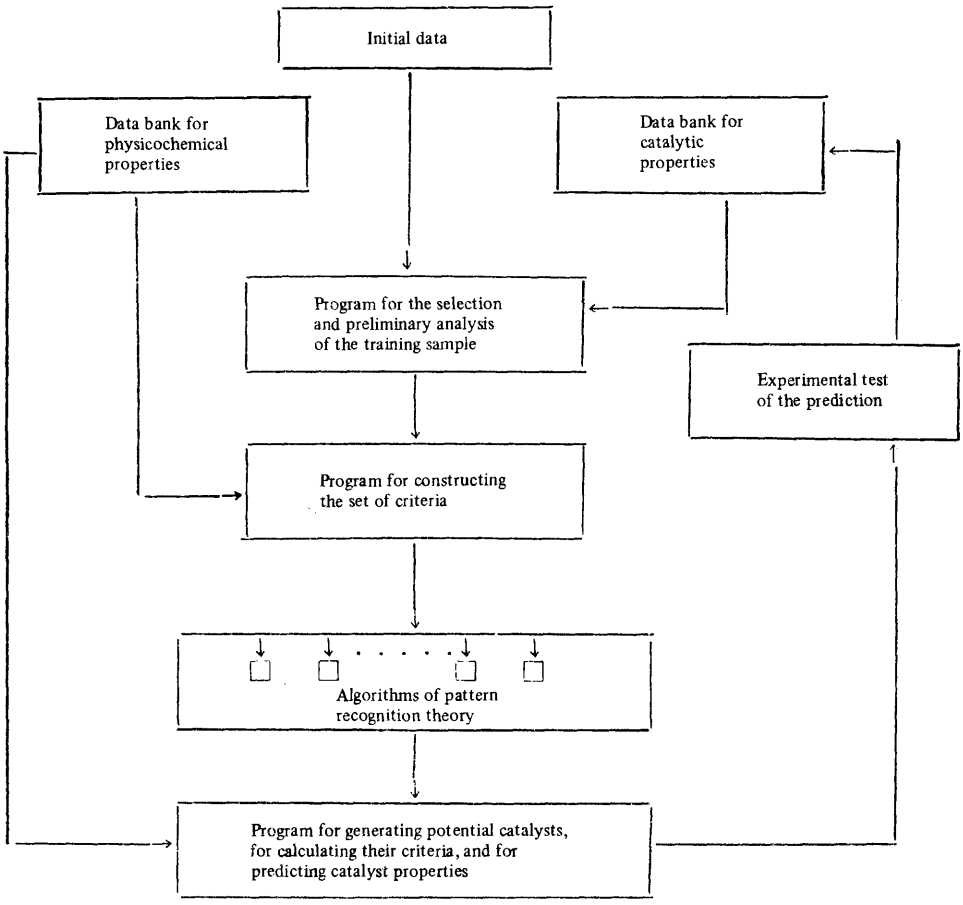
We should also stress another result, which is often ignored. In order to show good selectivity a catalytic reaction requires a definite correspondence in the combination of properties not only between the reactant and the catalyst but also between the reactant ("substrate") and the product. Thus in the separation of the above set of hydrocarbon oxidation reactions into two classes with a selectivity threshold of 25% different criteria of the reactants and the products are found to be influential (Table 6), but their interplay is logical and easily interpreted. Clearly, a hydrocarbon of class A must be a good electron donor, and therefore it should have a low ionisation potential and a well delocalised system of π-electrons (a low minimum free valency index according to Coulson). Correspondingly, the reaction product should be stable, i.e. it should be a poor electron donor (with a high ionisation potential) and it should not have a highly developed π-electron system (in order to facilitate desorption of the product).

For the class B hydrocarbons we expect the opposite properties, as well as a high structural correspondence between the C–C bond of the reaction product and the oxygen of the lattice, which favours breakdown of the product molecule. It can be shown that the predominant properties (and their relative values) for the product and the reactant vary with the value of the threshold chosen for the classification.

This example of the analysis of a reaction mechanism has established that the effectiveness of the catalytic act in the oxidation of hydrocarbons depends on a favourable conjunction of two types of factor: enthalpic (related to the energetics of the electronic transitions) and entropic (related to the geometry and symmetry of the molecules and of the lattice). The catalyst, reactant, and product make equally important contributions to the process, and the outcome is determined by an appropriate combination of their properties.

Table 6. Combinations of properties in molecules which determine the selectivity of the reaction.

Molecule	Properties	
	Class A ("good")	Class B ("poor")
Oxidised hydrocarbon	Low value of I, low value of κ	high value of κ
Oxidation product	High value of I, optimum ρ_π, high value of ΔE	high level of structural correspondence between the C–C bond and the O-atom of the catalyst, high value of ρ_π, low value of ΔE



Symbols: I ionisation potential, κ minimum free valence index (Coulson), ρ_π minimum π-electron density, ΔE difference between the sums of the dissociation energies of the initial and the final compound.

VI. PROSPECTS OF FUTURE DEVELOPMENTS

Pattern recognition theory was formulated as a new topic in applied mathematics towards the end of the 1950's, but its practical application in science and technology had to await the development (in the 1960's) of the second generation of computers, which made the laborious calculations involved a practical possibility. The earliest applications of recognition methods to catalyst prediction were reported during that period. However, until specially adapted computational methods became available the problem remained intractable because it tended to make unreasonable demands on computer time.

The appearance and wide adoption in the 1970's of third-generation computers offered entirely new possibilities of automating all the steps in the prediction of catalyst behaviour by pattern recognition methods, including the choice of components of the training sequence, the search for and calculation of the physical properties, etc., and also the automatic "splicing" of all the steps. An efficient way of exploiting these possibilities is to set up an automatic system for predictions by pattern recognition methods, consisting of data banks, problem modules, and training programs. The significance of these concepts will be explained below: at this point we shall only stress the fact that the work which initially had to be done manually is now handled by the algorithms of the system.

The most general type of system for the prediction of heterogeneous catalysts is illustrated in the diagram. Without entering into its details, we shall examine the basic principles which should be borne in mind when designing a system of this type.

The first step in the creation of such a system is the organisation of renewable data banks, i.e. tables of properties, stored in the archives of the external memory of the computer. One of these should contain data on the state of the catalysts, their activity and selectivity, and other "desired" properties, while the other is dedicated to data on the physicochemical properties of solids. As stated above, a comprehensive and well documented handbook on catalyst properties is now available[18], with regularly published supplements. This can provide the basis of the catalyst data bank, to be updated as new information becomes available.

An important consideration in the assembly of the catalyst data bank is the reliability of the initial data. In any recognition algorithm the inclusion of unreliable data in the training sample must lower the validity of the prediction. Unfortunately, in the field of catalysis unreliable data are especially numerous, with many deliberately misleading ("diversionary") data in open publications as well as in patent applications. To some extent this can be guarded against by introducing weighted reliability coefficients: for example, 1 for original and well substantiated data in reputable publications, 0.8 for other publications, and 0.5 for patents. Allowance for the reliability coefficients can be made in the training of the recognition algorithm. Thus if the potential functions method is used the contributions of the objects to the total potentials of the classes are simply multiplied by the appropriate reliability coefficient. Other methods of allowing for the reliability of the data either directly or indirectly are available for the other algorithms.

The physicochemical properties bank should include data on a wide range of solids of various classes. The choice of these properties is a fundamental problem in the development and application of recognition methods. At present it is helpful to subdivide the criteria into two classes (basic, and derived). Since chemical reactions take place at the atomic–molecular level the basic criteria should include data on the crystallographic and electronic characteristics of the catalysts, and also on the atoms of their constituent elements. The criteria should be, as far as possible, quantitative, though the use of qualitative characteristics (of the "yes" or "no" type) is not excluded.

Criteria related to the electronic structure of solids (width of the energy bands, Fermi level, electron density and density of states, strength of interatomic bonds, etc.) determine the energetics of the chemisorption and of the overall catalytic act. In this sense they can be termed enthalpic. The geometric parameters of the crystal lattice (in particular, its symmetry) can influence the probability of various elementary acts, i.e. they can determine the entropy factor, as well as being naturally related to the electronic structure.

The derivative criteria are obtained by functional relationships from the basic criteria. Practically any of the physical properties of solids can be used as an example. Thus the density is related to the crystal lattice parameters and to the composition of the substance, the depth of colour to the width of the forbidden energy gap, etc. Supplementing the

basic criteria with derived criteria can be helpful in the solution of the inverse recognition problem.

The first step in the operation of a prediction system is to search the catalyst bank for catalysts which accelerate the reaction of interest and to classify them according to activity (or other specified property), number of phases (presence of a carrier, etc.), and chemical composition. These catalysts are the training sample. If the bank contains few data (or no data) on the reaction under study a sample of reasonable size can nevertheless be assembled by using data for analogous reactions[27,29].

In the next step the properties of the components of the catalysts in the training sample are extracted from the bank of physicochemical properties. These are used to generate the criteria to be applied in the recognition. The formulation of these criteria may require special calculations (for example, quantum-chemical), and therefore this part of the system may include a whole set of programs. Before compiling tables of criteria it is advisable to sift out the criteria which are mutually correlated. Superfluous criteria can be excluded by ranking them according to their influence, using the fastest (though not necessarily the most effective) recognition algorithm. These algorithms can be termed first-level algorithms. They can conveniently be realised by using the programs of the potential functions method.

When the required correspondence between the size of the training sample and the number of criteria has been achieved, the main step in the operation of the system can take place: the training of the second-level recognition algorithms. The purpose of this step is to find the optimum recognition procedure, offering the highest classifying power. If the required classifying power cannot be achieved by any of the algorithms we must go back to the criterion formulation step and find additional criteria (and criterion correlations).

When a classifier offering an acceptable effectiveness has been defined, a prediction of the target property can be made for all the proposed objects. In the previous methods of prediction the target properties were listed by the experimenter, but the automated scheme includes a block which generates possible compositions of (hypothetical) effective catalysts. This block operates in two steps. At first, by using repeated dichotomies or other decision processes, it outlines a region of effective criterion space corresponding to the optimum value of the catalyst property of interest. Then it generates hypothetical catalysts whose criteria lie within the selected region. In the case of one-component catalysts or promoters this is equivalent to choosing from the catalyst bank the compounds with the most favourable set of properties. In the case of multi-component catalysts the system identifies combinations of substances having criteria close to the optimum values.

If the dependence of the physicochemical properties of the catalysts on the concentration of the components can be described by a simple functional relationship (for example, some form of averaging) the problem of finding the best composition can be formulated mathematically as the search for a minimum in some function of the composition. The most obvious choice of this function is the sum of the squared deviations of the criteria for the chosen catalysts from their optimum value:

$$\Phi(\nu) = \sum_i \rho_i [\chi_{oi} - \chi_i(\nu)]^2$$

The weighting coefficients ρ_i reflect the degree of influence of the criterion. The final result from the operation of this system is a recommendation of the relative amounts of active components likely to yield the best catalyst or promoter.

The results of experimental tests of the predictions can be used to supplement the catalytic properties bank. If a catalyst offering the required effectiveness has still not been found, a new prediction is made with the expanded data bank, and the search becomes an iterative procedure. In this variant the pattern recognition method can be used for planning experiments on catalyst selection when the initial information is insufficient for "training" the computer[9].

Study of the Acid-Base Properties of Heterogeneous Catalysts by Infrared Spectroscopy

E.A.Paukshtis and E.N.Yurchenko

The quantitative assessment of the acid-base properties of the surface of heterogeneous catalysts by i.r. spectral studies of adsorbed molecules is discussed. The quantities through which the protonic (Brønsted), aprotic (Lewis), acidic and basic centres of the surface can be most easily characterised are analysed. Reported methods of determining the number and strength of the surface centres are described. 135 references.

I. INTRODUCTION

Solid acids and bases are widely used to catalyse various reactions at the solid-gas or solid-liquid interface. In order to understand the mechanism of their catalytic action and to predict their activity and selectivity we need quantitative information on the number and strength of the acid or basic centres on their surface[1-3]. In the 1950's the indicator method of determining the strength of the acid centres[4] and the indicator titration method of determining their number[5] were proposed: both these methods were based on a study of the interaction of indicator molecules (probes) with the surface. More recently similar methods have been used to characterise basic centres[6,7].

The physicochemical foundation of these methods of quantitative assessment was the postulate that the interaction between the acid centres on the surface and bases from the external phase is analogous to acid-base equilibria in solutions. However, some differences in principle between solid acids (or bases) and acids or bases in solution were subsequently discovered. On a surface we find, at the same time, fixed, non-interacting acid centres (aprotic, L, and protonic, OH) and basic centres (B_S), of different strengths. This gives rise to independent, parallel reactions, seldom reaching equilibrium, between the added (probe) molecules and the surface centres. Under these conditions the above methods[4-7] cannot give the true characteristics of the acid–base properties of specified surface centres.

Some attempts[2,8] to develop more realistic methods of studying the acid-base properties of surfaces proved unsuccessful. However, they led to the formulation of the following list of requirements to be met by a successful quantitative method: 1) the interactions between the probe molecules and the protonic, aprotic, and basic centres should be

Table 1. Acidic and basic surface centres, and requirements on the probe molecules used to study them by i.r. spectroscopy.

Type of centre	Lewis (L) centres	Brønsted (OH) centres		Basic (B_S) centres
Type of complex with probe	donor-acceptor complex	H-bond	ion pair	H-bond
Spectral criterion of complex formation	change in frequency of the characteristic vibrations of B molecules ($\Delta\nu_B$)	change in ν_{OH}	disappearance of ν_{OH}, appearance of ν_{BH^+} and $\delta^{as}_{BH^+}$	change in ν_{HX}
Most exact method of determining the strength of the centres	from the change in frequency of the characteristic vibrations ($\Delta\nu_B = \nu_B - \nu_B^{gas}$) expressed in a scale of heat of adsorption; $Q = 10.5 + 0.5\nu_{CO}$ for CO	from ν_{OH}, in a proton affinity scale; $PA^{OH} = 1390 - \frac{\lg(\Delta\nu_{OH}/\Delta\nu_{OH}^{SiOH})}{0.00226}$	from the heats of formation of ion pairs	from $\Delta\nu_{HX}$ in the PA scale; $PA^{B_S} = \frac{3.54 + \lg\Delta\nu}{0.0057}$ CD for $CDCl_3$
Method of calculating the concentration of the centres	from the intensity of the characteristic bands of the B molecules	from the intensity of the ν_{OH} band	from the intensity of the most characteristic bands of the spectrum	from the intensity of the ν_{HX} band
Required physicochemical properties of the probes	to characterise the centres fully we must cover a range of dipole moment (μ) and of functional groups giving a $\Delta\nu_B$ shift on complex formation greater than the line width of ν_B (usually CN, CO)	absence of OH groups	the ν_{BH^+} band should not overlap the ν_B, H-complex, or M^{n+}:B bands	the ν_{HX} band should not overlap the ν_{OH} or ν_{CH} bands
Most widely used probes	acetone, pyridine, ammonia, acetonitrile, benzonitrile, carbon monoxide	nitromethane, acetonitrile, benzonitrile, acetone, dioxan, diethyl ether, tetrahydrofuran, pyridine and substituted pyridines, aniline, amines	ammonia, pyridine, and its derivatives	deuteriated chloroform

* A change in the number and position of the absorption bands of the B molecules may be observed under these conditions.

reliably identified and differentiated; 2) the strength of the individual centres should be determinable numerically, on a defined scale; 3) the concentration of each type of surface centre should be independently determinable.

These requirements are most easily met by spectroscopic methods, in particular the i.r. spectroscopy of adsorbed molecules. Unfortunately, very few studies of acidic or basic centres are mentioned in recent reviews[2,8,9] of advances in i.r. spectroscopy. The aim of the present review is to fill this gap.

The most basic application of i.r. spectroscopy to the study of the acid–base properties of surfaces is the spectral probe method, in which the properties of adsorption centres are characterised through the absorption spectra of molecules adsorbed on them and through the change in intensity of the bands associated with functional groups of the surface. The main features of this method as applied to the study of different types of centre are outlined in Table 1, which shows the types of complex formed by probe molecules with OH, L, and B_S centres, defines the vibrations used to measure the strength and number of surface centres, lists the most important physicochemical and spectral properties of the probe molecule, and names the probes most widely used as bases (B) to study acidic centres and as acids (HX) to study basic centres. Table 1 can be used as a starting point in the search for new probes and in the selection of a suitable method of characterising the acid–base properties of a particular catalyst. Let us examine each method in turn.

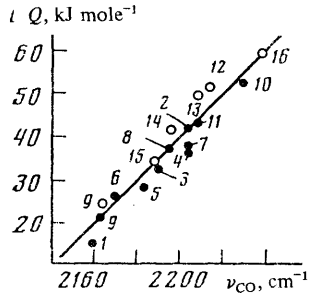

Figure 1. Correlation between νCO and the heat of adsorption Q of carbon monoxide on different surfaces: *1*) MgO, *2*) and *3*) γ-Al_2O_3, *4*) and *5*) ZrO_2, *6*) Ga_2O_3, *7*) and *8*) BeO, *9*) NaY, *10*) H-erionite, *11*) TiO_2, *12*) ZnY, *13*) MnY, *15*) CaY, *16*) Al_2O_3. The data *1–11* are taken from Ref.14, *9*, *12*, and *15* from Ref.15, *16* from Ref.16. The filled circles denote i.r. spectral data, the open circles calorimetric data. Points *2* and *3*, *4* and *5*, and *7* and *8* are for different complexes of the probe on the same adsorbent.

II. STUDY OF APROTIC CENTRES

1. Physicochemical Foundations of the Method

The strength of an aprotic centre is most correctly characterised by the free energy (ΔG) and the enthalpy (ΔH) of its interaction with a base[10]:

$$L + B \rightarrow L{:}B \qquad (I)$$

Since both protonic and aprotic centres are present simultaneously on the surface those quantities cannot be determined directly from measurements of the heat of reaction, as most probes react with both L and OH centres. It has therefore been suggested[11] that the strength of the L centres could be conveniently characterised by the quantity $\Delta\nu_B = \nu_B^{ads} - \nu_B^{gas}$, where ν_B^{ads} is the shifted absorption band in the spectrum of the adsorbed probe, on the assumption that $\Delta\nu_B$ is proportional to the extent of interaction of L and B in the donor–acceptor (D–A) complex. The main problem in using this assumption is that the formation of a D–A complex usually causes a rearrangement of both the electronic and the geometric structure of the probe molecule, both of which are reflected by the change in ν_B in the vibrational spectrum.

In specific cases this assumption has been confirmed both experimentally[12] and theoretically[13]. We have reported[14] an i.r. spectroscopic study of the correlation between the heat of adsorption of carbon monoxide and $\Delta\nu_{CO}$ on the metal cations for a series of silicate and oxide systems. The correlation (Fig.1) for the transition metal cations, and also Zr^{4+}, Zn^{2+}, and Mn^{2+}, can be described analytically as

$$Q, \text{ kJ mole}^{-1} = 10.5 + 0.5\,\Delta\nu_{CO} \qquad (1)$$

where $\Delta\nu_{CO} = \nu_{CO}^{ads} - 2143$ (cm^{-1}). By using this equation the strength of the aprotic centres can be determined (on the heat of adsorption scale) from the measured shift $\Delta\nu CO$ of the adsorbed carbon monoxide molecule.

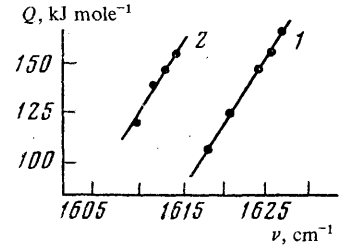

Figure 2. Relationship between the isosteric heat of adsorption of pyridine and the ν_{8a} frequency on aluminium oxide and zeolite (*1*) and on zirconium oxide (*2*).[17]

We have studied[17] the correlation between the heat of adsorption of pyridine on aluminium and zirconium oxides and the frequency of the absorption band for the pyridine ring which is most sensitive to co-ordination[18] ($\nu_{8a}^0 = 1580$ cm^{-1}). For the complexes with aprotic centres formed by the cations of one metal we found that ν_{8a} varies linearly with the heat of adsorption. For example, for Al^{III} (curve *1* of Fig.2) the correlation is

$$Q, \text{ kJ mole}^{-1} = 6.55 \cdot (\nu_{8a} - 1580) - 86 \qquad (2a)$$

whereas for the Zr^{4+} cation the correlation (curve *2* of Fig.2) is

$$Q, \text{ kJ mole}^{-1} = 7 \cdot (\nu_{8a} - 1580) - 26 \qquad (2b)$$

This means that in the case of pyridine the position of the ν_{8a} band in the D–A complex with an aprotic centre can be used as a measure of the strength of the centre if only one metal cation is present.

Thus it is essential to establish the correlation between $\Delta\nu_B$ and Q before using a compound as a spectroscopic probe to measure the strength of aprotic centres.

Table 2. Properties of probe molecules used to study surface Lewis-acid centres.

No.	Probe	μ, D	Interaction with Lewis-acid centres: Complex	Interaction with Lewis-acid centres: Frequency used to measure strength of centres	Interaction with Lewis-acid centres: Frequency used to measure concentration of centres	Possible complications from interaction with Brønsted centres	Remarks
1	Acetone	2.82	$M^{n+}:O=C(CH_3)_2$	ν_{CO} (ν^0_{CO} = 1720 cm^{-1}) decreases; $\Delta\nu \leq 150$ cm^{-1}	no data	H-complex is formed; ν_{CO} decreases by 20–40 cm^{-1}	easily oxidised
2	Ammonia	1.48	$M^{n+}:NH_3$	δNH_3 ($\delta^0_{NH_3}$ = 968 cm^{-1}) increases; $\Delta\nu \leq 300$ cm^{-1}	from δ_{NH} intensity, δ^0 = 1620–1640 cm^{-1}	H-complex is formed, with $\delta NH_3 \cong$ 1620–1640 cm^{-1}	unsuitable because of partial amination of surface
3	Pyridine	2.20	M^{n+}: 	$\nu_{CC(N)} = \nu_{8a}$ (ν^0_{8a} = 1583 cm^{-1}); increases, $\Delta\nu \leq 40$ cm^{-1}	from intensity of $\nu_{CC(N)}$ = 1583 cm^{-1}, $\nu_{CC(N)}$ = 1445 cm^{-1}	H-complex is formed, $\nu_{CC(N)}$ = 1445–1450 cm^{-1}; ion pair gives overlapping bands, $\nu_{CC(N)}$ = 1610–1640 cm^{-1}	correlation between $\Delta\nu_B$ and ΔH for complexes with same cation
				$\nu_{CC(N)}$ ($\nu^0_{CC(N)}$ = 1445 cm^{-1}) increases, $\Delta\nu \leq 20$ cm^{-1}			
4	Acetonitrile	3.94	$M^{n+}:N\equiv C-CH_3$	ν_{CN} (ν^0_{CN} = 2275 cm^{-1}) increases, $\Delta\nu \leq 60$ cm^{-1}	from intensity of ν_{CN}	H-complex formed, $\Delta\nu_{CN} \cong$ 5–10 cm^{-1}	deutero-acetonitrile is better, because the ν_{CN} band shows Fermi resonance with $\nu_{CC} + \delta CH_3$ = 2290 cm^{-1}
5	Benzonitrile	4.39	$M^{n+}:N\equiv C-Ph$	ν_{CN} (ν^0_{CN} = 2229 cm^{-1}) increases, $\Delta\nu \leq 65$ cm^{-1}	from intensity of ν_{CN}	H-complex formed, $\Delta\nu_{CN} \cong$ 5–10 cm^{-1}	convenient because of high intensity of ν_{CN}
6	Carbon	0.1	$M^{n+}:C\equiv O$	ν_{CO} (ν^0_{CO} = 2143 cm^{-1}) increases, $\Delta\nu \leq 100$ cm^{-1}	from intensity of ν_{CO}	H-complex formed, $\Delta\nu_{CO} \cong$ 30 cm^{-1}	very unstable complexes; low-temperature adsorption essential

* Allowing for Fermi resonance.

Though the series of aprotic acids (in order of strength) is not usually the same for solutions of different bases, we can define two classes of bases which give similar aprotic acids: the "hard" bases, usually with a large dipole moment (μ), and the "soft" bases, which have no dipole moment but are easily polarised[19]. It is reasonable to expect a similar behaviour when the bases form surface complexes. Some properties of soft and of hard bases which can be used to measure the strength of surface centres are listed in Table 2.

It is clear from published data[14,16,20,21,22] that even on a single catalyst the $\Delta\nu_{CO}$ values for a metal cation in different co-ordinations can be very different: for example, for Al^{3+} and ν_{CO} frequency varies from 2190 to 2240 cm^{-1}. Even in simple oxides several types of complex between CO and the L centres are observed[14,16]. Therefore this probe molecule, being a soft base, can be used to identify the different states of the cation of a given metal in different co-ordinations.

A different situation is observed when "hard" bases are used as probes. It is found[23] that the ν_B frequencies for pyridine, benzonitrile, and acetonitrile (the probes most often used to study electron-acceptor centres) are almost constant for the cation of a given metal in different catalysts (oxides, amorphous or crystalline alumina–silicas, phosphates, germanates, molybdates, and antimonates). Therefore the position of the ν_B band is determined by the nature of the cation. The quantity γ_r^{n+} can be used to characterise the cation: it is defined as the ratio I^{n+}/r, where I^{n+} is the appropriate value of the ionisation potential of the metal cation (in eV) and r is its orbital radius (in Å).[24] Physically the quantity γ_r^{n+} is closely related to e/r, but it allows for differences between metal cations formally in the same state of oxidation[24]. Fig.3 shows a plot of ν_{CN} in the spectrum of benzonitrile adsorbed on different substances[23,25] against the γ_r^{n+} value of the appropriate metal cation. The plot is fitted by the equation

$$\nu_{CN} = 2228\,(\pm 3) + 5{,}18\,(\pm 0{,}37)\,(\gamma_r^{n+})^{1/2} \qquad (3)$$

with a correlation coefficient $|R| = 0.97$ and a standard deviation of the ν_{CN} values of 5 cm^{-1}.

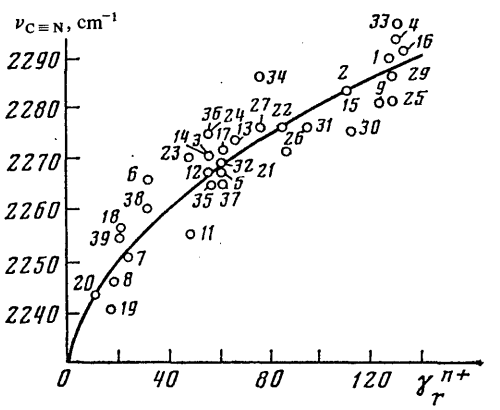

Figure 3. Dependence of ν_{CN} for benzonitrile adsorbed on catalysts upon γ_r^{n+}: *1*) Al_2O_3–SiO_2, *2*) Ga_2O_3–SiO_2, *3*) ZrO_2–SiO_2, *4*) BeO–SiO_2, *5*) MgO–SiO_2, *6*) Y_2O_3–SiO_2, *7*) La_2O_3–SiO_2, *8*) NaY, *9*) HNaY, *11*) CoNaY, *12*) NiNaY, *13*) CuNaY, *14*) ZrO_2–GeO_2, *15*) Ga_2O_3–GeO_2, *16*) BeO–GeO_2, *17*) MgO–P_2O_5, *18*) CaO–P_2O_5, *19*) SrO–P_2O_5, *20*) BaO–P_2O_5, *21*) Fe_2O_3–P_2O_5, *22*) Fe_2O_3–MoO_3, *23*) CoO–MoO_3, *24*) NiO–MoO_3, *25*) Al_2O_3–Sb_2O_5, *26*) Fe_2O_3–Sb_2O_5, *27*) Ga_2O_3–Sb_2O_5, *29*) γ-Al_2O_3, *30*) Ga_2O_3, *31*) TiO_2, *32*) ZnO, *33*) BeO, *34*) Cr_2O_3, *35*) ZrO_2, *36*) NiO, *37*) MgO, *38*) ThO_2, *39*) CaO. *1*)–*29*) from Ref.23, *30*)–*39*) from Ref.25.

Eqn.(3) can be used to study electron-acceptor centres in complex oxide systems containing various additives. Let us examine, for example, iron antimonate[26]. Taking tabulated values of γ_r^{n+} for all the cations which may be present on the surface (Fe^{3+}, Sb^{3+}, Sb^{5+}), and calculating the ν_{CN} frequencies by Eqn.(3), we obtain the ν_{calc} values 2276, 2255, and 2291 cm^{-1} respectively. By comparing them with

ν_{exper} (2270 and 2247 cm^{-1}) we conclude that the aprotic centres most likely to be present in iron antimonate are the iron and the antimony(III) cations.

No satisfactory explanation has yet been proposed for the low sensitivity of the position of the ν_B band to changes in the electronic state of the metal cation coupled with a high sensitivity to the nature of the metal cation. Some tentative suggestions appear in Ref.23.

It follows that in order to characterise fully an electron-acceptor centre on a catalyst surface we must use at least one hard and one soft base as probes (see Tables 1 and 2). The hard probe identifies the metal cations which form electron-acceptor centres, and the soft probe detects differences in the properties of a given cation in different environments.

2. Determination of the Concentration of L Centres

The surface concentrations are measured by assuming that the Beer–Lambert law is applicable to the bonds of adsorbed molecules. The most convenient form of this law is

$$A = 10^{-3} \cdot A_0 c_s \rho \qquad (4)$$

where A is the observed integral absorption for the analytical band in cm^{-1} (an analogous expression can be written for the optical density D), A_0 is the integral intensity of the band for a concentration of 10^{-6} mole $litre^{-1}$, c_S is the concentration of surface centres (expressed as μmole g^{-1} of catalysts), and ρ is the amount of catalyst (in mg) exposed to 1 cm^2 of the cross-section of the light beam. The product $10^{-3} c_S \rho$ gives the number of μmole of adsorbate in 1 cm^2 of the cross-section of the light beam. To find c_S we need to know A_0 (or the extinction coefficient ε if the optical density D is used). When overlapping bands (due to different forms of adsorption) are present, as is often the case since surface centres tend to be inhomogeneous, the complex band must be resolved into its individual components.

Unfortunately the A_0 coefficient has been obtained only in a few cases. The values of A_0 for the complexes of CO with Zn^{2+} are given in Ref.22. A_0 values for carbon monoxide forming D–A complpxes with a series of transition metal cations have also been reported[27]. A_0 has also been determined for the complexes of pyridine with aluminium cations[28], and the A_0 values have been studied[29] for some absorption bands of pyridine and of 2,6-dimethylpyridine interacting with NaY zeolite.

Thus it is clear that the absolute values of c_S for L centres can be measured only in a few cases from the i.r. absorption spectra of adsorbed molecules, and that the determination of the A_0 coefficients for the absorption bands of a wide range of individual probe molecules has become an urgent problem.

In studies of a series of chemically similar catalysts we can detect changes in the concentration of surface centres without knowing the A_0 coefficient. If the Beer-Lambert law is obeyed the parameter A for any of the ν_B bands is proportional to the concentration of the corresponding centres, and therefore the changes in A (normalised for $\rho = 1$) reflect the changes in the concentration of surface centres. This approach has been used[30–32] to reveal the nature of the catalytically active centres in a number of zeolites and zeolite-containing catalysts.

It is important in this connection to define the conditions under which the Beer–Lambert law is obeyed. Published data[14,22,28,33–35] suggest that this law is not infringed if two conditions are satisfied simultaneously: 1) the position of ν_B is unaffected by changes in surface coverage, and 2) the coverage of the adsorbent surface by adsorbate molecules is much less than a monolayer. Recommended values of ν_B for the most commonly used probes are given in Table 2. We should also bear in mind that the concentration of adsorption centres is not always equal to the number of adsorbed molecules per unit surface area. Adsorption should be carried out under conditions which ensure 100% filling of the centres of interest (or, at least, the same fractional filling in different experiments).

Thus the surface concentration of aprotic centres can be determined quantitatively by i.r. spectroscopy at three distinct levels of complexity and reliability. The first is suitable for qualitative studies of the changes in concentration of the centres in series of closely similar catalysts. We merely measure the change in intensity of the ν_B band, referred to 1 g of the catalyst. These experiments can be carried out in the simplest apparatus, using standard conditions for the adsorption of the probe. The second level of complexity is the determination of the concentration of surface centres by using published values of A_0. In this case the adsorption of the probe must be controlled to give almost 100% filling of the centres: this can be achieved by using a high relative pressure of adsorbate vapour or a low adsorption temperature. Usually under these conditions the probe is adsorbed in more than one form, and therefore the combined overlapping absorption bands must be resolved into the individual components before determining c_S. The third level of measurement complexity is reached when the concentration of acid centres on the surface has to be determined with a probe for which the A_0 value is not known. In this type of work the adsorption apparatus and the i.r. cell must be designed to allow simultaneous determinations of the adsorption and spectral measurements over a wide range of temperature and pressure. With this exception the third level does not differ from the second: it is potentially the most useful of the three levels, and it is attracting increasing interest.

We must now examine in detail the experimental methods of determining A_0. In order to find A_0 we need to know the surface concentration of the probe molecules, corresponding to the observed intensity of the experimental ν_B band. Some workers[36–40] have evaluated surface concentrations in parallel adsorption measurements, but as Little[41] has pointed out this can lead to serious errors because of the difficulty of reproducing exactly the conditions in adsorption experiments and i.r. spectral experiments.

An attempt[35] to make these conditions identical as far as possible by using pressed samples and by heating the adsorption sample to 50 °C (to simulate the heating of the spectral sample by i.r. radiation) was inconclusive, since no evidence was obtained that exactly equal amounts of pyridine were adsorbed on the same type of centre in the two pressed samples.

Undoubtedly the best approach is to determine the surface concentration of B centres and the parameter A for the ν_B band on a single sample in the same experiment. Two basic methods are available: the volumetric and the gravimetric method.

Volumetric method. The volumetric method often takes the form of a titration. Known amounts of adsorbate are added successively to the cell, and the spectrum is recorded after each addition. This approach has been used[28] to measure A_0 for the ν_B bands of pyridine and piperidine sorbed on decationated Y zeolite, aluminium oxide, and amorphous alumina–silica.

The use of the volumetric method is complicated in some cases by the adsorption of the probe molecules on the unheated parts of the cell. Quantitative corrections for the

adsorption on the cell walls are difficult to apply. In order to eliminate the effect provisions for heating the whole cell must be made, and the adsorption must be carried out at pressures well below the saturated vapour pressure of the probe at the temperature of the cell wall. The volumetric method can be used, without a correction for the adsorption on the cell wall and without heating the cell, to study the adsorption of carbon monoxide[14], ammonia ($T_b = 239.6$ K), acetone ($T_b = 329.6$ K), and acetonitrile ($T_b = 353.2$ K) at pressures up to 10 mmHg. With pyridine ($T_b = 388.4$ K) the adsorption on the cell wall at 300 K is negligible at pressures below 10^{-1} mmHg. For benzonitrile ($T_b = 463.8$ K) the volumetric method is probably inapplicable, since its vapour pressure at 300 K is 0.1 mmHg.

Gravimetric method. The gravimetric method consists in measuring the weight of the sample before and after admitting the adsorbate into the cell. Since the pressed samples used to measure the i.r. spectra are small, and the average concentration of acidic centres is also small, the precision of the measurement of sample weight should be at least 10^{-7} N.[42-44] As a result, a fairly complicated cell design is needed for simultaneous gravimetric and i.r. spectral measurements. For a detailed description of different types of these cells the reader is referred to recent monographs[18,41]. The apparatus must also include a system for introducing the adsorbate and means for measuring pressure.

The gravimetric method of measuring the amount of B molecules on the surface seems to be preferable to the volumetric method in two circumstances:

1) with weakly adsorbed gases (for example, alkenes[42]), when the precision of the volumetric method is inadequate. A comparison of the results obtained by both methods for the adsorption of unsaturated hydrocarbons is given in Refs.42 and 45.

2) for the adsorption of high-boiling probe substances, when the adsorption of B molecules on the cold wall of the cell is significant.

The gravimetric method should be chosen when pyridine is used as the adsorbate[35] (and probably also benzonitrile). A more detailed description of the properties of the probes listed in Table 2 and of their special features in use can be found in Refs.3, 11, 14–16, 18, 23, 24, 30–32, 42, and 46–54.

Evidently these difficulties in the determination of the surface concentrations of adsorbed substances from their i.r. spectra are not confined to the aprotic centres. Studies of protonic or basic centres present similar problems, which can be overcome in similar ways. Therefore we shall limit our discussion of the determination of the concentration of the latter types of centre to a few specific cases.

III. STUDY OF PROTONIC ACID CENTRES

1. The Concepts of "Acid Strength" and "Acidity", and their Measurement Units

The theory of acids and bases is most fully developed for aqueous solutions[55], but it includes a group of concepts which can be used in the qualitative and quantitative description of the properties of any solution. Three of these concepts are especially relevant to the present discussion: the acid (or base) strength, the acidity of the solution, and the solvation effect. According to Hammett[56] the acid or base strength denotes the extent to which the acid is converted into an anion (or the base into its conjugated acid) under standard conditions. These degrees of conversion are characterised by the appropriate equilibrium constants, or in pK_a units.

Thus the "acid strength" is a thermodynamic quantity which describes the properties of substances in relation to a chosen standard medium. The second concept ("acidity of the solution") describes the tendency of the solution as a whole to donate a proton to a base. This tendency increases with the concentration of the acid. In dilute aqueous solutions it is measured by the pH, or by the more universal acidity function H_0 (which is less dependent on the solvent)[56]. If the tendency of the acid to transfer a proton to the base is characterised by the protolytic base indicator equilibrium

$$HInd^+ \rightleftarrows Ind + H^+ \qquad (II)$$

for which we can write

$$K_a = \frac{a_{H^+} a_{Ind}}{a_{HInd^+}} \quad \text{or} \quad pK_a^{Ind} = -\lg \frac{a_{H^+} f_{Ind}}{f_{HInd^+}} + \lg \frac{[HInd^+]}{[Ind]}$$

where a is the activity and f the activity coefficient in the given medium, the acidity function is given by the expression

$$H_0 = pK_a^{Ind} - \lg \frac{[HInd^+]}{[Ind]} \qquad (5)$$

The quantity $H_0 = -\lg a_{H^+} f_{Ind}/f_{HInd^+}$ is a measure of the acidity of the medium. It is important to note that the scale of H_0 characterises the acidity of the solution but not the acid strength, since it depends on the concentration of the acid. It is applicable when: 1) the protonation of the base [described by Eqn.(II)] has reached equilibrium, and 2) the properties of the uncharged Ind molecules allow the ratio f_{Ind}/f_{HInd^+} in the given medium to be constant for any indicator. For equal concentrations of the protonated and of the initial base the H_0 value is equal to the pK_a of the indicator.

The indicator method was later extended by Walling[4] to solid acids by postulating that the ability of a surface to convert a base into a protonated acid can be characterised in the H_0 scale. The surface is treated as a medium with a high dielectric constant, and H_0 as a measure of the acid strength (determined from the pK_a value for the weakest of the protonated base indicators adsorbed from non-polar solvents). The second term of Eqn.(5) was ignored. Thus a confusion in the use of the "acid strength" concept arose at that early stage in the development of the study of the acidity of solids.

The need to quantify the strength of solid acids arose during the development of heterogeneous acid–base catalysis. However, in catalytic reactions the base is in the gas phase, and therefore it is more correct to examine the tendency of the catalyst surface to protonate the base after it has been adsorbed from the gas phase. In other words, whereas the acid strength in an aqueous solution is characterised by the equilibrium constant for the dissociation

$$AH \overset{K_a}{\rightleftarrows} A^- + H^+ \qquad (III)$$

no such dissociation takes place on the surface, and the protonation of the base cannot be described by the simple equation (II).

The mechanism of the interaction of a molecule of a gaseous base B with a protonic acid centre on a solid surface can be described[57] by the scheme

$$\underset{A}{|-OH} + B^{gas} \rightarrow \underset{H\text{-complex}}{|-O-H \ldots B} \rightarrow \underset{IP}{|-O^- \ldots {}^+HB} \qquad (IV)$$

where A is the initial state of the system, H-complex is a complex in which B is hydrogen-bonded to an acidic OH group, and IP is an ion pair. A similar mechanism applies to the interaction between an acid and a base in non-polar

solvents[58]. According to this scheme the tendency of protonic acid centres to interact with the base B can be determined by studying the reaction between A and the H-complex or between A and IP. In the following sub-sections we shall examine both these approaches, which have been called respectively the "hydrogen bond method" and the "ion pair method".

Recent work[59–74] has established that the strength of a Brønsted acid or base in the gas phase is more correctly defined through the "proton affinity" (PA). In the case of acids the PA is determined by the enthalpy (ΔH) of the reaction

$$AH \rightarrow A^- + H^+ \qquad (V)$$

and the PA of bases by the enthalpy of the reaction

$$HB^+ \rightarrow H^+ + B \qquad (VI)$$

Both reactions are assumed to take place in the gas phase.

Table 3. Probes used to study Brønsted acid centres.

No.	Probe	pK_a [75—78]	PA, kJ mole^{-1} (Ref. 59,60, 68–74)	$\Delta\nu_{OH}$, cm^{-1} **		Criterion for the formation of an ion pair (IP)

Notes. The bases in this Table are classified into groups as follows: Nos.1–8 do not show basic properties in aqueous solutions, Nos.9–18 are oxygen-containing bases, Nos.19–28 are nitrogen-containing bases, Nos.29–35 are pyridine and its derivatives, Nos.36 and 37 are sulphur-containing bases. The dash denotes the absence of suitable data. Probes No.1–5 were adsorbed at low temperature, No.13 is difficult to use (readily oxidised), No.21 tends to aminate the surface. With probes No.21–28 the donor–acceptor complexes are difficult to distinguish from protonated molecules, Nos.29–31 have a low vapour pressure.

* Ion pairs are not formed on protonic centres with PA > 1200 kJ mole^{-1}.

** Data taken from Refs.41, 91–93, 96–98.

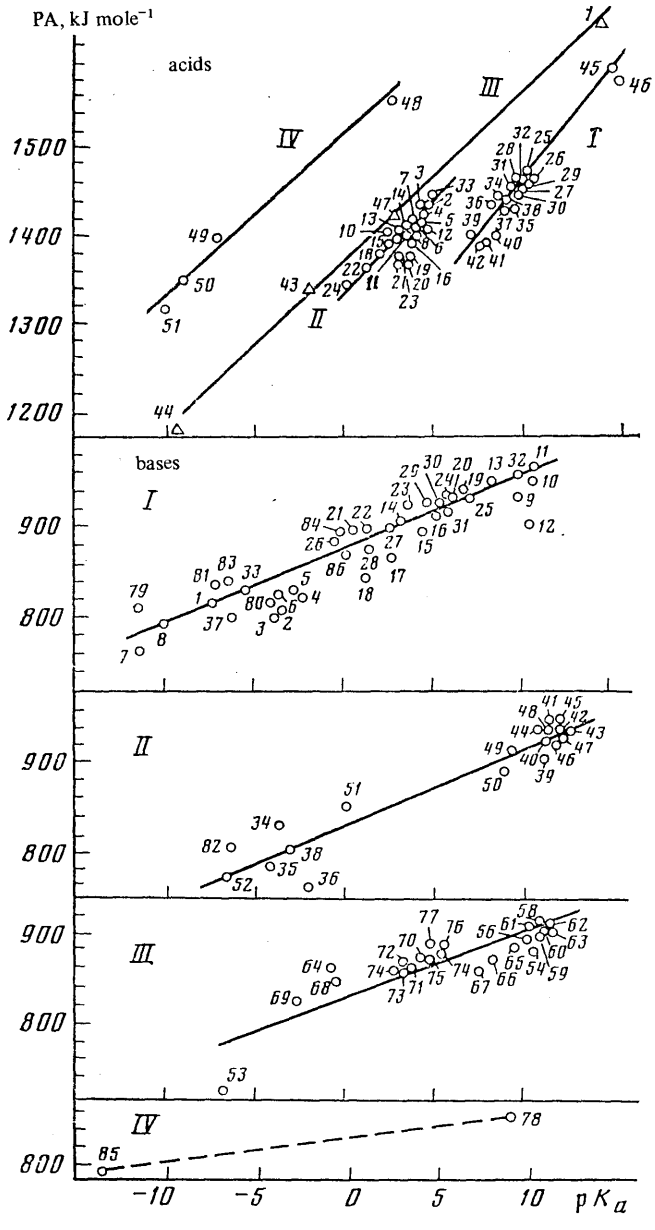

Figure 4. Correlation between PA and pK_a for different types of acid and base. Bases: (*I*) no protons on the proton-acceptor atom, (*II*) one proton, (*III*) two protons, (*IV*) three protons. Acids: (*I*) alcohols and phenols, (*II*) carboxylic acids, (*III*) inorganic oxygen-containing acids, (*IV*) hydrogen halide acids. 39) dimethylamine, *40*) diethylamine, *41*) di-n-propylamine, *42*) di-isopropylamine, *43*) di-n-butylamine, *44*) di-isobutylamine, *45*) di-s-butylamine, *46*) cyclopropylamine, *47*) cyclobutylamine, *48*) cyclopentylamine, *49*) diallylamine, *50*) dipropylamine, *51*) pyrrole, *52*) methyl sulphide, *53*) water, *54*) methylamine, *55*) ethylamine, *56*) n-propylamine, *57*) isopropylamine, *58*) n-butylamine, *59*) isobutylamine, *60*) s-butylamine, *61*) t-butylamine, *62*) n-pentylamine, *63*) t-ethylamine, *64*) hydrazine, *65*) allylamine, *66*) propylamine, *67*) 2-isocyanoethylamine, *68*) acetamide, *69*) formamide, *70*) aniline, *71*) 3-fluoroaniline, *72*) 3-chloroaniline, *73*) 4-chloroaniline, *74*) 3-methylaniline, *75*) 4-methylaniline, *76*) 3-methoxyaniline, *77*) 4-methoxyaniline, *78*) ammonia, *79*) benzonitrile, *80*) ethyl methyl ether, *81*) benzaldehyde, *82*) phenol, *83*) methyl phenyl ether, *84*) *N,N*-dimethylacetamide, *85*) phosphine, *86*) dimethylsulphoxide. Acids: *1*) water, *2*) acetic acid, *3*) 4-methylbenzoic acid, *4*) 2-methoxybenzoic acid, *5*) 3-methylbenzoic acid, *6*) benzoic acid, *7*) 3-methoxybenzoic acid, *8*) 2-methoxybenzoic acid, *9*) 2-methylbenzoic acid, *10*) fluoroacetic acid, *11*) 2-fluorobenzoic acid, *12*) 3-fluorobenzoic acid, *13*) 2-chlorobenzoic acid, *14*) 4-fluorobenzoic acid, *15*) chloroacetic acid, *16*) 4-chlorobenzoic acid, *17*) 3-chlorobenzoic acid, *18*) 2-nitrobenzoic acid, *19*) 3-nitrobenzoic acid, *20*) 2-cyanobenzoic acid, *21*) 3-cyanobenzoic acid, *22*) dichloroacetic acid, *23*) 4-nitrobenzoic acid, *24*) trifluoroacetic acid, *25*) 4-methylphenol, *27*) 3-methylphenol, *28*) phenol, *29*) 2-methylphenol, *30*) 2-methoxyphenol, *31*) 3-methoxyphenol, *32*) 4-fluorophenol, *33*) propionic acid, *34*) 2-fluorophenol, *35*) 3-fluorophenol, *36*) 2-chlorophenol, *37*) 4-chlorophenol, *38*) 3-chlorophenol, *39*) 2-nitrophenol, *40*) 3-cyanophenol, *41*) 3-nitrophenol, *42*) 4-cyanophenol, *43*) nitric acid, *44*) perchloric acid, *45*) methanol, *46*) ethanol, *47*) nitrous acid, *48*) hydrogen fluoride, *49*) hydrogen chloride, *50*) hydrogen bromide, *51*) hydrogen iodide. PA data taken from Refs.59, 60, 64, 65, 67 for acids and from Refs.60, 61, 68–71, 73, 74 for bases. Data on pK_a taken from Refs.71, 75–78.

Experimentally the parameter PA is found by studying the equilibrium gas-phase proton transfer reactions between the acid and the acid residue or between the protonated and the free base. The enthalpy of the reaction is determined in relation to a chosen standard: in particular, ammonia, whose PA [determined directly by reaction (VI)] is 846 kJ mole^{-1}.[69]

Thus we can use the PA to characterise the interaction of acidic OH groups of the surface with B molecules in the gas phase, and the problem reduces to finding the functional relationship between any measurable property of the system which reflects the extent of proton transfer and the quantities PA_{AH} and PA_B. Under these conditions PA_B is always known (see Table 3). However, in many current publications the acid–base properties of surfaces are measured in pK_a units, and therefore the reported PA values have to be compared with the properties of the solute in water, i.e. on the pK_a scale. Data on pK_a and on the PA can be found in many recent papers[59–78] and in their References. In general, an increase in the PA of bases from 710 to 960 kJ mole^{-1} is accompanied by an increase in pK_a from (−14)–(−11) to (11)–(12). However, we should note that often the pK_a values differ by 10 or more units for substances with almost identical PA, and conversely for substances with similar values of pK_a the PA can differ by 100–120 kJ mole^{-1} (see Table 3).

Since the pK_a value is largely determined by the state of solvation of the ionised base, we can use specific features of the solvation as a basis for classification. In particular, we can expect bases with different numbers of protons on the acceptor atom (for example, primary, secondary, and tertiary amines) to form different numbers of hydrogen bonds with water molecules, and therefore to show differences in solvation energy for the same basicity.

This criterion is used in Fig.4 to establish correlations between pK_a and PA values for compounds containing equal numbers of protons. In each group of bases we find an obvious proportionality between the two parameters: the mean scatter is ~40 kJ mole^{-1} for the PA and ~3 units for pK_a. Even closer correlations between pK_a and the PA are found in series of isostructural bases[68,72].

We can also compare the PA and pK_a values of acids by classifying the acids into several groups (see Fig.4). Group I includes alcohols and phenols, group II the carboxylic acids, group III oxygen-containing inorganic acids and water, while group IV is reserved for hydrogen halides. It is clear from these results that only bases or acids of a given type can be arranged in order of strength (in the gas phase) from pK_a data obtained for these substances in aqueous solutions: to a first (and rough) approximation we can use the classification suggested above.

It has recently been suggested[79–81] that the thermodynamic characterisation of the proton-donor properties of catalysts should be supplemented by a kinetic criterion: the activation energy (E_a^H) for the transfer of the proton from the surface to the adsorbed molecule. A spectroscopic method of calculating E_a^H from measurements of ν_{OH} for the surface before and after adsorption was developed, using the specially established correlation between $\Delta\nu_{OH}$ and E_a^H.

Let us now examine in detail each of the above methods of quantifying the proton-donating properties of solid acids.

2. The Hydrogen Bond (HB) Method

a) *Physicochemical basis.* Attempts to characterise the strength of acids or bases through the properties of the H-complex [see reaction (IV)] raise two important questions: can the influence of the acid or base strength on the properties of the complex be revealed explicitly, and what is the relationship between the various properties of the H-complex and the thermodynamics of the proton transfer reaction.

Detailed and precise studies of the enthalpy of formation of the H-bond (ΔH_H) and of the change in frequency of the stretching vibrations ($\Delta\nu_{HX}$, $\Delta\nu_{OH}$) for the formation of the complex in non-aqueous solutions have been reported[82]. An unambiguous correlation between these quantities was demonstrated[82–86]. Since $\Delta\nu_{HX}$ is directly measurable from the i.r. spectra we shall use only this parameter to characterise the H-complexes.

The answer to the first question is given in a comparison [87–89] of various characteristics of the H-bond (including $\Delta\nu_{HX}$) with the properties of the acid or based involved, which led to the formulation of the following "factor rule": any parameter used to characterise the H-bond can be expressed as a product of a function describing the dependence of the stated parameter of the complex on the nature of the i-th acid (P_i) and a function describing its dependence on the nature of the j-th base (E_j). It was shown[86–88] that the ratio of $\Delta\nu_{HX}$ for any acid interacting with the base B to $\Delta\nu_{OH}$ for phenol (chosen as a standard) interacting with the same B is the same for all bases B, and depends only on the nature of HX: $\Delta\nu^B_{HX}/\Delta\nu^B_{OH(PhOH)} = \text{const} = P_i$. This suggests that the nature of the base has the same influence on

the $\Delta\nu_{HX}$ value of any acid: thus, if the P_i values are calculated for a series of acids the dependence of $\Delta\nu_{HX}$ on the nature of the acid can be obtained to the precision of a constant factor.

Furthermore, the ratio of the shift of the ν_{HX} frequency for different acids (HX) interacting with the same base B to the $\Delta\nu_{HX}$ value of the same acids interacting with another base chosen as a standard (for example, diethyl ether[87]) is also constant, and depends only on the nature of B and on the chosen standard: $\Delta\nu^{B}_{HX}/\Delta\nu^{(C_2H_5)_2O}_{HX} = \text{const} = E_j$. Thus the change of E_j for a series of B is a function describing the dependence of $\Delta\nu_{HX}$ on the nature of the base B to a precision determined by the choice of the standard B.

The full form of the function describing the effect on $\Delta\nu_{HX}$ for any acid of the interaction with the base B (taking PhOH and $(C_2H_5)_2O$ as standards) is

$$\Delta\nu_{HX} = C\left(\frac{\Delta\nu^{B}_{HX}}{\Delta\nu^{B}_{OH(PhOH)}}\right)\cdot\left(\frac{\Delta\nu^{B}_{HX}}{\Delta\nu^{(C_2H_5)_2O}_{HX}}\right)$$

where the constant C reflects the properties of the chosen standards. It is easily shown, by putting HX = PhOH, that $C = \Delta\nu^{(C_2H_5)_2O}_{OH(PhOH)}$. According to Iogansen[87], in this case $C = 282$ cm^{-1}, and therefore

$$\Delta\nu_{HX} = 282 P_i \cdot E_j \qquad (6)$$

By using Eqn.(6) we can establish the dependence of P_i on the relevant property of the acid (or the dependence of E_j on the property of the base) from experimental $\Delta\nu_{HX}$ data. Direct correlations between $\Delta\nu_{OH}$ in the H-complexes and the K_p (or $\lg K_p$) value (which characterises thermodynamically the proton transfer from the acid to the base) have not so far been reported. However, in a series of different B with the same OH acid or in a series of different acids with the same base the dependence of $\Delta\nu_{OH}$ on K_p is equivalent (to the precision of a constant term) to the dependence of $\Delta\nu_{OH}$ on pK_a^{base} or on pK_a^{acid}, since $-\lg K_p = pK_a^{acid} - pK_a^{base}$. This dependence of $\Delta\nu_{OD}$ (for deutero-methanol) on the pK_a values of various bases was first demonstrated by Hammett[90], and the dependence on pK_b by Gordi and co-workers (see Ref.82). According to Arnett[77] the dependence of $\Delta\nu_{OH}$ on pK_a^{base} can be described by the correlation equation

$$\Delta\nu_{OH}/\nu^{0}_{OH} = a + b\,pK_a^{base} \qquad (7)$$

This equation was proposed[91,92] for a strong H bond, formed on Aerosil, phosphates, or HNaY zeolite. For example, for Aerosil $a = 0.145 \pm 0.004$ and $b = 0.0096 \pm 0.0007$.

The dependence of $\Delta\nu_{OH}$ on the pK_a of adsorbed bases for Aerosil, with additional results from Ref.93, is shown in Fig.5. For bases of group I the dependence on pK_a^{base} can be fitted more accurately to the following equation than to a linear equation:

$$\Delta\nu_{OH} = 530(\pm 14)\cdot 10^{0.026(\pm 0.0015)pK_a^{base}} \qquad (8)$$

According to this equation we can calculate pK_a^{base} to a precision better than ± 1.4 pK_a units if $pK_a > -12$ and $\Delta\nu_{OH} > 150$ cm^{-1}. The standard deviation of the $\Delta\nu_{OH}$ values is less than ± 20 cm^{-1}.

The few available data on the adsorption of bases in groups II–IV gave $\Delta\nu_{OH}$ values lower by 100–200 cm^{-1} than the $\Delta\nu_{OH}$ values for group I bases at the same pK_a. This is consistent with the above conclusion that the correlation between pK_a and the characteristics of the acids (or bases) applies only within a single group of compounds.

Eqn.(8) is physically analogous to (6), since the factor 530 cm^{-1} is determined by the strength of the Aerosil (or other acid) and is proportional to P_i, and the term $10^{0.026}\,pK_a^{base}$ is proportional to E_j.

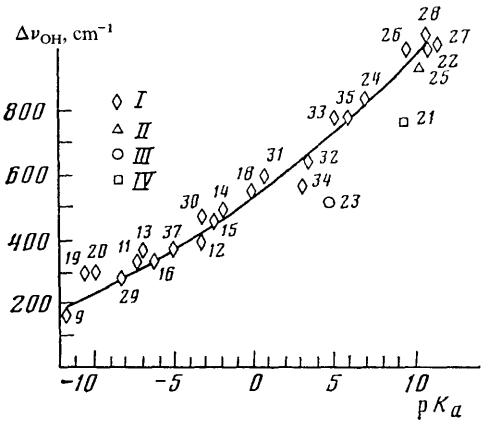

Figure 5. Dependence of $\Delta\nu_{OH}$ for the hydroxyl groups of Aerosil on the pK_a value of adsorbed bases: (*I*) bases from group I, (*II*) from group II, (*III*) from group III, (*IV*) ammonia. The numbering of the points corresponds to Table 3.

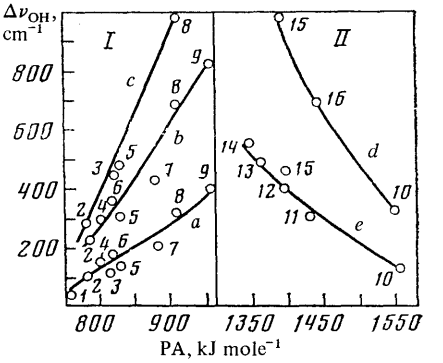

Figure 6. Dependence of $\Delta\nu_{OH}$ of the H-complexes on the PA of the bases (*I*) for t-butanol (*a*), 4-fluorophenol (*b*), and 4-nitrophenol (*c*), and on the PA of the acids (*II*) for acetone (*d*) and pyridine (*e*) in non-polar solvents. The numbering of the points denotes the base: *1*) nitromethane, *2*) acetonitrile, *3*) acetone, *4*) dioxan, *5*) diethyl ether, *6*) tetrahydrofuran, *7*) dimethylfluoramide, *8*) pyridine, *9*) triethylamine, *10*) t-butanol, *11*) acetic acid, *12*) chloroacetic acid, *13*) dichloroacetic acid, *14*) trifluoracetic acid, *15*) 4-nitrophenol, *16*) 4-fluorophenol. Data from Refs.88, 89, 99, and 100 were used.

Until recently there had been no attempt to find a correlation between $\Delta\nu_{OH}$ of the H-complex and the PA of acids or bases. Fig.6 shows the dependence of $\Delta\nu_{OH}$ for the H-complexes of some acids on the PA of bases (I), and for the complexes of some bases on the PA of acids (II) in non-polar

solvents, calculated from published data[89,90,99,100], with PA values taken from Refs.59–74. The dependences are practically linear, and the $\Delta\nu_{OH}$ values increase with the PA of the base, the slope of curves showing a marked increase as we change from the weak acid t-butanol (curve *a*) to the stronger acids 4-fluorophenol (curve *b*) and 4-nitrophenol (curve *c*). The $\Delta\nu_{OH}$ values decrease as the PA of the acid increases.

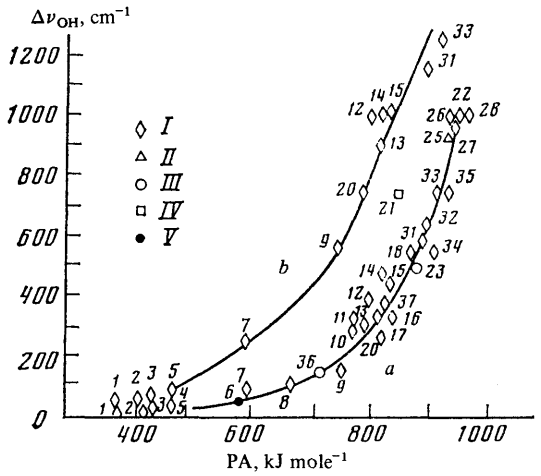

Figure 7. Dependence of $\Delta\nu_{OH}$ for H-complexes on the PA of adsorbed bases. Curve *a* refers to Aerosil, curve *b* to HNaY zeolite: (*I*) bases of group I, (*II*) group II, (*III*) group III, (*IV*) ammonia, (*V*) cyclohexane on Aerosil. The numbering of the points corresponds to Table 3.

We have observed[94] a correlation between $\Delta\nu_{OH}$ for the solid acids Aerosil and HNaY zeolite and the PA of adsorbed bases (Fig.7). For both acids, with $\Delta\nu_{OH} < 400$ cm^{-1} (weak hydrogen bond), the dependence is described by the equation

$$\Delta\nu_{OH} = \alpha' \cdot 10^{0.0036(\pm 0.0002)PA^{base}} \qquad (9)$$

where α' is a coefficient dependent on the properties of the acid. Changing from SiO_2 to a stronger acid (HNaY zeolite) causes α' to increase. Eqn.(9) also is similar to (6), with α' functionally related to P_i and the term $10^{0.0036}$ PAbase related to E_j. From Eqn.(9) we can find the PA of the base from the $\Delta\nu_{OH}$ values with a precision of ±20 kJ mole^{-1}.

For $\Delta\nu_{OH} > 400$ cm^{-1} we again find a clear correlation between $\Delta\nu_{OH}$ and PA^{base}. For bases with a PA between 850 and 960 kJ mole^{-1} the variation of $\Delta\nu_{OH}$ of Aerosil (say) with the PA of the base is accurately linear. With the exception of ammonia, all the bases (groups I–III) in Fig.7 accurately lie on the curves *a* or *b*. However, since the study of strong hydrogen bonds is often complicated by Fermi resonance[95], and since a base forming weak bonds can always be found for any solid acid (see Table 3), we shall confine our discussion to weak bonds.

Let us examine in detail the reported functional relationships between *b*, P_i (i.e. $\Delta\nu_{OH}$) and the pK_a or PA values of acids. The $\Delta\nu_{OH}$ values of silica gel, magnesium oxide, phosphoric acid, and B_2O_3 (on silica gel) have been measured[101] for the interaction with various aromatic compounds, CCl_4, and oxygen- or nitrogen-containing bases, and also $\Delta\nu_{OH(PhOH)}$ in a solution of CCl_4 in the presence of the same bases, in order to determine $\Delta\nu_{OH}^{sol}/\Delta\nu_{OH(PhOH)}$. At the same time the P_i values were obtained for non-aqueous solutions of the H-complexes of the acids and bases, and their dependence on the pK_a of the acids was analysed. Lastly, assuming that the same relationship is retained in heterophase systems, the pK_a values for the OH groups of Aerosil and magnesium oxide were obtained from the plot of P_i against pK_a and the $\Delta\nu_{OH}^{sol}/\Delta\nu_{OH(PhOH)}$ values. The results were +7 and +15.6 respectively.

A similar approach, with a wider range of P_i values for the acid solutions, has been used[102] to calculate the strength of the protonic centres in amorphous alumina-silicas. The pK_a value of the most acidic OH groups in this material was found to be $-(6 \pm 2)$.

It was also found[91,92] that in practice only the parameter *a* of Eqn.(7) depends on the strength of the acidic centre. This means that for a strong H bond the $\Delta\nu_{OH}$ value is determined (by an additive formula) by the strength of the acid and of the base. Since the relationship between *a* and pK_a^{acid} for a strong H bond in solution is not known, it may be described approximately by an expression analogous to Eqn.(7). Taking the value[101] of +7 for the pK_a of the OH groups in Aerosil we obtained[91,92] the following expression for calculating the strength of acidic surface OH groups on the pK_a scale to a precision of ±2.5 pK_a units:

$$\frac{\Delta\nu_{OH}}{\nu_{OH}^0} = 0.216 - 0.0096(\Delta pK_a) \qquad (10)$$

where $\Delta pK_a = pK_a^{acid} - pK_a^{base}$.

Table 4. Strength of the Brønsted acid centres, measured by different methods.

Method*	HNaY zeolite and alumina–silica	P_2O_5 on SiO_2 and on M_xO_y	SiO_2	MgO
Weak H-bond method, in pK_a units	−6	−0.4	+7	+15
Strong H-bond method, in pK_a units	−9	−5	+7	—
Weak H-bond method, on the PA scale (kJ mole^{-1})	1200	1300	1390	1560(±40)

* The methods are described in the text.

We have used Eqn.(10) to determined pK_a for the OH groups of HNaY zeolite and of metal phosphates (Table 4). We also studied[94] the correlation between the P_i values averaged over many bases in non-aqueous solutions and the PA for a series of acids (Fig.8). For oxygenated acids in $\lg P_i$—PA co-ordinates the dependence is accurately fitted by the straight line.

$$\lg P_i = \lg\beta + 0.00226(\pm 0.00016)\,PA^{acid} \qquad (11)$$

or, from the definition of P_i,

$$\Delta\nu_{OH}^{B} = \beta \cdot \Delta\nu_{OH(PhOH)}^{B} \cdot 10^{0.00226(\pm 0.00016)PA^{acid}} \qquad (12)$$

We note that the coefficient β, being the value of P_i at PA = 0, is independent of the strength of the base B. Eqn. (12) is valid for any B, but is assumes that $\Delta\nu_{OH}$ and

$\Delta\nu_{OH(PhOH)}$ have been measured for the interaction of the respective acids with the same base. By using this equation we can measure $\Delta\nu_{OH}$ and $\Delta\nu_{OH(PhOH)}$ in non-aqueous solutions and hence obtain the PA of the acid to a precision (defined as the standard deviation of P_i in Fig.8) better than ±25 kJ mole^{-1}. Eqn.(12) was assumed to be equally applicable to hetero-phase systems[94]. In other words, it was assumed that the points for which $P_i = \Delta\nu_{OH}^{sol}/\Delta\nu_{OH(PhOH)}$ could be included in the plot of Fig.8. By writing Eqn.(12) for SiOH(SiO_2) and for the solid acid OH†, and by dividing one expression by the other, we can eliminate the term $\beta.\Delta\nu_{OH(PhOH)}$, and solving for PA^{acid} we arrive at the following expression for PA:

$$PA^{OH} = PA^{SiOH} - \frac{1}{0.00226}\lg\frac{\Delta\nu_{OH}^{B}}{\Delta\nu_{OH(SiO_2)}^{B}} \qquad (13)$$

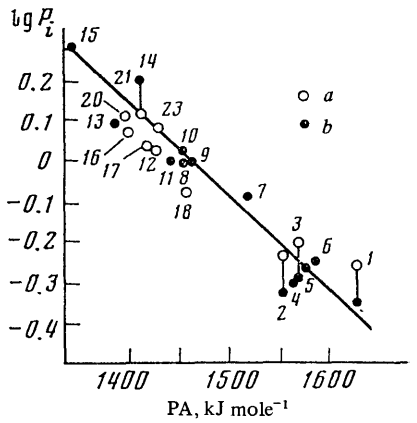

Figure 8. Correlation between lg P_i and the PA of the corresponding acids: *1*) water, *2*) t-butanol, *3*) isopropanol, *4*) n-propanol, *5*) ethanol, *6*) methanol, *7*) 2-trifluoroethanol, *8*) phenol, *9*) 4-methylphenol, *10*) 3-methylphenol, *11*) 4-fluorophenol, *12*) 4-chlorophenol, *13*) 4-nitrophenol, *14*) benzoic acid, *15*) trifluoroacetic acid, *16*) 4-nitrophenol, *17*) 3-chlorophenol, *18*) 4-methoxyphenol, *19*) acetic acid, *20*) chloroacetic acid, *21*) 3-methoxybenzoic acid. Points *a* from Ref.87, points *b* from Ref.102, PA values from Refs. 59, 66, and 73.

By changing to a new standard (Aerosil, with a PA of 1390 kJ mole^{-1} determined[102] according to Eqn.(11) (Fig.8) for $P_i = 1.2$)[102] we can not only avoid the need to calculate β and $\Delta\nu_{OH(PhOH)}$ when using different bases B, but also use a much wider range of bases. This is because phenol does not form stable H-complexes with some of the bases most commonly used to study solid acids, such as CO, probes No.1–6 in Table 3, etc.

To calculate the PA values of solid acids by Eqn.(13) we need to know $\Delta\nu_{OH}$ for the interaction of the base B on SiO_2 and on the solid acid under study. Like Eqn.(12), Eqn.(13) is valid only for oxygen acids. The precision of the determination of the PA by Eqn.(13) is ±25 kJ mole^{-1}. As the data in Fig.7 show, the choice of the base B cannot be arbitrary, since for $\Delta\nu_{OH} > 400$ cm^{-1} the logarithmic relationship between the PA and $\Delta\nu_{OH}$ ceases to apply. The study of the acidity of the OH groups on solids by using Eqn.(13) or the P_i–pK_a^{acid} correlation (which is limited in practice to the range of $\Delta\nu_{OH}$ values from 0 to 400 cm^{-1}) has been called the weak hydrogen bond method, whereas the study by Eqn.(10) is known as the strong hydrogen bond method.

By using Eqn.(13) we have shown[94] that the PA of the OH groups in decationated HNaY zeolite is 1200 kJ mole^{-1}. The difference in PA between Aerosil and zeolite is consistent with quantum-mechanical calculations[103].

Thus we can compare the different methods of determining the strength of acidic centres by listing their results for given systems (Table 4). On the whole all the methods yield similar sequences for the strength of the OH groups on different substances, but the last method [using Eqn.(13)] offers a higher relative precision in the determination of the parameter of interest.

It follows that the weak hydrogen bond method of determining the PA value can be recommended both from the point of view of the quantity used to characterise the protonic centres and of the precision obtainable. All three methods rely on doubtful assumptions, of which the least satisfactory are:

1) the assumed equality of the scales of "influence" of the pK_a values of acids and bases on $\Delta\nu_{OH}$ [91,92] in the strong hydrogen bond method, which seriously restricts the general validity of Eqn.(10), and

2) the need to define three groups of acids (I–III in Fig.4) in describing the dependence of pK_a on P_i. On the other hand the main assumption of the third method (which is made also in the second method) that the dependence of P_i on PA^{acid} is the same for P_i values obtained in non-aqueous solutions and in the adsorption of bases on solid acids appears to be confirmed, since the $\Delta\nu_{OH}$ values obtained in the gas phase are not very different from those obtained in solutions from ν_{OH}^{0} and ν_{OH}^{B} measurements in the same solvent.

b) *Determination of the concentration of protonic centres.* The concentration of protonic centres can be determined in various ways during the measurement of the strength of the centres by the hydrogen bond method. The simplest consists in measuring the integral intensity or the optical density of the ν_{OH} bands (in arbitrary units, normalised for $\rho = 1$) before interaction with the molecules of the base B. This approach has been used[30,31] to study the influence of the composition of zeolites on the concentration of hydroxyl groups: the result was that OH groups with $\nu_{OH} = 3640$ cm^{-1} are involved in the catalytic action of these materials. In a study of the acidic and catalytic properties (towards the formation of acrylonitrile) of TiO_2–Sb_2O_5 oxide catalysts the changes in the D/ρ ratio for the ν_{OH} bands showed that the concentration of acidic OH groups ($\nu_{OH} = 3730$ cm^{-1}) decreases as the concentration of Sb_2O_5 increases, and that the catalytic reaction on these centres is mainly in the direction of destructive oxidation of propene[52]. Thus even this very simple approach can yield important information on the nature of the catalytically active centres.

In some cases (for example, in amorphous alumino-silicate systems) OH groups of different strength have almost identical ν_{OH} values and the measured intensity of the band corresponds to the total number of centres. In this case the changes in concentration of the different centres can be monitored by measuring the intensity of the OH stretching vibration bands, which are shifted by the formation of an H bond with a B molecule (ν_{OH}^{B}). This type of analysis is reported in Ref.104.

† This term denotes the surface of any solid containing acidic OH groups.

The absolute concentration of OH groups can be determined when the integral molar absorption coefficients (A_0) of the ν_{OH} bands are known. Unfortunately, these coefficients are known only for a very few substances at present. Hughes and White[28] found that the A_0 value for the ν_{OH} 3640 cm^{-1} band of HNaY zeolite is 12.2 cm $\mu mole^{-1}$, whereas for the 3550 cm^{-1} band it is 19.5 cm $\mu mole^{-1}$. For Aerosil the value $A_0 = 9.8$ cm $\mu mole^{-1}$ has been reported[105].

The total number of OH groups can be deduced from the weight loss of the catalyst after heat treatment[18], but it may be difficult to distinguish the true surface OH groups from the co-ordinated or physisorbed water. The concentration of surface OH groups accessible to adsorbed molecules can be identified by specific chemical reactions for water: these methods are fully discussed in Ref.106. However, this approach only gives the total number of OH groups, and even if combined with a full analysis of the spectra it cannot yield the A_0 coefficients for the different classes of OH groups.

A determination of A_0 for the OH groups of zeolite by "titration" with pyridine and piperidine has been reported[28]. Unfortunately, when the strength of the protonic centres was insufficient to form the pyridinium ion, or if the centres were not accessible to the pyridine molecules, or in the presence of a large number of aprotic centres, the method was found to be inapplicable. Methods relying on H–D exchange can also be used. Knowing the total amount of deuterium in the cell, and the degree of exchange of H by D in the OH groups when the isotope exchange reaction comes to equilibrium, the concentration of OH groups can be calculated. A detailed account of these methods is given in Ref.107.

When the concentration of OH groups has to be inferred from the intensity of the stretching vibration bands of the hydroxyl groups (shifted by hydrogen bond formation) the dependence of A_0 on $\Delta\nu_{OH}^{B}$ must be known. There is substantial evidence[82,89,90,99,100,105] of the existence of a functional relationship between ΔA_0 (where $\Delta A_0 = A_0^{H\text{-bond}} - A_0$) and $\Delta\nu_{OH}^{B}$ for a wide range of acids and bases.

3. The Ion Pair Method

a) *Physicochemical basis of the method.* As was pointed out above, the ion pair method consists in studying the transfer of a proton to the adsorbed base with formation of an ion pair, which can be represented by reactions (V) and (VI) followed by association of the A^- and HB^+ ions. Therefore the heat of protonation of the base on the surface can be described by the expression

$$Q_{IP} = PA^{base} - PA^{acid} - \Delta H_{ass}. \qquad (14)$$

Using the adsorption of pyridine on HNaY zeolite as an example we shall examine the possible contributions of the various terms to the parameter Q_{IP} (according to the data in Ref.108, $Q_{IP} = 170$ kJ $mole^{-1}$). For pyridine PA = 912 kJ $mole^{-1}$ (Table 3), and for the acidic centres of the zeolite the PA found by the weak hydrogen bond method is 1200 kJ $mole^{-1}$. Hence Eqn.(14) gives $-\Delta H_{ass} = 460$ kJ $mole^{-1}$, which is comparable (in order of magnitude) to the PA of the base.

In a series of chemically similar catalysts interacting with the same base we can expect ΔH_{ass} to be almost constant. In this case the difference between the Q_{IP} values for two catalysts will be approximately equal to the difference between PA values of their OH groups.

An approach essentially similar to the above was first discussed in Refs.53 and 109. Direct measurements of Q_{IP} can be made calorimetrically[2], though the type of centre on which the probe molecules are adsorbed cannot be identified without spectroscopic control. We have suggested[108] a method of measuring Q_{IP} for pyridine by analysing the ν_{OH} bands of the surface OH groups (the IPT method). From the change in intensity of the stretching vibrations of the free OH groups the adsorption isobars of pyridine on HNaY zeolite and on zirconium phosphate were measured at 4 mmHg pressure and temperatures between 423 and 723 K. The heat of protonation of pyridine on zeolite was 170 ± 15 kJ $mole^{-1}$, and on zirconium phosphate 65 ± 10 kJ $mole^{-1}$.

Historically, however, the first method used to study the proton-donor properties of solid acids was the indicator method outlined above[4]. Since on a surface the protonated indicator consists of an ion pair with an oxygen anion (rather than, as in a solution, of an ion solvated by solvent molecules) we shall classify this method as one variant of the IP method. The basic propositions of the indicator method are fully described by Benesi[5,110], and his method of visually determining the protonation of the indicator from the change in colour of the system was used by later workers almost without change. We shall only refer to publications containing new view-points or results. Refs.111 and 112 appear to be the first report of an attempt to analyse quantitatively the relationship between the H_0 value of the OH groups on catalyst surfaces and the rate constants of heterogeneous chemical reactions.

At about the same time it was found[113,114] that in some systems (for example, zeolite cracking catalysts and alumina–silicas) the Hammett indicators cannot distinguish between protonic and aprotic centres and give the same colour for both. It was suggested that the acidity of proton-containing surface centres could be determined by using indicators which form carbonium ions on the surface, the strength of the centre being calculated by the function

$$H_R = -\lg a_{H^+} + \lg a_{H_2O} + \lg (f_{R^+}/f_{ROH}) \qquad (15)$$

Similar problems stimulated other workers[115,116] to improve the indicator method by abandoning the visual observation of colour changes, and replacing it by measurements of the diffuse reflectance spectra of the catalyst surface covered with an adsorbed base. The same workers[115,116] were the first to use an indicator adsorbed not from solution in a non-polar solvent but from the gas phase. A more detailed discussion of this approach is given in Ref.117. Both in that work, and in later work[118], the strength of the acid centres was determined from the minimum value of pK_a for the base being protonated, the second term in Eqn.(5) being either ignored without comment or assumed[118] to be close to unity. However, the assumption appears to be incorrect[117], and in general the $[BH^+]/[B]$ term in Eqn.(5) can be quite small, making the H_0 value determined as $H_0 = pK_a^{base}$ much too low and the acidity of the OH groups on the surface much too high. We should stress that equating pK_a for the acid to pK_a for the indicator is legitimate only when the number of molecules of the base B in the system is equal to the number of OH groups, and the latter are 50% ionised. In practice no attempt is made to check whether these conditions apply. The first attempt to allow for the concentration term in Eqn.(5) led to the conclusion[119] that the pK_a scale of the base is not a suitable basis for measuring the acidic properties of the surface.

We have recently described[120,121] the development of an i.r. spectroscopic method of identifying the formation of an ion pair. Its main advantage over methods in the u.v. and the visible region of the spectrum is that the formation of

ion pairs, their adsorption on aprotic centres, and the formation of a hydrogen bond by the B molecules are all readily distinguished by their i.r. spectra, so that in principle the concentrations of BH^+ and B can be measured by analysing the intensities of the ν_{OH} bands and the characteristics of the bands in the spectrum of BH^+. However, in practice the calculation of $[BH^+]/[B]$ from the i.r. spectra is complicated by the lack of reliable data on the extinction coefficients (or on A_0) for the characteristic bands of the various adsorbed forms of the base B.

We should stress that the principles of Benesi's method were not questioned in any of the investigations mentioned above (except Ref.119). Though many of the results obtained made the method appear incorrect (see references quoted by Deeba and Hall[122]) no attempt was made to analyse the discrepancies before the paper[122] drew attention to them. It should not be forgotten that the indicator method of measuring acidity postulates not only constancy of the ratio f_B/f_{BH^+} but also maintenance of the equilibrium $B_{ads} + H^+ \rightleftharpoons BH^+_{ads}$ at all times, and independence of H_0 on the concentration of B. Accurate quantitative work[122] showed that on a surface this equilibrium is not reached. Taking a strong base (n-butylamine) in an amount much smaller than the total number of OH groups on the surface we find that the molecules of the base do not distribute themselves over the surface so as to be protonated by the most acidic centres: they remain on the acidic centres (both strong, and weak) with which they first came into contact. Similar effects occur with other bases. Therefore the amount of base which is protonated depends (among other things) on the physical conditions of the experiment (temperature, flow rate and amount of B, size of pores on the surface, etc.). These effects explain the reported discrepancies[119], and they suggest that the alternative approach to the study of catalyst surfaces should be preferred[4,5,110].

It has been pointed out[122] that the strength of acidic centres could be measured from the heat of desorption of a base (E_d) previously adsorbed on the surface (the adsorption being irreversible at the given temperature). The concentration of centres having different strengths can be estimated from the amounts of irreversibly adsorbed molecules of base B of different basicity. This approach is a natural development of the calorimetric method proposed earlier (see Ref.123, and list of references in Forni's review[3]).

Thus the H_0 values of the acidic centres on the surface obtained by the ion pair method need critical scrutiny. They are unacceptable as a measure of the acid strength of a surface centre. At best they can give an indication of the relative acidity of the centre. Isolated examples[2,118,124] of the successful use of this method can be explained by the fortuitous similarity of the concentrations of acidic centres on the different catalysts, the use of compounds of a given class as probe molecules, and the constancy of the indicator adsorption conditions, the aim of the experiment in every case being not to produce reliable values of H_0 but to assign a given solid acid correctly within a series of similar compounds in order of increasing acid strength.

The shortcomings of the proposed[122] method of determining the acid strength and the number of centres of a given strength include the failure to distinguish between the different adsorption forms of the molecules of the bases B. If the base is adsorbed irreversibly also on the aprotic centres at ordinary temperatures, its desorption from those centres may invalidate the results of the measurement of the heat of desorption from the H-centres. Furthermore, E_d is not so universal a parameter as the PA.

We therefore consider the most promising approach to be a combination of measurements of heat of adsorption (or desorption) and of measurements by i.r. spectroscopy of the number and nature of different compounds formed by the B molecules with the surface centres. Since the relative precision of the measurement of Q by the IPT method is ±10% the method could advantageously be combined with more accurate, purely calorimetric measurements. The advantages of using i.r. spectral methods are even more evident in studies of reaction mechanisms for different bases on catalyst surfaces.

A convenient indication of the formation of ion pairs is obtained by using nitrogen bases (Nos.21-37 in Table 3), because protonated amines and pyridines are easily distinguished from the unprotonated bases by their i.r. spectra. On the other hand, since these bases can also form D–A complexes with L centres (which are invariably present on the surface), and since the i.r. spectra of these complexes[28] are often similar to those of protonated bases, the identification of the formation of ion pairs is only seldom unambiguous. Clear identifications have been made only by using ammonia, pyridine[18,23], and some derivatives of pyridine[121]. The use and the properties of some other probes are discussed in Refs.125–127.

b) *Determination of the concentration of protonic centres.* In studies of protonic centres by the IP method the concentration of the centres can be determined not only from the intensity of the ν_{OH} bands (as discussed above) but also from the intensity of the bands of the BH^+ ions. Hughes and White[28] have measured the A_0 coefficient for the 1540 cm^{-1} band, assigned to the pyridinium ion. By using A_0 values we can determine the concentration of proton centres on zeolites and zeolite-containing catalysts.

The integral absorption coefficients for some absorption bands of 2,6-lutidine adsorbed on protonic centres have been measured[29]. We should note that in practical studies of adsorption all the protonic centres should be filled (if the stoichiometry of the interaction is known). The possibility of departures from the stoichiometric OH : B ratio of 1 : 1 has been demonstrated[33]. In some cases the role of the protonic centres in catalytic reactions can be identified simply by studying the dependence of the intensity of the 1540 cm^{-1} band of adsorbed pyridine on the preparation conditions of catalysts of a given composition or of a series of catalysts of different composition but similar properties [30–32].

4. Method of Calculating the Strength of Protonic Centres on the Scale of the Activation Energy of the Proton Transfer Process

The method proposed[79–81,128] for determining the activation energy of the transfer of the proton (E_a^H) from the acidic centre to the base in the H-complex assumes that the dependence of the potential energy of the system on the O–H distance can be fitted by a Morse function, and that the distribution of vibrational levels can be described in the isolated diatomic molecule approximation. In this case the energy needed for complete removal of the hydrogen from oxygen (i.e. the dissociation energy) is given by the expression

$$D_0 = \frac{\omega_e}{4x} - \frac{\omega_\varepsilon}{2} \qquad (16)$$

where x is the anharmonicity coefficient [$x = (2\omega_{0\to1} - \omega_{0\to2})/2\omega_e$], ω_e is the harmonic frequency ($\omega_e = 3\omega_{0\to1} - \omega_{0\to2}$), and $\omega_{0\to1}$ and $\omega_{0\to2}$ are the observed frequencies of the fundamental i.r. transition and of the first overtone (in the symbols used in Ref.128). It is also assumed that these expressions can be used to determine the dissociation energy of the hydrogen in the -O-H...B complex ($D_{0,\mathrm{eff}}$), and that $D_{0,\mathrm{eff}}$ is the upper limit of E_a^H. The parameter $D_{0,\mathrm{eff}}$ was calculated for several H-complexes of Aerosil with different bases: with bases having PA < 700 kJ mole^{-1} ($\Delta\nu_{OH} \leq 70$ cm^{-1}) the perturbation of the O-H bond is slight and $D_{0,\mathrm{eff}}$ is independent of the strength of the base. At the same time with bases whose PA lies between 700 and 850 kJ mole^{-1} ($\Delta\nu_{OH} \cong$ 200-350 cm^{-1}) $D_{0,\mathrm{eff}}$ was found to decrease with increase of PA. It was shown that varying the base has little effect on ω_e, and it was suggested that ω_e should be treated as a constant, thus allowing $D_{0,\mathrm{eff}}$ to be calculated simply from the correlation between E_a^H and $\Delta\nu_{OH}$. By using the latter approximation the $D_{0,\mathrm{eff}}$ values were obtained for several H-complexes of bases with the OH groups of Aerosil (505 kJ mole^{-1}) and zeolite (545 kJ mole^{-1}), and compared with the activation energies of proton transfer calculated from catalysis data. The activation energy of the deuterium-hydrogen exchange on OH groups is 105-118 kJ mole^{-1}: the calculated value of E_a^H for this reaction is 126-146 kJ mole^{-1}.

Data on the adsorption of various amines and isobutanol have also been compared. In the adsorption of n-butylamine on Aerosil[120] $\Delta\nu_{OH}$ is 1050 cm^{-1} and in the adsorption of pyridine on HNaY zeolite[120] it is 1250 cm^{-1}. The interaction of the alcohol with zeolite[120] shifts ν_{OH} by 1000 cm^{-1}. The calculated values[79-81] of the three paramters lie in the range $E_a^H = 68$-78 kJ mole^{-1}, whereas the experimental values of the activation energy of proton transfer from zeolite are $\leq$8 kJ mole^{-1} for pyridine and 88 kJ mole^{-1} for the alcohol[120]. n-Butylamine is not usually protonated on Aerosil.

Thus calculations by this method for both large ($\geq$1000 cm^{-1}) and small ($\leq$70 cm^{-1}) values of $\Delta\nu_{OH}$ are inconsistent with experiment. For large values of $\Delta\nu_{OH}$ this discrepancy may be due to the inadequacy of the diatomic molecule approximation when applied to strong H-complexes. In the intermediate range of $\Delta\nu_{OH}$ values the method gives reasonable values of E_a^H.

In conclusion we note that in spite of the useful information on the ability of a catalyst to interact with a stated substance implicit in a knowledge of E_a^H this quantity is largely determined by the properties of the adsorbate and cannot be used as an independent measure of the acidic properties of the surface. Of course, solid acids can be arranged in order of increasing proton-donating power in terms of their E_a^H values for the same base B. However, the data needed for this assignment are not available, and in any case such a sequence could make the base B a model compound for acids which (for various reasons) do not catalyse its reactions, thus depriving the criterion of its main advantage. Lastly, of course, the mechanism of the reaction must be known before E_a^H can be meaningfully used.

For these reasons we consider the thermodynamic methods to be the only acceptable approach to the solution of these problems, since they allow the acidic properties of the surface to be calculated in terms of a constant which characterises the substance. We believe this information to be an essential basis of any mechanism used to explain the effect of the composition and structure of catalysts on their surface properties. The kinetic approach can also be useful, but only at the stage of detailed study of the mechanism of a specified catalytic reaction.

IV. METHODS OF STUDYING BASIC CENTRES

1. General Formulation of the Problem

The interaction of acids with basic centres (like the interaction of bases with acidic centres) probably takes place in two steps:

$$HX + B_s \to B_s \ldots HX \to B_s H^+ \ldots \bar{X} \qquad \text{(VII)}$$

By analogy with the determination of the acidic properties, the basicity of a surface can be studied by the H-bond method and by the IP method. It is again convenient to characterise the strength of the centres through their PA, and to use the pK_a values only within defined groups of acids.

Thus all the statements made in the above discussion of acidic centres are equally valid (*mutatis mutandis*) in the study of the basicity of surfaces. A suitable choice of probe molecule is extremely important in the development of accurate methods of studying the base properties of catalyst surfaces. The use of carboxylic acids and phenols is complicated by a number of factors. Firstly, the acids and phenols have fairly well developed acceptor properties (pK_a between -7 and -4,[77] PA = 750-800 kJ mole^{-1} [59]) which allow them to form D-A complexes with aprotic centres. Secondly, the most commonly used adsorbents and catalysts have surface OH groups whose i.r. absorption bands overlap the ν_{OH} bands of the acids and phenols which are sensitive to the interaction with B_S. Thirdly, if strong protonic centres are present on the surface they can cause the formation of surface esters[129], with spectral characeristics similar to those of the surface complexes of B_S with acids or phenols.

The proton-acceptor properties of surfaces can be assessed by using NH acids (in particular, pyrrole[130]), which form hydrogen bonds with the basic centres on the surface. However, the high proton affinity of the pyrrole nitrogen can cause complications (interaction of the nitrogen with the OH groups).

We have shown[131] that CH acids (in particular, $CDCl_3$) can be used as probes. The method relies on the ability of $CDCl_3$ to form H-complexes with bases[82,132]. The main advantage of this method is that hydrocarbons and their halogen derivatives are weak bases, and their interaction with aprotic or protonic surface centres is negligible. Furthermore, the νCH (or νCD) bands do not overlap the bands of the surface OH groups, and therefore the complexes of the probes with the basic centres are easily indexed.

Thus only the H-bond method has been widely used so far, and mainly in experiments with $CDCl_3$. The ion pair method has not been developed towards the study of basic centres. On the whole the search for suitable probes and the development of new methods of investigation present more serious difficulties in the study of basic centres than for protonic or aprotic (acid) centres.

2. Physicochemical Basis of the Method

By using published data[133,134] we have established[131] a correlation between the pK_a values of bases and $\Delta\nu_{CD}$ for deutero-chloroform. The relationship has been used as a calibration plot to determine pK_a for basic surface centres, and it was found that the strength of basic centres in oxides increases in the series γ-Al_2O_3 < MgO $\cong$ BeO < CaO. At least two types of centre were shown to be present on the surface of these oxides: weak basic centres, possibly consisting of OH groups, and strong centres, thought to be associated

with the presence of a bridging oxygen atom M–O–M. By using the pK_a scale the basic properties of Fe/Sb catalyst were investigated[26], and two types of centre were again identified.

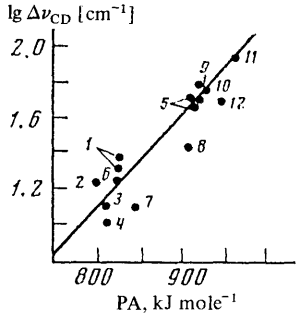

Figure 9. Dependence of $\lg \Delta\nu_{CD}$ ($\Delta\nu_{CD} = \nu_{CD} - \nu_{CD}^{gas}$) for deutero-chloroform on the PA of bases forming a hydrogen bond to it. The data[60,70,71,133–135] are for: *1*) diethyl ether, *2*) dioxan, *3*) ethyl acetate, *4*) acetone, *5*) pyridine, *6*) tetrahydrofuran, *7*) ammonia, *8*) methylamine, *9*) dimethylamine, *10*) trimethylamine, *11*) triethylamine, *12*) 2,6-dimethylpyridine. The points *1*, *5*, and *9* are typical examples of the scatter of published $\Delta\nu_{CD}$ data.

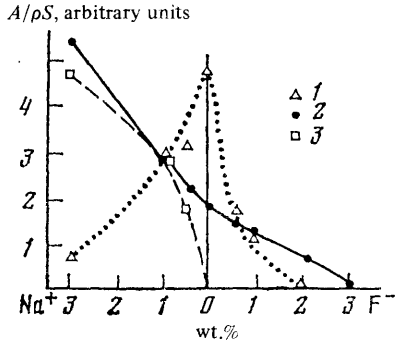

Figure 10. Variation of the relative concentrations ($A/\rho.S$) of basic centres on γ-Al_2O_3 samples modified by Na^+ or F^- ions for different PA values: *1*) 897, *2*) 810, *3*) 927 kJ mole^{-1}.

An attempt to extend the observed correlation[131] between the $\Delta\nu_{CD}$ values and the pK_a of the bases to $\Delta\nu_{CD}$ data from Ref.135 showed that methylamine and ammonia (i.e. bases from groups III and IV) cannot be included in the correlation. However, the data can all be included in a unified relationship if $\Delta\nu_{CD}$ is plotted against the PA of the base. The dependence (Fig.9) is described by the logarithmic equation

$$\lg \Delta\nu_{CD} = 0.0057\,PA - 3.54 \qquad (17)$$

which can be used to determine the PA of the basic centres. The deviation of the $\Delta\nu_{CD}$ values from the correlation curve is less than 15 cm^{-1}.

3. Determination of the Concentration of Basic Centres

Absolute integral intensity data for the $\Delta\nu_{CD}$ bands of adsorbed deutero-chloroform are not available. Therefore, by using the apparent integral intensity of the ν_{CD} band normalised to $\rho = 1$ we can only determine relative concentrations of basic centres of a given strength (i.e. centres having the same ν_{CD} frequency). This simple approach can be very useful, for example in studying the effect of treating Al_2O_3 catalysts with acids or alkalis. Plots of the intensity of the ν_{CD} bands in the spectrum of adsorbed $CDCl_3$ against the type of modifying additive are shown in Fig.10: we note that the addition of Na^+ increases the concentration of basic centres with a PA = 810 kJ mole^{-1}, while centres with PA = 897 kJ mole^{-1} disappear, and new centres with PA = 927 kJ mole^{-1} are created. The addition of F^- lowers the concentration of both strong and weak basic centres, though the effect on the former (PA = 897 kJ mole^{-1}) is more marked. No other method of obtaining this type of detailed information on the properties of basic centres exists.

V. CONCLUSIONS

The results discussed in this review show that the i.r. spectroscopy of adsorbed molecules is a revealing method of studying quantitatively the acidic and the basic properties of surfaces. By using the method with an appropriate choice of probe molecules, and by establishing the functional relationships between the normal vibration frequencies which are sensitive to the interaction with the surface centres and the thermodynamic characteristics of this interaction, we can determine the strength of the protonic, aprotic, and basic centres. The concentrations of acidic centres can be determined also by combined i.r. and adsorption measurements.

According to our experience, the following sequence of operations can be recommended for rating the acid–base properties of substances.

1) Carry out the adsorption of benzonitrile, and from the position of ν_{CN} in the absorption spectrum determine the number and type of cations acting as aprotic centres.

2) Carry out the low-temperature adsorption of CO, and measure the strength of the aprotic centres on a heat of adsorption scale. Using published data on A_0 for ν_{CO} calculate the number of aprotic centres.

3) Determine the number of different types of protonic centre from the i.r. absorption spectra of the OH groups on the surface of the sample.

4) Carry out the adsorption of a suitable weak base, and by using Eqn.(13) calculate the PA of the protonic centre. Carry out the adsorption of pyridine at different temperatures and from the intensity of the 1540 cm^{-1} band determine the number of H-centres (if PA $\leq$ 1300 kJ mole^{-1}). From the temperature dependence of the band intensity find the heat of absorption and the PA for the H-centres.

5) Carry out the adsorption of $CDCl_3$. Determine the number of types of basic centre, and calculate their PA values from $\Delta\nu_{CD}$. From the integral intensity of the ν_{CD} bands determine the relative numbers of different basic centres.

The further development of methods for the quantitative characterisation of the acid–base properties of surfaces should, in our view, proceed along the following directions: firstly, measuring the integral absorption coefficients for

the characteristic bands of the most commonly used probe molecules, and also for the individual stretching vibration bands of different types of OH group; secondly, extending the range of probe molecules which can be used to identify different types of centre; thirdly, establishing the correlations between the acid–base and the catalytic properties of catalyst surfaces (thus stimulating the practical application of these methods in heterogeneous catalysis).

Hydrochlorination of Unsaturated Compounds

G.B.Sergeev, V.V.Smirnov, and T.N.Rostovshchikova

The mechanism of the hydrochlorination of unsaturated compounds in condensed media is considered on the basis of modern data concerning the kinetics and products of the reaction and also the intermolecular interactions in the reaction system. It is shown that, like other addition processes, hydrochlorination can be carried out in non-polar media at low temperatures without the intermediate formation of ionic species, i.e. via a molecular mechanism. The factors which determine the competition between the ionic and molecular process mechanisms are analysed in detail.
The bibliography includes 184 references.

I. INTRODUCTION

The study of the addition of hydrogen halides to multiple bonds promoted the formulation of the fundamental concepts of modern chemistry. On the basis of the investigation of these reactions, ideas were developed concerning the involvement of carbonium ions and π-complexes in chemical reactions and have been used to formulate the familiar Markovnikov rule.

Hydrochlorination processes are of great theoretical and practical importance. The catalytic addition of hydrogen chloride to unsaturated compounds constitutes the basis of the large-scale syntheses of organochlorine products: ethyl chloride, vinyl chloride, methylchloroform, etc. Despite the large number of studies in this field, the process mechanism has been investigated inadequately. This is partly associated with the difficulty of obtaining reproducible kinetic data due to the catalytic influence of microimpurities on the rate and mechanism of the reaction.

The addition of hydrogen chloride to multiple bonds is usually considered mainly from the standpoint of an ionic mechanism[1,2]. Ideas concerning the ionic mechanism of the addition of halogen and hydrogen halides were formulated in the 1920's and have been developing vigorously up to the present time. On the other hand, many experimental facts do not fit within the framework of the traditional ideas. The possibility of hydrohalogenation without the preliminary ionisation of the reactants, i.e. via a molecular mechanism, has been noted by Shilov[3]. The high rate of addition at low temperatures in non-polar solvents and in the solid phase is consistent with the molecular mechanism[4]. Evidence in favour of the molecular mechanism of hydrohalogenation has been obtained in recent years in a number of investigations[5-7].

Thus the traditional ideas about the ionic mechanism of the addition of hydrogen chloride to olefins are of limited applicability. There is no doubt that the ideas formulated concerning the mechanism of electrophilic addition reactions, including hydrochlorination, will require re-examination and revision.

The mechanism of the hydrochlorination of olefins in the condensed phase is considered in the present review on the basis of modern data for the kinetics and products of reaction and also the intermolecular interactions in the hydrogen chloride–unsaturated compound–catalyst–solvent systems. The factors determining the competition between the ionic and molecular hydrochlorination mechanisms are analysed in detail. As regards the gas-phase process, only data necessary for the discussion of the general aspects of hydrochlorination are examined. Among unsaturated compounds, attention has been concentrated on olefins.

II. PRODUCTS OF THE HYDROCHLORINATION OF UNSATURATED COMPOUNDS

1. Addition to Asymmetric Compounds

In the liquid phase the majority of unsaturated compounds slowly combine with hydrogen chloride. In the presence of catalysts, hydrochlorination takes place at a high rate at room and lower temperatures[8-10]. The most reactive olefins—3,3-dimethylbut-2-ene, 2-methylbut-2-ene,[11] and isobutene[12]—readily react with hydrogen chloride in the solid phase at low temperatures. The mode of addition to asymmetric compounds is determined by the Markovnikov rule in the absence of radical initiators: "the halogen adds to the least hydrogenated carbon atom, i.e. the atom subject to the greatest extent to the influence of other carbon moieties".[13] This rule holds in the gas[14] and solid[12] phases. Some examples of the validity of the Markovnikov rule in the liquid phase are presented below[15-22]:

$$CH_3CH=CH_2 \xrightarrow{HCl} CH_3CHClCH_3 ;$$
$$(CH_3)_2C=CH_2 \rightarrow (CH_3)_3CCl ;$$
$$CH_3CX=CH_2 \rightarrow CH_3CXClCH_3 ;$$
$$CH_2=CHCl \rightarrow CH_3CHCl_2 ;$$
$$(CH_3)_2C=CHCH_3 \rightarrow (CH_3)_2CClC_2H_5 ;$$
$$CH_3C(C_2H_5)=CH_2 \rightarrow (CH_3)_2CClC_2H_5 ;$$
$$C_6H_5CH=C(CH_3)_2 \rightarrow C_6H_5CH_2CCl(CH_3)_2 ;$$
$$CH_3C\equiv CH \rightarrow CH_3CCl=CH_2 \rightarrow CH_3CCl_2CH_3 ;$$
$$CH_3CH=CHCH=CH_2 \xrightarrow{DCl} \begin{cases} \rightarrow CH_3CH=CHCHClCH_2D ; \\ \rightarrow CH_3CHClCH=CHCH_2D . \end{cases}$$

If there are two different alkyl substituents at the double bond, then both possible addition products are formed in approximately equal amounts[23]. If one of the substituents is aromatic, then chlorine adds to the carbon atom linked to the aromatic ring. Thus, $C_6H_5CHClCH_2CH_3$ is obtained from $C_6H_2CH=CHCH_3$ [24] and $C_6H_5CCl=CHCH_3$ is obtained from $C_6H_5C\equiv CCH_3$.[25]

The addition of hydrogen halides to compounds containing simultaneously a double and a triple bond has been examined[26]. As a rule, the triple bond reacts more readily than the double bond. In the presence of a deficiency of hydrogen halide, vinylacetylene and allylacetylene give rise exclusively to products of addition to the triple bond.

Addition contrary to the Markovnikov rule (anomalous addition) is not characteristic of hydrogen chloride. The photochemical hydrochlorination of dodec-1-ene yields 10–30% of the anomalous addition product and 70–90% of the normal product[27]. 1-Chloropropane is formed as a side product in the high-temperature hydrochlorination of propene[28]. Small amounts of anomalous products have been obtained in the presence of peroxides[16]. The efficiency of the action of peroxides depends on the choice of solvent, the reactant ratio, and the nature of the unsaturated compound[29]. The yield of the anomalous addition products increases after the introduction of electron-accepting substituents into the molecule. Thus the contribution of the anomalous process is 12% for propene and as much as 29% for 3-chloropropene[30]. Addition contrary to the Markovnikov rule is associated with the involvement of radicals in the reaction. In contrast to the analogous reactions of hydrogen bromide, a quantitative yield is not observed in hydrochlorination.

Anomalous addition to acetylenic hydrocarbons under the influence of catalysts is attributed to the participation of organometallic compounds[31,32].

The Markovnikov rule formally breaks down in the hydrochlorination of 3,3,3-trifluoropropene in the presence of aluminium halides[33,34]. The formation of $CF_3CH_2CH_2Cl$ is associated with the high electronegativity of the CF_3 group and agrees with the modern interpretation of the Markovnikov rule[35].

The interaction of equimolar amounts of hydrogen chloride with diene compounds leads to the formation of 1,2- and 1,4-addition products. Under mild conditions (at low temperatures), 1,2-addition predominates in the absence of catalysts. Thus at 193 K but-1,3-diene reacts with HCl to form about 80% of the 1,2-addition product[36]. The hydrochlorination of isoprene in nitromethane at 198 K leads to the exclusive formation of 3-chloro-3-methylbut-1-ene.[19] 3-Chloro-1-phenylbut-1-ene has been obtained from 1-phenylbutadiene[37]. The formation of 1,4-addition products is promoted by an increase of temperature, an increase of the polarity of the medium, and the addition of water[22,38]. The reactions of dienes with hydrochloric acid in aqueous solutions lead to 1,4-addition[39–42]. In the hydrochlorination of dienes, the 1,2-addition products are probably formed initially and subsequently isomerise to the thermodynamically more stable 1,4-addition products[43,44].

The hydrochlorination of allene and many of its derivatives takes place in accordance with the Markovnikov rule[45,46]:

$$CH_2{=}C{=}CH_2 \xrightarrow{HCl} CH_2{=}CClCH_3 \xrightarrow{HCl} (CH_3)_2CCl_2 .$$

An exception is phenylallene[47] and allene homologues having two substituents at the double bond[46], a characteristic feature of which is protonation at the central carbon atom. A characteristic feature of allene is the formation of cyclic compounds together with the usual addition products[48,49]. Cyclodimerisation in the interaction with hydrogen chloride is characteristic also of certain acetylene derivatives[50–52].

Hydrochlorination may be accompanied by a rearrangement of the carbon chain of the organic compound in the intermediate stages of the process where the structure of the addition products does not correspond to the structure of the initial unsaturated compound. For example, the hydrochlorination of *cis*- and *trans*-1-phenylbuta-1,3-dienes yields a single product—*trans*-1-methyl-3-phenylallyl chloride[53].

The gas-phase hydrochlorination of but-1-ene in the presence of the $CaCl_2$ catalyst leads to the formation of t-butyl chloride. But-2-ene gives rise to the non-rearranged product—2-chlorobutane—under the same conditions[54].

The rearrangement of an unbranched olefin is a rare phenomenon. On the other hand, the products of the hydrochlorination of branched olefins containing a tertiary carbon atom in the α-position relative to the double bond frequently do not correspond to the structure of the initial compound. For example, two products of the reaction via the mechanism[55]

$$H_3C\diagdown\!\!\diagup CHCH{=}CH_2 \xrightarrow{HCl} \begin{cases} \rightarrow (CH_3)_2CHCHClCH_3 & (33–40\%)\ , \\ \rightarrow CH_3CH_2C(CH_3)ClCH_3 & (67–60\%)\ , \end{cases}$$

were obtained in the hydrochlorination of 3-methylbut-1-ene. A rearrangement of the carbon chain occurs in the hydrochlorination of 3,3-dimethylbut-1-ene[29,56]. The ratio of the normal and rearranged chlorides is approximately 1:1 in a non-polar medium and changes to 1:6 on passing to the polar nitromethane[55]. The hydrochlorination of chlorine-containing olefins is also accompanied by rearrangements[57]:

$$CH_2{=}CClC(CH_3)_3 \xrightarrow{HCl} \begin{cases} \rightarrow CH_3CCl_2C(CH_3)_3\ , \\ \rightarrow (CH_3)_2CClCCl(CH_3)_2\ , \\ \rightarrow ClCH_2CH(CH_3)CCl(CH_3)_2\ . \end{cases}$$

The mechanism of the rearrangement of the carbon chain is examined below (Section V). The literature data[55–57] show that the rearrangement takes place at intermediate stages of the reaction and is not associated with the isomerisation of the final product. Rearrangements of the carbon skeleton are also characteristic of the hydrochlorination of norbornene and related compounds[58–60].

2. Stereochemistry of the Addition of Hydrogen Chloride

The stereochemistry of the hydrochlorination products is determined by the structure of the unsaturated compound and the reaction conditions. *trans*-Addition is characteristic of acetylene and its aliphatic derivatives[61–64]. Table 1 shows that there is no trans-stereospecificity in the hydrochlorination of tolane and other arylacetylenes. The yield of the *cis*-product increases steadily with increase of the bulk of the alkyl substituent. As the solvating capacity of the solvent becomes more pronounced, the ratio of the *cis*- and *trans*-additions in the catalytic hydrochlorination of tolane approaches 1.

Data on the stereochemistry of the products of the hydrochlorination of olefins are summarised in Table 2. The characteristic features of the process stereochemistry are difficult to trace clearly. A classification of olefins on the basis of the stereochemistry of their hydrohalogenation has been proposed in a review[69], where compounds with a double bond have been divided into four groups: (1) arenes and dienes yielding *cis*-addition products; (2) cyclic olefins and olefins without conjugated bonds, for which *trans*-addition is a characteristic process; (3) bicyclic olefins forming *cis*-products; (4) α,β-unsaturated carbonyl compounds, which combine with hydrogen halides exclusively in the *trans*-position. A deficiency of this classification consists in the fact that no account has been taken of the influence of conditions on the stereochemistry of the reaction which is extremely important, as can be seen from Table 2.

Table 2. Stereochemistry of the hydrochlorination of olefins.

Olefin	Solvent	ε	*T*, K	Yield, %			Refs.
				cis	*trans*	other products	
1-Methylcyclopentene	CH_3NO_2	38.6	298	4	96	0	[55]

1,2-Dimethylcyclohexene	sulpholane	44	298	53	47	0	[72]
1,2-Dimethylcyclohexene	CH_3OH	32.6	298	9—30	70—91	0	[72]
$\Delta^{9,10}$-Octalin	CH_2Cl_2	8.9	195	54	46	0	[74]
$\Delta^{9,10}$-Octalin	CH_2Cl_2	8.9	177	61	39	0	[73]
$\Delta^{9,10}$-Octalin	HCl (liq.)	9.1	177	64	36	0	[73]
$\Delta^{9,10}$-Octalin	$(C_2H_5)_2O$	4.2	273	2	98	0	[73]
$\Delta^{9,10}$-Octalin	aq.HCl	—	273	6	94	0	[74]
Indene	CH_2Cl_2, C_5H_{12}	—	195	50	50	0	[75]
Acenaphthene	CH_2Cl_2	8.9	273	85	15	0	[76]
Norbornene	various	—	195	49	1	50	[58]
Apobornylene	various	—	195	90	0	10	[60]
Bornylene	various	—	195	100	0	0	[59]

The data in Table 2 agree with the above classification[69] for norbornene and other bicyclic compounds, for which only *cis*-addition does indeed occur. For indene, acenaphthalene, norbornene, and related compounds in the absence of steric hindrance in weakly polar and non-polar media, the preferential formation of the *cis*-product has been observed. The exclusive formation of the *trans*-product has not been observed for cyclohexene and cyclopentene homologues[72]. The direction of the process varies as a function of the choice of the solvent. In the case of 1,2-dimethylcyclohexene an increase of the polarity and ionising capacity of the solvent promotes *cis*-addition. It has so far been impossible to formulate a general rule governing the influence of the medium on the stereochemistry of the hydrochlorination. Treatment of the results is hindered by the influence of steric factors on addition to systems containing the cyclopentene or cyclohexene ring.

Additional possibilities for the formation of stereoisomers arise in the reactions of dienes. Thus 1,4-addition to conjugated dienes can lead to *cis*- or *trans*-alk-2-enes. The hydrochlorination of 2,3-dichlorobuta-1,3-diene[77] and *trans*-penta-1,3-diene[22] results in the formation of mainly the *trans*-isomers. Both possible products have been noted in the hydrochlorination of chloroprene[78].

Hydrochlorination at room and elevated temperature, particularly in the presence of catalysts, is frequently complicated by the polymerisation[30,36,79–83] and isomerisation[45,46,72] of the olefins as well as the decomposition of the addition products[10,84] occurring under the influence of the same catalysts. The addition of hydrogen chloride in hydroxylated solvents competes with the addition of the solvent[56,57,71,85,86].

III. KINETICS OF HYDROCHLORINATION

1. Kinetics of the Gas-Phase Reaction

Non-catalytic hydrochlorination in the gas phase takes place slowly. The reaction of isobutene with hydrogen chloride at 300–500 K is described by a second-order kinetic equation, whose rate constant can be represented in the following form[87]:

$$k_2 = 10^8 \exp(-28800/RT)\ (\mathrm{dm^3\ mol^{-1}\ s^{-1}}).$$

At high temperatures the equilibrium is displaced towards the starting materials and the kinetic parameters of the majority of the hydrochlorination processes have been calculated from data for the molecular elimination of HCl from the corresponding alkyl chlorides. The results of such calculations are presented below[14]:

Olefin	C_2H_4	C_3H_6	iso-C_4H_8
E, kJ mol^{-1}	167	141	106
lg$A$ (dm^3 mol^{-1} s^{-1})	8.8	7.8	6.1

The reactivity of olefins increases rapidly with increase of the number of substituents at the double bond. The activation energy for addition contrary to the Markovnikov rule is higher by at least 30 kJ mol^{-1} than for normal addition[14].

Extrapolation of the elimination data to room and lower temperatures leads to the conclusion that the rate of the gas-phase hydrochlorination of the majority of olefins should be negligible under such conditions. However, recent studies have shown[88,89] that the hydrochlorination of many olefins proceeds at an appreciable rate at 300 K and below and that the kinetic process parameters are different from those found earlier[14,87]. The hydrochlorination of isobutene is accelerated on passing from 373 K to lower temperatures[88]. The rate of the process is higher by a factor of 10^9 than might have been expected on the basis of data for the high-temperature process. The gas-phase hydrochlorination of allene is described by a second-order equation and takes place with zero activation energy[45]. The following equation has been obtained for the low-temperature hydrochlorination of propene in the gas phase[89]:

$$v = k_4 [C_3H_6] [HCl]^3 .$$

A negative temperature coefficient was observed in the reaction: the rate of the reaction at 293 K is three times higher than at 373 K. Traces of water, nitrogen oxides, and the surface of the vessel have a catalytic influence on the reaction; quantitative data have not been obtained for the catalytic process.

The data for the reaction kinetics permit the conclusion that in the gas phase the hydrochlorination takes place via two pathways. At high temperatures a bimolecular reaction with a high activation energy takes place. At temperatures below 373 K another pathway predominates, for which the

effective activation energies are negative or close to zero and whose rate is described by a second-order or a higher-order equation.

2. Kinetics of the Non-catalytic Reaction in the Liquid Phase

The kinetic equation for the liquid-phase hydrochlorination depends on the solvent selected. In non-polar solvents the kinetics are complex. For example, the hydrochlorination of isobutene is approximately described by the equation[90]

$$v = k_4 [C_4H_8] [HCl]^3 \ .$$

The rate of the process at 273 K is higher than at 195 K. However, it has been noted that preliminary cooling of the reaction mixture to 195 or 77 K leads to an increase of the degree of reaction on subsequent heating to 273 K. A negative temperature coefficient has been observed in the hydrochlorination of 1-methyl-2-methylenenorbornene in pentane[91]. Overall, the hydrochlorination kinetics in polar media have been inadequately investigated.

An increase of the polarity of the solvent leads in a number of instances to an increase in the rate of hydrochlorination. For example, on passing from pentane to methylene chloride, the time required for the quantitative addition of HCl to norbornene is considerably reduced[92]. Dilution of acetic acid with cyclohexane retards the hydrochlorination of 1-phenylpropyne[66]. Instances are known where an increase of the dielectric constant of the solvent ε has a weak influence on the rate of hydrochlorination. Thus in pentane and methylene chloride a specific degree of hydrochlorination of acenaphthene is attained during the same period[76]. The rate of hydrochlorination of a number of dienes depends little on the dielectric constant[93]. The retardation of hydrochlorination is sometimes observed on passing to more polar media. The rate of hydrochlorination of hex-3-ene and cyclohexene diminishes in the following sequence of solvents: heptane > xylene > nitrobenzene > ether[94]. The authors[94] attribute this influence of the medium to the electron-donating capacity of the solvents and specific solvation and not to the dielectric constant of the solvent.

The kinetic equation for hydrochlorination in polar media can be represented in the following form:

$$v = k_2 [RH] [HCl] + k_3 [RH] [HCl]^2 \ . \qquad (1)$$

The ratio of the two terms of Eqn.(1) is determined by the nature of the solvent. In highly polar solvents without hydroxy-groups such as nitromethane, the hydrochlorination of various olefins is described by an equation of third order overall[19,55,95]. The third order is characteristic of the hydrochlorination of isoprene in the absence of a third component[96]. In acetic acid both terms of Eqn.(1) are significant. The third and higher orders have been observed in the hydrochlorination of 1-phenylpropyne[66] and hex-3-yne[56]. In the case of olefins in acetic acid a termolecular hydrochlorination process competes with the bimolecular reaction. The interpretation of the reaction kinetics in acetic acid is hindered by the inadequate accuracy of the kinetic data[85]. The most reliable results appear to be those of the studies of Okuyama and co-workers[47,53], where the kinetics of the hydrochlorination of dienes were investigated over a wide range of hydrogen chloride concentrations. A change in the kinetic equation for the reaction with increase of the HCl concentration was observed. For phenylallene, the reaction is described by an equation of second order overall at an HCl concentration of 0.1–0.25 M and of third order at 0.64–1.3 M. Hydrochlorination in acetic acid is accelerated in the presence of salts containing the Cl^- anion[56,85].

The hydrochlorination of propene in organochlorine solvents is described by a second-order equation, of first order with respect to each reactant[97]. In the analysis of the kinetic equations for hydrochlorination in organochlorine solvents, it is necessary to take into account the possibility of the self-association of hydrogen chloride[98].

Table 3. Kinetic parameters of liquid-phase hydrochlorination.

Hydrocarbon	Solvent	n*	$-\Delta H$, kJ × × mol^{-1}	$-\Delta S$, J × × mole^{-1} K^{-1}	Refs.
Propene	$C_2H_2Cl_4$	2	39	162	[97]
Propene	$C_2H_3Cl_3$	2	25	229	[97]
Propene	$C_2H_4Cl_2$	2	27	213	[97]
Propene	$C_3H_6Cl_2$	2	43	160	[97]
Hex-3-yne	CH_3COOH	3.5	96	84	[56]
Hex-3-yne	$(CH_3)_4NCl+CH_3COOH$	1	60	138	[56]
Phenylallene	CH_3COOH	3	81	53	[47]
1-Phenylbuta-1,2-diene	CH_3COOH	3	74	69	[53]
cis-1-Phenylbuta-1,3-diene	CH_3COOH	3	69	22	[53]
trans-1-Phenylbuta-1,3-diene	CH_3COOH	3	89	47	[53]

*Here n is the overall reaction order.

The overall order of certain liquid-phase hydrochlorination reactions and their activation parameters are listed in Table 3. The kinetic data make it possible to identify the main types of non-catalytic hydrochlorination in the liquid phase. The processes proceed at a low rate in non-polar solvents, are described by high-order equations, and can be accelerated at low temperatures. The kinetics of hydrochlorination in non-polar media resemble those of the low-temperature gas-phase reaction. In a polar solvent the hydrochlorination process proceeds via two pathways described by second- and third-order equations. The activation energies are in this instance 25–100 kJ mol^{-1}. The relative contributions of the processes depend on the nature of the solvent and the reactants.

The reactions of concentrated hydrochloric acid, in which the main bulk of hydrogen chloride is dissociated, must be considered separately. For example, the order of the reaction of cyclohexene and methylcyclohexenes with respect to HCl is first and that with respect to the olefin is first or zero. The observed activation energies are 32–76 kJ mol^{-1}.[99] Activation energies of 4 and 10 kJ mol^{-1} have been obtained for the 1,2- and 1,4-addition respectively in the hydrochlorination of isoprene in hydrochloric acid[42].

3. Kinetics of Catalytic Hydrochlorination

Hydrochlorination is catalysed by various substances. The simplest catalyst is water. Its catalytic action has been observed in the hydrochlorination of isoprene[38], isobutene[90], and dicyclopentadiene[100]. The acceleration of the addition and the increase of the yield of the *trans*-product in the presence of water have been noted for a series of reactions in acetic acid[72,85,101]. A slight acceleration of the hydrochlorination of 3,3-dimethylbut-1-ene has been observed after the addition of water to a concentration of 0.6 M, while a further increase of its concentration to 2.5 M retards the reaction[56]. No kinetic data are available for the influence of water on the rate of hydrochlorination.

Metal halides are the most effective hydrochlorination catalysts. In the presence of the halide MX_n, the kinetic equation for hydrochlorination usually assumes the form

$$v = k_3 [RH] [HCl] [MX_n] \quad . \qquad (2)$$

It describes satisfactorily the kinetics of the hydrochlorination of ethylene in nitrobenzene[102], of vinyl chloride and the isomeric 1,2-dichloroethylenes in the presence of $AlCl_3$,[103] of propene in the presence of $FeCl_3$,[104] and of styrene in the presence of $SnCl_4$.[105] A decrease of the reaction order with respect to the olefin in the presence of an excess of the latter has sometimes been observed[104]. A decrease of the reaction order with respect to the catalyst with increase of the $SnCl_4$ concentration above 0.04 M has been noted in the hydrochlorination of styrene[105].

Overall orders in excess of the third are rarely encountered for the catalytic process. An overall fourth order, second with respect to the olefin, has been noted for the catalytic hydrochlorination of vinyl chloride under the influence of $FeCl_3$.[106] An increase of the order with respect to the catalyst occurs in the hydrochlorination of ethylene in the presence of $AlCl_3$ in organochlorine solvents[104] and of acetylene in the presence of CuCl in aqueous solution[107].

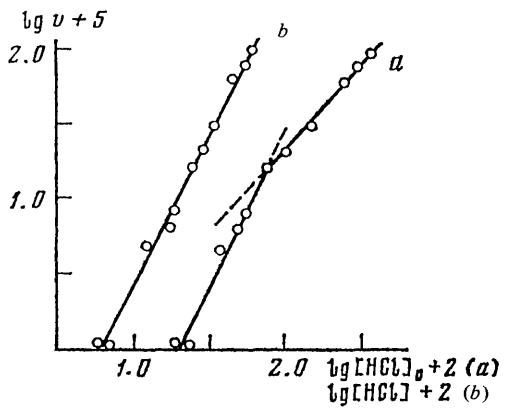

Figure 1. Dependence of the logarithm of the initial rate of hydrochlorination of cyclohexene in the presence of $SnCl_4$ in hexane at 183 K on the logarithm of the initial concentration of hydrogen chloride $[HCl]_0$ (*a*) or on the logarithm of the concentration of "free" hydrogen chloride [HCl] (*b*).[108,109]

The catalytic hydrochlorination of cyclohexene in non-polar and weakly polar media has been investigated taking into account complex formation in the system[6,108,109]. It is seen from Fig. 1*a* that the kinetics of the reaction with a variable order with respect to hydrogen chloride are described satisfactorily by the equation for a fourth-order reaction:

$$v = k_4 [C_6H_{10}] [HCl]^3 [SnCl_4] \quad , \qquad (3)$$

where [HCl] is the concentration of hydrogen chloride not bound in associated species, which can be calculated from the material balance equation

$$[HCl]_0 = [HCl] + 2K_{(HCl)_2} [HCl]^2 + K_{C_6H_{10}\cdot HCl} [C_6H_{10}] [HCl] + K_{SnCl_4\cdot HCl} [SnCl_4] [HCl] .$$

The $\lg v - \lg [HCl]$ relation (Fig. 1*b*) does not have a break and the slope of the straight line is 2. At low temperatures and high HCl concentrations, where $[HCl]^2 = [HCl]_0/2K_{(HCl)_2}$, Eqn. (3) becomes identical with the kinetic equation for a third-order reaction:

$$v = k_4/2K_{(HCl)_2} [C_6H_{10}] [HCl]_0 [SnCl_4] = k_3 [C_6H_{10}] [HCl]_0 [SnCl_4] .$$

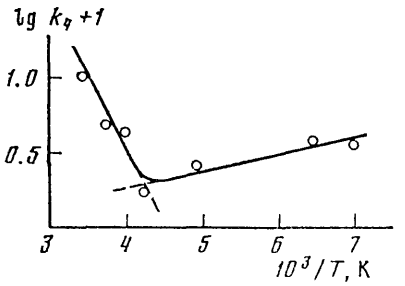

Figure 2. Dependence of the logarithm of the rate constant k_4 for the hydrochlorination of cyclohexene in the presence of $SnCl_4$ in hexane on the reciprocal of temperature[109].

Table 4. Activation energies for the liquid-phase catalytic hydrochlorination.

Hydrocarbon	Solvent	Catalyst	*E*, kJ mol^{-1}	Refs.
Ethylene	$C_6H_5NO_2$	$AlCl_3$	70	[102]
Acetylene	H_2O, NH_4Cl	CuCl	42	[107]
Propene	$C_2H_2Cl_4$	$FeCl_3$	40	[104]
Vinyl chloride	$C_2H_2Cl_4$	$AlCl_3$	56	[106]
Vinyl chloride	$C_2H_2Cl_4$	$FeCl_3$	88	[106]
cis-Dichloroethylene	$C_2H_2Cl_4$	$AlCl_3$	73	[106]
trans-Dichloroethylene	$C_2H_2Cl_4$	$AlCl_3$	84	[106]
Styrene	CCl_4	$SnCl_4$	39	[105]
Cyclohexene	C_6H_{14}	$SnCl_4$	18 *	[109]
Cyclohexene	C_6H_{14}	$SnCl_4$	0 **	[109]
Cyclohexene	CCl_4	$SnCl_4$	0	[109]
Cyclohexene	CH_2Cl_2	$SnCl_4$	14	[109]
Cyclohexene	CH_2Cl_2—CCl_4	$SnCl_4$	10	[109]

*In the temperature range 233–293 K.
**In the temperature range 143–203 K.

On passing from hexane to methylene chloride, the reaction rate increases slightly and at 183 K is almost independent of the dielectric constant of the medium.

The temperature variation of the reaction rate constant k_4 is illustrated in Fig. 2 in terms of the variables of the Arrhenius equation, the Figure showing that the activation energy for the reaction decreases with decrease of temperature.

A complex form of the temperature variation of the rate of the process has also been observed in the catalytic hydrochlorination of ethylene in ethyl chloride: at 273 and 163 K the reaction is slow, the rate of the process being a maximum at 213–218 K.[81]

In the majority of cases, the rate constants for catalytic hydrochlorination obey the Arrhenius equation. The activation energies for a number of homogeneous catalytic hydrochlorination reactions are listed in Table 4. Evidently, for

the simplest unsaturated compounds, the activation energies are 40–90 kJ mol^{-1}. For the more reactive olefins (cyclohexene and styrene), the activation energies are less than 40 kJ mol^{-1}. For cyclohexene in non-polar solvents at low temperatures, the activation energy for hydrochlorination is close to zero. In a more polar solvent (methylene chloride) the activation energy increases.

4. The Isotope Effect

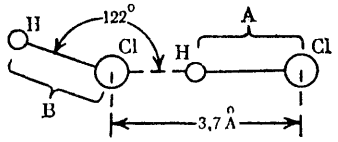
The isotope effect in hydrochlorination in polar and hydroxylated media varies in the range 0.7–2.3. For example, isotope effects of 1.3 for cyclohexene[71], 1.15 for 3,3-dimethylbut-1-ene[56], 1.4 for styrene[56], and 1.54 and 2.3 for *cis*- and *trans*-1-phenylbuta-1,3-dienes respectively[53] have been obtained in acetic acid. In nitromethane, HCl adds to 1-methylcyclopentene 1.6 times more slowly than DCl.[55]

When the polarity of the medium is reduced, the ratio k_H/k_D increases. For catalytic hydrochlorination of cyclohexene (at 183 K), the isotope effect changes from 0.7 to 4.2 on passing from methylene chloride to hexane[110].

The kinetic characteristics of the hydrochlorination reactions of unsaturated compounds—a high, frequently variable, reaction order, a negative temperature coefficient, and an activation energy close to zero—may be due to the association of the reactants in the reaction system.

IV. INTERMOLECULAR INTERACTIONS IN HYDROGEN CHLORIDE–UNSATURATED COMPOUND–CATALYST–SOLVENT SYSTEMS

In systems containing hydrogen chloride, an unsaturated compound, and a catalyst in a condensed phase, a number of complex formation processes take place. The ability of hydrogen chloride to form hydrogen bonds, which leads to self-association, plays an important role.



1. Self-Association of Hydrogen Chloride

The polymeric species $(HCl)_n$ are formed in all the phase states. In the gas phase, $n = 2$. The study of gaseous HCl by infrared spectroscopy showed that at 293 K and 10 atm approximately 1% of the substance exists in the form of the dimer $(HCl)_2$. The enthalpy of dimerisation is close to −10 kJ mol^{-1}.[111]

In polar and hydroxylated solvents, the complex formation reaction with the solvent suppresses the self-association of hydrogen chloride. In a non-polar inert solvent (1,2-dibromotetrafluoroethane) at an HCl concentration below 0.5 M, the dominant type of self-association is the dimerisation of HCl. The dimerisation equilibrium constant is 0.84 litre mol^{-1} at 293 K and the enthalpy and entropy of the process are −8 kJ mol^{-1} and −31 J mol^{-1} K^{-1}. The degree of self-association increases with decrease of temperature: 70% of the hydrogen chloride molecules are dimerised at 173 K for [HCl] = 0.5 M.[98]† In organochlorine solvents complex formation with the solvent competes with the dimerisation of hydrogen chloride and the degree of dimerisation of HCl decreases[98,112].

The self-association of hydrogen chloride in the solid phase has been observed in an infrared spectroscopic study of HCl in an argon matrix at 10–30 K; the spectra show bands due to the hydrogen chloride dimers, trimers, and tetramers[113–115]. In order to obtain isolated hydrogen halide molecules, a 400-fold excess of a diluent is necessary[116].

Two types of associated hydrogen chloride species—linear and cyclic—have been considered in the literature. In the trimers and tetramers all the HCl molecules are equivalent, which indicates a cyclic structure. In the dimer the HCl molecules have different force constants[115]. The study of the structure of the hydrogen chloride dimer by pulsed ^1H NMR showed that it is as follows[117]:

The distance between the hydrogen atoms is 3.3 Å. The greater stability of the linear structure compared with the cyclic structure is consistent with the results of a quantum-mechanical calculation[118]. In the dimer there is charge transfer from molecule B to molecule A. The negative charge is concentrated on the chlorine atom of the A molecule and the positive charge is distributed between the remaining atoms.

2. Complexes of Hydrogen Chloride with Unsaturated Compounds

The formation of molecular 1:1 complexes in solid mixtures of hydrogen chloride with olefins and acetylenes has been demonstrated in studies of fusion diagrams[11,119]. Complexes of the type 2HCl.RH are also known for a number of unsaturated compounds and the complexes 4HCl.RH are known for alkylacetylenes[119]. Application of low-temperature infrared spectroscopy led to the discovery of the complexes HCl.2RH.[120] The enthalpy of formation of the 1:1 complexes in the solid phase is between −10 and −22 kJ mol^{-1} according to infrared spectroscopy[121]. The contribution of pair or collective interactions to the stabilisation of such complexes is low[122,123]. The 1:1 complexes are the most stable in the solid phase[120,123].

In the liquid and gas phases these complexes have been inadequately studied. The first quantitative data were obtained as late as 1978 using low-temperature infrared spectroscopy[124,125]. In liquid nitrogen at 93 K the equilibrium constant for the complex formation with hydrogen chloride increases from 8 to 6×10^3 litre mol^{-1} on passing from ethylene to 2,3-dimethylbut-2-ene, while the enthalpy of complex formation changes from −5.8 to −13.4 kJ mol^{-1}.

The degree of charge transfer in the complexes of hydrogen chloride with olefins is considerable and amounts to 0.1 to 0.3 of a unit electronic charge[121]. There are no direct experimental data for the disposition of the molecules in these complexes. It has been suggested that the hydrogen chloride molecule is arranged at right angles to the plane of the olefin. On the basis of the satisfactory correlations between the shift of the vibration frequencies and the enthalpy of complex formation characteristic of hydrogen-bonded complexes, it is believed that the interaction in such complexes involves a hydrogen bond[122,126,127]. However, quantum-mechanical calculation by the CNDO/3 method showed

†During the preparation of this review for the press, B.Desbat and P.V.Huong published their study (Bull.Soc. chim.France, 1981, 301), in which the dimerisation of hydrogen chloride in the liquid phase was additionally confirmed by infrared and Raman spectroscopy and the structure of the dimers was considered.

that the configuration in which the hydrogen chloride molecule assumes the disposition with the chlorine atom pointing towards the olefin is the most stable[128]. The negative charge is concentrated on the chlorine atom and the positive charge is distributed over the molecule of the unsaturated compound. The calculated degree of charge transfer in the ethylene–HCl complex is close to 0.1.

Several types of orientation can probably occur in complexes of hydrogen chloride with olefins. Comparison of the experimental entropy for the formation of the ethylene–hydrogen chloride complex with the values calculated for different models of the complexes showed that agreement can be achieved only on the assumption that internal movements occur in the complex, namely rotation or vibration, with a high amplitude[129]. There is apparently no rigorously fixed molecular orientation in the complexes of hydrogen chloride with olefins and their structures are extremely labile.

3. Complexes with Participation of the Solvent

The majority of organic solvents form complexes with hydrogen chloride. We shall confine ourselves to a brief consideration of the most important types of interactions.

The formation of complexes of HCl with compounds of the benzene series was observed in a study of fusion diagrams[119] and of the solubility of gaseous hydrogen chloride in aromatic compounds[130]. The thermodynamic characteristics of the complex formation reactions are comparable to those obtained for olefins. For example, the equilibrium constant for the formation of the benzene–HCl complex at 293 K is 0.17 litre mol^{-1} and $-\Delta H = 12.5$ kJ mol^{-1}.[131] The nature of the bonding in the complexes is various. In the case of olefins charge transfer plays the main role, while for aromatic compounds dipole–quadrupole and dispersion interactions are important[126]. The higher energy of the interaction of HCl with benzene in the presence of water indicates the possibility of the formation of ternary complexes[132].

Organochlorine compounds form hydrogen-bonded complexes with hydrogen chloride[98,112,133,134]. The enthalpies of formation of such complexes are in the range between −6 and −10 kJ mol^{-1} and the equilibrium complex formation constants at room temperature are approximately 0.1 litre mol^{-1}.

Substances containing ether or carbonyl oxygen form more stable complexes with hydrogen chloride. When ethers interact with hydrogen chloride, 1:2 complexes[136] as well as associated species with three, four, and six HCl molecules[137] are formed in addition to the well known 1:1 complexes[135]. In the interaction with aromatic ethers, the coordination involves the oxygen atom[138]. The enthalpies of formation of 1:1 complexes of HCl with ethers are in the range between −23 and −30 kJ mol^{-1}.[131] The 1:2 complexes are weaker and are characterised by $-\Delta H \cong 10$–16 kJ mol^{-1}.[136] Experimental and computational studies on the structures of such complexes have been described[138,139,140]. When HCl interacts with ethers, there is a possibility of the protonation of the latter with the formation of onium salts[140,141]. However, HCl_2^- ions could not be detected by NQR in the solid phase, which is inconsistent with the hypothesis of spontaneous protonation[138].

The complexes of hydrogen chloride with other oxygen-containing compounds, including water, have been considered in a number of studies[142–146].

The universal ability of hydrogen chlorides to form complexes is indicated by the observation of intermolecular interaction of HCl with argon[147] and nitrogen[148].

The interaction between unsaturated compounds and an organochlorine solvent (CCl_4) is indicated by the increase of the negative enthalpy of mixing compared with hydrocarbons without a double bond[149]. For aromatic hydrocarbons and olefins, the enthalpies of formation of their complexes with CCl_4 are −(1–5) kJ mol^{-1}.[150]

4. Complexes of Metal Halides in Hydrochlorination

The typical hydrochlorination catalysts, namely metal halides, are strong complex-forming agents. The stability of the complexes of Group IV metal halides is low. Thus the enthalpy of formation of the complex of hydrogen chloride with tin tetrachloride in a non-polar medium is −6 kJ mol^{-1}.[112] The shifts of the stretching vibration band of HCl in $TiCl_4$ and CCl_4 relative to the gas phase are approximately the same, which indicates the similarity of the bond energies[151]. Such complexes can be formed as a result of the usual classical van der Waals interactions. The enthalpies of reaction of HCl with a number of metal halides, estimated from adsorption measurements, are −8 kJ mol^{-1} for solid $BiCl_3$, −9 kJ mol^{-1} for $ZnCl_2$, and −15 kJ mol^{-1} for $CdCl_2$.[152] The Group III metal salts form more stable complexes with HCl: the enthalpies of formation of such complexes are −16 and −41 kJ mol^{-1} for $FeCl_3$ and $AlCl_3$ respectively[104]. The most probable composition of the complex of HCl with $AlCl_3$ corresponds to the formula $HAl_2 \cdot Cl_7$;[153] the structure of the complex depends on the nature of the solvent[104,154].

The majority of metal halides form complexes also with unsaturated compounds and their strength varies within wide limits. A high stability is characteristic of aluminium halide complexes. The appreciable shift of the stretching vibration bands of the double bonds in the ethylene, propene, cyclohexene, and other olefin complexes with $AlHal_3$ indicates perturbation of the π-electron cloud[155,156]. The structure of a typical π-complex with coordination of the aluminium atom to the centre of the double bond has been proposed for such complexes. Aluminium halides are involved in complexes of this kind in a monomeric form, which indicates their stability. The equilibrium constant for the formation of the propene–$AlCl_3$ complex is 7.3 litre mol^{-1} at 293 K and the enthalpy of formation is approximately −100 kJ mol^{-1}.[104]

The complexes of Group IV metal salts with olefins are less stable; thus $K_p = 0.33$ litre mol^{-1} and $-\Delta H = 6$ kJ mol^{-1} (at 298 K) for the complex of $TiCl_4$ with isoprene[157].

Metal halides can form complexes with the majority of organic solvents[158].

Thus a wide variety of complex formation processes occur in hydrogen chloride–unsaturated compounds–catalyst–solvent systems. The most important of these are the formation of a complex by hydrogen chloride with olefins and also by the catalyst with olefins and hydrogen chloride. In concentrated solutions in non-polar media hydrogen chloride is to a large extent associated. Without studying these processes, a correct treatment of kinetic data is impossible. Complex formation is a characteristic feature of the systems considered and must be taken into account in the study of the mechanism of the hydrochlorination reaction. Complexes in which there is a significant rearrangement of the electronic structure of the molecule and comparatively strong intermolecular bonds are formed are the most important for the reaction.

V. THE MECHANISM OF THE ADDITION OF HYDROGEN CHLORIDE TO MULTIPLE BONDS

The hydrochlorination reactions can proceed via radical and molecular mechanisms. The radical addition of hydrogen chloride takes place slowly and fairly rarely[30,159–162]. This

pathway is not characteristic of hydrochlorination. The ionic and molecular mechanisms are much more important.

1. The Ionic Mechanism of Hydrochlorination

(a) *Evidence for the involvement of ions in the reaction.* The idea of the involvement of ions or ion pairs in hydrochlorination is based mainly on the results of the study of the composition of the addition products. The validity of the Markovnikov rule is typical for ionic processes; it is based on the tendency of the proton to attack the sites with the highest electron density at the C–H bonds in the olefin molecule[35]. The modern interpretation of the Markovnikov rule is based on the rapid rearrangement of primary alkyl cations to the more stable secondary cations:

$$RCH=CH_2 \xrightarrow[-Cl^-]{HCl} \left[\begin{array}{l} \longrightarrow RCH_2CH_2^+ \\ \longrightarrow RCH^+CH_3 \end{array} \right] \xrightarrow{\text{just}} \quad .$$

Quantum-mechanical calculations, including non-empirical calculations, predict that the primary cations of the type $CH_3CH_2CH_2^+$ or $ClCH_2CH_2^+$ are unstable and cannot exist under the usual conditions. They should be converted without activation energy into the more stable cations $CH_3CH^+CH_3$ or $ClCH^+CH_3$.[163] Thus the protonation is thermodynamically controlled and the Markovnikov rule can be explained within the framework of an ionic mechanism.

The involvement of ions in the hydrochlorination in hydroxylated solvents explains the simultaneous formation of solvent addition products. The carbonium ions formed in the reaction are subjected to nucleophilic attack not only by Cl^- anions but also by solvent molecules:

$$RCH=CH_2 \xrightarrow[-Cl^-]{HCl} RCH^+CH_3 \left[\begin{array}{l} \xrightarrow{Cl^-} RCHClCH_3 \\ \xrightarrow[-H^+]{R'OH} RCHCCH_3 \\ \qquad\quad | \\ \qquad\quad OR' \end{array} \right] .$$

The rearrangements of branched olefins can be attributed to rapid isomerisation reactions of the carbonium ions:

$$(CH_3)_2CHCH=CH_2 \xrightarrow[-Cl^-]{HCl} (CH_3)_2CHCH^+CH_3 \xrightarrow{\text{just}} (CH_3)_2C^+CH_2CH_3$$
$$\downarrow Cl^- \qquad\qquad \downarrow Cl^-$$
$$(CH_3)_2CHCHClCH_3 \qquad (CH_3)_2CClCH_2CH_3 \ .$$

The involvement of ionic species in a catalytic process is believed to be confirmed by the exchange of the halogen between HCl and the catalyst, which has been observed in the hydrochlorination of styrene[79]:

$$C_6H_5CH=CH_2 + HCl + SnBr_4 \rightarrow C_6H_5CH^+CH_2SnBr_4Cl^- \left[\begin{array}{l} \longrightarrow C_6H_5CHClCH_3 \ ; \\ \longrightarrow C_6H_5CHBrCH_3 \ . \end{array} \right.$$

The acceleration of hydrochlorination in polar media and also the isotope effect in the reaction close to unity, indicating that the H–Cl bond is broken in the transition state, are consistent with the ionic character of the process.

In the ionic mechanism, the hydrochlorination is treated as a stepwise process consisting of a sequence of ion or ion pair formation reactions and the addition of a nucleophilic species. According to a number of workers[1], ionisation is preceded by the formation of complexes of HCl with the unsaturated compound or the catalyst.

In the simplest case the reaction can be represented schematically as follows:

$$RH + HCl \ (\text{or } RH \cdot HCl) \underset{(a)}{\rightarrow} RHH^+Cl^- \underset{(b)}{\rightarrow} RH_2Cl \ .$$

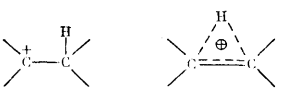
Processes which are the reverse of reactions (*a*) do not play a significant role in hydrohalogenation, since there is no isotope exchange between olefins and deuterium halides[22,56,164]. 1,2-Dimethylcyclohexene, where the migration of the double bond indicates the reversibility of the ionisation stage, constitutes an exception[72].

(b) *The ionisation stage.* The accumulation of measurable amounts of ionised species has not been observed in hydrochlorination. Inductive periods on the product accumulation curves are not characteristic of hydrochlorination either. This suggests that the formation of ionic species is the rate-limiting stage of the reaction. Only reactions in aqueous media, where the degree of dissociation of HCl into ions is high, may be exceptions.

Ions can arise in the reaction system as a result of the interaction of Cl with the unsaturated compound or after the preliminary dissociation of HCl and the reactions of the resulting ions with the multiple bonds. The majority of organic compounds have proton affinities in the range 500 to 800 kJ mol^{-1}.[165] Ions of the protonated solvent should be formed in solution. The degree of dissociation of HCl in organic solvents is low and is usually in the range 10^{-3} to 10^{-10}%.[19,25,104,166] The dissociation is facilitated by the interaction with a second HCl molecule and the formation of the HCl_2^- ion. The dimer $(HCl)_2$ is a stronger acid than HCl. Thus the dissociation of HCl in an organic solvent(Solv) can be represented schematically as follows:

$$Solv + (HCl)_2 \underset{}{\overset{K_{(HCl)_2}}{\rightleftharpoons}} Solv\,H^+ + HCl_2^- \quad (\text{or } Solv + 2HCl \rightleftarrows Solv\,H^+ + HCl_2^-) \ .$$

This process is significant if the bond between the proton and the solvent is stronger than that between the proton and the unsaturated compound. For reactions in hydrocarbons and halogeno-derivatives, whose proton affinity is lower than that of olefins, preliminary ionisation is unimportant. It plays a major role in oxygen-containing solvents such as nitromethane, ethers, and carboxylic acids, whose proton affinities are comparable with those of olefins[165]. However, in this case the hypothesis of preliminary ionisation is inconsistent with the frequently observed second order of the reaction with respect to hydrogen chloride. If the rate of reaction were proportional to the concentration of the ions [Solv H^+] formed in the preliminary stage, defined by the expression

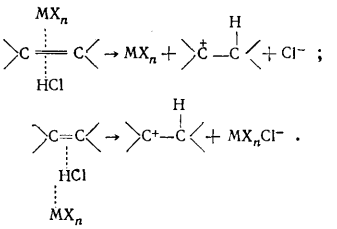


$$[Solv\,H^+] = \sqrt{K_{(HCl)_2}[HCl]^2[Solv]} = [HCl]\sqrt{K_{(HCl)_2}[Solv]} \ ,$$

subject to the condition [Solv H^+] $\ll$ [HCl], then the order of the reaction with respect to HCl should not exceed unity.

Thus the most probable pathway leading to the formation of ions in the reaction is the interaction of hydrogen chloride with the unsaturated compounds.

An ion pair can arise either directly on collision of the molecules or on decomposition of the complex of the unsaturated compound with one or several HCl molecules. These two pathways are kinetically indistinguishable. The enthalpies of formation of the complexes of HCl with olefins are much lower than the activation energy for hydrochlorination and complex formation does not therefore influence significantly the rate of ionisation.



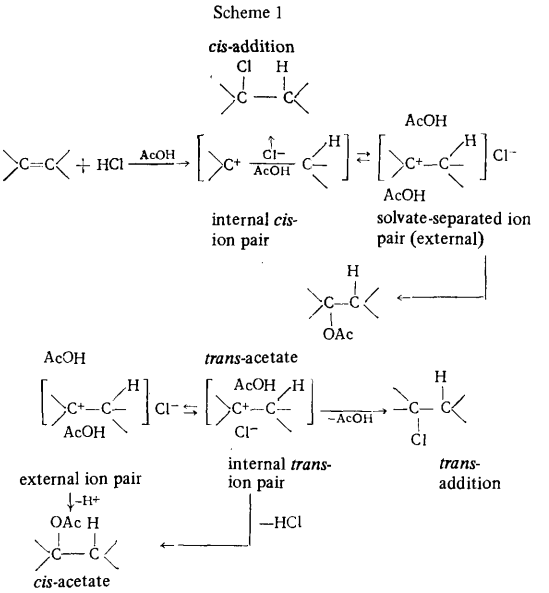
Ionisation results in the formation of an ion pair consisting of the carbonium ion and the HCl_2^- or Cl^- anion. These cations can have the classical (open-chain) or bridged structure:

Quantum-mechanical calculations indicate a greater stability of the bridged structure in the case of the $C_2H_5^+$ ion and approximately equal bond energies for the two structures of the vinyl cation $C_2H_3^+$.[163] In solutions the relative stabilities

of the two forms of the cations are determined by their solvation energies. Delocalisation of the charge diminishes this energy and for this reason in solution the stability of the ion with the classical structure increases. This structure of the carbonium ion is indicated by the high yield of the products of *cis*-addition in many hydrochlorination processes.

In the presence of a catalyst the transition state contains at least three molecules. Their interaction can occur in the following ways:

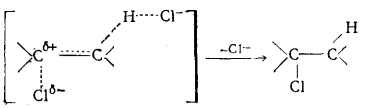
In the second case the formation of an ion pair is facilitated by the interaction of the catalyst MX_n with the anion Cl^- and this pathway appears to be the most probable.



The formation of a stable complex of the olefin with the catalyst should not promote hydrochlorination. Indeed, the binding of $AlCl_3$ in a complex with an excess of the olefin inhibits the hydrochlorination and gives rise to side processes[103,104]. However, in the hydrochlorination of acetylene the catalytic activity of metal halides is correlated with the stabilities of the corresponding complexes of acetylene, which is due to the formation of ternary complexes[167]. The involvement of such complexes in the process is consistent with the molecular mechanism of hydrochlorination and is considered below in Section V.

According to Velichko-Shkurchenko[104] and Flid[106], in catalytic hydrochlorination ionisation precedes the formation of the complex acids $HMCl_{n+1}$ and ternary complexes involving the olefin. In certain cases the kinetic data demonstrate the simultaneous involvement of two olefin molecules in the ionisation stage[106].

(c) *The reaction product formation stage.* The hydrochlorination products are apparently formed directly from the ion pair[2,69,72]. This claim is based on the high (up to 100%) yields of the *cis*-addition products. The involvement in the process of the free open-chain ion, where there is a possibility of hindered rotation, should lead to identical amounts of the *cis*- and *trans*-products, which happens for a number of hydrochlorination reactions in highly polar media. For the bridged cation, preferential *trans*-addition is to be expected. *cis*-Addition is possible only for the ion pair[168], which agrees with the thermodynamics of the dissociation process. In solvents with $\varepsilon < 15$, the dissociation of the ion pair into singly charged ions requires an expenditure of up to 200 kJ mol^{-1} of energy and this process should not take place to an appreciable extent in media of moderate polarity[169].

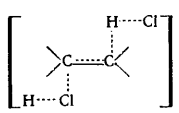


The conversion of ion pairs into reaction products can be considered within the framework of the competition between two mechanisms—the bimolecular Ad_{E^2} mechanism and the termolecular Ad_{E^3} mechanism[56,66,72,85]. The Ad_{E^2} mechanism describes the reaction of the ion pair obtained from the unsaturated compound and HCl. It is also applicable to a third-order reaction if the HCl_2^- anion is involved in it. The bimolecular process mechanism is presented below (Scheme 1) in relation to the interaction of the olefin with HCl in acetic acid[66]:

Scheme 1

Scheme 1 explains satisfactorily the formation of the *cis*- and *trans*-products of the addition of hydrogen chloride and the solvent. For 3,3-dimethylbutene, the ion pair is rapidly converted into the products; the ions external in relation to the ion pair cannot influence the formation of the products and the addition of salts and a change in the concentration of HCl do not affect their composition. The increase of the stability of the ion pair on passing to styrene increases the selectivity of the reaction: the ratio of the yields of the chloro-derivative and the acetate increases[56]. The Ad_{E^2} mechanism is characteristic of hydrochlorination at an insignificant concentration of the Cl^- anion; the occurrence of the reaction via this mechanism is promoted by an increase of temperature and the possibility of the delocalisation of the positive charge on the cation[85].

The termolecular mechanism is significant at high HCl concentrations or in the presence of additives of the type of $(CH_3)_4NCl$.[56,85,170] The transition state in Ad_{E^3} process can be represented as follows:



cis-Addition via this mechanism should be sterically hindered. The synchronous dissociation of the H–Cl bond and the formation of two new bonds and the delocalisation of the change in the transition state decrease the activation barrier to the reaction relative to the bimolecular process. A decrease of temperature promotes the occurrence of the reaction via the Ad_{E^3} mechanism. A similar Ad_{E^3} mechanism was first proposed for the addition of acids to acetylene derivatives in ionising media in the presence of LiCl as early as the 1950's.[171,172]

The presence of the Cl^- or HCl_2^- anions is of decisive importance in the termolecular process. The Ad_{E^3} mechanism explains satisfactorily the *trans*-stereospecificity of many hydrochlorination reactions under specific conditions. Addition via the Ad_{E^3} mechanism takes place in the absence of additives in the case of cyclohexene[71,170] and alkylacetylenes[85]. Highly polar and strongly ionising solvents tend to

increase the concentration of Cl^- anions and favour the Ad_{E^3} addition. The increase of the yield of the *trans*-product of hydrochlorination on passing from acetyl chloride to acetic acid and methanol is attributed to this[72]. The relative contributions of the bimolecular and termolecular mechanisms of ionic hydrochlorination depend on the choice of solvent and on the structure of the initial compound.

Thus the ionic mechanism of hydrochlorination with allowance for the competition between the Ad_{E^2} and Ad_{E^3} processes explains satisfactorily the characteristics of the reactions in strongly polar and hydroxylated solvents. Many characteristic features of the hydrochlorination in weakly polar media are inconsistent with the hypothesis of the involvement of ionic species in the reaction.

According to the ionic mechanism of addition in non-polar solvents of the type of pentane, the Ad_{E^2} pathway should operate with formation of the *cis*-hydrochlorination product. However, Table 2 shows that *trans*-addition is characteristic of many reactions in pentane. This is attributed to the fact that the hydrochlorination takes place by a synchronous mechanism with participation of two hydrogen chloride molecules via the transition state[70]

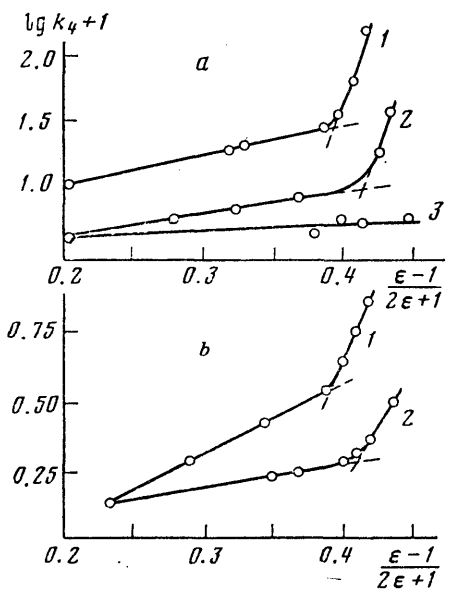


Figure 3. Dependence of the logarithm of the rate constant for the hydrochlorination of cyclohexene on the dielectric constant of the medium ε in terms of the Kirkwood variables at different temperatures (K): *1*) 293; *2*) 253; *3*) 183; *a*) C_6H_{14}–CH_2Cl_2; *b*) CCl_4–CH_2Cl_2.[6,109]

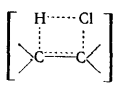
It is impossible to classify such a reaction as rigorously ionic, since the product is not formed via the ions but simultaneously with the formation of the latter. It has already been mentioned that the appearance of free ions in non-polar solvents requires a large expenditure of energy, while the hydrochlorination reaction in such media is characterised by a low activation energy. Thus it is not possible to account for the stereochemistry of the addition of hydrogen chloride in non-polar media from the standpoint of the ionic mechanism.

Nor does the ionic mechanism explain the fact that in many instances where the protonation of different olefins yields the same cation the products of the hydrochlorination of these olefins are different[46,93,173].

If the rate of the ionic process is limited by the ionisation stage, one must expect the acceleration of hydrochlorination on passing to polar solvents. In reality the increase of the rate of reaction with increasing polarity is frequently slight or does not occur at all. The ionic mechanism is not consistent with the kinetic isotope effect in the hydrochlorination of cyclohexene in hexane in the presence of $SnCl_4$.[110]

Estimation of the degree of charge separation in the transition state of the hydrochlorination reaction indicates the absence of ions from weakly polar media. For processes with a rate-limiting ionisation stage of the type of the solvolysis of alkyl halides and acid chloride or the Menshutkin reaction, the degree of charge separation $q^{\neq}$ is in the range 0.7–1.0 of an electronic charge unit[174]. Fig.3 illustrates the dependence of the rate of catalytic hydrochlorination of cyclohexene in terms of the Kirkwood variables on the polarity of the medium[6,109]. At temperatures in the range 253–293 K for media with dielectric constants below 6–8, $q^{\neq}$ is small and amounts to 0.2–0.4. At 183 K, $q^{\neq}$ does not exceed 0.3 over the entire range of dielectric constants $\varepsilon < 16$. The values $q^{\neq} \cong 0.5$–0.9, corresponding to an ionic reaction, have been obtained at 253–293 K in media of moderate polarity ($6 < \varepsilon < 12$).

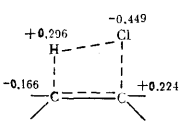
Thus the ionic mechanism is unsuitable for the description of hydrochlorination in weakly polar media, particularly at low temperatures. The characteristic features of such reactions can be accounted for by a molecular mechanism, which is probable also for gas-phase processes where there are no solvation effects stabilising ions or ion pairs.



2. The Molecular Mechanism of Hydrochlorination

The molecular mechanism of hydrochlorination presupposes the formation of the addition product via a synchronous rearrangement of the bonds in the reactant molecules without their preliminary dissociation into ions or radicals. The energy consumed in the dissociation of old bonds is compensated by the energy of formation of new bonds. The synchronous rearrangement without dissociation takes place when the molecules in the transition state form a ring incorporating the carbon atoms of the double bond and one or several molecules of hydrogen chloride.

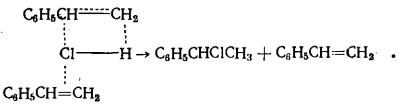
The energy of formation of the cyclic transition state from the molecules A and D is determined, according to modern ideas, primarily by the form of the potential curves for the ground and lowest excited configurations of the reacting system[175]. In those cases where the reactant molecules do not exhibit distinct electron-donating and electron-accepting properties, the excited configuration with charge transfer D^+A^- has a high energy and does not play a significant role in the formation of the transition state. Low activation energies may be observed if the ionisation potential I_D is relatively low and the electron affinity of the molecule A is high, i.e. under the conditions of a strong donor–acceptor interaction. In the reaction system considered, such interaction occurs, for example, on formation of complexes of



hydrogen chloride with unsaturated compounds. The formation of a cyclic transition state with a low energy in the HCl–olefin system is therefore possible. Four-membered and six-membered transition states are the most likely. The second and third orders of the reaction correspond to the four-membered and six-membered transition states respectively.

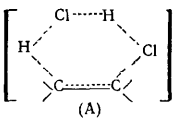
(a) *Second-order reactions with a four-membered transition state.* The addition to multiple bonds via a cyclic transition state of the type

has been considered in the literature before the appearance of the hypothesis that carbonium ions are involved in the reaction. Interest in such processes arose again after the publication of a study[14] in which the characteristics of the hydrohalogenation of olefins in the gas phase were accounted for by the involvement of the so called semi-ion pairs. In these pairs the reactant molecules are polarised and the charge on the hydrogen atom and one of the carbon atoms is +0.5, while that on the chlorine atom and the other carbon atom is −0.5. The energy of formation of ion pairs in the gas phase exceed significantly the observed activation energies for the addition reactions and the hypothesis of the polarisation of the molecules in the transition state and not their ionisation was therefore put forward. This hypothesis explained the validity of the Markovnikov rule and the correlation of the reactivities of olefins with their ionisation potentials. The choice of a charge of 0.5 is arbitrary, but calculation of the energies of formation of four-membered rings, where the molecules are polarised in this way, agrees satisfactorily with the activation energies for the gas-phase addition and elimination reactions. The proposed model agrees in the main with the results of semiempirical quantum-mechanical calculations[176].



It has been suggested recently that the transition state be regarded as an asymmetric ring[177]. The quantum-mechanical calculation on the transition state in the ethylene–hydrogen chloride system by the INDO/3 method leads to a similar structure[128], for which the following charge distribution in the ring was obtained:

The asymmetric charge distribution leads to the large dipole moment $\mu^{\neq} = 2.88$ D. The overall charge on the HCl molecule is −0.153, which indicates charge transfer from ethylene to hydrogen chloride. The results obtained in the above study[128] agree better with the donor–acceptor properties of the reacting molecule than the hypotheses developed previously[14].



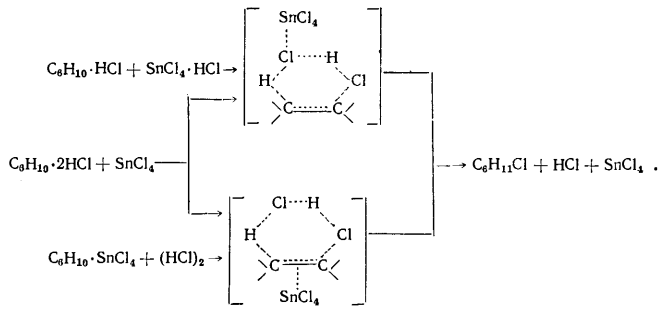
The agreement between the molecular mechanism of addition via a four-membered transition state and the orbital symmetry rules has been considered in a monograph[175] and in another publication[178]. It was shown that, in the presence of an appreciable charge transfer in the asymmetric transition state, molecular addition via a four-membered ring is possible.

The molecular mechanism with a four-membered transition state in the gas phase has been adequately proved. The possibility of a similar reaction in the liquid phase has been postulated[69,85], but so far this problem has not been analysed in detail and preference has been given to the traditional ionic mechanism. For the hydrochlorination of styrene, the following structure of the four-membered transition state, stabilised by a second styrene molecule, has been postulated[179]:

Although adequate confirmation of this mechanism has not been obtained, one cannot rule out the possibility of the stabilisation of cyclic structures by the molecules of olefins or other organic donors. For example, the characteristics of the hydrobromination reaction, which resembles the hydrochlorination process, in the absence of radical initiators can be explained, if it is assumed that the anomalous addition product is formed via a four-membered cyclic transition state stabilised by a second olefin molecule[5].

(b) *Higher-order reactions with a six-membered transition state.* The hydrochlorination products can be obtained via a synchronous rearrangement of the bonds in the six-membered ring formed by two molecules of hydrogen chloride and the double bond of the unsaturated compound:

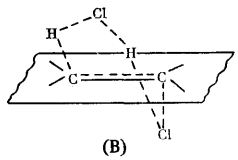
(A)



Addition via such a transition state has been demonstrated for the Diels–Alder reaction[180] and also for the exchange of atoms between the molecules of mixed halogens and their dimers[181] in the gas phase. This mechanism is most probable for bromination[182] and hydrobromination[5] in non-polar media. The above reactions are characterised by high negative activation entropies, low or negative activation energies, and a weak dependence of the rate of reaction on the polarity of the medium. The characteristics enumerated above are observed also in the hydrochlorination of many olefins in non-polar and weakly polar media. Large negative activation entropies are associated with the formation of highly oriented cyclic structures in which the gain in the free energy of activation is compensated by the decrease of the energy of the transition state as a result of the increase of the strength of the donor–acceptor bonds and the delocalisation of the electron density in the ring.

Six-membered cyclic transition states in hydrohalogenation were first proposed by Shilov to account for the *cis*-stereospecificity of the addition of HBr to acetylene derivatives[183]. According to the results of Smirnov-Zamkov and Piskovitina[184], the *trans*-addition of HBr to cyclohexene is also consistent with the molecular six-centre mechanism if account is taken of the steric disposition of the bonds in the cyclohexane molecule. The stereochemistry of the addition cannot serve as adequate evidence for or against the molecular mechanism. Our analysis[108] of the transition state in hydrochlorination reactions on molecular models showed that, under the conditions of a slight extension of the H–Cl bonds, a six-membered ring can be constructed for both *cis*- and *trans*-addition. The *trans*-pathway of the addition reaction does not therefore justify the rejection of the molecular mechanism as has been done by some investigators[75,168].

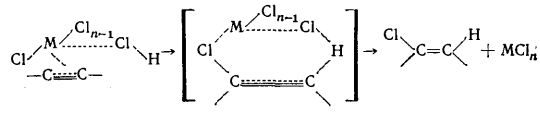
The formation of a six-membered transition state with a relatively low activation energy explains the finding that at room temperature HCl adds to olefins in the gas phase at a rate higher by many orders of magnitude than would follow from the extrapolation of the kinetic data for the high-temperature process[89]. The interaction of the transition state



with a third hydrogen chloride molecule can lower the energy of the system. This mechanism appears to be the most likely for gas-phase reactions at room and reduced temperatures.

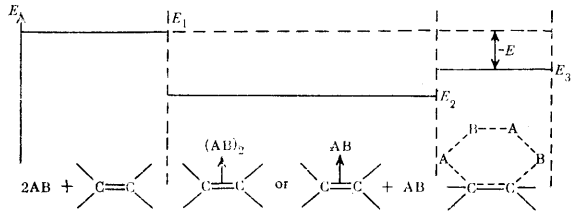
A molecular mechanism of a catalytic liquid-phase reaction has been proposed for the hydrochlorination of cyclohexene[6] in view of the low degree of charge separation in the transition state and the second order of the reaction with respect to hydrogen chloride. The reaction products can be formed via the following mechanism:

The transition states in the reactions have the same compositions but different structures and correspond to different stereochemistries of the addition. The nearly zero process activation energies in non-polar media at low temperatures and high (230–270 J mol^{-1} K^{-1}) negative activation energies as well as the appreciable isotope effect in the reaction of hexane are consistent with the molecular mechanism[6,108–110].



The orientation in the transition state is determined by the nature of the unsaturated compound. For the majority of olefins, the nearly planar structure (A) is more probable. Structure (B), which leads to the formation of the *trans*-addition product, may be more favourable for cyclic compounds:

(B)



Lewis acids facilitate the reaction by stabilising the cyclic transition state. The catalyst can interact with a hydrogen chloride or olefin molecule. Both types of complex formation are accompanied by an energy gain; in the hydrochorination of cyclohexene in the presence of $SnCl_4$, the interaction of the catalyst with hydrogen chloride is more favourable.

Another six-membered transition state, incorporating in the ring the molecules of the unsaturated compound, hydrogen chloride, and the catalyst, has been proposed for the catalytic hydrochlorination of acetylenic derivatives[167]. The transition state of the process has a structure intermediate between a ternary complex of the starting materials and the reaction products:

This mechanism can be due to the ability of acetylenic compounds to form carbon–metal bonds and appears less likely for olefins. The absence of halogen exchange in the products of the hydrochlorination of cyclohexene in the presence of $SnBr_4$ at low temperatures rules out the formation of such a transition state[110]. At higher temperatures cyclohexyl bromide is formed in the reaction (after an inductive period). If the cyclic transition state incorporated a catalyst molecule, the bromide should have been obtained with a high yield simultaneously with the chloride, which has not been observed in a non-polar solvent.

High-order molecular reactions are characterised by low or negative activation energies E, which can be explained by the contribution of the heats of reversible intermediate stages, including complex formation[7], where the energy of formation of the cyclic transition state from the complexes is low and the energy level of this states lies below that of the initial molecules. The addition of the reactant AB to the double bond can be illustrated schematically in the following manner:

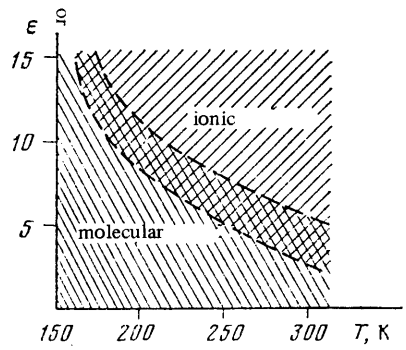


Figure 4. Schematic illustration of the preferential operation of different mechanisms of the hydrochlorination of cyclohexene in the presence of $SnCl_4$ as a function of the process conditions.

In this case E is determined by the expression $E = E_3 - E_1 < 0$. At high concentrations and low temperatures, the degree of binding in the complex is close to 100% and it is then to be expected that $E = E_3 - E_2 > 0$. A negative temperature coefficient, associated with the complex formation, is possible only when the complex lies on the reaction coordinate. If other causes of this phenomenon have been ruled out, then a negative activation energy serves as a criterion of the involvement of the complex in the process[7,182].

It is at present still difficult to formulate sufficiently unambiguous conditions for the occurrence of hydrochlorination via the molecular mechanism. The majority of the characteristic features of the processes in the gas phase and in non-polar solvents agree better with the molecular mechanism than with the ionic mechanism. The ionic mechanism has been demonstrated for reactions in highly polar and

hydroxylated media. In solvents with a moderate solvating capacity a transition from one mechanism to another is to be expected. A change in mechanism has been observed in the catalytic hydrochlorination of cyclohexene by noting the sharp breaks in the linear plots in terms of the Kirkwood variables (Fig.3) and has been confirmed by other data[6,110]. At room temperature the transition from the molecular to the ionic mechanism occurs even in the range of dielectric constants from 4 to 6. A decrease of temperature extends the region in which the molecular mechanism operates and at 183 K the majority of the features typical for the molecular pathway are observed even for $\varepsilon > 10$. Fig.4 illustrates the regions of the operation of the two mechanisms of the addition of hydrogen chloride in relation to the catalytic hydrochlorination of cyclohexene. Presumably the presence of substituents at the double bond stabilising the carbonium ion and also the introduction of Lewis acids stronger than $SnCl_4$ increase the region where the ionic mechanism operates.

The mechanism of hydrochlorination in frozen hydrogen chloride–olefin systems is of great interest. Reactive olefins such as isobutene react rapidly with hydrogen chloride below the melting point[12]. Presumably, as in the liquid phase, at low temperatures the solid-phase process takes place via the molecular mechanism.

* * *

The data on the product composition and the kinetics of the spontaneous and catalytic hydrochlorination show that the process proceeds via two mechanisms: ionic and molecular. Considerable activation energies and low activation entropies, a marked dependence of the reaction rate on the polarity of the medium, a high degree of charge separation in the transition state, the absence of an isotope effect in the reaction, and the formation of mixed addition products are characteristic of the ionic process. Zero or negative activation energies, high negative activation entropies, a weak dependence of the rate on the dielectric constant of the medium, the presence of an isotope effect, and the absence of mixed addition correspond to the molecular mechanism.

There is no reason to treat these mechanisms as mutually exclusive. They can operate simultaneously and have features in common. Thus ionisation can proceed via cyclic transition states characteristic of the molecular pathway and the energy expended on the formation of ions may be compensated by the energy of the C–H and C–Cl bonds formed. This mechanism may be called molecular-ionic. A molecular reaction without the participation of ions is characterised by a considerable charge separation. There apparently exist a whole series of intermediate cases between purely ionic and purely molecular reaction pathways.

The ideas which we have described differ from those in the scientific and monograph literature familiar to the majority of chemists. The new approach to the mechanism of the classical addition reaction became possible as a result of the development of kinetic studies, the application of modern experimental techniques, and the expansion of the range of experimental conditions. Further studies in this field will introduce additional revisions to the ideas being developed. The hydrochlorination reaction is not exceptional. The application of modern physicochemical methods in the study of the kinetics and intermolecular interactions, the expansion of the temperature and reactant concentration ranges, and the use of the results of quantum-mechanical calculations will undoubtedly lead to a significant revision of the traditional ideas concerning the mechanisms of many processes.

The Determination of the Physicochemical and Chemical Forms of Trace Elements in Natural Waters

A.K.Prokof'ev

Published material on methods for determining the physicochemical and chemical forms of trace elements (micro-elements) in natural waters in relation to their presence in definite water fractions (inorganic, organic, colloidal, surface-film, and suspended), magnitude, lability with respect to the analytical technique used, and the natural stability of their chemical compounds and oxidation state has been reviewed. All stages of the analysis, from the selection of the position for the removal of the samples and their preliminary treatment to the instrumental determination of the forms of the trace elements have been examined. The bibliography contains 175 references.

CONTENTS

III. Physicochemical forms 277
IV. Chemical forms 279

I. INTRODUCTION

The degree of contamination of inland and coastal waters in many industrially developed countries now exceeds an ecologically safe level. The principal contaminants of natural waters (NW), in addition to pesticides and petroleum, are the trace elements (TE), with concentrations below 1 mg litre^{-1} water (1 p.p.m.), many of which are highly toxic—Hg, Pb, Cd, As, etc. Only in recent years has it been possible to obtain reliable values of the total concentrations of Te in various NW, which have proved to be at the level of several micrograms per litre, or in many cases tenths or hundredths of this figure.

The determination of the total concentration of TE, however, does not give definite information on the toxicity of water, since there is no direct relationship between these parameters. A knowledge of the forms in which TE exist in NW has therefore become of primary importance, since in addition to different biological accessibility[1] they have a significant influence on the geochemical cycles and the transfer of TE in NW, the methods of obtaining domestic water and water for industry, etc.

There are two basic approaches to the study of the forms of TE in NW. The first of these is theoretical, and calculates the equilibrium concentrations of all dissolved forms by means of mathematical models based on the use of the experimentally determined concentrations of TE and ligands, and also the published values of TE–ligand stability constants. Chemical modelling now covers all competing equilibria, and computer programs are used for thermodynamic calculations. The accuracy of computer modelling is lowered considerably, however, by variations in published data on stability constants and activity coefficients. Moreover, the calculation generally does not include many of the parameters influencing the form of TE, since qualitative and quantitative data are not available for many of them: pH, redox potential, the great majority of organic ligands, colloidal particles and adsorption on them, inter-phase reactions of precipitation, solution, and sorption, biological and physical processes, etc. These factors, and also the lack of information on the non-equilibrium conditions existing in many NW, cast doubt on the relation to reality of the results of the calculation of the forms of TE. Chemical modelling has been described in detail elsewhere[2-9].

The second approach to the study of the forms is analytical. It is convenient to divide all experimentally determined forms of any TE in NW into two large groups: 1) the physicochemical forms present in definite fractions of NW (for example, dissolved organic and suspended), which are subdivided either according to size (for example by ultrafiltration and gel filtration) or their lability with respect to the analytical technique used (for example, ion exchange and stripping voltammetry); 2) the chemical forms, characterised either by definite chemical compounds (for example, MeHgCl and Ph_4Sn) or by a definite oxidation state in different classes of TE (for example, inorganic Se^{IV} and Se^{VI}). According to this classification, the chemical forms of TE represent a fraction of their physicochemical forms, which in sum give the total concentration of TE in NW.

At the very low concentrations of TE in NW, the determination of their forms has proved to be an extremely difficult analytical problem, which has not yet been solved. The forms of TE are very sensitive to large variations in salt composition, pH, the concentration of dissolved organic and macromolecular compounds, colloidal and suspended particles, etc., which also depend on the type of NW and the time of year[10]. The equilibrium concentrations of the forms of TE present in NW are unavoidably changed on the removal of samples, as a consequence of their contact with oxygen and with the walls of the sampling equipment, changes in temperature and pressure, and the methods of separation (isolation) and analysis used. The extent of these changes is not known, but it is important to reduce all these effects to a minimum.

The aim of the present work is to summarise methods for determining the physicochemical and chemical forms of TE in NW in the last 5–7 years. The former have been reviewed[2,11,12], and their development followed[7], while the latter have been partly reviewed, but only for sea water[13]; in recent years, however, new experimental results have extended considerably existing views on the physicochemical and chemical behaviour of TE.

Since most errors in the determination of the concentration of TE and their forms in NW due to the introduction of contaminants are made during the removal and preliminary treatment of specimens for analysis, these stages will be examined, and recommendations given for carrying them out correctly. Colloidal particles which pass through a filter with a pore

diameter of 0.45 μm will be assigned to the dissolved fraction, although they introduce some ambiguity into the definition of the colloidal and dissolved forms of the elements.

The analytical methods most frequently used for determining the forms of TE are stripping voltammetry (SV) (its use for NW has been reviewed[14]), atomic-absorption spectrophotometry (AAS), emission spectrometry (ES), gas–liquid chromatography (GLC), neutron-activation analysis (NAA), mass spectrometry (MS), liquid chromatography (LC), and spectrophotometry. The last method will not be considered, however, because of its low selectivity and the consequent impossibility of taking correct account of the interfering influence of many other TE and chemical substances present in NW.

II. THE REMOVAL AND STORAGE OF NATURAL WATER SAMPLES

The reliable determination of the concentration of TE and their forms in NW is possible only when contamination is excluded at all stages of the analysis: in the laboratory on shore when containers are being washed for an expedition, in the removal of samples and their filtration on board the vessel, during their conservation and storage, and also during the measurement using the instrument. All these stages must be checked for the possible introduction of contaminants, since attempts to achieve high purity at any one stage may be nullified by contamination at another stage. It is therefore recommended[15] that specimens be treated both on board the vessel and in the laboratory on shore in so-called "clean" rooms with dust-free air, in which there are no metal surfaces, and the work is carried out in special clothing in an extraction cupboard. It is difficult to observe all these requirements, but an essential condition is the absence of dust, which is achieved by working in a clean extraction cupboard. The preparation of ultrapure water for trace analysis has been described[16].

Experience has shown that the most vulnerable stages of the analysis to the introduction of contaminants are the collection, filtration, and storage of the samples.

a) Sample Collection

The choice of position is important only for surface specimens. The chief danger is possible contamination of the water surface by the vessel. Samples of all types of NW should therefore be taken at a distance from the vessel, either from a ship's boat[15] or from a rubber boat at its moving front in uncontaminated water from the windward side[17]. This method cannot be used, however, when there are waves or when a large number of specimens is required.

The procedure for collecting samples is now well developed[17–20]. Samples are collected using bottles, sampling devices, and suction systems. The best materials for these are Teflon, polycarbonate, polypropylene, and polyethylene. Various types and their characteristics were recently described[15] and compared in the removal of identical samples[16]. Unfortunately, they all show unsatisfactory features. Thus bottles and suction assemblies are suitable only for the collection of relatively shallow specimens, whereas the widely-used Niskin and Go-Flow deep-water sampling devices are open when they pass through the surface layer and are often made of polyvinyl chloride, which is usually contaminated by TE. Sampling device designs free from these unsatisfactory features have now been developed, however[15].

b) Filtration

When the forms of TE have to be determined, it is necessary to filter the specimen as soon as possible after collection, through a membrane filter with a pore size of 0.45 μm, since the distribution of the forms of TE in unfiltered water may change rapidly, mainly as a consequence of bacterial activity and, to a lesser extent, adsorption–desorption processes. If the time required is greater than several hours, the sample must be cooled to ~4 °C before filtration is complete. All phytoplankton and most bacteria remain with the suspended matter on the filter[19]. Filtration is particularly important for fresh water and estuarine water, in which the suspended form makes up a significant fraction of the total concentration of an element. By general agreement[21], the filtrate contains the dissolved fraction of TE, which, however, also contains colloidal particles and a fraction consisting of very fine particles of mineral and biological origin which pass through the filter[22].

Polycarbonate or cellulose acetate Nuclepore, Millipore, Gelman, and Synpore filters are generally used; these must be purified from TE before use by washing thoroughly with mineral acid, distilled water, and the sample[2,19,22,23]. The absence of clean conditions in the determination of TE has been discussed[24]. The separation of the phases is carried out in a vacuum, under pressure, and by centrifuging. Their advantages and disadvantages, and types of filtration apparatus, have been described[19].

c) Storage

It is often impossible to analyse samples for TE immediately after collection and filtration. It then becomes necessary to store them before analysis. Here the main problems are adsorption losses, which depend on the storage time[25], and contamination[19,26,27]. Sorption depends chiefly on the TE concentration, the material of the storage vessel, pH, and salinity[27]. NW samples must be kept in vessels of Pyrex glass, Teflon, or high-density polypropylene or polyethylene. Wash solutions, consisting chiefly of a mineral acid[28], have been proposed for cleaning them, and the treatment conditions are generally different. It is not possible to compare their efficiency for different NW, vessel materials, and storage conditions, however, because of the inadequate experimental conditions. This comparison has been made only for the storage of fresh water in polyethylene vessels at 1 °C;[28] it was found that it is best to clean the vessels by shaking with 10% HNO_3 for 48 h. It has also been suggested that vessels for the storage of all types of NW should be cleaned by shaking with 2 M HCl and then washing with a filtered sample[19], since acid washing removes surface contamination from the walls of the vessels, but at the same time activates adsorption centres capable of removing TE from the sample.

To ensure minimum adsorption losses during the storage of samples in which it is necessary to determine only the total concentration of TE, the samples after filtration are usually acidified with HCl or HNO_3 to pH $\leq$ 2.[19,20,26] In the case of germanium, for example, they can be kept for several years[29]. In the determination of the physicochemical forms of TE, however, acids cannot be added. When filtered samples are stored at natural pH and room temperature, bacterial activity leads to the appearance of suspended particles and a decrease in the concentration of organic substances and hence to either the removal of TE from the solution or a change in their forms[19]. Thus to decrease bacterial activity and hence the loss of TE, it is suggested

that NW samples be kept in a refrigerator at 4 °C [30] for up to 1–3 months[31–33]. For the same purpose, sea water samples are kept in the frozen state between −20 °C and −45 °C, for up to three months without treatment[34], after filtration[22,32], and after filtration and acidification[22,35]. In the case of fresh water, a decrease in the labile form of TE has been observed[33].

The storage of samples for the determination of the total concentration of mercury shows differences, however, related to the characteristic features of its chemical and physical properties. Firstly, they cannot be kept in polyethylene vessels, whose walls are permeable to mercury vapour[36–38], but only in glass vessels. Secondly, Hg^{II} is readily sorbed on the walls and reduced to Hg_2^{II}, followed by disproportionation to Hg^0. In sea water, these processes are suppressed by acidifying with mineral acids[37], and in fresh water and dilute standard solutions by the further addition of oxidising agents, for example $K_2Cr_2O_7$ to a concentration of 0.05%,[36,39,40] or complex-forming agents, for example NaCl to a concentration of 3–4%.[37,41] Under these conditions, specimens and standard solutions can be kept for several months.

There are no general methods, however, for the storage of samples for the subsequent determination of the chemical forms of TE, in contrast to the case of their physicochemical forms. These are usually found empirically. Samples with inorganic forms of As^{III} and As^{V} can be kept for three weeks at room temperature[42], 10 days at ~4 °C,[43] for a long time below −15 °C,[44,45] for several days when acifified to 0.05 M HCl,[46] and for 125 days at pH 1.5.[47] In the case of inorganic forms of Se^{IV} and Se^{VI}, samples can be kept for a long time at 4 °C,[48] in the frozen state[49], or when acidified[49,50], for 125 days at pH 1.5,[48] and for 4.5 months at pH 2.[51] Different storage conditions of pH, concentration, and type and size of storage vessel material have been studied for the storage of As^{III}, As^{V},[36] Se^{IV} and Se^{VI}.[48] Samples containing methylarsinic acid (MAA) and dimethylarsinic acid (DMAA) can be kept indefinitely when acidified to 0.05 M HCl.[44] The vessels must be sealed to exclude atomospheric oxygen.

Very little is known about the storage of samples with chemical forms of other TE. Thus $MeHg^{II}$ can be kept for not more than 10 days at pH 2.5,[38] but it is lost quantitatively on lyophilisation[52], and Ph_2Hg and RHg^{II} (R = Me, Et, Ph) are only slightly converted to Hg^{II} after 30 days in 1% H_2SO_4.[40] It has also been noted that little Cr^{VI} is lost at pH 6–8,[53] but R_4Pb cannot be stored at all[54], since in river water it decomposes to the extent of 60% in 24 h.[55]

III. PHYSICOCHEMICAL FORMS

For most TE determined, stripping voltammetry (SV) has low detection limits, which for the most part coincide with their average concentrations in NW, and does not require preliminary chemical preparation of the samples. Thus combined with various methods of separation and decomposition it has been made the basis of recently developed general schemes for determining the physicochemical forms of trace metals (TM).

In the first of these[2,56,57], the following are measured in the sample after filtration through a membrane filter with a pore size of 0.45 μm: a) SV-labile metal, and b) total metal. The determinations are carried out systematically: 1) before treatment of the sample; 2) after it has passed through a column of Chelex-100 ion exchange resin; 3) after ultraviolet irradiation; and 4) after passage of the photo-oxidised specimen through a column of resin. This makes it possible to separate the physicochemical forms of the TM into the four classes given below, of which the last three are further divided into inorganic and organic forms, so that it is possible to determine seven dissolved forms of each metal: 1) free metal ions and labile complexes (in sea water at natural pH, this form corresponds to simple inorganic complexes such as chlorides and sulphates, and in fresh water to citrate and aminoacid complexes); colloidal metals; 2) SV-active and 3) SV-inactive (these classes in sea water correspond chiefly to metals adsorbed on organic and inorganic colloidal particles, or included in them, since the presence of appreciable concentrations of metal complexes which would not be held by the resin is unlikely; in fresh water the picture may be different, because of the higher concentrations of organic substances, particularly such powerful complex-forming agents as humic and fulvic acids; 4) labile complexes which dissociate on passage through the resin, for example those with cysteine, and also dissolved sulphides and silicates. There are no strict boundaries between these classes, however, and there is some overlap. An important advantage of the scheme is the low reagent background[58]. The dependence of the possible physicochemical forms of metals on their size is given in Table 1.

Table 1. Possible physicochemical forms of TE in NW in relation to their dimensions[2].

Form	Example	Approximate dimensions (μm)
Suspended	remains on a filter with pore diameter 0.45 μm	>0.45
Simple hydrated metal ions	$(H_2O)_6Zn(II)$	0.0008
Simple hydrated complexes	$(H_2O)_5ClZn(II)$	0.001
Simple organic complexes	Cu glycinate	0.001—0.002
Stable inorganic compounds	PbS, $ZnCO_3$	0.001—0.002
Stable organic compounds	Cu fulvate	0.002—0.004
Adsorbed on inorganic colloids	Cd(II)—MnO_2 Cu(II)—Fe_2O_3	0.01—0.50
Adsorbed on organic colloids	Pb(II) -humic acid; Zn(II) -organic detritus	0.01—0.50

Note: In this and subsequent tables M(II) = M^{II}, M(III) = M^{III}, etc.

The use of this scheme has shown that in coastal sea water[32], up to 40–60% Cu, 45–70% Pb, and 15–35% Cd, relative to their total concentrations, are combined with colloidal particles; in fresh water[33], Cu also predominates in these forms, but Pb is present in suspended inorganic form, and Cd exists only in labile ionic forms.

The results obtained using this scheme, however, do not necessarily reflect the true equilibrium concentrations of the forms of TM, because of their decomposition when an acid, the acetate anion, or a mercury salt are added to the sample being analysed[59,60].

Another general scheme for fresh water[61] is based on the fractionation according to the dimensions of the forms bearing the metals by filtering the samples through membrane filters with pore sizes of 12 μm and 1.0 μm, followed by ultrafiltration of the last filtrate through filters with pore sizes of 0.4, 0.08, and 0.015 μm (it is possible to divide the forms into even finer fractions by ultrafiltration through filters with pore sizes of 0.014, ~0.005, and ~0.0012 μm, but it has been found that ultrafilters do not have absolute pore sizes and

show variable adsorption, so that it has not been possible to obtain consistent results). The last six fractions are analysed for the total metal concentration by SV after photo-oxidation (Cd, Pb, and Cu) and by flameless AAS (Fe and Mn). In the series of filtrates, SV-labile metals are found at natural pH before and after ultraviolet irradiation. Particular attention has been paid to the limitations of the different schemes, and it has been shown that photo-oxidation is not suitable for the quantitative estimation of the forms in fresh water.

The continuum of the dimensions of the forms in this scheme makes it possible to avoid an arbitrary distinction between dissolved and suspended metal, and also emphasises the importance of colloidal fractions of the metals. The scheme has been used for fresh water[61,62]. In particular, it has been shown that the difference in the forms of metals in the waters of two rivers is due to a marked difference in the concentration of suspension, and that only a small fraction of the metals is SV- and Chelex-100-labile. The results[61] have also revealed a marked lack of agreement with the physico-chemical model for TM in fresh water[63], due to the inability of the latter to take account of suspended and colloidal forms of the metals.

Another approach to the continuum of dimensions of dissolved form of TM in fresh waters[64] is based on the principle of successive ultracentrifuging[65]. The sample is first filtered through a filter with a pore size of 0.45 μm, and then fractionated successively according to molecular mass through ultrafilters with pore sizes of 100 K, 25 K, 10 K, and 1 K (where K is the molar mass in multiples of 1000); this makes it possible to divide the dissolved organic matter and the forms of TM into definite fractions, depending on their molecular masses. In each of the fractions obtained, the metals are determined by SV and AAS. The highest concentrations of Cd, Pb, and Cu are found in fractions with molecular mass 10^3–10^4, and correlate with the concentration of organic carbon; there are no free or labile forms present. On the other hand, Fe and Mn are often found in fractions with higher molecular mass, and do not correlate with the concentration of dissolved carbon, and Ca and Mg are bound in fractions with lower molecular mass. The same regular features were observed for Cu by ultrafiltration and gel filtration[66].

A combination of a large number of analytical methods[12] can be used to determine the following forms of TM in fresh water: total, suspended, dissolved, free ionic, and combined, and also the distribution of the complexes with respect to molecular (ionic) mass in the range ~500–150000. Its advantages include the possibility of finding the sign of the charge of the free and complexed metal ions and studying complex formation, including its kinetics. Dissolved Mn is present chiefly as anionic complexes with high molecular mass. A serious disadvantage of the scheme is the insufficient attention to colloidal forms.

These general schemes cannot be used in many laboratories, however, because they are relatively complex and laborious. Simplified schemes for determining the physicochemical forms of TM, or individual fragments of general schemes, or details of the latter, have therefore been widely used.

In one simplified scheme[67,68], Cd, Cu, Pb, and Zn are determined in the suspended and dissolved forms, and in the latter the ion-exchangeable (free metal ions and simple inorganic and organic complexes) and combined (mainly a colloidal fraction with molecular mass less than 1000) forms. It has been applied to fresh and estuarine waters[69].

In another scheme[34], the sample is first filtered through a filter with a pore size of 0.22 μm to remove micro-organisms, after which part of the filtrate is passed through a filter with a pore size of ~0.001 μm with a restricted nominal molecular mass of 1000 to separate the forms with high and low molecular masses, that is colloidal and true dissolved forms. The three fractions obtained are analysed for the concentrations of total metal, the SV-labile forms at natural pH, and the SV-acid-labile forms at pH 2.8 (in the last case except the original specimen). This scheme has shown that in sea water, Cd is present exclusively in labile forms of low molecular mass, and Pb chiefly in non-labile forms of low molecular mass, while the distribution of Cu was irregular, with appreciable binding in colloidal and organic forms.

The range of experimentally determined physicochemical forms of TM is not restricted to the above schemes. To improve understanding of the role of TM in NW, it is necessary to have finer sub-divisions within each form or fraction. Thus depending on the time of contact with Ca-Chelex-100 resin, SV makes it possible to define the relative lability of TM as very labile, moderately labile, and inert[70,71]. This kinetically based classification may be useful for estimating the bio-availability of TM. In particular, Cd and Zn exist in forms more labile than Cu and Pb.

Identification of the lability of TM with their bio-availability may lead to serious errors, however, since the measured concentrations of labile metals depend markedly on the analytical conditions and the method used—SV, ion exchange, solvent extraction, absorption, etc. In particular, in SV the labile forms are free metal ions, together with metal complexes, which will dissociate in the diffuse layer, liberating the metal ion. The possibility of a more exact treatment of this term from the viewpoint of the values of the equilibrium and rate constants has been discussed[7]. For example, this method has shown[72] that in sea water, with decrease in pH from 8.1 to 2.0, there is a sharp increase in the proportion of labile Cd, Pb, and Cu detected: 0.17 → 0.45, 0.34 → 1.91, and 0.67 → 2.43 μg litre^{-1} respectively. When they are concentrated on Chelex-100 resin at pH 1 with subsequent determination by the same method, however, the Cd, Pd, and Cu concentrations obtained were 0.31, 0.81, and 2.03 μg litre^{-1} respectively. An increase in the labile fraction of TM when the samples were acidified has been observed by other workers[73]. This can be attributed to the conversion of colloidal, acid-sensitive, and acid-exchangeable forms into labile forms. Labile mercury is defined as that fraction in NW which is reduced by $SnCl_2$.[74–76]

The labile fractions of TM usually make up only a small proportion of their total concentration in NW. Most of the TM are combined with organic, colloidal, and suspended fractions, particularly in fresh, estuarine, and coastal sea water. The first of these fractions may contain an appreciable and even a greater proportion of TM, both in fresh water: Cu,[31,33,77] Cd,[78,79] Al, Cr, Fe, Pb,[80] and Hg;[78,81] and in sea water: Cu,[73,82,83] Zn,[73,83], Pb,[73] and Hg.[74,84]

Organic forms of TM are separated from the sample on anion-exchange resins[77,83], and organic mercury together with inorganic mercury on resin[85] and polyurethane[86] treated with dithiocarbamate, or on silica gel covered with benzothiazole-2-thiol.[87] They can be fractionated according to molecular mass or size by ultrafiltration[78,84,88], centrifuging[79,88], ion-exchange membranes[88], gel chromatography[80], and gel filtration[89,90]. The organic fraction of TM can be found less accurately from the difference between the total and labile metal in the same sample, determined by the same method. For this purpose it is necessary to separate the TM from their organic complexes and compounds, and also their colloidal particles. This is achieved by boiling the sample at pH 0.7 [58] or by ultraviolet irradiation[31,82,91,92]. The last method, involving irradiation by a 550 W mercury

lamp for 4 h, is particularly noteworthy, since it is suitable for all types of NW and gives a low reagent background[92]. In the determination of total Hg, because of the fairly high stability of its organic derivatives, the latter are decomposed by ultraviolet irradiation[91,93], or oxidising agents such as $K_2S_2O_8$, $KMnO_4$, Br_2,[37,39,74,94] or reducing agents such as $NaBH_4$,[95] $SnCl_2$ and $CdCl_2$, after concentrating the Hg on a resin treated with dithiocarbamate[96], or by combustion of the resin with the Hg at 850 °C.[85]

The important role in the binding of TM of colloidal particles of inorganic (hydrated oxides of Fe, Mn, Si, clays, and sulphides) and organic (humic substances, biota residues) origin has been emphasised[2,58]. Metals present in ionic forms and combined with colloidal particles are separated by dialysis, ultrafiltration, centrifuging, ion exchange, and electrophoresis, the methodology of which, together with methods of determining colloidal forms of TM, is given in the above schemes (see also Refs.2, 58, and 82). In particular, the concentration of more than 30 metals in colloids can be determined by NAA after ultrafiltration of the sample through a filter with a pore size of 0.0012 μm.[97] Cation exchange resins apparently do not concentrate colloidal forms of TM at natural pH,[58] which are too large to enter the pores of the resin. An important feature is that it is often difficult to prove unambiguously whether TM are present in the colloidal, particularly organic, fraction or in the dissolved organic fraction, if they are not clearly separated from one another. Thus the extent of the distribution of the TM between them is often only tentatively determined.

Most NW show coordinative unsaturation, revealed by the binding of added ionic TM. It is assumed that this so-called complex-forming power of NW is due to the presence of organic substances of the fulvic acid type. Analytical methods for determining it (amperometric titration, ion-selective electrodes, ion-exchange equilibria, etc.) and the theoretical basis of the concept have been reviewed[98].

Suspended particles play an important role in the distribution of TM in NW. Thus rivers may carry most of them (up to 80–90%) to the ocean in suspended form[83,99]. Mercury may also be present chiefly in this form in estuarine[100] and sea[101] water. The concentration of TM in the suspension may vary considerably, however, depending on the time of year[102].

Usually, suspended fractions of TM are separated from dissolved fractions by three methods—filtration, centrifuging, and precipitation[103]—but most frequently the suspension is removed on membrane filters with a pore size of 0.45 μm. The concentration of TM in the suspension remaining on the filter can be determined by several methods, depending on the availability of methods for treating the suspension and on available analytical methods. A number of the latter (NAA and ES) make it possible to determine many TM simultaneously without any treatment of the suspension[104,105]. Combustion of part of the filtrate with the suspension in an atomiser has been proposed for the determination by flameless AAS of a number of metals having approximately equal volatilities[106].

In most cases, before determination, the TM together with the filters are transferred to solution either with complete solution of the suspension or with extraction using acids without affecting the crystal lattices of the suspension. In the first case, a necessary component of the decomposition mixture is hydrofluoric acid, together with various other mineral acids[107–109]. It can also be achieved by fusing the suspension at 1000 °C with $LiBO_2$ with subsequent solution in HNO_3.[109] The extraction is usually carried out either by heating the suspension with mineral acids under different conditions[109–113] or with their mixtures[101,114], or with acid and 30% H_2O_2,[85] or by combustion of the suspension in a furnace at 450–600 °C followed by solution in HCl.[115,116] The TM in the solutions obtained are most frequently determined by AAS.

Suspended TM are sometimes found from the difference between their concentrations in the unfiltered and filtered samples[100,117]. Dispersion of the suspension in an ultrasonic bath after solution of the filter in $CHCl_3$, with subsequent determination by flameless AAS, has also been described[118].

In addition to the two phase forms of TM, dissolved and suspended, MW also contain a third form, the film (surface micro-layer), which contains the highest concentrations in NW of dissolved and suspended TM, and also organic substances, biogenic elements, etc. Compared with the layer under the water surface, the concentrations of dissolved TM may be several times greater[117], and the concentrations of suspended TM greater by a factor of up to 10, in fresh[117] and sea[114] water. The organic and inorganic forms of TM can be determined in the suspended film fraction[119]. Usually, the surface film of thickness <0.3 mm is removed, by various methods[120], including sampling devices[121].

Of the analytical methods for determining the dissolved physicochemical forms of TM without preliminary separation from the sample, only SV is used, because of its high sensitivity and simplicity of operation, and also the availability of instruments and equipment. Its use to determine the forms of metals has been described in detail[2,122]. The main limitation of SV is that it is applicable to only a small number of TM—Cd, Pb, Cu, and Zn. In recent years, the development of polarographic methods has made it possible to obtain information on the chemical state of a number of other elements—Tl, Cr, Sb, As, Bi, and U.[2,7]

The use of other analytical methods involves the preliminary concentration of the TM, which can be achieved by various methods[123], including filtration of the sample through chelating filters[124]. Methods of concentration have been compared[125,126]. All the stages in the analysis of TM in NW have been described in detail for the following methods: AAS,[20,126–128] NAA,[129] ES,[130] and X-ray fluorescence[131].

IV. CHEMICAL FORMS

Because of the extremely low concentrations of the chemical forms of TE in NW, only a few examples of their determination without concentration have been described. The determination of Cr^{III} by a chemiluminescent method with a detection limit of 0.02 μg litre^{-1} has been proposed[132]. As^{III} can be determined by differential pulse polarography (DPP) with a detection limit of ~10 μg litre^{-1},[46] but As^{V} is found from the difference between As (total inorganic) and As^{III} after reductive evaporation of the sample, with a detection limit of ~1 μg litre^{-1}. Hg^{II}, $MeHg^{II}$, and $PhHg^{II}$ have been determined separately by AAS in an automatic system on the basis of the selective reduction of combinations of these forms by EDTA, $SnCl_2$, and $CdCl_2$. The low detection limit of ~0.001 μg litre^{-1} was obtained as a result of the equilibrium of mercury vapour with a small volume of air at 90 °C.[40]

Because of the insufficient sensitivity of present-day analytical methods, the determination of most chemical forms of TE requires concentration, which can be achieved using liquid extraction, solid extracting agents, and the formation of volatile hydrides.

Methods for determining the chemical forms of TE with concentration by liquid extraction are given in Table 2. Inert compounds, for example R_4Pb, are extracted by

organic solvents such as hexane or benzene. After separation by GLC, the forms are determined by AAS with a detection limit of 0.2–0.5 μg litre^{-1}.[54,55] Most chemically active forms of TE must be concentrated by extraction with organic solvents in the presence of complex-forming agents. For Bu_nSn^{IV} (n = 1–3), tropolone is used. The forms in the extracts are alkylated by Grignard reagents to the corresponding methyl[133] and pentyl[134] derivatives of tin, and the latter are analysed. $MeHg^{II}$ and $PhHg^{II}$ are concentrated using dithizone, and RA makes it possible to determine them with a detection limit of 0.01 μg litre^{-1}.[135] Se^{IV} can be determined with detection limits of 0.0008 μg litre^{-1} and 0.002 μg litre^{-1} using 4-nitro-o-phenylenediamine[51] and 1,2-diamino-3,5-dibromobenzene[137] respectively. By oxidising $Se^{-II,0}$ with bromine and reducing Se^{VI} with a mixture of bromine and bromide to Se^{IV} with the last ligand, it is possible to determine all these forms separately. Their distributions in river and sea water have been given[138].

Table 2. Methods for determining the chemical forms of TE with concentration by liquid extraction.

Chemical form of TE	Extraction	Method of determination	Refs.
R_4Pb (R=Me, Et)	hexane	GLC-AAS	[55]
Me_nEt_mPb (n=m=0–4)	ditto	ditto	[54]
Bu_nSn(IV) (n=1–3)	tropolone	GLC-MS	[133]
ditto	ditto	GLC	[134]
MeHg(II), PhHg(II)	dithizone	RA*	[135]
Hg(II)	mixture of amines	GLC	[136]
MeHgCl	4-nitro-o-phenylenediamine	ditto	[51]

Cr (VI)	»	»	[147]

*RA = radioanalytically.

In a similar method, As^{III} is first determined using dithiophosphate (detection limit 0.006 μg litre^{-1}), and then As^V is determined after reducing to As^{III} using sulphite[139].

Pyrrolidine- and diethyldithiocarbamates are used particularly frequently as complex-forming reagents. They have been used for the selective extraction of As^{III},[140–142] Sb^{III},[142,143] Se^{IV},[142,144] Te^{IV},[145] Cr^{VI}.[146,147] The interfering influence of many metal ions is masked by adding EDTA.[141,143–145] The total concentration of these elements is then found by using KI [140,141] with acidification[143], heating[146], or boiling[144,145] with acids to convert all the inorganic forms of these elements into the above forms, and, from the difference between them, the forms As^V, Sb^V, Se^{VI}, Te^{VI}, and Cr^{III}. The detection limit is 0.2 to 0.4 μg litre^{-1} [140,141,143–145] or 0.02 μg litre^{-1}.[147] In NW, the highly oxidised forms of these elements predominate.

The use of GLC to determine organomercury compounds and inorganic mercury compounds by converting them into organic compounds has been reviewed[148]. LC has been used for the quantitative separation of RHg^{II} (R = Me, Et, Ph), R_3Pb^{IV} (R = Me, Et), and $MePh_3Sb^V$,[149] organic derivatives of Hg, Sn, Pb, and As,[150] and metal ions[151].

Methods for determining the chemical forms of TE with concentration on solid extracting agents are summarised in Table 3. Cr^{III} is coprecipitated quantitatively at pH 8 with $Fe(OH)_3$, and Cr^{VI} is either coprecipitated with cobalt pyrrolidinedithiocarbamate (CPDC) [154] or found from the difference between the total dissolved Cr, concentrated by coprecipitation on $Fe(OH)_2$ [111] or on $Bi(OH)_3$,[152,153] and Cr^{III}. Cr(inorganic) amounting to up to 60% of all dissolved forms of chromium has been detected for the first time in sea water[152,153]. This may be of considerable importance for other TE in NW, whose organic forms have not been studied.

Table 3. Methods for determining the chemical forms of TE by concentration on solid extracting agents*.

Chemical form of TE	Solid extracting agent	Method of determination	Refs.
Cr (III), Cr (VI)	$Fe(OH)_3$ and $Fe(OH)_2$	AAS	[111]

*CDTC = cobalt pyrrolidinedithiocarbamate, F = fluorescent, CL = chemiluminescent.

Promising methods for concentrating other TE are the adsorption of Se^0 on active carbon after selective reduction of Se^{IV} by l-ascorbic acid[50] and the electrodeposition of Cr^{III}.[155] These methods detect down to 0.05 μg litre^{-1}. Volatile mercury compounds are blown from the sample, Hg^0 is amalgamated on a column of silver wool, and Me_2Hg after thermal decomposition at 900 °C. The detection limit is 0.001 μg litre^{-1}.[156]

Cation- and anion-exchange resins are used both to concentrate and to separate the chemical forms of TE. In the case of Se^{IV}, dithiocarbamate is added to the specimen before concentration on the resin[160]. The detection limit is 2 μg litre^{-1} [158] or 10 μg litre^{-1} [157] for the forms of As^V, 0.005 μg litre^{-1} for Cr^{VI},[161] and 0.01 μg litre^{-1} for the forms of V.[162]

Because of the appreciable stability in water and relative simplicity of the preparation of the hydrides of a number of TE, considerable use has recently been made of methods for determining the chemical forms of TE, in which, depending on the pH of the sample, the forms of TE are selectively reduced by $NaBH_4$ to the corresponding hydrides, which are then concentrated by blowing out in a stream of helium into cryogenic traps cooled with liquid nitrogen. The

hydrides, after separation by GLC or successive evaporation, are determined by various analytical methods (Table 4). The detection limit may reach thousandths of a microgram per litre[49,165,166,169,171] or less[44,168,170]. The interfering action of various cations and anions in the reduction by $NaBH_4$ has been studied, and it has been shown that the actual concentrations in most NW do not interfere in the determination of the forms of the TE.[165,168–170]. The use of EDTA as a masking agent has been proposed[167]. The distribution in NW has been determined for the forms of As,[44,165–167] Sb,[168] Se,[49] Ge,[169] and Sn.[170,171]

Table 4. Methods for determining the chemical forms of TE with hydride formation.

Chemical form of TE	Method of concentration	Method of determination	Refs.
As (III) + As (V), MAA DMAA	cryogenic trap	ES	[165]
As (III), As (V), MAA, DMAA	ditto	AAS	[166]
ditto	»	AAS-GLC	[44]
»	»	AAS	[167]
Sb (III), Sb (V), MSA*, DMSA	»	ditto	[168]
Ge (IV), MeGe (IV), Me_2Ge (IV)	cryogenic trap	ES	[169]
Se (IV)	ditto	AAS	[49]
Se (VI)			
Me_nSn(IV) (n=0–3)	»	ES	[170]
R_nSn (IV) (R = Me, n-Bu, n=1–3; R=Ph, n=1; R=Et, n=2, 3)	»	AAS	[171]
Sn (IV)			
Se (IV)	$Fe(OH)_3$	ditto	[172]
Ph_nSn (IV) (n=1–4)	hexane	GLC	[173]

*MSA = methylstibonic acid, DMSA = dimethylstibinic acid.

Se^{IV}, Se^{VI}, Te^{IV}, and Te^{VI} are determined by AAS without the separation and concentration of the hydrides[174], but serious difficulties may be encountered in the interpretation of the results when this method is used for the determination of As^{III}, As^{V},[174,175] Sb^{III}, and Sb^{V},[174] in particular because of the influence of the oxidation state of the TE hydride on the magnitude of its AAS signal[174].

The reduction of the forms of TE can be carried out, however, not in the sample but after their concentration by precipitation with $Fe(OH)_3$ [172] or by extraction with hexane[173]. The detection limits are <1 μg litre^{-1} and <10 μg litre^{-1} respectively.

* * *

The methods for determining the physicochemical forms of TE in NW are only beginning to be developed. The main difficulties are the insufficient sensitivity of the analytical methods and the consequent need to concentrate the forms for the determination; this generally leads to breakdown of their natural equilibrium and to uncertainty in the relationship between the measured and actual forms present in water. The question of the bio-availability of the forms of TE and related analytical problems are poorly understood and have been little studied. Greatest attention should therefore be paid to these problems in the future.

Nitronium Salts in Organic Chemistry

Yu.V.Guk, M.A.Ilyushin, E.L.Golod, and B.V.Gidaspov

The review is devoted to the methods of synthesis and properties of nitronium salts. The characteristics of the nitration of various classes of organic compounds by nitronium salts are considered and new aspects of the mechanism of the nitration of aromatic compounds, discovered following the application of nitronium salts, are discussed.
The bibliography includes 144 references.

I. INTRODUCTION

The first solid nitronium salts were synthesised by Hantzsch in 1925. In the 1950's general methods were developed for the synthesis of nitronium salts and these compounds became available as reagents. The introduction of new nitrating agents into chemical practice was very important for the study of nitronium salts. Firstly, nitronium salts have many specific properties and their application greatly expands the synthetic possibilities of the nitration reaction. Secondly, the study of the characteristics of the nitration of aromatic compounds by nitronium salts and the discussion which arose in connection with this problem in the last 10–15 years have played a major role in the further development of our ideas about the nitration mechanism.

There have been few surveys of the literature on nitronium salts—after the review of Olah and Kuhn[1] in 1964, in which data relating to the initial investigation of this class of compound were compiled, no new reviews were published. The literature published up to 1980 is used in the present review.

II. SYNTHESIS AND PROPERTIES OF NITRONIUM SALTS

1. Synthesis of Nitronium Salts

Nitronium salts are ionic compounds containing the NO_2^+ cation and the anions of Lewis oxy-acids or complex acids—ClO_4^-, HSO_4^-, FSO_3^-, SO_4^{2-}, BF_4^-, PF_6^-, etc. The structure of nitronium salts was not established correctly immediately. Hantzsch[2] attributed the structures of nitracidium perchlorate $[H_2NO_3]^+ClO_4^-$ and dinitracidium perchlorate $[H_3NO_3]^{2+}2ClO_4^-$ to the nitronium perchlorate which he obtained for the first time. Later other workers[3,4] reproduced Hantzsch's synthesis and showed that his compounds are simply mixtures of nitronium perchlorate ($NO_2^+ClO_4^-$) and hydronium perchlorate ($H_3O^+ClO_4^-$).

Nitronium perchlorate can be obtained in several ways: by the reaction of nitrogen pentoxide with perchloric acid[3] or of nitrogen oxides with ozone and dry chlorine oxide[5], by the reaction of ClO_2F with nitric acid[6], or by the reaction between nitric acid and chlorine heptoxide[7]. Nowadays the most widely used method involves the synthesis of $NO_2^+ClO_4^-$ from ozone, nitrogen oxides, and chlorine oxide[8–10]. Another chlorine-containing nitronium salt, namely nitronium hexachloroantimonate, has been obtained by the reaction of antimony pentachloride with nitryl chloride in liquid chlorine[11]:

$$NO_2Cl + SbCl_5 \xrightarrow{Cl_2} NO_2^+SbCl_6^-$$

The synthesis and study of the properties of stable nitronium salts based on fluorine-containing Lewis acids have received considerable attention. Several general and specific methods of synthesis of these compounds have been proposed. Woolf and Emeleus[12–14] obtained $NO_2^+BF_4^-$, $NO_2^+PF_6^-$, $NO_2^+AsF_6^-$, $NO_2^+SbF_6^-$, $(NO_2)_2^{2+}SnF_6^{2-}$, $NO_2^+AuF_4^-$, and $NO_2^+FSO_3^-$ by the reaction of nitrogen dioxide with bromine trifluoride and the corresponding oxide (for example, boron oxide) or halide. $NO_2^+VF_6^-$, $NO_2^+NbF_6^-$, and $NO_2^+TaF_6^-$ were synthesised by the same method[15]:

$$NO_2 + B_2O_3 + BrF_3 \rightarrow NO_2^+BF_4^- ,$$
$$NO_2 + PBr_5 + BrF_3 \rightarrow NO_2^+PF_6^- .$$

Aynsley et al.[16] developed a general method of synthesis of nitronium salts by the reaction of nitryl fluoride with metalloids or their fluorides[17,18]:

$$Si + 6NO_2F \rightarrow (NO_2)_2^+SiF_6^- + 4NO_2 ,$$
$$BF_3 + NO_2F \rightarrow NO_2^+BF_4^- .$$

The reactions of oxides (V_2O_5, SO_3, etc.) with an excess of nitryl fluoride also lead to the formation of nitronium salts, for example:

$$SO_3 + NO_2F \rightarrow NO_2^+SO_3F^- .$$

The corresponding nitronium salts has been synthesised by the reaction of nitrogen dioxide with iridium hexafluoride[19].

The above methods of synthesis of nitronium salts are complex and require the use of compounds such as BrF_3 and NO_2F, which are difficult to obtain.

Nitronium salts became readily available reagents for extensive laboratory use only after the studies of Schmeisser and Elisher[20] and also Olah and co-workers[21], who showed that stable fluorine-containing nitronium salts can be obtained by the reaction of nitrogen pentoxide, anhydrous hydrogen fluoride, and a fluorine-containing Lewis acid in nitromethane:

$$N_2O_5 + HF + BF_3 \rightarrow NO_2^+BF_4^- + HNO_3 .$$

The replacement of N_2O_5 by concentrated nitric acids made it possible to simplify still further the synthesis of nitronium tetrafluoroborate[22,23]:

$$HNO_3 + HF + 2BF_3 \rightarrow NO_2^+BF_4^- + BF_3 \cdot H_2O .$$

Other Lewis acids, for example, phosphorus pentafluoride, arsenic pentafluoride, etc., react in the same way[22,24].

When it is necessary to obtain a salt free of an admixture of a nitrosonium salt, it is possible to employ modified methods in which the nitronium cation is generated from alkyl nitrates[25]

or nitryl chloride[26]:

$$RONO_2 + HF + 2BF_3 \rightarrow NO_2^+BF_4^- + ROH \cdot BF_3,$$

$$NO_2Cl + HF + 2BF_3 \rightarrow NO_2^+BF_4^- + HCl \cdot BF_3,$$

The nitronium salt of one of the strongest acids, namely trifluoromethanesulphonic, has been obtained recently[27-29].

Fairly convenient methods of synthesis of various nitronium salts have now been developed. Nitronium tetrafluoroborate, nitronium hexafluorosilicate, nitronium hexafluorophosphate, nitronium hexafluoroantimonate, and nitronium trifluoromethanesulphonate have found most applications as nitrating agents.

2. Physicochemical Properties of Solutions of Nitronium Salts

The solubility of nitronium salts has been inadequately studied. Nitronium tetrafluoroborate (NTFB) and nitronium fluorosulphonate[30] have been most fully investigated (see Table).

The solubilities of nitronium salts at 20 °C.

Solvent	Solubility, wt.%	
	NTFB	nitronium fluorosulphonate
Acetonitrile	3.1	1.6
Nitromethane	1.2	1.0
1,4-Dioxan	1.2	0.3
Methyl ether of ethylene glycol acetate	0.7	—
Methyl acetate	4.1	3.8
Ethyl acetate	0.1	0.1
Trimethyl phosphate	19.9	12.7
Tripropyl phosphate	6.0	5.4
Tributyl phosphate	1.9	1.6

NTFB dissolves only slightly in nitroethane and nitropropanes[1,31]. The rate of dissolution of NTFB is determined by diffusion processes and varies in parallel with its solubility in a number of solvents[30].

Nitronium hexafluoroantimonate, hexafluorophosphate, and hexafluoroarsenate are more soluble in organic solvents than NTFB and 50% solutions of these salts can be obtained for example in nitromethane.

The salts also dissolve readily in nitroethane, nitropropanes, sulpholane, and trifluoroacetic acid[31]. Less than 0.3% of NTFB and ~0.5% of $NO_2^+ClO_4^-$ dissolve in nitromethane at 25 °C.[21,31] The saturated NTFB solution in sulpholane at 25 °C contains 7% of the salt, while that in acetonitrile contains 10% of the salt. The solubility of NTFB in nitroethane and nitropropane is insignificant but there are no quantitative data[1,31].

A solution of NTFB in liquid hydrofluoric acid is a true electrolyte, like a KBF_4 solution[32]. Cryoscopic studies of NTFB solutions in sulpholane[31] showed that, at a concentration of ~ 3 mole %, NTFB exists in the form of ion pairs, of which less than 2% are dissociated into ions. With increase of the NTFB concentration in sulpholane, the conductivity of the salt rises linearly[21,27,31]. Solutions of nitronium trifluoromethanesulphonate[27] and NTFB[21] have very similar specific conductances. Conductimetric measurements on solutions of nitronium salts of monobasic and dibasic acids have shown that the nature of the anion has little influence on the degree of dissociation of the salt[33]. A solution of nitronium perchlorate in nitromethane is less than 6% dissociated[1].

On the basis of cryoscopic[34] and other data, Olah and Kuhn[1] believe that in concentrated solutions nitronium salts exist in the form of conducting ion triplets. On dilution of the solution, the triplets are converted into non-conducting ion pairs. Further dilution of the solution leads to the separation of the ion pairs into simple ions, which are also conducting; this enabled the authors to account for the minimum in the conductivity of nitronium perchlorate solutions in nitromethane with increase of the nitronium salt concentration. A conductivity minimum has also been observed for solutions of a series of uni-uni- and uni-bi-valent solutions of nitronium salts in ethyl acetate[33] and is also due to the existence of ionic associated species. On the other hand, a linear relation has been found[35] between the specific conductance of a solution of nitronium hexafluorophosphate in nitromethane and the concentration, no signs of the formation of ionic associated species being observed up to a nitronium salt concentration of 0.4 M.

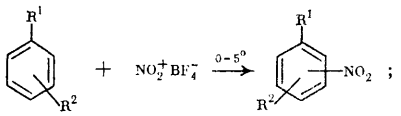
The interpretation of the conductimetric data for nitronium salts in aprotic solvents is at present obscure. The problem is complicated by the fact that many physicochemical characteristics of nitronium salts in organic solvents and particularly their stability and electrical conductivity are to a large extent determined by the content of moisture and impurities and also by the nature of the interaction with the solvent employed. However, in the communications published up to 1970[1,21,31,36] no characteristics of the impurity and water contents in the solvents are given, which is the reason for the contradictory nature of the results.

Spectroscopic studies have been particularly important for the elucidation of the structure of nitronium salts. The study of infrared spectra led to the conclusion that nitronium ions have a linear structure in solution[37]. In nitronium perchlorate crystals the linearity of the nitronium ion breaks down[36,38]. Studies of the infrared and Raman spectra of a series of nitronium salts have led to the conclusion[39] that the nitronium ion in NO_2-X compounds is bent and that the amount of ionic character of the NO_2-X bond increases in parallel with the ONO angle in the sequence $NO_2Cl < NO_2F < NO_2^+SO_3F^- < NO_2^+S_2O_6F^- < NO_2^+ClO_4^- = NO_2^+BF_4^-$. These results are extremely interesting but they require additional tests, particularly since some experimental data do not agree with the measurements of other workers[27].

III. NITRATION BY NITRONIUM SALTS

An extremely important stage in the research into nitronium salts involves the choice of solvent. As mentioned above, nitronium salts have a limited solubility and interact with the majority of organic solvents. Solvents such as acetonitrile, acetic and phosphoric acid esters, nitromethane, dioxane, and sulpholane are usually employed for nitration. Nitroderivatives of aromatic hydrocarbons have been synthesised in an excess of the aromatic compound or in ether[21]. However, ethyl ether interacts with NTFB on mixing. Apart from the solvents indicated, aliphatic hydrocarbons, methylene chloride, and acetic anhydride have been used for nitration by nitronium salts. Nitration by NTFB has been carried out[40] in anhydrous acetic acid, but the latter interacts with NTFB at room temperature to form another nitrating agent—acetyl nitrate.

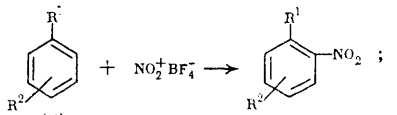
Nitration by nitronium salts is complicated by the liberation of the corresponding inorganic acids (tetrafluoroboric, hexafluorosilicic, etc.) which can also react in their turn



with the solvent, particularly since many of these acids are superacids (for example, trifluoromethanesulphonic acid is 14 times stronger than sulphuric acid[28]).

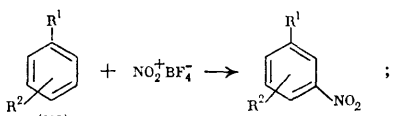
Some investigators have used solutions of nitronium salts in strong protic acids for nitration—sulphuric[28,40,41], methanesulphonic[40], trifluoromethanesulphonic[28], and fluorosulphonic[41]. However, such nitrating systems differ from the corresponding nitric acid solutions only by the water content and the acidity of the medium and will not be considered in this review.

1. Nitration of Aromatic Hydrocarbons



In 1950 it was observed[3] that a solution of nitronium perchlorate in nitromethane nitrates benzene to nitrobenzene almost instantaneously and slowly converts nitrobenzene into dinitrobenzene. However, the low stability of nitronium perchlorate and the risk of the explosion of its mixtures with organic solvents inhibited further investigation of the nitrating activity of this salt.

Olah and Kuhn were the first to carry out extensive studies on nitronium salts as nitrating agents. They showed that not only nitronium perchlorate but also other stable nitronium salts, namely the tetrafluoroborate, hexafluorosilicate, and hexafluoroantimonate, are active nitrating agents[1,21,42]. They investigated NTFB most fully and showed that, in sulpholane[22] or an excess of the substrate[42], $NO_2^+BF_4^-$ nitrates benzene and alkylbenzenes (I) very readily to the corresponding mononitro-derivatives in 80–95% yield:

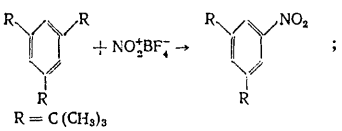


(a) $R^1=H$; $R^2=H$, CH_3, C_2H_5, iso-C_3H_7, n-C_3H_7, n-C_4H_9, iso-C_4H_9, or t-C_4H_9;
(b) $R^1=CH_3$; $R^2=CH_3$(o-, *m*-, or *p*-).

Monohalogenobenzenes react under approximately the same conditions, while dihalogenobenzenes are nitrated at a higher temperature (30–50 °C), but the yield is in all cases 80–90%. The nitration of benzene derivatives containing other electron-accepting substituents takes place just as successfully although the reaction is in this case slower and takes place at a higher temperature (up to 40–50 °C, in a few instances 90–100 °C). By nitrating *o*-tolunitrile with NTFB in sulpholane, it proved possible to obtain for the first time 3-dinitro-*o*-tolunitrile in 75% yield[1]. The reactions with other nitrating agents lead to the oxidation of the nitrile group:

(II)

(a) $R^1=Cl$, $R^2=o\text{-}NO_2$, $p\text{-}NO_2$; (b) $R^1=F$, $R^2=o\text{-}NO_2$, $p\text{-}NO_2$;



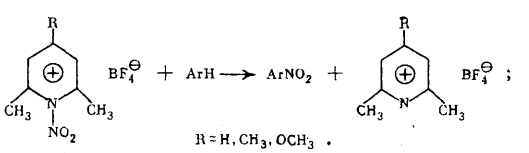
(III)

(a) $R^1=NO_2$, CN, $COOCH_3$, COCl, COF; $R^2=H$; (b) $R^1=CN$, $R^2=o\text{-}NO_2$; $m\text{-}NO_2$; $p\text{-}NO_2$; (c) $R^1=COOC_2H_5$, $R^2=m\text{-}NO_2$.

The readily oxidisable triaryl- and alkyldiaryl-phosphines were nitrated for the first time with NTFB and a series of *meta*-nitro-derivatives of arylphosphines were obtained[43].

The nitration of alkylbenzenes containing the isopropyl or t-butyl group with $NO_2^+BF_4^-$ is accompanied by substitutional nitration with elimination of one of the alkyl groups (*ipso*-substitution)[44]. In the nitration of *p*- and *o*-cumenes the degrees of substitution of the isopropyl group are 9.5 and 41% respectively. In the nitration of 1,4-di-isopropylbenzene one of the isopropyl groups is 56% substituted, while in the nitration of 1,4-di-t-butylbenzene the degree of substitution of the t-butyl group is 20%.

Steric hindrance interferes with the direct nitration of 1,3,5-tri-t-butyl-benzene: on treatment with NTFB, only substitutional nitration takes place with formation of 1,3-di-t-butyl-5-nitrobenzene:



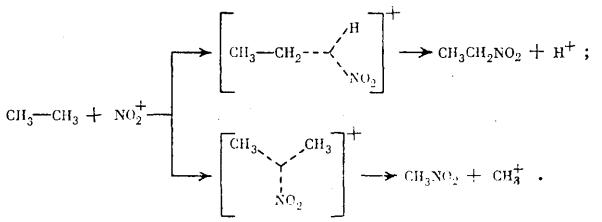
$R = C(CH_3)_3$

The interaction of polyalkylbenzenes with nitronium salts also leads to different hydroxymethyl derivatives[45,46]. Polynuclear aromatic compounds (biphenyl, naphthalene, and phenanthrene) are nitrated quantitatively by NO_2BF_4,[1] more than 50% of α-nitronaphthalene being obtained from naphthalene and only 9-nitrophenanthrene being formed from phenanthrene.

Comparison of the nitrating capacities of three nitronium salts, namely the tetrafluoroborate, the hexafluorophosphate, and the trifluoromethanesulphonate, with respect to toluene showed that the highest reaction rate or the highest yield of nitrotoluene are obtained when nitronium trifluoromethanesulphonate is used[28]. On the other hand, Olah and Kuhn[47] were unable to detect the influence of the nature of the anion on the yield of *o*-nitrotoluene; they explained the decrease of the content of the *ortho*-isomer from 65 to 55% on passing from sulpholane to nitromethane and toluene by the difference between the degrees of solvation of the ion pairs of the nitrating agent. In the nitration of toluene by nitronium trifluoromethanesulphonate in alkyl halides, the ratio of the *ortho*- and *para*-isomers at temperatures between −60° and −90 °C remains almost constant at 1.63, while at −110 °C it decreases to 1.03. The yield of the *meta*-isomer does not exceed 0.33% under these conditions[47].

Alkylnitropyridinium salts are interesting nitrating agents. The alkyl groups in the 2- and 6-positions of pyridine (VI) prevent the conjugation of the nitro-group with the ring (owing to their non-coplanarity), which leads to a high nitrating capacity of these salts. In contrast to inorganic nitronium salts, pyridinium salts make it possible to carry out nitration readily under homogeneous conditions. Furthermore, the acid formed as a result of the reaction is bound by alkylpyridine, which is very important in the nitration of compounds sensitive to the action of acids[48]:

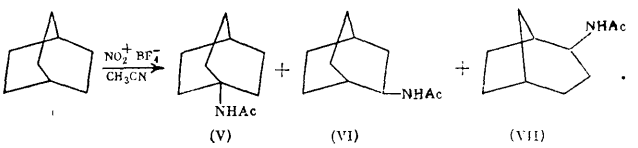
(IV)



R = H, CH_3, OCH_3 .

The solvent apparently has a considerable influence on the nitrating activity of nitronium salts, but this problem has as yet been little investigated.

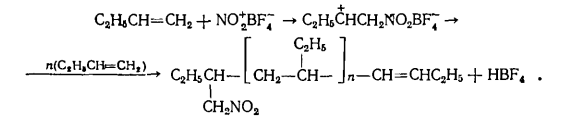
2. Nitration at a Saturated Carbon Atom



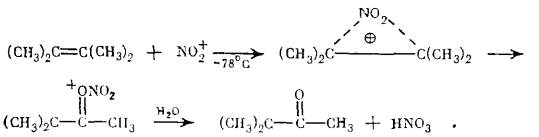
All the nitration reactions of paraffinic and naphthenic hydrocarbons known hitherto take place via a free-radical mechanism involving the $NO_2^{\cdot}$ radical[108]. It has been shown only recently[49] that the nitration of paraffinic hydrocarbons can be achieved with the aid of stable nitronium salts in the methylene chloride–sulpholane system under conditions which virtually rule out the formation of the radicals. Thus the authors obtained nitromethane from methane, albeit with a low yield, nitroethane from ethane, etc. The tertiary C–H bond exhibits the highest reactivity: adamantane is nitrated to 1-nitroadamantane in 10% yield. Nitronium salts can be replaced by the nitro-group and a proton in a methyl group of polyalkylbenzenes[46].

The nitration of paraffinic hydrocarbons is accompanied by nitrolysis with the dissociation of a C–C bond, the process occurring more readily than the nitration at secondary and primary carbon atoms. The nitration of alkanes with the normal structure therefore results in the preferential formation of nitrolysis products. For example, a mixture of 1- and 2-nitrobutanes, nitroethane, and nitromethane has been obtained from n-butane in proportions of 1:1.5:4:5, while a mixture of t-nitrobutane and nitromethane in proportions of 3:1 was obtained from isobutane. According to Olah's hypothesis[50], nitration, like other electrophilic processes (deuterium exchange, alkylation, and acid-catalysed isomerisation), proceeds via the "frontal" attack on a C–H or C–C bond with formation of a triangular transition state and not via the attack by the electrophile on a tetragonal carbon atom:

In the first excited state the linear nitronium cation can be converted into the bent form[51] and can react as an electrophile.

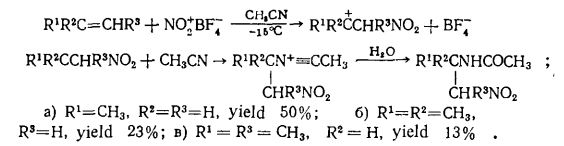


The nitronium cation is also capable of oxidising secondary and particularly tertiary carbon atoms with formation of a carbenium ion[52]. If the reaction takes place in acetonitrile, then the carbocation is converted by the Ritter reaction into the corresponding amide. Thus *N*-(1-adamantyl)acetamide was obtained from adamantane (yield 88%) and *N*-(*exo*-2-norbornyl)acetamide was obtained from norbornane (yield 78%). Bicyclo[2.2.2]octane is converted in 73% yield into the corresponding amides (V)–(VII) in proportions of 65:22:13:



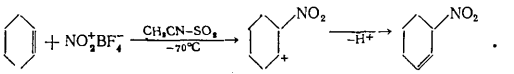
It is striking that the ratio of isomers (VI) and (VII) formed is approximately the same as in the similar isomerisation of the carbocation obtained in the solvolysis of bicyclo[2.2.2]-octyl-2-*p*-bromobenzenesulphonate[53,54], which is also evidence in support of an ionic mechanism of the reaction of polycyclanes with NTFB under consideration. Both *exo*- and *endo*-2-norbornyl bromides react analogously with nitronium salts[55].

3. Nitration at the Double Bond

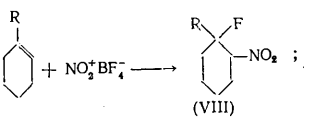


The reactions of nitronium salts with olefins do not take place unambiguously and depend to a large extent on the nature of the alkene and the reaction conditions. When alkenes react with nitronium salts, a reactive nitrocarbenium ion, which can initiate polymerisation, is formed[56]:

The nitrocarbenium ion can be also stabilised as a result of an intramolecular rearrangement to the oxonium ions. The latter reacts with water to form a ketone[57]:

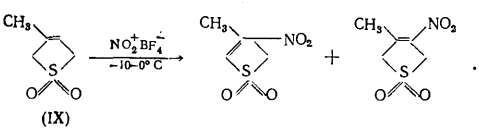


If the nitration of olefins by nitronium salts is carried out in acetonitrile, then the nitrocarbenium ion undergoes the Ritter reaction with the solvent to form nitroacetamides[58]:



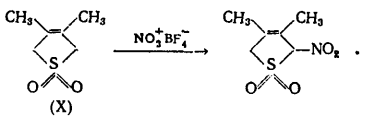
a) $R^1=CH_3$, $R^2=R^3=H$, yield 50%; б) $R^1=R^2=CH_3$, $R^3=H$, yield 23%; в) $R^1=R^3=CH_3$, $R^2=H$, yield 13%.

The mode of the reaction between olefins and nitronium salts depends on the structure of the substrate and the process conditions. For example, cyclohexene reacts with NTFB to form a nitrocarbocation, which is stabilised in the form of 3-nitrocyclohexene (yield 40%)[59,60]:



The nitration of 1-substituted cyclohexenes is accompanied by the formation of 2-fluoro-1-nitro-2-R-cyclohexanes (VIII):

(a) R = CH_3, yield 30% [61]; (b) R = Cl, yield 60%.[62]



The mechanism of the formation of the fluoro-derivative has not been studied but the stereochemistry of the process has attracted attention—the reaction proceeds via a vicinal-addition mechanism[61].

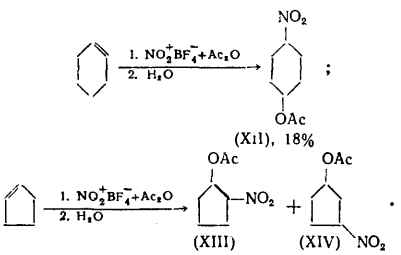
Alkenes with a reduced electron density, for example 3-methyl-2,5-dihydrothiophen 1,1-dioxide (IX), react with NTFB more or less unambiguously:

The reaction of 3,4-dimethyl-2,5-dihydrothiophen 1,1-dioxide (X), in which the double bond is blocked by the methyl groups, apparently proceeds via an electrophilic substitution

mechanism[63]:

(X)

As mentioned above, the reactions of nitronium salts with olefins proceed via the formation of a nitrocarbocation and the decisive factor which determines the success of the reaction is the ease of the stabilisation of nitrocarbocation by its conversion into the final product. One of the methods for such stabilisation involves nitration in acetic anhydride. It has been suggested that the complex $NO_2^+BF_4^-.Ac_2O$ reacts and that 2-acetoxy-1-nitroalkane is obtained in 36–60% yield after the hydrolysis of the reaction mixture with water[64]. The reaction involves mainly *cis*-addition:



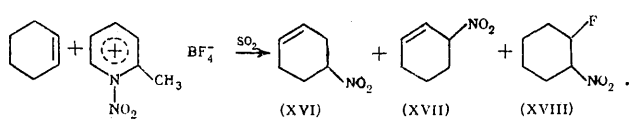
$$R^1R^2C{=}CHR^3 + NO_2^+BF_4^- \xrightarrow{Ac_2O,\,H_2O} AcOCR^1R^2CHR^3NO_2 \ ;$$

(XI)

a) $R^1{=}CH_3$, $R^2{=}R^3{=}H$; б) $R^1{=}R^2{=}CH_3$ (*cis, trans*), $R^3{=}H$; в) $R^1{=}R^2{=}CH_3$, $R^3{=}H$

4-Acetoxy-4-methyl-2-pentanone was isolated together with the nitroacetate (XIc) after the nitration of isobutene, which indicates the formation of an acylium cation in the reaction mixture.

The nitration of cyclenes is as a rule accompanied by the transfer of the reaction centre and the formation of the β- and γ-nitroacetates (XII)–(XIV) in 18–29% yields[65]:



(XII), 18%

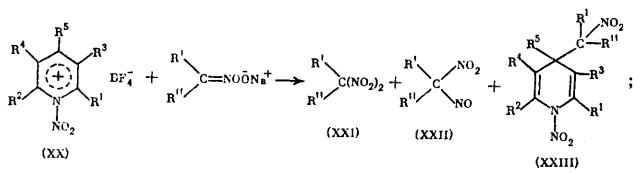
(XIII) (XIV)

The high degree of stabilisation of the nitrocarbocation in the nitration of norbornene in acetic anhydride ensures a high (86%) yield of two conformers of 2-acetoxy-7-nitrobicyclo[2.2.1]heptane formed.

Overall, one should say that the nitration of olefins, particularly those containing electron-donating substituents, by nitronium salts is complicated by side reactions and does not always lead to the expected result. In many instances nitration with nitronium tetrafluoroborate takes place with higher yields in the presence of α-picoline[62,66]. In this case the nitrating agent is apparently not the nitronium salt but 1-methyl-*N*-nitropyridinium tetrafluoroborate(XV), which is formed rapidly when NTFB is mixed with α-picoline[48]. The yields of products (XVI)–(XVIII) are respectively 40, 25, and 13%:

(XVI) (XVII) (XVIII)

The interaction of nitronium salts with the heteropolar C=N double bond in nitroalkane salts is of great interest. Olsen et al. showed that *gem*-dinitro-compounds are formed in the nitration of 2-nitropropane and nitrocyclohexane salts with NTFB in acetonitrile[67]:



$$R^1R^2C{=}NO_2M + NO_2^+BF_4^- \rightarrow R^1R^2C(NO_2)_2 + MBF_4 \ ;$$

(XIX)

(a) M=Li, (b) M=Na, (c) M=K .

The reaction takes place between −35° and −40 °C and its character depends on the nature of the cation. When the lithium salt (XIXa) is used, the yield is 35%, in the presence of the sodium salt (XIXb) it is 25%, while the potassium salt (XIXc) does not react. Apart from the *gem*-dinitro-compounds, the nitration of nitroalkane salts gives rise also to the pseudonitroles $R^1R^2C(NO)NO_2$. In contrast to dinitroalkanes, their yield increases on passing from the lithium to the potassium salts from 5 to 25%.

N-Nitropyridinium tetrafluoroborate salts, which are very mild nitrating agents, can also be used for the nitration of mononitroparaffin salts[68,69]. However, the nitration is in this case complicated by the alkylation of the *N*-nitropyridinium salt of the nitroalkane and the formation of a pseudonitrole (for secondary nitro-compounds):

(XX) (XXI) (XXII) (XXIII)

(a) $R^1{=}R^2{=}R^3{=}R^4{=}R^5{=}H$; (b) $R^1{=}R^2{=}CH_3$, $R^3{=}R^4{=}R^5{=}H$; (c) $R^1{=}R^3{=}R^4{=}R^5{=}H$, $R^3{=}C_2H_5$; (d) $R^1{=}R^2{=}R^3{=}H$, $R^4{=}R^5{=}CH_3$; (e) $R'{=}CH_3$, $R''{=}H$; (f) $R'{=}C_2H_5$; $R''{=}H$; (g) $R'{=}R''{=}CH_3$; (h) $R'R''C$— cyclohexylidene

The extent of these side reactions depends on the structure of the nitrating agent. *N*-Nitropyridinium tetrafluoroborate (XXa) does not enter into the nitration reaction; only the alkylation product is formed—*N*-nitro-4-nitroalkyl-1,4-dihydropyridine [compounds (XXIII, a and e)–(XXIII, a and g)] in 60–85% yield. The introduction of substituents into the 4- and 2,6-positions of the pyridine ring [compounds (XX, b–c)] promotes the formation of the pseudonitroles (XXII, g and h) (up to 20%) and *gem*-dinitroalkanes (XXI, e–h), whose yield reaches 42%. Primary nitroalkanes react with 3,5-lutidine derivatives (XXd) to form mainly the alkylation products (XXIII, d and e), while secondary nitroalkanes give rise to the *gem*-dinitro-compounds (XXI, g and h) in yields up to 56%. The anion of 1,1-dinitroethane reacts with the salt (XXc) to form only the alkylation product (XXIIIc, $R' = CH_3$, $R'' = NO_2$).

An interesting example of nitration is the reaction of NTFB with the sulphonium dinitro ylide to form a trimethylsulphonium salt[70]:

$$(CH_3)_2\overset{+}{S}{-}\bar{C}(NO_2)_2 + NO_2^+BF_4^- \xrightarrow{CH_3CN} [(CH_3)_2\overset{+}{S}{-}C(NO_2)_3]\,BF_4^- \ .$$

Compounds containing three nitro-groups and an onium cation at the same carbon atom were previously unknown. Such derivatives of trinitromethylselenonium are less stable—all attempts to synthesise such compounds have led to the formation of tetranitromethane. The reaction can be formally regarded as electrophilic substitution at a saturated carbon atom attached to nitro-groups[71]:

$$(C_6H_5)_2\overset{+}{S}e{-}\bar{C}(NO_2)_2 + NO_2^+BF_4^- \xrightarrow{CH_3CN} C(NO_2)_4 \ .$$

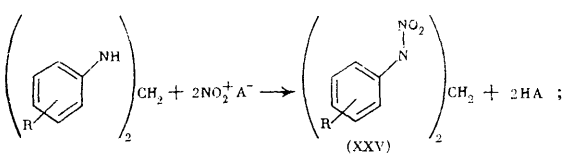
NTFB reacts with aliphatic, carbocyclic, or aromatic ketoximes in the presence of pyridine to form the corresponding ketones[72].

NTFB reacts just as smoothly with ketone dimethylhydrazones:

$$\begin{matrix} R^1 \\ R^2 \end{matrix}\!\!>\!C{=}N{-}N(CH_3)_2 \xrightarrow{NO_2^+BF_4^-} \begin{matrix} R^1 \\ R^2 \end{matrix}\!\!>\!C{=}O \ .$$

The reactions take place with high yields and can serve as a preparative method for the regeneration of ketones from their oximes and hydrazones.

4. Nitration at a Nitrogen Atom



The first indication of the possibility of the nitration of amines by nitronium salts was given by Olah and Kuhn[1]. Olsen et al.[67] found that NTFB reacts readily with secondary amines in methylene chloride or acetonitrile to form *N*-nitroamines (XXIV), whose yield is 50–70%:

$$2R^2NH + NO_2^+BF_4^- \rightarrow R^2N{-}NO_2 + R^2NH_2 + BF_4^- \ ;$$
(XXIV)
$R^2 = (C_4H_9)_2$, $(NCCH_2CH_2^-)_2$, or morpholinyl .

In a later study[73] it was shown that the nitration of aromatic amines proceeds differently depending on their basicity. Amines of moderate and low basicity, namely bis(2-cyanoethyl)amine ($pK_a = 5.25$), bis(2,2-dinitropropyl)amine ($pK_a = 3.08$), and bis(2,2,2-trinitroethyl)amine ($pK_a = 0.05$) are nitrated by NTFB to the corresponding *N*-nitroamines in acetonitrile or ethyl acetate in yields of 87–98%. Despite the data of Olsen et al.[67], the nitration of highly basic dialkylamines ($pK_a = 8.70–11.25$) is accompanied by the partial reduction of $NO_2^+BF_4^-$ to nitrosonium tetrafluoroborate and the formation of nitrosoamines. The content of nitrosoamine in the reaction mixture increases with increase of the reaction temperature. Nitronium hexafluorosilicate proved to be a milder nitrating agent; its application makes it possible to reduce greatly the formation of nitroso-derivatives.

The nitration of aliphatic-aromatic amines also proceeds smoothly and the low acidity of the medium makes it possible virtually to avoid the *N*-nitro-*C*-nitro-rearrangements[73].

Aromatic methylenebisamines, which are unstable in an acid medium, were nitrated for the first time with nitronium salts and *N,N'*-diarylmethylenedinitroamines (XXV) were obtained in a high yield[74]:

$A^- = BF_4^-, SiF_6^{2-}$; R = 2-NO_2, 3-NO_2, 4-NO_2, 2,6- and 3,5-$(NO_2)_2$.

The reactions of nitronium salts and nitrogen pentoxide with ammonia have been investigated[24,39,75,76] and it has been shown that nitramide (XXVI) is formed at the temperature of liquid nitrogen:

$$2NH_3 + NO_2^+A^- \rightarrow NH_2NO_2 + NH_4^+A^- \ ;$$
(XXVI)
$A^- = SO_3F^-, ClO_4^-, BF_4^-, NO_3^-$.

The formation of nitramide is determined by the nature of the anion: on passing from nitronium chlorosulphonate to NTFB, the yield increases from 8 to 43%.

On treatment with nitronium salts, primary aliphatic amines are converted into alkyl nitrates (apparently via diazotisation by the nitronium cation), but *N*-2,4,6-tetranitroaniline was obtained in a high yield from the weakly basic picramide[67].

Nitronium salts proved to be particularly useful in the synthesis of *N,N*-dinitroamines which had been previously difficult to obtain. It was shown[77] that the interaction of primary nitroamines with NTFB, nitronium pyrosulphate, fluorosulphonate, fluorosilicate, as well as other nitronium salts leads to the formation of the *N,N*-dinitroamines (XXVII):

$$RN(NO_2)X + NO_2^+A^- \rightarrow RN(NO_2)_2 \ ;$$
(XXVII)
X=H, NH_4, K, Li etc. ; $A = BF_4^-, S_2O_7^{2-}, FSO_3^-, SiF_6^{2-}, ClO_4^-, SbF_6^-, SnF_6^{2-}$.

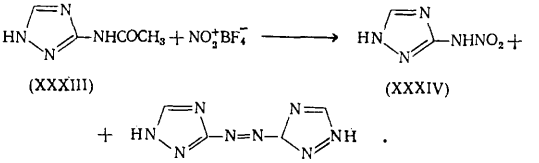
Aliphatic and aromatic amines, including those with other functional groups, readily participate in the reaction. According to the authors' data, best results are obtained in nitration by nitroamine salts in chloroalkanes or acetonitrile. However, the employment of more basic solvents, such as ethers and esters, ensures equally high yields in the nitration of both free nitroamines and their salts[78].

Olsen et al.[67] suggested that NTFB be used in acetonitrile or methylenechloride for the synthesis of the primary nitroamides (XXVIII):

$$RCONH_2 + NO_2^+BF_4^- \rightarrow RCONHNO_2 + HBF_4 \ ;$$
(XXVIII)
$$HBF_4 + KOCOCH_3 \rightarrow KBF_4 + CH_3COOH \ .$$

The nitroamides of benzoic and chloroacetic acids were obtained in satisfactory yields by the method proposed, but the yield of nitroacetamide was only 12%. This can be explained by the fact that the aliphatic nitroamides are hydrolysed in the solvents indicated even in the presence of potassium acetate. Only the use of more basic solvents—ethyl acetate, 1,4-dioxan, or trimethyl phosphate—made it possible to obtain nitroamides of different structure in 40–90% yield[79]. Succinimide is nitrated by NTFB in ethyl acetate in 43% yield[67].

The general method of synthesis of sulphonic acid nitroimides (XXIX) consists in the reaction of NTFB with imide salts[80]:



(XXIX)
(a) X=*n*-$CH_3C_6H_4SO_2$; Y=COOR; (b) X=Y=CH_3SO_2; $C_6H_5SO_2$

One of the known methods of synthesis of dialkylnitroamines involves the reaction of dialkylamides with nitric acid, which leads to the substitution of the acyl group by the nitro-group (nitrolysis). However, when nitric acid or its mixtures with acetic anhydrides are used, the yield of nitroamines is as a rule low and only the employment of the HNO_3–$(F_3CCO)_2O$ mixture makes it possible to raise it to 90%.[81] For preparative purposes, it is more convenient to nitrate the dialkylamides (XXX) by nitronium salts[82]. The reaction takes place at 20 °C in acetonitrile or esters. The dialkylnitroamines (XXXI) are formed in yields up to 90% and the acyl group is converted into acylium tetrafluoroborate (XXXII):

$$R_2NC(O)R' + NO_2^+BF_4^- \rightarrow R_2N{-}NO_2 + R'CO^+BF_4^- \ ;$$
(XXX) (XXXI) (XXXII)
R=CH_3, C_2H_5, *n*-C_3H_7, *n*-C_4H_9, R'=CH_3, C_2H_5, CH_2CN, CH_2Cl, $CHCl_2$, CCl_3 .

The possibility of the nitrolysis of secondary amides with formation of the corresponding primary *N*-nitroamines (XXXIV) [together with 3,3'-azo-1,2,4-triazole (XXXV)] has been demonstrated for an *N*-acyl derivative of 3-amino-1,2,4-triazole (XXXIII)[83]:

(XXXIII) (XXXIV)
(XXXV)

Under the reaction conditions, alkyl-*N*-nitroamines decompose in the presence of the organic acids liberated[84]. Amides containing electron-accepting substituents at the nitrogen

atom also undergo nitrolysis by nitronium salts. Thus *N*-fluoronitroamines (XXXVI) were obtained from *N*-fluoroamides[85]:

$$RNFCOOCH_3 + NO_2^+BF_4^- \rightarrow \underset{\underset{F}{|}}{RNNO_2} \ ;$$

(XXXVI)

R=Alk .

Alkyl-*N*,*N*-dinitroamines (XXXVIII) are formed in high yields from *N*-alkyl-*N*-nitroamides (XXXVII)[84]:

$$\underset{\text{(XXXVII)}}{RN(NO)_2C(O)R'} + NO_2^+BF_4^- \rightarrow \underset{\text{(XXXVIII)}}{RN(NO_2)_2} + R'CO^+BF_4^- \ ;$$

R=CH_3, C_4H_9, R'=CH_3, C_3H_7, CCl_3 .

The reaction of NTFB with *N*-alkylamides has been investigated[67,84] under insufficiently comparable conditions, but nevertheless comparison of the results permits the conclusion that at a low temperature (−30 °C) *N*-butylacetamide and ethyl n-butylcarbamate in acetonitrile are nitrated to the *N*-nitro-derivatives[67], while at higher temperatures (up to +10 °C) nitrolysis takes place with formation of the corresponding carboxylic acid and an alcohol as well as N_2O.[86] The question of the order in which the C–N bond is *N*-nitrated and cleaved in the reactions of *N*-alkylamides with NTFB requires additional study. Aliphatic isocyanates react with NTFB in ethyl acetate or acetonitrile with formation (after hydrolysis) of alkylnitroamines[87]:

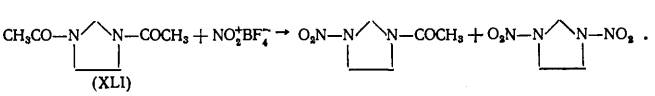
$$R(N{=}C{=}O)_n + NO_2^+BF_4^- \xrightarrow{+H_2O} RNHNO_2 + CO_2 + HBF_4 \ ;$$

n=1; R=C_2H_5, C_3H_7, C_4H_9; n=2; R=$(CH_2)_4$, $(CH_2)_6$.

The study of the nitration of a series of *N*,*N*-diacylmethylamines showed that the acetyl group is substituted by the nitro-group and, depending on the conditions and the component ratio, methylnitroacetamide or methyl-*N*,*N*-dinitroamine is formed[88]:

$$CH_3N(COCH_3)_2 + NO_2^+BF_4^- \begin{cases} \rightarrow CH_3N(NO)_2COCH_3 \ ; \\ \rightarrow CH_3N(NO_2)_2 \ . \end{cases}$$

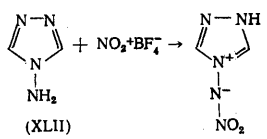
The methanesulphonyl group can also be substituted by the nitro-group. The tosyl or an alkoxycarbonyl group do not enter into this kind of reaction.



The mode of reaction of NTFB with substituted methylenediamines depends on the nature of the substituents[88,89]. Alkanesulphonyl, arenesulphonyl, or methoxycarbonyl derivatives (XXXIX) undergo nitrolysis at the C–N bond with formation of substituted nitroamines. This reaction pathway is favoured by the formation of the carbonium-immonium ion (XL) stabilised by the mesomeric effect of the amine nitrogen:

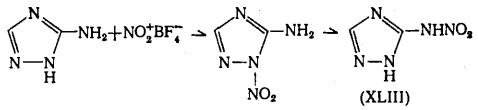
$$\underset{\underset{R''}{|}\ \underset{R''}{|}}{R'NCH_2NR'} + NO_2^+BF_4^- \rightarrow \underset{\underset{R''}{|}}{R'N{-}NO_2} + \underset{\underset{R''}{|}}{R'NCH_2^+}BF_4^- \ ;$$

(XXXIX) (XL)



R'=Alk, R''=Alk, $SO_2C_6H_5$, $COOCH_3$.

N,*N*-Diacetylimidazolidine (XLI) undergoes substitutional nitration by nitronium salts to *N*-acetyl-*N'*-nitro- or *N*,*N'*-dinitro-derivatives:



(XLI)

Nitronium salts are convenient nitrating agents for the synthesis of *N*-nitroimides. 4-Amino-1,2,4-triazole (XLII) reacts with NTFB in acetonitrile to form 4-nitroimino-1,2,4-triazole in 65% yield[90]:

(XLII)

1-Aminobenzimidazole is nitrated analogously, 1,1'-azobenzimidazole being formed as a side product. 3-Amino-1,2,4-triazole reacts with NTFB in acetonitrile to form *N*-nitrotriazole, which rearranges to the nitroaminotriazole (XLIII):

(XLIII)

Both nitronium and nitrosonium salts readily react with azodicarboxylate anions in accordance with the following scheme:

$$NO_2^+ + {}^-OOCN{=}NCOO^- \rightarrow N_2O_4 + 2CO_2 + N_2 \ .$$

The reaction of alkyl azodicarboxylates depends on the reactivity of the electrophilic species. NTFB, for example, reacts with ethyl azodicarboxylate, while the weaker electrophile nitrosonium tetrafluoroborate does not react.

The reaction of NTFB with lithium azide in acetonitrile results in the formation of covalent nitronium azide, which is converted into nitrous oxide above −10 °C[91]:

$$NO_2^+BF_4^- + LiN_3 \rightarrow LiBF_4 + NO_2N_3 \xrightarrow{\Delta} 2N_2O \ .$$

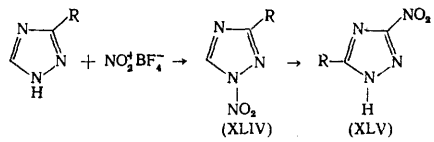
5. Nitration of Heterocyclic Compounds

The possibility of the nitration of heterocyclic compounds by nitronium salts was initially demonstrated in relation to pyridine[1,92,93]:

$$C_5H_5N + NO_2^+BF_4^- \rightarrow [C_5H_5NNO_2]^+BF_4^- \ .$$

In the presence of an excess of pyridine, the resulting salt is converted into derivatives of glutaconic aldehyde[92]:

$$[C_5H_5NNO_2]^+BF_4^- \xrightarrow{C_5H_5N} \left[C_5H_5^+NCH{=}CH{-}CH{=}\underset{\underset{NO_2}{|}}{CHCHN}\right]BF_4^- \rightarrow$$

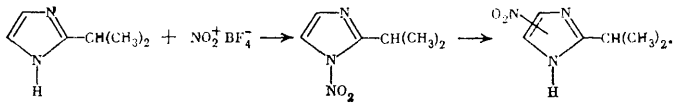


$$\xrightarrow{H_2O} [C_5H_5NCH{=}CHCH{=}CHCHO]^+BF_4^- \ .$$

N-Nitropyridinium salts are fairly stable and the N–C migration of the nitro-group is not observed even on heating. On the other hand, alkylnitropyridinium salts are "mild" nitrating agents (see Section III, subsection 1, subsection 3, and subsection 6).

Olah and Kuhn reported that thiophen[1] forms nitrothiophen in 91% yield on nitration with NO_2BF_4, while the nitration of furan results in a 14% yield of nitrofuran. 3-Nitro-6-phenyl-2-pyridone has been obtained in 40% yield by the nitration of 6-phenyl-2-pyridone with NTFB[94].

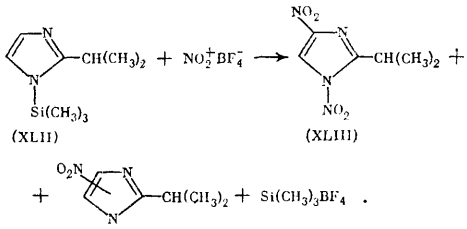
C-Nitroazoles are known to be difficult to synthesise by direct nitration with nitric acid. The use of NTFB in acetonitrile made it possible to obtain a series of 3-substituted 1,2,4-triazoles. The reaction proceeds via a stage involving



the formation of the *N*-nitro-derivative (XLIV), which isomerises to the *C*-nitro-compound (XLV)[95]:

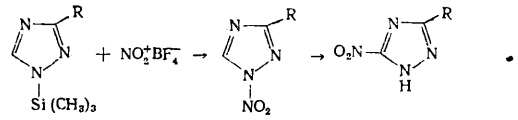
(XLIV) (XLV)

R=H, CH_3, Cl, Br



2-Isopropylimidazole (XLVI) is apparently nitrated analogously[96]:

(XLVI)

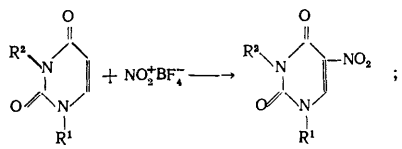


The yield of *C*-nitrotriazoles is as a rule low as a consequence of the dinitration of the *N*-nitro-compounds under the influence of fluoroboric acid formed on nitration.

A very interesting modification of this method, which rules out the formation of acid, has been proposed, namely one involving the nitration of trimethylsilyl derivatives. It has been shown for 2-isopropyl-1-trimethylsilylimidazole (XLVII) that this method makes it possible to obtain compounds which could not be synthesised previously, for example, 2-isopropyl-1,4-dinitroimidazole (XLVIII)[96]:

(XLVII) (XLIII)

The nitration of *N*-trimethylsilyl-1,2,4-triazoles (XLIX) makes it possible to obtain *N*-nitrotriazoles, which can be used to synthesise *C*-nitro-derivatives in yields up to 90%[95]:



(XLIX)

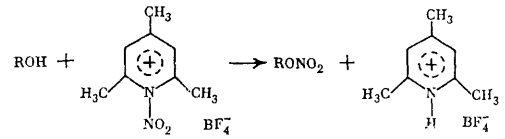
R=H, CH_3, Cl, Br

Despite the additional labour involved in the synthesis of the trimethylsilyl derivatives, this method is most convenient for the preparation of 3(5)-nitro-1,2,4-triazoles.

Uracil and its 1-methyl and 1,3-dimethyl derivatives are nitrated to 5-nitro-derivatives (L) in high yields by NTFB in sulpholane:

(L)

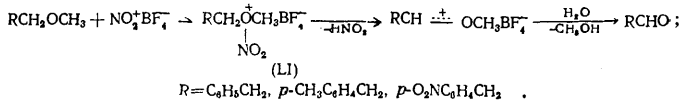
R^1, R^2=H or CH_3 .



The attempts to nitrate a pyrimidine nucleoside (a 2'-deoxyglycoside) by NTFB as a rule leads to the degradation of the molecule or the formation of 5-nitrouracil, but the corresponding nucleotide (nucleoside 5'-monophosphate) is nitrated in the 5-position in the pyrimidine ring[97].

6. Nitration of Alcohols and Ethers

Aliphatic alcohols are readily nitrated by NTFB to the corresponding nitrates in 70–90% yields[98]:

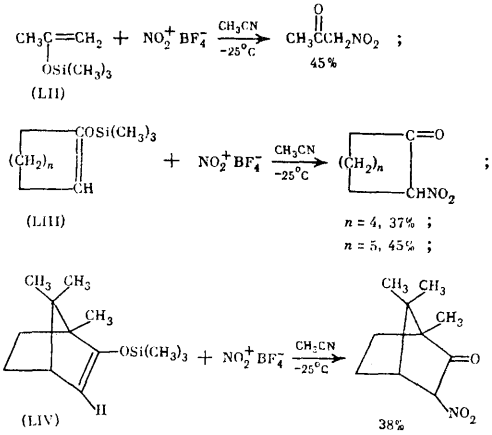


$$ROH + NO_2BF_4 \rightarrow RONO_2 + HBF_4 ;$$
R=Alk, $HalCH_2CH_2$, CF_3CH_2 .

The use of *N*-nitrocollidinium tetrafluoroborate in acetonitrile instead of a nitronium salt makes it possible to nitrate alcohols under milder, readily controlled conditions:

Aliphatic and carbocyclic alcohols enter into the reaction, the yield of nitrates being almost quantitative even in the nitration of the readily oxidisable diols and glycerol. It has been shown for benzyl alcohol that the reaction is fairly selective and permits nitration at the oxygen atom without involving the benzene ring[99].

Nitronium salts also react with the oxygen of the ether linkage. The nitroxonium ion (LI) formed in the reaction is readily converted, in high yields, into the corresponding aldehyde or ketone[100]:



(LI)

R=$C_6H_5CH_2$, *p*-$CH_3C_6H_4CH_2$, *p*-$O_2NC_6H_4CH_2$.

The methyl ethers of cyclohexanol and cyclopentanol are converted into the methyl esters of the corresponding ω-hydroxyiminocarboxylic acids.

The nitration with nitronium salts of derivatives of the enolic vinyloxysilanes (LII)–(LLIV), leading to α-nitroketones which are usually difficult to obtain, is of special interest[101]:

(LII) 45%

(LIII) *n* = 4, 37% ; *n* = 5, 45% ;

(LIV) 38%

The reaction apparently proceeds via the formation of a substituted vinyl nitrate, which is comparatively stable in aprotic media and rearranges to an α-nitroketone.

7. Reactions of Nitronium Salts with Organoelemental and Complex Compounds

Diphenyl sulphide reacts with NTFB or $NO_2^+PF_6^-$ at −78 °C with formation of diphenyl sulphoxide. Dialkyl(aryl) selenides, triaryl(acyl)phosphines, triarylarsines, and triarylstibines undergo analogous reactions[102]. ^{13}C, ^{15}N, and ^{31}P NMR studies have shown that the reaction proceeds via the formation of the corresponding nitro-onium salts (LV), which are irreversibly converted into the nitrato-onium salts (LVI) and further into the corresponding oxides:

$$R{-}S{-}R' + NO_2^+ \rightleftarrows \underset{(LV)}{\left[\begin{array}{c} NO_2 \\ | \\ R{-}S{-}R' \end{array}\right]^+} \rightarrow \underset{(LVI)}{\left[\begin{array}{c} ONO \\ | \\ R{-}S{-}R' \end{array}\right]^+} \rightleftarrows \begin{array}{c} O \\ \uparrow \\ R{-}S{-}R' \end{array} + NO^+ .$$

This is the first reliably demonstrated instance of the isomerisation of a nitro-derivative to the *O*-nitrite. Similar reactions have also been postulated for $C{-}NO_2$ carbonium ions (see Section III, subsection 3).

Organotin compounds, for example, trimethylstannylacetylenes (LVII), undergo substitutional nitration by nitronium salts with formation of nitroacetylenes[103]:

$$\underset{(LVII)}{R_3SnC{\equiv}CR'} + NO_2^+BF_4^- \xrightarrow[-20^\circ]{} R'C{\equiv}CNO_2 + R_3SnBF_4 .$$

An analogous reaction of a derivative of another Group IV element (silicon) is described in subsection 5.

Ferrocenyl(triphenylphosphine)gold reacts with NTFB to form a complex mixture of products: ferrocene, biferrocenyl, [ferrocenyl(triphenylphosphine)gold]triphenylphosphinegold tetrafluoroborate[104]. The reaction of dichlorodicymantrenylstannane with NTFB is accompanied by the reduction of the latter[103] and proceeds via the mechanism

$$[C_5H_4Mn(CO_3)]_2SnCl_2 \xrightarrow[-2CO_2]{2NO_2^+BF_4^-} \{[C_5H_4Mn(CO)_2NO]_2SnCl_2\}^{2+}(BF_4^-)_2 .$$

Nitroso-complexes are also formed on interaction of platinum group transition metals with NTFB[105,106]:

$$Ir(CO)Cl[P(C_6H_5)_3] + NO_2^+BF_4^- \rightarrow Ir(CO)(NO)Cl(BF_4)[P(C_6H_5)_3]_2 ;$$
$$RhCl[P(C_6H_5)_3]_3 + NO_2^+BF_4^- \rightarrow RhCl(NO_2)[P(C_6H_5)_3]_3^+BF_4^- .$$

The reduction of nitronium salts to NO^+ is also observed in the reaction of NTFB with nitrogen-containing iron(II) and cobalt(II) complexes[105].

IV. THE MECHANISM OF THE NITRATION OF AROMATIC COMPOUNDS

The range of studies devoted to the kinetics and mechanism of nitration by nitronium salts is fairly wide. They are all devoted to the nitration of aromatic hydrocarbons, but the absolute rates of reaction have been measured only for deactivated substrates containing nitro-groups in the aromatic ring, such as nitrobenzene[32,40,41], nitrotoluenes, 1,3-dinitrobenzene, and 2,4- and 2,6-dinitrotoluenes[41]. In these studies the nitration by nitronium salts was carried out mainly in acids (sulphuric, hydrofluoric, and methanesulphonic) and it was shown that nitration by nitronium salts in such media takes place analogously to nitration by nitric acid. The nitrating activity of nitronium salts solutions in acetonitrile[40] and nitromethane[41] is much higher than that of nitric acid.

Measurement of the absolute rates of nitration of benzene and alkylbenzenes by nitronium salts proved to be impossible even by the stopped flow method, because a sufficiently rapid way of arresting the reaction could not be found[107]. All the experiments on the nitration of benzene and alkylbenzenes were therefore carried out by the competitive method developed by Ingold[108,109].

Processes involving nitration by nitronium salts and nitric acid solutions differ most markedly as regards the rate of nitration of benzene and toluene. The ratio of the rates of nitration of toluene (K_t) and benzene (K_b) by nitric acid solutions is 25.[108,110] In competitive nitration by nitronium salts, the ratio $K_t/K_b = 1.67$ was obtained, approaching unity with increase of temperature from 25° to 55 °C (K_t/K_b = 1.13).[111] The relative rate depends also on the nature of the anion in the nitronium salt and on the solvent[47]. In the nitration of 4-methoxy-2,6-dimethyl-*N*-nitropyridinium tetrafluoroborate, $K_t/K_b = 44.5$.[48]

The sharp decrease of the sensitivity with respect to the nature of the substrate in nitration by nitronium salts (decrease of substrate selectivity) is apparently due to the increase of reactivity and the associated decrease of the directing influence of the substituent, i.e. the ratio of the *ortho*- and *para*-isomers formed in the nitration of toluene should approach the statistical value (2:1). This situation is observed, for example, in free-radical nitration by nitrogen dioxide, where a low substrate selectivity ($K_t/K_b = 2.6$) is accompanied, as was to be expected, by a decrease of the positional selectivity (37.2% of the *ortho*-isomer, 38.1% of the *meta*-isomer, and 24.7% of the *para*-isomer)[107].

The fundamentally novel feature of Olah's data for nitration by a nitronium salt was that, with a sharp decrease of substrate selectivity, the authors obtained almost the same ratio of the isomers as in nitration by nitric acid. These two results—decrease of substrate selectivity with retention of positional selectivity—were very difficult to reconcile.

Nowadays it has come to be believed that electrophilic substitution in aromatic compounds (including nitration by nitric acid solutions) proceeds via stages involving the formation of π- and σ-complexes[108,110,112,113]. Initially the π_1-complex is converted into the σ-complex, which is then converted into the π_2-complex and finally into the reaction product. The rate-limiting stage of the process is the formation of the σ-complex, which is particularly indicated by the correlation between the basicity of arenes (which determines the stability of the σ-complexes) and the rates of the electrophilic substitution reactions[110,113,114,115]. The energy profile of the reaction is presented in Fig. 1.

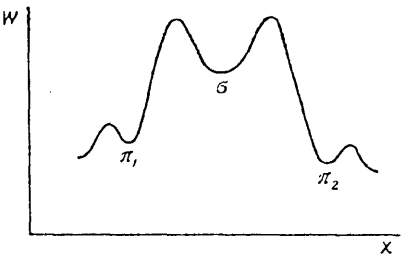


Figure 1. The energy profile of the electrophilic substitution reaction; W = energy; χ = reaction coordinate.

Olah observed that the rates of nitration by nitronium salts are better correlated with the stability of the π-complex[1,41,116,117], which led him and his co-workers to suggest that, in nitration by nitronium salts, the rate-determining stage is the formation of the π-complex and not the σ-complex (Fig. 2). This concept is extremely unusual for the theory of aromatic substitution.

Olah also believes that, in contrast to nitration by nitric acid solutions in which the π-complex arises on interaction with the electron system of the ring as a whole, nitronium salts form a directional π-complex where the nitronium cation is oriented towards the carbon atom with the maximum electron density. In the transformation of the π-complex into the internal σ-complex there is therefore no great energy expenditure and preferential *ortho–para* direction is achieved. The substrate selectivity in the nitration reaction is low, since the π-electron density in aromatic compounds depends little on the number of alkyl groups[112].

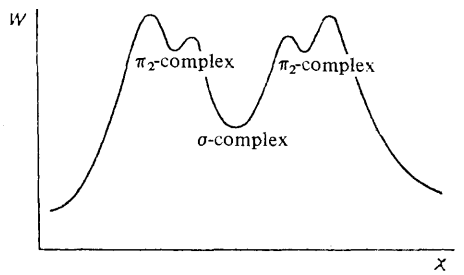

Figure 2. The energy profile of the reaction involving nitration by nitronium salts: $ArH + NO_2^+ \rightarrow ArNO_2 + H^+$; π_1-complex = $ArH...NO_2^+$; π_2-complex = $H^+...ArNO_2$; σ-complex = $ArHNO_2^+$.

Olah's interpretation of the experimental data has been criticised by a number of investigators[34,108,110,118–120]. Sikiguchi et al.[119] questioned the reliability of the ratios K_t/K_b obtained. They observed that in the competitive nitration of the benzene–toluene pair the ratio K_t/K_b depends on the dielectric constant ε of the solvent and changes from 2.15–2.31 for CCl_4 (ε = 2.23) to 16.3–19.7 for CH_3NO_2 (ε = 35), i.e. from a quantity close to that obtained by Olah to the usual values for nitric acid solutions. However, their study[119] nevertheless does not account for the low substrate selectivity in nitration by NTFB (also in nitromethane). Furthermore, their results[119] might have been influenced by the heterogeneity of the system, since nitric acid is very sparingly soluble in CCl_4 and aliphatic hydrocarbons.

Ritchie and Win[121] found that competitive nitration by NTFB in sulpholane caused different relative rates for binary (toluene–benzene) and quaternary (benzene–toluene–chlorobenzene–fluorobenzene) mixtures. They suggested that the nitration by nitronium salts is not fully kinetically controlled and that this might have been the cause of the "anomalous" results obtained by Olah and co-workers.

Doubts about the justification of the application of the competitive method to the study of the relative reactivities have been expressed by Tolgyesi[122], who showed, in relation to the nitration of the toluene–benzene pair by NTFB in sulpholane, that the ratio K_t/K_b increases with increase of the efficiency of mixing and the concentration of the hydrocarbons in solution and also with decrease of the NTFB concentration. Under certain conditions, the ratio K_t/K_b reaches 25–30, i.e. values corresponding to the reactivity in nitration by nitric acid solutions. However, it was shown later[107] that these results are due to the interaction of NTFB with the impurities present in the solvent.

In the nitration of durene (1,2,4,5-tetramethylbenzene) by solutions of nitronium hexafluorophosphate in nitromethane the yield of dinitrodurene was 8–10 times higher than that of mononitrodurene. On the other hand, under conditions of a more effective mixing of the reactants, mononitrodurene predominates[34]. These facts show that the reaction in essence occurs as soon as the components are mixed and that mass transfer processes therefore determine the reaction rate and the composition of the products. The nitration of pentamethylbenzene proceeds at a rate which is so high that the process is limited solely by the rate of mixing of the components[118,123]. The role of the mixing of the components has been confirmed by the nitration of bibenzyl in sulpholane. The main product of this reaction is the symmetrical dinitrobibenzyl even when there is a deficiency of the nitronium salt[124–126]. Thus the reactivity of NO_2^+ in nitronium salts is so high that the role of mass transfer increases sharply in the nitration process and to a greater extent the higher the reactivity of the substrate. Studies of the kinetics of the heterogeneous nitration of a number of substrates by NTFB using the "rotating disc" method[127] showed that, whereas the nitration of benzene takes place in the kinetic region, toluene is nitrated in the mixed region and the kinetics of the nitration of the still more reactive xylene and mesitylene are determined solely by diffusion processes. As was to be expected, the mass transfer conditions influence the substrate selectivity but not the positional selectivity[120,128,129].

Thus, in nitration by nitronium salts the concentration of the more reactive reactant at the site of mixing of the reactants diminishes so rapidly that the reactant cannot be supplied sufficiently rapidly by diffusion and the second reactant therefore reacts faster than would correspond to the ratio of the reactant concentrations, i.e. it is seemingly more reactive. This type of macroscopic diffusion effect can be eliminated in principle by rapid mixing and by employing a very low concentration of the more reactive substrate[110,122,126]. Furthermore, a second diffusion effect may appear in the system—a microscopic effect, whose essential feature is that the rate-determining process in the reaction becomes the collision of the reactants and not the formation of the reactive σ-complex. It has been shown[110,126,130–133] that the rate of nitration of alkylbenzenes by nitric acid in various media is limited by the number of encounters of the nitronium cation with the aromatic hydrocarbon, i.e. there is a limit to the reactivity of the substrate above which the introduction of activating substituents into the ring no longer increases the reaction rate. It is striking that, under conditions close to those corresponding to the maximum reaction rate, low substrate selectivities are obtained. The authors believe that, also in the case of very rapid nitration of alkylbenzenes by nitronium salts, the reaction rate is likewise limited by the rate of encounters with the substrate and this is why low substrate selectivities are obtained. Diffusion effects have been observed also in chlorination and bromination as well as nitration[134].

In later investigations[41,116,117] Olah admitted that the kinetics of the nitration of benzene and alkylbenzenes are determined by the encounter rate. Nevertheless he continues to believe that the mechanisms of the nitration of highly reactive compounds (benzene and alkylbenzenes) and deactivated substrates such as nitrobenzene and nitro- and dinitrotoluenes are different. An "early" transition state resembling an aromatic compound (a π-complex) is formed for highly reactive compounds. A low substrate selectivity (from 27 to 1) and a high (in the range 1–2) ratio of the *ortho*- and *para*-isomers are then usually observed. Relatively unreactive compounds (nitrobenzene, *o*- and *p*-nitrotoluenes, 2,4- and 2,6-dinitrotoluenes, etc.) give rise to

"late" transition states resembling a σ-complex. A high substrate selectivity is characteristic of such compounds (for example, the ratio of the rates of nitration of nitrotoluenes and nitrobenzene K_{nt}/K_{nb} is 100–500 and more for a low ratio of the *ortho*- and *para*-isomers (0.3–0.8).

According to Dewar[135,136] the "early" transition state retains aromatic properties to a considerable degree and is in many respects similar to an unperturbed aromatic system: the bond with the electrophile is still weak. The reaction with a strong electrophile is highly exothermic and one may therefore expect a relative stability of the intermediate and an appreciable difference between the latter and the transition state, which should be similar to the reactants in this instance according to Hammond's postulate[137]; the higher the reactivity of the electrophile, the smaller the influence of the substrate structure.

Schofield and co-workers reject Olah's concept of the "early" and "late" transition states[126,138] and, as already mentioned, explain the low substrate selectivity by the fact that the rate of nitration is limited by the diffusional process involving the formation of the "encounter complex" $ArH.NO_2^+$. The aromatic molecule as a whole and not just one carbon atom of the latter is involved in the formation of such a complex[126,130,138].

Stock[139] adheres to analogous views, believing that there are at present no data permitting the interpretation of Schofield's "encounter complex" as an oriented π-complex. He suggests the following mechanism of the nitration of aromatic compounds:

$$HNO_3 + H^+ \underset{K_{-1}}{\overset{K_1}{\rightleftharpoons}} H_2O + NO_2^+ \ ;$$

$$NO_2^+ + ArH \underset{K_{-2}}{\overset{K_2}{\rightleftharpoons}} ArHNO_2^+ \ ;$$

encounter complex

$$ArHNO_2^+ \underset{K_{-3}}{\overset{K_3}{\rightleftharpoons}} + \text{(H, NO}_2\text{)} +$$

$$+ \text{(H, NO}_2\text{)} + B \xrightarrow{K_4} \text{(NO}_2\text{)} + BH^+ \ ;$$

B = base.

However, it has been noted[126] that the concept of the "encounter complex" which Schofield took from the diffusion theory, resembles somewhat Olah's concept of the "oriented π-complex". This became particularly apparent in a study[138] in which it was claimed that an intermediate preceding the σ-complex must be included in the nitration mechanism. The formation of such an intermediate, i.e. of the "encounter complex" is the rate-determining diffusion stage and the rearrangement of the complex to the σ-complex determines the composition of the products.

In his latest studies Olah[140,141] also assumes that the formation of the σ-complex is preceded by two stages:

$$RC_6H_5 + NO_2^+ \overset{\text{stage 1}}{\rightleftharpoons} [RC_6H_5NO_2]^+ \overset{\text{stage 2}}{\rightleftharpoons} \underset{\text{(LVIII)}}{RC_6^+H_4\text{(H, NO}_2\text{)}} \overset{\text{stage 3}}{\xrightarrow{-H^+}} RC_6H_4NO_2 \ .$$

Stage *1* determines the overall rate of reaction and is responsible for the substrate selectivity, while stage *2* is responsible for the positional selectivity, i.e. the proportions of the isomers in nitration. The author explains by the presence of these two stages the high positional selectivity accompanied by a very low substrate selectivity in the nitration of highly reactive aromatic hydrocarbons by nitronium salts. The nature of the intermediate (LVIII) has been elucidated and Olah believes that this can be a π-complex, Schofield's "encounter complex", or even a radical pair of NO_2 and ArH^+, whose existence has been postulated for aromatic hydrocarbons with a high electron density[144]. The closeness of Olah's and Schofield's views is evident.

The question of the position of the transition state on the reaction coordinate, i.e. the determination of the stage responsible for the formation of a π- or σ-complex in nitration by nitronium salts, is more complex. The differences between Olah and Schofield as regards this question arise apparently from the different interpretations of the Hammett equation and Hammond's postulate. Johnson and Schofield[143,144] believe that it is quite inadmissible to employ the reaction constant as a characteristic of the selectivity–reactivity relation derived from Hammond's postulate. The large variations in selectivity found by Olah are a consequence of the inaccuracy of the competitive method for high reaction rates. Johnson[144] notes that the principle of selectivity implies the validity of the isokinetic relation, but the proportionality between the enthalpy and free energy by no means always holds. In many instances Hammonds postulate is invalid, i.e. one cannot regard as valid the hypothesis that the reaction constant ρ always reflects exactly the character of the transition state. The author believes that Hammond's postulate is insufficiently justified for electrophilic substitution reactions and that the conclusions usually associated with the values of ρ determined from the Hammett equation are exactly the opposite of those which follow from Hammond's postulate. If an attempt is made to determine the nature of the transition state for a given reaction with the aid of the Hammett equation on the basis of the different reaction rates in the presence of different substituents, then it follows from Hammond's postulate that the character of the transition state itself varies with the rate of the process.

Evidently a more detailed description of the conflict in the interpretation of the Hammett equation and Hammond's postulate is outside the framework of the present review.

New conclusions and the controversy concerning the nitration reaction and other electrophilic aromatic substitution reactions, whose mechanism appeared to be rigorously proved and understood after the publication of Ingold's book[108], have shown that studies in this field must be continued and that the treatment and interpretation of experimental data must be particularly thorough with allowance for diffusion processes.

Structural Chemistry of Hydrides of Intermetallic Compounds

V.A.Yartys', V.V.Burnasheva, and K.N.Semenenko

The contemporary state of the structural chemistry of the hydrides of intermetallic compounds is discussed. X-ray and neutron diffraction data on hydride phases are surveyed and critically analysed. Tetrahedral and octahedral coordination are shown to be most typical for hydrogen atoms in the structures of multi-component hydride phases. Rules for the structure of intermetallic hydrides are formulated, permitting us to forecast the structures of compounds not yet studied and to predict the maximum capability of the parent intermetallic compounds to absorb hydrogen. 204 references are given.

I. INTRODUCTION

Compounds of hydrogen with metals are of great interest for the solution of practical and theoretical problems in the new field of science, atom–hydrogen energetics. Metal hydrides can be considered as effective chemical storage and sources of hydrogen, but only if the reaction of hydrogen with the metal in question occurs rapidly and with sufficient completeness under comparatively mild conditions, and the hydrogen weight content in the hydride proves to be high enough.

At pressures up to several kilobars molecular hydrogen reacts only with the limited number of metals which have low ionisation energies: the alkali, alkaline-earth, and lanthanide metals. Titanium, vanadium, and zirconium approach these in respect of their reactivity with hydrogen. It is only recently that a number of unstable hydrides of the transition metals Mn, Fe, Co, Mo, and Rh have been obtained under high pressure conditions[1-5].

However the preparation of hydrides by direct reaction of hydrogen with the metal is not always easily realisable in practice. In the majority of cases the kinetics of absorption and desorption of hydrogen are very sensitive to the presence of minor impurities in both the hydrogen and the metal, the "absorption $\rightleftharpoons$ desorption" equilibrium is established slowly even at relatively high temperatures (300–400 °C), and products with a high content of the primary substance are obtained only in isolated cases.

This is why such great interest was aroused by the discovery at the end of the 1960's of a new type of reaction between hydrogen and intermetallic compounds (IMC) and alloys, one of whose components is a metal capable of forming a stable binary hydride. Chance observations made almost simultaneously by various independent research groups opened up a

new chapter in the chemistry of metal–hydrogen compounds. Their work showed that many IMC's containing Ti, lanthanides (Ln), or Mg react readily with hydrogen at 25–100 °C under 0.1 to 100 atm pressure. The kinetics of this reaction are unique and have no analogy in the chemistry of binary hydrides—the absorption of hydrogen by the metallic phase begins almost immediately and close to room temperature the "absorption ⇌ desorption" equilibrium is as a rule established in a few minutes, depending on the nature of the metallic phase and the purity of its surface.

Up to the present there have been about 500 publications devoted to study of the reaction of various IMC's and alloys with hydrogen. A large amount of experimental data, of interest not only to chemistry but also to those areas of physics, technological and applied sciences bordering on chemistry, has been accumulated. However the structural chemistry of the hydrides remains relatively unstudied—as regards both strictly structural research, little of which was carried out until recently, and also work on the nature of the metal–hydrogen chemical bond.

Finally, structural investigations based on the application of diffraction methods cannot give direct information on the valence state of hydrogen in its compounds with metals, but they are necessary for the development of descriptive crystal chemistry of metal hydrides and they can be very useful (as we have remarked repeatedly) for solving certain definite practical problems connected with the prediction of and search for new polymetallic compositions which absorb a large quantity of hydrogen reversibly at given temperatures and pressures.

The purpose of this review is to discuss the structural chemistry of hydrides containing two or more metal components. Questions of the crystal chemistry and structure of binary hydrides are considered only in so far as they are necessary for the analysis of general rules determining the structure of both binary and more complex hydride phases. We were aware also that substantial reviews of work on the structure of binary metal hydrides have previously been published by Mueller et al.[6], Goldschmidt[7], Mackay[8], Libowitz[9], Stalinski[10], Galaktionova[11], and Andrievskii and Umanskii[12].

II. THE STRUCTURE OF BINARY METAL HYDRIDES

The descriptive crystal chemistry of metal hydrides can be based on the idea that they are unusual "interstitial phases" of hydrogen in a metal lattice-matrix. The alternative view, according to which metal hydrides are regarded as ionic compounds M^+H^-, does not in the majority of cases correspond[12] to the actually observed picture of the structure and physical properties of the hydrides of metals of groups III–VIII.

Analysis of structural relationships in binary hydrides shows that insertion of hydrogen into the metal lattice can occur in two ways:

(1) it is accompanied by a fundamental reorganisation of the metal lattice or in other words by a change in the type of packing of the metal atoms, e.g. by a transition from body-centred cubic (b.c.c.) packing in the structure of the metal itself to face-centred cubic (f.c.c.) packing in the metal sublattice of the hydride; or

(2) it does not lead to a substantial change in the metal structure—in this case the packing of the metal atoms in the metal sublattice of the hydride is no different from the packing in the structure of the metal itself or only an insignificant deformation of the unit cell occurs.

The overwhelming majority of metals react with hydrogen in the first way. It is only for such elements as V, Ni, Nb, Pd, Ta, Ce, and Th that the unit cells of the hydride phases have a simple relationship to or match the original unit cells of the metals.

The hydrogen atoms in the binary metal hydride structures have three types of coordination polyhedra: tetrahedra, octahedra, and triangles. The largest size holes, the octahedral holes in the f.c.c. and the hexagonal close packed (h.c.p.) lattices, are the first to be filled by hydrogen atoms in the structures of hydrides of elements with small atomic radii (metals of groups VI–VIII). However, on passing to the lanthanides, which have considerably larger atomic radii, the tetrahedral holes are filled first and only after that the octahedral. It is only in the structures of HoD_3,[13] YD_3,[14] and Th_4D_{15} [15] that the deuterium atoms have a triangle form of coordination polyhedron.

Thus the general rule of crystal chemistry, that the coordination number (c.n.) of an atom M′ falls as the atomic radius ratio $r_M/r_{M'}$† (r_M/r_H in the present case) increases, is obeyed also in the metal hydride structures—the c.n. of the hydrogen atom changes from 6 to 4 or to 3 as the metal radius increases.

If the M–H(D) interatomic distances in the binary hydride structures are taken to be the sum of the atomic radius of the metal M and the effective radius of the hydrogen atom, it is possible to form a qualitative estimate of the latter#.

It is known that in interstitial structures the size of the holes in the lattice matrix, made up of atoms of radius r_M, increases in the sequence: triangular (c.n. =3; $r_{hole} = 0.22\, r_M$) < tetrahedral (c.n. = 4; $r_{hole} = 0.41\, r_M$) < octahedral (c.n. = 6; $r_{hole} = 0.73\, r_M$).[17] This implies that the radius of the hydrogen atoms, which occupy various types of hole, cannot generally speaking be constant but depends markedly on the type of environment. It is also clear that this effect will be more marked the more complex is the structure of the parent matrix, of metal or an IMC.

These rules are followed in the binary metal hydride structures. The hydrogen atoms with the "largest radius" are those in octahedral holes, their size decreasing with decrease in the metal atom dimensions from 0.7–0.8 Å in lanthanum and cerium hydrides to ~0.6 Å in the hydrides of the metals of groups VI–VIII. The hydrogen atoms with a c.n. of 3 in the $ScH_{2.65}$ structure[18] have the smallest radius (~0.3 Å); this is close to the covalent radius of hydrogen, 0.28 Å.[8] Hydrogen atoms occupying tetrahedral holes have radii in between the values for c.n. 3 and c.n. 6 (0.4–0.5 Å).

The H–H interatomic distances in the structures of binary hydrides of metals of groups VI–VIII are fairly large owing to the low density of hydrogen nuclei in them (~2.6 Å). However, on increasing the hydrogen content in the hydride phases the smallest H–H distances are reduced considerably (to ~2.1 Å in the lanthanide trihydrides and even to ~1.9 Å in the $ScH_{2.65}$ structure).

In conclusion we note a characteristic feature of binary hydride structures: notwithstanding that in the f.c.c. and h.c.p. structures the holes occupied by hydrogen atoms are regular polyhedra, these atoms do not always lie exactly in the centres of the holes. In the hexagonal hydride structures MH_3 and also in $CeD_{2.29}$ [19] the hydrogen atoms are displaced from the centres of both the tetrahedral and octahedral holes, and in the HoD_3 structure this displacement from

†M denotes the element whose atoms have the larger radius and M′ the smaller.

#Values for the metal radii were taken from Pearson[16].

the octahedron centre is so marked that the c.n. of the hydrogen atom becomes equal to 3. The structures of $CeD_{2.51}$ [20] and LaD_3 [21] are particularly representative in this respect; in these, in addition to the shift of the hydrogen atoms from the centres of the octahedral holes, a feature typical of the crystal chemistry of metal hydrides is exhibited: statistical occupation by the hydrogen atoms of a fraction of the crystallographic equivalent positions in the hydride phase structure.

III. GENERAL RULES OF THE REACTION OF HYDROGEN WITH INTERMETALLIC COMPOUNDS

Hydride phases, containing two or more metal components, can be obtained either by hydrogenation of alloys or IMC's of the composition $M_nM'_m$ or by high-temperature synthesis from the binary hydride of one metal and a second metal in an atmosphere of hydrogen. In the latter case a hydride phase $M_nM'_mH_x$ is formed, whereas in the former case three types of reaction are possible[22–24] (the first two of these correspond entirely to the schemes described above for the reaction of individual metals with hydrogen).

1. A compound with a new type of structure is formed.
2. The intermetallic compound absorbs a significant quantity of hydrogen without a substantial deformation of the original crystal structure.
3. There is complete decomposition of the initial IMC and formation of a stable binary hydride MH_x and an intermetallic compound enriched in the metal M′ which is inactive towards hydrogen, with the composition $M_{n-y}M'_m$ (or a hydride phase based on this), or of the metal M′ directly—a hydrogenolysis reaction[23].

The hydrogenolysis reaction of intermetallic compounds does not come within the scope of this review. Therefore the crystal chemistry of the phases formed only by the first or second mechanisms is discussed.

Before proceeding to examine the structural relationships between the IMC and the hydride phases based on them an important feature of IMC structure should be noted. In contrast to the structure of pure metals, in which all the interatomic distances within the range of the closest coordination sphere are as a rule identical, a greater diversity is observed in an IMC—there are distances both shorter and longer than the sum of the respective metal radii, and the variations may be considerable. It will further be shown

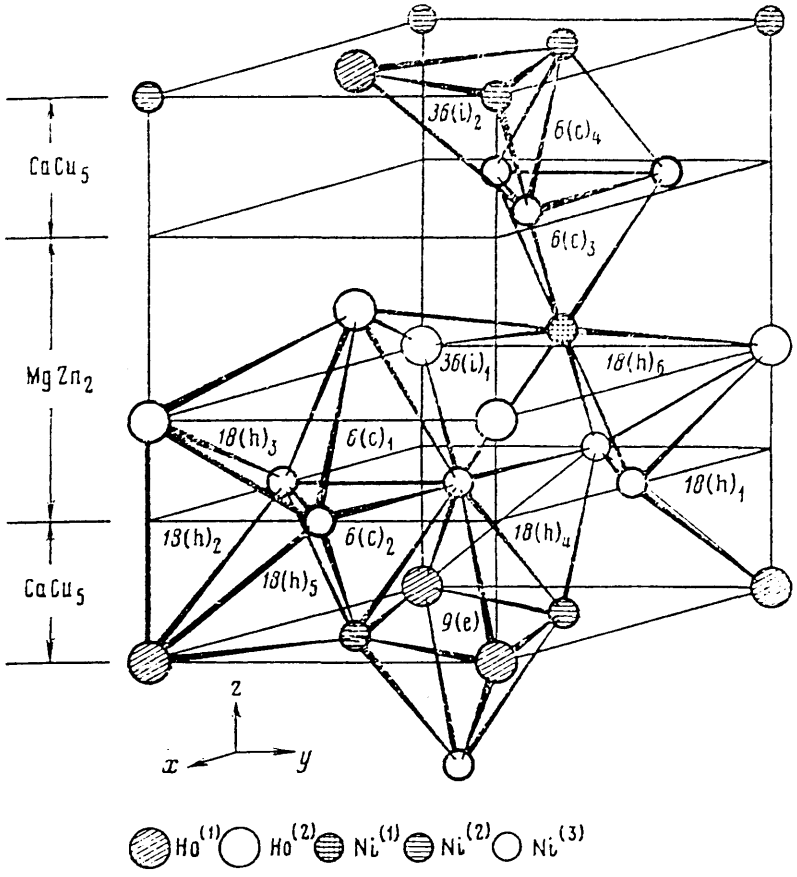

Figure 1. Holes in the $HoNi_3$ structure[40] (the part of the unit cell with $z = 0–1/3$ is shown); the $CaCu_5$ and $MgZn_2$ type sections are marked. The holes (13 different types) are designated by symbols (number of positions and Wyckoff notation) for the equivalent positions in the space group $R\bar{3}m$ corresponding to the centres of the holes.

that the insertion of hydrogen atoms takes place preferentially in those holes whose periphery includes precisely those "long", most easily deformed bonds.

A principal feature of the reaction of IMC's with hydrogen is that, in contrast to metals, in the overwhelming majority of cases the IMC structures do not undergo serious reorganisation on hydrogenation, and the mutual arrangement of the metal atoms in the structure of the hydride phase remains the same, or almost the same, as in the parent IMC.

The structure of hydride phases based on IMC's with structures of the $CaCu_5$, $MgCu_2$ and $MgZn_2$ (Laves phases), $PuNi_3$, Ce_2Ni_7, Gd_2Co_7, Th_6Mn_{23}, Ti_2Ni and CrB types have been investigated most fully. Note that the first six structure types are related and are members of one homologous series of structures MM'_5–MM'_2.[16,25,26] The structures of compounds with a composition intermediate between MM'_5 and MM'_2 can be regarded as consisting of fragments of the $CaCu_5$ and Laves phase type structures. The superposition of these fragments occurs along the [001] direction of the hexagonal unit cell owing to the presence of identical planar nets in the Laves phase and $CaCu_5$ structures. For example, the $PuNi_3$ type structure can be obtained by successively placing one above the other a $CaCu_5$ type unit cell and half of an $MgZn_2$ type unit cell (see Fig.1). As will be shown below, the homologous relationship of these structures predetermines also the similar nature of their reaction with hydrogen.

The hydride phases based on the intermetallic compounds $LaNi_5$ and $CaNi_5$, and also on the alloys $ThNi_3Al_2$, MNi_4Al (M = La, Ce, Pr, Nd, Sm, Gd, Tb, Dy, Ho), $MNi_{5-x}M'_x$, where M' = Al, Cr, Fe, Cu,[27–30] retain the hexagonal symmetry of the original MM'_5 structures of the $CaCu_5$ type and the unit cell expands on their formation to an equal extent both in the basal plane and in the [001] direction. Some other structure is evidently possessed by the hydride phases based on the alloys $LaNi_{5-x}Co_x$ (x = 0.5–3.0) because the increase in the unit cell volume occurs mainly through an increase in the lattice parameter a, while the change in the c parameter is insignificant[31].

The hydride phases MCo_5H_x have orthorhombic unit cells which are produced from the original MCo_5 structure by an anisotropic expansion in the basal plane of the hexagonal unit cell with a negligible change in the c parameter[27]. $LaCo_5$ absorbs the largest quantity of hydrogen ($H/LaCo_5$ = 4.3).§ In the γ-hydride so formed the lattice parameter ratio $a/b\sqrt{3} < 1$, in contrast to the hydride phases with $H/MCo_5 < 4$, the so-called β′-, β″-, and β‴-hydrides, for which $a/b\sqrt{3} > 1$.[27] In the β″- and β‴-hydride structures the c parameter is doubled, as indicated in the case of the β‴-hydride by neutron diffraction data. Studies of hydride phases based on alloys of the $La_{1-x}Pr_xCo_5$, $Ce_{1-x}Pr_xCo_5$ and $La_{1-x}Ce_xCo_5$ systems showed[33,34] that they have the β-hydride structure with a doubled c parameter.

The reaction of hydrogen with IMC's of the MM'_2 composition with Laves phase structures, where M is Sc, Y, Ta, Th, a lanthanide, or a Group IV metal and M′ is a transition metal from either period IV or V, has been investigated[30,35–68].

The unit cells retain the original hexagonal symmetry in all cases of hydride phases based on IMC's with the $MgZn_2$ type structure containing Ti, Zr, Er, Lu, and Th as the M component, and also in $ScFe_2$ crystallised with the $MgNi_2$ type structure[30,35–48].

IMC's with $MgCu_2$ type structures react differently with hydrogen. Although in the majority of cases there is an isotropic expansion of the unit cells without a change in their f.c.c. symmetry, for some hydrides of the MM'_2H_x type it was established that there are three different modes of deformation of the original unit cell, leading to unit cells which are primitive cubic with a doubled a parameter[61], orthorhombic with $a \sim b \sim a_{cubic}/\sqrt{2}$ and $c \sim c_{cubic}$,[49,50,54,61] or rhombohedral[66].

With a gradual change in the hydrogen content in the phases ZrV_2H_x and $ZrCr_2H_x$ from $x \sim 0$ up to saturated hydrides the structure of the matrix does not change, but the unit-cell parameters are increased[35]. Analogous results were obtained for YMn_2H_x.[60]

Hydrogenation of MM'_5 compounds (M = lanthanide, Y, Ca) with $PuNi_3$ type structures, when M′ is Co or Ni, leads to formation of di- and tetra-hydride phases and is not accompanied by a change from the symmetry of the original rhombohedral lattices[55,56,68–73]. When hydrogen is absorbed by the intermetallic compound up to the H_2-phase composition there is an expansion of the lattice matrix in the [001] direction of the trigonal unit cell with a negligible change in the a parameter. In the tetrahydride phases, in contrast to the dihydrides, the parameter a increases markedly, i.e. a further increase in the unit cell volume occurs as a result of expansion in the basal plane. When M′ = Fe only one hydride phase, similar to the phase $MCo(Ni)_3H_{\sim 4}$ in composition and crystallographic characteristics, is formed[71,72].

Also, on exceeding a certain critical temperature, below which a two-phase region of α-solid solution and saturated hydride exists, the hydride phases MFe_3H_x (M = Dy, Er)[74–76] acquire the characteristics of a solid solution: a change in their hydrogen content is accompanied by a continuous increase in the unit-cell dimensions.

The data[77] on the existence of the mono- and di-hydrides $DyCo_3H_{1.0}$ and $DyCo_3H_{1.8}$, whose unit cells are "contracted" in the z axis direction as compared to the $DyCo_3$ structure, evidently require experimental verification, since they are not in agreement with other results[70–72].

The $CeCo_3$–H_2 system, in which only one hydride phase $CeCo_3H_3$ is formed, occupies a special place amongst MCo_3–H_2 systems. This phase is analogous in crystallographic characteristics to H_2-phases but the increase in its c parameter is anomalously large, amounting to 32%,[56,72] which is 3–5 times greater than in the dihydrides $MCo(Ni)_3H_{\sim 2}$.

The intermetallic compound $CeNi_3$ which crystallises in an analogous structural type reacts with hydrogen in a similar way—only one hydride phase, $CeNi_3H_3$, is formed and then only the c lattice parameter is substantially increased[56].

Hydrogenation of IMC's of composition M_2Co_7 with the Ce_2Ni_7 and Gd_2Co_7 type structures leads in both cases to formation of two hydride phases $M_2Co_7H_{\sim 3}$ and $M_2Co_7H_{\sim 6}$, but whereas the transition from α-solution to the hydride phase $M_2Co_7H_{\sim 3}$ is accompanied by expansion of the hexagonal (or trigonal) unit cells only in the z axis direction, when the hydride phase $M_2Co_7H_{\sim 6}$ is formed the a parameter increases[56,72].

The hydride phases Ti_2NiH_x (x = 0.5, 1.0, 2.0, 2.5) have been interpreted as individual compounds[78]. However there is no change in the structure of the metal matrix on hydrogenation—the cubic structures of these phases merely have enlarged unit-cell parameters as compared to the original intermetallic compound Ti_2Ni (which crystallises in an analogous structure type). On hydrogenation of the alloys $Ti_2Co_{1-x}Fe_x$,[79] $Ti_2Ni_{1-x}Fe_x$,[80] $Ti_2Ni_{1-x}Co_x$,[80] and the compounds Hf_2M' (M′ = Co, Fe, Mn, Rh),[81,82] which have the same type of structure as Ti_2Ni, the volume of the unit cells of the original structures increases but their cubic symmetry does not change.

The compounds Ti_2Ni, Ti_2Cu, Ti_2Fe, and Ti_2Co are able to absorb oxygen without a change in the initial structure up to the composition $Ti_2M'O_{0.5}$.[83–86] Hydrogenation of the oxygen-containing phases leads to mixed oxyhydride phases whose structures also possess the original cubic symmetry[83–86].

§ With a high pressure of hydrogen (up to 1400 atm) the phase $LaCo_5H_9$ is formed[32].

Judging from neutron-diffraction data[87], several hydride phases are formed on hydrogenation of the intermetallic compound Y_6Mn_{23} with the complex cubic structure of the Th_6Mn_{23} type. The move to phases richer in hydrogen is accompanied by a gradual increase in the volume of the cubic unit cells. However, in most of the work the values of the unit-cell parameters are quoted only for the hydride phases richest in hydrogen[56,57,68,88,89].

The hydride phases based on IMC's with structures of the types CrB ($ZrNiH$,[90] $ZrNiH_3$ [91]), ZrAg ($ZrAgH$ [92]), Th_7Fe_3 ($Th_7Fe_3H_{14.2}$ [93]), $CuAl_2$ (Hf_2NiH_3 [82], Th_2AlD_4 [94]), UNi_5 ($YNi_4.MnH_{4.5}$ [95]), $CeCo_4B$ ($CaNi_4BH_{4.5}$ [55]), CsCl [$TiFeH(D)$,[96,97] $TiFeD_{1.9}$ [98]], Zr_4Al_3 ($Zr_4Al_3H_{4.3}$ [99]), $MoSi_2$ ($Hf_2CuH_{2.8}$, $Ti_2PdH_{2.0}$, $Zr_2PdH_{2.7}$, $Hf_2PdH_{1.9}$ [100]), and Cr_3Si ($V_3GaH_{2.0}$ [101]) also have structures whose unit cells either correspond to the unit cells of the parent IMC structures or are derived from them. In contrast to these, the hydride phases based on the intermetallic compounds TiNi,[78] Mg_2Ni,[102,103] Zr_2Cu,[100] HfCo,[82] HfNi,[82], ZrCo,[104] Ti_3Al,[105] and TiCo [106] have crystal structures whose unit cells are not simply related to those of the parent IMC structures.

The structure of hydride phases obtained by high-temperature synthesis at low hydrogen pressures (~1 atm) from a mixture of the binary hydride of a metal M and a metal M′ have been studied[107–116]. The phases formed are $M_2M'H_{4-6}$ (M = Ca, Sr, Eu, Yb; M′ = Ru, Rh, Ir),[107,108,112,114,115] Sr_2PdH,[110] Sr_2PdH_4 and $Ca_3Pd_2H_4$ [111] with cubic structures and also Li_4RhH_4 and Li_4RhH_5,[116] whose structures possess tetragonal and orthorhombic symmetry respectively; from a mixture of two binary hydrides the phases $LiEuH_3$,[109] $LiBaH_3$ and $LiSrH_3$ [110] with antiperovskite type structures are formed. Saturation of the alloys $ThZr_2$ and $ThTi_2$ with hydrogen at elevated temperatures leads to formation of the phases $ThZr_2H_7$ and $ThTi_2H_6$ and it is accompanied by ordering of the metal atom arrangement as in the Laves phases $MgZn_2$ and $MgCu_2$.[113]

The formation of hydride phases richest in hydrogen leads to a 20–25% increase in the unit-cell volume of the IMC structures, although for a number of structures the ratio $\Delta V/V_0$ exceeds this amount by almost a factor of two (approximately 37% for hydrides based on $CeRu_2$ [143] and $ThMn_2$ [42]). The ratio of the change in the IMC unit-cell volume on hydrogenation ΔV to the number of absorbed hydrogen atoms is close to 2.5–3.5 Å^3 for all the hydride phases studied.

Li_4RhH_4 and Li_4RhH_5 are representative of a few metal hydrides for which an X-ray structure examination has been carried out on single-crystal specimens[116]. In Li_4RhH_4 the c.n. of the hydrogen atom is 6 and its coordination sphere comprises one Rh and five Li atoms forming a distorted octahedron. The structure needs refining by neutron diffraction. The structure of Li_4RhH_5 was not determined so reliably, the positions of all the atoms being deduced from geometrical considerations and from the relationship between the Li_4RhH_4 and Li_4RhH_5 structures.

As a rule, X-ray powder diffraction investigations of the structure of hydride phases do not make it possible to determine the positions in the crystal lattice occupied by hydrogen atoms. To solve this problem it is necessary to use neutron diffraction.

IV. CRYSTAL-CHEMICAL ANALYSIS OF THE STRUCTURES OF INTERMETALLIC COMPOUNDS AS MATRICES FOR THE ADSORPTION OF HYDROGEN

As hydride phases based on IMC's are as a rule powders in which the individual grains are not large enough for them to be used for single-crystal structure determination, neutron powder diffraction has up to the present been used in all the work carried out. The absence of single-crystal specimens creates certain difficulties for the solution of the structure—the traditional methods of structure analysis can be used only in isolated favourable cases to obtain results from a powder diffraction experiment owing to the limited number and overlapping of the reflections in the diffraction pattern. The method of line profile analysis[117] has considerably widened the possibilities of neutron powder diffraction analysis; however its use does not of course enable us to overcome the principal deficiencies of the powder experiment mentioned. The only possible method for solving the structure from the neutron powder diffraction data is to show that there is agreement between the intensities of the reflections calculated theoretically for the proposed model of the structure and those measured experimentally. Since the positions of the metal atoms in the hydride phase structures are close to their positions in the original IMC, the problem becomes one of determining the positions occupied by the hydrogen atoms on entry into the metal lattice.

The principles for constructing the most probable models for the structure of hydride phases based on IMC's can be formulated in the following way[30,40,118].

1. The positions in the parent metal lattice most preferable for filling with hydrogen atoms are the tetrahedral holes with a radius $\geqslant$0.4 Å.

2. The M–H interatomic distances in the IMC hydride lattice are similar to those in the binary hydride lattices; the minimum permissible value is equal to the sum r_M + (0.2 to 0.3) Å.

3. The H–H interatomic distances must not be substantially less than 1.8–2.0 Å.

In addition the following hypotheses are very important when analysing a model for the structure:

4. The preferable holes for occupation are those surrounded to a maximum extent by atoms of the metal M which is more active towards hydrogen (capable of forming a stable binary hydride).

5. The greater the M–M distances between the atoms making up the hypothetical coordination polyhedron in comparison to the sum of the corresponding metal radii, the more easily is this polyhedron deformed and hence the more easily is a hydrogen atom inserted in the hole.

The last hypothesis was put forward *a priori* in 1979 [119] and has been confirmed by an analysis of experimental results obtained over the last three years.

An analysis of possible models for the structures of hydride phases based on IMC's has been carried out, using the hypotheses set out above, for the structure types $CaCu_5$ (on the example $LaNi_5$),[118] $MgCu_2$ (example $ZrCr_2$),[120,121] $MgZn_2$ (example ZrMoFe),[40,121] $PuNi_3$ (example $HoNi_3$),[70] Th_6Mn_{23} (example Y_6Mn_{23}),[87] CrB (examples ZrNi and LaNi),[122–124] and for some other types. Considering that at the present time the structure of the majority of the corresponding hydrides (or deuterides) is already established by neutron diffraction, a detailed account of the results obtained is hardly necessary and so we restrict ourselves to an enumeration of the most characteristic features of the models for the structures of the hydrides of intermetallic compounds which distinguish them from the structures of binary metal hydrides. The main difference is that, as already noted, the number of different types of hole in IMC structures as a rule significantly exceeds the corresponding number in binary hydride structures. Thus, in the $CaCu_5$ type structure there are 5 types of hole suitable in principle for filling by hydrogen atoms[118], in the $MgZn_2$ structure 7 types[40,121], in the Th_6Mn_{23} structure 9 types[87], in the CrB structure 7 types[124], and in the $PuNi_3$ structure (Fig.1) as many as 13 types[70]. The

second, and no less important, difference is that in IMC structures three groups of hole can be distinguished according to the metal atoms surrounding them: (a) holes formed only by atoms of the metal M; (b) holes formed only by atoms of the metal M'; (c) holes with mixed surroundings (metals M and M'), whereas in the binary hydride structures the holes cannot of course be divided into different groups on this basis.

The analysis has shown that insertion of hydrogen atoms in the tetrahedral holes¶ [hM'_4] of the parent IMC structures is least probable because, firstly, they are smallest in size and, secondly, they are formed by atoms of the metals M' which are inactive towards hydrogen (nickel, chromium, manganese, molybdenum, or iron). In addition, the M'–M' interatomic distances on the periphery of these holes are as a rule less than double the radius of metal M', so making filling of the holes difficult.

Table 1. Characteristics of the types of hole most preferred for introduction of hydrogen atoms into the structures of $LaNi_5$,[118] $ZrCr_2$,[120] ZrMoFe,[30] $HoNi_3$,[30] Y_6Mn_{23},[87] and LaNi [163] (r is the effective radius of the hole).

*According to published data[16], the metal radii (in Å) (for c.n.$_M$ = 12) are as follows: r_{La} = 1.877, r_{Ni} = 1.246, r_{Ho} = 1.766, r_{Zr} = 1.602, r_{Cr} = 1.282, r_{Mo} = 1.400, r_{Fe} = 1.274, r_Y = 1.801.

**Data on the metal atom arrangement in the structures of the parent intermetallic compounds are given in refs. 30, 87, 118, 120, and 163.

***n is the maximum possible occupation factor of the holes under the condition $d_{h\text{-}h} \geqslant 1.8\text{–}2.0$ Å.

¶In this article the method adopted by Soviet authors (see, for example, Kripyakevich's monograph[25]) is used to signify holes (h) and coordination polyhedra of atoms: following specification of a hole or the central atom of the polyhedron (in this article D or H) the metal atoms forming the hole or coordination polyhedron are stated in decreasing order of their radii.

The holes in the parent IMC structures most preferred for filling by hydrogen atoms are the largest: the tetrahedral [$hM_2M'_2$] ($LaNi_5$, $ZrCr_2$, ZrMoFe, and $HoNi_3$ structures), the octahedral [hM_6] (Y_6Mn_{23} structure) and the hole of form [$hM_3M'_2$] at the centre of a trigonal bipyramid (LaNi and ZrNi stuctures), because their periphery involves a high proportion of atoms of the metal M which is active towards hydrogen (Y, Zr, La, Ho) as compared to other holes. In addition, filling of these holes by hydrogen atoms is favoured by the fact that their periphery contains a larger number of M–M distances which exceed the sum of the corresponding metal radii than do other types of hole. The basic data describing the types of hole listed above are given in Table 1.

In the structures under consideration the tetrahedral holes [hMM'_3] ($LaNi_5$, $ZrCr_2$, ZrMoFe, $HoNi_3$, and Y_6Mn_{23} structures), [$hM_2M'_2$] (Y_6Mn_{23}, LaNi, and ZrNi structures), [hM_3M'] (LaNi and ZrNi structures), and the octahedral holes [$hM_2M'_4$] ($LaNi_5$ and $HoNi_3$ structures) can also be singled out. If we take into account the dimensions of these holes, the nature of their periphery, and the magnitudes of the distances between the metal atoms forming the holes, we see that they are less likely to be filled than the holes listed in Table 1; however it is quite possible that hydrogen atoms are placed simultaneously in the most preferred holes (see Table 1) and in these latter holes [hMM'_3], [$hM_2M'_2$], [hM_3M'], and [$hM_2M'_4$] in hydride phase structures.

The specified hypotheses on the principles for setting up models for the structures of hydride phases have been confirmed by neutron-diffraction studies.

V. NEUTRON-DIFFRACTION STUDIES OF THE CRYSTAL STRUCTURES OF THE HYDRIDE PHASES $M_nM'_mH(D)_x$

The largest number of hydride structure investigations published up to the present are of those based on IMC's with the hexagonal structure of the $CaCu_5$ type[27,40,118,125–134]. Although the introduction of hydrogen into the MM'_5 lattice leads to a different deformation of the unit cells in nickel-containing ($LaNi_5D_{6.0}$, $LaNi_4AlD_{4.1}$, etc.) and cobalt-containing ($CeCo_5D_{2.55}$, $PrCo_5D_{3.6}$) hydrides (or deuterides) (see Table 2), all these structures are related to each other and are different versions of the model for the structure of the phase $MM'_5H(D)_x$, in which the tetrahedral holes [$hM_2M'_2$] and [hMM'_3] (or the octahedral holes [$hM_2M'_4$]) of the parent IMC lattice are filled. The most substantial differences between the $MNi_{5-y}Al_yD_x$ structures and the MCo_5D_x structures are connected with some displacement of the deuterium atoms from the layers of metal atoms, situated in planes perpendicular to the z axis, since in the MCo_5D_x structures the deuterium atoms are in the planes of these layers (see Figs. 2 and 3). These displacements lead to a change in the form of the coordination polyhedron and the c.n. of the deuterium atoms from 6 in the octahedral [$hM_2M'_4$] holes of the MCo_5D_x structures to 4 in the tetrahedral [hMM'_3] holes of the $LaNi_5D_{6.0}$ and $LaNi_4AlD_{4.1}$ structures and from 4 in the tetrahedral [$hM_2M'_2$] holes of the MCo_5D_x and $LaNi_4AlD_{4.1}$ structures to 3 in the $LaNi_5D_{6.0}$ structure (resulting from displacement of the deuterium atoms into the $LaNi_2$ triangular plane).

For the deuterides MCo_5D_x ordered occupation of two of the six [$hM_2M'_2$] holes and two of the three [$hM_2M'_4$] holes in the parent lattice is characteristic. Such an occupation evidently explains the anisotropic expansion of the original hexagonal unit cells leading to their orthorhombic deformation. In accordance with structure models proposed for β-hydrides on the basis of neutron-diffraction data[27], β'- and β''-hydrides have the limiting stoichiometric composition MCo_5H_4, but for β'''-hydrides this composition is MCo_5H_3.

**$d_1 = d_{M-H}$, $d_2 = d_{M'-H}$, $d_3 = d_{H-H}$. The values in parentheses after d_1 and d_2 are the effective radius of hydrogen, calculated from $r_{H(D)} = d_{M(M')-H(D)} - r_{M(M')}$.

***The shortest H–H distances cannot be determined precisely from the published data because in the structures there are statistically occupied hydrogen atom positions 1.0–2.1 Å apart.

****Low-temperature modification.

*****High-temperature modification.

However, from data on the absorption–desorption isotherm of hydrogen from the same paper[27], with a rise in pressure the composition of the β′- and β‴-hydrides approaches MCo_5H_4 and MCo_5H_3 respectively, but for β‴-hydrides it does not exceed MCo_5H_3, which contradicts the proposed model for the structure [This sentences does not make sense. The Russian probably has a misprint, possibly in the primes (Ed.of Translation)].

In the structures of the β″- and β‴-hydrides the octahedral holes are filled to a lesser degree as compared to the β′-hydride, while for the β‴-deuteride $CeCo_5D_{2.55}$ ordered filling of half of the [hCe_2Co_4] holes occupied in the β′-hydride structure is characteristic[27]. This ordering, and also some deformation of the metal sublattice in the structures of the β″- and β‴-hydrides, leads to doubling of the *c* parameter of their unit cells.

The orthorhombic γ-hydride structure $LaCo_5H_{4.3}$ has not yet been elucidated although a neutron diffraction study has been carried out on it[27].

A number of publications have been devoted to an investigation of the structure of $LaNi_5D_{6+x}$.[40,118,125–128,132,134]. This is partly because the structure of $LaNi_5H(D)_6$ has been studied independently and also simultaneously in the USSR,[118]

Switzerland[125], and Norway[126].† In addition some inaccuracies in the earlier work gave rise to the need for new publications[129,132]. All the structural models proposed for $LaNi_5.D_{6+x}$ differ rather substantially from each other in some of their features, although each of them is quite satisfactorily verified by the specific neutron-diffraction results of the different authors.

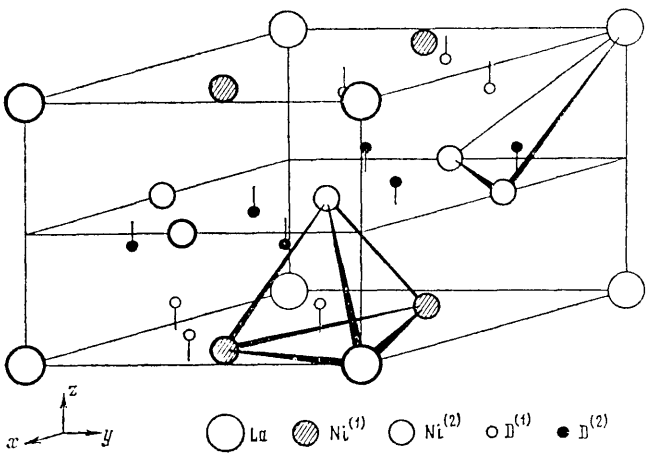

Figure 2. Structure of $LaNi_5D_{6.0}$;[132] the coordination polyhedra of the D atoms are outlined.

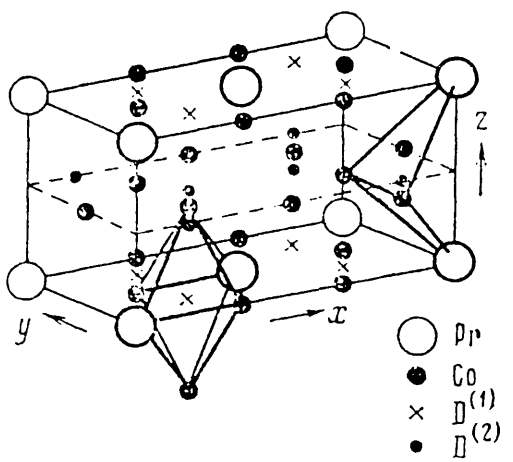

Figure 3. Structure of β'-$PrCo_5D_{3.6}$;[27] the coordination polyhedra of the D atoms are outlined.

†Although the earliest publication on the structure of $LaNiD_{6.8}$ was that of Bowman and co-workers in 1973,[134] their results cannot be considered reliable because of the presence in their structure of D–D and Ni–D interatomic distances equal to 1.30 and 1.17 Å: such small distances are inadmissible from stereochemical considerations; the latter distance is less than the metallic radius of nickel (1.246 Å [16]).

In this situation only those structural results which correlate satisfactorily with the results of research on hydride phases by physicochemical analysis methods can be considered sufficiently conclusive. The broad line n.m.r. method is very informative for crystalline hydrides. The magnitudes of the second moments M_2 determined by this method depend on the H–H and La–H interatomic distances in the hydride phase and indicate clearly the presence of short interatomic contacts. M_2 has been measured experimentally and the values, 12.7 G^2 for $LaNi_5H_{6.0}$ [136] and 13.4 G^2 for $LaNi_{5.3}H_{6.0}$,[135] do not agree with the value M_2 = 20.1 G^2 calculated theoretically by us for the model of the $LaNi_5H(D)_6$ structure proposed by Fischer et al.[125] Hence their hypothesis[125] that positions 6(*d*) in space group *P*31*m* are statistically occupied by deuterium atoms, leading to H–H interatomic distances of 1.58 and 1.68 Å, does not correspond to the facts and the incorrectness of their structural model is indicated.

The same conclusion can be drawn regarding the model proposed[126] for the $LaNi_5D_{5.6}$ structure.

However the model for the $LaNi_5D_{6+x}$ structure proposed[40,132] within the space group *P*321 agrees quite satisfactorily with the experimental n.m.r. results. In considering possible versions of the $LaNi_5H(D)_{6.0}$ structure the assumption was made that in each unit cell the occupation of holes in the metal sublattice by hydrogen atoms proceeds in an ordered way—up to three hydrogen atoms are found in the $[hMM'_3]$ and $[hM_2M'_2]$ holes which are most remote from each other. In this case the minimum H–H interatomic distance is 2.29 Å, which agrees well with the value calculated on the basis of n.m.r. spectra. At the composition $LaNi_5H_{6.0}$ the value calculated for M_2 on this assumption (10.9 G^2) is very close to the experimental values. The n.m.r. results therefore fully confirm the proposed model[40,132] for the $LaNi_5D_{6.0}$ structure.

An argument in favour of this same model is that it is the only model that allows us to explain the presence of the wide homogeneity range in $LaNi_5H_{6+x}$ right up to $LaNi_5H_8$ which exists at −40 °C and a hydrogen pressure of 50 atm,[137] or at room temperature and 1400 atm pressure[32]. In fact the maximum stoichiometric composition which can be achieved by filling all the $[hMM'_3]$ and $[hM_2M'_2]$ holes is $LaNi_5H_9$ whereas in all the other models the composition $LaNi_5H_{6.0}$ cannot be exceeded because of the occurrence of H–H contacts of ~1.5 Å.

The recently published results on the structures of $LaNi_5.D_{6.0}$ and $LaNi_{5-y}M'_yD_x$ (M' = Al, Mn) [127,129] cannot apparently be considered reliable. The authors draw the conclusion that all forms of hole present in the MM'_5 structure including those such as $[hM'_4]$ are statistically occupied by deuterium atoms. However the insertion of hydrogen atoms into holes formed by atoms of elements, which are inactive towards hydrogen and whose binary hydrides are unstable and can be obtained only by the use of special methods, is very improbable. In every case such a conclusion requires careful verification and reliable confirmation by other physicochemical methods as well as structural.

Structural research on hydride phases based on other members of the homologous series of structures MM'_5–MM'_2 has been conducted to a considerably lesser extent than in the case of $MM'_5H(D)_x$. The structure of the hydrides of the Laves phases $MM'_2H(D)_x$ has been studied more completely than the others. The structure of a hydride phase based on an IMC crystallising in the $MgZn_2$ type ($ZrMoFeD_{2.6}$) was first investigated by Yartys' et al.[138,139]. In accordance with the most likely models discussed above for the structure of $MM'_2H(D)_x$ phases, in this deuteride there is ordered insertion of deuterium atoms into two of the four types of $[hZr_2(Mo, Fe)_2]$ holes.

The structure of $ZrMn_2D_{3.0}$ has been investigated (as with ZrMoFe the parent IMC has the $MgZn_2$ type structure).[140] The main results agree with those of Yartys' et al.[138,139]: in $ZrMn_2D_{3.0}$ all four types of $[hZr_2Mn_2]$ hole are statistically occupied.

An attempt to examine the structure of the hydride phase based on $ZrCr_2$, one of whose polymorphic modifications crystallises in the $MgZn_2$ type, was undertaken by Irodova et al.[141] However the authors did not succeed in obtaining a single-phase specimen of the parent IMC and so the structure of the hydride phase was not worked out.

A richer spectrum of structures is obtained by hydrogenating IMC's which crystallise in the $MgCu_2$ type. As in the structures of other Laves phases, there are three different types of hole: $[hM_2M'_2]$, $[hMM'_3]$ and $[hM'_4]$ in the parent $MgCu_2$ structure. For the structures $ZrCr_2D_{3.5}$,[120] $ZrCr_2D_x$ (x = 2.9, 3.1, 3.8),[142] $TiCr_2D_{0.15}$,[49]# $CeRu_2D_{5.2}$,[143] and the low-temperature modifications $HfV_2D_{4.0}$ [144] and $ZrV_2D_{3.6}$,[145] filling of only the largest-in-volume $[hM_2M'_2]$ holes, when their periphery includes the greatest number of atoms of element M (Zr, Ti, Ce, Hf), is characteristic as in hydrides based on IMC's with the $MgZn_2$ type structure. Besides these, two other structural variations are known—a mixed filling of the $[hM_2M'_2]$ and $[hMM'_3]$ holes in the high-temperature modifications of the hydride phases based on HfV_2 and ZrV_2 (the $ZrV_2D_{4.5}$,[146] $ZrV_2H_{3.7}$,[142] $ZrV_2D_{2.3}$,[142] and $HfV_2.D_{4.0}$ [144] structures) and filling of only the $[hMM'_3]$ holes ($ZrTi_2D_4$ structure[147]), as a result of which a spinel type structure is formed§.

It is of interest that in structures with mixed filling of $[hM_2M'_2]$ and $[hMM'_3]$ holes, the degree of filling is identical for zirconium and hafnium compounds. In contrast to $ZrV_2.H(D)_x$ phases in which hydrogen atoms are found in approximately equal or similar quantities in the two types of hole, in the $HfV_2D_{4.0}$ structure five times as many atoms occur in the $[hM_2M'_2]$ holes as in the $[hMM'_3]$ holes. The phase transition which occurs at 298 K in $HfV_2D_{4.0}$ is accompanied by a reduction in the lattice symmetry from f.c.c. to body-centred tetragonal (b.c.t.) and by a redistribution of deuterium atoms in the holes in the metal matrix; the $[hMM'_3]$ holes remain vacant but the $[hM_2M'_2]$ holes are filled in an ordered manner—of the three possible positions which are related by symmetry operations in the f.c.c. unit cell but are independent in the b.c.t. cell, only one is occupied. Similar results were obtained for $ZrV_2D_{3.6}$.[145]

Neutron-diffraction studies of hydride phases based on IMC's located in the homologous series of related compounds between the compositions MM'_5 and MM'_2 have been carried out for only one compound, namely the deuteride $HoNi_3D_{1.8}$ based on an IMC with the $PuNi_3$ type structure[40,148]. As was expected, the structure of $HoNi_3D_{1.8}$ corresponds to one of the most probable models for the structure—a large proportion of the deuterium atoms occupy the $[hHo_2Ni_2]$ holes, which are the most preferred from the point of view of their size and periphery, and which are similar to the holes with the same periphery and which are occupied in the MM'_5D_x deuteride structures, and they are located near the boundary of the $CaCu_5$ and $MgZn_2$ type portions of the structure (Fig.4). However, the most distinctive feature of the $HoNi_3D_{1.8}$ structure is the occupation of holes with an $HoNi_3$ periphery. This type of hole lies within the $MgZn_2$ type section of the structure and is vacant in the $ZrMoFeD_{2.6}$ and $ZrMn_2D_{3.0}$ structures.

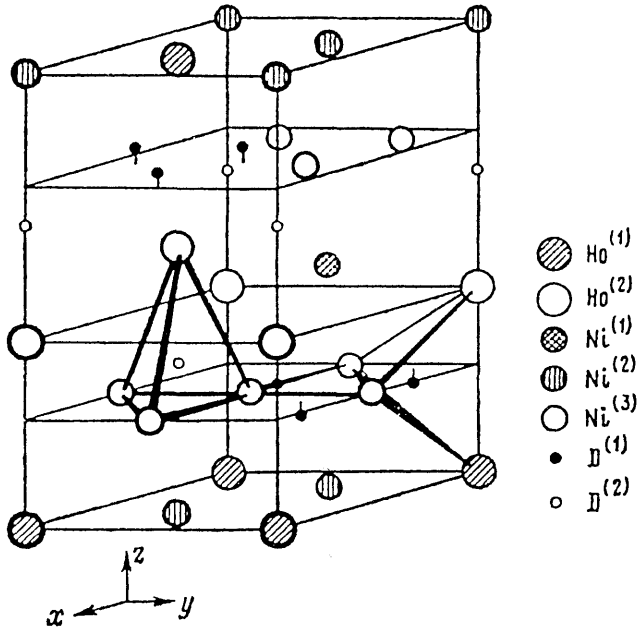

Figure 4. Structure of $HoNi_3D_{1.8}$ [148] (z = 0–1/3); the coordination polyhedra of the D atoms are outlined.

The special features of the structure of $HoNi_3D_{1.8}$ permit the unusual type of deformation of the metal matrix on the insertion of hydrogen into it (expansion of the unit cell only in the z axis direction) to be explained. Analysis of the M–M interatomic distances in the $HoNi_3$ structure shows that they vary over a fairly considerable range—some of them exceed the sum of the corresponding metal radii while other distances are markedly "shortened", i.e. significantly less than the sum of the radii, with all the "shortened" distances lying either in planes perpendicular to the z axis of the unit cell, or at a very small angle to these planes, and the "elongated" distances, on the other hand, lying either parallel to the z axis or at some angle to this axis. It thus seems quite natural to suppose that expansion of the unit cell must take place most easily in that direction where resistance to the deformation resulting from the insertion of hydrogen atoms is least. It is evidently just this ease of deformation of the "elongated" M–M bonds, which lie along the z axis, that explains the expansion of the unit cell only in the [001] direction. The holes in the metal matrix preferred for insertion of hydrogen atoms are of course those whose periphery contains "elongated" M–M bonds. As might have been supposed two of just such holes are occupied in the $HoNi_3D_{1.8}$ structure.

#The stoichiometric composition corresponds to the α-solution.

§Although $ZrTi_2D_4$ is formed by the reaction of deuterium with an alloy of composition $ZrTi_2$ which does not possess the $MgCu_2$ type structure, in the structure of this deuteride the metal atoms occupy crystallographic positions characteristic of a C15 type phase and therefore the $ZrTi_2D_4$ structure can be regarded as a derivative of insertion type in the structure of the hypothetical compound "$ZrTi_2$".

The choice of hydride phases based on other structural types of IMC which have been investigated by neutron diffraction has been to a considerable degree accidental. Much interest has been shown for some time past in the study of the structure of hydride phases formed on the basis of TiFe. This is quite understandable as $TiFeH_{1.9}$ is one of the most promising substances for hydrogen storage[149]. There have been neutron-diffraction studies of all the hydride phases formed in the TiFe–$H(D)_2$ system: α, β, and γ with compositions corresponding to the formulae $TiFeD_{0.057}$,[150] $TiFeD_{1.0-1.1}$,[96,97] and $TiFeD_{1.9}$.[98]

These researches showed that deuteriation is not in this case accompanied by reorganisation of the parent metal matrix and leads only to some deformation. In the α-phase $TiFeD_{0.057}$ [150] there is ordered occupation by the deuterium atoms of one of the three octahedral holes with a Ti_4Fe_2 periphery present in the unit cell of TiFe. The difference between the Fe–D interatomic distances and the metallic radius of iron (0.22 Å) is significantly less than the corresponding value for the Ti–D distances (0.65 Å). The coordination of the deuterium atom can be interpreted as linear $[DFe_2]$ and its coordination number is as a result decreased from 6 to 2.

Further introduction of hydrogen into the structure gives the β-phase which has a composition close to $TiFeH(D)_{1.0}$.[96,97] The orthorhombic $TiFeD_{1.1}$ structure was examined for the first time by neutron diffraction by Thompson et al.[96], who showed that the deuterium atom $D^{(1)}$ occupies the octahedral $[hTi_4Fe_2]$ hole. The small amount of deuterium in excess of the composition $TiFeD_{1.0}$ occurs in octahedral holes of a second type, also having a Ti_4Fe_2 periphery, but they are somewhat displaced from the ideal centres. A second examination of this structure[97] confirmed the main results of Thompson et al.[96], but found that the $D^{(2)}$ atoms are exactly in the centres of the $[hTi_4Fe_2]$ holes.

In the *P–C* diagram of the TiFe–H_2 system[151] two two-phase regions α + β and β + γ exist. However, on the basis of unverified data[152] as to the existence of a subsidiary plateau in the composition range $1 < x < 1.4$ on the isotherm for absorption–desorption of hydrogen by the hydride phase $TiFeH_x$ at 274 K (note that these data were not confirmed in a study of deuterated specimens[153]), Schefer et al.[153] concluded that there is a hydride phase close in composition to $Ti_3Fe_3D_4$. Examination of the structure of this phase showed that it is isostructural with $TiFeD_{\sim 1}$ and further introduction of deuterium atoms into it takes place in the holes filled with the $D^{(2)}$ atoms in the $TiFeD_{\sim 1}$ structure.

The γ-phase $TiFeD_{1.9}$ (Fig. 5) has a monoclinic unit cell in which the deuterium atoms occupy four different positions[98]. Three of these are octahedral holes with a Ti_4Fe_2 periphery, two out of the three corresponding to the positions of atoms $D^{(1)}$ in the β-phase structure, but for atom $D^{(4)}$ the coordination polyhedron is the octahedron $[D^{(4)}Ti_2Fe_4]$. Rather unexpectedly the holes occupied by atoms $D^{(2)}$ in the β-phase structure are vacant in the γ-phase.

The TiFe–$H(D)_2$ system was also studied with neutron diffraction by West German authors[154,155]. The results obtained are on the whole in agreement with the data discussed above[96,97].

A detailed discussion of all the neutron-diffraction data on the TiFe–$H(D)_2$ system has been given in a recent review[156].

$TiCuD_{0.9}$, which has been examined by neutron diffraction[157], was obtained by starting with the γ-modification of the IMC which possesses tetragonal symmetry. Unfortunately the reliability of the experimental results is reduced considerably by the presence as an impurity in the IMC of another of its allotropes, the δ-phase, which also has a tetragonal structure and whose reaction with hydrogen was not studied by these authors. In this connection the exclusion of some parts of the neutron-diffraction pattern (in which the diffraction lines of the γ- and δ-hydrides $TiCuD_x$ were superposed) from consideration was not sufficiently justified. Nevertheless these results are quite reasonable and correspond to the most probable model for the deuteride structure: the holes occupied by hydrogen are those most preferred for filling, the tetrahedral holes $[hTi_4]$ which have a periphery of atoms of the element (titanium) more active with respect to hydrogen.

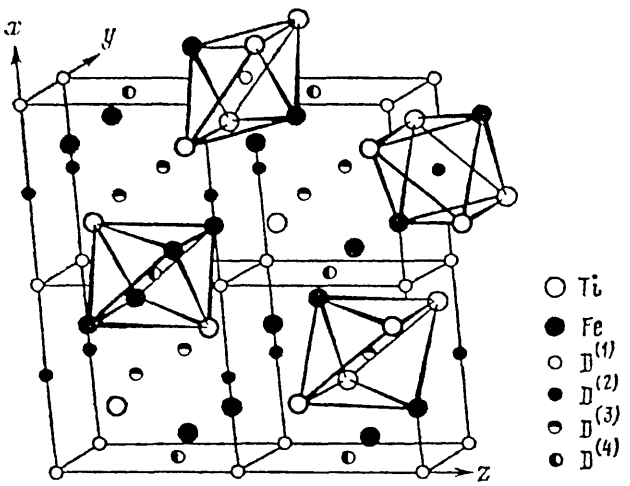

Figure 5. Structure of γ-$TiFeD_{1.9}$; the coordination polyhedra of the D atoms are outlined.

The investigation of the deuterides $Y_6Mn_{23}D_x$ (x = 8.3, 18.0, 23.0) based on an IMC with the Th_6Mn_{23} type structure[87] is of considerable interest. The parent IMC crystallises with a complex cubic structure, the unit cell of which contains 116 metal atoms and has 9 different positions which can be occupied by deuterium atoms. The sequence of filling of the different positions as the deuterium content is increased corresponds on the whole to the rules set out above for the structure of multicomponent IMC hydrides. When the first hydride phase $Y_6Mn_{23}D_{8.3}$ is formed, the deuterium atoms enter the $[hY_6]$ and $[hY_3Mn]$ holes whose periphery contains the largest contribution of atoms of yttrium which is the element active towards hydrogen. In the second phase $Y_6Mn_{23}D_{18}$ the $[hYMn_3]$ holes are filled as well and then in the $Y_6Mn_{23}.D_{22.9}$ structure deuterium atoms enter the $[DY_2Mn]$ position with trigonal planar coordination. As expected, the $[hMn_4]$ holes formed by manganese, which is the inactive element with respect to hydrogen, are not filled in any of the deuterides. From the last of the proposed models we may arrive at the maximum stoichiometric composition for the hydride phase of $M_6M'_{23}H_{33}$.

$Th_6Mn_{23}D_{16.2}$ has been examined by neutron diffraction[158]. The structure of this compound might be expected to be analogous to that of $Y_6Mn_{23}D_{18}$ described above. It was however found that they are not isostructural—firstly, the deuterium atoms are displaced substantially from the centres of the $[hMM'_3]$ holes and two holes of this type are arranged with an Mn_3 triangular face in common, leading to a change in the form of the coordination polyhedron of the deuterium

atom from a tetrahedron in $Y_6Mn_{23}D_{18}$ to a trigonal bipyramid $[D^{(3)}Th_2Mn_3]$. In addition, the degree of occupation of the $[hM_6]$ holes in the structure of the Th compound is relatively small, in contrast to the $Y_6Mn_{23}D_{18}$ structure in which they are completely filled[87].

The intermetallic compound LiPt crystallises in the LiRh type structure[159], which is a superstructure to the Mg type. In the $LiPtD_{0.66}$ structure[160,161] the deuterium atoms occupy the tetrahedral holes in the hexagonal close packing. The coordination polyhedra of the deuterium atoms are the $[D^{(1)}.Li_3Pt]$ and $[D^{(2)}LiPt_3]$ tetrahedra. The $LiPtD_{0.66}$ structure has no analogues among the structures of binary hydrides with hexagonal close-packed metal atoms, for which as is known filling of octahedral, and not tetrahedral, holes is typical.

The intermetallic compound LiPd exists in two polymorphic modifications, with structures of the LiRh and CsCl types[162]. Only one of these (the LiRh type) is capable of reacting with hydrogen, and the hydride formed has a tetragonal structure[160]. The hydrogenation process is accompanied by reorganisation of the metal matrix from the LiRh type to a tetragonally distorted CsCl type. If the $LiPdD_{0.7}$ structure[160] is regarded as derived by insertion to the CsCl type, then the deuterium atoms are found to occupy only one out of three octahedral holes present in the b.c.c. unit cell with Li_2Pd_4 periphery, evidently as a result of which there is an anisotropic expansion of the structure.

The structure of Th_2AlD_4 [94] can be regarded as a packing of $[AlTh_8]$ tetragonal antiprisms with aluminium at the centre and unfilled $[hTh_4]$ tetrahedra, which the hydrogen atoms occupy on introduction into the IMC lattice. At the stoichiometric composition Th_2AlD_4 all 16 of these tetrahedra are occupied but when D/Th_2Al is less than 4 the filling is disordered.

The $ZrNiH_3$ structure[91] is a derivative of the insertion type to the CrB type structure. The structure of ZrNi consists of layers of $[NiZr_6]$ trigonal prisms with nickel at the centre and layers of unoccupied rhombic pyramids and tetrahedra of zirconium atoms alternating one above the other[25]. In the $ZrNiH_3$ structure the hydrogen atoms of one sort are at the centre of the base of the trigonal prisms; their coordination polyhedron is the trigonal bipyramid $[H^{(1)}Zr_3Ni_2]$. The hydrogen atom is displaced from the ideal position at the centre of the bipyramid in the plane passing through the nickel atoms and one of the zirconium atoms. The coordination of the atom $H^{(1)}$ can be regarded as triangular $[H^{(1)}ZrNi_2]$. The hydrogen atoms of the second sort occupy distorted tetrahedra $[H^{(2)}Zr_3Ni]$.

Deuteriation of the intermetallic compound ZrCo, which possesses the CsCl type structure, gives $ZrCoD_3$, isostructural with $ZrNiH_3$, with ordered Zr and Co atoms in the CrB type[104]. In contrast to the $ZrNiH_3$ structure, the atom $D^{(1)}$ is only slightly displaced from the centre of the trigonal bipyramid, so that it has a c.n. of 5, $[D^{(1)}Zr_3Co_2]$. Atom $D^{(2)}$, as in the $ZrNiH_3$ structure, has a c.n. of 4 and tetrahedral coordination $[D^{(2)}Zr_3Co]$.

The third representative of hydride phases based on an IMC with the CrB type structure, whose structure is known, is $LaNiD_{3.7}$. When the D/LaNi ratio exceeds 3.0, the deuterium atoms have linear coordination, which is unusual for metal hydrides, with nickel atoms as neighbours (Fig.6).[124,163] The structure of $LaNiD_{3.7}$, together with $TiFeD_{0.057}$,[150] is a rare example of a metal hydride structure in which the hydrogen atoms have a c.n. of 2. The atoms $D^{(1)}$ and $D^{(2)}$ in this structure occupy the same positions as in the structures of Zr-containing compounds with trigonal bipyramids and tetrahedra as coordination polyhedra.

Sr_2IrD_5 and Sr_2RuD_6 [114] are obtained by deuteriation of a mixture of SrD_2 and Ir (or Ru). Their structures are cubic with the metal atoms ordered in the antifluorite positions. The $Sr_2M'D_{6-x}$ structure (M' = Ir, Ru) can be regarded as a packing of equal numbers of vacant and occupied cubes $[hSr_8]$ and $[M'Sr_8]$. The deuterium atoms are centred over all the cube faces, and their coordination polyhedron is a tetragonal pyramid $[DSr_4M']$. In defect structures ($H/Sr_2M' < 6$) the hydrogen atoms are statistically distributed in the holes. These hydrides are isostructural with K_2PtCl_6.

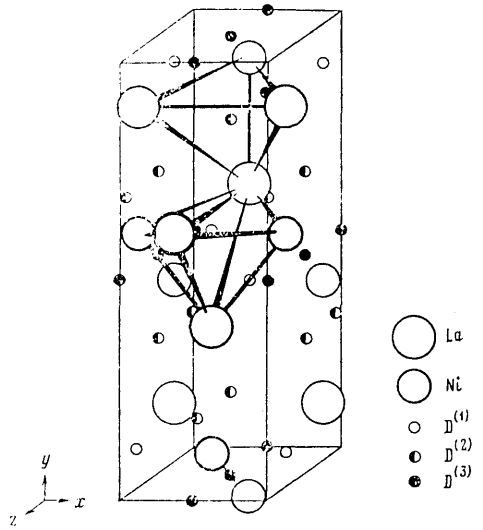

Figure 6. Structure of $LaNiD_{3.7}$; the coordination polyhedra of the D atoms are outlined.

Among compounds crystallising in the K_2PtCl_6 type the greatest defect nature of the hydrogen sublattice is shown by the high-temperature modification of Mg_2NiD_4 [164] (the phase transition is at 483–518 K) which, in contrast to the phases discussed above, can be obtained by starting with Mg_2Ni. In the deuteration process the hexagonal Mg_2Ni structure reorganises to the cubic antifluorite type. However, the defect nature of the sublattice does not lead to a change in the c.n. of the deuterium, which is 5, nor in its coordination ($[DMg_4.Ni]$ tetragonal pyramid).

The details of the crystal structures of the hydride phases described above are given in Table 2, and the crystallographic data for the parent IMC's and hydride phases based on them are in Table 3.

Table 2 shows the shortest M–H and H–H interatomic distances as well as the symmetry of the structures and the form of the coordination polyhedron of the deuterium atoms. In the majority of the structures the mean values of the M–H(D) distances are equal to the sum: r_M + 0.4 to r_M + 0.6 Å. They are as a rule similar in size to the analogous distances in the structures of binary hydrides.

However, for half of the structures in Table 2 (to be precise, 17 out of 35) the minimum effective radius of the hydrogen atom is substantially less, lying in the ranges 0.18 to 0.26 Å (10 structures) or 0.27–0.33 Å (7 structures), and a comparable value occurs for only two binary hydrides (0.31 to 0.32 Å in Y and Sc trihydrates[18,14]).

*The hydride phase is formed by high-temperature synthesis from two binary hydrides or from metal M' and the hydride of metal M in a hydrogen atmosphere.

**$\beta = 93.2°$.

***Data for deuterated specimens.

****$\beta = 97.0°$.

*****Composition of hydride phase not given in original work.

******$\alpha = 93.5°$.

The results presented suggest that the minimum radius for the hydrogen atom in metal hydrides is close to 0.2 Å. However, like other results suggesting that hydrogen can have an effective radius less than 0.2 Å (0.11 Å in the $LiPtD_{0.66}$ structure[160,161]), this requires careful experimental verification by carrying out more detailed and systematic structural researches.

The minimum H–H distances are either similar to or a little greater than the analogous distances in binary hydride structures. There is one exception, the Th_2AlD_3 structure[165], in which the presence of short H–H distances of length 1.66 Å was confirmed by n.m.r.

While this review was in the press a whole series of new papers on the structural chemistry of IMC hydrides[166–202] was published. The results of the most important of them are discussed briefly below.

The range of subjects for neutron-diffraction investigation has been broadened mainly through the study of new representatives of hydride phases formed on the basis of IMC's with structures belonging to the homologous series MM'_5–MM'_2 ($CaCu_5$ type—Laves phases). The deuterides $ZrVFeD_{3.6}$, $ZrVCuD_{4.0}$, and $ZrVNbD_{5.4}$ [166] based on IMC's with the $MgZn_2$ type structure are particularly interesting as the stoichiometric composition of the last of them is the maximum for hydrides based on the Laves phases. The tendency for preferential occupation of the $[hM_2M'_2]$ holes in the metal lattice was found to be maintained also in the structures of hydride phases richer in hydrogen than $ZrMoFeD_{2.6}$[138,139,167] and $ZrMn_2D_{3.0}$.[140] Thus in the $ZrVFeD_{3.6}$ and $ZrVNbD_{5.4}$ structures the $[hM_2M'_2]$ holes are occupied by up to 97% of the hydrogen atoms, and in the $ZrVCuD_{4.0}$ structure 89%. In addition a small number of hydrogen atoms are in $[hZrM'_3]$ holes, and for $ZrVCuD_{4.0}$ filling of the $[hM'_4]$ holes is also typical.

A comparison of all five ZrM'_2D_x structures based on IMC's with the $MgZn_2$ type structure which have been studied up to now shows that an equally probable distribution of hydrogen atoms in the $[hZr_2M'_2]$ holes does not occur in any of the structures. It is of interest that all the structures with $D/ZrM'_2 \leq 4.0$ are related to each other and may be regarded as derivatives of $ZrMoFeD_{2.6}$ which is the "poorest" in hydrogen: when the D/ZrM'_2 ratio exceeds 2.6, in addition to the two types of $[hZr_2M'_2]$ hole filled in $ZrMoFeD_{2.6}$, hydrogen atoms enter into two more types of hole in the metal sublattice different for each particular structure. The way in which the hydrogen atoms are distributed in the holes in the $ZrVNbD_{5.4}$ structure differs in principle from that in the other structures. There is a redistribution of the hydrogen atoms between two groups of $[hZr_2M'_2]$ holes in six-fold equivalent positions, as a result of which not only can the limiting composition $MM'_2H_{4.5}$ for the alternative model be exceeded without substantial distortion of the $MgZn_2$ type structure, but also the maximum stoichiometric composition $MM'_2H_{6-6.5}$ can be attained.

Returning to the results given in the main part of the review, we may conclude that an almost complete analogy exists between the structure of the hydride phases $MM'_2H(D)_x$ based on IMC's with $MgCu_2$ and $MgZn_2$ type structures: at low hydrogen concentrations only the $[hM_2M'_2]$ holes are filled, and on increasing the hydrogen content the preference for filling these holes is retained, but hydrogen atoms are also inserted into holes with a smaller content of metal M, in the $[hMM'_3]$ holes in the first place.

Several recent publications[168–170] are devoted to hydrides based on MM'_5 compounds with the $CaCu_5$ type structure.

The structure of the mixed oxyhydride phase $Ti_4Fe_2.OD_{2.25}$ [171] (the parent IMC Ti_2Fe crystallises in the Ti_2Ni type only in the presence of oxygen) is of undoubted interest. The presence of chemisorbed oxygen in the lattice must indicate fairly definitely the choice of positions for the introduction of hydrogen atoms. As with the shortest H–H interatomic distances characterising the "blocking radius" of neighbouring holes, an analogous value can also be determined for the O–H(D) contacts. The experimentally determined value $d_{O-D} = 1.68$ Å for the $Ti_4.Fe_2OD_{2.25}$ structure, as expected, substantially exceeds the value 0.96 Å typical of an O–H covalent bond in the water molecule, and lies in the typical range for the length of O...H hydrogen bonds, which undoubtedly indicates a definite interaction between the oxygen and hydrogen atoms.

Three types of hydrogen atom in the structure occupy two different types of hole, their coordination polyhedra being the octahedron $[D^{(1)}Ti_6]$ and the tetrahedra $[D^{(2)}.Ti_3Fe]$ and $[D^{(3)}Ti_3Fe]$, as atoms $D^{(2)}$ and $D^{(3)}$ occupy the same type of hole. The crystallographic positions, which these atoms can occupy inside a specific hole, are within a sphere of diameter ~0.3 Å.

A characteristic feature of IMC hydrides is that they are, as a rule, non-stoichiometric and that in their structures there is a statistical distribution of hydrogen atoms in crystallographic positions, with the number of positions substantially exceeding the number of inserted atoms. When the temperature is reduced, owing to the non-zero configurational entropy, phase transitions of the order-disorder type[172,173] must take place, leading to removal of the "degeneracy" of the equivalent holes—some of them are filled in an ordered way, and the remainder become vacant. In addition to $ZrV_2D_{3.7}$ [145] and $HfV_2D_{4.0}$ [144] discussed above, such transitions were observed as the temperature is lowered in Sr_2IrD_5.[174] The order-disorder phase transition in the last case is accompanied by a lowering of the lattice symmetry from cubic to tetragonal and a reduction in the deuterium atom occupation factor of each of five Sr_4Ir pyramids ($n = 0.70$), while the occupation factor of the remaining [hSr_4Ir] holes is close to the possible limit ($n = 0.96$). A similar phase transition on reducing the temperature also takes place in a hydride phase based on the IMC Y_6Mn_{23} [175]—here the lattice symmetry is lowered from cubic (space group $Fm3m$) to tetragonal ($P4_2/mnm$).

X-Ray diffraction studies, like neutron-diffraction work, have been carried out mainly for hydride phases based on IMC's with Laves phase and $CaCu_5$ type structures. A study of the process of hydrogenation and subsequent dehydrogenation of $CaNi_5$, carried out under conditions of equilibrium saturation of specimens with hydrogen directly in the course of the X-ray diffraction experiment[176], showed the presence of three hydride phases, α' ($CaNi_5H_{0.8-1.2}$), β ($CaNi_5H_{4.5-5.6}$), and γ ($CaNi_5H_{6+x}$), whose symmetry changes from hexagonal to orthorhombic and again to hexagonal (trigonal) as the hydrogen content in the hydride is increased. Data on the existence of $CaNi_5H_5$ with an orthorhombic structure had been obtained independently and previously[177].

For hydrides based on the alloys $LaNi_{5-x}Fe_x$ [178] the hexagonal symmetry of the IMC is retained.

Among Laves phase hydrides studied in the most detail are alloys, whose composition corresponds to the quasi-binary section MM'_2–MM''_2, namely $Zr(Cr, Fe)_2$, $Zr(Cr, Co)_2$,[179] $Tb(Co, Fe)_2$, $Dy(Co, Fe)_2$,[180] $Zr(Mn, Fe)$,[181] $Zr(V, Fe)_2$, $Zr(V, Cr)_2$,[182] $Ti(Be, Cu)_2$,[183] $Ho(Co, Fe)_2$ and $Er(Co, Fe)_2$.[184] The systematic investigation of the hydrides MM'_2H_x (M = lanthanide, M' = Fe, Co, Ni) has also been continued[185–187]. It was found that the original symmetry of the unit cells of the IMC structures is retained and their volume increases by $\Delta V \sim 2.5$ Å^3 for each H atom.

Systematic researches on the hydrides MM'_3H_x (M = Y, Gd, Dy, Ho; M' = Ni, Co),[188–190] based on IMC's with the $PuNi_3$ type structure, and also $M_6M'_{23}H_x$ (M = Y, Sm, Gd, Ho, Er; M' = Mn, Fe) [191,192] (parent IMC's of the Th_6Mn_{23} type) have been continued. The results confirmed earlier conclusions as to the crystallographic characteristics of the hydride phases in the related systems MM'_3–H_2 [70–72] and $M_6M'_{23}$–H_2.[87–89] Similar conclusions can be drawn for the hydrides based on the alloys $TiFe_{1-x}M'_x$, where M' = Al, Cr, Mn, Co, Ni.[193,194] The structure and properties of hydrides based on IMC's of titanium have been investigated[195,196]. A re-examination of the structural phase transitions in Mg_2NiH_4 [197] is in agreement with earlier results[102,103].

The reaction of the compounds UNiAl and ThNiAl with hydrogen has been investigated[198]. These compounds belong to the Fe_2P structure type, which can be regarded as a packing of trigonal prisms and is in this sense similar to one of the structure types whose reaction with hydrogen was studied previously, namely CrB. The hexagonal unit cells of the parent intermetallic compounds behave differently on hydrogenation: in ThNiAl the expansion is practically isotropic and fairly small ($\Delta a/a_0 \sim \Delta c/c_0 \sim 0.04$), whereas the UNiAl structure is "compressed" in the z axis direction and substantially expanded in the basal plane ($\Delta a/a_0 \sim 0.07$).

In addition to neutron and X-ray diffraction experimental researches, work has been published in which, by identifying all possible types of hole in the metal matrix, the most probable models for the structure of hydride phases based on IMC's crystallising in the Th_6Mn_{23} [199] and CrB types[200] have been considered. The most probable models for the structure of the hydrides $MM'H_x$ (CrB parent type) and MM'_3H_x ($PuNi_3$ parent type) have been discussed in connection with elucidation of the structure of $HoNi_3D_{1.8}$.[202]

There is also a review in the field of binary hydride structural chemistry[203] giving results on the synthesis of transition-metal hydrides by direct reaction of the metals with hydrogen at high hydrogen pressures and on their properties. This synthetic method has recently permitted the range of "hydrogenated" metals to be extended to gold, which forms a hydride of approximate composition $AuH_{0.4}$ with an orthorhombic structure[204].

Thus, in the structures of complex metal hydrides studied up till now the hydrogen atoms most frequently have a c.n. of 4 or 6 with tetrahedral or octahedral coordination, more rarely a c.n. of 3 or 5, but linear coordination is observed only for two structures. In most cases there is no reorganisation of the IMC structure when hydrogen atoms are introduced into their lattices.

Of the different types of hole in the metal lattice, those filled first in the hydrides are those surrounded by the greatest number of atoms of the metal M. This rule is general for metal hydride structures and can be explained by the simultaneous effect of a number of factors: (1) the activity of metal M on reaction with hydrogen; (2) the greatest effective size of these holes of all those present in the metal lattice; (3) the M–M distances in the periphery of the holes occupied by hydrogen atoms exceed the sum of the corresponding metal radii, so that these holes are the most easily deformed when the hydride phases are formed.

New Problems and Prospects in the Electrochemistry of Semiconductors

Yu.Ya.Gurevich and Yu.V.Pleskov

This review gives a unified discussion of current theoretical ideas in semiconductor electrochemistry and in the interpretation of physicochemical processes at the semiconductor/electrolyte interface (mainly, the electrochemical phenomena associated with the photo-excitation of the electron-hole ensemble of the semiconductor and used in practical devices for solar energy conversion, laser etching of semiconductors, photo-corrosion protection, etc.). New problems and likely future developments in the electrochemistry of semiconductors are discussed. 90 references.

I. INTRODUCTION

The electrochemistry of semiconductors, identified as a new branch of science over a quarter of a century ago, has been developed intensively as a part of electrochemical physics† since the 1960's. Its scientific foundations were laid, and new methods of treating semiconductor surfaces were developed and adopted in the technology of semiconductor devices[1]. The results stimulated a reconsideration of the most general electrochemical concepts, such as the zero-charge potential, the exchange current, the transfer coefficient of an electrochemical reaction, etc. This was followed by a period of decreasing interest in semiconductor electrochemistry, mainly because the practical applications were found to be more limited than had been expected.

The resurgence of research activities in this area, which is still in progress, arose from the discovery (in the 1970's) of solar energy conversion by the photo-electrolysis of water with semiconductor electrodes to give hydrogen. Partly because of the increasing concern with the danger of exhausting natural resources, and partly with the aim of minimising the contamination of the environment, substantial effort has been directed[2] towards the development of ecologically "clean" liquid solar cells which exploit renewable sources of energy. Practical developments in "solar semiconductors" gave a new impetus to the study of semiconductor electrochemistry (mainly, the photo-electrochemistry of semiconductors). In their turn, advances in semiconductor electrochemistry stimulated new developments in conventional electrochemistry. For example, the study of semiconductor electrodes has led to a critical reappraisal of general concepts such as the electrochemical potential of electrons in solution, the relationship between the "physical" energy scale and the "electrochemical" scale of electrode potentials, etc. These problems will be examined in the first part of the present review.

In the later Sections we shall discuss some new problems in the electrochemistry (and photo-electrochemistry) of the semiconductors themselves, such as the "clamping of the Fermi level" on the surface of a semiconductor electrode (as an alternative to the more usual "clamping of the band edges"), the quasi-thermodynamic description of electrode reactions (in particular, the concept of the quasi-Fermi level, and its limitations), etc. We shall also briefly outline the principles of some very recent practical developments in the electrochemistry of semiconductors.

For information on the physics of semiconductors and semiconductor surfaces the reader is referred to Bonch-Bruevich and Kalashnikov's monograph[3]; general problems in semiconductor electrochemistry are discussed in Refs.1, 4, and 5. A more detailed and comprehensive discussion of some of the problems mentioned in this review is given in our textbook[6].

II. CHARACTERISTIC ENERGY LEVELS IN THE ELECTRODE–ELECTROLYTE SOLUTION SYSTEM

The description of the energy characteristics of electrons in electrochemical systems is of the greatest importance both in method development and in practical terms. The concept of the electrochemical potential of electrons in a solution containing an oxidation–reduction system is valuable when applied to electrochemical and photo-electrochemical processes. Also, the reorganisation energy of the solvent can substantially affect the kinetics of the reactions which accompany the charge transfer act. Lastly, the electronic energy levels, directly related to the oxidation or reduction state of the components, determine the quantitative aspects of the related electron flows.

1. The Electrochemical Potential of Electrons in a Solution

Consider an electron in a solution which contains an oxidation–reduction system taking part in a reversible electron transfer reaction:

$$\mathrm{Ox} + n\,\mathrm{e}^- \rightleftarrows \mathrm{Red}\,. \qquad (1)$$

In this expression Ox and Red denote the oxidised and the reduced form of the substance in the solvated state, and n is the number of electrons involved in the electrode reaction. Under conditions of thermodynamic equilibrium we must have

$$\tilde{\mu}_{ox} + n\tilde{\mu}_e = \tilde{\mu}_{red} \qquad (2)$$

where $\tilde{\mu}_{\mathrm{ox}}$ and $\tilde{\mu}_{\mathrm{red}}$ are the electrochemical potentials of the components of the oxidation–reduction system in the solution

†The term "electrochemical physics" was officially adopted by the International Electrochemical Society to denote all the aspects of electrochemistry which have strong associations with physics.

(referred to one mole of substance), and $\tilde{\mu}_e$ is the electrochemical potential of the electrons in the solution. We can define the quantity $\tilde{\mu}_{ox,red}$ as

$$\tilde{\mu}_{ox,red} = RT \ln c_{ox,red} + z_{ox,red}\mathcal{F}\emptyset + \mu^0_{ox,red} \qquad (3)$$

where R is the gas constant, T is the absolute temperature, $c_{ox,red}$ is the concentration (more generally, the activity) of the reactants Ox and Red in solution, $z_{ox,red}$ are their charges, $\mathcal{F}$ is the Faraday, $\emptyset$ is the electrical potential, and $\mu^0_{ox,red}$ are constants independent of $c_{ox,red}$ and of $\emptyset$.

From (2) and (3) we can calculate the equilibrium electrode potential ϕ^0 of an electrode on which reaction (1) is taking place:

$$\varphi^0 = \varphi^0_0 + \frac{RT}{n\mathcal{F}} \ln \frac{c_{ox}}{c_{red}} \qquad (4)$$

where ϕ^0_0 is the standard electrode potential for the given solution. This quantity depends on the difference $\mu^0_{ox} - \mu^0_{red}$, and therefore also on the nature of the electrode reaction and on the choice of reference electrode.

At the same time, when thermodynamic equilibrium according to reaction (1) has been established we can introduce the concept of the electrochemical potential of electrons in the electrolyte solution, $\tilde{\mu}^{el}_e$, which is quite unrelated to the presence (or absence) of the electrode. This possibility follows from the general thermodynamic principle that the detailed mechanism by which an equilibrium is established is immaterial. Thus we can, for example, assume that the electron transfer reaction between the Ox and the Red component does not in general involve the participation of the electrode. Under these conditions the quantity $\tilde{\mu}^{el}_e$ for reaction (1) is given by the expression

$$\tilde{\mu}^{el}_e = \frac{1}{n}(\tilde{\mu}_{red} - \tilde{\mu}_{ox}) \qquad (5)$$

where $\tilde{\mu}_{red}$ and $\tilde{\mu}_{ox}$ are defined for the potential $\emptyset$(el) in the bulk of the electrolyte solution. Since the parameters $\tilde{\mu}_{red,ox}$ are a function only of the properties of the reactants Ox and Red and of the solvent, it follows that $\tilde{\mu}^{el}_e$ also is independent of the nature of the electrode and of the structure of the phase boundary. Furthermore, it is the quantity $\tilde{\mu}^{el}_e$ which defines the electrochemical potential of the electrons in the given electrode at equilibrium. In particular, this electrochemical potential must be the same for any electrode in equilibrium with the given Ox/Red system.

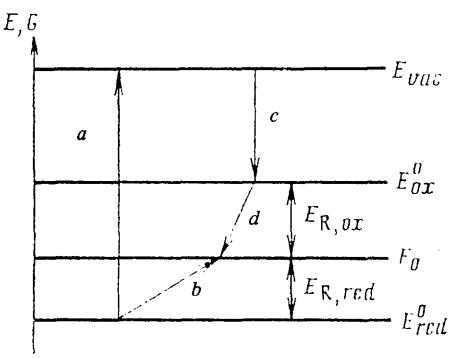

Figure 1. Position of the energy levels of an electron in a solution containing an oxidation–reduction system: E is the internal energy, G is the free energy.

To establish the relationship between μ^{el}_e and the characteristic parameters of the oxidation–reduction system we shall consider a solution containing only one particle of Red. We shall denote the most probable (thermodynamic) electronic energy level of the Red particle as E^0_{red}, and that of an Ox particle as E^0_{ox}, and the potential energy of an electron in vacuum (or, more exactly, in the vapour phase) at a point close to the surface of the solution but outside the region of influence of the surface forces will be termed E_{vac}. If the surface is uncharged the parameter E_{vac} is the same as the energy of an electron at rest at infinity. Putting $n = 1$ in Eqn.(1) to simplify the argument, we can now examine the following thermodynamic cycle[7,8] (see Fig.1).

a) An electron is transferred in a single jump from a solvated Red particle (energy level E^0_{red}) to the level E_{vac}.

b) The state of the solvent near the oxidised Red particle (now an Ox particle) is changed to bring the Ox particle into thermodvnamic equilibrium with the solution.

c) The electron from the level E_{vac} is suddenly transferred to the resulting Ox particle (level E^0_{ox}) without changing the state of the solvent.

d) The necessary rearrangement of the solvent near the resulting Red particle is carried out, and as a result the system as a whole returns to its initial equilibrium state.

In this cycle the changes in internal energy of the system corresponding to steps (a) and (c) are a measure of the position in energy of the levels E^0_{red} and E^0_{ox} relative to E_{vac}: they are equal to the ionisation energy of the Red particle and to the electron affinity of the Ox particle in the solution respectively. The energy characteristics of steps (b) and (d) are the reorganisation energies of the solvent $E_{R,red}$ and $E_{R,ox}$ for the particles Red and Ox respectively.

In this process $E_{R,red} > 0$ and $E_{R,ox} > 0$ are the absolute measures of the energy (or, more accurately, of the free energy) needed to change the equilibrium state of the medium (solvent) from its initial state to the final state for a unit change in the charge on the particle[9,10].

Thus according to the above analysis we can write

$$E^0_{red} + E_{R,red} - E^0_{ox} + E_{R,ox} = 0. \qquad (6)$$

The quantity F_0, defined according to Eqn.(6) by the expression

$$F_0 = E^0_{red} + E_{R,red} = E^0_{ox} - E_{R,ox} \qquad (7)$$

is a measure of the change in free energy of the system accompanying the removal (at equilibrium) of an electron from a Red particle from the solution into the vacuum (or the equilibrium transfer of an electron from the vacuum to an Ox particle). From (6) and (7) we obtain

$$F_0 = \tfrac{1}{2}(E^0_{ox} + E^0_{red}) + \tfrac{1}{2}\Delta E_R \qquad (8)$$

where

$$\Delta E_R = E_{R,red} - E_{R,ox}$$

and

$$E^0_{ox} - E^0_{red} = E_{R,ox} + E_{R,red}. \qquad (9)$$

We note that Eqn.(9) can be obtained also by considering the equilibrium transfer of an electron directly from the reactant Red to the reactant Ox within the solution.

In polar liquids like water (especially in the case of outer-sphere reactions[11]) we can assume that $E_{R,ox} = R_{R,red} = E_R$. From Eqns.(8) and (9) we then obtain

$$F_0 = \tfrac{1}{2}(E^0_{ox} + E^0_{red}), \quad E^0_{ox} - E^0_{red} = 2E_R. \qquad (10)$$

It follows therefore that in the simplest case (which we are now considering) the characteristic level E_0 lies half-way between E^0_{ox} and E^0_{red} in energy, and the distance in energy between E^0_{ox} and E^0_{red} is twice E_R.

Thus, starting from (3) and (5), and noting that the parameter F_0 as defined above relates to one particle, we obtain the following expression for the electrochemical potential $\tilde{\mu}_e^{el}$:

$$\tilde{\mu}_e^{el} = N_A F_0 - RT \ln (c_{ox}/c_{red}) \qquad (11)$$

where N_A is Avogadro's number. Eqn.(11) can be obtained also by statistical mechanics[6,8] without using Eqn.(5) and without carrying out the thermodynamic cycle. In other words, the concept of the electrochemical potential of electrons in a solution can be introduced strictly and logically in both the thermodynamic and the statistical mechanics approach.

By analogy with the Fermi level of the electron in solids, which refers to a single electron, we can define the quantity $F_{redox} = \tilde{\mu}_e^{el}/N_A$ as the electrochemical potential of the electrons in solution referred to a single particle (sometimes loosely called the Fermi level of the electrons in solution).

We should stress that the position of F_{redox} is quite unrelated to the concentration of "free" electrons in solution, and is determined by the properties of the oxidation–reduction Ox/Red system (which contains only "bound" electrons). The quantity F_{redox} does not describe the energy of any one particle, since in general there are no electrons of energy F_{redox} in the solution (in contrast to metal systems, say, where the Fermi level F_{met} coincides with the energy of the conduction electrons on the Fermi surface). Therefore during an electrochemical reaction the electrons are not transferred from the level F_{redox} to the electrode or from the electrode to F_{redox}: all the electron transfers take place through the levels E_{red}^0 and E_{ox}^0. Nevertheless it is the position of the level F_{redox} which defines the thermodynamic properties of the oxidation–reduction system, and also the properties of the interface between the electrode and the solution which contains the system. For example, using the condition of thermodynamic equilibrium in the semiconductor–solution system in the form of

$$F = F_{redox} \qquad (12)$$

where F is the Fermi level of the electrons in the semiconductor, the conditions which determine the course of the electrochemical reaction can be defined as

$$F > F_{redox} \quad \text{(cathodic reaction)}, \qquad (13a)$$

$$F < F_{redox} \quad \text{(anodic reaction)}. \qquad (13b)$$

The electrochemical potentials of oxidation–reduction systems in solution can be calculated by standard methods from the thermodynamic characteristics of the components. For many reactions in which the material of the semiconductor electrode takes part (for example, anodic or cathodic dissolution) the F_{redox} values can be found in Refs.12–14.

2. Relationship Between the Energy Scale and the Electrode Potential Scale

The position of the levels E_{ox}^0, E_{red}^0, and F_{redox} with respect to E_{vac} can be defined by establishing a quantitative correspondence between the "physical" energy scale, in which the zero value is identified with E_{vac}, and the electrochemical scale of electrode potentials, which are measured from the potential of some arbitrarily chosen reference electrode. The general form of this correspondence is

$$F_{redox} = -e\varphi^0 + \text{const} \qquad (14)$$

where $e > 0$ is the absolute value of the electronic charge.

Let us choose an Ox/Red system for which the equilibrium potential ϕ^0 is arbitrarily taken to be zero. A solution of this system in contact with an inert electrode [i.e. one which does not take part in reaction (1)] is by definition the reference electrode. In this case the constant in Eqn.(14) is equal to F_{redox}, and describes the change in free energy attending the reaction

$$Ox + e_{vac}^- \rightleftarrows Red. \qquad (15)$$

In other words, the term "const" in Eqn.(14) is the change in free energy resulting from the transfer of an electron from a point in the vacuum close to the solution surface to the Fermi level of the metal of the reference electrode (which is equal to F_0 when $c_{ox} = c_{red}$). The quantity F_0/e is sometimes called the "absolute potential" of the electrode[15]. The first attempt to determine this quantity was described by Kanevskii[15]; Lohmann also calculated it by analysing a fairly complex thermodynamic cycle[16].

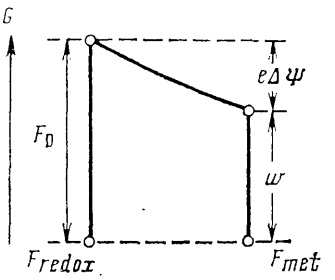

Figure 2. Relationship between the "physical" and the "electrochemical" energy scale.

A simple and accurate method of comparing energy and potential scales[17] relies on a calculation of the electronic work function for the metal in a solution of electrolyte at the potential of the reference electrode. The metal in equilibrium with the Ox-Red system in solution (so that their electrochemical potentials are equal, $F_{redox} = F_{met}$) is shown diagrammatically in Fig.2. The change in free energy for the reaction (15) is the sum of the energies for the steps (c) and (d) of our cycle (Fig.1), i.e. the quantity F_{redox}. We see from the cycle in Fig.2 that

$$-F_{redox} = w + e\Delta\psi \qquad (16)$$

where w is the thermodynamic work function for the emission of an electron from the uncharged metal into a vacuum and $\Delta\psi$ is the Volta potential difference in the metal–solution system produced by the mutual charging of the "free" metal and solution surfaces when brought into contact.

A calculation for a specific case (for example, the normal hydrogen electrode) is easily made by using data[18] for the difference in Volta potentials in the mercury–aqueous solution system: $\Delta\psi = -0.07$ V at the potential of the normal hydrogen electrode. Taking $w = 4.50 \pm 0.03$ eV for the work function of an electron from mercury into a vacuum[19] we obtain from formula (16)

$$-F_{redox}\,(\text{NHE}),\ \text{eV} \quad = 4.50 - 0.07 = 4.43 \simeq 4.4\,.$$

Thus the electrochemical potential of the normal hydrogen electrode F_{redox}(NHE) lies 4.4 eV below the level E_{vac}.[6]

We also note that w (the thermodynamic work function of the electron in the semiconductor) is given by the expression $w = \chi + |F - E_c|$, where χ is the electron affinity of the semiconductor. The position of the level F with respect to the bottom of the conduction band in the bulk of the semiconductor (E_c) is given by the expressions

$$F - E_c = -E_g/2 + kT \ln (N_v/N_c)^{1/2}, \quad n_0 = p_0 \qquad (17a)$$
(intrinsic semiconductor)

$$F - E_c = -kT \ln (N_c/n_0), \quad n_0 \gg p_0 \qquad (17b)$$
(*n*-type semiconductor)

$$F - E_c = -E_g + kT \ln (N_c/p_0), \quad p_0 \gg n_0 . \qquad (17c)$$
(*p*-type semiconductor)

In these expressions E_g is the width of the forbidden gap, N_c and N_v are the effective densities of states in the conduction band and in the valence band, and n_0 and p_0 are the concentrations of electrons and holes in thermodynamic equilibrium in the bulk of the semiconductor.

3. Calculation of the Reorganisation Energy of the Solvent

By using these results we can calculate the reorganisation energy of the solvent from data on the photo-emission of electrons from solutions into the vapour phase (see our recent review[20]). When a solution containing "Red" species is illuminated with light of sufficiently short wavelength electrons are emitted into the vapour phase. Since photo-ionisation is a relatively fast process, the photo-electric work function w_{ph} is equal to $-E^0_{red}$ if $E_{vac} = 0$. It follows from (7) and (11) that for $c_{ox} = c_{red}$ this quantity differs from the thermodynamic work function (which is equal to F_0) by the amount $E_{R,red}$. Thus $E_{R,red}$ is calculable as the difference between the photo-electric work function $w_{ph} = -E^0_{red}$ and the parameter $-F_{redox}$. (A similar method of determining E_R was used previously[21] for solutions in which the "emitters" were solvated electrons.)

The work function $w_{ph} = 5.95$ eV has been obtained[22] for photo-emission from aqueous solutions of $Fe(CN)_6^{4-}$. Using the above value of $F_{redox} = -4.4$ eV, and also a value of +0.36 V (against the normal hydrogen electrode) for the standard potential of the $Fe(CN)_6^{4-}/Fe(CN)_6^{3-}$ system, we obtain 5.95 - 4.4 - 0.36 ≅ 1.2 eV for the reorganisation energy of the water surrounding the ferrocyanide and ferricyanide ions. Since in this case the electron transfer reaction takes place in the outer sphere we can assume that $E_{R,ox} = E_{R,red} = E_R$.

Few reliable experimental data on E_R are available at present[9]. According to Memming[23] the $E_{R,ox}$ and $E_{R,red}$ values for aqueous solutions at room temperature lie between 0.5 and 2 eV. We should also note that the "homogeneous" values of E_R (determined, for example, by photo-electron emission from solutions) are substantially higher than the "heterogeneous" values (which can be obtained from measurements of tunnelling currents from semiconductor electrodes into solutions[23]). In the simplest model the "homogeneous" reorganisation energy of the solvent is approximately double the "heterogeneous" value[9,11].

As regards the $Fe(CN)_6^{4-}/Fe(CN)_6^{3-}$ system, the "homogeneous" value $E_R = 1.24$ eV obtained by a model calculation[23] agrees very well with the value given above. However, the same workers[23] obtained a much lower value for the "heterogeneous" reorganisation energy of the solvent ($E_R = 0.4$ eV) from experimental measurements of tunnelling currents from heavily doped SnO_2 electrodes.

III. STRUCTURE OF THE SEMICONDUCTOR/ELECTROLYTE INTERFACE

At the interface between a semiconductor electrode and a solution of electrolyte an electrical double layer is produced (as at the metal/solution interface). The double layer consists of regions carrying charges of opposite sign, and located in the two contacting phases. In the semiconductor the charge in the surface layer is produced by a redistribution of the electrons and holes present in this region, and in the solution by a redistribution of the ions. At equilibrium the absolute values of these charges are equal.

1. Model of the Electrical Double Layer

The fundamental reasons for the formation of an electrical double layer are quite general. They include the overflow of charges through the interface during the establishment of thermodynamic equilibrium between the phases, and charging processes which are independent of the transfer of electrons through the interface (for example, the charging of surface states, some types of adsorption, etc.).

According to the generally accepted model[1,24] we can define three regions within the electrical double layer: a region of space charge in the solution, an intermediate region (usually called the Helmholtz layer), and a region of space charge in the semiconductor.

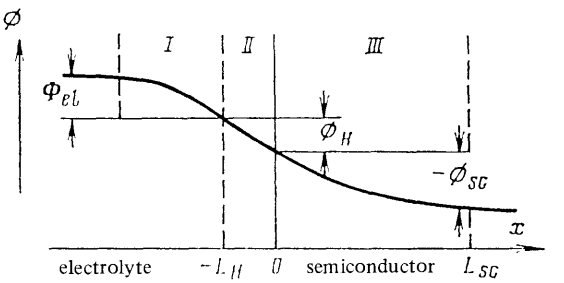

Figure 3. Composition of the potential step at the semiconductor–electrolyte interface: *I*) Gouy layer, *II*) Helmholtz layer, *III*) space-charge layer.

The distribution in space of the potential difference at the interface (Galvani potential) between a semiconductor and an electrolyte, Ø(el/sc), is shown in Fig.3. The semiconductor occupies the space to the right of the vertical full line which defines the interface ($x = 0$). To the left of this line we find the Helmholtz layer, consisting of ions attracted towards the electrode surface and of solvent molecules: the thickness of this layer (L_H) is of the order of the diameter of the ions. Beyond the Helmholtz layer we find, on the solution side, the space-charge region of the solution (the Gouy–Chapman layer).

We shall denote the electrical potential in the bulk of the semiconductor (at $x \to \infty$) as Ø(sc), and in the bulk of the solution (at $x \to -\infty$) as Ø(el), as before. The overall potential drop at the interface, Ø(el/sc) = Ø(sc) - Ø(el), is therefore given by

$$Ø(el/sc) = [Ø(L_H) - Ø(-\infty)] + [Ø(0) - Ø(L_H)] + [Ø(\infty) - Ø(0)], \qquad (18)$$

In this expression $\emptyset(L_H) - \emptyset(-\infty) \equiv \emptyset(el)$ is the potential drop in the space-charge region of the electrolyte solution, i.e. between the bulk of the solution and the outer Helmholtz plane: this quantity is usually called ψ' (the "psi-dash" potential). The second term $\emptyset(0) - \emptyset(L_H) \equiv \emptyset_H$ is the potential drop in the Helmholtz layer. Lastly, the third term $\emptyset(\infty) - \emptyset(0) \equiv -\emptyset_{sc}$ is the potential drop in the space charge region of the semiconductor.

We must lay special stress on the following consideration. In electrochemistry an electrode potential is traditionally taken as positive if it increases the amount of positive charge on the electrode. On the other hand in semiconductor physics a positive surface potential [conventionally measured from $\emptyset(\infty)$] corresponds to electron enrichment of the space charge region, i.e. to the formation of negative space charge. In other words, the potential axes adopted in electrochemistry and in semiconductor physics point in opposite directions. The result is that the potential step in the semiconductor with respect to the bulk potential $\emptyset(sc)$, defined as $\emptyset(sc) = \emptyset(0) - \emptyset(\infty)$, has a sign opposite to that of the last term in the expression for the Galvani potential [Eqn.(18)].

Polarisation of the electrode, i.e. a change by $\Delta\phi$ in the electrode potential, usually affects all three components of the Galvani potential. However, in the not too dilute solution (>0.1 M) which are usually used in electrochemical experiments the quantity $\emptyset_{el} = \psi'$ is negligibly small, and therefore the changes in this quantity are also negligible. We shall assume this to be the case throughout this review. We shall also assume that the ohmic potential drop is negligible, so that we can write

$$\Delta\varphi = \Delta\emptyset_H - \Delta\emptyset_{sc}. \qquad (19)$$

In addition to the charge carriers, dipoles present at the interface can also contribute to the formation of the double layer: these dipoles could be the surface dipoles accompanying bond formation between atoms on the semiconductor surface and atoms adsorbed from the solution, or surface dipoles produced by the oriented adsorption of solvent molecules.

The formation of an array of dipoles does not contribute to the charge on the electrode, but it produces an additional potential step included in the parameter $\emptyset_H$. This step ($\emptyset_{H,dip}$) is usually found experimentally to be relatively insensitive to changes in the electrode potential ϕ, but very sensitive to the previous treatment of the electrode surface and to the composition of the surrounding medium.

A dependence of the potential on the coordinate in the semi-conductor [$\emptyset(x)$] is equivalent, in the band model, to a bending of the energy bands. The bending is downwards if $\emptyset_{sc} > 0$, and upwards of $\emptyset_{sc} < 0$. In the latter case, corresponding to electron depletion in the surface layer, a depletion layer (the Mott–Schottky layer) is formed near the interface of *n*-type semiconductors if the following inequality applies:

$$-\frac{kT}{e}\ln\frac{n_0}{p_0} < \emptyset_{sc} < -\frac{kT}{e} \qquad (20a)$$

The space charge in this case consists mainly of ionised impurity donors, present at a concentration $N_D \cong n_0$. Similarly, on *p*-type semiconductors the charge of the depletion layer produced by downward bending of the bands in the potential region

$$\frac{kT}{e} < \emptyset_{sc} < \frac{kT}{e}\ln\frac{p_0}{n_0} \qquad (20b)$$

consists mainly of acceptor impurities containing trapped electrons (present at a concentration $N_A \cong p_0$).

The formation of a depletion layer is the most important case in practice, since in the wide-band doped semiconductors used in modern semiconductor electrochemistry experiments the potential range defined by the expressions (20) is quite wide.

If $\emptyset_{sc} = 0$ the bands remain "flat" up to the interface. In this case the space charge in the semiconductor is zero. The potential ϕ of the semiconductor electrode measured against some reference electrode and corresponding to the condition $\emptyset_{sc} = 0$ is called the flat band potential $\phi = \phi_{fb}$. The flat band potential in the electrochemistry of semiconductors is equivalent to the zero-charge potential in the electrochemistry of metals (more precisely, to the zero free charge potential[25]), and it plays an important role in the kinetics of electrochemical processes on semiconductor electrodes.

We should note that for $\phi = \phi_{fb}$, though $\emptyset_{sc} = 0$, the parameter $\emptyset_H$ is finite (usually as a reult of the specific adsorption of ions from solution). Thus in the case of oxide semiconductors (TiO_2, ZnO, etc.), or of semiconductors whose surface is oxidised in aqueous solutions (for example, Ge), the concentrations of OH^- and H^+ ions chemisorbed on the surface are not equal, and this effect can made a substantial contribution to $\emptyset_H$. Because of the thermodynamic equilibrium between the ions adsorbed on the surface and those in the bulk of the solution this contribution to $\emptyset_H$ should be a linear function of the pH of the solution. At a pH value depending on the nature of the semiconductor electrode the total charge of the adsorbed ions is zero. This pH value (or the analogous parameter for the adsorption of ions other than hydrogen), called the point of zero zeta-potential or the isoelectric point, is equivalent to a zero total charge potential for the condition $\emptyset_{sc} = 0$ in Rzhanov's terminology[26]. We note that even at the isoelectric point the parameter $\emptyset_H$ is usually different from zero as a result of adsorption of dipolar solvent molecules at the interface, and also (in the case of oxidised semiconductors) because of the polarity of the bond between the semiconductor atom and the oxygen.

Electronic surface states (including interfacial states) play an important role in semiconductor electrode processes. Adsorbed particles and defects are always present at the contact between the semiconductor and the solution. As a result, a real semiconductor surface contains different types of electronic level, characterised by a complex (usually, quasi-continuous) energy spectrum, at concentrations which can be as high as 10^{14} cm^{-2}. For a more detailed discussion of these aspects the reader is referred to Refs.26 and 27.

The existence of electronic surface levels causes two very important effects. Firstly, electrons and holes can be trapped at the surface, forming an electric charge which induces an equal and opposite charge in the bulk. This effect is responsible for the influence of the surface on the equilibrium properties of the semiconductor. Secondly, surface levels can radically influence the kinetics of processes involving electrons and holes, partly by providing additional carrier recombination and generation centres and partly by acting as intermediate energy levels in processes involving charge transport through the phase boundary.

2. Potential Distributions. "Clamping" of the Band Edges and of the Fermi Level at the Surface

Let us now examine the distribution of $\emptyset(el/sc)$, the overall potential step, between its components $\emptyset_H$ and $\emptyset_{sc}$. According to the basic laws of electrostatics, the following expression should apply at the phase boundary:

$$\varepsilon_H\mathscr{E}_H = 4\pi Q_{ss} - \varepsilon_{sc}\mathscr{E}_{sc}. \qquad (21)$$

In this equation $\mathscr{E}_H$ and $\mathscr{E}_{sc}$ are the electric field strengths near the interface on the side of the Helmholtz layer and of the semiconductor respectively, ε_H and ε_{sc} are the corresponding static dielectric constants, Q_{ss} is the density of charge on the surface states (depending on ϕ_{sc}), and the minus sign before the second term of Eqn.(21) allows for the inconsistency in the sign convention mentioned above. For approximate calculations we may put $|\mathscr{E}_H| \cong |\phi_H|/L_H$ and $|\mathscr{E}_{sc}| \cong |\phi_{sc}|/L_{sc}$, where L_H and L_{sc} are the thicknesses of the Helmholtz layer and of the semiconductor space charge layer respectively, related to the corresponding capacities by the expressions $C_H = 4\pi\varepsilon_H/L_H$ and $C_{sc} = 4\pi\varepsilon_{sc}/L_{sc}$. If the charge on surface states is small we conclude from Eqn.(21) that $|\phi_H| \ll |\phi_{sc}|$ if the following inequality applies:

$$\varepsilon_{sc}L_H/\varepsilon_H L_{sc} \ll 1 \qquad (22)$$

For reasonable values of the parameters ε_{sc} and ε_H the condition (22) is usually satisfied, since $L_H \ll L_{sc}$. However, in strongly doped semiconductors (in which the concentrations n_0 or p_0 are very high) or at high values of $|\phi_{sc}|$ the thickness L_{sc} may be so small that the inequality (22) fails to apply.

In order to establish the influence of surface states on the potential distribution we must calculate their capacity $C_{ss} = -dQ_{ss}/d\phi_{sc}$. This can be done very simply in the monenergetic model, which assumes that all the electronic energy levels on the surface have the same energy E_{ss}. We can easily show (see, for example, Ref.6) that if

$$N_{ss} > \varepsilon_H kT/(\pi e^2 L_H) \qquad (23)$$

where N_{ss} is the number of surface states per unit surface area of the interface, we must have $|\Delta\phi_H| > \Delta\phi_{sc}|$. In other words, if the condition (23) is satisfied, a change in the potential of the electrode causes a more substantial change in the potential of the Helmholtz layer than in that of the space-charge layer. The critical value of N_{ss} (for which the inequality (22) reduces to an equality) is of the order of 10^{13}–10^{14} cm^{-2}.

Thus, since in most cases $L_H < L_{sc}$, we also have $|\phi_{sc}| \gg |\phi_H|$, and therefore the parameter ϕ_{sc} in reasonably concentrated solutions of electrolytes probably accounts for the greater part of the potential step at the interface [ϕ(el/sc)]. However, this conclusion does not apply in the following cases:

1) when the electrode is strongly charged, and the Fermi level at the surface is brought close to the edge of the appropriate band ("metallisation" of the surface);

2) at high concentrations of surface states, when a change in occupancy (i.e. in the charging) of the surface states causes a marked redistribution of the potential and can significantly increase the contribution of the component ϕ_H at a fixed value of ϕ(el/sc);

3) in heavily doped semiconductors, when the Fermi level in the bulk of the material is close to the edge of the band of current carriers (or even lies within that band, as it does in metals).

All we have said so far applies equally to the distribution of potential at the interface under equilibrium conditions and with polarisation applied to the electrode from an external source of current.

Let us consider the two most important special cases[28–30].

1. Assume that when the electrode potential is changed $|\Delta\phi_{sc}| \gg |\Delta\phi_H|$. This condition means that the potential jump in the Helmholtz layer is practically unaffected by the polarisation of the electrode ($\Delta\phi = -\Delta\phi_{sc}$). Therefore the energy levels on the surface (and, in particular, those of the band edges $E_{c,s}$ and $E_{v,s}$) remain in a fixed position relative to the energy levels of the solution and of the reference electrode (Figs.4*a* and 4*c*). This situation is described as "clamping" of the band edges at the surface.

The physical explanation of the "clamping" effect is that the parameter ϕ_H is mainly determined by the chemical interactions between the semiconductor and the solution and is not affected by external influences (such as polarisation, or illumination). As a result, the position of the band edges at the surface ($E_{c,s}$ and $E_{v,s}$) are the same for all samples of the given semiconductor material in contact with the given electrolyte solution, whatever the type and magnitude of the conductivity, since the chemical nature of the solid is practically unaffected by the doping. Experimental determinations of $E_{c,s}$ and $E_{v,s}$ for various semiconductors[31] have confirmed this conclusion.

2. Assume, conversely, that the polarisation of the electrode gives $|\Delta\phi_H| \gg |\Delta\phi_{sc}|$, i.e. that the change appears mainly in the potential of the Helmholtz layer. Under these conditions (Fig.4*a* and 4*c*) the energy levels at the surface are shifted relative to the energy levels in solution by an amount $\Delta\phi = \Delta\phi_H$. On the other hand, with respect to the Fermi level in the semiconductor (F) the band edges $E_{c,s}$ and $E_{v,s}$ at the surface keep the same position as before the change in the potential of the electrode, since the parameter ϕ_{sc} is unchanged. In order to stress the difference between this case and the previous case the band edges are said to be "unclamped" from the surface (the same phenomenon is sometimes referred to, less accurately, as "clamping" of the Fermi level with respect to the band edges).

The Fermi level "clamping" effect allows the parameter F to reach the value F_{redox} even in systems with very high positive or negative values of the equilibrium potential, in which the level F_{redox} lies outside the forbidden energy gap of the semiconductor. Thus the "clamping" of the Fermi level on a semiconductor electrode allows the electrochemical reaction to proceed under the conditions (13), which could not be achieved with "clamped" band edges.

In real systems we often observe an intermediate case in which polarisation of the electrode affects both the potential steps ϕ_H and ϕ_{sc}, so that in practice neither the band edges nor the Fermi level are clamped. Some results illustrating the "clamping" effects and a more detailed discussion of their origin are given below (Section IV).

3. Determination of the Flat Band Potential

The flat band potential is one of the most important physicochemical characteristics of the semiconductor electrode. In the electrochemistry of semiconductors this concept has become even more important than the zero-charge potential in the electrochemistry of metallic electrodes. The parameter ϕ_{fb} is used in the quantitative description of the double layer structure and of the kinetics of electrochemical reactions on semiconductor electrodes, especially in the photoelectrochemistry of semiconductors, since photocurrents of reasonable magnitude can flow only if the photo-generated electrons and holes can be efficiently separated in the space-charge region (see p.326). This carrier separation is effective only at electrode potentials more positive (for n-type photoelectrodes) or more negative (for p-type) than the flat band potential of the semiconductor (though this necessary condition for the separation of the photo-carriers is not sufficient to ensure the flow of photocurrent).

The capacity of the space-charge region of the semiconductor (C_{sc}) is related, in the case of the formation of a depletion layer, to the potential step in the space-charge layer

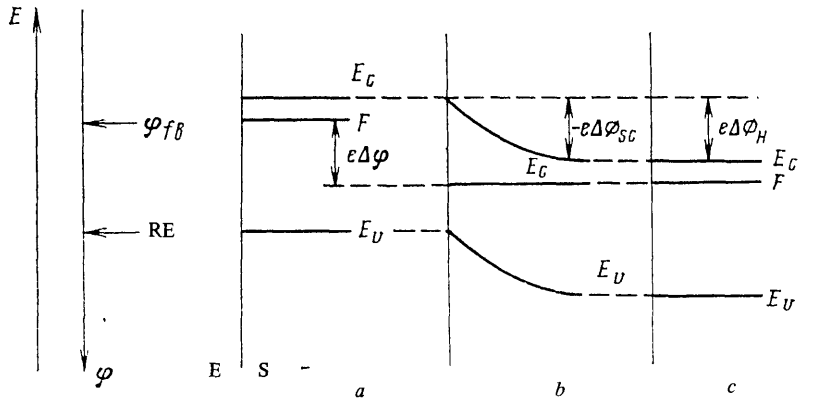

Figure 4. Energy diagram of the interface with an externally applied voltage, showing "clamping" of the band edges (transition from *a* to *b*) and of the Fermi level (transition from *a* to *c*) at the surface of the semiconductor electrode. The initial state *a* is the flat-band case; RE is the reference electrode, E is the electrolyte, S is the semiconductor.

Φ_{sc} by the following expression (written for an *n*-type semiconductor)[1]:

$$C_{sc}^{-2} = \frac{8\pi}{eN_D\varepsilon_{sc}}(|\Phi_{sc}| - kT/e), \qquad (24)$$

According to this equation the plot of C_{sc}^{-2} against Φ_{sc} should be a straight line. Plots in these coordinates are usually called Mott–Schottky graphs (Fig.5). On the assumption that the changes in electrode potential ϕ affect only the component Φ_{sc} and that the capacity C of the contact is equal to C_{sc} we can obtain the concentration of ionised donors from the slope of the straight line, and the flat band potential ϕ_{fb} from its intercept with the potential axis.

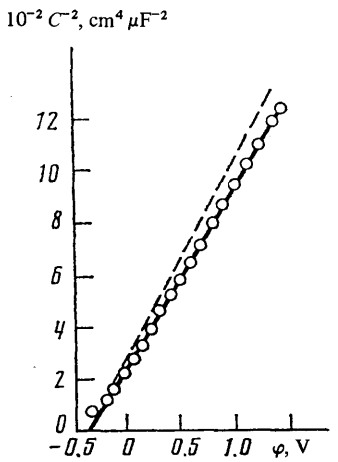

Figure 5. Mott–Schottky plot for a zinc oxide electrode (of conductivity 0.59 Ω^{-1} cm^{-1}) in a 1 *N* KCl solution (pH 8.5).[32] The broken line is calculated by formula (29).

The differential capacity method is widely used in practical electrochemical measurements. We should note, however, that the direct application of formula (24) to the determination of ϕ_{fb} involves a number of assumptions (often not explicitly examined) concerning the properties of the contact between the semiconductor and the electrolyte. The most important of these are:

1. It is assumed that the measured capacity C is not perturbed by the leakage current flowing through the interface, by the finite ohmic resistance of the electrode and of the electrolyte, etc. Accurate corrections for these effects can be calculated (see, for example, Ref.33).

2. It is assumed that the donors (or acceptors) in the semiconductor are fully ionised and uniformly distributed in the space charge region. Deviations from (24) are observed also in the presence of donors (or acceptors) lying deep in the forbidden gap, which are not ionised at room temperature in the bulk of the semiconductor but are partially ionised in the electric field of the space-charge region, thus contributing to the capacity[1].

3. It is assumed that the measured capacity is the capacity of the space-charge region of the semiconductor, and does not include (for example) the capacity of fast surface states, the adsorption capacity, etc. In some cases this condition is satisfied (for example, on the zinc oxide electrode, see below), but often the contribution from the capacity of surface states is substantial.

4. It is assumed that the measured electrode capacity C is unaffected by the Helmholtz layer capacity C_H. Linear plots of the measured capacity C in C^{-2}–ϕ coordinates are usually interpreted (according to formula (24) and to the relationship $C^{-1} = C_H^{-1} + C_{sc}^{-1}$) as evidence that the following conditions are satisfied:

$$C_{sc} \ll C_H, \quad |\Delta\Phi_{sc}| \gg |\Delta\Phi_H|. \qquad (25)$$

However, a detailed study has shown[34] that the possibility of an effect from C_H needs more careful analysis. Thus, if we allow for the change in the potential drop in the Helmholtz layer $\Delta\Phi_H$ caused by the polarisation of the electrode and for the contribution of the capacity C_H to the measured capacity C we obtain [from (24)] the following expression[34] for the

relationship between C and ϕ:

$$C^{-2} = C_H^{-2} + \frac{8\pi}{e\varepsilon_{sc}N_D}(\varphi - \varphi_{fb} - kT/e). \quad (26)$$

We note from (26) that C^{-2} varies linearly with ϕ, i.e. in the same way as C_{sc}^{-2} varies with $\varnothing_{sc}$ (for C_{sc}^{-2} varies with ϕ on the assumption of $\varnothing_H$ = const and $\Delta\phi = -\Delta\varnothing_{sc}$). Furthermore, the slope of the corresponding straight line in $C^{-2}-\phi$ coordinates is the same, according to (26), as the slope of the $C_{sc}^{-2}-\varnothing_{sc}$ straight line (or of the $C_{sc}^{-2}-\phi$ straight line for constant $\varnothing_H$). But in this case the intercept of the straight line with the ϕ axis corresponds, according to (26) to the potential

$$\varphi' = \varphi_{fb} + kT/e - e\varepsilon_{sc}N_D/(8\pi C_H^2). \quad (27)$$

As compared to the potential defined by (24) this potential is shifted by an amount $-e\varepsilon_{sc}N_D/(8\pi C_H^2)$. This shift is far from negligible, especially in heavily doped semiconductors.

Thus the linearity of experimental plots of C^{-2} against ϕ does not necessarily prove that the effect of the Helmholtz layer on the measured value of ϕ_{fb} is negligible, i.e. that the inequalities (25) are satisfied. Conversely, non-linearity of the plot of C^{-2} against ϕ is no proof that the conditions (25) are infringed, i.e. that the Helmholtz layer is responsible for the deviation from linearity.

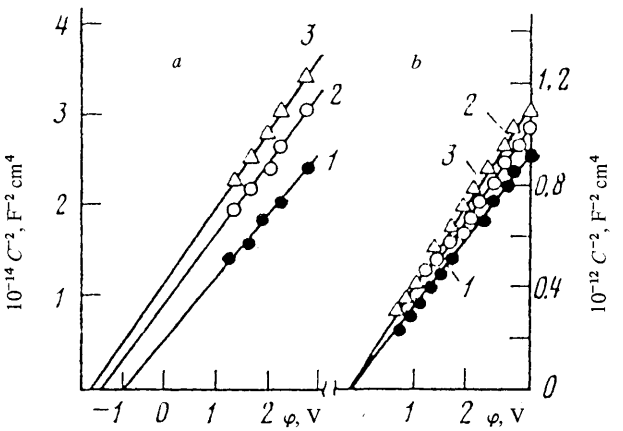

Figure 6. Effect of the frequency of the measuring current on the Mott–Schottky plot[35]: (*a*) CdSe ($N_D = 10^{15}$ cm^{-3}) in a solution of 0.25 M K_2SO_4 + 0.05 M CH_3COOH + 0.05 M CH_3. .COONa, frequency (Hz) 320 (*1*), 2440 (*2*), and 7080 (*3*); (*b*) TiO_2 ($N_D \cong 10^{18}$ cm^{-3}) in a solution of 0.25 M K_2SO_4 + 0.1 M $Na_2B_4O_7$, frequency (Hz) 320 (*1*), 980 (*2*), and 2440 (*3*). Potentials are quoted relative to the normal hydrogen electrode.

Lastly, we should note that ambiguities can arise from the frequency dependence of the Mott–Schottky plots if higher measurement frequencies are adopted in order to minimise the contribution from surface states to the measured capacity. Changes in frequency alter these plots in two ways (see Fig.6). In most cases only the slope changes, and the intercept on the potential axis is unaffected (Fig.6*b*). Sometimes, however, the straight line suffers a shift along the potential axis (as well as a change in slope), and the intercept with the potential axis becomes a function of frequency (Fig.6*a*).

Though a full explanation of these effects has not yet been proposed, plots such as those of Fig.6*b* can be used to measure ϕ_{fb} by extrapolation to the potential axis, though the parameter N_D (or N_A) of course cannot be calculated from the slope. Plots like those of Fig.6*a* are unsuitable even for the determination of ϕ_{fb}.

In addition to the direct experimental determination, a method of calculating the flat band potential ϕ_{fb} from the properties of the semiconductor and those of the solution has been suggested[36].

It follows from (17) and (18) that at thermodynamic equilibrium, and for a high enough concentration of the electrolyte, we can write

$$e(\varnothing_H - \varnothing_{sc}) = F - F_{redox(ref)} = -\chi + F - E_c - F_{redox(ref)} \quad (28)$$

where $(F - E_c) < 0$ is the difference between the F level and the band edge E_c, and $F_{redox(ref)}$ relates to the reference electrode. The electron affinity of the semiconductor χ which appears in Eqn.(28) can be obtained from semi-empirical formulae relating χ to the first ionisation potential I_1 and the electron affinity A_f of the chemical components of the semiconductor, and also the width of the forbidden gap. Thus, in the simplest case of a binary semiconductor MX we have

$$\chi = {}^1/_2(A_f + I_1 + E_g).$$

The difference $F - E_c$ is given by the expression (17), and the quantity $F_{redox(ref)}$ is assumed to be known (see Section II). Lastly, assuming that at the point of zero zeta-potential (i.e. at the iso-electric point) $\varnothing_H = 0$, we can calculate the band bending ($e\varnothing_{sc}$) from (28), and hence arrive at the flat band potential.

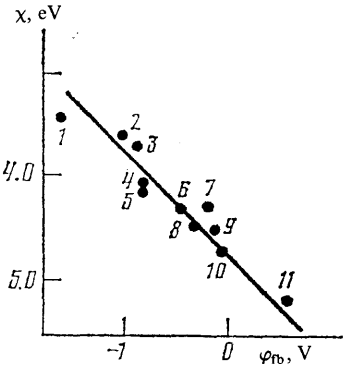

Figure 7. Relationship between the calculated electron affinity and the measured flat band potential (relative to the saturated calomel electrode) for various semiconductors at their isoelectric point[36]: *1*) ZrO_2, *2*) $BaTiO_3$, *3*) $SrTiO_3$, *4*) Ta_2O_5, *5*) ZnO, *6*) TiO_2, *7*) $FeTiO_3$, *8*) SnO_2, *9*) CdO, *10*) Fe_2O_3, *11*) WO_3.

The pH value corresponding to the isoelectric point can be calculated if the standard electrochemical potentials of the reactions involving the adsorbed ions are known, or it can be determined experimentally (as was stated above). This suggests an experimental test of formula (28). In particular, an approximately linear relationship is found between $\varnothing_{sc}$ and

the pH for a large number of oxide semiconductors. An empirical linear relationship between the calculated χ values and the measured ϕ_{fb} has also been reported (see Fig.7). This plot can be used to estimate the flat band potential of any oxide semiconductor for which the parameter χ can be calculated.

To conclude this Section we should note that a linear relationship between χ and ϕ_{fb} is fully analogous to the well known dependence of the electronic work function w on the zero-charge potential in the electrochemistry of metals[25]. The analogy is particularly clear for wide-gap doped semiconductor, for which $E_c - F$ is quite small ($\lesssim$0.1 eV), so that $\chi \cong w$. Under these conditions, as was pointed out in the previous Section, the deviations from the linear relationship found experimentally in some metals can be ascribed to the differences in the dipole potential step created by the adsorption of solvent on different metals[25]. A similar effect can be expected in semiconductor electrochemistry, though of course it cannot be very marked in the case of a series of semiconductor electrodes of similar chemical type.

IV. QUASI-THERMODYNAMIC DESCRIPTION OF PHOTO-ELECTROCHEMICAL PROCESSES

In this Section we shall examine some of the photo-electrochemical phenomena in semiconductor–electrolyte systems under the influence of light. In addition to their intrinsic scientific interest, these phenomena also have a high relevance to the practical exploitation of electrochemical systems involving semiconductor electrodes. The strongest effects on the electrode processes are obtained by using light of frequency higher than the intrinsic (fundamental) absorption threshold of the semiconductor, so that the energy of the light quanta is sufficient to generate electron–hole pairs. The redistribution of the charge carriers in the semiconductor near the solution boundary caused by the photo-generation can drastically affect not only the rate but also the nature of the electrochemical processes in progress.

1. The Quasi-Fermi Level

Several different methods of describing photo-electrochemical processes have been proposed. For example, the kinetics of photo-electrochemical processes have been studied theoretically by solving the transport equations allowing for the photo-generation of carriers, in conjunction with various boundary conditions[37–40]. This approach offers an exact solution of the problem in a number of simple cases, but if the boundary conditions are relatively complex the method becomes laborious and the resulting equations unwieldy. A qualitative understanding, and often a quantitative treatment, can be achieved more simply, on the other hand, by using a quasi-thermodynamic as opposed to a kinetic approach, based on the quasi-Fermi level concept.

It may be helpful to remind the reader of the significance of the quasi-Fermi level[3]. Assume that illumination of the semiconductor leads to additional generation of current carriers. In a stationary regime under these conditions a dynamic equilibrium is established between the generation and the recombination of electron–hole pairs, resulting in the appearance of steady-state (but not equilibrium!) values of the carrier concentrations n_0^* and p_0^*:

$$n_0^* = n_0 + \Delta n, \quad p_0^* = p_0 + \Delta p. \tag{29}$$

Except in the space-charge region $\Delta n = \Delta p$, since the photo-generation process creates pairs of carriers.

By inserting the concentrations n_0^* and p_0^* into (17) we can calculate the position of the "quasi-Fermi" levels F_n and F_p produced by the splitting of the original Fermi level F. Thus, for an n-type semiconductor in which $\Delta n \ll n_0$ we find from (17b) that $F_n \cong F$. At the same time, since $p_0 \ll n_0$, the condition $\Delta p \gtrsim p_0$ may also apply, and therefore the parameter $F - F_p$ according to Eqn.(17b) becomes

$$F - F_p = kT \ln\left(\frac{p_0 + \Delta p}{p_0}\right); \quad F - F_p \simeq kT \ln\frac{\Delta p}{p}, \quad \Delta p \gg p_0. \tag{30}$$

Similar relationships can be written for p-type semiconductors.

Thus according to Eqn.(30) a significant shift in electrochemical potential can be obtained by photo-generation only for the minority carriers.

2. Description of the Main Types of Photo-electrochemical Reaction

Let us now use the concept of the quasi-Fermi level to describe some qualitative aspects of the development of photo-electrochemical reactions at an illuminated semiconductor–electrolyte interface[12,41].

The basic idea underlying our quasi-thermodynamic approach is that the electrode reaction is accelerated by light as a result of the formation of the quasi-levels F_n and F_p, displaced with respect to the equilibrium position of the Fermi level F. We now need to modify the condition (13). The anodic reaction (with the participation of holes) will take place if

$$F_p > F_{redox} \tag{31a}$$

and the cathodic reaction (with the participation of electrons) will take place if

$$F_n > F_{redox}. \tag{31b}$$

Consider first a semiconductor electrode under open-circuit conditions. An example could be a single particle of a suspension of a semiconductor in a conducting liquid. There will be a region of potential for which no electronic transitions take place at the semiconductor–electrolyte interface in the dark, i.e. for which the semiconductor behaves as an ideally polarisable electrode. The upper and the lower limit of this region of potential are the decomposition potential of the solvent and (or) the decomposition (corrosion) potential of the semiconductor. The stationary potential of the electrode in the ideal polarisability region is determined by chemisorption processes (usually, in aqueous solutions, oxygen chemisorption). The same processes also determine the steady-state band bending.

The energy band diagram of a semiconductor (n-type, in this case) in contact with a solution is shown in Fig.8. In addition to the energy levels of the semiconductor (the bottom of the conduction band E_c and the top of the valence band E_v) the diagram gives the electrochemical potential levels for the anodic dissolution of the semiconductor $E_{dec,p}$ and for the cathodic hydrogen evolution E_{H_2/H_2O} (assuming that the most likely anodic reaction is the decomposition of the semiconductor with the participation of holes and the most likely cathodic reaction the evolution of hydrogen from water with the participation of electrons from the conduction band).

The diagram (Fig.8) assumes the formation of a depletion layer in the surface region of the semiconductor. Electrons and holes generated by light in the electric field of the depletion layer move in opposite directions: in the present case

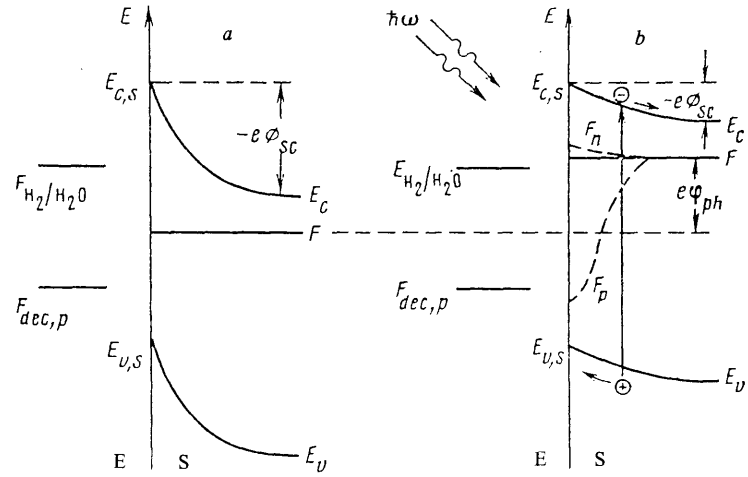

Figure 8. Energy diagram for the contact between a semiconductor and an electrolyte: (*a*) in the dark, (*b*) illuminated; E is the electrolyte, S is the semiconductor.

the holes move towards the interface and the electrons move towards the bulk and away from the interface. The electric field produced by this charge separation partially compensates the field originally present. As a result the bending of the bands ($e\varnothing_{sc}$) decreases, i.e. the bands are flattened.

The flattening of the bands produces, in turn, a change in the mutual configuration of other energy levels in the system. We shall assume, to simplify the problem, that the potential step in the Helmholtz layer is unaffected by illumination ($\varnothing_H$ = const), and hence that the position of the band edges at the surface ($E_{c,s}$ and $E_{v,s}$) is fixed with respect to the reference electrode and therefore also with respect to the energy levels in the solution (band edges "clamped" at the surface, see Section III). At the same time the position of the electrochemical potential F of the semiconductor (Fermi level) is rigidly fixed with respect to the band edges in the bulk of the semiconductor[3]. The result is that under illumination the unbending of the bands "drags" the Fermi level away from the position for the electrode in the dark, as shown in Fig.8. This shift ΔF can be measured by using a reference electrode, and gives rise to the photo-potential $\phi_{ph} = \Delta F/e$.

Consider the effects which accompany the formation of quasi-Fermi levels for electrons and holes. For the majority carriers (electrons) the shift of the level F_n relative to F is very small, as was said above, and can usually be ignored, but for the minority carriers (holes) the quasi-Fermi level F_p can lie relatively far from F in the energy diagram.

At some level of illumination the quasi-Fermi level for holes F_p will reach the level of the anodic reaction on the semiconductor surface (in Fig.8 this is the semiconductor decomposition reaction). Also, because of the shift in the Fermi level F, the quasi-Fermi level for electrons F_n can reach the level of the cathodic reaction (in Fig.8, the evolution of hydrogen from water). The two reactions are induced simultaneously, producing photo-corrosion of the semiconductor. In this way the electrons and holes generated under non-equilibrium conditions in a corrodible semiconductor by illumination are used to accelerate the partial reactions.

In principle the decomposition (dissolution) of the semiconductor could be replaced by another anodic reaction: for example, the oxidation of a dissolved substance or the evolution of hydrogen from water. Obviously, in the latter case the result of the illumination of the semiconductor is the photo-electrolysis of water with formation of hydrogen and oxygen, i.e. the conversion of light (solar) energy into the chemical energy of the products of photo-electrolysis.

When the semiconductor–electrolyte interface is uniformly illuminated the two conjugated reactions proceed at equal rates at each point of the surface. The steady-state potential of the uniformly illuminated semiconductor is a mixed potential. If, on the other hand, the surface of a semiconductor having uniform composition and properties is unevenly illuminated the conditions for the electrochemical reaction are different on the illuminated and on the dark parts of the surface. In this case the conjugated reactions are separated in space, and we can think of local anodes and cathodes. This situation is artificially created, for example, in the selective photo-sensitive etching of semiconductor materials (see below, Section V).

The spatial separation of the anodic and the cathodic reaction on an illuminated semiconductor can be achieved also in other ways: for example, by imparting to specific parts of the semiconductor surface special electrochemical (in particular, electrocatalytic) properties, different from the properties of the rest of the surface. These regions act as local electrodes, and the system as a whole acts as a galvanic couple. An example of this type of micro-heterogeneous system is a suspension of platinised strontium titanate in an aqueous solution. Illumination of this system generates electrons and holes which are separated in the electric field of the depletion layer close to the surface (Fig.9), the holes moving towards the surface of the semiconductor and the electrons towards the bulk, eventually crossing the semiconductor–metal interface into a microscopic inclusion from which they finally enter the solution. In this way hydrogen is generated on the metal surface (in this case, platinum),

and oxygen on the illuminated surface of the strontium titanate. This type of micro-heterogeneous system is currently attracting a great deal of interest for solar energy conversion[42,43].

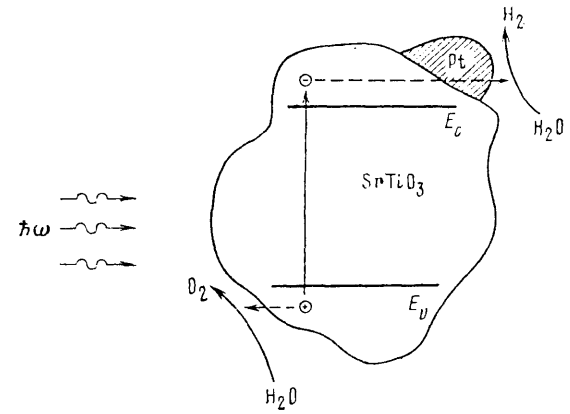

Figure 9. Energy diagram for the photo-electrolysis of water on a particle of a suspension of a semiconductor (platinised $SrTiO_3$) in an aqueous solution.

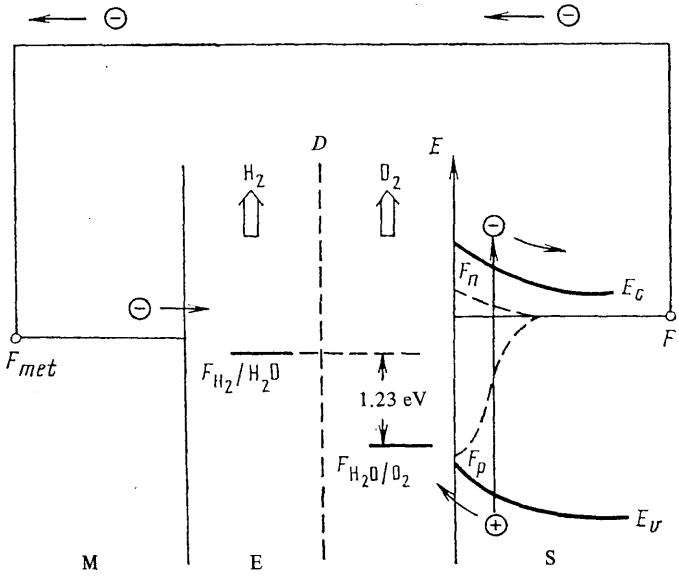

Figure 10. Energy diagram of an illuminated photocell with an *n*-type semiconductor photo-anode for the electrolysis of water: M is the metal, E is the electrolyte, S is the semiconductor, D is the diaphragm.

An obvious development of this approach is to create a macro-heterogeneous system, i.e. a short-circuited electrochemical cell consisting of a semiconductor photo-electrode and a non-photosensitive (e.g., metallic) auxiliary electrode (Fig.10). By making the photo-electrode (as before) of strontium titanate in an aqueous solution we can produce photo-electrolysis of water in the illuminated cell, the products (gaseous hydrogen and oxygen) appearing at the separate electrodes of the cell. The reliable and simple separation of the products of the photo-reaction, which is a direct consequence of the spatial separation of the primary photogenerated current carriers (electrons and holes) under the influence of the field in the space-charge region, is the most important advantage offered by semiconductor photo-electrochemical devices for the conversion of light energy into chemical energy.

The spatial separation of anodic and cathodic partial reactions stimulated by illuminating the semiconductor–electrolyte interface can be useful for two reasons. Firstly, by "leading" the current carriers of different sign to different parts of the surface we can greatly reduce the losses due to recombination and raise the quantum yield of the photocurrent and the efficiency of the conversion of solar into electrical energy. Secondly, the efficiency of the photo-electrolysis can be increased very substantially by transferring one of the two conjugated reactions (the one involving majority carriers) to a separate auxiliary electrode. Thus the cathodic partial reaction (hydrogen evolution, say) can be conveniently carried out on a metallic electrode chosen for its favourable electro-catalytic properties towards this reaction.

Let us now consider a system in which equilibrium is established between the semiconductor and the solution in the dark. This is usually the case when the solution contains an easily reversible oxidation–reduction system. Under these conditions the semiconductor acquires the equilibrium potential of the system, i.e. $\phi = \phi^0_{redox}$, or in other words $F = F_{redox}$.

A similar argument shows that illumination of the semiconductor causes a shift in both the Fermi level F and the quasi-Fermi levels for holes and electrons. Both the forward and the reverse reaction described in Eqn.(1) are accelerated. In other words, the most immediate result of the illumination is an effective increase in the exchange current of the Ox/Red system[44]. This is not the only result, however. If the illuminated semiconductor is an electrode in an electrochemical cell, connected to a counter-electrode through a load resistance, spatial separation of the cathodic and the anodic reaction is obtained as in the photo-decomposition of water discussed above (see Fig.10). The reaction involving minority carriers takes place on the auxiliary electrode. As a result, illumination of the semiconductor electrode induces a current in the external circuit, and in conjunction with the load resistor this produces useful power. In other words, light energy has been converted into electrical energy. This is the operating principle of the photo-electrochemical cell which has been called the "liquid solar cell".

Let us examine in detail the operation of such a photocell taking one specific example (Fig.11): the *n*-type CdS|alkaline solution of S^{2-} and S_2^{2-}| metallic cathode system. In the dark the equilibrium in the cell is

$$S_2^{2-} + 2e^- \rightleftarrows 2S^{2-}, \qquad (32)$$

Both electrodes acquire the equilibrium potential of this oxidation–reduction system, because the Fermi levels of the metal and of the CdS and the level $F_{redox} = F_{S^{2-}/S_2^{2-}}$ in the solution are brought to the same level. Since the equilibrium potential of the oxidation–reduction system is more positive than the flat band potential of the semiconductor ($\phi^0_{redox} > \phi_{fb}$) the surface of the semiconductor becomes depleted, thus allowing the spatial separation of the photogenerated electrons and holes. Illumination of the electrode unbends the bands, shifting the Fermi level F of the semiconductor with respect to its dark value F_{dark} (see Fig.11),

and this produces a change in the potential of the electrode (i.e. it produces a photo-potential ϕ_{ph}).

In the simplest case (which is often met in experiments) the potential step in the Helmholtz layer (Φ_H) is unaffected by illumination, and is also independent of ϕ^0_{redox}. In other words the edges of the energy bands are "clamped" at the surface (see Section III). Under these conditions the maximum value of ϕ_{ph} (corresponding to the open-circuit photo-potential for fully straightened bands) is equal to the initial (dark) potential step in the space-charge layer ($-\Phi_{sc}$), i.e. to the difference $|\phi^0_{redox} - \phi_{fb}|$. Efficient energy conversion is achieved by choosing a combination of semiconductor and oxidation–reduction system in solution for which this difference is as large as possible.

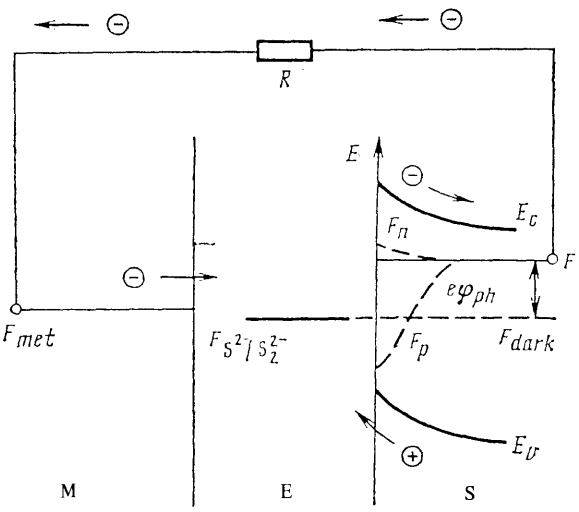

Figure 11. Energy diagram of an illuminated "liquid solar cell" with a CdS photo-anode and an S^{2-}/S_2^{2-} electrolyte; F_{dark} is the Fermi level of the CdS in the dark.

The photo-generation of electron–hole pairs produces quasi-Fermi levels for the minority and the majority carriers, F_p and F_n (see Fig.11). Since on the surface $F_p < F_{S^{2-}/S_2^{2-}}$, and $F_n > F_{S^{2-}/S_2^{2-}}$, both the forward and the reverse reaction are accelerated by illumination in the sulphide–polysulphide system. Closing the circuit through the external load R separates the anodic and the cathodic reaction: the holes flow from the semiconductor photo-anode into the solution, oxidising the S^{2-} ions to S_2^{2-}, and the electrons flow through the external circuit to the metallic counter-electrode (cathode), where they reduce S_2^{2-} to S^{2-}. The potential difference generated across the photo-cell is $I_{ph}R$, where I_{ph} is the photo-current, and the power conversion is $I^2_{ph}R$.

In some cases, however, the potential step in the Helmholtz layer does not stay constant under illumination or after changes in ϕ^0_{redox}. This results in a redistribution of the potential in the double layer, and the photopotential is invariably lower than the difference $|\phi^0_{redox} - \phi_{fb}|$. This occurs, for example, on silicon, gallium arsenide, or molybdenum diselenide electrodes in solutions of various oxidation–reduction systems. In other words, the band edges become "unclamped", and in the limit the Fermi level becomes "clamped" on the semiconductor surface. As a result, a gradual change in the potential ϕ^0 of the oxidation–reduction system causes the open-circuit photo-potential ϕ_{ph} of the cell to increase linearly with ϕ^0 at first ("clamped" band edges), before becoming independent of ϕ^0 ("clamped" Fermi level, see Fig.12).

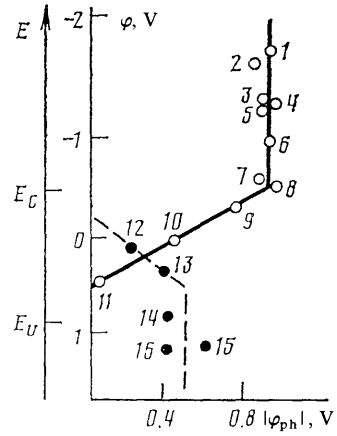

Figure 12. Plot of the absolute value of the open-circuit photo-potential $|\phi_{ph}|$ against the equilibrium potential of the oxidation–reduction system[45]. Photo-electrode of WSe_2, *p*-type (full line) or *n*-type (broken line) in acetonitrile solutions. The oxidation–reduction systems (with charges on the Ox and Red forms shown in brackets) are: *1*) anthracene (0/−1), *2*) phthalonitrile (0/−1), *3*) nitrobenzene (0/−1), *4*) 2,2′-bipyridyl complex of ruthenium (+2/+1), *5*) azobenzene (0/−1), *6*) anthraquinone (0/−1), *7*) benzoquinone (0/−1), *8*) methylviologen (+2/+1), *9*) tetracyanoquinonedimethane (+1/0), *10*) tetramethyl-*p*-phenylenediamine (+1/0), *11*) tetraphenyl-*p*-phenylenediamine (+1/0), *12*) I^-/I_3^-, *13*) Br^-/Br_3^-, *14*) Cl^-/Cl_3^-, *15*) thianthrene (+1/0), *16*) 2,2′-bipyridyl complex of ruthenium (+3/+2). The potentials are quoted against the saturated calomel electrode.

No explanation has yet been put forward for this phenomenon, which seriously limits the application of photo-electrochemical cells to the conversion of solar energy into electrical energy. Possible causes include (see Section III) the strong charging of the semiconductor electrode as the Fermi level approaches the edges of the forbidden gap (for example, during the formation of an inversion layer in the semiconductor[30,46]), a high density of surface states[28,29], or a shift in flat band potential in solutions of oxidation–reduction systems caused by the partial oxidation (or reduction) of the semiconductor surface by the components of this system, making ϕ_{fb} a function of ϕ^0.[47] All these situations could lead to a redistribution of the potential step at the interface between the space charge layer and the Helmholtz layer which could favour the latter layer.

3. Photo-corrosion and Stability

In the field of corrosion and photo-corrosion of semiconductor electrodes the quasi-thermodynamic approach offers useful criteria for determining the propensity of a semiconductor to

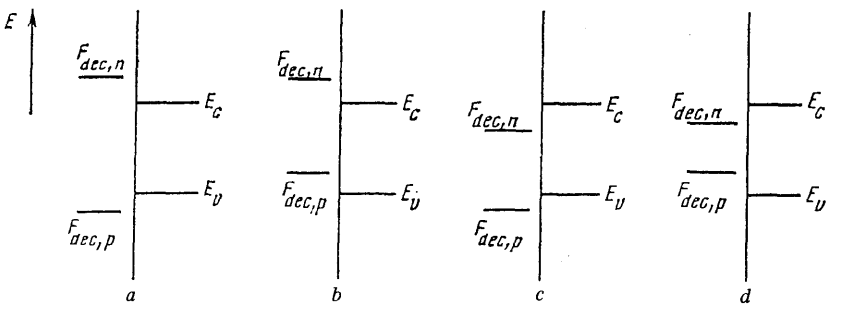

Figure 13. Diagrammatic presentation of the thermodynamic stability of a semiconductor with respect to decomposition in solution: *a*) absolutely stable, *b*) stable towards cathodic decomposition, *c*) stable towards anodic decomposition, *d*) unstable.

photo-corrosion and for identifying means of corrosion protection[12]. For example, in the case of the binary semiconductor MX (where M is the electropositive and X the electronegative component) we can write the following equations for the partial electrochemical reactions: for the cathodic decomposition with the participation of electrons from the conduction band

$$MX + ne^- \rightarrow M + X^{n-} \qquad (33a)$$

and for the anodic decomposition with the participation of holes (h^+)

$$MX + nh^+ \rightarrow M^{n+} + X\,. \qquad (33b)$$

Taking (as a concrete example) the hydrogen electrode as the reference level we can describe the overall reaction in the cell by one of the following equations (with the electrochemical potential of the reaction shown in brackets):

$$MX + \frac{n}{2}H_2 \rightleftarrows M + nH^+ + X^{n-}\,(F_{dec,n})\,, \qquad (34a)$$

$$MX + nH^+ \rightleftarrows M^{n+} + X + \frac{n}{2}H_2\,(F_{dec,p})\,. \qquad (34b)$$

By calculating the free energy change for these reactions we can determine the standard equilibrium potentials for the cathodic ($\phi^0_{dec,n}$) and the anodic ($\phi^0_{dec,p}$) decomposition of the semiconductor.

The thermodynamic condition for an electrode reaction (including a partial corrosion reaction) can be written for the cathodic reaction involving electrons from the conduction band as

$$\varphi < \varphi^0_{dec,n} \quad \text{or} \quad F > F_{dec,n} \qquad (35a)$$

and for the anodic reaction involving holes from the valence band as

$$\varphi > \varphi^0_{dec,p} \quad \text{or} \quad F < F_{dec,p}\,. \qquad (35b)$$

In order to determine the susceptibility of a semiconductor to electrochemical decomposition (or corrosion) in a specific environment we must insert into the energy band diagram the electrochemical potential levels of the electron for reactions (34a) and (34b).

Different possible situations are shown in Fig.13. The semiconductor is stable towards cathodic decomposition if the electrochemical potential level for this reaction lies within the conduction band, and it is stable towards anodic decomposition if the appropriate level lies within the valence band. In both cases if the change in potential takes place entirely within the semiconductor ("clamping" of the bands at the surface) the level becomes "inaccessible" to the Fermi level of the semiconductor. Thus in the situation illustrated in Fig.13*a* the semiconductor is absolutely stable, since the levels of both decomposition reactions lie outside the forbidden gap. More often the semiconductor is found to be stable towards only one type of decomposition reaction: the cathodic (Fig.13*b*) or the anodic (Fig.13*c*). Lastly, when both the $F_{dec,n}$ and the $F_{dec,p}$ level lie within the forbidden gap (Fig.13*d*) the semiconductor can decompose, in principle, under both cathodic and anodic polarisation.

The thermodynamic description of photo-corrosion assumes that the electrode reaction causing decomposition of the semiconductor is accelerated (under the influence of light) by the shift in the quasi-Fermi levels for electrons (F_n) and holes (F_p). We must therefore modify the conditions (35). The cathodic photo-decomposition of the semiconductor involving electrons from the conduction band is subject to the necessary condition [see (31)]

$$F_n > F_{dec,n} \qquad (36a)$$

and the anodic photo-decomposition involving holes to the condition

$$F_p > F_{dec,p}\,. \qquad (36b)$$

As soon as either of the conditions (36) is satisfied the corresponding reaction becomes thermodynamically possible.

We should note that the reaction may nevertheless be kinetically hindered. Thus in many cases it is kinetic rather than thermodynamic features of the electrode reaction which determine the corrosion (or photo-corrosion) behaviour of semiconductor electrodes.

In order to identify means of protection against corrosion (or photo-corrosion) we must consider what other reactions can compete with the photo-decomposition process. For example, at the highest levels of illumination the cathodic reaction with the most positive equilibrium potential is the most probable, and the predominant anodic reaction is the one with the most negative equilibrium potential. It follows that the photo-corrosion process can be suppressed by adding suitable oxidisers or reducers to the solution.

Thus anodic photo-corrosion can be prevented by systems whose oxidation–reduction potential is more negative than the decomposition potential: $\phi^0_{redox} < \phi^0_{dec,p}$, i.e. $F_{redox} > F_{dec,p}$ (see Fig.14). The condition for stabilisation towards cathodic photo-decomposition is $\phi^0_{redox} > \phi^0_{dec,n}$, or $F_{redox} < F_{dec,n}$. These protection systems, which stabilise the semiconductor by being thermselves oxidised or reduced,

are used in photo-electrochemical solar energy conversion cells[48-51]. The solvent (for example, water) can act as the protection additive if it is oxidised (or reduced) more readily than the material of the semiconductor electrode. This occurs, for example, in many oxide electrodes (TiO_2, $SrTiO_3$, etc.), for which the most probable anodic photo-reaction is the oxidation of water to oxygen.

Let us examine from this point of view the photo-corrosion behaviour of GaAs and GaP in aqueous solutions. The electrochemical potential levels for the decomposition reactions of these materials are indicated in Fig.15 in relation to the levels E_C and E_V,

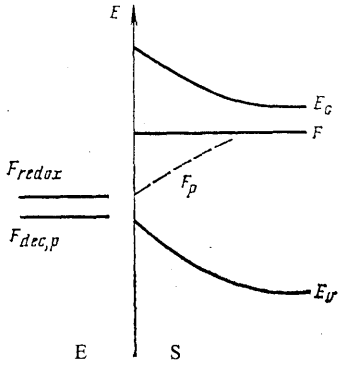

Figure 14. Protection of an n-type semiconductor from anodic photo-decomposition by the addition of an oxidation–reduction system to the solution.

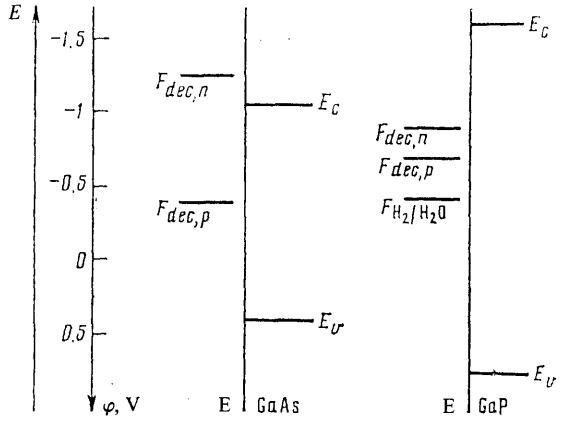

Figure 15. Energy levels at the contact between GaAs or GaP and an aqueous solution at pH 7.[52] The potentials are quoted against the normal hydrogen electrode.

For GaAs the level $F_{dec,n}$ corresponds to the reaction

$$GaAs + 3H^+ + 3e^- \rightleftarrows Ga + AsH_3$$

and $F_{dec,p}$ to the reaction

$$GaAs + 5H_2O + 6h^+ \rightleftarrows Ga(OH)_3 + HAsO_2 + 6H^+.$$

For GaP the level $F_{dec,n}$ corresponds to the reaction

$$GaP + 3H^+ + 3e^- \rightleftarrows Ga + PH_3$$

and $F_{dec,p}$ to the reaction

$$GaP + 6H_2O + 6h^+ \rightleftarrows Ga(OH)_3 + H_3PO_3 + 6H^+.$$

By comparing these diagrams with Fig.13 we note that GaAs is an example of case 13*b*, i.e. it is stable towards cathodic decomposition but potentially unstable towards anodic decomposition, whereas GaP is potentially liable to both cathodic and anodic decomposition, since the levels of both reactions lie within its energy gap (as in Fig.13*d*).

4. Limitations of the Quasi-Fermi Level Concept in Photoelectrochemical Kinetics. Alternative Approaches

As we have shown the quasi-thermodynamic approach based on the concept of quasi-Fermi levels is widely used and, on the whole, effective. It has the undeniable advantages of being physically meaningful and simple. However, it should not be forgotten that the use of the quasi-Fermi level concept is not always justified.

The definition of the quasi-Fermi level within a semiconductor is meaningless unless the following conditions are satisfied:

$$\tau_c, \tau_v < \tau_{cv} \qquad (37)$$

where τ_C and τ_V are the times for the establishment of thermodynamic equilibrium in the electron ensemble of the conduction band and in the hole ensemble of the valence band, and τ_{CV} is the time for the establishment of equilibrium between the electron and the hole ensembles.

The conditions (37) are usually obeyed, but there are additional conditions to be met before this approach can legitimately be applied to the description of electron transfer processes at interfaces. We need to define the times ($\tau_{n,s}$ and $\tau_{p,s}$) elapsed between the photo-excitation of an electron or hole and its capture by the surface (for example, as a result of the electrode reaction). The quasi-Fermi level concept is valid only if these times are greater than τ_C and τ_V, because if the opposite were true insufficient time would be available for the establishment of quasi-equilibrium in the bands, and the "hot" particles would take part directly in the electrode process. On the other hand, the times $\tau_{n,s}$ and $\tau_{p,s}$ must be less than τ_{CV}, because otherwise the electron–hole system would reach full equilibrium and we would revert to $F_n = F_p = F$ close to the surface.

Thus, in addition to (37), the following systems of inequalities must be satisfield:

$$\tau_c < \tau_{n,s} < \tau_{cv}, \quad \tau_v < \tau_{p,s} < \tau_{cv}. \qquad (38)$$

If only one type of carrier is involved in the reaction, only one of these two systems of inequalities has to apply.

If the capture of electrons or holes by the surface is fast, the parameters $\tau_{n,s}$ and $\tau_{p,s}$ are identical to the times of arrival at the interface. If, on the other hand, the surface process cannot be treated as infinitely fast, the times $\tau_{n,s}$ and $\tau_{p,s}$ can be identified with the characteristic times of the process (for example, the time for the elementary act of the electrode reaction). Since the difference between the times τ_C and τ_V (on the one hand) and the time τ_{CV} is fairly large ($\approx 10^{-13}$–10^{-8} s) the conditions (38) are often satisfied, and this explains the success of the quasi-Fermi level concept when applied to various types of heterogeneous process.

Nevertheless, for a quantitative description (see, for example, Ref.53) still further conditions have to be satisfied. In particular, the quasi-levels in the space-charge regions must be reasonably smooth, and the amount of recombination within the space-charge region must be small. Clearly, also, if the carriers are photo-generated near a surface at which a fast electrode reaction is taking place they could be "sucked out" of the semiconductor before coming to equilibrium with the thermalised carriers in the appropriate band. Under these conditions the carrier cannot be described in terms of the quasi-Fermi levels F_n and F_p: it would be more correct to treat the transitions of the carriers from the electrode into the solution not as a quasi-equilibrium but as a dynamic situation, i.e. as separate events[54-56].

The choice between the two approaches to the description of photo-electrochemical reactions (quasi-thermodynamic, or dynamic) in any particular system can be based, in principle, on experimental data[55]. However, the necessary data are scarce and unreliable at present, and this remains a problem for the future.

V. SOME NEW PRACTICAL APPLICATIONS OF SEMICONDUCTOR ELECTRODES

1. Photo-electrochemical Solar Energy Conversion

The photosensitivity of semiconductor electrodes makes the semiconductor–electrolyte interface a potential energy converter for light[57]. A brief description of the mechanism by which photocurrent is induced in a semiconductor electrode was given above (Section IV) for the two most important cases: in the presence of a highly reversible oxidation–reduction system in solution and without such a system (i.e. under conditions which suppress the electrochemical reaction in the dark). In the first case the light energy is converted into electrical energy, in the second into chemical energy. The photo-electrochemical cells corresponding to these two cases are called "liquid solar cells" (or photo-electrochemical cells of the regenerative type) and photo-electrolysis cells respectively. Among the most important photo-electrolysis reactions is the decomposition of water, a possible source of hydrogen as a fuel or as a raw material.

The main advantage of photo-electrochemical cells with semiconductor electrodes (as compared, say, with solid-state semiconductor solar cells) is their relative insensitivity to the crystal lattice perfection and the purity of the semiconductor. Polycrystalline semiconductor electrodes in electrochemical "solar cells" give very effective energy conversion, both in absolute terms and in comparison to monocrystalline electrodes. This offers, at least in principle, the possibility of developing cheap and simple solar energy converters.

The detailed mechanism of the operation of photo-electrochemical converters and the characteristics of specific systems have been discussed in several recent reviews[6,41,48-51,55,58-60], and lie outside the scope of this review. However, it is important at this stage to examine the main problems still to be solved before photo-electrochemical cells can find extensive practical applications.

The main obstacle to the development of "liquid solar batteries" is the photo-corrosion of the semiconductor electrodes, which seriously limits their useful life. In order to eliminate anodic photo-corrosion, for example, a reversible oxidation–reduction system is added to the solution, so that the oxidation of the Red component (a "consumer" of photo-generated holes) competes with the photo-decomposition of the electrode material (see Section IV). In this way it has been possible to eliminate photo-corrosion almost completely in many types of photocell, and to increase the period of continuous operation of the photocell to almost one year. Nevertheless there are other, less obvious mechanisms of degradation of the electrodes[51,61] which prevent photo-electrochemical cells from competing with the useful service life of solid-state solar cells (up to 20 years).

A very real problem in photo-electrolysis is to make the energetics of the electrochemical reaction compatible with the spectrum of solar radiation. The energy distribution of the photons in the solar spectrum is such that the optimum threshold energy of the quantum process chosen for the conversion of the solar energy (i.e. of the semiconductor electrode reaction) lies in the range 1.1–1.4 eV. The free energy for the decomposition of water into hydrogen and oxygen is 1.23 eV, i.e. it lies within the calculated range. However, in practice the reaction requires a large overvoltage. Allowing also for other unavoidable losses, the quantum energy needed for the photo-electrochemical decomposition of water becomes ~2 eV,[58,60] i.e. it is much higher than even the upper limit of the calculated optimum energy range. In other words, in the solar spectrum only a small fraction of very energetic quanta is used directly in the photo-electrolysis of water. (Note that this is far from accidental: indeed, were it not for this condition the relative stability towards solar radiation of a wide variety of living or inanimate systems in nature could not be explained.) This obstacle can be overcome, in principle, in several ways.

1. Carry out the reaction in the photo-stimulated electrolysis regime. In this case the main bulk of the quanta in the solar radiation (of energy in the range 1.1–1.4 eV) is used to excite the photo-electrochemical reaction, and additional energy (to the required 2 eV) is provided from an auxiliary source. The most successful use of this procedure is reported in Ref.62.

2. Carry out a process of the "two-quantum" type. By combining within the same photo-electrochemical cell two semiconductor photo-electrodes (an n-type anode and a p-type cathode) we can achieve effective addition of the photopotentials developed on the two electrodes (if their characteristics are suitably chosen) and thus obtain the energy needed for the photo-electrolysis of water[63].

Another approach is to carry out the water decomposition reaction in two separate steps, each in a separate photo-electrochemical cell. The two cells are connected by an intermediate substance which acts as a charge transfer medium and is not consumed by the reaction, but ensures that the chemical potentials developed in the two cells are "connected in series"[6,64]. The analogy between this system and the combination of two photo-systems in natural photosynthesis processes is easy to see.

All these approaches rely on the use of two photo-electrodes, and therefore the overall reaction is formally a two-quantum process, which makes possible the required energy gain.

3. Separate the overall process into two steps: the conversion of the solar energy into electrical energy and the electrolysis of water[65-67]. The single photo-electrochemical cell is replaced by a combination of a solar cell (of the solid-state or of the "liquid" type) and an ordinary electrolysis cell. In this case the two functions (development of an electrical voltage and electrochemical decomposition of water) which were combined in the photo-electrolysis cell are now separately assigned to two specially designed pieces of apparatus. In this way we can generate the required voltage by connecting in series several solar cells; greater flexibility in the choice of the photoelectric and electrocatalytic properties of the electrode materials is also possible.

4. Dehydrogenation of cheap and readily available substances. Since the only wanted product is hydrogen, we can abandon the photo-electrolysis of water and choose an alternative electrochemical reaction with a smaller free energy change: for example, the dehydrogenation of various industrial by-products. Photo-electrochemical processes of this type have been studied intensively in recent years[50,68-71].

Other systems of interest include the use of the invisible (infrared) part of the solar spectrum in addition to visible light[72], and the exploitation of non-traditional reactions such as photo-intercalation into the semiconductor crystal lattice of atoms produced by the electrode reaction[73].

The extensive work currently in progess in this area should result in the development of simple and economically attractive photo-electrochemical processes able to compete with other, non-electrochemical methods of utilising the sun's energy.

2. Laser Etching of Semiconductors

Recent advances in quantum optics have led to the development of a new technology: the laser electrochemistry of semiconductors[74,75]. This field includes several topics related to the stimulation of electrochemical processes on semiconductor electrodes by laser radiation. The most successful of these so far has been the photo-sensitive etching of semiconductors with coherent laser radiation for optical information storage (for example, in holography[76]). Light-sensitive etching in conjunction with polarisation from an external source is called photo-anodic etching, whereas etching in an oxidising solution is called photochemical.

The basis of light-sensitive etching is the influence of illumination on the concentration of minority carriers, which determines the rate of dissolution and corrosion processes in semiconductors.

In laser etching an initially flat semiconductor surface immersed in a solution of electrolyte is exposed (through the solution) to two coherent monochromatic beams of light, incident at equal angles, lying in the same plane, and having the same intensity and wavelength. The interference between these beams produces bands of light and dark regions, and stimulates non-uniform etching of the surface.

The theory of laser etching[74,77] can be used to calculate in simple but practically important cases the characteristics of the etched outline as a function of the parameters of the radiation, of the properties of the semiconductor, and of the special features of the electrode reaction. The profile of the etched pattern is very close to sinusoidal. For the case of "surface-absorbed" light (i.e. light with a very high absorption coefficient) and a fast electrochemical reaction the repetition frequency of the profile (having the dimensions of reciprocal length, d^{-1}) is found to be very high. The physical meaning of this observation is the following: if the holes are generated immediately below the surface, and used in the reaction effectively in the same place, we can ignore the diffusion of photo-generated holes beyond the illuminated regions of the semiconductor.

Thus the spatial resolution of light-sensitive etching, i.e. the maximum achievable value of d^{-1}, is not determined by the diffusion length L_p of the holes, as could have been expected ($d \cong L_p$), but it can have a much higher value ($d^{-1} \gg L_p^{-1}$).

It is now experimentally established that the resolving power of the photo-electrochemical information storage processes d_{max}^{-1} (the maximum number of lines etched in the grating per 1 mm) can be very high: for GaAs and CdS it is greater than 6000 mm^{-1}. We should stress that in materials with a high diffusion length L_p (like silicon and germanium) the resolving power is appreciably higher, as could have been predicted theoretically from the L_p values.

In conclusion we note that the laser electrochemistry of semiconductors is not confined to light-sensitive etching. It includes, for example, the study of threshold electrochemical reactions stimulated by powerful laser pulses. These reactions can occur by new paths, yielding new products, owing to the participation of strongly excited species from the solution and of the non-equilibrium electron–hole plasma of the semiconductor. Therefore they offer new possibilities for the development of unconventional processes in chemical technology.

3. The Ion-selective Field-effect Transistor

The combination in a single device of an ion-selective electrode and a field-effect transitor has yielded a new type of detector of ion concentrations called the ion-selective field-effect transistor. Because of its high sensitivity and selectivity coupled with a small size this device has found wide applications in industry, in medicine and biology, and in scientific research.

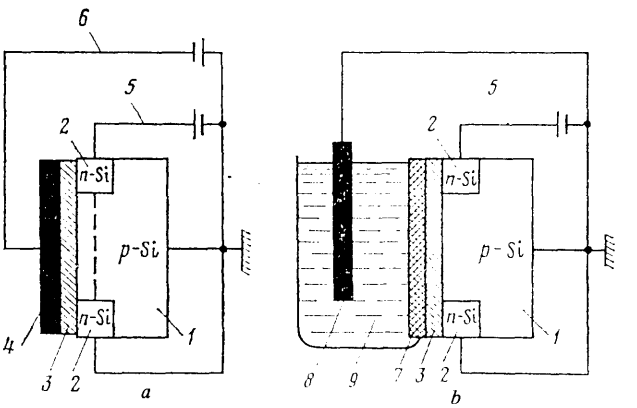

Figure 16. Electrical circuit of a field-effect transistor (*a*) and of an ion-selective field-effect transistor (*b*): *1*) base, *2*) source and drain, *3*) dielectric layer, *4*) gate, *5*) and *6*) low-impedance and high-impedance electric circuits, *7*) ion-selective membrane, *8*) reference electrode, *9*) experimental solution of electrolyte.

The operating principle of the field-effect transistor can be briefly described as follows (see, for example, Ref.78). The transistor (Fig.16*a*) is a metal–dielectric–semiconductor system, i.e. it consists of a semiconductor base on which a dielectric layer and a metallic electrode (the "gate") are deposited. The base is usually a plate of *p*-type silicon, and the dielectric a layer of SiO_2 or Si_3N_4 100–200 nm thick and having a resistance of ~10^{13} Ω. Two regions in which the conductivity type of the silicon is inverted are prepared in the base by localised doping: these *n*-type regions are called the "source" and the "drain" respectively. By inserting voltage sources into the gate–base and source–drain circuits (Fig.16*a*) we can induce a field effect in the transistor. In the absence of a gate voltage the current in the

source–drain circuit is almost zero, because one of the two p–n junctions in this circuit is always reverse-biassed. We now apply to the gate a voltage of sign and magnitude such that an inversion layer is formed near the silicon–dielectric interface (i.e. a layer in which the concentration of minority carriers is greatly increased). In the case shown in Fig.16*a* the gate bias has to be positive with respect to the base. The resulting n-type "channel" short-circuits the source and the drain, allowing current to flow in this circuit (whose resistance is now of the order of 10 Ω). Thus a change in voltage in the high-impedance gate–base circuit effectively controls the current in the low-impedance source–drain circuit, i.e. the device offers a high current gain.

This property of the field-effect transitor is exploited in the ion-selective field-effect transitor to achieve a high sensitivity. The dielectric layer is replaced by an ion-selective membrane, permeable to one kind of ion#, and the metallic gate is replaced by a solution of electrolyte in which the reference electrode needed to complete the electrical circuit is immersed (Fig.16*b*). The role of the external gate voltage is now played by the potential generated on the membrane by the presence of ions to which the membrane is selectively permeable. The magnitude of this potential is given by the Nernst equation [see also formula (4)]

$$\varphi = \varphi^0 + RT/z\mathcal{F} \ln a \qquad (39)$$

where a and z are the activity (in the simplest case, the concentration) and the charge of the potential-determining ion, and ϕ^0 is the standard potential (i.e. the value of ϕ when a = 1 mole litre^{-1}).

For a membrane potential produced in this way the current in the measuring circuit is a function of the activity of the ions (a), thus making the ion-selective field-effect transistor a very sensitive ion detector. A great variety of specific types of this device has been produced, covering a wide range of membrane composition, type of reference electrode, operating regime (for example, including a small auxiliary polarising voltage), etc. A list of the most important of these systems, with a statement of their characteristics and of their application regions, can be found in recent review articles[79,80].

VI. CONCLUSIONS

We have not been able to include in this review all the new ideas and approaches now being actively developed in the field of semiconductor electrochemistry. In conclusion, therefore, we shall simply list the directions which we believe to be the most interesting and promising, though in some cases (for various reasons) interest has only been transient and developments only preliminary. A special discussion of these topics is given in Heller's monograph[61].

New systems. Among the most interesting new materials for practical applications in electrochemistry are the semiconductors with a layer crystal structure[81]. Being d-semiconductors they could be more stable towards photo-corrosion than the semiconductors (mainly sp) discussed above; furthermore, semiconductors with a layer crystal structure can be used as hosts to non-tranditional types of photo-electrochemical reaction: for example, the photo-intercalation of atoms from the solution into the crystal lattice of the semiconductor electrode. Semiconductors with d bands are potentially suitable as electrodes in photo-electrochemical cells. The synthesis and study of new materials with a prescribed set of photo-electric and electrochemical properties have grown into a major activity in the "electrochemical materials science" of semiconductor technology (see, for example, Ref.82).

Another promising area is the study of the photo-electrochemical properties of micro-heterogeneous semiconductor systems: porous electrodes, and suspensions of different particle size (down to colloidal dimensions), in which the photosensitivity of semiconductors is combined with the high catalytic activity of systems having a developed surface.

The modification of semiconductor electrode surfaces by "attached" catalysts (charge carriers)[83] is also being intensively studied at present.

New methods of investigation. Important new information can be expected to flow from the new methods of investigation, both those developed independently within the electrochemistry of semiconductors and of metals and those imported from other disciplines (mainly from surface physics), which have been called non-traditional. The latter relate almost invariably to the effect of radiation on a phase boundary. They include photo-temperature spectroscopy, in which the part of the absorbed light energy used in the photo-electrochemical reaction and that dissipated as heat are distinguished by monitoring the temperature of the photo-electrode, thus allowing the "true" quantum yield to be calculated[84,85], high-time-resolution measurements of the photocurrents induced by nanosecond laser pulses[86,87], electro-luminescence studies of recombination processes in electrodes[88], the photo-emission of electrons from semiconductors into solutions of electrolytes[20], and also the electro-reflectance of light at the semiconductor–electrolyte interface[89]. Photo-acoustic spectroscopy also has been used to study the fine details of the absorption of light by semiconductors[90].

Thus the recent advances have given a fairly comprehensive formulation of the electrochemical behaviour of semiconductors. Because of the number and importance of the new problems, semiconductor electrochemistry has become one of the "growth areas" of modern science.

#In some types of device the membrane is placed directly over the dielectric layer, giving a "four-layer" system.
